II. *Tycho*, as is clear from vol. 1 of the *Progymnasmata*, pp. 113, 116 and 123, in the example of the lunar calculation, did use the customary astronomical equation of days in the calculation of the Sun, say in the time of the solstices and equinoxes; but in the Moon he also applied a second equation, since he had learned by experiment from many eclipses that the Moon regulates its elongation from the Sun not from the Sun's mean place but from its true place. Later, however, he approved the plan of *Longomontanus*, and in lunar syzygies kept only that difference of days and equation which arises from the difference between the right ascension of the Sun's true place and the true place of the Sun itself, converted into time. By this device was made *Tycho's* small table in vol. 1 of the *Progymnasmata*, p. 116, which *Magini* also gives in the *Supplementum Ephemeridum*, p. 10. The earlier one, according to the eccentricity and apogee of his own time, *Tycho* gives in vol. 1, p. 113. Both are given by *Kepler* in the tables, p. 32; by *Mulerius* in the Frisian Tables, pp. 130, 280 and 281, explaining them on p. 378; and by *Origanus* in vol. 1 of the *Ephemerides*, p. 100, who adds that Tycho in the earlier table nearly neglected the inequality arising from the Sun's unequal motion, because he had rejected the excessive inequality of the year asserted by Copernicus.

[Margin: Longomontanus's opinion.]

III. *Longomontanus*, in Book 1 of the *Theorica*, ch. 2, in the commentary on the Sun, confesses that *in all his astronomical study he never laboured with greater difficulty than here*, namely in seeking a more solid cause for equating time; and that the old method of Ptolemy, which we treated in the first rule, ch. 31, no. 5, is not safe enough, because it is derived variously from various epochs, and because the inequality of the solar motion has no certain starting-point in the ecliptic but the one established by the line of the apogee. So after restoring the Moon's course in Bohemia in the year 1600, he retains a single cause of the inequality, namely the one arising from the obliquity of the ecliptic, that is, the difference of the right ascension and the Sun's true place; because lunar eclipses and the necessity of demonstration demand it, without denying meanwhile a moderate difference arising from the unequal precession of the equinoxes, which for *Longomontanus* does not exceed 4′. The other cause of inequality, flowing from the Sun's unequal motion, he says he abandoned *almost without reason*, except that in respect of this too the Moon conforms itself to the Sun's apparent motion; but that this cause is removed, or rather compensated, if the motion of the diurnal rotation is supposed to be adjusted to the Sun's approach to and recession from the Earth. Thus with the Sun at apogee, for example, where the natural day would be shorter because of the slowness of the Sun's own motion, which resists the motion of the primum mobile least, the day nevertheless becomes longer because of the retarded motion of the primum mobile. Conversely, with the Sun at perigee, when the day ought to be longer,

it nevertheless becomes shorter from another source, because of the quickened motion of the primum mobile, or rather of the Earth's diurnal rotation. For from this, on his account, a great argument can also be drawn in its favour. But this compensation seems assignable no more to the Earth than to the primum mobile itself in the heavens, if one were granted, or to the Sun as it describes its spirals or helices, by which it accomplishes its diurnal and annual motion together.

[Margin: Longomontanus's argument for the Earth's diurnal motion, not a necessary one.]

IV. Mention of the Earth's motion, however, has led us to the opinion of *Kepler*. In the *Epitome of Copernican Astronomy*, Book 3, from p. 279, he ascribes the natural day not to the Sun but, with the Pythagoreans and Copernicans, to the Earth turning in diurnal rotation about its own axis. This, he holds, is the motion of the primum mobile, which with *Longomontanus* he considers irregular, increased by the Earth's annual approach to the centre of the Sun and slowed by its departure. But in the *Ephemerides*, p. 10, no. 30, he teaches that Tycho's equation, derived from a single cause, does not satisfy the eclipses observed by *Simon Marius*, by himself and by others, and that a third equation must be applied. This at times extends to 21′ 41″, but it is of the contrary sense to the one Tycho omitted, is double it and more, and begins from the Sun's apogee. This equation, he says, arises from certain supernumerary times, namely from the 5^{d} 6^{h} remaining beyond 360 days to the end of the solar year, and it is a property of the inequality of the motion of the primum mobile. The common equation, however, arising from the two known causes, he adapts so that it begins from 2° of Cancer. This way of equating, he says, he has not yet been able to refute from observations. Likewise in the Rudolphine Tables, chaps 15 and 32, Precept 71, he sets out three forms of equating time.

[Margin: Kepler's view.]

[Margin: Three forms of equating time.]

The first is the Tychonic, which he calls *empirical*, because it has been confirmed by experiment and by observations of many eclipses since Tycho's time. He therefore prefers it to the others in the calculation of the Moon, especially since it is very simple and serves for every age, being nothing other than the difference between the Sun's true place and its right ascension.

[Margin: The first, empirical, or Tychonic.]

The second is called by Kepler *astronomical* and *demonstrative*. It arises from the inequality of the Sun's motion, which begins from the apogee, and from the inequality of right ascensions, which begins from the equinoctial or solstitial points. The beginnings of both causes coincided, both in the year 3993 before the era of Christ, April 24, when the Sun and the Sun's apogee were at the beginning of Aries, and in the year of Christ 1466 June 14, when the Sun and the Sun's apogee were at the beginning of Cancer; and the mean natural day was then equal to the true and apparent day. This also happens twice in any year, when the one cause compensates the other; that is, the equation of the

Sun is as great as the difference between the right ascensions and the mean motions, but the one is additive and the other subtractive. The universal rule of this equation is the one I gave in chap. 31, no. 5. In imitation of the Prutenic Tables, however, he gives on p. 32 a temporary table adapted to the year of Christ 1616, but serving without perceptible error for more than 50 years before and after. This equation, then, which he says some eclipses support, he affirms must be applied, so that it may afterwards be established from observations whether it suffices, or whether some other form of equating that satisfies more phenomena must be substituted.

[Margin: Second form of the equation: astronomical.]

The third equation is called *physical* by Kepler, as arising from a physical cause, namely from the power of the Sun, which aids the Earth, the body of the primum mobile, and accelerates its diurnal motion through the whole of that semicircle of the annual orb in which the Earth approaches the Sun, but relaxes it in the other, in which the Earth recedes from the Sun. He imagines an archetypal year of 360 days, which is a figured number; but the supernumerary 5 days and 6 hours, reduced to 7560^{m} of time, he divides by 360, from which 21^{m} results in the quotient, and that is the greatest physical equation. He wants the physical equation to be added where the astronomical would have to be subtracted, and subtracted where it would have to be added; and he wants the Sun to aid the Earth by a one-hundred-and-eightieth part of the annual semicircle, distributed through it. So it comes about, he says, that by this not only is that which Tycho had discarded from the astronomical equation compensated, but even more is restored in the contrary direction. He admits that some eclipses favour this form of equating, and that many oppose it. For it he gives on p. 32 a second table, not in time but in parts of the equator, to be converted into time; there the excess of the physical over the astronomical, applied separately, is the physical equation correcting the astronomical. This excess is at its greatest $3^{\circ}\ 21'$, that is, $13^{m}\ 24^{s}$ of time, and is to be applied around the quadrant of the Sun's equated anomaly. The equation, however, that he teaches must be applied to eclipses in chap. 31, Precept 171, is monthly; for he says it has been observed that around the points of the vernal equinox the Moon enters the Earth's shadow later, and around the autumnal one earlier. That physical equation, however, is called by *Boulliau*, Book 2, chap. 7, *altogether chimerical*.

[Margin: Third form of the equation: physical.]

[Margin: Spring and autumn eclipses.]

V. *Lansbergen* too, in Precept 8, besides the astronomical equation (on which, chap. 31, no. 5), affirms that another must be applied in eclipses of the Sun and Moon, arising from a hidden cause in the Moon. It is very irregular, suspect for its awkwardness, and seems rather to have been devised to reconcile with observations the Lansbergian tables, which would otherwise go astray. It is of this kind:

[Margin: Lansbergen's opinion.]

Signs and degrees in which the luminary is eclipsed	*Equation to be applied to mean time*	
♈ 0°	30′	Add
♋ 18°	10′	Subtr.
♌ 7°	18′	Subtr.
♌ 18°	16′	Subtr.
♍ 0°	1′	Subtr.
♎ 0°	5′	Subtr.
♎ 18°	10′	Subtr.
♏ 24°	10′	Subtr.
♓ 20°	*uncertain*	

VI. *Ismaël Boulliau*, an astronomer of no common depth, in Book 2 of the *Astronomia Philolaica*, chap. 6, condemns Tycho's equation as diminished in the calculation of the Moon, on the ground that the diurnal revolution is the measure of all motions, to which the Moon too must be subject. He therefore establishes three causes of the inequality of days. The first is from the right ascensions of the terrestrial equator, which are unequal while the arcs of the zodiac are equal. The second is the difference of those same ascensions, insofar as it comes from the inequality of the annual motion arising from the eccentricity. The third is from the unequal motion of the diurnal revolution about its axis, which represents the primum mobile. For from the very fact that the Earth moves by its annual motion faster at perihelion and slower at aphelion along the ellipse, it follows too that the Earth's diurnal spinning [turbinatio], or rotation about its centre, is swifter when it approaches the Sun and slower when it recedes from it. In the same way, with a sphere descending an inclined plane and meanwhile spinning in rotation about its axis, if the descent is faster on a more inclined plane, the rotation is faster too, as is the return of any one point to contact with the plane.

[Margin: Boulliau's opinion.]

Let then the ellipse of the annual orb be CFDH, with centre A; let the Sun be B, the line of aphelion CD, and that of the equinoxes FH; the aphelion C, the perihelion D; the Earth's globe IOK, and its axis IK, always parallel to itself. While the Earth's centre moves from C towards F under the zodiac in the annual orb, let the Earth spin about the centre E, from Q to E, towards O, etc.; and let the Earth's equator be OEQ, and the terrestrial zodiac OVQ. Now let the Earth come from aphelion C to E, the middle of Aquarius, and in 45 days of equal motion let it have made 44° 31′ 15″. For to the arc VZ of the ecliptic there will correspond the arc EL of the terrestrial equator, 47° 0′ 15″, belonging to apparent time, and the difference between the time and true place, and the equal one, will be 2° 29′, which are lacking to apparent time for it to be reduced to mean time. The same thing happens proportionally if the Earth is at G, 15° of Leo. Now let the arc EX, or GX, on the equator be 45°, the measure of mean time. The place of mean time, IXK, will therefore cross the meridian sooner than the ap- parent-time place ILK, by 2° 29′, or 10^{m} of time.

Another cause of inequality is added, namely the Sun's unequal motion, because of the eccentricity AB and because of the physical acceleration of the Earth along the ellipse.

Diagram. A woodcut in the left column, between the lines of the paragraph. A large ellipse, the annual orb, is crossed by a vertical axis CD and a horizontal axis FH, which meet at A. The point B lies on the axis below A. Two straight oblique lines run up and to the left: one from A towards the first globe, one through B stopping short of that globe. Two small globes stand on the ellipse: one at the upper left, centred on the orbit at E, and one at the lower right, centred at G. Each is drawn with its axis IK, a horizontal equator OQ, a curved zodiac and further curved meridians.

- C (top of ellipse): with the sign ♑ beside it
- H (right end of the horizontal axis): with the sign ♎ beside it
- F (left end of the horizontal axis): with the sign ♈ beside it
- D (bottom of ellipse): with the sign ♋ above it
- A (centre): intersection of the two axes
- B (on the vertical axis, below A)
- First globe, upper left: I (top); K (bottom); O (left); Q (right); E (centre); X and L (on the equator, right of E); V (below E); R (left); S (right); Z (small and oblique, inside the globe beside S); the sign ♒ (near E, to the left)
- Second globe, lower right: I (top); K (bottom); O (left); Q (right); G (centre); L and X (on the equator, left of G); Δ (below the equator, near O); V (above G); S (left, upper); R (right, upper); Z (small and oblique, inside the globe beside S); the sign ♌ (on the equator, right of G)

But we supposed the Sun's equal place to be at 15° of Aquarius, that is, the Earth at G, at 15° of Leo. For Boulliau the equation here is additive, 1° 18′ 6″, so that the Sun's apparent place is at 16° 18′ 6″ of Aquarius, whose right ascension, counted from the tropic of Capricorn, is 48° 47′, at Δ. But the place of mean time was found above on the line IXK, at 45°. Therefore XΔ, the equation of time, is 3° 47′, that is, 15^{m} 18^{s} of time, by which mean time is greater than apparent; for the point X crosses the midheaven sooner than Δ. There remains now the third cause, namely the inequality of the Earth's diurnal revolutions, which are slower around aphelion and in the semicircle HCF than in the semicircle FDH; and these accelerations and retardations are similar. For Boulliau the annual motion has become faster here by 38′ 54″ in the ecliptic. So the place of apparent time, Δ, will be nearer the meridian by 38′ 54″ at the moment when the place of mean time is on the meridian itself. Because of the acceleration, therefore, the difference of mean from apparent, which was 3° 47′, must be reduced by subtracting 38′ 54″, so that 3° 8′ 6″ remain, namely 12^{m} 32^{s} of time, by which in this case mean time precedes apparent; and so for the rest. On this foundation rest the three tables of *Boulliau*, set on pp. 8 and 9 of the tables.

VII. Among so many disagreements of astronomers, no method seems to me more certain than the customary astronomical one, on which already chap. 31, no. 5: both because it rests on sure foundations, not on ones made up at will or by ingenuity, and because, all things weighed, it satisfies the eclipses I have observed more than the others do. The objections brought against this method flow either from false hypotheses about the exact motions of the Sun and Moon, or from an incorrect difference of meridians, or from observations of eclipses that are deceptive for the reasons indicated by *Kepler* in the *Ephemerides*, p. 12, by *Wendelen* in the preface to the *Eclipses* and to the *Idea of the Atlantic Tables*, and by ourselves below, on eclipses. But tables must be used whose epochs pertain to mean time; and thus the second part of the precept, on which chap. 31, no. 5, is to be employed. This will be the simpler for us, the fewer the causes of the inequality of days we acknowledge, having of course rejected the mutations, let alone the anomalies, of the obliquity of the ecliptic, of the eccentricity and of the equinoxes, according to what was said in chap. 31, no. 3.

[Margin: Our opinion.]

SCHOLIA.

Scholia.

I. Boulliau, *Book 2, chap. 7, refutes Ptolemy because he used epochs adapted to apparent time. From this it comes about that, when the epoch is varied, the Ptolemaic equation varies, and that ancient method does indeed show how much some one span of apparent time, elapsed as a whole, differs from mean time, but cannot reduce any point of time from apparent to mean, or conversely. These points also tell against the Alphonsine and Prutenic tables, whose epochs pertain to apparent time. In this, however, this method is not false, if it serves the use for which it was born: namely to show by how great an interval apparent and mean time differ from each other over some given span, but not to equate time by reducing from apparent to mean.* Tycho *too, on p. 56, although he knew that time must be equated, nevertheless omitted the equation with the Sun observed at the beginning of Aries, because there is no right ascension there. But see the end of our second precept, chap. 31, no. 5.*

[Margin: The imperfection of the Ptolemaic, Alphonsine and Prutenic equation.]

[Margin: A blemish of Tycho's in the epochs.]

II. Jean-Baptiste Morin, *in the treatise on longitudes, part 7, chap. 4, admits two causes of inequality,* the Sun's eccentricity and the obliquity of the ecliptic: *for from the eccentricity arises the Sun's unequal apparent motion in the ecliptic. But in chap. 6, forgetting himself, he applies only one, when he says:* "For a given mean time, let the mean and true place of the Sun be taken from the tables, as well as the right ascensions of those places themselves; and let their difference, if there is any, be converted into time." *And earlier, says* Boulliau, *he had concluded in these words:* "Therefore the equation of time is nothing other than the difference of

the right ascensions of the mean and true place of the Sun at the same instant, converted into time." *But this is to admit no other cause than the difference of the mean and true place of the Sun: for, without perceptible difference, in the proportion in which the mean and true place of the Sun differ, the ascensions of the mean and true place differ too. So Morin was deservedly thrashed by* Boulliau, *Book 2, chap. 7, and by* Pierre Hérigone, *at the end of vol. 5 of the* Cursus Mathematicus; *and not without much salt of acrimony was the swelling of his boasting dried up, the boast in which he had gloried that he had found a new method of equating time, unknown to others. He had also accused Tycho and others on a false charge, as if they had used not only the equator as the measure of time but also the ecliptic.*

[Margin: Morin's blunders on the equation of time.]

III. *In chap. 31, no. 2, we compared the solar day with the sidereal and with the pure day of the primum mobile, and indicated two kinds of tables: one for the mutual conversion of parts of the equator and times of the primum mobile, the other for the mutual conversion of parts of the equator and times of the solar day. Someone will perhaps therefore wonder when one should be used rather than the other. We reply to him that the small table of solar times must be used whenever the measures and limits of time are referred to the Sun, and the day and parts of the day depend on its motion, which indeed happens in most cases. But if the times do not depend on the Sun's motion, as when we count the interval between the transit of two fixed stars across the meridian, the other small table must be used. Granted, because of the small difference, most people use the table of times of the primum mobile, in which to one hour there correspond exactly 15° of the equator, and to one minute of an hour exactly 15′ of the equator.*

[Margin: The use of the double table of the equator converted into times.]

IV. *The way of perceptibly distinguishing the time of the primum mobile, and one day of it from one solar day, is this: by means of a pendulum, subtract* 4^m *from the solar day; or count its oscillations exactly from the transit of some fixed star across the meridian to the transit of the same star the following night across the same meridian, and then with the same pendulum count the oscillations from the transit of the Sun's centre to the second transit of the Sun across the same meridian, as I said in Book 3, chap. 20, where the motion of the pendulum is treated. For one revolution of the fixed stars differs imperceptibly from the diurnal revolution of the primum mobile.*

[Margin: A way of distinguishing the day of the primum mobile from the solar day.]

CAPVT XXXIII.

Chapter 33.

De Conſtituendis Epochis, ſeu Radicibus Motuum Solis, Ordinandiſq. Tabulis Solaribus.

On establishing the epochs, or radices, of the Sun's motions, and on arranging the solar tables.

I. *Epocha*, in Greek ἐποχὴ [Greek: epochē, "epoch"], from ἐπέχω [Greek: epechō, "I hold back"], that is, "I restrain, I stop, or I occupy", is a fixed position on which something stands and rests, and from which, as from an immovable starting point, things arise. Hence the epoch of times and motions among astronomers and chronologers is some certain and fixed moment of time from which the other times and motions are counted, backward or forward, with respect to a certain place on Earth. It is also called the radix [Radix] and the era [Aera]. Thus if motions and times are counted from the beginning of the world, or of the Olympiads, or of the reign of Nabonassar, of Augustus, etc., or from the death of Alexander, or from the birth of CHRIST our GOD, or from the making of King Alfonso's tables, it is called the epoch, or radix, of the world, the epoch of the Olympiads, etc. Now, so that the motions of the Sun and of the other stars can be collected for any given time whatever, there must be some certain and known starting point from which the count of the motion is to be begun, and it must be known what place in the heavens that star held at the moment of time assumed as the epoch, or radix. The way of establishing epochs, especially of the solar motion, is indicated by *Ptolemy*, Book 3, at the end of chaps 8 and 10; the *Alphonsines*, Canon 8 and at the end of 33, and pp. 33 and 41; *Reinhold* in the Prutenic Tables, Precepts 3 and 4, and in the tables, p. 1; *Copernicus*, Book 3, chap. 26; *Tycho*, vol. 1 of the *Progymnasmata*, p. 56; *Johannes Stadius*, Canon 3; *Giovanni Antonio Magini* in the tables of the second mobiles, from Can. 14, and in the tables, p. 40; *Mulerius* in the *Tabulae Frisicae*, pp. 90, 132, 294 and 309; *Longomontanus*, p. 188; *Lansbergen*, Precepts 3 and 8; *Boulliau*, Book 2, chap. 7, and in the tables, Prec. 1; *Kepler* in the Rudolphine Tables, chaps 15 and 18. From these, take the following rules.

[Margin: What an epoch is.]

[Margin: Authors on establishing epochs.]

II. *First*, the meridian must be determined, indeed the horizon too, that is, the longitude and latitude of the place to which the epochs of the motions are to be attached. And it is surely best that those who build astronomy not from others' observations but from their own should use the place on Earth in which they themselves carried out the observations, even if it was otherwise obscure; or at least the one in which observations were made by the most eminent practitioners. Granted, the epochs can be transferred to other places, if the difference of meridians is known from eclipses or otherwise. *Secondly*, a definite beginning of the year, starting from the first day of the year, must be fixed: not indeed from the rising or setting of the Sun, for the reason already given in chap. 31, no. 3, cause 4, but from the noon of the first artificial day of the year, or from the midnight before the first artificial day of the year, or from the noon immediately preceding, at which the last natural day of the preceding year was completed. This last pleases me more, because on account of meridian observations of the Sun at the equinoxes and solstices, most astronomers have begun natural days from noon rather than from midnight. And if the beginning of the first day is taken from the preceding noon, it will not be necessary in

computing motions always to subtract one day from the given day, as is done in tables that begin the day from the current noon. Nevertheless, most have preferred to start the day and the year from this point, as is clear from the following catalogue.

[Margin: The choice of meridian and horizon.]

III. One must have some observation of the Sun's true place, made exactly at apparent time on some meridian, and the Sun's mean place for the same time. And if the epoch is to be set for apparent time, as *Ptolemy, Alfonso* and *Copernicus* did, one must collect the years, months, days, hours and minutes of hours that intervene between the time of the observed true place and the moment of the assumed epoch. For the interval of time just mentioned, one must seek out from the tables, or from elsewhere, the mean motion that corresponds to it, and add it to the mean motion of the apparent time of the observation made, if the epoch follows that time, but subtract it if the epoch precedes; and you will have the mean or equal motion belonging to the epoch that represents apparent time. But if the epoch is to be adapted to equal or mean time, as we showed must indeed be done in chap. 31, Scholium 1, and as *Tycho, Longomontanus, Lansbergen, Ke- pler, Boulliau, Renieri* did, then the apparent time of the observation must be equated and converted into equal time, following the second part of the rule given in chap. 31, no. 5. Next, the interval of time up to the moment of the assumed epoch must be collected. The mean motion corresponding to this interval must then be collected and added to the mean motion of the equal time at which the observation was made, if the epoch is later than that time, but subtracted, if it is earlier; and you will have the mean or equal motion belonging to the epoch of mean time. But suppose what has been observed is the vernal equinox, that is, the Sun's true ingress into Aries, where there seems to be no right ascension and therefore no equation of time. *Tycho* (p. 56) omitted this equation; but it should not have been omitted. Now to an example of the second case.

EXEMPLVM.

Example.

Tycho, as given in vol. 1 of the *Progymnasmata*, pp. 52 and 56, observed the vernal equinox at Uraniborg in the leap year 1588 March 9, Old Style, at $20^{h}\ 45^{m}$ after noon. The Sun's simple or mean motion, according to the same Tycho, was then $11^{s}\ 27^{\circ}\ 57'\ 25''$. From this apparent time to noon of the preceding January 1 there are 68 days $20^{h}\ 45^{m}$. To these, according to the mean quantity of the Tychonic year, there belong $2^{s}\ 7^{\circ}\ 52'\ 35''$ of mean motion. Subtracted from the Sun's mean motion at the equinox, $11^{s}\ 27^{\circ}\ 57'\ 25''$, these leave $9^{s}\ 20^{\circ}\ 4'\ 50''$. So in the epoch of the year 1587 complete and 1588 beginning, Tycho set the Sun's place or mean motion at $9^{s}\ 20^{\circ}\ 4'\ 50''$, with no other correction.

[Margin: Tycho's epoch corrected.]

But proceeding more rigorously, the apparent time of the equinox should have been corrected and changed into equal time, in this way. At the equinox the Sun's mean place was near the beginning of Aries and its true place at the beginning of Aries, that is, at the end of the ecliptic and the completed 360th degree, or 12 signs. Take away from these the mean place, $11^s\ 27^\circ\ 57'\ 25''$, and there remain $2^\circ\ 2'\ 35''$, by which the right ascension taken for the Sun's true place exceeds the mean place. This excess, converted into time, corresponds to $8^m\ 10^s$ of an hour, to be added to the apparent time of the equinox, so that the equal time is March 9, $20^h\ 53^m\ 10^s$. From here to noon of the preceding January 1, therefore, there are 68 days $20^h\ 53^m\ 10^s$, to which there belong $2^s\ 7^\circ\ 52'\ 55''\ 7'''$ of mean motion. Subtracted from the simple motion, or the Sun's mean place, $11^s\ 27^\circ\ 57'\ 25''$, these leave the Sun's mean place at noon on the first day of January of the year 1587 complete, at Uraniborg, as $9^s\ 20^\circ\ 4'\ 29''\ 53'''$. For the rest, let us establish from our own observation our epoch of the solar motion for the year 1646, which will be the second example.

EXEMPLVM ALTERVM.

Second example.

[Margin: See the end of Chapter 14]

In 1646 September 22 we observed the equinox at Bologna at $14^h\ 56^m$ after noon in apparent time, when the Sun entered Libra, whose right ascension is exactly 180°, or 6 signs. But from our prosthaphaeresis the Sun's mean place was $6^s\ 1^\circ\ 58'\ 57''$. So the mean motion was greater than the right ascension by $1^\circ\ 58'\ 57''$. This difference, converted into time, is $7^m\ 53^s\ 48'''$ of an hour, to be subtracted from the apparent time of the equinox, leaving as the equal time September 22, $14^h\ 48^m\ 6^s\ 12'''$. From here to the end of the year and the last noon of December there are 99 days $9^h\ 20^m\ 5^s\ 28'''$. To these, from our mean motion of the Sun, treated in chap. 17, there belongs a simple motion of the Sun of $3^s\ 7^\circ\ 57'\ 24''\ 40'''$. Added to the Sun's mean motion found at the equinox, $6^s\ 1^\circ\ 58'\ 57''$, these give, for the end of the year 1646 complete, at the last noon of December, the Sun's mean motion as $9^s\ 9^\circ\ 56'\ 22''$, at Bologna.

[Margin: Our epoch of the Sun.]

IV. Once one epoch has been properly established in this way, it is easy to establish others before and after it, by subtracting or adding the mean motions corresponding to the intervening years. But in the jump from the Julian years to the Gregorian, account must be taken of the mean motion corresponding to 10 days. Thus, since for me the Sun's mean motion in 46 years is $11^s\ 29^\circ\ 51'\ 50''$, this, subtracted from the mean motion of the epoch of the year 1646 complete, gives the mean motion of the Gregorian year 1600, complete, at Bologna at noon on the last of December, as $9^s\ 10^\circ\ 4'\ 32''$ in equal time. If to this is added the motion of 10 days, which is $9^\circ\ 51'\ 23''$, the result is the root of the year 1600 in the old Julian style, $9^s\ 19^\circ\ 55'\ 55''$. Subtracting from this the motion of 1600 years, which for us is $0^s\ 12^\circ\ 24'\ 43''$, gives the root of Christ, that is, the epoch at

the beginning of the years of the common Christian era, $9^s\ 7°\ 31'\ 12''$. Granted that, from Hipparchus's equinoxes, this root has elsewhere been $9^s\ 7°\ 28'\ 55''$.

V. Let us now compare our epoch with the epochs of others. For those that begin the day from noon of January, in order to bring them back to the preceding noon of the last day of December, we shall subtract the Sun's diurnal motion, $59'\ 8''\ 20'''$; for those that begin it from midnight, the half-diurnal motion, $29'\ 34''\ 10'''$. And we shall add the time corresponding to the difference of meridians between Bologna and the places of the other epochs. The epochs of Nabonassar, Augustus, etc. we shall set out in the chronological book; meanwhile, see them in *Alfonso*, pp. 33 and 41; in the Prutenic Tables, Can. 10 and at the end; in *Gaurico*, in the notes to Ptolemy, bk. 3, chap. 10; in *Kepler*, in the Rudolphine Tables, p. 39; in *Lansbergen*, in the tables, p. 3; in *Boulliau*, in the tables, pp. 5 and 11; and in *Renieri*, in the *Tabulae Mediceae*, p. 15.

[Margin: Epoch of the Sun's apogee.]

VI. Once the epochs of the Sun's mean motion are established, the epochs of the Sun's apogee must be established. In these it is not necessary to equate the time, because the apogee's very slow motion produces no sensible difference

within one month. Therefore, since we found the Sun's apogee in 1646 July 28 at Cancer 7° 26′ 15″, from what was said in chap. 24, no. 3, and chose its annual motion as 1′ 1″ 10‴, from what was said in chap. 25, no. 6, then, keeping this ratio, its root at the beginning of the years of Christ comes out for us at Gemini 9° 28′ 45″. For the motion of 1646 years is 27° 57′ 32″, which, subtracted from Cancer 7° 26′ 15″, leaves Gemini 9° 28′ 45″.

[Margin: On tables of equations.]

VII. Now that the epochs of the mean motion have been established, together with tables showing the mean motions of the Sun and of the apo- gee per hour, day, month and year, tables must be constructed of the prosthaphaereses, or equations, of the Sun, at least for each degree of anomaly, according to the ratio of the eccentricity to the radius of the Sun's orb, following the rules given in chap. 21.

[Margin: On tables of distances, parallaxes and apparent semidiameters.]

VIII. Finally, a table must be constructed in which, for every five or at least every ten degrees of the Sun's anomaly, the Sun's distances are to be placed opposite those degrees. For this task, repeat here the figure treated in chap. 19, no. 5, or p. 143, since the hypothesis of the eccentric is the more common and the simpler. In triangles BET or IET, given the eccentricity ET and the radius of the Sun's orb EB or EI, and the angle of mean anomaly HEB or HEI, and therefore its complement to two right angles, namely angle BET or IET, you will find by the rules of triangles the distance TB or TI. And so for the rest. The semidiameter of the epicycle, substituted in place of the eccentricity, does this in the same way. It is useful, moreover, to express these distances not only in abstract parts, of which the radius of the orb is 100000, but also in semidiameters of the Earth, which are treated in the table of Chapter 7. In addition, opposite the same degrees of anomaly the Sun's horizontal parallaxes must be placed, following the Problem of Chapter 8, and the Sun's apparent semidiameters, following Problem 3, treated in chap. 11, no. 4. And if to this table you add another table of the Sun's parallaxes for each degree of distance from the vertex, both apparent and true, at the greatest, mean and least distance of the Sun from the Earth, following what was likewise said in chap. 8, the work will be complete. We shall give such tables, God willing, at the end of the work. Now let us descend from Phoebus to Phoebe.

LIBRI TERTII FINIS.

End of the third book.

LIBER QVARTVS DE LVNA.

Book Four: On the Moon.

CAPVT I.

Chapter 1.

De Lunæ Nominibus, Encomijs, & Varietate qua exercuit hactenus Aſtronomorum ingenia.

On the Moon's names and praises, and the variety with which she has so far exercised the talents of astronomers.

[Margin: Etymology of the Moon's name.]

I. The name *Luna* seems to have been formed by contraction from *Lucuna*, because she alone and single sometimes shines together with the Sun; or from the name of *Lucina*, with the middle syllable dropped, as Isidore prefers (*Origines*, bk. 8). In Hebrew she is *Lebanah*, from whiteness. In Greek she is [Greek: Σελήνη (Selēnē)], or [Greek: Σελάνα (Selana)], or [Greek: Σελαναῖα (Selanaia)], from radiance and new splendour, as *Cleomedes* notes (bk. 2, chap. 3). For in Greek [Greek: σέλας, σέλατος (selas, selatos)], or [Greek: σελέας (seleas)], is "radiance", and [Greek: νέον (neon)] is "new". Hence the Arcadians, to boast that they were older than the Moon, also called themselves [Greek: προσεληναῖος (proselēnaios)], that is, "Antelunares", those before the Moon.

[Margin: Why Phoebe?]

The same goddess is called *Phoebe*, as the sister of Phoebus and his deputy, a nocturnal Sun as it were, and *Latois*, a patronymic from Latona. *Euripides* in the *Phoenissae* did call her the daughter of the Sun, [Greek: ὦ θύγατερ ἀιλίε σελάνα (ō thygater ailie selana, "O daughter of [?], Selana")]: I believe because, since she borrows her light from him, she may seem to have been begotten by him. But in the myths she is commonly held to be the daughter of Jupiter and Latona. So she is also called [Greek: Ἄρτεμις (Artemis)] and *Diana*, as Jupiter is [Greek: Διός (Dios)]; or because she shines by day and by night, and is as it were *Duana*, says Isidore.

[Margin: Why Diana?]

I pass over the countless names derived from the places where she grew up or was worshipped, above all from Delos and Cynthus, which gave *Delia* and *Cynthia*.

[Margin: Why Hecate and Proserpina?]

She was further held to be *Hecate* among those below, because unless appeased with a hundred victims she ordered the shades of the unburied to wander for a hundred years, as *Servius* attests. Some think she is *Proserpina*, by whose moisture the crops creep forth [proſerpant], as *Isidore* interprets it; or because the same goddess is the Moon in Heaven, Diana on Earth, and [Greek: Περσεφόνη (Persephonē)] under the earth. To this refers that line of *Ovid*, *Fasti* 1:

> *You see the faces of Hecate turned in three directions.*

And that of *Virgil* in the Eclogues: "— the three faces of the maiden Diana." And to that threefold attire, of which, in *Isidore*, bk. 8, the poet sings thus:

> *But when the Moon shines, she gleams in a dim robe; When, girt up, she shoots her arrows, she is the maiden of Latona; When she sits enthroned, she is Pluto's consort.*

[Margin: Why Trivia?]

Hence she is everywhere called *Trivia* and the Three-formed Goddess, and by Virgil *Tergemina*: either from the threefold phase and face in which, as *Cleomedes* teaches (bk. 2, chap. 3), she chiefly appears in the sky, since she is seen now full of light, now sickle-shaped or curved into horns, now bisected and half-full; or because she was believed to preside over fowling, hunting and fishing, and to have taught that three kinds of nets, for birds, wild beasts and fish, should be handled in silence and in shadow, under a dim sky and by a scant light.

[Margin: Why Dictyna?]

So from nets, which are called [Greek: δίκτυα (diktya)], she was named *Dictyna*.

[Margin: Isis and Astarte.]

Lastly, she is the same who among the Egyptians under the name of *Isis*, and among the Sidonians as *Astarte*, as Queen of Heaven, held temples truly profane, with an impious cult often condemned in Holy Scripture; and she who, as Macrobius says (*Saturnalia*, bk. 7, chap. 16), was called among the Latins *Juno* and *Lucina*, from helping births and happily bringing them forth into the light, as Virgil confirms in Ecl. 3 with this verse:

Be favourable, chaste Lucina: your Apollo now reigns.

I am not unaware, however, that the names of Isis and Juno are assigned to Venus by *Pliny the Elder*, bk. 2, chap. 8. But the Moon herself surpasses all variety of names by the admirable variety of her phases and motions.

[Margin: Praises of the Moon.]

II. This, moreover, is that lesser Light which God made and set in the firmament of Heaven to rule the night, and to be the forerunner not only of the New Moon [Neomeniæ] but also of Easter and of the movable feasts that depend on Easter, according to that passage of *Ecclesiasticus* 43: *And the Moon in all things in her season, a showing of time and a sign of the age. From the Moon is the sign of the feast day, a light that wanes at its completion. The month is according to her name, increasing wonderfully at its completion.* There is no contradiction in this passage, granted that she is said both to increase and to wane at her completion: whether because, as the synodic lunar month is completed, she wanes in such a way that she begins to increase immediately after new moon, which is why at that time the Greeks called her old and new Moon; or because, as she approaches new moon, although she seems to us to wane in light, she is nevertheless illuminated from above by the Sun over a greater portion of herself than at other times.

She is also a most splendid symbol: both of the Catholic Church, which receives all the light it shines with from Christ, its Sun; and, by antithesis, of the Virgin Mother of God, who therefore has the Moon under her feet (Apocalypse 12), because she never felt the alternations of sin and grace, but was always clothed with the Sun of original grace. Of the Moon's remarkable power over sublunary things I shall say something in the Scholia. It was certainly for this reason that *Macrobius* (bk. 1 on the *Dream of Scipio*, chap. 11) called her *the*

boundary of life and death, and said in chap. 21: *As she is of aether and air, so the Moon is the boundary of things divine and perishable.*

III. Above all, astronomy seemed to Pliny the Elder to owe so much to the motions and changes of the Moon that he said of her (bk. 2, chap. 9): *I do not know whether she is not the teacher of all that could be learned in the heavens: that the year must be divided into spaces of twelve months, since she herself overtakes the Sun that many times as it returns to its starting point.* Indeed, the apparent proper motion toward the east was taught most plainly of all by the Moon's recession from the meridian, conspicuous at about 13 degrees a day. Moreover, like the chorus-leader of the other stars, she so connects them with the Sun that, as the sole or chief sharer of both day and night, she shows us their right ascensions and declinations, and likewise their longitudes and latitudes: on the one hand through her distance taken from the Sun rising or setting, on the other through the interval between herself and the stars observed at night.

[Margin: Pliny the Elder's encomium of the Moon, in most elegant antitheses.]

I cannot restrain myself from copying into our subject that entire encomium of the Moon from bk. 2, chap. 9 of Pliny the Elder. *But what surpasses the admiration of all is the last star, the most familiar to the Earth, found by nature as a remedy for darkness: the Moon. With her many-formed riddle she has tormented the minds of those who contemplate her and who resent that the nearest star should be the least known, always waxing or waning. Now curved into horns, now divided in equal portion, now rounded into a circle; blotched, and then suddenly shining bright; immense with full orb and suddenly nothing; sometimes up all night, sometimes late, and for part of the day helping the Sun's light; failing, and yet visible in her failure; she hides at the month's end, when she is now believed to be labouring. Again, she is low and high, and not even that in one way, but at times brought close to Heaven, at times touching the mountains; now raised to the north, now cast down to the south. Endymion, first among men, detected each of these things in her, and for that reason, it is recounted, was seized with love of her. We are surely not grateful to those who by labour and care have opened up light for us in this light.*

Or rather, I say, in this darkness. For after her ancient anomalies *Tycho* discovered a new variation in the Moon, and *Boulliau* suspects yet another, either a variation or a libration, but still awaits greater light from the test of observations and begs the help of those who possess Tycho's logbooks. And her monthly equations seemed to *Kepler*, before the Ephemerides, no. 16, suspect of wild behaviour, so much so that in the Rudolphine Tables, before rule 171, he exclaims as if in despair:

[Margin: Many inequalities in the Moon.]

After all the craftsmen's counsels have been exhausted, after so many inequalities of the Moon have been brought to light, she is still a stubborn star, spurning laws, and strays off course by tiny amounts here and there. Above all, for a reason proved by many examples, around the point of the vernal equinox she is found to come under the Sun, or into the shadow, later, and around the autumnal point sooner, than the

calculation so far set out indicates. But so far only eclipses have supplied the tests: what happens to the Moon when she crosses the equinoctial points with the Sun absent, no one, as far as I know, has attended to. So to seek the causes is premature, and no part of this book. Meanwhile, therefore, until time brings them forth, we shall follow the rule shaped from moderate experience.

And in the *Epitome of Astronomy*, p. 558, you say that observations of the Moon still disagree in the smallest quantities with any calculations whatever, and that it is uncertain to what this discrepancy should be referred. But will it ever come about that these things become known to some Endymion, and that what *Seneca* foretold on another occasion (*Natural Questions*, bk. 7) proves true, when he said:

[Margin: Seneca's near-prophecy.]

There are many peoples today who know the heavens only by their face, who do not yet know why the Moon is eclipsed, why she is darkened. A time will come when the day, and the diligence of a longer age, will draw into the light those things that now lie hidden. A time will come when our descendants will wonder that we did not know things so plain.

SCHOLIA.

Scholia.

I. The Moon's power over these lower things is manifest in innumerable effects, of which I should like here to review the more remarkable in some order. First, then, the Moon's power over the conceptions and births of animals is wonderful. That shrewd saying of Pliny the Elder (bk. 18, chap. 32) runs: "Set eggs to hatch at new moon"; and *Columella* (bk. 8, chap. 5) and *Palladius* (bk. 1, chap. 27) confirm it.

[Margin: The Moon's power over eggs.]

But Ptolemy, in prop. 51 of the *Centiloquium*, says: "Whatever sign the Moon is in at the time of birth, make that the Ascendant at conception; and whatever sign she is found in at conception, make that or its opposite the Ascendant at birth." And in bk. 3 of the *Apotelesmatics* he teaches that the position of the heavens, but chiefly with regard to the Moon, contributes to the fetus's moving and coming forth into the light, once it has ripened, in the same position as at conception.

[Margin: The Moon's power in the conception and birth of human beings.]

So it comes about that those conceived at the interlunium also come forth into the light at the interlunium, granted that those so conceived are for the most part weak through lack of moisture. Again, it has been observed in most of Greece, Italy and Spain that infants born in even forties of days, counted from the day of conception, are mortal, while those born in odd forties are viable. This is why a seven-month, nine-month or ten-month birth, and sometimes an eleven-month one, is viable, but an eight-month birth mortal. But these months are lunar, as is taught by Hippocrates in the book *On the Seven-Month*

Birth and the book *On the Eight-Month Birth*, by Aristotle (*On the Generation of Animals*, bk. 4, chap. 10), by Bonaventura (*On the Eight-Month Birth*, bk. 7) and by Turnebus [Adrien Turnèbe] (*Adversaria*, bk. 4, chap. 15), together with the more learned physicians and natural philosophers. Granted, Avicenna (*Canon* 3, Fen 21, chap. 2) and our own Lorinus [Jean Lorin] (on chap. 7 of Wisdom) think that in this matter months of the true or civil solar year should be used.

[Margin: The power of the forty days in the concoction and ripening of the fetus.]

Therefore, according to the observation of the Pythagoreans and of Hippocrates, if an infant is born after the 160th day from conception, when four forties are completed, and before the 200th day, when the fifth forty is completed and the sixth begins, it will be viable, and a child of 7 months. These are not indeed completed months, unless they are all short, since 7 mean lunar months have 206 days 17^{h} 8^{m}; but it is so called because it will have a great part of the seventh lunar month. Again, if it is born after the 240th day, when the sixth forty is completed, and before the 280th, when the eighth begins, it will be viable, and it can be a nine-month or a ten-month child, not, however, so as to complete ten lunar months, but so as to take part of the tenth; for mean lunar months, if nine, amount to 265 days 18^{h} 36^{m}, and if ten, to 295 days 7^{h} 20^{m}. But if it is born after the 200th day and before the 240th, that is, within the sixth forty of days, it is not viable. And since those born within this time are usually and almost always eight-month births, eight lunar months amounting to 236 days 5^{h} 52^{m}, so that they either complete the eighth month or take the greater part of it, an eight-month birth is therefore as a rule held to be not viable.

[Margin: At what Moon hair and sheep are to be shorn.]

II. Among physicians, certainly, ignorance of the Moon's motion and place cannot be tolerated without danger to the sick. For, to pass over critical days, surgery needs the Moon, in support of which Pliny the Elder (bk. 16, chap. 39) says: "Tiberius likewise observed the interlunia in cutting his hair as well. M. Varro prescribed, against falling hair, that it be observed from the full moons." And in Varro (*De re rustica*, bk. 1) it reads thus: "I keep these things too," says Agrasius, "received from my father, not only in shearing sheep but with my own hair, so as not to go bald by cutting it when the Moon is waning." Ptolemy, in the *Centiloquium*, prop. 20, rules as follows: "Do not strike a limb with iron when the Moon occupies the sign that rules that limb."

[Margin: Which signs rule which limbs.]

And which signs of the Zodiac rule which limbs, *Manilius* (bk. 1) expressed elegantly in these verses:

> *For Aries clings to the head; Taurus to the neck; The arms are reckoned under Gemini; the breast under Cancer; The shoulder-blades call you, Nemean, and the flanks you, Virgo; Libra tends the buttocks, and Scorpio reigns in the groin, And the Archer in the thigh; Capricorn too has loved the knees; The Youth guards the shins; Pisces, the feet.*

Macrobius (bk. 1 on the *Dream of Scipio*, chap. 11) calls the Moon the foundress and increaser of mortal bodies; and in bk. 11 of the *Saturnalia*, chap. 19, the Moon is called [Greek: τύχη (tychē, "fortune")] of the human body.

III. The day would fail me if I wished to gather here the laws of agriculture laid down to the Moon's standard. Let Colu- mella be read (bk. 2, chap. 10), and Palladius (bk. 2, chap. 6), and Pliny the Elder passim. For in bk. 16, chap. 39, speaking of the felling of oaks, Pliny the Elder says: "The Moon's reckoning matters enormously, and they will have timber felled only from the twentieth to the thirtieth. All agree, however, that it is laid low most usefully at her conjunction, a day which some call the interlunium and others that of the silent Moon. [Margin: At what Moon trees are to be planted or felled.] Some say that the Moon should be both in conjunction and under the earth, which cannot happen except at night. But if the conjunction falls on the last day of the winter solstice, that timber becomes everlasting." Next he draws this rule from Cato: "Elm, pine, walnut: this and all other timber, when you dig it out, take out at the waning Moon, after midday, with no south wind blowing. Do not touch timber except at the intermenstrual Moon and the half Moon. At that time do not dig it out or cut it off from the ground. In the four days next after the Moon has been full it is best taken out ——" After this, in bk. 18, chap. 25: "Others say that the bean should be sown at full Moon, and the lentil from the 25th to the 30th; the vetch too on the same days of the Moon." The whole of chap. 32 of bk. 18 is worth reading, where Pliny the Elder lays down first of all: "Everything that is felled, picked or stored is done with less harm at the waning Moon than at the waxing." And likewise: "Castrate boars, bullocks, rams and kids at the waning Moon." Again: "Make trenches at night at full Moon, cover the roots of trees at full Moon, sow in moist places at the interlunium and during the four days around the interlunium." Macrobius chimes with this (bk. 7 of the *Saturnalia*, chap. 16), saying that timber brought down at a full or waxing Moon is unfit for building; that grain should be gathered from the threshing-floors only at a waning Moon, so that it stays dry; and that nurses cover infants when they pass under the Moon, so that they are not moistened too much.

[Margin: The Moon, mistress of fluids.]

IV. For it is admitted that fluids grow as the Moon waxes and diminish as she wanes. And so Pliny the Elder says (bk. 2, chap. 99): "From this arises the true conjecture that the Moon's star is not without reason reckoned the star of breath: that this is what saturates the lands, and that in approaching she fills bodies and in withdrawing empties them; that for this reason shellfish grow with her increase, and those creatures that have no blood feel the breath most; and that even a human being grows and shrinks in blood with her light." And in chap. 101 he calls the Moon's star feminine and soft, because "it dissolves moisture, melts ice, reduces the slain bodies of wild animals to putrefaction, and loosens all things with its moistening breath." And in bk. 9, chaps. 7 and 31, and bk. 2, chap. 41: "the bodies of crabs and shellfish grow with the Moon's

increase." Macrobius too (bk. 1 on the *Dream of Scipio*, chap. 19) says that just as the power of sensing in us comes from the Sun, so that of growing comes from the Moon; and in bk. 7 of the *Saturnalia*, chap. 16, that boars killed in the hunt and carried in by night under a full Moon went putrid, while others brought in by day did not, because in the Moon's light there is a hidden warmth, one that diffuses moisture all the more. Yet the distinction Pliny the Elder makes (bk. 18, chap. 28) must be noted: "For at the interlunium the Moon is hottest in summer and icy in winter; conversely, at full Moon she makes the nights icy in summer and mild in winter." He gives the reason: that in summer, at new Moon, the Moon is nearer to us, as the Sun also is, that is, she strikes with more direct rays; but in winter she is nearer at full Moon. And he concludes: "Therefore, being of herself dewy, whenever she is cold she freezes to an immense degree the frosts falling at that time." Alcman too, in Macrobius, calls dew the son of the air and the Moon.

[Margin: Wonders of the tide of the sea, owing to the Moon.]

V. But nothing is more wonderful for showing the Moon's power than the tide of the sea, of which we showed the Moon to be the governor in bk. 2, chap. 15. To what was said there, two points must be added here. The first is what Pliny the Elder notes (bk. 2, chap. 98): "All seas are purged at full Moon." And shortly after: "No animal dies except when the tide is going out. This has been much observed on the Gallic Ocean, and established only in the case of man." The second comes from the same Pliny the Elder (bk. 2, chap. 97): the seas flow in and out twice within 24 hours, and all the periodic variation of the tides is completed in eight years, namely in 2922 days, in which nearly 99 lunations occur and the Moon goes round the Earth 2823 times, that is, 99 times less often than the Sun. Doubling the 2823, then, gives 5646 alternating tides in eight years, and thus 706 alternating tides in one year. But see the commentary on Pliny the Elder for this chapter written by Iacobus Mylichius [Jakob Milich]. On forecasts of winds and storms from the Moon, moreover, see Ptolemy at the end of bk. 2 of the *Apotelesmata*, Pliny the Elder (bk. 18, chap. 5), and Virgil, *Georgics* 1.

To conclude these scholia: I say that many things are brought about by the Moon of which man is shamefully ignorant, though the brute animals are not ignorant of them, since, on the testimony of Pliny the Elder (bk. 2, chap. 41, and bk. 18, chap. 29), [Margin: The ant feels the Moon's changes.] the ant, the smallest of animals, rests at the interlunium, and at full Moon works even by night.

CAPVT II.

Chapter 2.

De Lunæ Subſtantia, & vtrum ſit altera Terra, habeatq. ſuam atmoſphæram ſuoſque incolas.

On the Moon's substance, and whether she is another Earth and has her own atmosphere and her own inhabitants.

I. Apart from the controversy the Moon shares with the other heavenly bodies — whether they are of a substance different from the elementary, as the Peripatetics prefer, or rather elementary, those everlasting fires having been kindled from water on the fourth day of the world by divine command (a matter on which we gave a few indications in bk. 3, chap. 1, and which remains for us to discuss in bk. 9, on the system of the world) — certain things peculiar to this planet must be touched on briefly at this point. For to most writers she has seemed to be of an elementary nature, though to some fiery, and to others rather watery or earthy. [Margin: Opinions of the ancients on the nature of the Moon.] Let us hear first of all Plutarch, *De Placitis Philosophorum*, bk. 2, chap. 25, where he writes this on the Moon's nature: *Anaximander: that she is a circle nineteen times the proportion of the Earth, like the Sun full of fire, and that the failure of her light befalls her through the turning of the wheel. For she is like the wheel of a chariot, which has a hollow rim filled with fire and is furnished with one vent for breathing out. Xenophanes: that she is a compacted cloud. The Stoics: that she is mixed of fire and air. Plato: that the greater part of her is earthy. Anaxagoras and Democritus: a fiery firmament containing within itself plains, mountains and valleys. Heraclitus: an Earth enclosed in a murky cloud. Pythagoras: that the body of the Moon follows a fiery nature.*

[Margin: The Stoics' opinion: by whom and on what reasoning defended.]

Further, one Pharnaces, in the same Plutarch (the essay *On the Face in the Orb of the Moon*), defends the Stoics' opinion with roughly these arguments: that she is the lowest body and the nearest to the Earth, and is therefore fiery in such a way that her fire requires a hypostasis from admixed earth, by right of kinship and neighbourhood; yet she is not heavy as our Earth is, and even if she is, she does not fall downward, either because, like stones whirled round in a sling, she is held in her circle by the speed of her motion, or because she is herself the centre of other small bodies or of parts more akin to her. And even if it were granted that a place in Heaven is given to earthy things against nature, it would still not be shown by this that the Moon is not an Earth, but only that she is an Earth set in a place foreign to her nature, just as the fire of Etna is under the earth against nature, and yet is fire. Nor is it for the good of the universe that its parts should shun communication and mixture; rather, it belongs to the Providence of God the Maker that not each thing should lie where it was born to lie, but that heavy things should at times be carried upward and light things downward, and that, tempered with one another, they should make up a certain harmony and fellowship. After Pharnaces, Apollonides, in the same essay, affirms that the Moon is earthy rather than watery, but *a heavenly Earth, having wonderful beauties of place: flaming mountains, and separate purple*

things [?]*, and gold and silver not scattered in the depths, but such as gleam on her plains or are spread about on her hills.* Finally, a little before the end of this essay it is said, on the opinion of Plato and Heraclitus, that the Moon and all the stars are tempered from fire and earth; according to Xenocrates, however, that the stars and the Sun are composed of fire and the first dense, the Moon of the second dense and an air of her own, the Earth of the third dense, water and fire. Pliny the Elder, on the other hand (bk. 2, chap. 101), seems to have allowed her a watery nature, when he said: *that the Moon's nourishment is in fresh waters, as the Sun's is in salt ones*; although earlier (bk. 2, chap. 9) he had pronounced: *that the stars doubtless feed on earthly moisture, because at half orb she is never seen without spots, the power being evidently not yet sufficient for drawing beyond the due measure. For the spots are nothing other than the dirt of the earth carried up with the moisture.* And in Laertius [Diogenes Laertius], bk. 7, Zeno of Citium affirms that the Moon has more of earth, and is nourished [?] by waters. Macrobius (bk. 1 on the *Dream of Scipio*, chap. 19) says that the Moon is an ethereal and solidified Earth. Theodoret too, in Sermon 4, tells it thus: *The philosophers on the Moon, as follows: Thales thinks she is earthy; Anaxagoras and Democritus, a fiery solid mass containing plains, mountains and valleys set within it; Pythagoras, a stony body; Heraclides, an Earth hedged round with cloud.* After these, Longomontanus (*Theorica*, bk. 1, p. 315) called the Moon an ethereal Earth. Kepler too (*Epitome of Copernican Astronomy*, bk. 1, p. 100) says most expressly that the lunar globe is of the same nature as the Earth in this: that on its outermost surface it has mountains and valleys, continents and seas; and yet heavy things, such as the lunar waters, do not fall either to our Earth or to the middle of the world, but work their way into the places nearest the centre of the lunar globe. And in his dissertation with the *Sidereus Nuncius* he reports the opinion of Giordano Bruno, who says that the fixed stars and the Sun are of a fiery nature, the remaining planets of a watery one, and that by an inviolable law of Nature it comes about that neither can fire do without its water, that is, the Sun without the planets, nor in turn these without it; and that Jupiter is a kind of Earth. He also reports that of Mästlin, in the *Theorems of Eclipses*, who affirms that the Moon is of an earthy nature. Kepler himself, however, thinks that the Moon is another Earth, but one gaping everywhere like pumice with very frequent and very large pores, and rarer and less fit to resist the circular motion by which our Earth moves her round by magnetic force, in proportion as the Sun moves the other planets. On this see his *Commentaries on Mars*, chap. 34. In the *Astronomia Optica* too, p. 228, he says that the Moon's body is dense as the Earth is, and approves the opinion of Posidonius in Macrobius, who says that the Moon's matter is the same as the Earth's. Our own Athanasius Kircher, too (*Ars Magna Lucis et Umbrae*, bk. 1, chap. 4), holds that the Moon is a heavenly Earth and a watery body made by God so that the Sun's heat may be tempered and cooled. Galileo, in the first Dialogue *De Systemate Cosmico*, asserts that there is a great conformity between the Moon and the Earth by reason of proximity, of shape and of the manner of illumination, and because

the matter of both is dense and opaque and the surface rough with mountains and valleys; yet he denies that she is composed of land and sea, or that there are on her rains and other generations like ours. But David Fabricius, as Argoli reports (*Ephemerides*, bk. 1, chap. 10), said that lynx-like eyes are to be found which see men and the other animals on the Moon: but these are old wives' tales.

[Margin: The author's opinion.]

II. For my part, I judge it more probable that the Moon does not have a mixed form composed of our elements, in act or in power, nor one generated from them or resolvable into them, but has a heavenly form, altogether different from the forms of our elements and of the mixtures generated from them. This seems more in keeping, on the one hand, with Divine Omnipotence, so that we do not, as only too narrow a mind would, restrict it in the fashioning of the heavenly bodies to our elements, to which we are accustomed, as though there did not remain many other species of forms nobler than the elementary; and on the other with Providence, lest those heavenly bodies which it willed to be superior in place, in influence and in power of rule should not be of a higher and more excellent nature. Whether, then, they consist of the same prime matter as sublunary things, or of a different one, or of none really distinct from the form, does not much trouble me, since the whole or the chief account of a nature is to be sought from its form. Nor can agreement in certain qualities which can be common equally to elementary and non-elementary forms, such as rarity, density, opacity, transparency, roundness of figure, evenness, roughness, light, colour and the like, be an argument for this rather than that kind of forms. I judge nonetheless that the Moon was placed next to the Earth for this reason: that she has the greatest analogy with it, and, if the Sun were granted to be fiery, she herself should rather be called terraqueous from the effects we experience. But absolutely speaking she was made so that she may transmit to us more quickly and with less harm the influences of the higher stars, especially of the Sun, tempered by the speed of her course through the zodiac, and received and reflected downward by the varied roughness of her surface; and so that, like a cupbearer, she may foretaste for us what, poured on us without the Moon, we could hardly drink in and bear.

[Margin: Whether there is an air around the Moon, and whether it is the Moon's own.]

III. Akin to the preceding question is this other: whether the Moon has her own atmosphere around her, or at least some air spread about her, in roughly the way our Earth is clothed with vaporous and rather thick air, and her own dawn, by which the Moon's compass is enlarged. For not a few authors, and not contemptible ones, affirm it. First of all Plutarch, in the essay *De Facie Lunae*, insinuating his own opinion under another person's mask, acknowledges an air around the Moon that is not rainy, yet is dewy, when he says: *But what wonder is it if on the Moon roots, seeds and plants are born, needing no help from rains or winter, but content with a summery and tender air fitted to their nature? And why is*

it not probable that breaths are given off, which are affected with heat by the Moon, and that gentle airs and light dews and moistures gradually accompany her turning, which, spread around, suffice as nourishment for the plants, since the temperature of the Moon herself is not fiery, not parched, but soft and watery? Mästlin acknowledges the same air, or a denser aether, around the Moon, and with him Kepler, in the *Epitome of Astronomy*, p. 893, in the *Dissertatio cum Nuncio Sidereo*, p. 14, in the *Optica*, pp. 252 and 302, and in the book *De Stella Nova*, chap. 23, not around the Moon only but also around the Sun, and before the *Ephemerides*, pp. 9 and 21; Galileo in the *Sidereus Nuncius*, p. 12; Longomontanus (*Theorica*, bk. 1, chap. 9, p. 315), who concedes this peristasis, denser than the vaporous air surrounding our Earth, because of the greater quantity of moisture on the Moon, from which the Sun's rays draw vapours; Giordano Bruno, in the book *De Immenso*, who holds the same of all the heavenly bodies. David Fabricius too, in Kepler at the place cited from the *Ephemerides*, and Antonius Maria de Rheita [Antonín Maria Šírek] (*Radius Sidereomysticus*, bk. 4, chap. 2, Member 10), admits a vaporous atmosphere around the Moon, though with no clouds visible around her, because they are quickly baked out and scattered by the Sun's rays, which are nearer to the Moon than to us, and by the Moon's swift turning. And Mario Bettini (*Apiarium* 8, prog. 2, prop. 10) does not reject a vaporous circumlunar air, very thin but still apt to refract the Sun's rays. Michael Florent van Langren affirms to me, in a letter most courteously sent to me in 1646, that this same air is seen with telescopes; and so does Wendelen, both in letters written to me and in the *Idea of the Atlantic Tables*, p. 5. From this Longomontanus, Kepler, Fabricius, Bettini and Wendelen infer that some variation passes over from this circumsolar or circumlunar air into eclipses of the Moon and Sun: either the Sun's rays refracted in it enlarge the Sun's image and diminish the solar eclipse, or the Moon appears to be eclipsed sooner, since this air falls into the Earth's shadow before the Moon's body does, and emerges from it later. On this, however, see Kepler's limitation, which we treat below, chap. 16, no. 7. Wendelen adds that from the Sun's rays refracted in the air surrounding the Moon it comes about that the lunar dichotomy, or the Moon shining half-lit to us, appears to us sooner in the first quadrature and later in the second, since, as I interpret it, a greater part of the Moon is lit by the refracted rays than if there were no refraction; just as our Earth is somewhat more lit because of rays refracted by our denser air. But see what I shall say in chap. 18, no. 6. [Margin: The author's opinion on this air, held in suspense.] Meanwhile, with no telescope I have used has this air yet appeared to me so plainly that I should be compelled to acknowledge it near and around the Moon rather than in our own air, in which halos also form. Further, Vincentius Lagalla [?], in his book *De Phaenomenis in Orbe Lunae*, chap. 10, flatly denies that the atmosphere already mentioned exists around the Sun or the Moon.

[Margin: Whether there are inhabitants or dwellers on the Moon.]

IV. Of those who, from the sight of the lunar spots, have recognised mountains, valleys, forests and seas on the Moon like ours, a great part have also

assigned the Moon her own inhabitants, whom they have also named [Greek: Αντίχτονας [recte: Ἀντίχθονας] (antichthonas, "counter-earthers"; rendered by the page itself as "dwellers on another, opposite Earth")], that is, people living on another, opposite Earth. Cicero, *Academic Questions*, bk. 4: *Xenophanes says that the Moon is inhabited, and that she is an Earth of many cities and mountains.* Achilles Tatius reports similar things in the *Isagoge*, saying: *Some think there is on the Moon another region for inhabiting, with rivers and the other things seen on earth.* But let us hear Plutarch, *De Philosophorum Placitis*, bk. 2, chap. 30: *The Pythagoreans say that the Moon appears earthy because, like our Earth too, she is inhabited all round, by animals indeed larger and more beautiful, which contain fifteen times the size of ours, and casting off no excrement.* But in the celebrated essay *On the Face in the Orb of the Moon*, *they say that the Moon hangs over the heads of those who live below as over so many Tantaluses, and that in turn those who inhabit her, bound like Ixions, are rolled round and back with such force that it is no wonder if, by the force of the shaking, the Lion fell into the Peloponnese.* But he counts these among fables. He adds, however, that there are caverns on the Moon, and that the greatest of the caverns is called *the Inner Chambers of Hecate*, where souls render an account of, and pay the penalty for, what they did or suffered once born; that the parts of the Moon turned towards Heaven are called *the Elysian Field*; and that the Genii do not always dwell on the Moon, but come down to us for various tasks, and if they do not perform these rightly, they are thrust back to the Earth and made to struggle with bodies. Hence Macrobius (bk. 1 on the *Dream of Scipio*, chap. 11) places lunar peoples and a Purgatory of souls on the Moon. Nikolaus von Kues (*De Docta Ignorantia*, bk. 2, chap. 11) did not shrink from this opinion about inhabitants of the lunar globe. Bede too, in the book *De Mundi Constitutione*, under the title on the aether, attributes to certain natural philosophers the same opinion about souls and Genii living on the Moon as on an ethereal Earth, or ascending and descending through her. Kepler, moreover (*Astronomia Optica*, p. 250, and the *Dissertatio cum Nuncio Sidereo*, p. 10), though he may seem to place inhabitants on the Moon in jest, seems nevertheless to lean seriously towards this opinion, since he says that *it is not unlikely that there are inhabitants not only on the Moon, but on Jupiter itself*, and he does not despair of their being discovered, if ships or sails are granted for the heavenly breeze. Yet he adds: *Let these things be interposed for pleasure, as a marvel of human daring, which presents itself above all in the men of this age.* What, though, is more daring than Kepler's intellect? That Sagredo, in Galileo (Dialogue 1 on the system of the world), was more sober when he pronounced: *Whether on the Moon or another planet there are generated grasses, plants, animals, rains, thunderbolts, etc., I neither know nor believe, much less that men live there.*

[Margin: Censure of those who assert inhabitants of the Moon.]

Our own Adam Tanner, further, in the dissertation *De Caelis*, q. 4, judges rash the opinion affirming that the Moon is inhabited by men living a mortal and natural life, as resting on no foundation, and indeed as little in accord with Sacred Scripture. For it is evident from Genesis 1 that the stars were destined

by God for a far different office than to be seats of men, and that all men were begotten from Adam, who was produced on our Earth (Genesis 1 and 2). Again, in Deuteronomy 4 it is said: *Lest perhaps, lifting up your eyes to Heaven, you see the Sun and the Moon and all the stars of Heaven, and, deceived by error, adore and worship those things which the Lord God created for the service of all the nations that are under Heaven.* And in Psalm 14 the Earth alone is assigned to men for dwelling: *The Heaven of Heaven is the Lord's, but the Earth he has given to the children of men*; and in Acts 17: *And he made of one every race of men, to dwell upon the whole face of the Earth.* Thus there is one Church militant on our Earth, whose God wills all men to be saved. Whether Enoch and Elijah were carried off to the Moon and are preserved there by divine miracle, Tanner does not discuss there, nor is this the place to weigh these matters with the dignity and diligence that would befit them. If anyone, however, imagines inhabitants on the Moon, I shall at last show, below in chap. 9, in the Scholia, how our Earth would appear to them.

CAPVT III.

Chapter 3.

De diuerſis Lunæ Phaſibus earumq. Varietate, ſed præcipuè de Prima Phaſi.

On the various phases of the Moon and their variety, but especially on the first phase.

I. *Phasis* in Greek is the same as appearance. Now the Moon appears to us at one time full, at another half-full, at another gibbous, at another horned or sickle-shaped, and indeed with her horns turned now to the east, now to the west, and these sometimes erect, sometimes inclined: a truly wonderful variety of illumination through the whole month in which she returns from conjunction with the Sun to conjunction with it again. To put these phases before our eyes, in the following figure let the Sun be at S, illuminating the Moon, as I assume on the basis of what will be said in chap. 5; let the Earth, from which we view the luminaries, be at T; and let the Moon's orbit under the zodiac be AFMG, whose diameter AM is bisected at T, at right angles, by the other diameter FG. Let the Moon now be at A, interposed between the Sun S and our eye T; for she will appear either lit by no light or very dark, like a black round little cloud, and then there will be the synod or conjunction of the luminaries, or new Moon. Then, after about one or two days, she will appear in the evening at the western horizon, a little after sunset, very thinly but very sharply horned, as at B, whereas the previous evening she did not appear; and this is called the first phase. Afterwards, about the fourth or fifth day, increased in light and with a fuller horn, about the first sextile aspect, that is, elongated 60° from the Sun, she will be seen at D. From here, about the seventh day, she will be 90° from the Sun, or a whole quadrant, and will appear at F, half-full or bisected, and there will be the first quadrature. Then, more than half-full,

about day 11 from conjunction, she will appear at H, gibbous, and near the first trine aspect, that is, 120° from the Sun. Finally, about day 13, she will be seen at K so gibbous that she appears almost full, until about day 14 or 15 she appears at M, opposite the Sun, with us at T placed between her and the Sun; and then she will be seen full of light and with a round phase, and there will be the full Moon. She will rise as the Sun sets and shine all night, whereas previously she began to shine after sunset, and shone for us longer and longer the further she was from the Sun, but still not all night. In the first semicircle AFM, in which she waxes, the lit part of the Moon will always face west, and the horns, turned away from the Sun, east.

When the full Moon is over, she will begin to wane, and after sunset will not rise at once at the eastern horizon, but later and later; and in the whole latter semicircle MGA, or the second part of the lunar month, in which she wanes, her lit part will face east and her dark part west. She will appear gibbous one or two days after full Moon at L, then at I, in the second trine aspect, distant from the Sun's place, in the order of the signs, by the arc AFI of 240°, but on the other side by the arc AGI of 120°. Afterwards she will be seen in the second quadrature at G, and in the second sextile aspect at E, and finally in the extreme and last phase at C, and again, after this, in conjunction with the Sun at A. Do not be troubled that the engraver seems to have made a Moon at S in place of the Sun, as he left out the rays; for the Sun seen through a telescope, and without deception of the eyes, appears without the hair of rays, *and an Apollo not only beardless but shorn.*

[Margin: Explanation of the diagram of the lunar phases.]

Diagram. Woodcut set in the right column, below the sentence on the engraver. At the top, a disc bearing a human face and no rays, lettered S beneath it. Below it, a circle (the Moon's orbit) carrying twelve small globes, each shaded in part. Two diameters cross at right angles in the centre of the circle, one upright and one level, with T beside their crossing. The topmost globe, lettered A, is wholly dark; the shading shrinks down each side of the circle through B and C, D and E, F and G (half dark, the dark half below), H and I, and K and L; the bottommost globe, lettered M, carries no shading.

- A (top of the circle): the Moon in conjunction
- B (upper left), C (upper right)
- D (left, below B), E (right, below C)
- F (left end of the level diameter), G (right end of the level diameter)
- H (left, below F), I (right, below G)
- K (lower left), L (lower right)
- M (foot of the circle): the Moon at the full
- S (below the disc at the top): the Sun
- T (at the crossing of the diameters): the Earth

[Margin: The names of the phases.]

II. The Latin and Greek names of the phases already mentioned, used now as adjectives, now as nouns, are those written below, to which add *Syzygy*: for

[Greek: συζυγία (syzygia, "conjunction")] means a conjoining or coupling, and above all the conjunction ☌, when Cicero speaks of its being "in the yoke" [in iugo]; although the word is also used for the diametrical opposition ☍. These names are recorded by Vitruvius, Book 9, chapter 4; Pliny the Elder, Book 2, chapter 14; Marcellinus [Ammianus Marcellinus], Book 20; Macrobius, Book 1 on the *Dream* [Somn.], chapter 6; Geminus, *De Elementis Astronomicis*, chapter 7; and Martianus Capella, Book 8, where he treats the course of the Moon; besides very many more recent writers.

A. New Moon [Nouilunium], the silent Moon [Luna ſilens]; conjunction [Coniūctio], meeting with ☉ [Cōgreſſus cum ☉]; *Neomenia*; synod [Synodus]; kindling of the Moon [Lunæ accenſio]	☌	[Greek: νεομηνία (neomēnia, "new Moon")], or [Greek: νουμηνία (noumēnia, "new Moon", contracted form)]; [Greek: σύνοδος (synodos, "meeting")]
B. First phase [Prima Phaſis]; new Moon [Noua Luna]		[Greek: πρώτη φάσις (prōtē phasis, "first phase")], or
C. Last phase [Vltima Phaſis]; the latest Moon [Luna nouiſſima]. The interlunium [Interlunium] or intermenstruum [intermenſtruum] is the time between the last and the first phase, from C to B		[Greek: νέα σελήνη (nea selēnē, "new Moon")], or [Greek: ἐσχάτη φάσις (eschatē phasis, "last phase")], or [Greek: ἔνη σελήνη (enē selēnē, "last Moon")], or [Greek: ἀφανισμός (aphanismos, "disappearance")]
B, D, C, E. Horned [Corniculata], sickle-shaped [Falcata], curved into horns [curuata in cornua]		[Greek: μηνοειδής (mēnoeidēs, "crescent-shaped")], and [Greek: μηνοειδῆ (the same, another form)]
D. First sextile aspect [Primus Sextilis aſpectus]; and **E.**, second	✶	[Greek: ἑξάγονος [recte: ἑξάγωνος] (hexagōnos, "hexagon")]
F. First quadrature [Prima Quadratura]; **G.**, second; the divided Moon [Luna diuidua], bisected [biſecta], halved [dimidiata], half-full [ſemiplena]	□	[Greek: τετράγωνος (tetragōnos, "square")]; [Greek: διχότομος (dichotomos, "cut in two")]; [Greek: διχότομος ἡμίτομος (dichotomos hēmitomos, "cut in two, half-cut")]
H, K, L, I. The gibbous Moon [Luna Gibba, Gibboſa]		[Greek: ἀμφίκυρτος (amphikyrtos, "convex on both sides")]
H. First, **I.**, second trine aspect [aſpectus Trinus]; the Moon in trine [Luna in triquetro]	△	[Greek: τρίγωνος (trigōnos, "triangle")]
M. Full Moon [Plenilunium], opposition [Oppoſitio], the whole Moon [Luna Totilunis]; in diameter [in diametro], rounded into a full circle [ſinuata in orbem], mid-month [medius menſis]	☍	[Greek: πανσέληνος (pansēlēnos, "full Moon")]; [Greek: διχομηνία (dichomēnia, "mid-month")]
The waxing Moon [Luna creſcens], from A, through F, to M		[Greek: σελήνη αὐξανομένη (selēnē auxanomenē, "waxing Moon")]
The waning or ageing Moon [Luna decreſcens, ſeu ſeneſcens], from M, through G, to A		[Greek: σελήνη φθίνουσα (selēnē phthinousa, "waning Moon")]

---

[21] On the leaf the Greek lines do not stand level with the Latin entries line for line. The word *vel* ("or") closing the line for B leads on to the next Greek line, which stands level with the first line of C.

[Margin: Inclination of the horns: what is it?]

III. Besides the phases already mentioned, the inclination or erection of the Moon's horns [Lunarium Cornuum Inclinatio aut Erectio] also deserves consideration. Inclination is when the points of the two horns do not lie in the plane of one vertical circle, but a line drawn through the tips of the horns is inclined to the vertical circle, so that one horn is found on one vertical and the other on another. So it is in the following figure, in which let the horizon be HR, the meridian HBR, the pole of the world P, the pole of the ecliptic Z, the vertex B, and portions of different vertical circles FBZ, or BKN, or BLO. For if the Moon is inclined as at NO, the distance of horn N from the vertex, arc NB, will be equal to arc BO, by which horn O stands from the vertex; but if it is as at KL, one horn, at K, will be farther from the vertex B, namely by the arc KB, than the horn at L, by the arc BL.

[Margin: Erection of the Moon's horns: what it is.]

Erection of the horns, on the other hand, is when both horns are on the same vertical, as when the Moon is at FG, through which points the same vertical circle ZBGF would pass. This variation of phases or positions is not to be despised by an astronomer. Meanwhile, three notable rules are to be handed on to beginners.

Diagram. A woodcut in the left column. The meridian arches from H at lower left over B at the top to R at lower right, with the curved horizon closing the figure below. Arcs of vertical circles descend from B. Three Moons are drawn as dark discs with a pale crescent: one at F–G on the arc towards the upper left, one at K–L in the middle, and one at N–O at the foot. A small circle stands at the upper right around P, with Z on the arc above it. Labels read, all on the block; labels not read: none.

- B (top): the vertex
- F (left of the upper Moon), G (right of the upper Moon)
- L (above right of the middle Moon), K (left, below the middle Moon)
- Z (upper right): the pole of the ecliptic
- P (centre of the small circle): the pole of the world
- H (lower left), R (lower right): ends of the horizon
- N (left of the lowest Moon), O (right of the lowest Moon)

[Margin: Rule for recognising the ecliptic.]

The first is this: if a straight line is drawn on through the Moon's two horns, it will mark the pole of the zodiac and cut the ecliptic at right angles if the Moon has no latitude, or very nearly at right angles if it has some latitude; and so it will show the position of the ecliptic in the sky.

[Margin: Rule for recognising the nonagesimal degree of the ecliptic.]

The second is this: whenever the Moon holds its horns erect, it will be in the nonagesimal degree of the ecliptic reckoned from the horizon, and the vertical circle will be the same as the circle of latitude and longitude. Therefore the Moon will have no parallax in longitude: strictly so if it has no latitude, and nearly so if it has latitude, as al-Battānī teaches (chapter 24), together with

Daniel Santbech (the book *De obſeruatione*, Proposition 14) and Kepler (in the *Optics*, p. 246). You will discern this with a thread hanging plumb, if the horns stand in the same straight line as the plumb-line at rest; or else from chapter 4, Problem 9.

The third: if the new Moon took place in the ascending signs, the Moon's horns point towards the zenith in the first phases; but if it took place in the descending signs, one horn faces the zenith and the other the horizon, for northern observers [apud Boreales], as Barozzi notes (*Cosmography*, Book 4, p. 289).

De Prima Lunæ Phaſi.

On the First Phase of the Moon.

[Margin: Which peoples were accustomed to begin the month from the first phase.]

IV. The first phase of the Moon is very celebrated because of the beginning of the civil month, which many nations were once accustomed to start from it. Even now the Arabs, as al-Battānī (chapter 41) and al-Farghānī report, begin the first day of their lunar months from the evening on which the Moon, rising heliacally in the west, is first seen after sunset. They call this first phase Hay or Helal, and they salute it. From its sickle shape the Turks adopt the form of the horned Moon for the tops of their towers and of their hats [petaſorum]. And, if we believe Joseph Justus Scaliger (*De emendatione temporum*, Book 5), they set the neomenia from the 3rd day after the coming together of the Moon with the Sun, and for that reason, at the neomenia of the month Muharram, in a clear sky, they always see the Moon horned.

Whether the Hebrews once began the neomenia from tables and the periods of cycles, or rather from the first phase of the Moon, we have already discussed in our *Chronological Book*, Book 3, chapter 28. From this I say here briefly, with Paulus Forosemproniensis [Paul of Middelburg] (part 2 of the *Summa*, Book 8) and Scaliger (in the *Prolegomena*, p. 6, and Book 2, p. 150), that the Jews had their own lunar cycles, arranged either by Gamaliel or by someone else, from which they determined the neomenias, and that they began their months from the conjunction, or mean new Moon. So it was truly said by St Dionysius the Areopagite that the fifteenth Moon, on which Christ the Lord suffered, after the fourteenth on which he celebrated the Passover, was at the diameter and opposite the Sun. This would not be right if the Jews had begun the month of Nisan from the first phase, since the first phase sometimes does not appear until the 3rd or 4th day after the new Moon.

Nonetheless, as the same Scaliger says, they used to observe, as they still do today, the first [Greek: φάσιν (phasin, "phase")], not in order to proclaim the neomenia from it, but in order to sanctify it, and on seeing it to exclaim [Greek: ἀγαθὸν τέρας ἔστω ἡμῖν, καὶ παντὶ Ισραὴλ [?] (agathon teras estō hēmin, kai panti Israēl)], *A good omen be to us and to all Israel*. Moreover, a certain few

Jews of the sect of the Sadducees, called Karraim, haters of the other Jews, wait for the first phase so as not to begin their months with them. And perhaps it is of these that a thing is true which Clement of Alexandria (*Stromata*, Book 6, p. 270), Onufrius Panuinus [Onofrio Panvinio] (in his commentaries on the *Fasti*, at the year of the City 786), Salmeron [Alfonso Salmerón] (volume 1, Prolegomenon 38) and Io. Georgius Heruartus [Johann Georg Herwart von Hohenburg] (chapter 171 of his *Chronology*) report of the Jews without qualification: namely, that they used to begin the neomenias from the first appearance of the Moon. But what if the Jewish cycles were once so arranged that the first day of the month, in the greater part of months, fell on the first phase, which usually occurs sometimes one, sometimes two, more rarely three or four days after the new Moon, as I shall say shortly?

That the Greeks, however, began their months from the day of the new Moon is learnedly shown by our Pétau, in the *Uranologion*, Book 4 of the *Dissertations*, chapter 7, especially from the scholiast of Aristophanes on the *Clouds*; by Vitruvius, following Aristarchus, Book 9, chapter 4, whose words we shall give shortly at no. 5; by Scaliger, Book 1, p. 9; and by Varro, *De lingua Latina*, Book 5, and *De re rustica*, Book 1, chapter 37. They teach that the first day of the month is called the Moon [Greek: ἔνην, καὶ νεὰν (enēn, kai nean)], that is, last and new, because *it shares old and new light, and on the same day can be seen as the last and the first Moon.*

De Interuallo inter Nouilunium verum & primam Phaſim vel vltimam.

On the Interval between the True New Moon and the First or Last Phase.

V. How long an interval of time is required, after the moment of the true new Moon, before the Moon's first phase or first illumination can be seen, has rightly been asked since long ago; for the length of this interval is not settled among all writers. For it is true that most, with Pliny the Elder (Book 2, chapter 9), suppose that the Moon when joined to the Sun cannot be seen except in an eclipse of the Sun, because of the excessive glare of the Sun around it, since not even stars much brighter than the part of the Moon turned away from the Sun appear by day.

[Margin: The Moon seen near the Sun, almost in ☌.]

Yet Kepler, in the book *De Nova Stella Serpentarii*, chapter 24, tells the following: *In the year 1553, as a serious and most learned man wrote to me, the Moon was seen at Seville [Hiſpali] standing next to the Sun in Pisces, in the very middle of the sky. The whole city watched and bore witness. But when has anyone seen a similar new Moon? Does not the teaching of the ancients claim two days and more after the union for the first sight of the Moon? This, then, is the fifth testimony to what we contend: that the matter of the heaven, since it is different at different times, differing greatly from itself in subtlety, also at times takes in more brightness than at other times; and so at some times blinds the eyes of men more, at others less, in seeing*

the stars. In the *Epitome of Astronomy*, moreover, Book 6, p. 839, he relates that this happened at Seville on 1553 March 13, with the Sun at 3° ♈ and the Moon at 23° ♓, and so at a distance from the Sun of about 10°. And he says that at such a distance the breadth of the Moon's horn was the 109th part of the Moon's diameter, that is, 19″ or 20″, so that it could hardly have been seen; but that the Moon was nonetheless seen because of the purity of the ether around the Sun, and because of the snows of the Mountains of the Moon in Africa, to which the Sun was then vertical, reflecting the Sun's light on to the Moon, so that the Moon at least, if not the horn itself, could be seen.

And Americus Vespuccius [Amerigo Vespucci] too, in Ramusio, volume 1 of the *Navigations*, p. 132, relates: *Likewise we saw the new Moon on the same day on which it was joined to the Sun*; and Io. de Barros [João de Barros], in the same place, p. 392: *But in summer, on the summit of those mountains, the air is so pure that some of our men saw the new Moon on the day of conjunction.* We ourselves, on 1648 March 25, after sunset, $29^{h}\ 40^{m}$ after the new Moon, saw the first phase so large that it must necessarily have been visible on the same natural day to those further east. Thus, if the rarity and subtlety of the air allow it, the new Moon can be seen a few hours after the moment of new Moon, especially around the meridian. On the other hand, Strabo and Pliny the Elder (Book 6, chapter 22) report that in Taprobane the Moon is not seen except from the 8th day after the new Moon up to the 16th; but this is on account of the position of the sphere.

[Margin: Pliny the Elder's opinion on this interval.]

For the torrid and temperate zones, however, Pliny the Elder says (Book 2, chapter 9): *Having lingered in conjunction with the Sun for two days when it is slowest, it goes out again from the thirtieth day to the same round.* And in chapter 14 he says that the Moon is always hidden within 14° of the Sun. In chapter 17, after saying that the Moon makes conjunction with the Sun twice in no other sign than Gemini, and that only in Sagittarius does it at times make none (in Gemini because of the slowness of the Sun, whose apogee was then in Gemini; in Sagittarius because of its speed at perigee), he adds:

[Margin: Lynceus sees the old and the new Moon on the same day.]

But that the last and the first Moon should be seen on the same day or night, in no other sign than Aries, has also fallen to few mortals, and from this comes Lynceus's fame for keen sight. Nevertheless we saw at the end of no. 4, from Varro and the scholiast of Aristophanes, that the last and the new Moon can be seen on the same day.

[Margin: Vitruvius's opinion.]

Vitruvius, for his part, has this about the Moon (Book 9, chapter 4): *Accordingly, in every month, on the first day, before it passes, it lies hidden beneath the Sun's wheel and rays and is darkened; and since it is with the Sun it is called new. On the following day, on which it is counted second, passing away from the Sun, it makes a slender appearance of the edge of its round.*

[Margin: And Geminus's.]

Now let us hear Geminus, an ancient author, who distinguishes these intervals more carefully in chapter 7 of the *Elements of Astronomy*, in these words: *When it is swiftest the Moon appears sickle-shaped on the very day of the new Moon, when slowest on the third day; and it remains sickle-shaped sometimes up to the fifth day, and sometimes, when it is slowest, up to the seventh. It becomes half when it is swiftest about the sixth, when slowest about the eighth; it becomes full when swiftest about the 13th, when slowest about the 17th.*

[Margin: Al-Battānī's teaching on the first phase.]

But al-Battānī, in chapter 41, after saying that knowledge of this phase was more necessary to the Arabs, since they begin their month from it, than to the ancients, and after touching on the error of those who confused the arc of declination with the arc of latitude in this matter, says that the arc of vision [arcum viſionis] required between the Sun and the Moon, for the Moon to be able to rise heliacally and be seen after conjunction, is 12°, to which a descension on the equator of about 48^{m} of time corresponds. But when the Moon is at apogee and the Sun at perigee, he says, the arc already mentioned is 10° 50′, while with the Moon at perigee and the Sun at apogee it is 13° 30′. So the time required between the new Moon and the first phase is as much as that in which the Moon, then passing through the said degrees, draws away from the Sun.

He adds, besides, rules for knowing whether the Moon's first phase is to be seen on the first or the second day after conjunction on a given horizon. These rules depend on the true place of the luminaries computed for the moment of sunset, on the apparent place derived through the parallaxes of longitude and latitude, and on the oblique or right descension of the Moon, as essential factors; and, as incidental factors, as al-Battānī observes, on the clarity, density and turbulence of the air, and on the sharpness of our sight. For these are the reasons why the Moon frees itself sooner or later from the stretch of the twilight. He assumes, however, that the new and the old Moon cannot be seen on the same day. Anyone who wants examples based on the 12° already mentioned may consult Reinhold above, p. 159.

[Margin: The month of illumination.]

Michael Neander, in the *Elementa sphaerica*, p. 161, says that the month of illumination [Menſem Illuminationis] is the span lying between the first and the last sight of the Moon, which Johannes de Sacrobosco fixes at 28 days. He adds, however, that no definite number of days can be assigned, because the Moon leaves the Sun sometimes sooner, sometimes later, for causes listed elsewhere.

[Margin: More recent authors on this interval.]

These causes are followed out most carefully by Erasmus Reinhold on Peuerbach's *Theoricae*, pp. 153 to 163; by Nonius on the same *Theoricae*, from annotation 3, that is, pp. 279 to 290; by Magini in the *Theoricae Planetarum*, Book 2, chapter 16; by Barozzi in the *Cosmography*, Book 4, from p. 288; and by Kepler in the *Optics*, p. 257.

[Margin: The causes of variation in the first phase are enumerated.]

From these writers I find three causes why the Moon begins to appear sooner or later after the moment of synod, a fourth, incidental cause, from the diversity of the horizontal vapours and of eyes, being passed over; and to these al-Battānī (chapter 21) adds three others. They are: 1. the obliquity of the zodiac and the horizon; 2. the Moon's latitude; 3. the Moon's slower or faster motion; 4. the parallax of the Moon relative to the Sun; 5. the Moon's distance from the Earth; 6. the true interval between the Moon and the Sun.

[Margin: Explanation of the first cause.]

VI. The first cause, then, according to Peuerbach, Reinhold, Magini and Barozzi, is the obliquity of the ecliptic and the horizon, because of which the Moon's descensions at sunset become more right, that is, slower, or more oblique, that is, faster. For if there are more degrees in the arc of the parallel of the equator on which the Moon stands, intercepted between the Moon and the horizon, than in the arc of the zodiac between the Moon and the setting Sun, the Moon will be seen sooner, for it will be above the horizon at the end of twilight. This happens when the Moon is placed in the ascending signs, that is, from the beginning of Capricorn to the end of Gemini, for it is then in signs of right, that is, slow, descension. But if the arc of the Moon's descension is less than the Moon's distance from the Sun in the zodiac, the Moon will set while the evening twilight still lasts, and with such brightness that the Moon's first phase is overwhelmed. This happens when the Moon is in the signs from the beginning of Cancer to the end of Sagittarius, for it is then in signs of oblique, that is, swift, descension; but this holds for northern observers, for among southern observers the opposite occurs, according to what was said in Book 1, chapter 23, Rule 5.

If, however, we are speaking of the morning occultation and the last phase, the Moon will be hidden sooner in signs of oblique ascension and later in signs of right ascension: that is, for northern observers, sooner in the signs from the beginning of Capricorn to the end of Gemini, and later from the beginning of Cancer to the end of Sagittarius; and this all the more, the greater the altitude of the pole. Indeed, as Reinhold acutely notes, this first cause has almost no place in the first, second and third climates. For, as the tables of ascensions show, Pisces and Aries do not descend rightly, that is, slowly, nor Virgo and Libra obliquely, that is, swiftly, unless the pole is raised 11°; nor do Gemini and Capricorn rise obliquely, nor Cancer and Sagittarius set obliquely, unless the pole is raised by 30°.

Nonius, however, above, p. 289, admits with Peuerbach that after conjunction the Moon appears sooner

[Margin: Qualification of the first cause, from Nonius.]

from the beginning of Capricorn to the end of Gemini, and later from Cancer to Sagittarius inclusive; not, however, because of the larger or smaller arc already mentioned, but because of the greater or lesser hiding of the Sun under the horizon, which depends on the larger or smaller angle of the ecliptic and the oblique horizon. On this point he adds excellent demonstrations,

discussed in the problems of the primum mobile, and he concludes that the new Moon in the evening after conjunction, when it stands in Aries, appears sooner, and the ageing Moon in the morning is hidden sooner in Aries, while the opposite happens in Libra. Yet in the opinion of Peuerbach and the Arabs, the Moon appears soonest in ♒ and ♊, and latest in ♎ and ♍; and in the morning it is hidden soonest in ♓ and ♈, and latest in ♋ and ♐.

[Margin: Explanation of the second cause.]

VII. The *second* cause is the differing latitude of the Moon, or its declination from the ecliptic. For the greater the northern latitude, the more slowly, other things being equal, the Moon will descend in the evening and the sooner it will be seen, while in the morning it will hide the sooner, for northern observers. But the more the Moon declines to the south, the sooner it will descend in the evening and the later it will hide in the morning. All the opposite happens for southern observers. This cause, as Nonius and Magini observe, holds in the temperate zones; for in the torrid zone the opposite can happen: namely, that the Moon has a northern latitude and descends sooner, and sometimes descends together with the degree of the ecliptic in which it stands, and sometimes later.

[Margin: Explanation of the third cause.]

VIII. The *third* cause is the greater or lesser speed of the Moon's true or apparent motion. For if the Moon is swift in its proper motion towards the east, it will certainly set later and be seen sooner in the evening, and in the morning will be hidden sooner. But if it is slow, it sets sooner in the evening and hides later in the morning.

[Margin: The three remaining causes.]

IX. The three other causes added by al-Battānī either produce an almost imperceptible difference or reduce to the others. For the parallax of latitude reduces to latitude and the second cause, and the parallax of longitude to the first; in these, authors can be understood to have spoken of apparent longitude and latitude, and from these arises the apparent interval between the Sun and the Moon. The distance from the Earth, for its part, varies either the parallaxes or the speed of the Moon, and so reduces to the other causes.

[Margin: When the Moon begins to be seen on the 1st day after the new Moon, when on the 2nd, 3rd or 4th.]

X. Now, if all the causes, but especially the first three, combine to retard the Moon's descent in the evening, the ageing Moon can be seen on the same day, especially far from the horizon, and in regions where the pole is much raised. If only two causes combine, the Moon can be seen on the second day after its meeting with the Sun, and hidden two days before it. If only one cause, it can be seen on the third day after, and hidden on the third day before the meeting with the Sun. But if the three former causes combine to hasten the Moon's setting, as when the Moon is in the signs from Cancer to Sagittarius inclusive, with southern latitude increased by parallax, and at apogee or slow in its course, then the first sight of the Moon can be delayed up to the 4th day. It is in this way that the statements of the authors, discussed in no. 5, are to

be reconciled or corrected. It should be added, with Reinhold, that both the length of a summer's day and the shortness of the twilight contribute greatly to seeing the last and the first phase on the same day.

[Margin: Kepler's opinion.]

Kepler, however, in the *Optics*, p. 25, despite Reinhold's teaching, judges that, with all causes computed, this matter cannot be comprehended by definite rules, and he lays all the blame on the summer and winter air. He adds that the Moon can be seen at the very moment of conjunction at mid-heaven, if it is at the limit and at a latitude of 5°; for it can then show us about a 70th particle of its body illuminated, and that much more easily if it is viewed from a well, because, I believe, of the example in the *Stella Nova*, related at no. 5. And he adds that if the Moon is at the limits, that is, at its greatest latitude, and swift, the old and the new Moon can be discerned on the same day, and indeed more easily at mid-heaven.

De diuerſitate Phaſium in Quadraturis □.

On the Variation of the Phases at the Quadratures □.

[Margin: The phase of the half Moon.]

XI. The lunar dichotomy, too, is of two kinds: one true, which occurs at quadrature, the other apparent, which occurs when the Moon shines half-lit to us.

[Margin: And its interval from quadrature.]

How long before the first quadrature, or after the second, this phase occurs is not yet settled among astronomers, as is clear from what was said in Book 3, chapter 7, from no. 10 to 13, which need not be repeated here. It is certain, however, that, other things being equal, the interval between the first quadrature and the phase of the half Moon will be the larger, the greater the Moon's apparent latitude towards the spectator's pole and the Sun's declination towards the other pole, or the slower the Moon; but that for these causes the interval between the second quadrature and the phase of the apparent dichotomy will be smaller. Wendelen, moreover, as we said in the same chapter, no. 12, judges that this phase is hastened in the evening and delayed in the morning, because a larger part of the Moon is illuminated by the Sun, through the force of the Sun's rays refracted by the air around the Moon towards the Moon's body, than if there were no refraction. To this is added the greater or lesser distance of the Sun from the Earth, which, however, we taught in the same chapter how to investigate by means of this phase once observed. See also chapter 4 below, Problem 8.

De diuerſitate Phaſium in Syzygijs ☌ et ☍.

On the Variation of the Phases at the Syzygies ☌ *and* ☍.

[Margin: Variation of new Moons and full Moons.]

XII. The phase of the new and the full Moon is without doubt varied by the Moon's latitude, especially its apparent latitude; and its greater or lesser illumination by its greater or lesser distance from the Sun. To begin from this point, let the following paradoxes be held worth noting.

[Margin: 1st paradox.]

The 1st paradox is: *The Moon is never less illuminated by the Sun than when it is full.* So say our Aguillonius [François d'Aguilon] (*Optics*, Book 5, prop. 48), Biancani (in the *Sphaera*, Book 9, chapter 3) and Bettini (*Apiarium* 8, Prog. 2, Proposition 8). The reason is that since the Moon's globe is smaller than the globe of the Sun illuminating it, more than a hemisphere of the Moon is illuminated, as is shown in optics; yet the further the smaller sphere is from the illuminating body, the smaller is that excess of the portion illuminated beyond the hemisphere. And at full Moon the Moon is at its greatest distance from the Sun, if this is compared with its distance from the Sun at new Moon.

[Margin: 2nd paradox.]

The 2nd paradox is: *The Moon is never more illuminated by the Sun than when it is dark to us.* So says Bettini, above; for the Moon is then nearest the Sun. Therefore, even if at ☌ and ☍ a still larger portion of the Moon is illuminated through the force of refraction than if refraction did not intervene, yet, other things being equal, more of the Moon is always illuminated at new Moon than if no refraction of the Sun's rays took place in the air around the Moon, as Bettini noted. How large this portion is will be stated after the Moon's distance and refraction have been determined; meanwhile see chapter 4, Problem 4.

[Margin: 3rd paradox.]

The 3rd paradox: *There has never been a pure full Moon in respect of us.* So Kepler lays down in the *Astronomia Optica*, p. 237, if indeed it pleases us to proceed subtly here and [Greek: ἀκριβολογεῖν (akribologein, "to speak with exactness")]. For if the Moon falls into the Earth's shadow, there will be no whole full Moon: either the whole Moon or a part of it will be cheated of the Sun's light that would otherwise fill it. If, on the other hand, it avoids every eclipse, about 64′ or 66′ must lie between the centre of the Moon and that of the Earth's shadow. But with the Moon at so great a distance from the place of opposition, there is already an intersection of the circle of our vision, as bounded on the Moon, and the circle of illumination by the Sun; for at a distance of the Moon from the place of opposition of 30′ they touch each other. Therefore we shall not then be able to see full illumination by the Sun on the Moon, and so no full Moon either. Yet Kepler admits that the particle of the Moon which, out of the illuminated portion, is hidden from us is imperceptible, and scarcely the 7000th particle of the Moon's semidiameter. But even if there were no intersection, and the Moon, lacking latitude, could be seen illuminated by the Sun, the portion seen would still be less than the portion illuminated.

He teaches very similar things about the new Moon. For wherever the Moon leaves the Sun untouched, it will have a residual horn, for the reasons just given. In a central conjunction, if it appears smaller than the Sun, the circle of

illumination will descend below the circle of vision, and the Moon's limb will be seen lit in a circle, so that it will not appear dark, as a new Moon requires, and the circle of vision will be greater than the circle of illumination. But he leaves out total eclipses of ☉, to which this exception does not apply.

[Margin: 4th paradox.]

4th paradox: *The moment of an apparent full Moon has a breadth of about two hours.* So Reinhold on Peuerbach, from p. 166, in agreement with Witelo, Book 4, Prop. 74. For since at full Moon the Sun illuminates 180° 28′ 12″ of the Moon, if refraction is meanwhile set aside, while we see the Moon under an angle of about 30′, and the arc of a great circle through the pole of vision is less than a semicircle by about 30′: if that excess and this deficit are joined, about 1° will be gathered, and to traverse it about two hours of lunar motion are required. For that whole time, therefore, the Moon will appear full for this cause at least, although strictly it does not appear as full as it is, for the cause stated in paradox 3.

[Margin: 5th paradox.]

5th paradox: *When the Moon has latitude, new Moon and full Moon are threefold.* For it is new Moon when the Moon is distant from the Sun by nothing in longitude, and full Moon when it is 180° distant from it. But these things can be understood as the conjunction or the distance being verified in three ways: by a circle of latitude drawn through the centres of the Moon and of the Sun or Shadow, making right angles with the ecliptic; or by a circle of latitude drawn through the centres of the luminaries, but making right angles with the Moon's orbit; or by a circle so drawn through the centres of the luminaries that they stand equally distant from the nearer node of the ecliptic with the lunar orbit. For although very many think that conjunctions take place in the first way, and therefore reduce the Moon's place from the lunar orbit to the ecliptic, yet, as Kepler says in the Rudolphine Tables, ch. 32, at the end of precept 155, this question is still left undiscussed: When the Moon is not on the ecliptic, the three moments at which the three species of new Moon or full Moon already mentioned occur are different; therefore ☌ and ☍ are threefold.

CAPVT IV.

Chapter 4

In quo Problemata ad Phaſes Lunæ Spectantia.

In which are the problems concerning the phases of the Moon.

PROBLEMA I.

Problem 1

De Lunæ Aetate cognoſcenda præcipuè ex Phaſium quantitate.

On finding the Moon's age, chiefly from the size of its phases.

I. You will achieve this in four ways. The computists [Computiſtæ] hand down the first three of them in the Rules of the Calendar: namely Bede, vol. 1, pp. 187 and 525, and vol. 2, p. 347; Maximus and Isaacius[22], and, drawing on them, Pétau at the end of the *Uranologion*, Book 8, ch. 13, canon 5; Pietro Pitati in his monthly canons, ch. 4; Moletti, Book 2 of the *Calendar*, ch. 4; Clavius, Book 3 of the *Calendar*, ch. 1; and Biancani in the *Sphere*, Book 9, ch. 13, prop. 7.

[Margin: 1st method, by the Golden Number.]

The first method is by the golden number [Aureum numerum] of the given year, which you will find from the tables at the end of this work. Look it up, then, in the Calendar: for opposite it stands the first day of the Moon, and counting inclusively from that day to the given day of the month, you will have the Moon's age.

[Margin: 2nd method, by Epacts or Regulars.]

The second method is by the current Epact [Epactam] of the year. Add it to the number of Kalends elapsed, but counting from March inclusive (for the Kalends of January and February are ignored), and to this sum add the given days of the month; for the whole sum will give the Moon's age, after discarding 30, however, if the sum comes to 30 days or more. As a rule, however, the Moon has some hours beyond the day found, and often it is, for example, the tenth day of the Moon that by this rule would be the ninth. Then again, it matters from where you begin the first Moon: from the kindling of the Moon, that is, the true new Moon; or rather, with the Hebrews, the Greeks and now the Latin Church, from the mean new Moon, at which the luminaries are conjoined according to their mean motions; or from the day following the true new Moon, as Theophilus and Cyril of Alexandria wished, and Bede, *De ratione temporum*, ch. 43; or lastly from the first phase, with the Agarenes and the Jews of the sect of the Karraim.

[Margin: What the Regulars of the Moon are.]

To this method is reduced the one said to go by the Regulars of the Moon [Regulares Lunæ], that is, certain numbers added to the months, which together with the Epact make up the age the Moon has on the Kalends themselves. The Regulars of the months in the new Calendar are as you see in the following small table. For example, if the Epact is 10 and the month April, adding the Regular number 2 makes 12, the days of the Moon that it has on the Kalends of April; from there, then, counting inclusively, you will have the Moon's age for other days, but discarding 30, as above, if they are reached or exceeded.

[22]probably Isaac Argyros

	Regulars
January	1
February	2
March	1
April	2
May	3
June	4
July	5
August	6
September	8
October	8
November	10
December	10

[Margin: 3rd method, by astronomical calculation.]

The third method is by astronomical calculation. For the given time, compute the mean places of the luminaries. If they happen to be conjoined, it will then be new Moon; but if the Moon is elongated from the Sun, divide that elongation by 12° 11′, the amount, that is, by which the Moon is elongated from the Sun each day in mean motion, and the quotient will indicate the Moon's age computed from the mean new Moon, and so also the moment of the mean new Moon. But if you investigate the true new Moon by the rules to be given in Book 10, you will be able to compute the Moon's age from it to the given moment much more exactly.

[Margin: 4th method, by the phases of the Moon.]

The fourth method is by the phases of the Moon and their size. Kepler teaches it in the *Astronomia Optica*, ch. 6, no. 5, or p. 235, taking it from Reinhold, and both of them from that obscure saying of Pliny the Elder, Book 2, ch. 14: *Lucere dodrantes ſemuncias horarum ab ſecunda adijcientem vſq. ad plenum orbem, detrahentemq. in diminutione* [that it shines, adding three-quarters and a semuncia of an hour from the second day up to the full orb, and subtracting them in the waning]; Iacobus Milichius [Jacob Milich], Reinhold's teacher, expounds this excellently in a commentary. And the sense is that from the second day, which according to Pliny the Elder is usually the first phase of the Moon, the Moon adds to its illuminated part a dodrans of an hour, that is 45^{m}, and a semuncia of an hour, that is the 24th part of an hour, which is $2½^{m}$; their sum is $47½^{m}$. From the second day after new Moon, therefore, the Moon shines after sunset for $47½^{m}$ of an hour, but of a temporal hour, and on the following day for $1^{h}\ 35^{m}$, and so on in succession, until it shines for the whole night, that is, for 12 temporal hours. From the time for which the Moon shines after sunset, then, the Moon's age can be known by dividing that time by $47½^{m}$. For the quotient will give the Moon's age; but after full Moon it subtracts just as much time: that is, on the first day after full Moon the Moon rises after sunset only by 47½ hour-minutes, and on the second day only after 1^{h}

35^m, and so on; so from this time too the Moon's age can be known by adding 14½ days to it.

[Margin: Two obscure passages of Pliny the Elder are explained.]

But Pliny the Elder, Book 18, ch. 32, drawing on some other author (for he was a glutton for books), says that this time, which he had called a dodrans and a semuncia of an hour, is *Horæ dextantem ſicilicum* [a dextans and a sicilicus of an hour], that is, $51¼^m$; for a dextans contains ten parts of an as, and in an hour is 50^m, while a sicilicus is a quarter part of an uncia, that is $1¼^m$. For the cause, see Rule 2, Problem 2.

[Margin: Another method, from estimating the digits shining: unreliable.]

One could also observe the digits, or unciae, of the Moon's diameter shining to us, the diameter being on average 32½′. So since the Moon is filled in about 15 days after ☌, it would seem that each day there should shine to us, of the lunar diameter, more than on the preceding day by a fifteenth part of it, that is, that the daily increase should be 2′ 10″, or four-fifths of one uncia. That is not so, however, both because of the Moon's anomaly and its varying latitude and, chiefly, because the illuminated segments of the Moon, other things being equal, even if they otherwise really did increase equally each day, nevertheless appear to us smaller and more contracted near the limbs, because on account of their remoteness they are seen under a smaller angle, just as the remoter columns of a portico look more slender to us and the intervals between them narrower. Hence it is that on the fifth day after ☌, when a third part of the lunar diameter, that is 4 unciae, or nearly 11′, ought to shine to us, nevertheless only about 3 unciae, or 8′, appear. So the certain day of the Moon cannot be estimated from them, especially since the difference of the first phase itself, on which the rest depend, is subject to a variation of nearly 4 days, as was said above.

PROBLEMA II.

Problem 2

Quot Horis Luna Noctu Luceat. Atque adeò quota hora occidat ante ☍, vel oriatur poſt ☍.

For how many hours the Moon shines at night; and so at what hour it sets before ☍, or rises after ☍.

II. This problem is akin to the preceding one. It is handed down by Pliny the Elder, Book 2, ch. 14, and Book 18, ch. 32; Bede, vol. 1, pp. 187 and 528; Isaac the Monk, ch. 7 of the *Computus*; Moletti, Book 2 of the *Calendar*, ch. 18; Clavius, Book 3 of the *Calendar*, ch. 13; Kepler in the *Epitome of Copernican Astronomy*, p. 839, explaining Pliny the Elder; Biancani in the *Sphere*, Book 9, ch. 13, prop. 8; and Hérigone, vol. 4 of the *Cursus Mathematicus*, p. 80.

[Margin: 1st Rule.]

From these, then, the first Rule, from Pliny the Elder, Book 2, ch. 14, as I taught in Problem 1, method 4, is that after sunset the Moon adds to the second day 47½^{m}, that is, very nearly 48 minutes of a temporal hour. So Bede, Isaac, Moletti, Biancani and nearly all the computists say that four-fifths, that is 48 minutes of one temporal hour, are to be added each day. So if they have found the Moon's age by the Epacts, they add one day to it to have a truer age, multiply this by 4 and divide the result by 5. For the quotient gives the temporal hours for which the Moon shines at night, to be counted from sunset, if the Moon is waxing and not yet full, and the Moon's age does not exceed 15 days. But if it does exceed them, they discard 15, multiply the remaining age of the Moon by 4 and divide the result by 5; for the quotient gives the temporal hours after which the Moon rises, counted from sunset, and their complement to 12 hours will give the hours for which it will shine from its rising up to the following sunrise. This Rule, however, gives the time of the Moon's shining somewhat too short, because it rests on the diurnal motion and does not include the time in which the Moon advances by its proper motion toward the east.

[Margin: 2nd Rule.]

The second, therefore, and more exact Rule, from Pliny the Elder, Book 18, ch. 32, is that from the first phase the Moon shines each day for *dextante ſicilico* [a dextans and a sicilicus] of a temporal hour, that is 51¼^{m}, or, following Clavius above, five-sixth parts. So increase by one the Moon's age found by the Epacts, to have a truer age, then multiply this by 5 and divide the result by 6; for the quotient will give the temporal hours for which the Moon shines after new Moon, to be computed from sunset, if the Moon's age has not exceeded 15. For if it has exceeded it, 15 days are to be discarded, the remainder of the lunar age multiplied by 5 and the result divided by 6, to yield the temporal hours after which the Moon rises after sunset; and their complement to 12 hours gives the temporal hours for which the Moon shines before the following sunrise. According to Pliny the Elder, however, the Moon's age would have to be multiplied by 51¼ and the result divided by 60. But since, because of the Moon's unequal motion and because the Moon's age is not exactly known from the Epacts, this rule does not agree with the truth to a hair, it will be enough for civil use to discard 15 days from the Moon's age, multiply it by 4 and divide the result by 5, or, what is better, to multiply it by 5 and divide this by 6. Consult, then, the following small table, and use by preference the last column, which is constructed in the second way.

[Margin: Small table showing the temporal hours for which ☾ shines at night.]

Age of the Moon [Aetas Lunæ], waxing [Creſcentis]: days	Age of the Moon, waning [Decreſc.]: days	Temporal hours for which the Moon shines at night from sunset or after rising [Horæ Temporales quibus Luna noctu lucet ab occaſu Solis vel poſt ortum]: hours	Fifth parts	Hours	Sixth parts
1	29	0	4	0	5
2	28	1	3	1	4
3	27	2	2	2	3
4	26	3	1	3	2
5	25	4	0	4	1
6	24	4	4	5	0
7	23	5	3	5	5
8	22	6	2	6	4
9	21	7	1	7	3
10	20	8	0	8	2
Remainder of the preceding table [Reſiduum Tabulæ Præcedentis]					
Days	Days	Hours	Fifth parts	Hours	Sixth parts
11	19	8	4	9	1
12	18	9	3	10	0
13	17	10	2	10	5
14	16	11	1	11	4
15	15	12	0	12	3
If it is waxing, it shines after sunset; but if it is waning, it shines before sunrise.					

[Margin: The instrument of Giovanni Battista Benedetti.]

As to how temporal hours are to be converted into equinoctial hours, I taught that in Book 1, ch. 29. But Io. Bapt. Benedictus [Giovanni Battista Benedetti], in his *Epistles*, p. 221, taught the way to make an instrument which, at a given altitude of the pole, shows the hour of the Moon's rising and setting. It rests on the semidiurnal arc, with a small wheel added, by which the day of the Moon's age is placed under the given day of the month.

PROBLEMA III.

Problem 3

Quota pars Lunæ noctu luceat, data Lunæ ætate, ſeu quantitatem Phaſeos æſtimare.

What part of the Moon shines at night, given the Moon's age; or, to estimate the size of a phase.

[Margin: The size of a phase.]

III. See what was said in no. 1, method 4; and add to it this rule from Kepler's *Epitome of Copernican Astronomy*, p. 819: As the diameter of a circle is to the sagitta, or versed sine, of the angle between the axes of the lunar shadow and of vision, so, very nearly, is the diameter of the lunar disc to the breadth of the phase. For a little more than half the globe is illuminated by the Sun; and so, when that angle is right and the circle of illumination appears as a straight line, a little more than half the disc is then illuminated.

PROBLEMA IV. V. & VI.

Problems 4, 5 and 6

Quota pars Lunæ à Sole illuminetur, aut à nobis videatur; & quota Terræ portio inumbretur à Luna.

What part of the Moon is illuminated by the Sun, or is seen by us; and what portion of the Earth is shaded by the Moon.

IV. Of the first two I shall speak more opportunely below, ch. 18, nos. 5 and 6, because they depend on the distances of the Moon, which are to be established below. Of the third I shall speak in Book 5, because it concerns eclipses of the Sun.

PROBLEMA VII.

Problem 7

Quanto tempore ante primam Quadraturam, aut poſt ſecundam Luna aimidiata nobis ſplendeat.

How long before the first quadrature, or after the second, the halved Moon shines to us.

[Margin: The time of the halved phase.]

V. Repeat here the figure of Book 3, ch. 7, no. 9, with its explanation, and let there be given the distance of the Moon from the centre of the Earth as the side TL, and the distance of the Sun from the centre of the Earth as the base TS, for the given day or even moment of quadrature. With these, seek in the triangle TLS, right-angled at L, the angle S: for this will be the distance of the Moon's apparent place from the place of quadrature. Convert this distance into time by the Moon's hourly motion, and you will have the time,

Diagram. Woodcut set in the right column, inside the sentence above. A large outer circle carries a horizontal diameter running from A at the left through G, T and R to S at the right. An inner circle centred on T passes through G and R. At the top of the inner circle stands a small circle half blackened, the Moon, with the label K above it and L at its centre, joined to T by a straight line and to S by a second straight line, which together with TS make the triangle TLS. A small circle stands at S, the Sun, on the outer circle's right-hand point.

- A (left end of the horizontal diameter, on the outer circle): A
- B (top of the outer circle): B
- C (foot of the outer circle): C
- G (left, where the diameter meets the inner circle): G
- T (centre, below the diameter): T
- R (right, where the diameter meets the inner circle): R
- F (foot of the inner circle): F
- K (above the small blackened circle): K
- L (small letter inside the small blackened circle): L
- S (inside the small circle at the right end of the diameter): S
- I (on the line from T to the small blackened circle, set aslant): I by which the halved phase, in itself and with refractions in the air around the Moon excluded, precedes the first quadrature or follows the second. Aristarchus, moreover, in prop. 8, teaches that the circle which separates the bright part from the dark in this phase is distant from the Moon's great circle by less than the 3960th part of one right angle, that is, by less than 1′ 22″. And although the phase of the bisected Moon is discerned within a few hours, in which it turns from concave to gibbous, yet an exact full Moon is scarcely distinguished from an inexact one within three days.

PROBLEMA VIII.

Problem 8

Tempus quo Luna erit in Nonageſimo Eclipticæ gradu, & ſi cornuta ſit cornibus erectis lucebit, inuenire.

To find the time at which the Moon will be in the nonagesimal degree of the ecliptic, and, if it is horned, will shine with its horns erect.

[Margin: The time of the nonagesimal phase.]

VI. Longomontanus, Book 1 of the *Theorica*, ch. 9, near the end, gives this instruction on the matter. For the noon of the day after which you want to predict this phase, seek from tables or an ephemeris the true place of the Sun and of the Moon. Next, from the table of houses, under the title of house 10, seek the time from noon corresponding to the given altitude of the pole and to the Sun's place. Third, add to the Moon's place 90°, or 3 signs, and for this aggregate seek in the table of houses, under the title of the first house, the time from noon. Fourth, subtract the lesser time from the greater, and for the remaining difference seek the proportional motion of the Moon from the Sun, with the help of the diurnal motion of each body, which is in the ephemeris. This is to be added to the Moon's motion previously aggregated, so as to make the ascending point of the ecliptic, that is, the point that will ascend at the moment when the Moon will be in the nonagesimal; and for this, again in the table of houses, seek the time under the first house. If you subtract from it the time corresponding to the Sun's place, already found in the second step, there

will be left the time from noon at which the Moon will be in the nonagesimal degree of the ecliptic, counted from the ascending point of the ecliptic. The nonagesimal degree, moreover, will be known if you subtract 90° from the ascending point of the ecliptic. But the precept, because it is of great moment in astronomy, is to be illustrated by an example.

EXEMPLVM Longomontani.

Example of Longomontanus

In the year 1617, on October 4, old style, at noon at Copenhagen, where the pole is elevated 55° 34′, the calculation from Origanus's *Ephemeris* stands thus.

	Arc of the zodiac [Arcus Zodiaci]	House [Domus]	Time from noon [Tempus à Meridie]
Place of the Sun [Locus Solis]	♎ 22° 6′	10	13^h 18^m
Place of the Moon [Locus Lunæ]	♈ 20° 20′		
With 3 signs added [Additis Signis 3.]	♋ 20° 20′	1	23^h 1^m
Difference of the times [Differentia tēporū]			9^h 43^m
Diurnal motion of the Moon from the Sun [Motus diurnus Lunæ à Sole]	14° 14′		
Motion of the difference [Motus differentiæ]	5° 46′		
Ascending point of the ecliptic [Punctum Eclipt. Aſcend.]	♋ 26° 6′	1	23^h 34^m
With the time of the Sun's place taken away [Ablato tempore loci Solis]			
Time of the Moon in the nonagesimal [Tempus Lunæ in Nonageſimo]			10^h 16^m
And the nonagesimal [Et Nonageſimus]	♈ 26° 6′		

Therefore at 10^h 16^m after the noon already mentioned, at Copenhagen, the centre of the Moon was in the nonagesimal degree of the ecliptic, and the ascending point of the ecliptic was then Cancer 26° 6′, while the nonagesimal point was Aries 26° 6′.

PROBLEMA IX.

Problem 9

Diem Primæ & Vltimæ Phaſis Lunæ coniectari in Zonis Temperatis.

To conjecture the day of the first and of the last phase of the Moon in the temperate zones.

VII. From what was said in ch. 3, nos. 6 to 11, we can gather rules for conjecturing the day of the last and of the first lunar phase, whether it will be the first, or the 2nd, or the 3rd, or the 4th before or after new Moon. For the sake of brevity and clarity we have reduced these, as if into a mirror, to the

following small table, whose use is as follows. Look up in the ephemerides the Moon's place and its latitude, whether northern or southern, and lastly whether it is in perigee or in apogee or nearer to these. Then, if the Moon is in the ascending signs, use the table Asc.; but if in the descending, the table Desc. In the first column of these, look for the southern or northern latitude, and in the second the nearness of the apogee or perigee. For opposite these you will have the day of the first phase, computed from new Moon: in the third small column for those living in the northern temperate zone, and in the fourth for the southern. And you will have the day of the last phase, computed before new Moon, in the fifth small column for the northern temperate zone and in the sixth for the southern. The table will be the truer the greater the Moon's latitude and its nearness to the apogee or to the perigee, and where the pole is highly elevated; if the air is clear and the eye lynx-like, where day 1 is given, it will be possible to see the first and the last phase on the same summer day.

If ☾ is in the ascending signs [Si ● in Signis Aſc.] ♑ ♒ ♓ ♈ ♉ ♊

Latitude of ●	Anomaly of ●	Day of the first phase after ☌ [Dies Phaſis Primæ poſt ☌]: for the northern [Borealibus]	Day of the first phase after ☌: for the southern [Auſtralibus]	Day of the last phase before ☌ [Vltimæ ante ☌]: for the northern	Day of the last phase before ☌: for the southern
B	Perig.	1	3	4	2
B	Apog.	2	4	3	1
A	Perig.	2	2	3	3
A	Apog.	3	3	2	2

If ☾ is in the descending signs [Si ● ſit in Signis Deſc.] ♋ ♌ ♍ ♎ ♏ ♐

Latitude of ●	Anomaly of ●	Day of the first phase after ☌: for the northern	Day of the first phase after ☌: for the southern	Day of the last phase before ☌: for the northern	Day of the last phase before ☌: for the southern
A	Apog.	4	2	1	3
A	Perig.	3	1	2	4
B	Apog.	3	3	2	2
B	Perig.	2	2	3	3

SCHOLIA.

Scholia

[Margin: Inclinations of the phases.]

I. The inclinations of the lunar horns, treated in ch. 3, can be applied to the Moon in lunar eclipses, in which, especially if they are total, horned phases of the Moon appear, with the horns turned toward the east on entering the Earth's shadow, but toward the west on leaving it. And in solar eclipses too the Sun becomes crescent-shaped [Lunatus], and the inclinations of the solar horns appear remarkable. Ptolemy calls them [Greek: προσνέυσεις (prosneuseis, "inclinations")], Book 6, and Kepler teaches how to measure them

in the *Astronomia Optica*, from p. 361 to 410. But this is not the place to teach that.

[Margin: Estimate of the diameter of ☾ from the 1st phase.]

II. The same Kepler, in the *Astronomia Optica*, p. 344, teaches how, from the horn of the Moon in the first phase, estimated somehow, to investigate the ratio of the Moon's apparent diameter to the Sun's apparent diameter; and he teaches that the former is usually found greater than the diameter of the Sun, and therefore that the whole Sun can be covered by the Moon. But the estimate of the circumference of the Moon shining to us against the rest not shining is very slippery, as he himself admits, so it is not worth while to linger over these matters.

III. It remains, for describing the phases of the Moon properly, that you should know how to draw the lines of the phases, a matter dwelt on at length by al-Battānī, chapters 30 and 40; Witelo, Book 4, from Proposition 24 to 77; d'Aguilon, Book 5 of the *Optics*, from Proposition 49 to 56; Reinhold, on Peuerbach's *Theoricae*, from p. 166; Rudolf Goclenius, in his *Urania*, chapter 20; and Kepler, in the *Astronomia Optica*, from p. 243. [Margin: How the lines and figures of the phases are to be drawn.] Al-Battānī, for his part, teaches how to draw the shape of the falcate Moon at the first phase from the Moon's longitude and latitude, but Kepler teaches that this method is not very safe. Nor, however, does it much matter to astronomy that these [Greek: σχέματα (schemata, "figures")] or [Greek: σχέσεις (scheseis, "configurations")] be drawn with exactness. Still, so as not to leave this topic wholly untouched, take the following propositions.

[Margin: Rule 1.] 1. The pyramid or cone of the illumination produced in the Moon has its vertex at the tip of the lunar shadow and its base on a lesser circle of the lunar sphere; the cone of vision, by contrast, has its vertex in our eye and its base on a lesser circle of the lunar sphere, since our eye is a smaller sphere than the Moon. But this very circle is usually smaller than the base or circle of illumination, since on the Ptolemaic hypothesis the portion illuminated by the Sun is 180° 31′ 20″, and so the circle of illumination stands 15′ 40″ from the great circle that bisects the Moon. But the portion of the Moon seen by us, when the Moon is not at apogee and joined to the Sun at apogee (for then these two circles, or bases of illumination and of vision, are equal), does not reach 179° 28′ 40″. Therefore the base and circle of vision stands more than 15′ 40″ from the Moon's great circle, and so the circle of vision is usually smaller than the circle of illumination.

[Margin: Rule 2.] 2. The axes of the cones of illumination and of vision, produced in imagination, terminate at the centre of the Moon. In reality, granted, the axis of illumination, if the Moon is opaque, would terminate on the Moon's surface, at the point called the point of incidence, which is the pole on the lunar sphere from which the circle of illumination is understood to be described; and our visual ray would terminate on the Moon's surface, at its own point of incidence, from which as from a pole the circle of vision is

described. But when these axes are produced in imagination, as I said, their common meeting takes place at the centre of the Moon.

[Margin: Rule 3.] 3. If Reinhold is to be heeded (p. 168), our sight takes in only that portion of the lunar body which the base of the cone of illumination has in common with the base of the cone of vision, since of the lunar hemisphere, or quasi-hemisphere, irradiated by the Sun and always turned towards the Sun, no more can be seen by us than the portion turned towards our eyes. Therefore at conjunction these bases have no portion of the Moon's body in common, and so the whole illuminated part is hidden. Understand "usually", my dear Reinhold, for sometimes a circle of illumination is seen around the Moon in a central eclipse of the Sun, when the Sun's apparent diameter is greater than the Moon's apparent diameter; and then the base of illumination, being smaller, is contained within the base of vision, or lies below it. At oppositions, however, the Moon appears full and round, because the base of illumination is larger than the base of vision and extends beyond it.

[Margin: Rule 4.] 4. Near the quadratures, a little before the first or a little after the second, when the circle of illumination inclines its plane towards our sight and the axis of illumination makes right angles with the axis of vision, the Moon appears [Greek: διχότομος (dichotomos, "cut in two")], that is, it appears to shine with half of its hemisphere. Yet the semi-periphery of the illumination appears not as a curve but as a straight line, because of the Moon's great distance from the eye. On account of this distance none of its points appears farther from the eye than the rest; they appear to lie in the same plane as the eye, and all of them appear equally distant from it, as Euclid shows in theorem 22 of the *Optics*.

[Margin: Rule 5.] 5. When the Moon is outside the syzygies and quadratures, the bases of vision and of illumination intersect at oblique angles. If the angle of the axes of the cones of illumination and of vision is acute, or the common portion of the already mentioned bases is less than a quadrant, then the Moon appears illuminated less than hemispherically, that is, it appears falcate. But if that angle is obtuse, and the common portion of the bases greater than a quadrant, then the Moon appears illuminated more than hemispherically, that is, gibbous. In either case, however, the line of illumination appears curved, because it does not lie in the same plane as our eye; and the line of the Moon, whether gibbous or falcate, is not strictly circular but elliptical, as Scheiner notes in the *Disquisitiones*, no. 26, as Kepler shows from conic sections in the place just cited, and as Aristotle had indicated, section 15, Problem 6.

CAPVT V.

Chapter 5.

An Luna proprio, an Solis lumine luceat, & an inſtar ſpeculi ad nos illud reflectat.

Whether the Moon shines by its own light or by the Sun's, and whether it reflects that light to us in the manner of a mirror.

I. That the Moon shines not by its own light but by another's has seemed so obvious to most people that Cleomedes, in Book 2 of the *Cyclical Theory*, chapter 4, confirmed it from the very etymology of the name. He says that it is called [Greek: σελήνην (selēnēn, "Moon", accusative)] because it receives [Greek: σέλας νέον (selas neon, "new light")], that is, a splendour ever new, and he adds: *For this is evidence of a light admitted from outside.* That was the reason why Euripides called the Moon the daughter of the Sun, as I related in chapter 1. Nevertheless there have been those who thought otherwise. For Plutarch, in Book 2 of the *De placitis philosophorum*, chapter 28, reports as follows: *Anaximander teaches that it has its own light, but a thinner one. Antipho* [Antiphon] *that the Moon shines with its own brilliance, and that when this is hidden, it happens through the approach of the Sun, because nature has so arranged that a stronger fire obscures a weaker.* [Margin: Authors who attribute a light of its own to the Moon.] And if you objected the failure of light in a lunar eclipse, they replied, as the same author adds in chapter 29, that this failure comes about: *Anaximander, through the mouth of the wheel being blocked; Berossus, through the part devoid of fire being turned towards us; Heraclitus, through the inverting of the bowl; certain Pythagoreans, through the blocking of a brightness proceeding from the Earth, which they call Antichthon, as if the opposite Earth. More recent thinkers, through the consumption of a fire kindled in due order little by little until it produces the perfect full Moon; after which, its proportion preserved, it decreases by degrees as far as conjunction, where it is entirely extinguished.*

But the opinion of Berossus, because it was more celebrated and needs a more solid refutation, is to be set out more fully from Vitruvius, Book 9, chapter 4. [Margin: The fiction of Berossus the Chaldaean about the light of the Moon.] After saying *Now I shall speak of the light of the waxing Moon and of its waning, as it has been handed down to us by our forebears*, he adds at once: *Berossus, who came from the city of the Chaldaeans and also disclosed his learning in Asia, taught as follows: that it is a ball white-hot in one half, the rest being of a sky-blue colour. When, completing the course of its journey, it passes beneath the orb of the Sun, it is then seized by the rays and the force of the heat, and turned with its white-hot part towards them, because of the affinity of light for light. And when that part, thus called up to the orb of the Sun, looks towards the upper regions, then its lower part, because it is not white-hot, appears dark from its likeness to the air. When it stands perpendicular to the Sun's rays, all the light is held at its upper face, and then it is called the first. When, passing on, it moves towards the eastern parts of the sky, it is released from the force of the Sun, and the outermost part of its white-hot portion sends its brilliance to the earth in an exceedingly thin line, and so from this it is now called the second. And by the daily slackening of its turning it is counted*

third and fourth, day by day. In these words, better suited to an architect than to an astronomer, he describes the monthly motion of lunar rotation about the centre of the Moon's own body, a motion invented by Berossus to explain the succession of the phases. But Cleomedes treats these motions more lucidly in Book 2 of the *Cyclical Theory*, saying in chapter 4: *For Berossus declared the Moon to be fiery in one half and to be moved by many motions: one in longitude, by which it moves with the world; a second in latitude; a third by which it is carried up and down; a fourth by which, like the other planets, it moves with a proper motion; a fifth, by which he thinks it revolves about its own centre and at times turns other parts towards us, and is thereby increased and diminished, a revolution he makes monthly, that is, equal to the synodic month. But his opinion can easily be refuted and disproved, etc.*

II. Very many philosophers and astronomers, however, have always judged that the primary light by which the Moon shines to us is not proper and innate to it, but received from the Sun and reflected from it to the Earth. [Margin: Authors who deny that the Moon's primary light is innate.] Of these I shall list certain chief ones, first from Plutarch, Book 2 of the *De placitis*, chapter 28, who says: *Thales and those who follow his teachings, that the Moon is lit by the Sun; Heraclitus, that the Moon is affected in the same way as the Sun: for these heavenly bodies have the shape of a bowl, and when they take in moist vapour, they are lit, as they appear: the Sun more brightly, since it is carried in purer air; the Moon more dimly, because in murkier air.* And in chapter 29, speaking of the cause of lunar eclipses, he goes on: *Plato, Aristotle, the Stoics and the mathematicians agree in this: that the monthly disappearances are brought about by the Sun, with which the Moon comes together and by whose rays it is overwhelmed; but that it fails in light when it falls into the shadow of the Earth, which stands between the two heavenly bodies; or rather when its illumination is obstructed by the Earth.* [Margin: Thales, Plato, Aristotle, the Stoics, the mathematicians.] This same point Aristarchus laid down as a most certain foundation in the book *On the Sizes and Distances of the Sun and Moon*, supposition 1, saying: *The Moon receives its light from the Sun.* [Margin: Aristarchus and Vitruvius.] Vitruvius subscribes to this in Book 9, chapter 4: *For it is no secret*, he says, *that the Moon has no light of its own and proper to it, but is like a mirror and receives its splendour from the force of the Sun.* Hence the saying of Cicero in the *Dream of Scipio*: *Among these the smallest, which was the last from the heaven and the nearest to the earth, shone with a borrowed light.* [Margin: Cicero and Pliny the Elder.] Pliny the Elder records that not only the Moon but all the stars are lit by the Sun, saying in Book 2, chapter 9: *that it is ruled by the Sun's brilliance, like the other stars, since it shines entirely with light borrowed from the Sun, such as we see flitting in a reflection on water —— and that it is seen with unequal light because only when opposite is it full, while on the remaining days it shows the earth as much of itself as it conceives from the Sun.* And in chapter 10, on the cause of eclipses, he says: *For it is manifest that the Sun is hidden by the intervention of the Moon, and the Moon by the Earth's being set against*

it, and that they repay each other in turn, the Moon by its interposition taking the same rays of the Sun from the Earth, and the Earth from the Moon.

[Margin: Macrobius.] Macrobius, on the other hand, in Book 1 of his commentary on the *Dream of Scipio*, chapter 19, thinks that the Moon indeed shines by the Sun, but the other stars of themselves, and he gives the reason, saying: *That the Moon, which lacks light of its own and borrows from the Sun, must lie below the source of its light. For this reason makes the Moon have no light of its own, and all the other stars shine with their own: that those, being placed above the Sun, are in the very purest aether, in which everything whatever is natural light and its own.* Macrobius holds, moreover, that Mercury and Venus too are carried above the Sun, and a little later he adds: *But the Moon, because it alone is below the Sun and next to the region of perishable things, which now lacks light of its own, could have no light except from the Sun placed above it, to which it shines back.*

But he who made this lesser light to rule the night, and the stars, knows other causes, far more numerous and nobler, in the secrets of his providence: so that the Moon should not, shining with its own splendour, so great and so near, overwhelm the light of the fixed stars and seem to preside over a second day rather than over the night. Therefore, just as the Sun, wholly a day in and to itself, had to preside over our day, so the Moon had to be president of our night, being no day in itself, and to present sheer night through the privation of light of its own; and, just as the Sun had to pour out an abundance of light, so the Moon had, as if only by indicating, to speak the great works of God. To this one might perhaps not inappropriately turn the saying of Psalm 108 [recte: 18]: *The heavens declare the glory of God, etc. Day to day utters speech, and night to night shows knowledge, etc.* But passing over the arguments *a priori*, as they say, let us come to the arguments *a posteriori*, which can be brought chiefly against Berossus.

III. The first argument is that of Cleomedes, Book 2 of the *Cyclical Theory*, chapter 4: [Margin: Argument 1, of Cleomedes, against Berossus.] *First, it cannot be that it is in the aether and is fiery in one half of itself and is not on the whole of a homogeneous nature, as the other stars are.* But this argument savours of physical fittingness more than of necessary proof [apodixim]. Let us therefore hear the second, taken from the lunar eclipse, for he continues: [Margin: Argument 2, from eclipse, of Cleomedes.] *Next, the Moon in eclipse plainly opposes this opinion: for how does its light vanish on running into the earth's shadow, when it ought to have been shown wholly turned towards us? For if it had been such, it would have had to be more splendid on running into the shadow, and not to vanish.* [Margin: And of Tycho.] Tycho pursues this argument more explicitly in volume 1 of the *Progymnasmata*, p. 743: *For who among astronomers or natural philosophers does not know that the Moon is endowed with no light of its own, or very little, and that what it has and reflects to us it merely borrows from the Sun? For as to the fanciful opinion of some, that half of the Moon has its own light and the other half is opaque, and that it so turns itself in order about its centre with respect to us and the Sun that it is therefore thought likely to draw its light from the Sun: this, I say, is*

plainly fictitious, as, if nothing else, lunar eclipses certainly and openly prove, when the Moon is deprived of light by the interposition of the Earth. For if the Moon enjoyed a genuine light, surely when it was in the shadow of the Earth it would not lose it, but would display it all the more evidently. For all light shines more in darkness, when it is not hindered by another, greater brilliance. Nor is the shadow of the Earth anything corporeal, or some dense substance, such that it could darken the Moon's light and snatch it from our sight; it is only a certain privation of solar light, on account of the interposed opaque body of the Earth.

IV. [Margin: Argument 3, our own, likewise from eclipse.] Add to this that, without a great and violent multiplication of motions, no account can be given on this hypothesis of why the Moon in eclipse, beginning its failure from its eastern part, is so deprived of light with respect to us that it turns out as if horned, with its horns turned to the east, while at the emersion from eclipse its horns face west. For either it begins to withdraw its bright hemisphere from us by turning itself eastward about its centre, and then it would fail for us, but from its western part, and yet not so as to appear to us horned towards the east, but gibbous towards the west; or by turning itself westward, and then it would begin to fail from its eastern part, but with a gibbous figure, not a falcate one. In partial eclipses, now, this argument has still more force, for one would have to imagine in the Moon a motion of rotation compounded of motion in longitude and in latitude, by which it would nevertheless appear gibbous towards the ecliptic or the poles of the world, and not, as it does now, falcate towards the ecliptic. But these phenomena, which we now actually see, are explained far more solidly if we posit that an eclipse of the Moon comes from its running into the shadow of the Earth, since it is certain from other sources that the Earth casts this shadow towards the side turned away from the Sun, and it is established that lunar eclipses occur there alone and nowhere else.

V. The fourth argument is drawn from the position of the spots and their successive illumination. [Margin: Argument 4, of Kepler, against Berossus, from the position of the spots.] The spots always appear in the same position towards us, in such a way that at new Moon they are dark, and then one after another they are successively illuminated. Kepler seeks this even from a single spot, in the *Astronomia Optica*, chapter 6, no. 2, and his words are worth quoting. Reporting, from Laërtius [Diogenes Laertius] and Cleomedes, the opinion of Berossus and the contrary opinion of Thales, who says that the Moon shines of itself in no part, he adds: *Berossus could have gathered this even from the fact that it is plain to the eye that the same parts of the Moon do not always shine. For the face we imagine for ourselves in the Moon from the disposition of the spots strives successively into the light, and, always unmoved, is turned downwards towards us, granting the light passage over itself. There is at the western edge of the Moon, a little above the eye towards the top, a very black spot like the Pontus, in the midst of very bright light, separated from the spots as an island from the mainlands, scarcely a finger's breadth from the outermost limb. You will see it there, namely at the western edge and a little towards the top, whether the Moon is halved, or gibbous,*

or entirely full. The circle of illumination therefore first reaches it, afterwards passes it more and more, and after the full Moon leaves it altogether. Therefore the same parts of the Moon are not always in the light, which is what Berossus thought; rather the same parts of its body are perpetually turned towards the Earth, the centre of its gyration. And by going round the Earth, the Moon presents different parts in turn to the Sun, roasting itself monthly at the Sun as if it were being turned on a spit: in much the way that Copernicus said the Earth is turned and roasted at the Sun, or at the fire so called. The comparison taken from the spit and from the rotation of the Earth, however, favours Berossus; but one must attend to Kepler's meaning, and I believe he is speaking of the spot called the Lake of Knowledge [Lacu Scientiæ].

VI. [Margin: Argument 5, our own, likewise from the spots.] The fifth argument is likewise drawn from the lunar spots, but I set it out differently, as follows. At full Moon, especially when viewed through the telescope, there appears in the western part of the Moon a large black spot towards the north-west, called by Langren, Gassendi and Boulliau the Caspian Spot [Macula Caspia], because its figure is almost like that of the Caspian Sea as depicted in geographical hemispheres. In the eastern part, on the other hand, there is so great an expanse of the old spot that it occupies almost half of the lunar disc, and it has earned from Langren the name of Oceanus Philippicus, as can be seen in the diagram to be placed in Chapter 7. Now if the opinion of Berossus were true, at the Moon's first quadrature the Caspian Spot would not appear, but the Oceanus Philippicus; and at the second quadrature the Oceanus Philippicus would no longer appear, but the Caspian Spot, as will be evident to anyone who considers the rotation invented by Berossus. But the opposite happens, for at the first quadrature you see the Caspian Spot towards the west, in the part of the Moon that is halved and illuminated; at the second it appears nowhere, but in its place the Oceanus Philippicus. Let it stand, then, that the Moon does not have in itself a primary light that is proper and inborn; that it does not by its rotation now grant that light to us and now withdraw it; and that it is not always bright in one half of itself and always dark in the other half. Rather, it has its light from the Sun, is successively illuminated as a whole, is as a whole dark of itself, and successively becomes luminous through different parts in turn.

Quomodo Luna Solis lumen ad nos reflectat: vbi de opacitate Lunæ, & ſpeculi analogia.

How the Moon reflects the Sun's light to us: where the opacity of the Moon and its analogy with a mirror are treated.

VI. There are three opinions on this reflection. Cleomedes too touches on two of them, in that most learned little book *On the Cyclical Theory*, Book 2, chapter 4, and Kepler on all three, in the *Optics*, chapter 6, no. 2, from p. 227. [Margin: Opinion 1, of those who assert that the Moon is a mirror.] The first

was that the Moon, like a convex mirror, reflects to us the light of the Sun, received not without some refraction. So Clearchus, in Plutarch's little work *On the Face of the Moon*; on him see below, chapter 6, no. 8. So Pliny the Elder, Book 2, chapter 9, said that the Moon shines with light borrowed from the Sun, *such as we see flitting in a reflection on water*; and more openly Macrobius, Book 1 on the *Dream of Scipio*, chapter 19: *The Earth, on receiving the Sun's light, only brightens, and does not shine back; the Moon, like a mirror, gives out the light by which it is illuminated: for although it is a denser body than the other heavenly ones, yet, as being much purer than the earthly, it becomes penetrable to the light received.* [Margin: The diaphaneity and opacity of the Moon.] Reinhold agrees with these in his work on Peuerbach's *Theoricae*, from p. 165, in the part where he subscribes to Macrobius, and he admits in the Moon many deeply diaphanous parts. For after reporting that there are some who judge that one hemisphere of the Moon, the one inclining towards the Sun, is diaphanous and is filled with the Sun's light like a sponge, while the other, turned away from the Sun, is perpetually dark because of its own opacity and density, he added: *This opinion indeed is by no means to be despised.* For Reinhold had not noticed that what we said above in nos. 4 and 5, on the position of the spots and on different parts of the Moon being illuminated, tells against this opinion. He adds, however: *But Witelo's opinion certainly seems to me more probable, even if it differs little. For he does not so divide the body of the Moon into a diaphanous hemisphere and an opaque one; rather, he holds that it is in any part of it partly rare and diaphanous, partly dense and opaque, yet that the opaque parts are far more numerous than the diaphanous.* Before these, moreover, Posidonius had attributed much diaphaneity to the Moon; for Cleomedes, in Book 2 of the *Cyclical Theory*, chapter 4, reports of him as follows: *Posidonius, then, says not only that the surface of the Moon is flooded with light by the Sun, as happens in solid bodies, but that the Sun's rays penetrate very far into its depth, as it has a rare body.* In this class too, as regards diaphaneity, our d'Aguilon is to be reckoned, Book 5 of the *Optics*, after Proposition 56, since after a long disputation he finally concludes as follows: *It is the opinion of others, which also pleases us more, that one hemisphere of the Moon is perfectly diaphanous, while the other, namely the one that presents to us the appearance of a human face, is only half-diaphanous, that is, sprinkled with a certain opacity, which transmits some of the light but retains the greater part, not only at the outermost surface but also in the depth.* To this our Scheiner also tends, in the *Disquisitiones Mathematicae*, no. 26 (though he, as much as d'Aguilon, openly denies that the Moon is a mirror), and above all Witelo, Book 4, on theorem 77, and Lagalla [Giulio Cesare Lagalla], *De phaenomenis in orbe Lunae*, chapter 11.

VII. [Margin: Opinion 2, of those who deny that the Moon is a mirror.] The second opinion, at the opposite extreme from this one, is that the Moon is not a mirror and does not shine back from the Sun but brightens, and yet by its rough opacity reflects the Sun's light to us, in the way that walls, or the mountains and rocks of the Earth, throw it back. So Plutarch, in the little work *On the Face in the Orb of the Moon*; some Amram [?], an Arab, in Scaliger;

Giovanni Battista Benedetti in his *Letters*, p. 413; Biancani, Book 9 of the *Sphere*, chapter 7; Galileo, Dialogue 1 *On the System of the World*; our Scheiner in the *Disquisitiones Mathematicae*, no. 26; Bettini, *Apiarium* 8, Prog. 6, proposition 1; d'Aguilon, Book 5 of the *Optics*, after Proposition 56; Tanner, *De caelo*, q. 7, par. 3; Cleomedes, Book 2 of the *Cyclical Theory*, chapter 4; and Kepler, in the *Optics*, chapter 6, no. 2. For all agree in this, that the Moon is not a mirror of the Sun. Plutarch indeed, taking the part of Lucius, says: *It is probable, then, that the Moon is not illuminated in the manner of glass or crystal*. And a little later, after saying that light is reflected to us from the Moon as voices are from rocks, which produce an echo, and having raised against himself, at the prompting of Sylla [Sulla], the objection that if this happens by reflection, it happens only at the points at which the angle of incidence can equal the angle of reflection, he adds after various evasions: *Indeed, even if we grant this, and gratify Geometry, so very dear to us, in the first place it is proper for this to happen in mirrors polished to perfection, namely because of the equality of the angles of incidence and reflection. But the Moon has many inequalities, many roughnesses, so that the flashes which come from a great body can shine back on one another from heights of no small size, and can be reflected in every way, be interwoven, and carry on their resplendence among themselves, as if it were being brought to us from many mirrors.* And again below, after saying that there are valleys and mountains in the Moon, and opaque parts, just as on the Earth, and having objected to himself that this seems to rule out the reflection of light from the Moon to us (for if it is granted, the Sun's image must be seen by us at night in the Moon, as it is seen in mirrors and in water), he replies that this by no means follows: both because of the great distance, which would not allow the Sun's image to be seen even if it were in the Moon as in a mirror, and because in reality the reflection does not occur as from a mirror but as from a rough surface, since not even milk, because of a certain roughness, which is nevertheless much less than the roughness of the Moon and the Earth, gives back mirror images.

VIII. [Margin: The argument by which it is established that the Moon is not a mirror.] The argument, then, of Plutarch as well as of Cleomedes, Galileo, Kepler, Scheiner, Biancani, Tanner and d'Aguilon, by which they prove that the Moon is not a mirror of the Sun, and that the Sun's light is not reflected to us from it as from a mirror, is this. If it were so, either we would not see the image of the Sun, because of the enormous distance of the Moon from the Earth (but then we would not see any other light either), or, if we saw the Sun's light, we would also see the Sun's image, though very tiny and like a bright point, both because of the distance and because of the convexity of the lunar globe, since convex mirrors give images smaller than their prototypes. Next, this little image of the Sun would be seen only at one point of the Moon, by one and the same spectator, and the whole Moon would not appear to shine at full Moon, or half of it at the quadratures, but only that small portion in which the Sun's image was seen, as is established from the laws of catoptrics and of the reflection produced in water, glass, crystal and other mirrors, especially convex

ones. The remaining part of the Moon would appear dark. Galileo proves this by a ready experiment and by comparing a mirror and a wall. For from a mirror facing the Sun there is no reflection except from a determinate small part of it, to a determinate place and position of the eye; and thus the image of the Sun is seen by one eye in such a way that it is not seen by another, and the eye that sees the Sun's image at the same time sees other parts of a larger mirror as dark. But from a wall facing the Sun, light is reflected from any sensible part, so that all who are present see together the brightness of the whole lit wall, yet not the Sun's image, because of the roughness of a surface made up of many small surfaces, some like little valleys, others like little hills, which with their sides carry on the reflection towards one part after another. This mode of reflection is excellently described, after Plutarch, by Galileo in the place cited above and by Gassendi, Letter 4 *On the Low and High Sun*, no. 14. Biancani, moreover, confirms the same from spheres on the tops of towers lit by the Sun: for the smoother and more polished they are, the less they reflect light to us, and the rougher they are, the more.

IX. [Margin: Opinion 3.] The third opinion, not wholly different from the second, is that of Cleomedes, Reinhold, Witelo, d'Aguilon, Scheiner, Lagalla, Tanner and Bettini: namely that the Moon, although it is not a mirror, since the unevenness and roughness of its surface stand in the way, nevertheless has some diaphaneity, by virtue of which it admits the Sun's light beyond the surface, and, so affected and altered, reflects it to us: whether in the manner of a half-rare and half-diaphanous cloud, as Scheiner puts it; or, as Cleomedes says, in the manner of iron glowing from fire; or by a certain fourth light, which Kepler, above and in chapter 1, proposition 22, calls communicated light and distin- ct from direct, reflected and refracted light. He confirms this from the fact that the Sun's light enters coloured bodies beyond their surface and, tinged and steeped with their colours, also carries the images [species] of those coloured bodies through a hole into a darkened chamber and paints them distinctly on paper. So it does not follow, if the Moon has a diaphanous surface, that it is for all that a mirror, unless it is polished and smooth and not made uneven by any roughnesses; or, as Bettini adds, if it is not homogeneous in density and rarity, opacity and transparency in a great part of itself, since otherwise a frequent heterogeneity of these can hinder the properties of a mirror.

CAPVT VI.

Chapter 6.

An Luna fecundarium aliquod lumen habeat, & vnde illi lumen, quod in Eclipſibus, aut prope Nouilunia omnia, aut in lucido annulo videtur habere.

Whether the Moon has some secondary light, and from where it gets the light that it seems to have in eclipses, or around all new Moons, or in a bright ring.

I. [Margin: A short summary of the phenomena bearing on the Moon's secondary light.] There is no new Moon near which, in the last and first phases, if the Moon is watched in a clear sky and rather far from the Sun's twilight glow, a certain bright ring is not seen around it. This ring swells and projects on the part turned towards the Sun, while on the rest of the Moon's body there is a certain light resembling burning ash that glows white. In eclipse new Moons, however, the Moon seems to shine on the part turned towards us with some light, though a faint one, and sometimes to be ringed by a bright limb, even when the whole Sun is believed to be covered by it. Finally, in eclipse full Moons, in which the whole Moon undergoes eclipse, it nevertheless often glows faintly with varied light and colours, almost in the depth of the Earth's shadow. From this have arisen controversies among authors: whether this secondary light is found in the Moon, and from where. For we established in chapter 5 that the primary light is derived into it from the Sun. We must therefore discuss these matters in order and distinctly.

De Annulo lucido circa Lunam.

On the bright ring around the Moon.

II. In the morning after the second quadrature, up to the last phase, and in the evening before the first quadrature and after the first phase, the Moon, if watched with the naked and simple eye without lenses, seems surrounded by a bright ring: slender on the part turned away from the Sun, but broader on the part turned towards the Sun, and indeed protruding like a little cap, so that lines drawn out from the centre to this part appear longer. This can be seen in the first part of the figure added here, where the more slender limb of the ring is F E K, and the swelling and projecting one F G K.

Diagram. Two circular woodcut figures set side by side in the left column. Each shows a vertically hatched lunar disc inside a bright outer ring. In the left figure the ring is visibly wider on the right, towards G, than on the left, at E. In the right figure the ring is narrow and runs around the disc. Labels read:

- F (top of the left figure)
- E (left of the left figure, outside the ring)
- I (right edge of the left figure's disc, inside the ring)
- K (foot of the left figure)
- G (between the two figures, at the outer right of the left figure and the outer left of the right figure)
- L (top of the right figure)
- N (right of the right figure)
- M (foot of the right figure)

Labels not read: none.

In some eclipses of the Sun, moreover, with the eye placed on the line through the centres of the luminaries, a certain bright belt appears around the Moon, encircling it, as in the second figure, G L N M. The cause of the

swelling F G K is not in the Moon itself or in vaporous air around the Moon, as Mästlin, theorem 148, and Galileo in the *Sidereus Nuncius*, p. 12, held; nor is the swelling real but apparent, a delusion of the naked eye. This is clear because, if you look at the Moon through a telescope, that protuberance ceases, and the first and last phases are seen as in the third figure, A D B C.

Diagram. A single circular woodcut inset at the right of the left column, the text wrapping around it on its left. A dark, mottled lunar disc stands inside a clear ring, which is wider on the right, at C, than on the left, at D. Labels read:

- A (top)
- D (left)
- C (right)
- B (foot)

Labels not read: none.

[Margin: The cause of the ring's swelling.] The cause of the deception is therefore optical, as Kepler teaches in the *Astronomia Optica*, chapter 5, no. 5, and in the dissertation with the *Sidereus Nuncius*, p. 15; and Scheiner in the *Disquisitiones Mathematicae*, no. 26. For white things, let alone bright ones, set beside black or darker things appear larger and more prominent, although they are not, and enlarge themselves in the eye; and they appear as whole figures, although they are in reality incomplete. This is because of the efficacy of the images produced by white or bright things, which are apter to move the sense organ of sight and to drive, as it were, the images of black and darker things out of possession. So it is that a white column beside a black or red one of equal size, seen from afar, looks larger, just as a sheet of paper bounded by parallel edges and blackened over half of it appears larger in its white half than in its black. So too a thread of spider's web looks ten times larger on the part lit by the Sun than on the remainder not directly lit by the Sun. So too a flame seen from afar looks round; and Venus, although horned if you use a telescope, nevertheless appears round to the naked eyes. Those who are purblind and of weak sight, so that they cannot see distant things, are deluded in this far more. For bright and white things illuminate strongly.

III. [Margin: The cause of the bright ring.] As for the annular limb F E K, or in eclipses of the Sun L G M N, some think its cause is an atmosphere or air, or a circumlunar aether, denser than the rest of the surrounding aether, which was discussed in chapter 2, no. 3. They hold that this shines more than the intervening parts of the lunar disc, by a doubled reflection or by refraction of the solar rays. Among them is Bettini, *Apiarium* 8, prog. 2, prop. 10, and prog. 6, prop. 3; and Fortunio Liceti in the *Quaesita per Epistolas* and in book 2 of *De Lunae luce subobscura*. Galileo, moreover, in the *Nuncius*, pp. 12 and 13, says: *To this reason another can be attached, namely that around the lunar body there is, as around the Earth, a certain orb of a substance denser than the rest of the aether, able to take up and reflect the irradiation of the Sun, although it is not endowed with such opacity that it can block the passage of the sight (especially while it has not been*

illuminated). This orb, illuminated by the solar rays, renders and represents the lunar body in the likeness of a larger sphere, etc. A sign of this is that the part of the Moon flooded with light appears of a wider circumference than the rest of the dark orb. By that very argument Mästlin, from theorem 145 to 149, had taught that air is spread around the lunar globe.

Afterwards, however, Galileo, in Dialogue 1 of *De Mundi systemate*, refuting Scheiner without naming him, teaches that the Moon's secondary light takes the form of a ring, since it appears brighter at the outermost edge than in the middle, although it is not in fact brighter, but appears so because of the difference of the boundaries that limit the Moon's inner disc. For the inner disc, at the boundary F I K in the former of the figures given above, appears darker because of the abundance of splendour of the neighbouring horn F G K, being obscured by it; but on the other side, F E K, where it has for its boundary a tract of twilight darker than the lunar horn, the Moon's secondary light appears brighter around the margin, and from this comes that bright little circle. He proves, moreover, that this is a delusion of the eye, which because of the relation just mentioned judges the limb of the Moon brighter than the rest of the disc: if someone does not see the primary splendour of the lunar horn, it being hidden meanwhile behind the wall of a chimney or of another more distant obstacle, while he does see the rest of the Moon's disc, he sees that whole disc grow bright with secondary light equally, without any difference at the margin, and sometimes with so much light that it seems to rival the light of Saturn. Indeed, as Biancani affirms in book 9 of the *Sphaera*, chapter 4, it appeared to him at such a time to have attained, as if by a miracle, the full Moon, although it was near new Moon. Nor was Scheiner unaware of this experiment, since he says in the *Disquisitiones Mathematicae*, no. 27: *So this second splendour of the Moon is greater than many suppose, since they have sometimes detected it with the Sun still above the horizon, which does not happen even for all stars of the first magnitude. So it is no wonder that it, if the primary lies hidden behind the ridge of some house and the secondary alone shines, is so great that it equals, if it does not surpass, stars of the third magnitude, I add sometimes also of the second, and, what is more incredible, the splendour of Saturn.* And no. 28: *Thus the eye, the dark part of the defective Moon being seen separately, with the bright part hiding behind a roof, beholds it as more brilliant than bright stars.* And yet in no. 27 he attributes the cause of the brighter lunar limb, as of a real effect, to the rays of the Sun that penetrate the Moon's semi-diaphanous body and pass through the Moon's margins by a shorter path, and so are less dulled than those that penetrate the diameter and the whole depth of the Sun, or that are nearer the diameter. Indeed, he tries to confirm the Moon's diaphaneity from this bright ring, saying: *This opinion is proved, first, from experience, because the waning and renascent Moon shines out greatly in the unlit part, especially at the limb.* But if it is a delusion of the eye, which ceases both when a telescope is applied and when the eye looks at the lunar disc from behind a chimney or tower, with the bright horn of the Moon meanwhile shut off, there is no reason to seek a

cause in the object, let alone to refer it either to our air with Lagalla, or to the circumlunar air with Mästlin, Kepler, Bettini, Liceti and formerly Galileo, or to the diaphaneity of the lunar margins with Scheiner. So much, then, for the bright ring that appears to us outside eclipse new Moons.

IV. [Margin: On the bright ring seen around the Moon in eclipses of the Sun.] But what about the ring that has more than once been seen shining around the Moon in eclipses of the Sun? For we cannot put this kind of phenomenon down to a mockery of the eye without force and a certain injury done to astronomical history. Plutarch certainly says in the little work *On the Face in the Orb of the Moon*: *Even if the Moon sometimes hides the whole Sun, yet that eclipse lacks breadth and duration, but a certain splendour shines out around the rim, not allowing the shadow to become deep and excessive.* Cleomedes supports this in book 2 of the *Cyclical Theory*, chapter 4, where, asking how the Moon, although smaller than the Sun as to true diameter, nevertheless optically covers the whole Sun, he says: *Some of the ancients, indeed, held that in perfect eclipses the centres of the luminaries fall on one and the same straight line, and that the rim of the Sun appears all around on every side. Nor is this any kind of invention, for projecting parts have been seen by us, most brilliant and displaying no slight projection, since the Sun is much larger than the Moon. It must be said, therefore, that the Moon is smaller than the Sun. But nothing prevents the whole Sun from being darkened by it optically or apparently, when, that is, it is made optically equal to it.* He therefore admits both kinds of eclipses, namely total ones, and partial ones with the bright circle of the Sun projecting all around the Moon; although others think his words ambiguous and translate the passage from the Greek original so that the second kind is denied.

Moreover, Proclus Diadochus said in the *Astronomical Hypotyposes*, q. 5: *Sometimes the whole Sun seems to be covered from our view; sometimes, at the very moment when the two centres and the eye fall on the same line, the Moon is seen within the Sun's circuit.* And he reports that Sosigenes wrote this very thing in the book *On Revolutions*: namely, that *the Sun at perigee in eclipses is seen not running forward entire, but that at the extremes of its circumference it escapes the circle of the Moon and gives light in no way impeded.* I shall point out examples of these eclipses in Scholium 1.

On these suppositions, the question is the cause of this phenomenon, namely of the bright corona G L N M around the Moon in central eclipses of the Sun. Longomontanus, in book 1 of the *Theorica*, chapter 9, attributes the cause both to rays of the Sun reflected from the Earth, which diminish the lunar shadow (for with the shadow diminished the Sun, which otherwise is then usually seen under the angle of the shadow, is seen under a larger angle), and to refractions of the solar rays made in the vapours of the horizon, by which the Sun's diameter is optically enlarged. But these causes, as we shall say in chapter 16, no. 8, do not hold when such eclipses appear around the meridian far from the horizon, as one appeared to Clavius according to what will be said here in chapter 16, no. 8; and that reflection dilutes the shadow but does not narrow

it. Kepler, however, in the *Astronomia Optica*, from p. 299 to 302, adduces two alternative causes. The first and more frequent, he says, is the varied and alterable matter of the sky, and the air, or if you prefer the aether, around the Sun, which is now thicker and denser than the rest of the aether, now rarer, and so shines more or less from the Sun's rays; this he confirms by the example of the eclipse observed at Naples, in the book *De Stella nova*, chapter 23. The other cause, to be substituted in support if this one should not suffice, he says is denser air around the Moon, and vapours drawn up from its seas, lakes, etc.; in this air the rays of the Sun, refracted towards the Moon's globe, represent the Sun under a wider angle, and thus render its diameter optically larger than it really is. Scheiner here too would have recourse to the diaphaneity of the Moon; but then this ring would have to be seen in every central eclipse of the Sun.

[Margin: Our opinion on this ring.] So when in central eclipses of the Sun a bright circle appears around the Moon, the Moon's apparent diameter is either equal to the Sun's apparent diameter or smaller. If smaller, it is at once clear that the objective cause of the circle just mentioned is in the Sun's disc itself, which extends all around the Moon, so that its direct rays are not all hidden from us by the Moon. But if it is equal, then, because the Sun nevertheless illuminates more than a hemisphere of the Moon, it would not be impossible for some part of the Moon, or some circle of it, to be seen illuminated by us, but through rays reflected from it, if the base of the circle of vision were not smaller than the base of the circle of illumination; or, if it is smaller, for this to come from circumlunar rather than circumsolar air. But since so great a thickness of circumlunar air is uncertain, I therefore hold absolutely that the diameters of the luminaries should be so reconciled that whenever that ring appears, the Moon's diameter is smaller than the Sun's. Granted, the Sun's rays refracted in our air may then make that ring wider. See again on this matter below, chapter 16, nos. 8 and 16.

De luce ſecundaria Lunæ prope Nouilunia, & in Eclipſi Solis.

On the Moon's secondary light near new Moons and in an eclipse of the Sun.

V. In figures 1 and 2 above you have seen that the Moon's disc within the bright periphery is not so dark that it does not show a secondary light. Such a light, then, is seen in the Moon both near new Moons, as anyone can easily observe, especially on the days nearer the new Moon, up to but not including the quadratures, and indeed when the Sun has sunk deeper below the horizon and the light of twilight has lessened; and in many new Moons in which the Sun is wholly, let alone partly, covered by the Moon, as I shall say in Scholium 2. Different authors give different causes of this secondary light.

VI. [Margin: Reinhold's opinion.] The first opinion, conforming to those ancients who attributed a light of its own to the Moon, is that of Erasmus Reinhold, p. 164, on Peuerbach's *Theoricae*. After approving Witelo's opinion

about the Moon's various parts, partly diaphanous and partly opaque, and ascribing the Moon's secondary light to rays of the Sun that penetrate the Moon where it is diaphanous, he nevertheless adds: *Lastly, there is in the Moon a certain peculiar or obscure light, and what this is like is plainly shown by its total eclipses, in which the entire orb is seen in a foul and horrible colour, which, however, is at times ruddy, when the Moon is higher and carried farther outside the ecliptic, at other times blacker, the lower it is, that is, and therefore the more deeply immersed in the Earth's shadow. But in a total eclipse of the Sun, some solar rays also mingle with the light that the Moon has as its own, which, as has been said, penetrate the body of the Moon a little.* So he attributes the chief cause to the Moon's own little light. But if this little light or native whiteness belonged to the Moon, it ought to appear more in the deeper shadow of the Earth, in which, however, sometimes none is seen. So the cause of this light in eclipses of the Moon is another, as we shall say below under the title on this matter.

VII. [Margin: Tycho's opinion.] The second opinion, that of Tycho, *Progymnasmata*, book 2, as cited by Kepler in the *Astronomia Optica*, p. 254, assigns the cause of this light to Venus, which could illuminate the Moon so brightly. But granted that the splendour of Venus, when it shines from that side, could illuminate the margins of the Moon, it could not illuminate the whole disc of the Moon turned towards us, since Venus is much higher than the Moon. And when Venus is above the Sun and joined to it, it can in no way illuminate the Moon on the part facing us; and I say the same of the remaining stars that are absent, or higher than the Moon. As for the fixed stars or planets opposite the new Moon, Kepler in the same work, chapter 7, agrees that the Moon is sometimes illuminated by them, so that through that illumination we see the Moon; but not always, because stars of the first or second magnitude, let alone planets, are not always placed opposite the Moon. And conversely, they are placed opposite the half of the Moon turned away from the Sun, which, however, does not shine. Lastly, the whole hemisphere of the fixed stars on a moonless night does not so illuminate our Earth that we, although nearest to it, see any trace of light reflected from there. Far less, then, can we see the light of the fixed stars reflected by the Moon, at so great a distance of the Moon from us, as Liceti rightly argues in book 1 of *De Lunae subobscura luce*, chapter 10. And if anyone maintains that the Moon is illuminated by the fixed stars, then it would also be illuminated at the quadratures and beyond, which is against experiment.

VIII. [Margin: The opinion of Witelo, d'Aguilon, Scheiner and Lagalla.] The third opinion is that the Moon's secondary light in eclipse conjunctions, or near other conjunctions, is rays of the Sun shining through, but refracted and weakened while they penetrate the Moon's semi-opaque and semi-diaphanous body, or a body opaque in some of its various parts and transparent in others. So think those most brilliant lights of optics: Witelo, *Optics*, book 4, theorem 77; d'Aguilon, *Optics*, book 5, p. 423; Scheiner in the *Disquisitiones Mathematicae*, no. 27, and in *Apelles post tabulam*, p. 53; Vincentius Lagalla, in the book *De*

Phaenomenis in Orbe Lunae, chapter 11. And Caesar Germanicus, in the *Aratea Phaenomena*, towards the end, indicates that it was also the opinion of ancient philosophers. I will not repeat what I said about the Moon's diaphaneity in chapter 5, no. 6. Against this opinion, Kepler in the *Optics*, chapter 6, no. 10, and Galileo in the *Sidereus Nuncius*, from p. 14, and in *De maculis solaribus*, p. 136, adduce the Moon's total opacity, which Kepler says he evidently demonstrated in no. 9, although he only suggested it by mere conjectures. Galileo adds that if the rays of the Sun penetrated the whole depth of the Moon, which is about 2000 miles, they could penetrate far more easily the peaks of the lunar mountains, which are discussed below, and through them the parts of the Moon that follow would be illuminated at the quadratures and at sextile aspects, which is against experience. For so great a transparency, which at a depth of 2000 miles would not impede the Sun's rays, could not prevent those same rays from showing us, with a confused light, the boundary of the directly illuminated part from the remaining part. Anyone can test this in a glass ball exposed to the Sun and viewed from such a position as we view the Moon [Greek: διχότομον (dichotomon, "cut in two", the half Moon)], unless you say that those mountains are opaque there.

Moreover, this secondary light would last at the quadratures and beyond, whereas in fact it vanishes a little before the first quadrature, begins to appear only one or two days after the second, and is always the greater the nearer the Moon is to the Sun; unless you say that this little light does not then appear when compared with the remaining splendour of the Moon. Nor should it seem unlikely to anyone that, if the Moon's globe were as it were glass and transparent like the body of celestial comets, the Sun's rays would produce on the part turned away from the Sun a tail of its own for the Moon, as for a great comet, were it not for the Moon's excessive depth, about two thousand miles, and its density. Because of these Posidonius did not dare to admit rays of the Sun penetrating the whole Moon: for Cleomedes says, in book 2 of the *Cyclical Theory*, chapter 4: *Posidonius, then, says that not only is the surface of the Moon illuminated by the Sun, as solid and opaque bodies are, but that it enters its thickness, as being rare, yet not everywhere nor very deeply, because the Moon has a huge diameter and the Sun is very distant from it; whereas misty air easily admits penetrating rays, as having no depth.* So Scheiner undeservedly adduces Posidonius for himself. Liceti, however, in book 1 of *De Lunae subobscura luce*, book 5, says that the opinion of Witelo and his followers can be defended if channels are posited in the body of the Moon, and certain streaks or veins of diaphanous parts, so disposed that their straightness, when the Moon stands near conjunctions, transmits the Sun's rays to us, while at other, greater distances from the Sun they cannot do this because of their obliquity. But in chapter 6 he rejects Witelo's opinion absolutely, because he considers it arbitrary to posit those channels, or indeed diaphaneity, in the Moon without experiments. Yet even if diaphaneity were present, because of the excessive depth of the Moon,

of more than two thousand miles, the rays would not reach the bottom of the Moon, as I have already said.

IX. [Margin: The opinion of Mästlin, Kepler, Galileo, Gassendi, René Descartes, Hortensius, Šírek and Longomontanus.] The fourth opinion is that this little light comes from rays of the Sun reflected from the Earth right to the Moon, from those parts of the Earth in which it is still day. So think Mästlin, in the *Eclipses*, from thesis 21; Kepler in the *Astronomia Optica*, p. 254, in the *Epitome Astronom.*, p. 832, and in the dissertation with the *Sidereus Nuncius*, p. 15; Galileo in the *Sidereus Nuncius*, p. 15, and in *De Maculis Solis*, p. 136, and in Dialogue 1 of *De Mundi Systemate*; Pierre Gassendi in the book *De Magnitudine apparenti Solis humilis & sublimis*, Letter 2, which is to Liceti, p. 95, and in the *Institutio Astronomica*, chapter 16; Descartes, Part 3 of his *Philosophy*, nos. 12 and 152; Martinus Hortensius in the dissertation *De Mercurio sub Sole viso*, p. 31; Antonín Maria Šírek in the *Radius Sidereomysticus*, book 4, c. 2, member 10; and Longomontanus, book 1 of the *Theorica*, at the end, or p. 315, although, besides the Sun's rays and the remnants of daylight, he also adds light shed by other stars and shining back onto the Moon as onto a mirror. Šírek, however, thinks that this phase of secondary light is helped by the shadow of the lunar body, in which it is more clearly distinguished. [Margin: What of Biancani?] Finally, Biancani, in book 9 of the *Sphaera*, chapter 4, does not dare to settle the dispute between the third and fourth opinions.

The foundation of this opinion is the position of the Moon relative to the Earth and the Sun, which is most apt for catching the Sun's rays reflected from the Earth at just the time when this secondary light in the Moon grows brightest. For in the Moon's extreme and first phase it appears greatest, and overcomes the brightness of the twilight and the density of the horizontal vapours; on the 3rd and 4th day before or after new Moon it is greater than on other days more remote from new Moon; and at the quadratures it now vanishes almost wholly and is seen only when the night is well advanced, because rays reflected from the Earth cannot travel towards the Moon. And yet it ought to appear more at that time, because the Moon is farther from the light of twilight. Hence too it comes about that in total eclipses of the Sun this dim light does indeed appear in the Moon, but not as much as outside eclipses, because the interposed Moon intercepts the greatest part of the solar rays from that tract of the Earth from which, once reflected, they could illuminate the Moon. In partial eclipses of the Sun, by contrast, the very brilliance of the Sun dazzles the eyes and so occupies them that they cannot see the Moon's lesser little light. Hence again is given the reason why, the farther the Moon moves from conjunction with the Sun and the nearer it is to the quadratures, the fainter this secondary light appears: namely, because of the greater obliquity of the reflected rays, and therefore their being fewer. To explain this, what we said in book 3, chapter 5, no. 1, can serve, and the diagrams to be given in chapter 8. And it is also the reason why, nevertheless, during the whole time within the last and first quadrature, some of this light is visible in the Moon: because within that time the Moon is

above the horizon of that terrestrial hemisphere in which it is day, and from which the Moon can be struck by the rebounding rays of the Sun.

Against this opinion, however, Scheiner in the *Disquisitiones*, p. 60, and Liceti in *De Lunae luce subobscura*, book 5, chapter 12, and book 2 throughout, but especially chapters 2, 4, 5, 9, 10, 12, and book 3, chapters 9 and 12, hurl not a few objections that are not to be despised at first sight. Galileo in Dialogue 1 of the *Systems*, and Gassendi in the letter to Liceti, suggest solutions to some of them; we shall indicate the rest summarily.

[Margin: Objections against the 4th opinion, and their solution.] [Margin: Argument 1.] 1. To illuminate is to act and to perfect; to be illuminated is to be perfected, to be acted upon and to be altered. But between things that do not have one matter, as the Earth and the Moon do not, there is no mutual alteration, from *De Generatione* 1, t. 1. And higher things, such as the Moon, ought not to be perfected by lower ones, since rather, from *Meteorologica* 1, chapter 2, this lower world is perfected by the higher, and by the celestial bodies. But these points hold at most of an alteration that is not merely perfective, but corruptive, or perfective connoting a lack; for they prove nothing about an alteration merely perfective as to some accident, one not owed to the Moon but possible.

[Margin: Argument 2.] 2. The distance of the Moon from the Earth is, to the senses, the same during the whole time between the last and first quadrature, and yet the Moon's secondary light varies to the senses; therefore this variation must be sought not from the Earth but from elsewhere. But the inference is invalid, because that variation arises not from the distance but from the varying obliquity of the reflected rays.

[Margin: Argument 3.] 3. The Moon's secondary light decreases as the Moon waxes, in the space or quantity of the illuminated disc, not in intensity, since it lasts the same up to the 8th day; and this would not happen if it came from the Earth. But this objection assumes something false. For it does decrease in intensity; but it must be observed in the first phases, when, with the Sun deeper, the light of twilight does not interfere with this light, so that it can be discerned as greater than the light of the following nights.

[Margin: Argument 4.] 4. If this light came from the Earth, the Moon ought to be illuminated more by the Earth at new Moons than the Moon illuminates the Earth at full Moons, both because the Earth is larger than the Moon, and because the Earth is nearer the Sun at conjunction, and so receives stronger and more intense solar rays than the Moon does at opposition; and yet the opposite evidently happens. I for my part concede the major premise when the Moon is not eclipsing the Sun, for in an eclipse it blocks very many of the Sun's rays that would come directly to the Earth. But I deny the minor premise. The Moon's light at these new Moons seems smaller because we view it through solar rays that reach us not by a primary but by a secondary reflection, since they are reflected first from the Earth to the Moon and then from the Moon to us. At full Moon, on the other hand, we see the light through a single, primary

reflection made in the Moon directly to us. Now if we were on the Moon at the time of conjunction, we would see the Earth like some full Moon; but if we were on the Moon at the time of opposition, we would see the Earth illuminated by the Moon, yet endowed with a lesser light than the Moon's secondary light, because the Moon is smaller than the Earth and casts back fewer solar rays onto it than, other things being equal, the Earth casts onto the Moon.

[Margin: Argument 5.] 5. If this light were reflected from the Earth to the Moon, then in a total eclipse of the Sun there would not be that horrible darkness which we know from the history of every age to have occurred. But the reply has already been given: at that time the greatest part of the Sun's direct rays is taken from the Earth by the Moon, and so very few, and almost none, are reflected to the Moon, and those only from the flanks of mountains or the hollows of certain valleys.

[Margin: Argument 6.] 6. The Moon's secondary light is livelier around the margins than in the middle of the lunar disc; but if it came from the Earth, it would be otherwise. But I have already said, at number 3, that this is an illusion of the eye, and that it disappears if one views the secondary light with the Moon's primary light covered.

[Margin: Argument 7.] 7. Venus is sometimes seen by us even near midday, and very bright, and the Earth is illuminated by the Sun no less than Venus is. So if the Moon is illuminated by the Earth, the Moon, although placed near the Sun, could be seen to shine. But Galileo and Gassendi deny the inference, because the light of Venus is primary and drawn directly from the Sun, whereas the secondary light from the Earth onto Venus is extremely faint because of the excessive distance. This light of which we are speaking, by contrast, is in the Moon secondary and mediate. Nor indeed did Galileo concede, as Liceti supposes on p. 255, that this light is as great as the light at full Moon.

[Margin: Argument 8.] 8. Venus has as much power to illuminate the Earth as the Earth has to illuminate the Moon; but neither Venus nor all the stars together, on a moonless night, impart so much light to the Earth as would suffice for reading, or as is the Moon's secondary light. And surely, who would deny that a person placed on the Moon could not read the characters of any book by the strength of this light? But that thesis is denied, both because Venus is far smaller than the Earth, and because she is far more distant. And so the Moon's primary light at full Moon, by reason of its nearness, supplies us with a quantity sufficient for reading, which Venus can hardly do, especially since she is never full at night with respect to us.

[Margin: Argument 9.] 9. If this light came from the Earth, the Earth would have as much power to illuminate the Moon as the Sun has to illuminate Saturn, because this secondary light in the Moon is so great that it rivals Saturn's light, if it is viewed with the primary light shut off behind the roof of some house, as was said at number 3 from Scheiner, whose objection this also is. But I reply by denying that parity. The Sun illuminates Saturn directly, though Saturn is very

remote; the Earth illuminates the Moon mediately, it is true, but the Moon is distant from it by fewer than 100 of its semidiameters, whereas Saturn is distant from the Sun by more than 10000 semidiameters of the Earth. And it is not unfitting that this nearness should compensate for the lack of a light of its own, which we admit in the Earth.

[Margin: Argument 10. Whether the middle region of the air feels the Sun's reflected rays.] 10. The cold of the middle region of the air does not allow the Sun's rays reflected from the Earth to pass beyond it; otherwise their doubling would hinder the formation of snow and hail. Moreover, the power of the Earth, convex as it is in its parts, and especially in the opaque and dark ones, to reflect the Sun's light is less than it was in the concave mirrors of Archimedes, both because these were hollow and better suited to gathering rays into one, and because they were less opaque; and yet the light reflected by them did not exceed a bowshot, as Tzetzes relates. But since the Sun's direct rays certainly pass through the middle region of the air, and yet hinder neither its cold, which arises from aqueous vapours, nor snow or hail, and since the same rays of the Sun reflected from the full Moon to the Earth overcome the cold not only of that region but not even of the night, and do not warm us, we must say that the argument from the absence of heat that burns or melts, or is strongly perceptible, to the absence of light is not valid, especially since so great a quantity and concentration of rays is not required for illuminating as for burning. Moreover, the mirrors of Archimedes were far too small in comparison with the terrestrial hemisphere illuminated by the Sun, which can therefore reflect far more rays to the Moon; and though these are individually faint, together they can produce this secondary light. And if transparency were required, as in mirrors, it would not be lacking in seas, lakes and ponds.

[Margin: The opinion of Fortunio Liceti.] X. The fifth opinion is that of Fortunio Liceti in the book *De Lunae luce subobscura*, most generously presented to me by the author himself. There he teaches that the Moon's secondary light comes both from light reflected from the circumlunar aether and from some native light, which is awakened proportionally by the Sun's rays, as in the Bologna stone called the light-bearing stone or light-drinker [litheoſphoro, seu lucibibo]. When this stone has been baked and, as the chemists say, calcined, then exposed to light and shortly afterwards withdrawn into a dark place, it appears fiery like live coals, and it keeps that appearance for almost half a quarter of an hour, as we ourselves have often found by experiment here in Bologna. So Liceti saw a great analogy between this stone and the Moon in retaining for some time the light received from the Sun, in the very darkness of a lunar eclipse. Further, in order to assert the same of the secondary light near conjunctions, he had to find a way by which this light would be communicated to the part of the Moon turned away from the Sun, or be awakened if already latent in it; and so he took refuge in the aether adjacent to the Moon and reflecting the Sun's rays into that part. But Gassendi objects to this opinion that this denser aether, which makes its own dawn around the Moon, is of very slight height,

and not so great that the parts nearer the silvery light grow brighter than those more remote, since over the whole of the rest of the disc the brightness is of one kind, and the telescope reveals no other difference than the one due to the spots. Second, just as twilight ceases when the Sun is placed about 18° below the horizon, which is a sign that the height of the twilight exhalations is almost imperceptible compared with the bulk of the Earth, so one must reason about that lunar atmosphere: relative to the Moon's depth it is so small that a solar ray cannot be reflected from it onto the whole disc of the Moon.

[Margin: Our opinion.] So, all things reckoned, Liceti's opinion seems to me ingenious indeed, but the third opinion not improbable, and the fourth much more probable; and when that opinion is properly understood, the phenomena of this light are explained in such a way that the objections against it are more easily and more prudently resolved. If, however, the whole Moon were supposed to be kindled by the Sun as the Bologna stone is, and the effect of this kindling to penetrate to its very bottom, then there would be no need to resort to reflection from the circumlunar atmosphere. It could then be said that this faint glow is not seen at the Moon's quadratures or gibbous phases because the excessive brilliance of the part directly illuminated by the Sun predominates in our eyes; and the cause of this faint glow would be one and the same at full Moons and outside them.

De luce Lunæ in Eclipſibus ipſius Totalibus.

On the Moon's light in her own total eclipses.

[Margin: The Moon, even in her own total eclipse, still glows faintly.] XI. Among the antitheses with which Pliny the Elder (book 2, chapter 9) praises the Moon there is also this: "Failing, and yet conspicuous in her failure." That is, because of that baleful, dark light which, taking on different colours according to the Moon's different immersion in the Earth's shadow, "terrifies the eyes of mortals ignorant of the cause." "For," says Pharnaces in Plutarch's essay *On the Face in the Orb of the Moon*, "she does not lie wholly hidden in eclipses, but shines forth with a certain terrible colour resembling a live coal, which is proper to her." Apollonides, refuting this, adds in the same place: "Therefore that the Moon is earthy and dense could hardly be shown by any other equally clear argument, if that coal-like colour were indeed proper to her. But it is not, my Pharnaces, and we see the Moon in eclipse take on one colour at one time and another at another; and the mathematicians distinguish these by the time, as follows. If the Moon fails toward evening, the Moon appears horribly up to the third hour and more than half an hour beyond; if at midnight, then she gives out this crimson and fiery colour; from the seventh hour and a half a red is shown; toward dawn she now takes on a blue, grim face, from which the poets above all, and Empedocles, also call her *glaucopin*, that is, grey-eyed." Nor is it an obstacle that Scheiner says in the *Disquisitiones*, no. 26: "But the Moon, since she is herself devoid of all light, which has often been noticed both by

us and by others in her full eclipses, where, deprived of all brilliance whatever, she grows black." For this is to be understood of the middle of a total eclipse, as appears from other observations, also of Scheiner, to be touched on in Scholia 2 and 3. Further, I find five causes of this light too in the Moon devised by natural philosophers or astronomers, and from them as many headings of opinions.

[Margin: The opinion of Pharnaces, Theon, Cleomedes, Reinhold, Cardano.] XII. The first was that of the ancients, who argued even from this that some light of her own is in the Moon. So indeed Pharnaces in Plutarch, adduced a little earlier, and Reinhold, cited at no. 6; and Theon in the Commentary on Book 4 of Ptolemy's *Almagest*, where he says of the Moon's body: "But since she has obtained a weaker light of her own, which cannot easily reach our sight, she appears more splendid by another light borrowed from the Sun, so as to illuminate the lands and the air. So when the Earth comes between the solar radiations, then the Moon, deprived of the Sun's light and darkened by the cone of shadow, becomes weaker and darker again." But Cleomedes too, in book 2 of his *Cyclical Theory*, acknowledged this proper light in the Moon; and Cardano, in book 3 of *De subtilitate*, says of the Moon: "Whose light does not (as some think) depend wholly on the Sun, and much less does that of the other stars. For it is agreed that in the greatest eclipses she glows red, like some live coal of fire, and this light is then proper to her. But since at night nothing is seen from afar more dimly than fire, and a flame appears red, and since the Moon is so far from us in eclipses, it is plain that the Moon has a light of her own clearer than any flame or candle. Imagine, then, that the Moon, of herself and aided by no rays of the Sun, is very like a very great and very bright flame." Rising by this argument from distance to the nearness of the Moon, he infers: "Therefore above the aether all things shine and flash so much that if, being there, we looked at the Moon even at the time of an eclipse, we would be dazzled by the brilliance, just as with countless most brilliant wax candles lit and our eyes fixed on them."

Against this opinion, however, there still stand both the varieties of colours which this secondary light takes on, as we heard Plutarch's Apollonides rightly arguing against Pharnaces, and the argument of Tycho in volume 1 of the *Progymnasmata*, p. 743, in that he asserts that this light would shine more in the deeper darkness of the Earth's shadow, whereas in fact it vanishes there as the Moon hastens toward the middle of the eclipse, or can be discerned only with the greatest difficulty.

[Margin: The opinion of Longomontanus, Aversa, Mastri, Belluto and, in part, Gassendi.] The second opinion assigns this light to the fixed stars, or also to some planets, if they stand in a place suitable for it. So indeed Longomontanus in the *Astronomia Danica*, book 1 of the *Theorica*, chapter 9; Aversa [Raffaele Aversa], *De caelo*, q. 32, sect. 2; Mastri and Belluto [Bonaventura Belluto], *De caelo*, disp. 2, q. 5. Gassendi does not deny the same of that faint glow which is scarcely discerned in the middle of a total eclipse, for on the rest he follows the opinion to be reported in fifth place. But against this stands that variety of

colours mentioned above, and the emptying away of this faint glow around the middle, where nevertheless this light ought to have appeared better; since in a clear sky there is no lack of very many fixed stars so placed opposite that they could illuminate the Moon with their rays even at the middle and centre of the Earth's shadow; and sometimes the superior planets are placed opposite together with Venus, and these, with the Earth's shadow no obstacle at all, can direct their rays onto the Moon. But if the faint glow on the Moon, placed so far off, comes from the fixed stars and is visible to us, why do the fixed stars on a moonless night not likewise illuminate papers or clothes near us?

[Margin: The opinion of Galileo.] The third opinion is that of Galileo in the *Sidereus Nuncius*, p. 15, and in the letter which Liceti reproduces in *De Lunae luce subobscura*, p. 262: that this light or coppery redness, which appears around the extremities of the Earth's shadow when the Moon is eclipsed, comes from the Sun's rays illuminating that denser aether which creates an atmosphere around the Moon, and from it pours a kind of dawn into the regions near the Moon. But here Kepler doubts, in the *Dissertatio cum Nuncio Sidereo*, p. 15, whether this dawn, being uniform, could account for this redness of the Moon, so inconstant and of various colours. Further, when the Moon is already wholly in the Earth's shadow, this redness appears also in the parts of the Moon tending toward the shadow's axis, yet the Sun's direct rays do not reach those parts. And if you resort to refracted rays, you will already be running into the fifth opinion, of which presently.

[Margin: The opinion of Wendelen and Liceti.] The fourth opinion is that of Fortunio Liceti in the treatise *De Lunae luce subobscura*, book 2, chapter 6, and book 3, chapters 4 and 11, and of Wendelen in the *Idea of the Atlantic Tables*, p. 5, where they attribute this light partly to the Sun's light reflected from the circumlunar air, partly to the Moon's native light, which is however awakened and brought into second act by the Sun, and preserved in darkness in the way the Bologna stone preserves for a while the light kindled in it by the Sun. But what we have just said against Galileo about light from the circumlunar air holds here too; and the remaining cause I cannot approve, because this light of the Moon which we are disputing gradually weakens from the beginning to the middle of a total eclipse, but shortly after the middle it generally revives and increases as the Moon hastens to emersion, and it is always greater toward the parts of the shadow at both extremes, and of different colours. No sufficient cause is offered for these variations if the Moon retains light conceived from the Sun; for from where does it rekindle that light, while not yet emerging from the shadow?

[Margin: The opinion of Apollonides, Giovanni Battista Benedetti, Gassendi, Kepler and ourselves.] So the fifth opinion, far more probable to my mind, is that this redness, or the other colours of this secondary light, comes from the Sun's rays, but rays twice refracted in the vapours of the air surrounding the Earth's globe: refracted, I say, as the convexity of the atmosphere requires, once on entering and again on leaving, toward the perpendicular and the axis of

the cone of the Earth's shadow. For this is why this light is greater in the parts of the Moon toward the margins of the shadow than toward the axis: there are more refracted rays there. And it varies its colours because the vapours around the Earth, through which the Sun's rays pass, are of different opacity and diaphaneity, from whose mixture with light we also see different colours in the dawn and in clouds illuminated by the Sun. [Margin: You have a diagram of this double refraction below, in book 5.] Finally, this light vanishes in the middle of a total eclipse or near the middle, as we shall say in Scholium 4, because the Moon is so low and so deeply sunk in the shadow, or the vapours so thick, that either almost no rays or only greatly weakened ones are refracted to that part. This opinion was first taught me by Apollonides in Plutarch's essay *On the Face in the Orb of the Moon*, in these words: "Therefore, since we see the Moon in the shadow take on so many colours, they are not right to seize on the coal-like one, which one might most of all say is foreign to her, and rather a mixture of light failing and shining through the shadow, etc." Next, Giovanni Battista Benedetti in the letter to Philibertus Pignonius [?] of Savoy, in my copy p. 255; Pierre Gassendi in the book *De apparenti magnitudine Solis*, letter 2, p. 97; and best of all Kepler in the *Astronomia Optica*, the whole of chapter 7, and in the *Epitome of Copernican Astronomy*, p. 871, and in the *Dissertatio cum Nuncio Sidereo*, p. 20.

[Margin: The cause of the variety of colours in eclipses.] From this you see what judgement is to be passed on the causes of the variety of colours in lunar eclipses that are thrust on us either by Pharnaces in Plutarch, already cited near the beginning at no. 11, or by the Arabs, and following them Cardano in the *Supplementum Almanach* and in the commentary on Ptolemy's *Quadripartitum*, and by the Alphonsine astronomers, partly from the Arabs, partly from Ioannes de Lineriis [Jean de Lignières] at the end of Proposition 32, and from there Magini in canon 89 of the *Secunda Mobilia*. Some derive them from evening or morning time, others from the Moon's approach to apogee or perigee, others from the Moon's varying latitude and nearness to the nodes. For the chief cause, as I have said, is the variety of the vapours encircling the Earth's globe, through which the Sun's refracted rays are coloured. Granted that the differing state of the morning, evening, summer, winter, spring and autumn air contributes to this variety of vapours; and that the place and position of the Moon undoubtedly contributes to receiving the different refracted rays. I say nothing of the prognostics from these colours among the astrologers, for instance Origanus, volume 1 of the *Ephemerides*, part 3, chapter 2, p. 463, and Wendelen, p. 4.

The fringes on the Moon's limb, on which Wendelen writes on p. 6, also belong here.

We shall give figures of the refraction of the rays in a lunar eclipse in book 5, chapter 5, and again in volume 2 of the *Almagest*, in its optical book; and there we shall also resolve what our Bettini objected to Kepler in *Apiarium* 8, Prog. 2, from Prop. 5 to Prop. 9.

SCHOLIA.

Scholia.

[Margin: Solar eclipses with a bright ring around the Moon.] I. I call eclipses of the Sun annular when around the Moon there is left a small circle or a kind of bright ring, that is, a segment of the solar disc not entirely covered by the Moon. Many authors admit eclipses of this kind, and I shall point out examples of them in chapter 16, no. 16, and more fully in book 5, chapters 19 and 20, where they will be treated.

[Margin: The Moon's colour and light in an eclipse of the Sun.] II. It is established that the Moon herself has at times been seen in an eclipse of the Sun, certainly in a black colour if not in another. Granted that Pliny the Elder, book 2, chapter 9, says of a non-eclipsing conjunction: "In conjunction she is indeed not seen, because, turned away, she sends back all the light she has drawn to the place from which she received it." For Longomontanus, in book 1 of the *Theorica*, chapter 9, p. 315, states that in the eclipse of the Sun of 1605 September 23, at Copenhagen, he observed the Moon with a blackish face. And Scheiner, in *Apelles post tabulam*, p. 49, states that on 1612 May 29 he and his companions saw the portion of the Moon that was covering the Sun wholly transparent like crystal or glass, though unevenly, so that in some places it was wholly white and in others was turning white. From this he infers that the Moon is transparent throughout, more or less according to its greater or lesser density. Kepler, in the book *De Stella Nova*, chapter 23, reports that in 1605, in a total eclipse of the Sun, the Moon was seen like a black cloud, but at Antwerp dusky and as if covered with soot, while its upper circumference was wholly white and as if fiery. I myself, on 1630 June 10, saw her swarthy and of a colour mixed from black and crimson. This redness Kepler, in the *Epitome of Copernican Astronomy*, p. 895, attributes to the Sun's rays reflected from the Earth onto the Moon, from that part of the Earth which is not covered by the Moon's shadow.

[Margin: The colours of a lunar eclipse.] III. As regards total eclipses of the Moon and her various colours, Frodoardus [Flodoard of Reims], in his *Chronicon* for 926 April 1, relates that the Moon, undergoing eclipse, turned to pallor, with a small particle of light left, and, as dawn was already beginning, changed wholly to a blood-red colour. And Cornelius Gemma, in book 2 of the *Cosmocritice*, p. 64, says that on 1569 March 3, in the morning at the third hour, Phoebe suffered a horrible eclipse, marked by dreadful colours. For first she shone dusky, then blood-red, soon also crimson, and green, and livid, and at last misshapen by an incredible variety. That is, as Kepler says on p. 274 of the *Optica*, almost with the colours of the rainbow. He adds that when he was a boy in Württemberg, in 1580, at the 10th hour of the night, the Moon in eclipse appeared to him plainly ruddy, and that he saw the same redness in the eclipse of 1599 February 9 and in 1603 on November 18; but in 1598, on August

16, so much of it that the Moon could hardly be believed eclipsed, although she was wholly in the shadow.

[Margin: The Moon extinguished in the middle of an eclipse.] IV. In the middle of a lunar eclipse, however, and in the deeper shadow, the Moon is sometimes barely visible, and to some people more, less, or not at all, according to the variety of the air and of the vapours. This is attested by the eclipses of 1580 and of 1583 March 3, observed by Kepler (from the *Astronomia Optica*, p. 227), and of 1588 by Tycho, and of 1620 June 15 by Wendelen. But above all by the two total lunar eclipses of 1642. For in the one that occurred on April 14, the Moon was seen at Venice by the most illustrious Iulius Iustinianus [Giulio Giustiniani] as of a red colour and like the light of Mars, as I gather from his letter copied to me through Fortunio Liceti; and Doctor Bonuicinus [?] and Master Pieronus [?] saw the same at Vienna at that time. Yet no one in Belgium, as Wendelen testifies on p. 4, nor we with many companions at Bologna, nor Vincenzo Renieri at Pisa, although the sky was clear, could make out the Moon at all in the depth of the shadow, and we searched for her in vain in the sky for almost one hour. On the contrary, in the one that followed on October 7, we saw the Moon crimson almost up to the middle, and pale in the middle. You will wonder less at all this, however, if you first understand what will be said below in book 5, chapter 5, about the refractions that curtail the Earth's shadow more or less, or even dilute it.

CAPVT VII.

Chapter 7.

De Selenographia, ſeu Lunaris faciei Teleſcopijs obſeruatæ Deſcriptione accurata.

On selenography, or the accurate description of the Moon's face as observed by telescopes.

I. What Endymion once noted in the spots of the Moon's face so beautiful that he judged it worthy of his love and of the contemplation of many years has not been handed down. Nor, in Plutarch's most learned essay *On the Face in the Orb of the Moon*, is there any treatment of spots other than the ancient ones, visible to the naked eye. [Margin: Authors of selenography.] But when Galileo first, and Scheiner, noticed new spots, or varieties of parts, with the recently invented telescopes, then Caesar Lagalla [Giulio Cesare Lagalla] also published a not inelegant disputation on them, entitled *De Phaenomenis in Orbe Lunae*. But neither the four figures of the Moon at dichotomy which he used, taken from Galileo, nor Scheiner's figure, likewise of the Moon at dichotomy, which is found in the *Disquisitiones Mathematicae*, nor the figures of the same Moon observed with telescopes [tubospicillis], published by Francesco Fontana of Naples and copied by Argoli into the *Pandosion Sphaericum*, are of such size or care that, beyond a certain first sketch of a new phenomenon, they offer the reader the matter of any complete discussion. The figure of

the Moon set out by Antonín Maria Šírek the Capuchin almost at the very beginning of the *Oculus Enoch et Eliae* is somewhat larger. But all these are surpassed by the selenographic figures, first of Michael Florent van Langren and Johannes Hevelius, then of Eustachius de Divinis [Eustachio Divini] and Father Hieronymus Sirsalis [Girolamo Sersale] of the Society of Jesus.

[Margin: Praise of Langren and Hevelius.] For Langren, long since Cosmographer to the Catholic King, began both at Madrid and at Brussels and elsewhere, with a very large and excellent telescope, to observe one by one even the smallest spots of the Moon, and especially those through which the Moon's section has been seen to pass, whether at dichotomies or in eclipses, and many other things most worthy of note. He distributed these into thirty figures, and large ones at that, engraved in copper with his own hands, with a complete work added, although he has not yet published anything except the figure of the full Moon and certain first leaves of the work itself, in 1645; he generously sent me a copy of these with many other observations. From these, compared with the observations of Hevelius, one may gather that Langren was much earlier in this labour; although Hevelius was more fortunate in bringing forth the whole work of his *Selenographia* and setting it before the public, with a multitude and elegance of figures likewise engraved by his own hand, and an abundance of learning; that work too appeared in 1645, to the great increase of astronomy.

[Margin: The difference between the selenographies of Langren and Hevelius in nomenclature.] They differ, however, both in other things and also in the nomenclature of the parts of the Moon. For Langren used the names of persons distinguished in this age either in mathematics or in ecclesiastical or secular dignity, or joined to him in friendship. The regions and great tracts of the lunar surface, on the other hand, he named with a kind of moral or civil nomenclature. So in him you may read the Land of Dignity, the Land of Virtue, the Philippic Ocean, the Copernican Sea [Terram Dignitatis, Terram Virtutis, Oceanum Philippicum, Mare Copernicanum], etc. Hevelius, however, as though the Moon were another Earth, transferred the geographical names of our Earth to the Moon, although in shape, position, symmetry, etc. there is almost no analogy between the surfaces of the two.

[Margin: The figures of the full Moon by Divini and Sirsalis.] Finally, Divini published a figure of a single full Moon, of 1649 March 28, observed by him with a telescope of 24 palms; and very recently Father Hieronymus Sirsalis of our Society likewise made public another diagram of a full Moon, of 1650 July 13, observed by him with Divini's telescope, with no explanation and no nomenclature of the parts added.

II. As for us, although we once contemplated the Moon's face with optical tubes and had certain diagrams cut in woodblocks, yet after it was granted us to look at the figures of Langren and Hevelius, and concerning the libration of the lunar

[Margin: The beginnings of our Selenography.] globe a rumour had spread, then indeed our spirit was fired to determine, by the most painstaking observations, whether the diagrams already mentioned agreed with the truth in all their details, and what the limits and the periods of this apparent libration were. For this task, besides the telescopes of Galileo, Fontana, Torricelli and Manzini, either given or lent to us, another, sold to us by a Bavarian craftsman, served best of all. It did so not so much by its length, although that is 15 feet, as by the coupling of its lenses, both convex, so happily associated that, although they show the whole disc of the Moon at one time, at least at apogee, they nevertheless so enlarge it and each of its portions that one can make out in them even the smallest details of even small parts, which we noticed had been either not seen or neglected by others.

Since I had long been sure of the diligence, prudence and trustworthiness of Father Francesco Maria Grimaldi in observations of this kind, and since he had more time and health left for it than I had, I unloaded the greatest part of this labour onto him. [Margin: The excellence of Grimaldi's Selenography.] So, having begun the observations afresh, he kept watch for several years with the greatest circumspection and assiduity in contemplating the Moon, a new but happier Endymion of our age. Examining all the large, middling and smallest parts of the Moon's face one by one through the telescope, and comparing them at once with the diagrams of Langren and Hevelius, which he had made a habit of keeping before him, he found that many things had indeed been done excellently by them, yet that not a few remained which had either to be added or to be corrected as to position, size, shape, proportion, and difference of darkness or brightness. He therefore drew new diagrams for himself, one after another, each better than those before it, and did not rest until he seemed to himself to have attained the evidence of the truth for even the smallest marks of the Moon's face. As for the limits, regions and periods of the libration, he has observed so much up to this day that a full volume could be written from it.

Therefore, although he acknowledges that much is owed to Langren, Hevelius, Eustachio and the other selenographers, freely grants them priority in time, and perhaps could not have attempted or accomplished so much had they not gone before, he has nevertheless brought so much of his own skill, trustworthiness and diligence to this study that he cannot set the evidence of his own eyes below what others have handed down. Nor do I, who together with many of our Society was repeatedly present at his observations and admired in him a prudence equal to his patience, think that anything more perfect of this kind can be either desired or hoped for (unless you except the great number of small spots, which seem almost infinite, and the excessive frequency of certain very faint shadings, deliberately neglected to avoid confusion). Descartes and others have judged the same of our Scheiner, too, in the matter of the sunspots he observed.

Would that, just as Father Grimaldi himself drew his diagrams with truly Daedalian fineness and elegance, he had found an engraver on the spot who

had used a more delicate stylus and a gentler hand, incising the copper rather than ploughing it, and had thinned the blackness here and there. For the rest the engraver represented correctly, and the last impressions, which came out when the plate was already worn from repeated printing, show, as regards the difference of dark and light, one more like the Moon's.

III. [Margin: The selection of diagrams for the Selenography.] Now from so many drawings and observations it was decided to choose only six, the others being reserved for a separate volume on this subject. The first, for the whole disc of the Moon, is composed from the more frequent phases, selected so as to represent as much as possible; the second is for the sickle Moon; the third for the gibbous Moon; the fourth and fifth for two dichotomies, such as appear not always, but at the extreme limits of the librations. For if all the variety of the Moon's face had to be drawn in separate diagrams, not even 300 diagrams of phases would suffice, much less (as Langren believed) 30, since the Moon scarcely ever turns exactly the same face to us, or, if she does offer the same one after long intervals, a favourable night and clear skies scarcely ever allow the observer to see it. So great, clearly, is the diversity of this phenomenon, which the Moon's apogee and perigee, the alternation of her latitudes and, most of all, the anomaly of the apparent libration display to mortals in this theatre of divine workmanship. For the libration, and at the same time for the nomenclature of the Moon's parts, we have added a sixth diagram, similar in most respects to the first, which carries the four smaller figures at its corners. These will be explained below, after the figures have been shown.

IV. [Margin: Where the nomenclature of the lunar parts was taken from.] Moreover, I did not take the nomenclature of the lunar parts from the geography of our Earth, as Hevelius did, because of the lack of analogy already pointed out. I took it rather from persons, not of just any standing, nor distributed indiscriminately or as if by chance, as may be seen in Langren's full Moon, but only from those who either were astronomers rather than genethliac astrologers, or from whose older writings or observations some astronomical learning has flowed into our Almagest. We declare, however, that we utterly reject the error of those who have imagined either that the Moon is inhabited by other men, or that the souls of heroes, or even of other mortals, migrate after death into different abodes in the Moon according to their different merits.

As for the regions of the lunar surface that resemble either continents or seas, lakes, marshes and so on, I did not name them from the species of mathematics, as I wished to do (for that would have stood in the way of a more convenient nomenclature of the smaller parts), but from that diversity of effects, mostly meteorological, on which the Moon, most of all the stars, is believed to exert her influence, because of her closeness to the Earth and the multiplicity of her motions and of her parts. Although in this I followed some analogy, almost by mere choice, I am not imbued with any such opinion that I would suspect, much less believe, that those effects in particular from which I drew the naming depend on that portion of the Moon, for instance snows on the Land of Snows

or dreams on the Marsh of Dreams, whether when the boundary of illumination reaches them, or when they are irradiated by other stars in certain aspects. For although great mysteries of nature certainly lie hidden in this treasury, we are nevertheless not permitted, by settling on fictions about them, imprudently to abuse the contemplation of the divine works, which has been granted to us within fixed limits.

V. [Margin: Its distribution was not made by chance.] I said that I did not distribute the names already mentioned over the Moon's disc by chance. In about the upper part I placed the more ancient: in about the first and second octants most of the physico-astronomers, and in the third and fourth, and as far as the beginning of the fifth and sixth, the rest of the ancients. In the lower part, which comprises about the fifth, sixth, seventh and eighth octants, I placed the more recent. Moreover, as far as could be done, I aimed at affinity or likeness of period, of studies or of school, or at correspondences of this kind. For example, to Meton I joined Euctemon, as his partner in observations; to Plato his intimates Theaetetus, Timaeus and Archytas, and I placed Aristotle not far from there. Likewise I set Callippus next to Eudoxus, Mercury to Atlas, Sosigenes to Caesar, Ptolemy to Hipparchus, al-Battānī to him, Alfonso to al-Battānī, al-Zarqālī and Thābit ibn Qurra to him, Peuerbach to these, and directly after, Regiomontanus, Walther and Werner. To Tycho, likewise, I set beside him William of Hesse, Hainzel, Sasserides [Gellius Sascerides] and Longomontanus; just as to Copernicus I set his own Rheticus, Mästlin, Reinhold and most of the others of that school, whom I also deliberately preferred to be tossed in the Stormy Ocean, like floating islands, because of the instability of the Earth they asserted, rather than to stand firm. And so in the other cases, as the learned reader may consider, I aimed at not a few analogies.

The Selenographic Figures follow, to be inserted immediately after this page 204, not sewn in but glued together, or rather enclosed in such a way that they can be drawn out by the reader and surveyed at a single glance.

Blank page (back of the plate that follows).

Diagram. Engraved plate, the sixth Selenographic figure: *VI. Figure for the nomenclature and the lunar libration.* Two mottoes stand above the disc: *Neither do men inhabit the Moon* at the left, *Nor do souls migrate to the Moon* at the right. The Moon's disc is drawn in hatched relief within a double rim. Four straight lines cross at the point A near the centre and divide the disc into eight octants, each named outside the rim, and the ends of the lines carry letters. Seas, marshes, bays, peninsulas and lands are named in larger letters, and the spots with the names of persons in small letters. A scale runs along the foot of the plate from X to Z, numbered from 10 to 200.

Labels as engraved, by region of the plate:

Blank back of a plate leaf: nothing is printed on it, and only the engraving on the other side shows through.

Blank back of a plate leaf: nothing is printed on it, and only the engraving on the other side shows through.

Diagram. Engraved fold-out plate, taken across the full opening. A title stands at the top centre, in two sizes of italic. Beneath it the upper edge of the plate shows three shaded lunar discs side by side: a large disc in the middle, and to either side a smaller figure with a ragged edge facing the centre.

Title as engraved (upper band of the plate):

- SELENOGRAPHIA P. FRANCISCI MARIÆ GRIMALDI SOC. IESV
- Optimo Telescopio ex plurib. Lunę phasib. Selecta, in qua Langreni, Heuelij, Euſtachij, Sirsalis etc. Selenogr. partim firmauit, partim ita
- correxit, et auxit, ut uel minimę particulę ex aliquib. phasibus euidentiam sit assecutus.

Selenography of Father Francesco Maria Grimaldi of the Society of Jesus, chosen with an excellent telescope from many phases of the Moon, in which he has partly confirmed the selenographies of Langren, Hevelius, Eustachio, Sirsalis, etc., and has partly corrected and enlarged them, so that he has secured a clear view of even the smallest particle from some of the phases.

Upper middle band of the plate. The large central disc is cut by no engraved name; its seas are shaded in horizontal hatching and its craters drawn with small shaded rings. The two side figures are partial phases, each with its ragged lit edge turned towards the centre.

- 5 Figª (below the left figure, under its lower limb)
- 2. Figª. (below the right figure, under its lower limb)

Lower middle band of the plate. The central disc continues, its lower half thick with ringed craters; a large rayed crater stands near its lower limb, with long fine streaks running from it across the seas. Two further partial phases stand below the side figures of the upper half, so that a phase figure lies at each corner of the plate.

- 4 Figª (above the lower left figure, over its upper limb)
- 3. Figª. (above the lower right figure, over its upper limb)

Lower band of the plate. Below the discs, inside the plate mark, stand a draughtsman's line at the left, a caption at the centre and an engraver's line at the right.

- Delineauit ipse P. Grimaldus. (lower left, with a swash D)

- I. Figura inserenda Almageſto Nouo P. Io: Bapt. Riccioli (centre)
- Statim poſt 1. tomi pag. 204. (centre, second line)
- Quę non eſt Plenilunij, sed ex plurib. phasib. conſtructa (centre, third line, smaller)
- Dominicus Fontana Sculp. Bononię (lower right)
- añ o 1651. (lower right, second line)

Father Grimaldi drew this himself.

Figure I, to be inserted in the New Almagest of Father Giovanni Battista Riccioli, immediately after p. 204 of Tome 1. It is not a figure of the full Moon, but is constructed from many phases.

Dominicus Fontana engraved this at Bologna, in the year 1651.

The figures that follow, although drawn from the rudiments of the earliest observations, are nevertheless not useless for confirming the roughnesses of the Moon and the light reflected from the Earth onto the dark part of the Moon.

Diagram. *Figure 7. For the 2nd or 3rd day of the Moon.* A woodcut disc of the Moon within a single rim. Nearly the whole disc is dark and closely hatched, with the lunar spots faintly visible through the hatching, and a thin lit crescent runs along the right limb from the top round to the foot, broken by dark oval spots and small ringed craters. The caption is the only lettering; no letters or numerals could be seen on the block.

Diagram. *Figure 8. For about the 5th day of the Moon.* A woodcut disc of the same kind, with the crescent broader than in Figure 7. Large dark spots stand in the lit limb at the upper right, and a row of ringed craters follows the lit edge along the lower right. The rest of the disc is dark and hatched. The caption is the only lettering; no letters or numerals could be seen on the block.

Diagram. *Figure 9. For the gibbous Moon.* A woodcut disc lit over its left part and dark at the right. The lit part shows hatched seas, ringed craters, ray-craters with radiating lines, and clustered rounded spots towards the foot. The boundary with the dark part is irregular. The caption is the only lettering; no letters or numerals could be seen on the block.

Diagram. *Figure 10. For about the 5th day after the full Moon.* A woodcut disc with its left part lit and its right part dark, as in Figure 9. The boundary is sharply toothed, with craters ranged along it, and hatched seas, ray-craters and clustered rounded spots stand in the lit part. The caption is the only lettering; no letters or numerals could be seen on the block.

NOMENCLATVRA LVNARIVM PARTIVM

Nomenclature of the Parts of the Moon

For the Selenography of Father Francesco Maria Grimaldi and for its Figures 1 and 6, constructed by the author of the New Almagest *and explained by him in Book 4, Chapter 7, No. 4. The synonyms added from the Selenography of Langren are indicated in advance by the letter L, and those from that of Hevelius by the letter H.*

Hiſtoria Selenographica ex ſelectis Obſertionibus indicata.

A Selenographic history, set out from selected observations. [recte: Obſeruationibus]

VI. [Margin: Summary of the argument of the Selenographic history.] The spots on the Moon's face are called Old when they can be discerned with the naked eye, without a spyglass [tuboſpicillo], and seem to imitate great seas. The New spots (which from now on we shall call simply spots) are those that can be discerned only with a telescope, because of their smallness. Most of them tend to a round or oval shape, whether they are dark wholly or always, or partly and sometimes. In both kinds the Belgian tube, especially our own, has in recent years detected marvellous things most worthy of note. This concerns both their number, shape, size and position; and above all the colour of their blackness or brightness, the alternation of light and shadows, their height or depth, and so the roughness of the Moon's surface; and finally and most of all the apparent libration of the lunar globe about its centre. Some of these are common to all phases, while others are proper to the Moon when full, or at dichotomy, or horned, or gibbous. These matters are to be explained more fully elsewhere; in this place they are to be touched on more sparingly, as far as is sufficient.

VII. [Margin: Number of the Moon's spots.] The number of new spots so far does not exceed 270 [CC LXX] in Langren's full Moon, 550 [DL] in that of Hevelius, and finally 600 [DC] in ours. This is not because we have not noted more, but because the rest, on account of their slight depth or height, or at any rate their minuteness, can be distinguished rarely, and only when they first or last catch the light of the Sun. These are truly innumerable, so much so that the whole surface of the Moon visible to us is rough with them, as if with little clods, or stony, or full of ledges. Apart from those larger parts that present the appearance of seas, or bays of seas, or lakes, or marshes, or sandbanks, or reefs, or streams and rivers, or islands or peninsulas, or finally the great continents of our Earth, we nevertheless note four things still more notable as regards the number.

[Margin: First notable point in the number of the spots.] *The first* is that some very small spots follow one another so closely, crowded together in a long tract, that when viewed either with a less perfect telescope or far from the boundary of the general illumination, they look like furrows of certain rays. Notable among these are the ones that spread from the spot of Tycho, as from their origin, through the Land of Fertility, of Heat and so on. Some liken them to the sections of melons, beginning from their flower or rose. But if they are viewed at the edge of the illumination with more perfect tubes, they are seen to be spots distinct from one another, just like the mass of stars in the Milky Way.

[Margin: Second notable point.] *The second* is that other, smaller spots adhere to certain spots or are bound into them, as gems are to rings. Such are the spots of *Hipparchus, Ptolemy, Peuerbach, Hainzel, Gassendi, Stöffler* and *Gemma Frisius*. Or they are so set in that a portion of one covers a portion of another nearly

equal to it, as with *Euctemon* with *Meton*, and *Peuerbach* with *Regiomontanus* and *Viète*. Or they are beaded all round with smaller spots clinging to them, or crowned on one part. Among these may be seen *Cleomedes, Riccioli* and above all *Tycho*, around which there are so many little hills and valleys that, according to the alternation of the illuminations, they present sometimes a rose of crowded spots, sometimes one continuous lake.

[Margin: Third notable point.] *The third* is that within certain spots, as if in wombs, there are one or more smaller ones, which cast their little shadow towards the same side as that to which the shadow of the spots enclosing them inclines. Such are *Hercules, Posidonius, Clavius* and some others.

[Margin: Fourth notable point.] *The fourth* is that some are likewise enclosed in larger ones in such a way that they cast their shadow to the side opposite the shadow of those enclosing them: namely *al-Zarqālī, Thābit ibn Qurra, Boulliau, Gassendi, St Catherine, Sts Theophilus and Cyril of Alexandria, Maurolico, Pétau, Langren, Piccolomini, Copernicus, Thābit ibn Qurra* and so on.

VIII. [Margin: Instability of the shapes.] The shape of the new spots mostly tends towards roundness or an ellipse, but in one and the same spot it not infrequently varies in appearance. This happens either because of the libration of the lunar globe, on account of which they appear compressed as they approach the edges of the lunar disc and widened as they recede from them, as you may often see in *Plato, Zoroaster, Endymion, Grimaldi, Riccioli, Langren* and *Pitiscus*, and as happens likewise in the larger, ancient spots, for example in the *Sea of Crises*, the *Sea of Moisture*, the *Bay of Dew* and the *Marsh of Sleep*. Or it happens because of the differing illumination, as a result of which the edges of the spots appear sometimes continuous, sometimes interrupted and separated into particles tending elsewhere, and these either truncated or bisected. Thus the *Lake of Pitati* is sometimes seen not as a lake cut off from the Sea of Clouds by a continuous shore, but as a kind of harbour, and not oblong but round. *Goclenius*, for its part, sometimes imitates an upturned bowl [ſcaphium]. Thus *Aristarchus* sometimes imitates three-bodied Saturn in the sky, with its companions at its sides sometimes joined to it and sometimes separated. And those companions themselves are seen now bounded by continuous edges and like little moons, now like wings, now like outstretched fingers, and that within one or two days. Finally, certain spots that are usually noted as round nevertheless sometimes become hexagonal, namely at full Moon, such as *Copernicus, Eratosthenes* and *Timocharis*. Nor must it go unmentioned that the spot of *Vitruvius* is displayed now as continuously round, now divided into rays, now crowned with the faint splendour of a halo.

IX. [Margin: Variation of the apparent size.] The true size of the spots depends on the true size of the whole lunar globe, or of a great circle on it. On that, as on the height of the lunar mountains, see what we shall say below, namely in the Scholium to chapter 8. The apparent size, on the other hand, varies for the same reasons as the shape, namely because of libration or of differing illumination. So you can draw not a few examples from what was

said a little earlier about the shape, or also from the first notable point on the number of the spots. But besides what has been said about the shape of the *Sea of Crises* and the *Sea of Moisture*, the *Sea of Nectar* too is at one time bounded by a shore extended from *St Catherine* to *Fracastoro*, as is seen in the first figure, and at another time is enlarged, with the same shore receding as it were towards the *Land of Fertility*, as happens in flow and ebb.

X. [Margin: The position of the spots relative to one another varies through the force of libration.] The position of the spots varies in a wonderful way and very frequently through the force of the lunar libration, whether you compare them with one another or with the centre, the limbs or other regions of the lunar disc. Countless examples of this variation are available, but we shall select a very few. First, then, we have quite often seen *d'Ailly, Bianchini* and *Werner* on the same straight line; likewise *Plato, Tycho* and *Clavius* on the same straight line; and on another such line *Maurolico*, set against now *Homelius* and *Pitiscus*, now *Agrippa* and *Aristotle*, now *al-Battānī* and *Meton*. Yet a little later we were astonished to find these off the line already mentioned, by an evident and notable bend. Furthermore, we have noticed the same *Maurolico* not infrequently more distant from *Walther* than from *Homelius*, and more than once equidistant from them; and likewise *Riccioli*, now nearer to *Grimaldi* and more northerly, now more remote and less northerly. And *Harpalus* too at one time shone out in the very middle of the *Bay of Dew*; at another, when the Moon's disc nodded towards *Pythagoras* or *Xenophanes* and narrowed the breadth of the already mentioned bay, it appeared much nearer the upper shore. Finally, the isthmus lying between the *Bay of Dew* and that of *Cold* is sometimes nearer to *Plato*, sometimes farther from it.

[Margin: The position of the same spots varies with respect to the edges of the Moon.] *Secondly*, several spots compared with the nearer edge of the Moon have been observed to change position with an incredible anomaly. To take only striking examples, the *Caspian Sea* or *Sea of Crises* stood off from the right limb of the Moon at its least, yet hardly less than by a quarter of its own breadth; at its greatest, yet hardly more than by three quarters of its breadth likewise. Similarly the spot of *Grimaldi* was seen to stand off from the left limb of the Moon, at its least, by an interval scarcely smaller than its own breadth, but at its greatest by one a little smaller than three times the same breadth. [Margin: Evidence of libration from rising to setting, etc.] By this means the libration of the lunar globe from east to west and back again was detected.

Again, at some times *Tycho* was seen to stand off from the southern edge by the smallest possible interval, namely the distance between its centre and *Pitati*; at others by the greatest possible, namely a little more than the distance between its centre and *Boulliau*. In the same way *Plato* sometimes withdrew from the northern edge of the Moon by the least gap, though one a little smaller than the space between it and *Anaxagoras*; and sometimes by the greatest, that is, beyond the already mentioned space by a further interval as large as twice the breadth of *Plato* itself. [Margin: Evidence of libration from north to south.] This was

the evidence by which the libration of the lunar globe from north to south and from south to north began to reveal itself. Nor is this the end of the marvels, for we have obtained clear evidence of libration towards other regions as well. [Margin: Evidence of libration towards other regions.] Indeed *Zoroaster* and *Endymion* are sometimes carried towards the limb of the third octant, so that *Zoroaster* scarcely appears, or not even scarcely. Indeed, not even *Endymion* is seen whole, but cut off along its upper edge. At times, conversely, both are seen not only whole but also distinctly removed from the Moon's limb, and *Endymion* by an interval as great as that between it and *Hercules*. With a like difference of approach and then of recession, the *Sea of Moisture* and the spots of the *Land of Heat* alternately nod away from the limb of the seventh octant or nod towards it. But at other times the regions of this libration became known towards the first octant or the part opposite it. Thus *Harpalus* several times stood off from the limb of the first octant by exactly the distance between its centre and the nearest shore of the *Bay of Rainbows*, and several times by twice as much. By contrast *Pitiscus*, which was frequently distant from the Moon's limb by about the length of the *Sea of Crises*, nevertheless not infrequently stood off by only a third of that length. Finally, just as, for example, the spot of *Langren* is sometimes distant by as much as the greatest breadth of the *Marsh of Sleep* and sometimes by twice as much, so in the opposite part the *Ecliptic Shore*, with a large part of the adjoining sea, sometimes vanishes from sight and sometimes becomes manifest.

[Margin: A warning about the position of the spots, which differs in different authors or in different figures of ours.] Now although, as regards the constant position of not a few spots and other parts, we have had to correct the *Selenography* of Langren, of Hevelius, of Šírek [Rheitenſis], of Eustachio, of Sirsalis and of others, as will be perfectly clear to anyone comparing figures with figures, the observer should nevertheless take care not to conclude at once that their *Selenography* or ours is faulty because of a differing position of the spots that he may have noted in some phase. For by far the greater part of this diversity arises from the anomaly of the libration in different phases rather than from the error of observers of some diligence; and what one observer did not see in one phase, another may have noticed more opportunely in other phases. It has likewise come about from this that some spots hold one position in the first and sixth of our figures, and another in the 2nd, 3rd, 4th and fifth, as the difference of phases and librations requires. The varying latitude of the Moon is also a reason why, even when the Moon is in the Nonagesimal, neither its whole disc nor the array of its spots holds the same position with respect to the vertical plane.

XI. [Margin: Twofold variation of colours, and its cause.] The colour of the spots is confined to the kinds of blackness and whiteness, but it too varies, whether you compare one spot with another or the same spot with itself at different times. For, other things being equal, some are always whiter than others, and among them *Aristarchus, Menelaus, Proclus, Dionysius Exiguus* and

Linemann gleam most brightly white; or, on the contrary, blacker, among which are *Xenophanes, Plato, Zoroaster, Hermes, Goclenius, Pitati, Christmann* and *Grimaldi*, which therefore seem to be lakes of a sort rather than mountains or valleys. Among the larger parts, the blackest are the *Bay of Surges*, the *Bay of Dew* and the *Lake of Dreams*. Again, the same spots sometimes become darker or brighter than themselves, according as they are lit less or more by the Sun's light, whether direct or oblique or reflected; or according as their hollow is more or less deep, or more or less smooth, polished or rough, and so differently suited to bounding and turning back the light. In this class the variation of *Aristarchus, Plato, Endymion, Posidonius* and *Vitruvius* is more evident, but still more notable is that seen in the *Sea of Vapours* and in the *Marsh of Sleep*. For this sea, when it is freshly lit, differs little in colour from the nearer land, and the isthmus that at other times separates it from the *Sea of Serenity* does not then seem to separate it. The *Marsh of Sleep*, however, when it has just been lit, is seen so furrowed that it nevertheless appears whiter than when it was lit long before. Moreover, those oblong tracts of the *Sea of Tranquillity* and the *Sea of Fecundity*, or of the *Ocean of Storms*, which imitate sandbanks stretched far out, are whiter at full Moons than at other times, and so are observed more evidently. But when the section of the illumination reaches them, they become very dark, which is no slight argument for a greater depth than that of the seas already mentioned. You have a specimen of these in figures 2, 3, 4 and 5.

Finally, some spots appear brighter than the land itself, especially at full Moons. Our figures, however, do not show this, lest it be wholly clouded over with little shadows.

[Margin: Spots visible even in the secondary light.] As for that secondary light which is reflected from the Earth onto the dark part of the Moon, we represent it after a fashion in figures 7 and 8, taken from the rudiments of the first observations. At such a time that part is seen so lit that even the differences of the darker parts, which are usually called seas, appear in that secondary light, and even to the naked eye, provided the Moon is in the signs of right ascension or descension, so that with the Sun sunk far below the horizon the Moon shines raised well above it. The farther the dark part is from the part the Sun lights directly, the less dark it is, and at the other limb it ends in a bright ring.

XII. [Margin: Alternation of the shadows cast by the spots towards the 4 regions of the world.] Moreover, the alternation of the shadows cast by the spots now towards this region, now towards that, proves, like not a few of the things said so far, the roughness and unevenness of the lunar surface, very like that of the Earth. Among the chief spectacles of this phenomenon it draws to itself, not without delight, the eyes and contemplation of those who watch. In general, the shadows that attend the higher parts begin to be cast from that side which faces the Sun as it lights the prominent parts, and they stretch out towards the opposite side. For this reason the great majority of them arise from the western part of the Moon and are cast towards the eastern part, from new Moon up to the following full Moon. But from full Moon to the following

new Moon, the beginning of the shadows is seen in the eastern part of the spots, and the shadows themselves extend towards the western part, until they fail either near the western edge of the spot or near its middle, according as the Moon is nearer to or farther from new Moon. [Margin: Disappearance of the shadows at certain full Moons.] Likewise, if at full Moon the Moon departs from the ecliptic by a marked latitude towards the north or the south, shadows, though thin, arise from that part of the spots which is farther from the ecliptic and pass off towards the part which is nearer. But if the Moon is full of light, and above all if it also then has no latitude or an imperceptible one, then no trace of shadows, or scarcely a perceptible one, appears either. In our Figure 1 and 6, however, since it does not belong to any full Moon, let alone to a single one, but is put together as if from two dichotomies, the shadows of the left part tend to the right and those of the right part to the left, and in the middle some are doubled.

As for that wonderful casting of little shadows by the smaller spots enclosed within the larger ones, whether towards the same side as that to which the shadows of the larger ones incline or towards the opposite side, enough was said when treating of the number, in the 3rd and 4th notable points. Here, however, four further things are to be noted.

[Margin: 1st notable point on the casting of shadows.] *The first* is that most of the edges of a given spot nearer the Sun begin to be lit first, and then the more remote ones, while the interior hollows or valleys do not yet enjoy the light but still lie hidden in a narrower, oblong shadow. Not much later, however, these gradually receive the light in succession, flooded with it either continuously or separately, so that certain points, as it were, of crags begin to emerge into the light from those valleys like bright dots, or else higher fields, as it were, stand out there from the middle of the valleys still in night. But the already mentioned points shine out more evidently and for longer within the surrounding shadow if they belong to those discussed in the third and fourth notable points already mentioned.

[Margin: 2nd notable point.] *The second* is that the very edges of the larger spots do not begin to be lit with continuous light, but are lit separately, like the many summits of hills arranged in a circle, as you will note with a more perfect telescope in *Hipparchus, Ptolemy, al-Battānī, Alfonso, Peuerbach, Regiomontanus, Walther, Plato, Langren* and others of this kind, and sometimes in *Tycho*.

[Margin: 3rd notable point.] *The third* is that while the line of section continuously divides the bright part of the Moon from the dark, many small spots, separated from the continuous bright part of the Moon by a notable interval, are meanwhile already or still bathed in the light of the Sun because of their eminence, while the other, lower parts, whether the hollows of the seas or great valleys, lie between them in darkness. See a specimen of this in figures 2, 3, 4, 5, 8, 9, 10. Thus *St Catherine*, around the 5th day of the Moon, is lit sooner than the portion of the *Sea of Nectar* nearer to it, and that portion is about twice as large.

[Margin: 4th notable point.] *The fourth* is that some tracts of land near the line of section cast so black a shadow onto the neighbouring seas that that part of the seas is by no means visible, while the rest is visible though more remote. We observed this most clearly in the *Land of Snows*, where not undeservedly Langren placed the Austrian Mountains and Hevelius the Apennine. For when the section passes near them, in the first dichotomy (which our figure 3 serves) that tract of mountains casts a most forbidding shadow over the part of the *Ocean of Storms* extending from *Eratosthenes* to *Conon*, or over the nearer part of the *Marsh of Decay*, or of the *Marsh of Mists*, or of the sea lying between. In the second dichotomy, however, the same mountains most blackly darken the part of the *Sea of Serenity* lying below them and stretching from *Calippus* to *Sulpicius Gallus*, as you see shown in figure 4. In the same way, as the section approaches, the shores of the *Sea of Crises* cloud over the nearer parts of that sea, the western shore of the *Land of Health* the eastern portion of the *Sea of Tranquillity*, and the western shore of the *Land of Hoarfrost* the *Bay of Rainbows*, with a more intense shadow. And almost all shores do the same. So it is that in figures 7 and 8 the darkened part of the Moon is darker still near the bright part of the Moon, namely because of the already mentioned shadows, and not only because the light reflected from the Earth fades in comparison with the greater light.

XIII. [Margin: Unevenness and roughness of the lunar surface.] The greater or lesser height and depth of the parts of the lunar surface is made certain by what has been said so far about illumination and shadows. It is confirmed by that wonderful roughness and those windings which are seen on the border of the bright and dark parts, away from full Moons, even with telescopes that are not of the most perfect, and which are indicated in figures 2, 3, 4, 5, 8, 9, 10. At full Moons, however, if the Moon has a notable latitude, the northern edge appears toothed like the land if the latitude is southern, or the southern edge if the latitude is northern. Indeed, at full Moons sometimes, and at other times too, as the libration allowed, we have more than once seen certain inequalities on the shining limbs of the Moon, though using an excellent telescope. They are not so large, because of their multitude and cohesion, and because there is no comparing them with any neighbouring sea, a comparison which elsewhere, far from the limbs, helps in estimating their height. The same prominence is the reason why many shores of the seas, which would otherwise not be lit by the Sun because of their distance from the luminous section, nevertheless shine, standing out like little handles beyond the Moon. The mountain of *St Catherine* rises 8 Italian miles, and some in the *Land of Snows* 12.

XIV. [Margin: Notable points in the horned, full and halved Moon.] As regards the notable points in the individual phases, the many things said so far are enough for the narrow limits of this compendium. It must be added, however, that the southern horn of the sickle Moon sometimes runs out longer than the northern, though very slenderly, in a curve as of the finest little gems, by as much as the breadth of the *Sea of Crises*; and that at full Moons certain spots

are crowned with an unusual little circle of light, or twinkle with a nucleus of more intense light, as in *Boulliau, Menelaus, Vitruvius* and so on. At the dichotomies or quadratures of the Moon, however, the line of section neither always nor usually divides the Moon in two at those parts which in our first or sixth figure lie on the diameter of the lunar disc, but coincides with another line placed off the centre of such figures. It is sometimes nearly parallel to the line G K, and sometimes cut by it, according as the libration carries it, not only towards rising and setting but also towards north and south, or towards other regions.

XV. That the libration so often named here is so great that its whole period is completed within about one month, the same spot returning to the same limb from which it had most receded, and that about 207° of the lunar surface are seen, whereas otherwise no more than 179½° of its hemisphere could be seen at once, will be shown in chapter 9 of this Book. There we shall also deal with the variation of the limits and nodes, with the terms of the period of libration, and with the anomaly of both; it is enough to have indicated these things here.

CAPVT VIII.

Chapter 8.

De Lunæ Figura, & Quid in ea ſint Maculæ Antiquæ ac Nouæ, & Quantæ magnitudinis, Deq. Lunæ Aſperitatibus, Montibus &c.

On the shape of the Moon; what the Old and New spots in it are, and of what size; and on the Moon's roughnesses, mountains and so on.

I. [Margin: Sphericity of the lunar body.] Besides what was said in chapters 2 and 3 about the variety of phases, in which the Moon is seen now full, now sickle-shaped, halved or gibbous, it may be asked whether the whole Moon is spherical or not. That it is spherical is apparently demonstrated from those very phases by d'Aguilon (Book 5 of the *Optics*, after Proposition 56), Biancani (Book 9 of the *Sphaera*, chapter 7), Scheiner (*Disquisitiones Mathematicae*, no. 26), Tanner (*Dissertation on the Heavens*, question 7, §. 3) and many others. For the Moon is lit spherically by the Sun, in the way anyone can test on those gilded spheres usually set on the tops of towers, by observing how the Sun's rays light them successively. You will experience something similar if, in a room otherwise dark, someone carries an opaque sphere around your head, opposite a torch or lamp, so that you have it now between your eye and the torch, now behind, now at the sides. So it is that the line dividing the bright part of the lunar disc from the dark appears straight to the naked eye at the quadratures, but in the other phases curved, a portion of an elliptical circumference, exactly as the successive illumination of a sphere seen from afar requires. From this, then, it is inferred that the Moon is spherical at the very least in that part which faces us, that is, in more than half of itself. This follows both because more

than a lunar hemisphere is lit by the Sun, which is far greater, and because the libration of the lunar globe brings out or hides one spot after another from us just as the shape of a globular body requires, and uncovers a portion of itself beyond the semicircle, by ten degrees on each side of the 360 that go around the whole Moon. Nothing, therefore, is more probable than that the whole Moon is spherical, rather than only half of it or only the two-hundredth part of 360.

II. Now just as this Earth of ours is physically round and yet rough and uneven, because of the hollows of seas and valleys and the height of hills, mountains, forests and towers, so the Pythagoreans thought that the Moon has its own valleys and caverns and its own mountains or hills. So did all those who for that reason called it [Greek: ἀντίχθονα (antichthona, "counter-Earth")], as if an Earth set opposite ours, led to that thought by a conjecture from its spots. Others, it is true, have tried to explain this phenomenon without any roughness or unevenness of the lunar surface, namely through a difference of opacity or density alone. This controversy must be settled here, after hearing the opinions and arguments of others: first concerning the Old spots, then the New.

§.I. Quid ſint Maculæ Lunares Antiquæ, & quid Partes in ea claræ.

§. 1. What the Old lunar spots are, and what the bright parts in the Moon are.

II. We call Old those spots which all antiquity knew, namely the large ones, visible without an optical tube.

[Margin: 1st opinion, of Anaxagoras, the Stoics and Pliny the Elder.] *First*, then, in Plutarch (*De placitis philosophorum*, Book 2, chapter 30), *Anaxagoras* puts the cause of this variety down to an admixture of dark, earthy and cold parts with fiery ones; the *Stoics*, in Laertius, to a tainting by the vapours on which the stars feed. *Pliny the Elder* seems to have followed them in Book 2, chapter 9, where he says: *But the stars are undoubtedly fed by earthly moisture, since at half orb they are always seen spotted, the just force for drawing up more being as yet not available. For the spots are nothing other than the filth of the earth carried off with the moisture.* Yet the constancy of the spots, always in the same shape, proportion and position, refutes the inconstancy and levity of this little tale rather than of an opinion.

[Margin: 2nd opinion, of unnamed persons.] *Secondly*, some in Plutarch (the book *On the Face in the Orb of the Moon*) and in d'Aguilon (Book 5 of the *Optics*, disputation after Proposition 56) attribute these to illusion, or to a condition of the sight yielding to the brightness through weakness. But since they are seen by everyone, whether with the naked eye or with the Belgian spyglass, and always in the same position, shape and so on, this phenomenon cannot, except fallaciously, be attributed to fallacy. Further, as Plutarch argues, we should see something of this kind in the Sun rather than in the Moon, and

should yield most to the Sun's glare, so as to note huge spots in it without any device; whereas the Moon's brightness is gentler and gladdening, and for that reason Empedocles calls it cheerful [Hiladrum] in this verse:

The Sun is sharp in its rays, but the Moon's brightness is cheerful [hiladrus].

[Margin: 3rd opinion, of Clearchus.] *Thirdly*, in the same book of Plutarch *Clearchus* held *that these spots are mirror-likenesses and images of the great sea appearing in the Moon; and that the Moon is of all mirrors the purest in evenness and brightness. Agesianax* supports him in these verses:

Or of the boundless sea, roaring on the part set opposite below, An image is represented in a burning mirror.

If you objected that the Ocean does not appear in the Moon to everyone in the place where it is situated, he answered: *just as the rainbow is seen in a cloud when the sight is refracted to the Sun, so the outer sea is seen in the Moon, not in the place where it is situated, but where the refracted rays of sight reach its brilliance.* For he speaks after the manner of the ancient opticians, who thought that vision occurs by the emission of rays to the object. *Kepler* relates that the Emperor Rudolf Augustus was delighted by this opinion, when he saw an image of Italy offered to him in the Moon, I believe in the place where Hevelius placed the Apennine and we the Mountains of Snows. But it is refuted by *Apollonides* in Plutarch, *Averroes* (2 *De caelo*, part. 49), *d'Aguilon* above, and *Giulio Cesare Lagalla* (*De Phaenomenis in Orbe Lunae*, chapter 11), chiefly by two arguments. First, there is a great dissimilarity between the lunar spots and the seas of the Earth, as also between the bright regions of the Moon and the continents of the Earth, in position, in shape and in size, as will be perfectly clear to anyone comparing the *Selenography* treated in the preceding chapter with geographical hemispheres. Second, if the Moon were a mirror of the terraqueous hemisphere, the spots would be seen in one position after another on this mirror, according to the different stations of the eyes, and the images of many parts of the Earth would be reflected elsewhere, far from our eyes, as is evident from catoptrics and the properties of other mirrors. Yet the spots seem to everyone, whether they look at the Moon at the same time or at different times, to hold the same position in the Moon. What we said against a lunar mirror in chapter 5, no. 7, is relevant here. Nor indeed would I believe that our Antipodes see a different shape and position of the spots in the Moon than we do, even though the terrestrial hemisphere belonging to them has a surface far different from ours; or that someone living in the Moon and seeing our Earth would be philosophizing correctly if he said that the spots of the Earth are images of the seas and continents of the Moon. For they would in fact be parts of the Earth differing either in colour, or in roughness, or in opacity.

[Margin: 4th opinion, as yet of no one.] *Fourthly*, someone could imagine, as *d'Aguilon* notes (Book 5, on Proposition 56), that the Moon's spots are images of the spots of the Sun. But the lunar spots are constant, and perpetually keep the same position, shape, size and number with no motion of their own, apart from the small libration of the Moon; the solar spots, on the contrary, are inconstant,

so much so that often none appear, and they move either of themselves or with the motion of the Sun's rotation.

[Margin: 5th opinion, of Reinhold, Cardano, Giovanni Battista Benedetti, Barozzi, d'Aguilon, Biancani, Bettini, Argoli, Lagalla.] *Fifthly*, then, many consider that the difference between the bright and dark parts of the Moon, although both are directly lit by the Sun, arises from a differing rarity and diaphaneity on the one side and density and opacity on the other. Some speak in this way, as if rarity and diaphaneity did not differ or as if each implied the other. So hold the Peripatetics, whom the following follow: *Benedetti* in his *Letters*, p. 229; *Reinhold* on Peuerbach's *Theoricae*, p. 164; *Barozzi*, Book 4 of the *Cosmographia*, p. 268; *Cardano*, Book 3 of *De subtilitate*; *d'Aguilon*, Book 5 of the *Optics*, Proposition 56; the Scotists *Mastri* and *Belluto*, Book 2 of *De caelo*, q. 2, art. 3; *Giulio Cesare Lagalla*, *De Phaenomenis in Orbe Lunae*, chapter 10; *Bettini*, *Apiarium* 8, Progymnasma 6; *Argoli* in the *Pandosion Sphaericum*, chapter 49; and *Biancani* in Book 9 of the *Sphaera*, chapter 4, where he says that this is the common opinion. [Margin: Are the spots diaphanous and watery parts, or opaque and earthy?] But among these, *Cardano*, *Benedetti*, *Barozzi*, *d'Aguilon*, *Biancani* and *Argoli* think that the spots lie in the rarer and transparent parts of the Moon, because these do not stop the Sun's light at the surface or reflect all of it at once, but absorb it as it penetrates inward, and reflect only a moderate part of it, mixed with refraction. This, they say, is what happens in water and in other mirrors. *Biancani* confirms it by the example of small windows and of openings in walls lit by the Sun: the rarer air in them drinks in the light, and does not reflect it to us with as much brightness as the light reflected from the rest of the wall. They therefore judge that the brighter parts of the Moon lie in its more opaque and denser parts, these being better suited to reflect the Sun's light immediately and in every direction.

[Margin: Opinion of Plutarch, Galileo and Kepler.] Of the same view are *Plutarch*, in the book *On the Face in the Orb of the Moon*; *Galileo*, in the *Sidereus Nuncius*, p. 9, and in Dialogue 1 on the system of the world; and *Kepler*, in the *Dissertatio cum Nuncio Sidereo*, p. 15. There, candidly singing a palinode, Kepler yields the palm to Galileo, saying: *With these arguments you have fully made your case: I grant that the spots are seas, I grant that the bright parts are land.* He confirms the same in the *Epitome of Astronomy*, p. 831; for elsewhere, as we shall shortly report, he had believed the opposite. So too does *Antonín Maria Šírek*, Book 4, chapter 2, member 10. Galileo's words are these: *So that if anyone wished to revive the old opinion of the Pythagoreans, namely that the Moon is, as it were, another Earth, its brighter part would rather represent the land surface, and its darker part the water surface. And for my part I have never doubted that the terrestrial globe, seen from afar and flooded with the rays of the Sun, would present its land surface as the brighter and its water surface as the darker.* Yet *Galileo* does not affirm that there are seas or lands on the Moon. Indeed, in Dialogue 1 on the system he denies it, as *Scheiner* does too, and he speaks only from hypothesis. *Kepler*, however,

seems to affirm it with the Pythagoreans; as for *Plutarch*, we shall speak of him shortly, in no. 4.

III. Against these, however, *Reinhold*, *Mastri*, *Belluto*, *Lagalla* and *Bettini* think that the spots lie in the denser and more opaque parts of the Moon, being parts to which the Sun can impart little light. And *Mastri* adds that they seem to be valleys, because in paintings what is less illuminated appears more sunken, as we were saying above about the ring of the Moon, chapter 6, no. 2. [Margin: Opinion of Scheiner, Giordano Bruno and Longomontanus.] *Scheiner* agrees with them in the *Disquisitiones Mathematicae*, no. 27, corollary 7, concluding: *The darker parts of the Moon are not watery: otherwise they would be more translucent, and, add this too, better suited to the repercussion of light. Kepler* was once of the same opinion, in the *Astronomia Optica*, p. 250, and in the *Epitome of Astronomy*, p. 101; and so is *Longomontanus* in the *Astronomia Danica*, Book 2, chapter 9, p. 315, and *Giordano Bruno* in the book *De Immenso et Innumerabilibus*, p. 289: namely, that the spots of the Moon resemble the continents of the Earth, and the brighter parts its watery or maritime regions. *Fortunio Liceti*, on the other hand, in *De Lunae subobscura luce*, Book 1, chapter 6, says that if the transparent parts of the Moon are bounded within, at the back, by opaque and denser parts, they will appear brighter, because they will reflect a greater and livelier light, as happens in other mirrors.

[Margin: Our opinion.] We, however, are compelled to side with the authors of the former opinion by an experiment open to anyone. When the Sun is rising or setting on the horizon of the sea or of some lake, an enormous reflection of rays scattered this way and that does come from the waves, and the image of the Sun seen in some determinate part of the water, or of a mirror, dazzles eyes placed not far off. Yet if you look from far away, at a distance, at great and entire surfaces of land and water illuminated by a high Sun, you will see that the watery ones give back a certain black and dusky appearance of light, and the land ones a bright one, sometimes so bright that the eyes can scarcely bear it, even if they are not sprinkled with snow or whitened by any other cause. For the mountains of the kingdom of Chile, and other similar whitening rocks and crags, throw back the Sun's rays with much greater splendour. But whether the distinction of the spots from the brighter parts arises solely or chiefly from this, or from roughness, or from the diversity of colours, of which more shortly, I scarcely believe can be decided if you set authority aside.

[Margin: 6th opinion, of Fortunio Liceti.] *Sixthly*, then, *Fortunio Liceti*, in Book 1 of *De Lunae luce subobscura*, chapter 6, attributes the spots to a livid and blackish colour of the Moon, and the brightness of the remaining parts to the Moon's whiteness. I consider this not improbable. In certain pearl shells and matrices, in clouds lit by the Sun facing them, and in white marbles themselves, we see some parts grow white, some grow pale, and some even turn livid; nor is it unfitting to recognise some diversity of colours in the planets, not indeed of colours arising from the elements or from mixed bodies, but of purer ones, akin to light. For these are no more repugnant to the heavenly bodies than

opacity is, as *d'Aguilon* notes in Book 5 of the *Optics*, Proposition 35. And so not a few have admitted these colours in the stars, according to Caelius Rhodiginus [Lodovico Ricchieri], Book 1 of the *Antiquae Lectiones*, chapter 17.

[Margin: 7th opinion, of Father Grimaldi.] *Seventhly*, that darkness or duskiness could be attributed to frequent small holes, or to roughnesses or wrinkles of the Moon, which disturb the reflection. For if someone looks at a whitewashed wall lit by the Sun, part of which is smooth and part rough in the manner of pumice or of a file, the rough part will look less bright, and when compared with the smooth part will seem shadowy and blackish. This appears even more in some bare field only partly ploughed. By this experiment *Father Francesco Maria Grimaldi* thinks that the lunar spots can be defended in this way, granted that he does not reject the two preceding ways. And the observation favours it by which, as in the figures set out above, these spots at the boundary of the lunar section appear somewhat broken and rough, and indeed like acres scored with furrows, as may be noticed in the Marsh of Sleep and of Mists etc. in figure 1. But from here we have gradually slipped down to the question, necessary at this point, of the inequality of the lunar surface.

§. II. De Nouis Maculis Lunæ, eiuſq. Aſperitatibus, Vallibus, Cauernis, Montibus, Collibus &c.

§. 2. On the New Spots of the Moon, and its Roughnesses, Valleys, Caverns, Mountains, Hills, etc.

IV. [Margin: Upholders of the Moon's evenness.] That there is no inequality on the surface of the Moon, but that it is perfectly spherical, and that all the variety of the spotted and bright parts proceeds from a mere difference of colours, or of rarity or transparency, of opacity or density: this is the judgement of *d'Aguilon*, Book 5 of the *Optics*, disputation on Proposition 56; of *Tanner*, *Dissertation on the Heavens*, question 7, paragraph 3; of *Bettini*, *Apiarium* 8, Progymnasma 6; and of *Giulio Cesare Lagalla*, *De Phaenomenis in Orbe Lunae*, chapter 10. Otherwise, says *Tanner*, if there were valleys and hollows in the Moon, they would either be empty, which is held absurd in philosophy, or filled with a diaphanous body, liquid or solid, which levels the roundness but does not prevent the appearance of valleys and hollows. But if the Moon itself is said to be perfectly round, yet to consist heterogeneously of opacity and diaphaneity, exactly the same things can appear on its surface as do in fact appear. So the inequality of the lunar surface is asserted in vain, especially if the heaven through which the Moon is carried is solid. Moreover, on the circumference of the lunar disc that is turned toward the Sun and lit directly by the Sun, inequality of parts nowhere appears, but an exact roundness, especially at full Moons; nor at other times (they say) do any prominent parts appear on its limb, even to one exploring with the telescope. *Cabeo*, for his part, on Book 4 of the *Meteorologica*, t. 14, q. 1, does admit that the opaque parts of the Moon

stand out in many places, but says it is not established whether among them there are diaphanous parts by which the Moon's roundness is levelled.

[Margin: Upholders of the inequality of the lunar globe.] More of the moderns, however, who have observed the Moon more carefully with tube-spectacles, have noted and asserted manifest inequalities on its surface: first of all *Scheiner*, in the *Disquisitiones Mathematicae*, no. 26; *Galileo*, in the *Sidereus Nuncius* and in Dialogue 1 on the system of the world; *Kepler*, in the *Epitome of Copernican Astronomy*, p. 101, in the *Dissertatio cum Nuncio Sidereo*, p. 15, and in the *Astronomia Optica* from p. 248, with his teacher *Mästlin*; *Longomontanus*, Book 2 of the *Theorica*, chapter 9, p. 315; *Biancani*, Book 9 of the *Sphaera*, chapter 7; *Descartes*, Part 3 of the *Philosophy*, no. 152; *Francesco Fontana*, in his observations, tract 2, chapters 2 and 3, and tract 3, chapter 1; *Antonín Maria Šírek*, Book 4 of the *Radius Sidereomysticus*, chapter 2, m. 10; *Athanasius Kircher*, in the *Ars Magna Lucis et Umbrae*, Book 1, chapter 4; *Michael Florent van Langren*, in his *Selenography*; *Johannes Hevelius*, *Selenography*, chapter 6; and *Mastri*, if a vacuum is not admitted and the heaven of the Moon is fluid. But before these, *Agostino Nifo*, on Book 2 of *De caelo*, part 49, and *Patrizi*, in *Philolog.*, Book 20, p. 112. And that same inequality was once asserted not only by the Pythagoreans and by Anaxagoras, according to Plutarch, Book 2 of *De placitis*, chapter 30, who regarded the Moon as another Earth, and by Democritus, Orpheus, Heraclides and Ocellus, but by *Plutarch* himself, in the opusculum *On the Face in the Orb of the Moon.* There he does indeed say: *However, it is not probable that the Moon has the same surface as the sea*; yet he adds: *As to the face that appears in the Moon, just as our earth has certain great bays, so we judge that the Moon too is opened by great depths and ruptures, containing water or dark air, into which the Sun does not penetrate with its light, but, abandoning them, produces a dissipated reflection.* As for the cause of these cavities, *Kepler*, in the *Dissertatio cum Nuncio* and in the *Optics*, though in sport and jest, refers it to men living in the Moon, who hollow out for themselves caverns and very high ramparts to protect themselves from the intolerable heat, since they have a continuous day of 15 days, the Sun's illumination persisting among them in the same region of the Moon. For this reason the Pythagoreans too said, according to Plutarch, Book 2 of *De placitis*, chapter 30, that the Moon is inhabited by animals fifteen times larger than ours. But, dismissing jests, let us come to the arguments by which this inequality is seriously proved.

V. [Margin: Arguments for the inequality of the lunar surface.] *First*, then, the Moon, not only when bisected but also before and after dichotomy, if viewed with the telescope, has the line dividing its bright part from its dark part tortuous and fringed; and that boundary is manifestly full of windings, not to say toothed or serrated, as can be seen in all the figures set out in the preceding chapter. This is an argument that some of its parts are low and others higher, to such a degree that they can be distinguished even at so great a distance of the Moon. For it cannot be said that the dark parts which insert themselves among those windings are impervious to light because of their density or

opacity. Afterwards, as the Moon's illumination grows, they become bright; and conversely those that previously shone turn black as the Moon wanes. And the diaphanous parts, which some insert in order to level the roundness, are too black at that time, and become bright at full Moon.

VI. [Margin: 2nd argument.] *Secondly*, on about the fourth day after New Moon and on the following days, on the left and eastern part of the Moon, which is still black, there appear certain bright points or small areas, like crags or small islands separated from the continental region of the Moon that is continuously illuminated. Between these and that region lie black parts that do not yet enjoy the direct light of the Sun. This appears in the second and eighth figures, and especially in the spot of Saints Catherine, Cyril and Theophilus, in the Mountains of the Snows, and in many other places lit by the Sun long before. Conversely, in the waning Moon there are, on its right and dark part, certain parts which are deprived of the Sun's light later than some others that lie between them and the continuously lit part of the Moon, or that are less distant from its bright portion, as you see in figures 4 and 5, and better still in 9 and 10. Where then does that anticipation of the light received from the Sun in the earlier half-lunation, and the postponement in the later one, come from, if not from the eminence of parts which, like our mountains, are lit by the Sun sooner and cease to be lit later than valleys and lower parts? For this diversity cannot be put down to a mere difference of density or opacity, since those parts that are meanwhile black, though nearer to the illuminated segment of the Moon, while the more distant ones are already or still shining, themselves shine a few hours later, or were shining a few hours before. Nor will you ever be able to imitate this variety of illumination of which we are speaking with any sphere free of all roughness, through a difference of opacity or density alone.

VII. [Margin: 3rd argument.] *Thirdly*, many things were said of the variety of colours and illuminations in chapter 7, no. 11; but everything we said in the same place, no. 12, on the interchanged projection of shadows proves the eminence of some parts of the lunar surface and the depression of others, as we also showed there in no. 13. For mountains and trees or towers cast their shadow to the western side at sunrise and to the eastern side at sunset, while at midday itself, if the Sun stands perpendicularly over them (as happens on solstitial days in the Tropics, and on equinoctial days to those living under the Equator), the shadows cease. In the same way, during the whole time from New Moon to full Moon, the shadows of the new spots and of the lunar shores are carried toward the eastern part of the Moon, and they are smaller and more diluted the nearer the full Moon is. At the full Moon itself they vanish, especially around the middle of the Moon, because those parts are struck more directly and more perpendicularly by the Sun's rays; but once the full Moon has passed, the shadows of those parts begin again, now going toward the western region. And they are always larger and more intense when the parts lying on the line of section, the line that divides the bright part of the Moon from the opaque, first begin to be lit, or first cease to be lit. Finally, those shores of which

we spoke in chapter 7, no. 12, notable point 4, would never overshadow the nearer seas with so manifest and so grim a darkness, now to the right, now to the left, and that shadow would never in turn cease in the same parts of the seas, unless there were tracts of mountains close to those shores, and very lofty ones at that.

VIII. [Margin: 4th argument.] *Fourthly*. It is not only at those full Moons at which the Moon has a notable latitude that its limb, viewed with an excellent telescope, appears roughened and scabrous, or toothed like a saw: namely the northern limb if the Moon's latitude is southern, or the southern limb if the latitude is northern. Outside full Moons too, the eastern and western limb of the Moon, rarely indeed but yet sometimes, when inspected likewise with the best telescopes, seems rough and uneven because of parts protruding on them. This is attested not only by *Hevelius*, above, as observed by himself, but we too have seen it not rarely. *Kepler* also, in the *Astronomia Optica* from p. 249 and in the *Dissertatio cum Nuncio Sidereo*, p. 7, teaches that the Moon's limb has sometimes been seen by him as rough; and to Galileo, who supposes the contrary, he replies: *I do not know how carefully you have examined this, or whether you are not rather asking here from the common opinion?* For *Galileo* on the one hand had recognised a variety of valleys and mountains in the Moon, but had never seen in its limbs lit by the Sun any roughness, which nevertheless ought to be seen. To dispose of this objection he has recourse to two causes. One, which *Kepler* does not refute, is a thicker air around the Moon, like its atmosphere, which always shows the Moon to us as perfectly circular. The other comes from the frequency and crowding of the peaks, which, although in fact separate, yet seen from afar seem continued into a round periphery.

[Margin: Solution of the objection.] But neither is that atmosphere perfectly round, if it is like ours and arises from a like cause; nor is it so thick that some clefts and gaps could not be discerned among the hills of the Moon situated at its margins. The true cause, then, why that roughness of the limbs is rarely seen is partly the imperfection of the telescope, partly the libration of the lunar globe, by force of which there are often no eminent parts on the limb itself, but beyond it or short of it; or if there are, they are among those that stand out least above the rest of the surface. And from what has been said the objection of Bettini and others is resolved: through a defect of the optical instrument, or of a suitable libration, or through the omission of observations at the time when the rough limb of the Moon could have been seen, they nevertheless never saw it as such.

[Margin: 5th argument, but insufficient.] The *fifth* argument, that of Biancani, is as follows: If the Moon, he says, were perfectly spherical, it would not reflect light in every direction, but only into some regions of the air, and we would see very little of its part as bright. But this argument establishes only this one thing: that the Moon is not polished like a mirror, but is at least rough enough to suffice for universal reflection. It does not, however, prove from this that there are valleys or mountains in it.

§. III. Quid ſint Lunæ Maculæ Nouæ.

§. 3. What the New Spots of the Moon are.

IX. What, further, the New spots of the Moon are, which we have shown to imitate our valleys and mountains by their eminence or depression, that is, of what substance, colour, density, etc., it has not yet been given to us to know. Granted that various people have tried to depict them for us by likeness or analogy with various things. *Galileo*, indeed, in the *Sidereus Nuncius*, makes them like crystal drops or icy cups sprinkled with light; *Scheiner*, in the *Disquisitiones*, likens them to large pearls and many-coloured pearls; *Kepler*, to the great pores and holes of a white pumice that has tubercles; *Giulio Cesare Lagalla*, to tufts of cotton, or to clouds in a half-clear sky, partly bright and partly dark; others, to the little eyes of a peacock's tail, but with only the difference of black and white colour. But there is no time to labour in vain on these matters.

SCHOLIA.

Scholia.

I. [Margin: Height of the lunar mountains.] We shall teach how to measure the Mountains of the Moon in Africa, so called because they seem to touch the Moon with their summit, from the fall of the Nile, which has its origin not far from them, in the Geographical book, which is the fourth of Tome 2 of the *New Almagest*. Now we must give the method of measuring the mountains of the Moon that have their roots and substance in the Moon itself. It is taught by Galileo in the *Sidereus Nuncius*, p. 13; by Biancani, Book 9 of the *Sphaera*, chapter 9; and by Bettini, *Apiarium* 8, Progymnasma 6, Proposition 4. They assume the Earth's diameter to be 7000 Italian miles, and the Moon's diameter to be to it as 2 to 7, that is, 2000 Italian miles, with a semidiameter of 1000 miles. They then take the distance of the illuminated lunar peaks from the limit of illumination, or from the lunar horizon, from Galileo's observation, as one twentieth of the lunar diameter, that is, 100 miles. From this they derive a perpendicular height of the lunar mountains of 4 Italian miles, which they think no mountain of our Earth reaches. Kepler agrees with Galileo in this, in the *Dissertatio cum Nuncio Sidereo*, p. 15, namely that the lunar mountains are absolutely greater than the terrestrial ones, whereas earlier, in the *Optics*, p. 250, he had said only that they are greater when the proportion of the globes is considered. Hevelius, however, taking for that distance one twenty-sixth of the lunar diameter, derives 3 Italian miles.

[Margin: Practice of measuring the lunar mountains.] The practice of this measurement is as follows. Let the bright hemisphere of the Moon be ADG and the dark one ABG, and let the nearly great circle separating them, and also the diameter of the Moon, be represented by the line ACG, and the Moon's semidiameter by AC. Then let there be, in the part still dark, a mountain MB, lit at its summit by the Sun's ray SM, which touches the Moon at A and there, by Proposition 16 of Book 3 of Euclid, makes the angle MAC right with the

semidiameter AC; and let the perpendicular height of the mountain, MB, be produced to the centre C, for triangle MAC will be right-angled. So if AC is given, the true semidiameter of the Moon, to which CB is equal, and MA is given, namely the distance of the illuminated summit M from the limit or Horizon of the Moon ACG, in parts of which AC is known, then by the rules of right triangles the base MC will certainly become known; and if BC is subtracted from it, the height of the mountain MB will be left known. Thus in the example assumed, if the side AC is 1000 miles and AM is 100, and these are squared, the sum of the squares will be 1010000, to which, by Proposition 47 of Book 1 of Euclid, the square of the base MC is equal. Its square root is less than 1005 and greater than 1004. So, taking away CB, 1000, there remains BM, of almost 5 miles, but certainly exceeding 4 miles.

Diagram. A small woodcut set into the right side of the left column: a circle representing the Moon, its left half hatched with horizontal lines (the dark hemisphere) and its right half white (the bright hemisphere), divided by a vertical diameter. A horizontal tangent runs across the top of the circle through the upper end of the diameter, extending left beyond the circle to M and right to S. A straight line runs from M down through the hatched area to the centre on the diameter. Dotted lines stand between M and the circle at upper left.

- M (upper left, outside the circle, on the tangent line): the summit of the mountain
- A (top, where the tangent meets the circle): the point of tangency
- S (upper right, on the tangent line): the end of the Sun's ray
- B (within the hatched area at upper left, on the line from M to the centre): the foot of the mountain
- C (centre, on the diameter): the centre of the Moon
- D (right, in the white half): on the bright hemisphere
- G (bottom, at the lower end of the diameter)

II. [Margin: Our opinion on the height of the lunar mountains.] I, however, observed, between the spot of St Catherine, lit on the fourth day after New Moon, and the limit of the usual illumination, the 16th part of the lunar diameter. For me, from what was said in Book 2, chapter 7, the Earth's diameter is 8278 Italian miles of Bologna, but 10348 ancient Roman miles. So if the lunar diameter is to the terrestrial as 2 to 7, it will be 2365 Bolognese miles and 2956 Roman, and its 16th part will be 148 Bolognese miles, but 184¾ Roman. Therefore, by the preceding problem, BM, the height of Mount Sinai or St Catherine, will be 9 Bolognese miles. For the square of the number 148 is 21904, and that of the lunar semidiameter, namely 1182 miles, is 1397124; and the sum, that is, the square of the base MC, is 1419028, whose nearest root is 1191. Taking away, then, BC, 1182, there remains MB, 9 Bolognese miles. But here it is supposed that the ray SA touches the globe of the Moon just as if the point A did not stand out at all; if A were the summit of another mountain, MB would be derived as much higher. This mountain we have elsewhere, with Langren, called Mount Piccolomini, and another, beyond the Mountains of the Snows,

Mount St Xavier, which, because of its distance from the lunar section of 2½′, we think to be about 12 Bolognese miles high. These measures, however, we shall somewhat refine below, chapter 17, problem 2.

III. [Margin: Size of the spots.] The true size of the spots, or of other parts viewed on the lunar surface itself, since it appears to us as if on a flat disc, as a part of the lunar diameter, can be derived from the true diameter of the Moon and from the particles belonging to each spot on the selenographic scale placed at the foot of figure 6 of chapter 7: namely, if the true diameter of the Moon is multiplied by them, and the sum so made is divided by 200. For example, the length of the Sea of Crises by the already mentioned scale is 21 particles, and its breadth, as it lies in figure 6, is 15 particles. Multiplying, then, 2169 Bolognese miles, which is what the Moon's diameter has according to what will be said in chapter 17, now by 21 and now by 15, let the sums be divided by 200, and the length of the Sea of Crises will be found to be 227¾ Bolognese miles, and its breadth 162⅔. However, since the optical measure of this sea varies by force of libration, and since it really lies not on a flat disc but on a spherical surface, this measure too must vary. Šírek [Schirlæus], for his part, in Book 4, chapter 2, member 10, gives the Sea of Crises 100 leagues in breadth, the Ocean of Storms 470, and the tract of mountains in the Land of Snows 100. Let it be enough to have indicated this to anyone with the leisure and the inclination to play in the Moon.

CAPVT IX.

Chapter 9.

De Motibus Lunæ ex ſitu Macularum deprehenſis, præcipuè de Libratione: & de mutuo Terræ Lunæque aſpectu.

On the Motions of the Moon detected from the position of the spots, especially on Libration; and on the mutual aspect of the Earth and the Moon.

I. The position of the lunar spots has seemed to indicate three kinds of motion of the lunar globe around its own centre: namely, of Rotation in latitude toward the poles of the Equator or of the Ecliptic; of Rotation in longitude from West toward East; and of Trepidation or Libration.

[Margin: First rotation of the Moon, idly asserted.] A rotation of the Moon in latitude, in the part visible to us, from north toward south, slightly slower than the daily motion of the Moon in longitude, was asserted by *Francesco Fontana* of Naples, both because he thought it consonant with reason that all parts of the Moon should exert influence on us, and because he seemed to himself to observe some spots becoming more southerly every day until they were hidden. But neither I, nor my colleagues, nor *Galileo*, nor *Scheiner*, nor *Langren* have observed any such thing. The spot of *Tycho* has always appeared to us near the southern limb, 3′ or 4′ distant from it, at full Moons as much as in the other phases in which it is seen lit; and it undergoes only that moderate

variation which a change of latitude, or some libration, of which I shall speak in no. 3, produces. Indeed, the greatest part of the Moon's face perpetually preserves the same position of its spots toward us. Nor can that argument of fitness prevail against the evidence of this experiment, open to everyone. This is especially so since it can itself be countered by saying it is fitting that the Moon, placed on the border of the heavenly and the subcelestial, should always look with one of its parts toward the supercelestial, and from there should drink in through its whole body a varied force of influence, which it pours through its other face into the subcelestial. Much less is it true that the spots themselves travel round the globe of the Moon, as someone has suspected; against that motion, *Langren* says, his more than a thousand observations fight.

II. [Margin: The rotation of the Moon in longitude: in what hypothesis it is necessary.] The motion of rotation in longitude, from the western part of the Moon to the eastern, by which it would revolve on its own centre, invented by *Berosus* the Chaldean, was already refuted in chapter 5, no. 1. For by that motion the same hemisphere of the Moon, and the same face, would not always be turned toward us. Further, in order that the same face of the Moon should always look at us, and that, for example, the *Caspian* or Sea of Crises should always appear to us, when it appears, near the western limb of the Moon, the spot of *Grimaldi* almost on the eastern limb, and the bright valley of *Tycho* at a distance from the southern limb of about 3′, and the spot of *Panciroli* or of *Plato*, a little more than 3′ from the northern limb, should always appear near their limbs, and finally that the spot of *Hipparchus* and the Bay of Heats [*Sinus Aestuum*] should constantly appear to us in the middle of the Moon's disc, no motion of rotation is needed, if the body of the Moon completes its monthly revolution on a pure eccentric, as happens in the hypothesis of *Magini*, *Kepler*, *Lansbergen* and *Boulliau*. But if the eccentric carries an epicycle on its circumference, and the epicycle carries the centre of the Moon, as in the hypothesis of *Ptolemy*, *Peuerbach*, *Copernicus*, *Reinhold*, *Barozzi*, *Tycho*, *Longomontanus*, *Scheiner*, *Biancani* and *Gassendi*, then the already mentioned monthly motion of rotation is certainly needed. Otherwise the same face of the Moon would not always be turned toward us, as can easily be shown by a mere drawing of the epicycle, of which more below; and this has been shown by *Barozzi* in Book 4 of the *Cosmographia*, p. 257, and by *Scheiner* in the *Disquisitiones Mathematicae*, no. 25. Both of these, like *Gassendi* in Book 2 of the *Institutio Astronomica*, chapter 15, assert this lunar rotation for this reason, and *Galileo* asserts in Dialogue 1 that it follows from the epicycle hypothesis; while *Longomontanus*, with little consistency, denied it in Book 2 of the *Theorica*, chapter 9, p. 316. *Magini*, however, in his *Theoricae*, page 70, abandons the lunar epicycles of Ptolemy and Copernicus for the reason that, as *Averroes* in the same place observes, the spots of the Moon that appear at perigee would be withdrawn from our sight when the Moon is at apogee. But the motion of rotation can meet this drawback, if anyone prefers to use an eccentrepicycle. [Margin: Kepler's fiction.] *Kepler*, however, who feared

that the excessive inclination of the lunar fibres would produce an excessive libration of the lunar globe, contrary to the phenomena of the spots, had to invent a globe of the Moon like a kernel inside a crust and rind, which would preserve the inclination of the fibres, while the rind and the surface of the lunar disc meanwhile preserved the position of the spots that we see, as may be seen in the *Epitome of Copernican Astronomy*, p. 613. On this matter see below, chapter 26, Scholion 7.

De Librationis Lunaris Motu per Maculas ope Teleſcopij detecto.

On the Motion of Lunar Libration, detected through the spots with the help of the Telescope.

III. [Margin: Galileo the first discoverer of this libration.] The telescope, as with many other marvels, first indicated to *Galileo* that the globe of the Moon librates about its own centre. With its help he detected that the spot of *Grimaldi* now approaches almost the eastern limb of the Moon, now recedes from it, by a difference in distance three times greater; while the Sea of Crises, which he calls the Corican spot [*maculam Coricam*] because it faces the north-west [*Corum*] when the Moon reaches the meridian, and which stands almost diametrically opposite the spot of Grimaldi, approaches the western limb and alternately recedes from it, by a difference of distance more than double; so that as one approaches its limb, the other recedes from its own. So he says in Dialogue 1 on the System of the World, p. 58 of the Italian and 44 of the Latin edition, where he also touches on the cause and theory of this libration, on which see below. [Margin: Langren observes the same libration.] The same libration was observed, but over more years and more accurately, by *Michael Florent van Langren*, Cosmographer to the Catholic King, as early as the year 1626, as can be gathered from his observations, sent to me with Belgian candour and generosity, in which he promises astronomers an admirable theory of this libration. [Margin: Gassendi likewise, Boulliau and Hevelius.] Later *Pierre Gassendi* also began to note the approach of the Caspian spot (which we call the Sea of Crises) to the western limb and its recession, as well as that of another spot from its own limb, which he calls the Eastern spot and we the spot of Grimaldi. His observations on this subject, from 1636 September 23 to 1642 April 14, are reported by *Boulliau* in Book 3 of the *Astronomia Philolaica*, chapter 13, and there he also lists his own observations of this libration, from 1643 April 1 to 1644 January 18. At about the same years *Johannes Hevelius* diligently brought together very many observations on the appearance of this motion, of which not a little will have to be said below; yet I find in him no observations older than those already mentioned; indeed, the oldest, which he takes from others, are those of Gassendi and Boulliau. The Sea of Crises he himself calls the Maeotic Marsh [*Paludem Męotidem*], and the spot of *Grimaldi* the Mareotic Marsh [*paludem Mareotidem*].

[Margin: Finally Zucchi, Bartoli, Sirsalis and Grimaldi.] Finally, observers of the sky from our Society, especially Fathers Niccolò Zucchi, Daniel Bartolus [Daniello Bartoli] and Hieronymus Sirsalis, confirmed this very libration by the testimony of their own eyes. And we ourselves, who at other times used to attribute this appearance simply to the effect of varied latitude, began to distinguish it from the other apparent motions of the Moon; how far the diligence and skill of Father Francesco Maria Grimaldi has advanced in this field up to the present day will be evident from what is to be said below. Meanwhile, how manifest are the arguments by which we, together with him, have detected this libration, from the approach to the nearer limbs and the recession from them not only of the two spots already mentioned but of others as well, and indeed toward the north and south too, and even from sets of three spots seen now in one straight line and now off it, is clear enough from what was said in chapter 7, from no. 10 on.

Quæſtio I. Quanta ſit prædicta Libratio, ſeu Quotam Lunæ partem vi illius vltra antiquorum opinionem videamus.

Question 1. How great the already mentioned libration is, or what fraction of the Moon we see by its force beyond the opinion of the ancients.

IV. Before we establish how large the portion of the lunar globe is that we can see by force of the already mentioned libration, beyond the portion that astronomers ignorant of this libration thought could be seen by us according to the ancient problem given on p. 234, we must determine how great the difference of distance is between the greatest and the least approach of one and the same spot lying nearer the limb of the Moon, and indeed of such a spot that at its greatest approach it reaches right up to the limb of the Moon, or as close to it as possible. [Margin: Drawing of the circles of the lunar disc.] To this end we shall first of all describe the lunar diagram; that is, we shall teach the method by which, in the sixth of the diagrams set out above after p. 204, we drew the circumferences of the circles that intersect one another, and their diameters.

First, take a diameter of the lunar disc as large as you please, for example as large as the selenographic scale XZ (which we chose to subdivide into 200 equal particles, so that the semidiameter would be of 100 parts). From it cut off with compasses a semidiameter, AB, and at that distance from centre A describe the circle BCDE. Having produced the semidiameter AB as far as D, the end of the whole diameter, take on it a portion AF of 12 parts, of which AB is 100. Then, taking F as a second centre, describe a second circle GHIK; for the circles will intersect at points L and M. A straight line drawn from these points perpendicular to the diameter BD, which is to be produced as far as I, would fall on point N, which bisects the little line AF, although to avoid confusion we have not drawn this line. Next, from point N, at distance AN, describe the little circle ATFV. *Second*, through point A draw the first circle's diameter EC at right angles to the common diameter BAI, touching the already mentioned

little circle at A. *Third*, with both quadrant EB bisected at P and quadrant BC at R, draw from points P and R, through point A, the straight lines PAQ and RAS. In this way the lunar disc will be left subdivided into 8 octants, so that the spots and lunar regions named in alphabetical order in the account given in chapter 7 can be found more easily in a smaller space.

[Margin: Method of observing the amount of the libration.] From the very size of the diameter AF the amount of the whole libration, GB, is apparent; for GB is as large as AF, namely 12 parts of which AB is 100, and DI is equally large. We have found that it is this large by comparing the distance between the greatest and the least recession of spots that reach the limb of the Moon in their approach in such a way that they are not hidden beyond it, with some other fairly large spot nearer to the spot in question; and then, more conveniently, by comparing that fairly large spot with the semidiameter of the lunar disc, already fixed in the diagram of the lunar disc itself. This diagram must be prepared on a small table set beneath, near the telescope, so that when the Moon has been viewed through the tube, and the eye moved repeatedly from the tube to the diagram, what has just been observed can be noted on it. For example, suppose that the spot of *Thales*, whose northern extremity in figure 6 is at point G, has at another time been observed right on the limb at point B, so that it has never appeared either beyond B or short of G. By that spot it will then be established that the whole range of libration on that side is as great as the apparent straight line BG. Therefore, when the Tha- letic spot has returned to G, compare the distance BG with the length of the spot of *Endymion*; for because of its nearness you will clearly see that the whole length of *Endymion*, and a third part of it besides, is contained in GB. We have used the length of *Endymion* rather than its breadth because its breadth varies by force of libration, but its length does not. Once this measure is obtained, it is easy to find with compasses what fraction the length of *Endymion* together with a third of it is of the semidiameter of the lunar disc, already drawn graphically with the due proportions observed. [Margin: Spots more suitable for measuring the libration.] It is assumed, moreover, that the spot at G is in the belly, that is, equidistant from the nodes of libration LM. This is recognized if the other spots, moderately and almost equally distant from it on either side, for example those of *Plato* and *Posidonius*, or *Meton* on one side and *Mercury* on the other, approach the same limb of the Moon together with it, or recede from it, with a similar motion. What has been said of the spot of *Thales* holds in its own way for the spots themselves of *Endymion*, *Meton*, *Mercury*, *Moretus*, *Zucchi*, *Bettini*, *Kircher*, *Riccioli*, etc. Besides these, those spots also serve the purpose secondarily which, although in their approach they do not reach the limb itself, yet come very close to it, and at their greatest recession are still less distant from the limb than from the centre of the Moon, especially if they have such advantages as to strike the observer's eyes more clearly. For us such have been the spots of *Plato*, *Aristotle*, *Atlas*, the Sea of Crises, those of *Langren*, *Pitiscus*, *Tycho*, *Grimaldi*, and the spot of *Harpalus*.

Let no one be surprised, moreover, if, considering libration, as is right, at the limbs of the Moon, namely so as to confine it within its definite extremes, we also employ spots nearer the limbs than the centre. For the variation of the distance between the spots and the centre is greater if the spots are nearer the centre, and more uncertain because of the difficulty of discerning exactly the centre of the lunar disc; as I assume from the laws of optics applied to a librating sphere seen from afar.

V. [Margin: Part 2 of the problem.] It remains for us to inquire how great the arc on the surface of the lunar globe is which corresponds to the quantity BG, that is, to that portion of the semidiameter that we see on the Moon as if on a flat disc. We shall do this by the following problem. From centre A describe BCD, the semicircle of the Moon's body, whose diameter is BAD; to this, from the eye E, placed on the Earth, draw the perpendicular ray EA, and another ray EF, touching the Moon at F. From this point draw FG parallel to BD; for FG will be the diameter of the lunar disc as it appears to us, and HF its semidiameter, which we divided above into 100 equal parts. Now let a spot, for example that of *Thales*, be first seen at point F on the very limb; and then, when it has receded furthest from it, let it be at point K, but appear at point L of the flat disc, by means of the visual ray EKL, which is produced as far as M. Finally, from centre A to point K, draw the semidiameter AK. The proposal now is to find the arc KF that by force of lunar libration we see beyond what we would see without libration. And since we see more of the Moon at apogee than at perigee, we shall have to use the semidiameter and distance of the Moon at apogee.

Diagram. Woodcut set into the right side of the left column, the text running down its left. A horizontal line carries B, A, M, D across the top; a semicircle hangs below it from B to D. Just beneath the top line a second horizontal line carries G, H, L, F. Three straight lines converge downward to E at the foot of the figure — from A through H and C, from M through L and K, and from D through F — and a further line runs from A to K; C stands at the bottom of the semicircle, and K on its right-hand arc.

- B (top line, left end): point of the diameter BAD
- A (top line, centre): centre of the semicircle
- M (top line, between A and D): end of the visual ray EKL produced
- D (top line, right end): point of the diameter BAD
- G (second line, left end): end of FG
- H (second line, left of centre): centre of FG
- L (second line, right of centre): point of the flat disc
- F (second line, right end): point of tangency of ray EF
- C (below the centre on the semicircle): point of the semicircle
- K (right, on the semicircle): position of the spot
- E (foot of the figure): the eye on the Earth

[Margin: Step 1.] *First*, then, from what is to be said in this Book 4, chapter 16, no. 18, the apparent semidiameter of the Moon at apogee, that is, the angle

AEF, is 14′. Therefore, since we have divided the semidiameter HF of the lunar disc, not as it really is but as it appears, into 100 equal parts, it is just as if we had divided the angle HEF into 100 equal angles. And so, since the part LF, which measures the amount of the whole libration, is of 12 parts, if we make: as HF, of 100 parts, is to LF, of 12 parts, so the angle HEF, of 14′, is to the angle LEF, then LEF will be found to be 1′ 41″, and the remainder HEL will be 12′ 19″.

[Margin: Step 2.] *Second*: in triangle AEK the angle AEK has been found, 12′ 19″; from what is to be said below in chapter 14, the distance AE of the Moon at apogee from the Earth is 64¼ semidiameters of the Earth; and from what is to be said below in chapter 17, problem 1, the true semidiameter AK of the Moon is of 26 parts, of which one semidiameter of the Earth is 100. From these three givens, therefore, by the laws of triangles, the angle EAK is found, and hence the arc CK, 62° 14′ 12″; so the remainder KD, to the quadrant, is 27° 45′ 48″. And the arc that we would see by force of libration beyond the arc visible without libration would be this large, if the visual ray EF saw the point D on the Moon. But we do not see the whole hemisphere of the Moon at one and the same time, since from what is to be said below in chapter 17, problem 3, we see of it only 179° 32′, and to complete the visible hemisphere it lacks the arcs FD on one side and BG on the other, each of 14′. If we subtract these from the arc KD, there will remain the arc KF, 27° 31′ 48″: namely, the arc of the Moon's surface that we see thanks to the greatest libration, sometimes toward one quarter of the world, sometimes toward the other, beyond what we would see without libration. [Margin: The portion of the Moon visible by force of libration.] Therefore, adding together everything of the Moon that is successively disclosed to us by means of libration, the visible portion of the Moon comes to 207° 3′ 48″.

Quæſtio 2. Quæ ſint maculæ, quæ ob librationem Lunarem non ſemper apparent.

Question 2. Which spots they are that, because of lunar libration, do not always appear.

VI. I reply that they are those contained within the arcs of the limits, namely, toward the north within the arcs LBM and LGM, and toward the south within the arcs ſtIM [recte: LIM] and LDM of figure 6. But besides these there are some others on the near side of the nodes L, M, because the limits of libration vary in accordance with what is to be said below; from which a conjecture will be made about these remaining ones that are sometimes hidden.

Quæſtio 3. De modis obſeruandi, versùs quas Mundi Lunæue plagas fiat Libratio Lunaris globi, & versùs quas dirigatur Axis huius Librationis.

Question 3. On the methods of observing toward which quarters of the world or of the Moon the libration of the lunar globe takes place, and toward which the axis of this libration is directed.

VII. There are three principal methods of this observation. In all of them the Moon is assumed to be in some determinate vertical, but principally in the meridian, or in the vertical passing through the nonagesimal degree of the ecliptic, so that with respect to these it may be known which quarter of the world a determinate part of the lunar limb faces. For this reason we have represented the Moon in the first figure and in figure 6, and indeed in the rest, almost in the position of the nonagesimal degree. [Margin: First method of observing the quarters of libration.] The first method is as follows: having first observed the approach of some more prominent spot to the nearer limb of the Moon, one then observes toward what point of the lunar limb the other spots situated round it on both sides converge in their approach, as toward a goal they seek. The same is to be done in observing recession. And if testimony is had from several spots, the quarter toward which the libration takes place will be much more evident, especially if, the Moon's phase permitting it, while some spots approach their limb, others on the opposite side recede from the opposite limb, which is nearer to them, and indeed from some common point of the limb diametrically opposite to the point toward which the former were seen to approach. For instance, if in figure 6 the spot of *Aristotle* has been seen to approach the limb LBM, and the spots of *Plato*, *Posidonius*, *Endymion*, etc. also seem to approach the same limb in such a way that the motion of all tends toward point G, recognizable by some indication, for example by the spot of *Thales*, or by a determinate distance from the horns of the Moon, then it will be right to conclude that the libration takes place toward the part of the world that point G faces. And if, on the opposite side, the spot of *Tycho* meanwhile seems to recede from the limb LDM, and similarly the spots *Walther*, *Stöffler*, *Pitati*, *Capuano*, etc. seem to recede, as from a common boundary, from point D, known from the nearer spot of *Zucchi*, the same will be gathered still more certainly. Yet one should not hesitate over this because of the unequal amount of approach compared with recession, since the cause of a moderate disparity can be the variation of latitude, or some anomaly of this libration. [Margin: Hidden cautions for the same observation.] Here too, moreover, one must beware of the apparent approach or recession that can arise from the cause of parallaxes. For if you observe the Moon not far from the rising horizon, and afterward not far from the setting horizon, a spot that at first was seen to be at a distance from the upper limb by, for example, a 10th part of the lunar semidiameter, will afterward be seen, near setting, to be somewhat less distant from the same limb, though now the lower one. This is because the same

limb will not appear to us in the west as appeared in the east, since we view the Moon not from the centre of the Earth but from its surface. Finally, the approach of the spots to the limb of the Moon on days of greatest libration, that is, near the limits, is less perceptible than at other times.

VIII. [Margin: Second method of observing the quarters of libration.] The second method is carried out with three or more spots first observed in one straight line, and then by observing the intermediate ones off it, and noting toward which side their recession from the straight line tends. But it is useful that the outermost of these be as close as possible to the limbs, and the intermediate ones more remote from the limbs; for their recession from the straight line will be more evident in a shorter time. For example, if you have seen *Tycho*, *Ptolemy* and *Aristotle* in one straight line, as they appear in the first figure and figure 6, and then *Ptolemy* has receded toward the limb QMR, this will be an indication of libration having taken place toward that limb. Or if you have observed *Tycho*, *Archimedes* and the western edge of *Plato* in the same straight line, and not much later *Archimedes* has moved away toward the limb SLP, libration toward the same limb will be indicated. And if you have seen in one straight line, for example, *Langren*, *Bede*, *Agrippa*, *Eratosthenes* and *Aristarchus*, and after some time *Bede*, *Agrippa* and *Eratosthenes* have pressed toward the limb PBR, leaving behind them the straight line drawn through *Langren* and *Aristarchus*, it will be a sign of libration begun toward the limb PBR. Conversely, if those which appeared off the straight line afterward come together into one straight line, you will conclude that libration is also taking place in that direction. [Margin: A twofold way of using the second method more evidently.] Further, in order that the determinate part of the lunar limb toward which libration tends may be identified more surely, one must also observe whether those spots that lie in a common straight line, cutting the former line at right angles and passing through the centre of the lunar disc, stay in that same common line; for if they stay, this very line will run into the limits of libration themselves. For example, if, while *Eratosthenes*, *Agrippa* and *Bede* recede toward PBR from the straight line drawn through *Langren* and *Aristarchus*, *Thales*, the eastern edge of *Ptolemy*, *Pitati* and *Bayer* meanwhile stay in the line DAB, it is clear that the limit toward which libration tends is the part B. This same point will be confirmed further by another notable argument, if two spots, one on either side, nearer the limbs of the Moon, stand a quadrant of the lunar circumference away from the limit toward which libration takes place, known beforehand in whatever way through the methods already mentioned, and yet they themselves have no perceptible motion, especially toward the nearest limbs. For from this you will find that the nodes or poles of libration lie on those same nearest limbs. So it would be if in the preceding example the spot of *Langren* toward C, and that of *Aristarchus* or *Seleucus* toward E, scarcely or not even scarcely move meanwhile, while *Eratosthenes*, *Agrippa* and *Bede* move toward B. For it will then be established both that libration takes place toward B and that its poles are near C and E.

IX. [Margin: Third method of observing the quarters of libration.] The third method rests on observing different dichotomies of the Moon, in which one must note through which spots, or other lunar particles, the section passes, that is, the straight line separating the bright part of the Moon from the dark. For although from a few dichotomies observed in this way nothing else can be established than whether libration always takes place toward the same parts or not, yet from more of them one can also gather toward what other parts the globe of the Moon librates. And there is no one who has observed the bisected phases of the Moon, even with a moderate telescope, and can affirm that the already mentioned section always passes through the same spots. Even so, there are definite, determinate courses on the lunar disc within which that section is contained. To represent these in a distinct diagram, as far as it has been possible to observe so far, we have presented the third figure drawn for the former dichotomy and the fourth for the latter. [Margin: Through which spots the outermost sections of the dichotomous Moon pass.] In the third figure the section passes between the centre of *Magini* and its eastern edge, through a point as far from the eastern edge of *Ptolemy* as the diameter of *Ptolemy* itself, through a point east of *Archimedes* by the semidiameter of *Archimedes*, almost through the eastern edge of *Plato*, and finally through the eastern edge of *Anaxagoras*, which is almost on the northern horn itself. In the fourth figure, on the other hand, the section passes almost through the eastern edge of *Maurolico*, through a point distant from the western edge of *al-Battānī* [*Albategni*] by three quarters of the diameter of *al-Battānī*, almost through the eastern limb of *Manilius*, and finally through the western limb of *Archytas*. Langren, indicating the variation of these sections, affirms in a letter to me dated 1649 August 22 that the section of the dichotomous Moon passes now between *Isabella* and the Empress *Maria*, which for us are *Manilius* and *Menelaus*, now between *Roma* and *Haro*, which for us are *Archimedes* and *Timocharis*. [Margin: The lines of sections at different dichotomies are not parallel to one another.] It is also very true, as Hevelius teaches in chapter 26 of his *Selenographia*, that the lines of different sections on the lunar disc are not always parallel to one another, but intersect one another in various ways, though within certain limits; this will also be clear from a careful inspection of his diagrams. Whether what he adds is true, however, that if the Moon's quadrature is about the beginning of Cancer the section is as far west as possible, and if about the beginning of Capricorn as far east as possible, depends on what is to be discussed below. Meanwhile, from the varied position of these sections, the variety of the quarters toward which libration tends will not be able to stay hidden from a shrewd observer. To this end it is convenient to append here some selected observations of the dichotomous Moon.

Obſeruationes Selectæ pro Situ ſectionum variarum Lunæ Dichotomæ prope 1. Quadraturam.

Selected Observations for the Position of various Sections of the dichotomous Moon near the 1st Quadrature.

X. [Margin: Observation 1, from Langren.] 1633 July 14, in the evening, when the quadrature was not yet at hand, the line of the section passed beyond *Eratosthenes* by as much as its diameter, and short of *Timocharis* by as much, likewise, as its diameter.

[Margin: Observation 2.] 1635 October 31, before midnight, the line of the section touched the western boundary of *Isabella*, which for us is *Manilius*, but it still seemed curved, since the dichotomy was not yet complete.

[Margin: Observation 3.] 1636 January 15, in the evening, the lunar section passed at a distance from the eastern edge of *al-Zarqālī* [*Arzachelis*] equal to the diameter of *al-Zarqālī* himself, a spot that Langren calls *Anne*, Queen of France; and it touched the eastern limb of *Roma*, which for us is *Archimedes*. Quadrature took place at the approach of midnight.

[Margin: Observation 4.] 1646 September 16, at 10^h p.m., quadrature having already taken place, the line of the section touched the western edge of *Innocent* and *Pozzo*; at the quadrature itself it had passed through the centre of the Emperor *Ferdinand*. For *Innocent* we substitute *Ptolemy*, for *Pozzo Aristillus*, and for *Ferdinand al-Battānī*.

[Margin: Observation 5.] 1647 June 9, at 10^h p.m., near quadrature, the lunar section passed through the centre of *Ferdinand*, that is, of *al-Battānī*. So far from Langren.

Our observations follow.

[Margin: Observations of ours and of Father Grimaldi.] [Margin: Observation 6.] 1649 August 15, in the evening, an hour and a half after sunset, the section passed near the eastern border of *Archimedes* and *Alfonso* [*Alfonſi*], quadrature having by then been past for some hours.

[Margin: Observation 7.] 1649 September 13, in the evening, quadrature being already past, the section was passing through *Aristillus* and *Autolycus*, and through the eastern extremity of *al-Battānī*, and finally through *Bianchini*, *Werner* and the eastern part of *d'Ailly* [*Aliacenſis*].

[Margin: Observation 8.] 1649 November 10, at the 3rd hour of the night, long before quadrature, the lunar section passed through the eastern edge of *Aristotle* and *Eudoxus*, yet *Menelaus* was not yet appearing. The spot of *St Catherine* was distant from the section toward the west by as much as the interval between its southern edge and the northern edge of *St Theophilus*.

[Margin: Observation 9.] 1649 December 10, at the 1st hour of the night, about the fifth hour before quadrature, the Moon's section was distant from *Aristotle* toward the east by as much as the breadth of *Aristotle*, and from the spot of *Maurolico*, likewise toward the east, by as much as its diameter, and yet nothing of *Manilius* was discerned.

[Margin: Observation 10.] 1650 January 9, at 1½^{h} after sunset, the section was distant toward the east from the western edge of *Aristotle* by as much as the northern edge of *Aristotle* from the southern edge of *Eudoxus*; it was likewise distant toward the east from *Manilius* by as much as the interval between the nearest edges of *Aristotle* and *Eudoxus*; and it passed through *Maurolico*. Although the line of the section appeared slightly curved, it does not necessarily follow from this that quadrature had not yet been completed, since that curvature arose from parallax, in accordance with what is to be said in the appendix to Book 3, chapter 7. At 5^{h} after sunset, however, all of *al-Battānī* and *Hipparchus* now appeared, standing on the line of the section, which now appeared straight, even though at 1½^{h} after sunset nothing of *Hipparchus* and *al-Battānī* had appeared; now, moreover, the section was distant toward the east from *Manilius* by exactly as much as *Manilius* is distant from *Menelaus*.

[Margin: Observation 11.] 1650 February 8, at 3½^{h} after sunset, the section passed through *Ptolemy*, of which only the bright circumference appeared, and half of this stood out toward the east beyond the Moon's bright semidisc. The same section grazed the eastern edge of *Walther*, which was bright but broken up as if into little gems. *Manilius* was distant toward the west from the section by almost double its distance from *Menelaus*.

[Margin: Observation 12.] 1650 March 10, at 4^{h} after sunset, the Moon's section, slightly bent toward the east, passed through the eastern edge of *Archimedes* and through the middle of *Magini*, and it was distant toward the east from *Alfonso* by about two-thirds of the Alphonsine diameter.

[Margin: Observation 13.] 1650 April 9, half an hour after sunset, the section ran through the eastern edge of *Meton*, through the middle of *Plato*, and through *Eratosthenes*.

[Margin: Observation 14.] 1650 May 8, at 1½^{h} after sunset, the Moon, even when seen through the telescope, appeared dichotomous, and its section was scarcely further east than the eastern edge of *Archimedes*. It was distant toward the east from *Ptolemy* by *Ptolemy's* semidiameter, and finally it passed through the middle of *Magini*.

[Margin: Observation 15.] 1650 June 6, at 1^{h} after sunset, although many hours before quadrature, the section was nevertheless observed through the eastern extremity of *Meton*, which occupies the Moon's limb and the horn itself. It was distant just a little toward the east from *Aristillus*, and likewise toward the east from *al-Battānī* by its semidiameter, and it went on through the middle of *Walther*.

[Margin: Observation 16.] 1650 October 2, half an hour after sunset, the Moon appeared through the telescope more than dichotomous, although to the naked eye it appeared otherwise. The section passed through *Walther*, and it was distant toward the east from the eastern edge of *al-Battānī* by its semidiameter. The spots of *Aristillus* and *Autolycus*, moreover, were conspicuous, in the bright part of the Moon indeed, but a little removed from the section.

[Margin: Observation 17.] 1650 October 31, an hour and a half after sunset, the section was distant toward the east from *Aristotle* by a little more than *Aristotle* and *Eudoxus* are distant from one another. It grazed the eastern shore of the *Sea of Tranquillity*, being distant from *Manilius* by half the interval between *Manilius* and *Menelaus*; and finally it was distant toward the east from *Maurolico* by scarcely more than one diameter of *Maurolico*.

[Margin: Observation 18.] 1650 December 29, at 3^{h} after sunset, the section was distant toward the east from *Aristotle* by almost two diameters of *Aristotle*, and from *Menelaus* by as much as the gap between *Menelaus* and *Pliny*; and it passed through *Abū al-Fidāʾ*.

[Margin: Observation 19.] 1651 March 28, at $2½^{h}$ after sunset, a line falling at right angles on the line of the lunar section passed through the centre of *Hipparchus*, and above *St Theophilus* by as much as the latter's diameter; and the Moon was almost dichotomous.

[Margin: Observation 20.] 1651 April 27, 40^{m} after sunset, the Moon was seen already dichotomous, and the section passed through the middle of *Ptolemy* and through the eastern edge of *Walther*, and it was distant toward the east from the centre of *Aristillus* by as much as the diameter of *Ptolemy*; of *Archimedes* nothing was seen except little gems and bright points. The northern edge of *Ptolemy* was equally distant from each of the Moon's horns, and a straight line drawn perpendicular through the line of the section and through the centre of *Ptolemy* passed above the spot of *Langren* by almost one diameter of that spot.

[Margin: Observation 21.] 1651 May 27, at 1^{h} after sunset, since quadrature had occurred almost 6 hours before, the Moon appeared scarcely gibbous, and the line of the dichotomy passed through the eastern edges of *Archimedes* and *Ptolemy*.

[Margin: Observation 22.] 1651 June 25, the section of the Moon, not yet dichotomous, passed through the eastern edge of *Ptolemy*, which had only its circumference bright. Some fragments of the perimeters of the spots of *Alfonso*, *al-Zarqālī* and *Walther* also appeared; through *Walther's* eastern limb the section passed, and it was distant toward the east from *Aristillus* by one diameter of *Ptolemy*; but nothing of *Archimedes* appeared. Finally, the line bisecting at right angles the line of the section, that is, the line passing through the horns, was just a little above *Ptolemy*, and above *Langren* by one diameter of *Ptolemy*.

[Margin: Observation 23.] On the 26th, an hour and a half after sunset, with quadrature now completed, the lunar section was distant toward the east from *Plato* by half of its length, and from *Eratosthenes* by a whole diameter of the same; and it passed through the centre of *Pitati*, and between the centre and the eastern limb of *Tycho*.

[Margin: Observation 24.] 1651 July 25, 8^{m} after sunset, the Moon appeared already gibbous in the largest telescope, but still crescent-shaped to the naked eye. The lunar section, departing little from a straight line, passed through the middle of *Plato*, and it was distant toward the east from *Archimedes* by one of

its diameters, from *Ptolemy* by almost one of the latter's diameters, and from the centre of *Magini* by a quarter of that diameter.

[Margin: Observation 25.] 1651 August 23, at 1^h after sunset, the section of the Moon, not yet bisected, passed through the eastern edges of *Ptolemy*, *Peuerbach* and *Regiomontanus*, and it was distant toward the east from *Aristillus* by as much as the interval between the centres of *Aristotle* and *Eudoxus*.

Obſeruationes Sectionum Lunarium prope 2. Quadraturam.

Observations of Lunar Sections near the 2nd Quadrature.

[Margin: Observation 26. From Langren.] XI. 1633 January 3, in the morning, with the Sun touching the horizon, the line of the lunar section passed over *Magini*, called *Leopold* by Langren, that is, through its western quarter; and it was distant toward the west from *Vladislaus* (who for us is *Tycho*) by the diameter of *Tycho*. It cut *Christiern*, for us *Peuerbach*, so that only a quarter of it was visible, and it touched the eastern edge of *Archimedes*, of which likewise only a quarter appeared; but *Eratosthenes* and *Timocharis* were equally distant toward the east from the line of the section, which touched the western edge of *Plato*.

[Margin: Observation 27. From Father Grimaldi.] 1649 July 31, 1^h before sunrise, that is, about 8 [hours] before quadrature, the line of the lunar section, still curved, passed through the western edge of *Walther* and of *al-Battānī*, and, bending beyond *Aristotle*, it was seen to end between *Democritus* and *Meton*.

[Margin: Observation 28.] 1649 September 28, in the morning at sunrise, the line of the section stood almost through the middle of *Hipparchus*, but more toward the east, and through the middle of *al-Battānī*, and there was not yet a dichotomy.

[Margin: Observation 29.] 1649 November 27, in the morning, at $13½^h$ in Italian civil reckoning, the Moon appeared already slightly crescent-shaped, and its section was between the centre and the western edge of *Plato*. It was distant toward the west from *Eratosthenes* by as much as the length of *Plato*, and from the bright nucleus of *Tycho* by as much as the thickness of its darker corona. The ephemerides, however, put off quadrature to 20^h after noon on the 26th.

[Margin: Observation 30.] 1650 January 25, in the morning, half an hour before sunrise, the Moon appeared to the naked eye, and in the telescope too, already crescent-shaped, but the section scarcely appeared concave at its middle. The line of the section ran through the western edge of *Plato*, and it was distant toward the west from *Eratosthenes* by scarcely more than half the interval between *Eratosthenes* and *Copernicus*; from *Tycho*, moreover, it was distant toward the west by twice the bright diameter of *Tycho* itself.

[Margin: Observation 31.] 1650 March 24, shortly before sunrise, the Moon, standing on the meridian itself, was still just slightly gibbous, for quadrature was to occur at about 2^h after noon. The lunar section, further, passed through

the western cusp of *Meton*, and it was distant toward the west from *Aristillus* by as much as *Aristillus* is from the centre of *Archimedes*; it grazed the western edge of *Hipparchus*, and from *Tycho* it was distant toward the west by as much as *Tycho* is distant from the northern edge of *Pitati*.

[Margin: Observation 32.] 1650 April 23, 1^h before sunrise, with the dichotomy now completed, the line of the section was almost straight in the telescope, although to the naked eyes it appeared curved. This line was distant toward the west from *Plato* by twice the length of *Plato*; from *Aristillus* by one diameter of *Archimedes*; from *Tycho* by the interval between *Tycho's* extremity and the northern extremity of *Pitati*; and it passed through the middle of *Hipparchus*, next to *Ptolemy*.

[Margin: Observation 33.] 1650 September 17, at the very moment of sunrise, the section was distant just a little toward the west from *Hipparchus*, and from *Aristillus* and *Autolycus*, likewise toward the west, by as much as the centre of *Aristillus* from the centre of *Archimedes*, and it passed through the middle of *Meton*. The Moon was still gibbous; yet a straight line drawn from horn to horn passed through *al-Battānī*.

[Margin: Observation 34.] 1650 October 16, at $5\frac{1}{2}^h$ after sunset, a straight line drawn through the horns of the still gibbous Moon passed through the eastern edge of *al-Battānī*. The section, however, stood through the middle of *al-Battānī* and *Hipparchus*.

[Margin: Observation 35.] 1650 December 16, an hour and a half before sunrise, the section of the Moon, then dichotomous and standing on the meridian, was through the western edge of *Plato* and through the middle of *Magini*; but it was distant toward the west from *Eratosthenes* by scarcely one of its diameters. And of the mountains of the *Land of Snows* a tract stretched straight out beyond the Moon's shining semidisc, as long as one and a half diameters of *Eratosthenes*.

[Margin: Observation 36.] 1651 May 12, in the morning, about half an hour before sunrise, the section of the dichotomous Moon was distant toward the west from *Aristillus* by almost one diameter of *Archimedes*, and from *Autolycus* by a little less; and it passed through the middle of *al-Battānī*.

[Margin: Observation 37.] 1651 July 9, at sunrise, the lunar section grazed the western edge of *Hipparchus*, and it was distant somewhat toward the west from *d'Ailly*; from *Tycho*, moreover, it was distant by about one length of the *Caspian* or *Sea of Crises*.

[Margin: Observation 38.] 1651 August 8, 1^h before sunrise, the lunar section ran through the western edges of *d'Ailly* and *Hipparchus*, and it was distant toward the west from *Aristillus* by as much as *Aristillus* itself from *Archimedes*. The Moon appeared crescent-shaped to the naked eyes, but in the telescope evidently dichotomous.

[Margin: Observation 39.] 1651 September 6, at $6\frac{1}{2}^h$ after sunset, the section of the almost dichotomous Moon passed through the western edge of *Walther*, and it was distant toward the west from the centre of *al-Battānī* by a quarter of

the diameter of *al-Battānī*; and from *Aristillus* and *Autolycus* it was distant by as much as they are from one another.

[Margin: Observation 40.] 1651 December 5, in the morning, at about $12\frac{1}{2}^{h}$ in Italian civil reckoning, the Moon was seen markedly crescent-shaped with the naked eyes, but scarcely crescent-shaped in the largest telescope. The Moon's section passed through the western edge of *Archimedes*, and it was distant toward the west from the western edge of *Plato* by almost one length of *Plato*; and it passed through the western edges of *Alfonso* and *Magini*.

Besides the already mentioned observations, observations of other lunar phases are very useful for inferring the various quarters of the libration, by considering the line from horn to horn as it passes through one spot after another. A line falling at right angles on the straight line drawn through the horn is likewise useful for this, if the spots through which it travels are noted, as in Observations 19, 20 and 22.

Quæſtio 4. De Obſeruandis Temporibus Librationum Lunæ maximarum.

Question 4. On observing the times of the Moon's greatest librations.

XII. The moment, or even the hour, of greatest libration, that is, of greatest approach to the Moon's nearer limb or of greatest recession from it, cannot be known from direct observation, because near its time that approach and recession, or their difference from the motion of the preceding days, is scarcely perceptible. Therefore one must observe the time between the last perceptible approach and the first perceptible recession of the same spot, or between the last recession and the first perceptible approach, and divide it in two, so that the almost exact moment of greatest libration may become known, and from it the period from one libration to the other. But if these cannot be observed, one must resort to the days on which the spots seem to stick in a position nearest the limbs. Which spots, further, are suited to discerning the greatest libration has been said sufficiently in Nos. 4 and 7.

[Margin: Spots suited to this observation.] Now although those spots might seem most apt that reach the Moon's very edges, yet because very few of them do not vanish in some part of themselves beyond the edges and do not, by their optical contraction, thrust ambiguity on the observer, it has seemed better generally to use those that do not indeed reach the Moon's edges but are much nearer to them than to the centre of the lunar disc, and that are very conspicuous because of their striking characteristics. Such are *Tycho*, *Pitiscus*, *Langren*, *Aristotle*, *Plato*, *Harpalus*, *Grimaldi*, and, diametrically opposite to the last, the *Sea of Crises*, which is discerned even with the naked eye, and indeed is sometimes recognised even when it stands in the dark part of the Moon, by the force of the light reflected from the Earth onto the Moon, provided the Moon stands clear of the horizon. Yet most have so far used in this only two spots, namely the *Sea of Crises* and *Grimaldi*, under other names. Granted that

the quarters of the greatest librations are not always or generally in that part of the lunar limb which is nearest to the already mentioned spots, nevertheless their approach to and recession from the limb, although oblique, has seemed to those authors sufficient for indicating the times of the greatest librations. Before we determine anything about these times, some observations must be set out first, both those of others and our own.

Obſeruationes Temporis Maximi Acceſſus Macularum binarum ad Lunæ limbum Occidentalem, aut Orientalem ex Gaſſendo, & Bullialdo.

Observations of the Time of Greatest Approach of the two Spots to the Moon's Western or Eastern Limb, from Gassendi and Boulliau.

XIII. Boulliau reports these in Book 3 of the *Astronomia Philolaica*, chapter 13. Although they call the *Sea of Crises* the *Caspian* spot and *Grimaldi* the Eastern spot, we shall nevertheless use our own names too in reporting the observations of others, so that the reader may use our Figure 6.

[Margin: Observations of Gassendi.] 1636 September 25, *Grimaldi* was seen as close as possible to the eastern limb; on October 20, again very near to it; and on November 19 and 20, nearest to it. But on 1642 April 14 it was seen far removed from the same limb. The *Sea of Crises*, on the other hand, on 1636 October 8 and likewise the 9th, was so close to the Moon's western limb that it had never been seen closer by Gassendi; and on November 9, in the evening, it was as close to the same limb as it had ever been at any other time, so that the gap was scarcely a quarter of the already mentioned sea, although the sea was more contracted than usual. On December 5 it was again very close to the same edge; and again, on 1637 February 27, in the evening, it was nearest to the same limb, and on the 28th nearer still. But on 1638 January 24, while the Moon was occulting the Pleiades, the same sea was very thin and near the limb; and on December 20, in an eclipse of the Moon, it was nearest, as also on 1639 February 13.

[Margin: Observations of Boulliau.] 1643 June 3, at 11^h, *Grimaldi* appeared in the same position as before, that is, distant from the eastern limb by a little more than its own length; and on October 1 it became so close that it had never before been seen so close by Boulliau; as also on October 27 it was very near to the same limb. On November 30, however, it was distant from the eastern limb by half its length. The *Sea of Crises*, on the other hand, on 1643 May 3, at $8½^h$, was distant from the western limb by scarcely a quarter of its breadth, and the oblong spots adjoining the western edge of the same sea had disappeared. Again, on May 30 it approached the limb, and on the 31st still more, and on June 2 the western edge of the same sea was less far from the western limb than a 5th part of its breadth. Then, on September 18, at $7½^h$, the western shore of the same sea almost grazed the Moon's western limb, and Boulliau attests that it had not been seen closer by him before, so that the interval scarcely

equalled a 6th part of the breadth of the sea itself, although that breadth was very contracted. But it is expedient to set out a synopsis of these observations in the following small table, adding the Moon's place and latitude, selecting, however, those in which the distance of the spots from the limb was least.

Least distance of the Eastern spot, that is, Grimaldi, or of the Western spot, that is, the Caspian or Sea of Crises, from the nearer limb of the Moon.

Year, Month, Day	Spot	Moon's Place	Moon's Latitude
1636 Sept. 25	*Grimaldi*	♍ 22°	South 2°
Oct. 8 & 9	*Sea of Crises*	♒ 5°	South ½°
Oct. 20	*Grimaldi*	♋ 21°	North 1½°
evening, Nov. 9	*Sea of Crises*	♈ 3°	North 4°
Dec. 5	*Sea of Crises*	♓ 14°	North 3½°
1637 Feb. 27, 28	*Sea of Crises*	♈ 18°	North 4¾°

Obſeruationes Tēporis Maximæ & Minimæ Diſtantiæ inſignium quarumdam macularum à limbo Lunæ propiore, ex P.Grimaldo: addita quantitate prædictæ diſtantiæ.

Observations of the Time of Greatest and Least Distance of certain notable spots from the Moon's nearer limb, from Father Grimaldi, with the amount of the already mentioned distance added.

[Margin: Observations of Father Grimaldi.] XIV. For brevity's sake we shall gather these observations into the following small tables, and we shall add the amount of the spots' distance from the Moon's nearer limb in parts of which the Moon's temporary semidiameter is 100, according to the selenographic scale placed at the foot of Figure 6. Let the reader note, however, that the greatest distance means that which occurs within each single period of the librations; otherwise, if the greatest of one period is compared with the greatest of different periods, they are not all equal to one another, just as the least are not either when compared with other least distances. For what purpose we have added the Moon's place and latitude will be clear from what is to be said; for some have suspected that the greatest librations return whenever the Moon has its greatest latitude, or whenever it returns to the beginning of Cancer or Capricorn. Remember, however, that the difference between the greatest and least distance of *Tycho* from the Moon's southern limb, which sometimes reaches 18 parts, is unsuited to determining the portion of the lunar surface that

we see by the force of libration beyond what we should see without libration, for the reason already indicated at the end of No. 4.

Distance of the western shore of the Sea of Crises, or Caspian, from the Moon's western limb, in parts of which the Moon's semidiameter was 100.

Quæſtio 5. Quanta ſit Periodus cuiuſuis Librationis ſingillatim ſumptæ.

Question 5. How long is the period of each libration taken singly?

[Margin: Boulliau's opinion on this period.] XV. Ismaël Boulliau, in Book 3 of the *Astronomia Philolaica*, chapter 13, after comparing the observations of Gassendi and his own falling within seven years, of which there are 13 in number, finally concludes that the period of the lunar libration, that is, the time in which the same spot returns to its least distance from the same limb of the Moon from which it had previously been least distant, is of 26 days 14 hours 40′; and so that the daily motion of this libration is 13° 29′ 8″ 54‴ 20⁗ 20⁗′, and the annual motion 8ˢ 2° 19′ 10″ 33‴ 41⁗ 40⁗′. But he admits that this measure does not answer to all the observations, and that this motion includes some anomaly which is still hidden from astronomers because of the small number of observations.

[Margin: Hevelius's opinion on this period.] Johannes Hevelius, in chapter 8 of his *Selenographia*, says that the motion of libration of the lunar disc is completed in about a month's space. For about 14 days, while the Moon moves through the descending signs, its disc librates backward, against the order of the signs, from the south-east toward the north-west [ab Euroauſtro Corum verſùs], that is, toward the upper part, which in the 6th figure is toward the limit B. For the remaining 14 days or so, while the Moon moves through the ascending signs, it librates forward, in the succession of the signs, from the north-west toward the south-east, that is, toward the limit I in our 6th figure. In this way, he says, this motion fits itself entirely to the motion of longitude, although it is made more intricate by the Moon's latitude. And in chapter 9 he affirms that the *Sea of Crises*, which for him is the *Maeotian Marsh*, attains by force of libration its greatest distance from the Moon's limb when the Moon is both in Cancer and has its greatest southern latitude, and its least distance when the Moon is in Capricorn, around the limit of northern latitude. And in chapter 18, speaking of the spaces around the Moon's periphery near the *Maeotis*, he says: *They are extended as far as possible when the greatest libration of all in the Moon stands toward the south-east: that is, when the Moon is, so far as it has been possible to gather up to now, at the beginning of Cancer; and again they are compressed as far as possible when the Moon lingers in Capricorn.* Again, in chapter 54, from various lunations he observed up to the year 1646, he tries to confirm that libration arises from the motion of longitude, of latitude and of the nodes; and that around the beginning of Cancer, especially near the limit of southern latitude, the greatest distance lies between the *Maeotis* and the Moon's western limb, but the least between the *Mareotic Marsh* (we have called this the spot *Grimaldi*) and the Moon's eastern limb. In confirmation he adduces observations of Gassendi and Boulliau taken from Boulliau's Book 3, chapter 13; but he admits that three of them are shaky. Finally, in the same chapter, on p. 438, he concludes in these words: *But whether, in the way just stated, the greatest and least libration persists constantly and perpetually in Cancer and Capricorn, or whether over the course of a longer time the Moon undergoes certain further inequalities, or whether the matter stands otherwise, I cannot for the present affirm with certainty. What I can above all affirm is this: that up to now, in the time*

of my observations, I have detected nothing else than that the limits of libration have been noticed continually in those signs, namely Cancer and Capricorn. I am therefore wholly of the opinion that the limbs of greatest and least libration in the Moon will indeed never vary with respect to the spots; but that the motion of greatest and least libration, or its limits, will not remain perpetually in the same signs, but will in time gradually pass out of Cancer and Capricorn, following the retrogression of the nodes. [Margin: Summary of Hevelius's doctrine.] He therefore urges astronomers to observe this from now on.

[Margin: Hevelius's 1st assertion.] We therefore have three things from Hevelius. *First*, that this period, from greatest to greatest distance of the same spot from the Moon's limb, is of about 28 days. [Margin: 2nd assertion.] *Second*, that the greatest libration, that is, the greatest distance of the western spot from the western limb, does at these times occur when the Moon is at the beginning of Cancer, but with its greatest southern latitude; and so that at that time also the disc of the Moon extends as far as the northern limit of libration, from G to B. Conversely, the least distance of the same spot occurs when the Moon is at the beginning of Capricorn and holds its greatest northern latitude; and so at that time the disc of the Moon extends as far as the southern limit of libration, from D to I. [Margin: 3rd assertion.] *Third*, that *the limits of the librations keep an invariable position on the Moon's disc with respect to the spots*: that is, that the limits of greatest libration are always on approximately the diameter BI of the sixth figure, which passes through the western edge of the spot *Thales* and through the eastern part of the spot *Pitati*; so that the northern limit is always near B and the southern near I, and so that the nodes or poles of this libration are always near the points L and M; but that the greatest librations will not always occur with the Moon at the beginning of Cancer or Capricorn, etc.

[Margin: How certain Hevelius's first assertion is.] As regards the period of this libration, however: compare the earliest observation of the least distance of the spot *Grimaldi* that is on record in the preceding small tables, which from Gassendi was 1636 September 25, with the latest observation of the least distance of the same spot, which for us was 1650 September 9. Between these observations lie 5097 days, which divided by 28 yield 182 periods of libration and 1 day. But compare the earliest observation of the least distance of the *Sea of Crises* or Caspian, which for Gassendi was between 8 and 9 October of the year 1636, with the latest, which for us was 1651 August 21. Between them lie 5440 days, which divided by 28 give 194 periods and 8 days; if you divide by 29 there are 187 periods and 17 days; if by 30, 181 periods and 10 days; if on the other hand you divide by 27, 201 periods and 13 days; and if finally you divide by 26, 209 periods and 6 days. So although in the first example, that of the spot *Grimaldi*, almost no fraction was left over, in the others one was, and therefore a divisor with a fraction would have had to be assumed. But with no divisor of this kind will you find a number of periods without a fraction; or if you do find one, it will still not by itself satisfy each and every one of the periods of the librations, unless you apply some prosthaphaeresis. [Margin: Our opinion

on this period.] Therefore a twofold difficulty in this motion still remains for posterity, if there are any who wish to pursue these matters further. The first concerns the mean motion, or mean period, of this libration; the second concerns the motion of its proper anomaly and the quantity of the equation to be added or subtracted, so that it can be known for a given time how great the distance of the already mentioned spots from the nearer limb of the Moon ought to be. Both inquiries, moreover, require observations not only of more years than we have so far, but even of several centuries. For the quantities of the lunar month, and of the anomalistic and of the draconitic or latitude month, have terms and revolutions that can be observed more surely from lunar eclipses, and without the error of a whole hour; and yet astronomers could not bring them to an exact standard until Hipparchus, Ptolemy and the others skilled in this art brought the observations of many centuries into counsel, as will be clear from what is to be said from chapter 21 to 25. How much more, then, are intervals of this kind needed in this business, since in discerning the terms of this libration by observation it is easy for an error to creep in, not of one or two hours, but of several hours. For the same spot usually lingers at its greatest or least distance from the same limb for two, three or more days before its first withdrawal or approach becomes perceptible. And this itself is often unobservable, not only for the two causes that also sometimes make lunar eclipses unobservable, namely clouds or the brightness of day, but also because lunar spots otherwise suited to this observation are not illuminated by the Sun in such a way that their approach or withdrawal can be noted. Consequently nothing certain has so far been known about this period, except that (speaking of the mean period) it is greater than 26 days and less than 30, and that it is not very unlike the other monthly revolutions of the Moon, nor indeed the monthly rotation of the solar spots, which from what was said in Book 3, chapter 3, no. 8, is of about 27 or 28 days. Finally, if we were to grant, what we shall nonetheless shortly deny, that this period is as long as the time the Moon spends in returning to the same beginning of Cancer or Capricorn, nor that this libration has its own peculiar anomaly underlying it, this period would still be unequal, and indeed with an inequality as manifold as is the anomaly in the Moon's motion of longitude and latitude, to which Hevelius thinks this libration fits itself entirely.

Quæſtio 6. Quibus Anni Menſiſue temporibus contingat Maxima Lunaris diſci Libratio.

Question 6. At what times of the year or month does the greatest libration of the lunar disc occur?

[Margin: Hevelius's 2nd assertion is attacked.] XVI. Now from what was said in the preceding number, especially in Hevelius's 2nd assertion, it is clear that, if you follow that author's opinion, the times of these librations are those when the Moon is at the beginning of Cancer with its greatest southern latitude,

or at the beginning of Capricorn with its greatest northern latitude; although he suspects that, as the nodes of the lunar orbit gradually regress, these greatest librations will at some time occur in other signs as well. But if we are to abide by the observations that exist not only in Hevelius himself, but in Boulliau's Book 3, chapter 13 (the very ones Hevelius adduces in his own favour), and in Father Grimaldi's papers, Hevelius is certainly mistaken. For according to him the western spot, called the *Caspian* by Gassendi and Boulliau and the *Sea of Crises* by us, ought in the years just past to have held its greatest distance from the western limb when the Moon occupied the beginning of Cancer and the greatest southern latitude, and at that time the eastern spot, namely *Grimaldi*, ought to have reached its least distance from the eastern limb. Conversely, when the Moon occupied the beginning of Capricorn and also had its greatest northern latitude, the western spot ought to have acquired its least and the eastern spot its greatest distance from the nearer limb. It is useful to have these alternations before one's eyes in the following synopsis.

Distance from the Moon's nearer limb, according to Hevelius.

Spots		The Moon being
Western, or Crises	Greatest	At the beginning of ♋ with greatest southern latitude
	Least	At the beginning of ♑ with greatest northern latitude
Eastern, or Grimaldi	Greatest	At the beginning of ♑ with greatest northern latitude
	Least	At the beginning of ♋ with greatest southern latitude

Now if you run through the observations of the two already mentioned spots reported in nos. 13 and 14, with the Moon's places in the zodiac and its latitudes added in the small tables of observations, not even one is found that supports Hevelius; indeed almost all oppose him. For in none do those three conditions concur, namely the beginning of Cancer, and southern latitude, and that the greatest, or the beginning of Capricorn with northern latitude, and that the greatest; in most of them, on the contrary, opposite or different conditions are found. You will notice this also in the observations reported above of the remaining three spots, namely *Endymion*, *Plato* and *Tycho*. And they oppose him not by a few minutes in latitude or by a few degrees in the Moon's longitude, but in the former by whole degrees, and even in the very kind of latitude, and in the latter for the most part by whole signs, and even by aggregates of several signs. Moreover, those very few observations that Hevelius sets out from his own stock, or those that he suppresses unexplained or merely indicates, although a great many ought to have been brought to light, were not sufficient to introduce a universal assertion for these times, and one of such moment in astronomy. And if the rest are to be judged from the very ones he brings forward, a great suspicion arises that, because of the novelty of the phenomenon, he brought forth this immature thesis in too hasty a birth. For in chapter 54, from p. 433, laying the foundations of this opinion of his, he says that in the year 1645, December 17, the conjunction of the Moon was near

the beginning of ♈ with a great northern latitude, and that he then observed the least libration at the right-hand limb of the Moon and the greatest at the left; and that in the year 1646, January 1, at 8^h in the evening, the true full Moon was near the beginning of ♋ with a great southern latitude, and that he then observed *almost the greatest* libration at the Moon's right-hand limb and the least at the left. And yet, although at the time of the already mentioned conjunction the Moon was a few degrees from the beginning of ♈, it did not have its greatest northern latitude, since it had one less than 4°; and at the time of the already mentioned opposition the Moon was almost 10° from the beginning of Cancer, and, what stands most in Hevelius's way, the Moon's southern latitude did not exceed 2½°, whereas it ought to have been 5° in order to be greatest. From this very example, moreover, it is clear that Hevelius was content with *almost the greatest* librations, and that he cannot take refuge, to defend his assertion, in the greatest of the greatest; these in turn occur so rarely that the life of one astronomer does not suffice to acquire as large a number of them as the already mentioned assertion would require.

[Margin: Our opinion on the times and places of these librations.] I therefore think it must be admitted that the greatest librations of the Moon, even in this our own time, occur indifferently in any degree of the zodiac; just as neither eclipses nor the nodes or limits of the lunar orbit are tied to fixed degrees of the signs, still less to the beginning of any sign. A sufficient foundation for this opinion is furnished both by the observations reported above and by not a few others.

Quæſtio 7. An in determinata parte limbi Lunaris ſint Limites maximæ Librationis, & Nodi eiuſdem vel Poli.

Question 7. Are the limits of the greatest libration, and its nodes or poles, in a determinate part of the Moon's limb?

[Margin: Hevelius's 3rd assertion is disproved.] XVII. From what was reported in no. 15 under the 3rd assertion, Hevelius held that the limits of each lunar libration keep the same position on the Moon's disc perpetually *with respect to the spots*; and so that the limit of northern libration, in the 6th figure (which we have drawn from Hevelius's plate to represent this very point, as regards the twin circumferences of the lunar disc), is perpetually at B, and that of southern libration at I, and their poles or nodes at L and M, or as nearly as possible. But Hevelius has beyond doubt been deceived, and anyone will be deceived who, in observing the quarters of the lunar librations, has not kept the rules given above in no. 7. That the position of the already mentioned librations and nodes changes *with respect to the spots* we shall show from observations selected for this purpose and carried out according to the already mentioned rules, and from four arguments drawn from them.

[Margin: 1st argument against Hevelius.] *First*, if the limits of the librations clung immovably to the same position on the lunar disc, then when spots very

distant from the limits and nearer the nodes withdraw very perceptibly from the Moon's nearer limb, spots nearer the limits assigned by Hevelius ought also at the same time to move away from the Moon's nearer limb by a perceptible withdrawal. This is said of pairs of spots contained within the same semicircle, that is, one that belongs to the same kind of libration, especially if the spot nearer the limit is nonetheless not so remote from the centre that its withdrawal from the limit is scarcely perceptible for an optical reason. And the same must be said of the approach of two such spots. For example, in the 6th figure, when within the semicircle LDM the spot *Grimaldi* was seen to move perceptibly away from the limb KS, the spot *Tycho*, being nearer the centre, ought to have been seen to withdraw from the limb DQ no less perceptibly, indeed more so. And yet the contrary plainly appeared from 22 to 25 September of the year 1649 and on 17 and 18 March of the year 1650; for at both times *Grimaldi* was seen to withdraw very perceptibly from the limb KS, while *Tycho* meanwhile appeared immovable in the same place on the lunar disc. *Tycho* also stood immovable on 19 and 20 March 1650, while *Grimaldi* was already perceptibly approaching the limb KS on the 20th. Similarly, in the year 1649, from 14 to 18 November, the shore of the *Sea of Crises* was approaching the limb RC with a perceptible motion, while *Endymion* remained immovable that whole time. And in the year 1651, from 27 to 30 August, the shore of the same sea was withdrawing markedly from the limb RC, while *Plato* meanwhile continued unmoved in the same position. We have observed similar things in other spots.

[Margin: 2nd argument.] *Second*, all the spots in the same semicircle, that is, all those in the semicircle EBC of northern libration, or all those in the semicircle EDC of southern libration, ought (if Hevelius's opinion were true) to librate in the same direction, or to agree in approaching the same limit of libration, or in moving away from it as from a common term in withdrawal. And yet in 1649 November 25, 26 and 27, and in 1651 February 11 and 12, while *Grimaldi* was withdrawing from the semicircumference EDC, *Tycho* was approaching it. Conversely, in the same year, on August 6, 7 and 8 and September 1, 2 and 3, while *Grimaldi* was approaching the semicircumference EDC, *Tycho* was withdrawing from it with a perceptible motion. Again, in 1651, from April 28 up to May 3 inclusive, the western shore of the *Sea of Crises* continually approached the limb RC, that is, the semicircumference EBC; and yet *Endymion* and *Aristotle*, placed within the same semicircle, were most plainly seen to withdraw from that same circumference, just as on the 1st, 2nd and 3rd *Plato* withdrew from the same place, having gone unobserved on the preceding days. Conversely, in 1651, from November 22 up to the 25th, the same shore of the same sea withdrew from the already mentioned semicircumference, which *Endymion* and *Plato* had meanwhile been approaching with a notable motion.

[Margin: 3rd argument.] *Third*, if Hevelius's doctrine held, spots in semicircles that differ as to the kind of libration would not at the same time approach, each its own limb of the Moon; rather, while the spots enclosed within the semicircle EBC approached the semicircumference EBC, the spots within the

semicircle EDC would withdraw from the semicircumference EDC; or, while the latter approached EDC, the former would withdraw from EBC. Nor would the opposite appear, and much less in those near the nodes L, M. But the exact opposite happened. For in 1651, from July 7 to 9, from August 5 to 8, and from August 31 to September 4, while *Plato* was approaching the semicircumference EBC, *Grimaldi*, which ought to have been withdrawing from the semicircumference EDC, was nonetheless approaching it. Conversely, in the same year, on March 7, both *Plato* and *Endymion* were seen to withdraw from EBC and *Grimaldi* from EDC. Likewise in the same year, on May 1, 2 and 3, both *Tycho* approached the semicircumference EDC and the western shore of the *Sea of Crises* approached the semicircumference EBC. Finally, also in the same year, from August 5 to 8 and from August 31 to September 3, while *Grimaldi* was approaching EDC, *Plato* and *Harpalus* were approaching EBC, a quarter from which, however, both of them ought to have been withdrawing.

[Margin: 4th argument.] *Fourth*, on Hevelius's hypothesis, while one of the spots in its semicircle moves perceptibly, approaching the Moon's nearer limb or withdrawing from it, another spot situated within the opposite semicircle, especially one far from the Hevelian nodes, ought not to appear immovable. And nevertheless in 1649, from September 22 to 25 and from November 21 to 25, while *Grimaldi* was withdrawing markedly from the semicircumference EDC, *Plato* stood immovable that whole time. Also in 1651, from August 26 up to the 30th, the western shore of the *Sea of Crises* withdrew continually from the limb RC, and meanwhile, through all those days, *Tycho*, which by force of the Hevelian libration should have been approaching the limb IQ, nonetheless remained immovable, in an entirely unvaried position.

These things and more like them, observed not indeed without amazement, but nonetheless with the greatest circumspection, and reported with equal good faith, I find in the records of Father Francesco Maria Grimaldi; and, as he himself pointed them out, I solemnly and scrupulously testify that they happened so. This being the case, the limits of the lunar libration must often be far from the points B and I, as the nodes must be from the points L and M, as these lie in the 6th figure with respect to the position of the spots on the lunar disc. It must nevertheless be granted to Hevelius, and it remains certain from many observations of ours, that the already mentioned limits and nodes are often near the position he assigns.

Quæſtio 8. In qua igitur parte debuerint eſſe Limites Librationis & Nodi, ſaluis obſeruationibus numeri XVII. & ſalua quoad cætera Hypotheſi Heueliana?

Question 8. In what part, then, must the limits of libration and the nodes have been, with the observations of number XVII preserved, and with Hevelius's hypothesis preserved as to everything else?

XVIII. If nothing else is supposed to need changing in Hevelius's hypothesis except the position of the limits and nodes, and if it is admitted that the libration of the lunar disc can actually occur about a movable axis of the Moon, yet in such a way that, with the Moon placed at the nonagesimal or on the meridian, the same spots keep the same position with respect to the sky (that is, for example, that the spot *Meton* is always toward the north in the upper part of the lunar disc, and the spot *Clavius* toward the south in the lower part, as appears in our 6th figure, which imitates Hevelius's as regards this position); if, I say, these things are supposed, we answer in general that the nodes or poles of this libration, and the axis passed through them, must have been near those spots that were seen to be immovable, according to what was reported in the first and 4th arguments. But if two or more spots were moving at the same time also with the same kind of motion, that is, by approach to or withdrawal from the nearest limb of the Moon, the axis of the poles had to be outside them; whereas if they were moving with different kinds of motion, it had to be between them.

[Margin: Places of the nodes from the first argument of Question 7.] Thus, by the examples of the first argument, when *Grimaldi* was withdrawing from the limb SKP or approaching it, while *Tycho* meanwhile was unmoved, the axis of libration had to be near the line BI; as it did also when, with the *Sea of Crises* approaching the limb BC, *Endymion* remained immovable. But when, with the *Sea of Crises* withdrawing from the same limb, *Plato* stayed immovable, the axis of libration had to be near the line PQ.

[Margin: Places of the nodes from the 2nd argument.] From the examples of the second argument, however, the axis of libration had to be between the lines BI and RS. For in this way it would be preserved, through what remains of the Hevelian hypothesis, how, with *Grimaldi* withdrawing from the limb KS, *Tycho* should approach the limb IQ, or, with the latter withdrawing, *Grimaldi* should approach; and likewise how, with the *Sea of Crises* approaching the limb RC, *Plato*, *Aristotle* and *Endymion* should withdraw from the limb PB, or, with that sea withdrawing, they should approach; yet in such a way that the axis of libration was on this side of *Endymion*, that is, between it and the *Sea of Crises*.

[Margin: Places of the nodes from the 3rd argument.] Now, from the observations brought for the 3rd argument, the axis of libration had to be not far from the line BI when, with *Plato* approaching the limb BP, *Grimaldi* also approached the limb KS. When, however, *Grimaldi*, *Plato* and *Endymion* were each withdrawing together from the nearer limb, the axis had to be between the lines BI and RS, but between *Endymion* and *Cleomedes*; just as it had then too, when both *Tycho* to its limb and the *Sea of Crises* to its limb were approaching together. When finally *Grimaldi*, *Harpalus* and *Plato* were approaching together toward the circumference BED, the axis had to be on a line nearer the line BI than the line PQ.

[Margin: Places of the nodes from the 4th argument.] Lastly, both when, with *Grimaldi* withdrawing from the limb SK, *Plato* stood immovable, and when, with the *Sea of Crises* withdrawing from the limb RC, *Tycho* appeared

unmoved, according to what was said in the 4th argument, the axis of libration had to be between the lines BD and PQ.

Once the position of the libratory axis is determined, moreover, its extremities on either side remain determined, namely the poles, which under another aspect can also be called nodes; and so also the limits of libration, since these are a quadrant from the nodes. But in what interval of time the axis of libration returns to the same position, and whether this change itself includes an anomaly, is matter for another investigation, and requires observations over a longer time.

Quæſtio 9. An libratio Lunaris diſci, de qua ſuprà, proueniat ex ſola Parallaxi, aut variatione Latitudinis, vel Diſtantiæ Lunæ à centro terræ.

Question 9. Does the libration of the lunar disc discussed above arise solely from parallax, or from the variation of latitude, or of the Moon's distance from the centre of the Earth?

[Margin: Galileo's opinion on the cause of the lunar libration.] XIX. This question was prompted by Galileo, in dialogue 1 *De duplici mundi systemate*, where he says that the Moon, because of the sympathy it has with the Earth, always looks toward the Earth with one determinate part of itself; and that it is therefore necessary that the straight line joining their centres always passes through the same point of the lunar surface, so that anyone gazing at the Moon from the centre of the Earth would always see the same disc of the Moon precisely bounded by the same circumference. But because the ray of one looking at the Moon's centre from the Earth's surface does not pass through the same point of the lunar surface through which the line joining the centres of the Earth and the Moon passes, unless the Moon is vertical to him, it comes about that, of the rising Moon, some small part of the lower limb is hidden from us which is seen at other times, and just as much on the other lower part of the setting Moon is hidden from us. He therefore attributes the cause of this hiding to parallax, which arises from the Moon's being considered from the centre of the Earth and viewed from its surface. A similar variation, he says, ought to be observed at the northern and southern extremities of the lunar disc: for when the Moon has its greatest or a great northern latitude, some part of the northern limb must be hidden and part of the southern uncovered, and conversely when it has southern latitude. He confirms these consequences from two lunar spots, one of which, when the Moon reaches the meridian, faces the north-west, while the other is diametrically opposite to it; and the first is visible without a telescope, but not the second. He is clearly speaking of the Sea of Crises and of Grimaldi's spot opposite it. And he says that the said variations are observed in both of these, and that they are, in contrary manner to each other, now close to the limb of the lunar disc, now far from it, yet with this difference: that the interval between the Corican spot and the limb of the Moon is more than twice

as great on one occasion as on another, and in the other spot three times as great. Boulliau, however, in Book 3 of the *Astronomia Philolaica*, reporting this opinion of Galileo as if Galileo had said that this libration occurs *so that the Moon may keep a certain direction toward the axis of the Earth* — the Earth being moved, as both of them believe, along the annual orb — brings a demonstration against him, of which we shall speak in the scholium. [Margin: Galileo's opinion is rejected.] To us, meanwhile, Galileo's doctrine seems seriously defective on another head. For, speaking of the already mentioned eastern and western spots, parallax alone cannot bring it about that the space between them and the lower limb of the Moon is two or three times narrower on one occasion than on another. Next, if this phenomenon came from parallax alone, it would have to be the case every day, in one and the same night, at least when the Moon is full, that the Corican spot appears as far as possible from the upper limb of the rising Moon, and that the eastern spot opposite it then appears as close as possible to the lower limb; and conversely that the Corican appears as close as possible to the lower limb of the setting Moon, and the other as far as possible from the upper limb. But this is utterly false. For often, when the Moon is rising, the Corican is at its greatest approach to the upper limb and Grimaldi's spot recedes furthest from the lower limb; and conversely, when the Moon is setting, the Corican is furthest from the lower limb and the Grimaldian nearest the upper limb of the Moon. [Margin: Neither parallax nor latitude are the chief causes of libration.] Parallax, therefore, is not the sole or the principal cause of the lunar libration that is at times seen toward the east or the west.

Nor is parallax combined with the greatest or a great latitude the sole or the chief cause of that libration which appears toward the south or the north. For in our 6th figure the spots of Thales or of Endymion, which according to Galileo ought then to be as close as possible to the upper limb of the Moon when it stands on the meridian, when the Moon has its greatest northern latitude, are nevertheless often very far from that limb; and on the contrary they not rarely come very close to it, even when the Moon has its greatest southern latitude; and similar variations are observed in the southern spots.

[Margin: The Moon's apogee and perigee are not the cause of the Moon's libration.] Gather from what has been said that the chief cause of the lunar libration is not the difference of the Moon's distance from the centre of the Earth, arising from apogee and perigee. For this varies the Moon's parallax, and that by only very few minutes; and of itself, when the Moon is at perigee, it does not hide one limb of the lunar disc rather than the other, but from the whole lunar disc, all round, it hides a scarcely sensible small portion, as will be clear from what is to be said in chapter 17, problem 3.

Quæres igitur 10. Quænam ſit cauſa Librationis in Luna apparentis, ſeu Qua motuum hypotheſi explicari poſſit.

You will ask, then, tenth: What is the cause of the libration apparent in the Moon, or by what hypothesis of motions can it be explained?

XX. Would that it were as easy to construct our own hypothesis as it was to demolish those of others. But the fewness of the years since this libration began to be observed stands in the way; we shall nevertheless indicate what has come to our mind. [Margin: The first hypothesis, by a little circle seen in the middle of the lunar surface.] The first hypothesis, then, seems to rest on the little circle AVFT, marked in the middle of the sixth figure, if the centre of the lunar disc is understood to be carried round through its circumference, alternately now from A through V toward F and T, against the order of the signs, now from A through T toward F etc., in the order of the signs. This holds provided that the centre A of the apparent lunar disc is conceived as in reality becoming, on the surface of the lunar globe, a pole, from which there is described a circle very nearly great, cutting the lunar globe and separating the segment seen by us from the unseen one; and provided next that the little circle described on the spherical surface of the Moon is much larger than the one described in the 6th figure, which, being plane, is drawn only for this purpose, that the quantity of the librations BG and DI can be represented on the same disc near the limb. And if the observations should require the diameter of the said little circle to be now larger, now smaller, this can be managed either by a spiral or helicoid line, or by another little circle, as an epicyclion.

[Margin: The second hypothesis, by 2 little circles around the limbs of the Moon.] The second hypothesis rests on two little circles near the limbs of the Moon, described in much the same way as Scheiner in his diagram describes his little circles around the limbs of the Sun, as will be said in Book 9, section 4, chapter 12, number 21; provided that only that part of the hypothesis is applied here which suffices for libration, and not that which suffices for a complete rotation of the lunar globe, since we have already excluded this rotation from the Moon.

[Margin: The third hypothesis, relying on the centre of the eccentric.] The third hypothesis would rest on the eccentricity of the Moon: namely, if we were to understand that the Moon, either by itself or fixed to an epicycle, always faces with the same face not the Earth but the centre of the lunar eccentric, so that a line drawn from the centre of the lunar body to the centre of the eccentric would always pass through the same point of the lunar surface. [Margin: 1. The case if the Moon has no latitude.] First, then, if the Moon had no latitude and were either at apogee or at perigee, there would be no libration: for the straight line joining the Earth with the Moon would pass through the centre of the eccentric. We here disregard the modest variation that could come from parallax. But if the Moon lacked latitude yet were descending from apogee, then Grimaldi's spot would begin to recede from the nearer limb, and would

recede more and more through the whole first quadrant of the Moon's anomaly, and the Sea of Crises would approach the western limb; then through the 2nd quadrant the distance of Grimaldi would diminish more and more, but that of the Sea of Crises would increase. After perigee is passed, in the 3rd quadrant of the anomaly the nearness of Grimaldi and the distance of the Sea of Crises from the nearer limb would grow; and in the 4th quadrant, finally, both would diminish. [Margin: 2. The case of greatest northern latitude.] Secondly, if the Moon had been carried up to its greatest northern latitude and were at apogee, Plato, Endymion and the other spots of that tract would be at their greatest distance from the northern limb, while Tycho, Longomontanus, Clavius etc. would come nearest to the southern. Conversely, at perigee Plato etc. would approach, while Tycho would recede furthest. But if the Moon were exactly a quadrant from the apogee on either side, no variation from the force of latitude would appear for this libration to explain; there would, however, be another libration at its greatest, namely toward the east or toward the west. [Margin: 3. The case of greatest southern latitude.] Thirdly, if the Moon had been carried down to its greatest southern latitude and were at apogee, Tycho etc. would recede furthest from the southern limb and Plato etc. would approach the northern; but at perigee Plato would recede from the northern and Tycho would approach the southern. But if it were a quadrant from the apogee on either side, there would be no libration of this kind. [Margin: 4. The case of middling latitude.] Fourthly and lastly, if the Moon held a middling latitude and were found neither at apogee, nor at perigee, nor at the end of the quadrants of distance from apogee or perigee, the libration would be greater or smaller according as the Moon shared in different ways in the conditions listed in the preceding cases.

[Margin: The falsity of the third hypothesis on two counts.] XXI. But for the said hypothesis to stand, two things are required. First, that the eccentricity be as great as the greatest libration requires, or so great that by its force we could at some time see of the Moon's disc 12 parts of which its semidiameter is 100, or 28° of the lunar surface beyond what we see without libration, according to what was said in Question 3. But the eccentricity of the Moon deduced by us from selected observations does not exceed, even at the quadratures, where it is greatest, 13053 parts of which the radius of the eccentric is 100000, as will be said in chapter 28; and so, with the laws of trigonometry preserved, the force of the eccentricity cannot represent a portion of the Moon's surface, beyond the usual one, greater than 7°. Second, that the variation set out in the 4 cases above should satisfy all the observations. But even if it satisfies very many of those obtained so far, not a few nevertheless resist it. We are therefore forced to reject this hypothesis as abortive. And indeed, as we shall warn more than once in examining the hypotheses of the planets, the centre of the eccentric does not seem to have in itself the character of an end, or of a desirable good, for the sake of which a planet should direct its motions toward it.

[Margin: What is to be said of the reticle of Hevelius's figure.] Further, the reticle that Hevelius describes in the 6th figure in place of the little circle AVFT does not serve to defend the whole hypothesis of libration, and it rests on a twofold but false foundation: namely, that the greatest librations occur at those times when the Moon has its greatest latitude at the beginning of Cancer or Capricorn, and that the limits and nodes of the libration perpetually keep almost the same position with respect to the spots of the lunar disc.

Quæſt. 11. An Lineæ diuidentis Lunæ ſplendidum ab obſcuro tranſitus non per eaſdem ſemper maculas, oriatur ex ſola Libratione, An etiam ex Latitudine.

Question 11. Does the passage of the line dividing the Moon's bright part from its dark part, not always through the same spots, arise from libration alone, or also from latitude?

XXII. I answer that, whether the question is about the extreme spots on which the Moon's horns fall or about the rest, through which the said line passes, in both a variation arises both from differing libration and from differing latitude; but the variation of the centre in the apparent lunar disc arises from libration alone, or a very little from parallax. [Margin: The line of dichotomy varies with varying latitude.] Considering now only the variation that comes from latitude: since the same plane of a great circle on the lunar globe always lies in the plane of the lunar orbit (if we set aside all libration), therefore, if the dichotomous Moon has its greatest latitude, the plane in the Moon separating the bright from the dark will make right angles with that same plane of the lunar body, always the same, namely the one that lies in the lunar orbit; and whether the latitude is southern or northern, the section will still pass through the same spots. But if the Moon is without any latitude, the said plane will be inclined to the lunar orbit at as great an angle as the lunar orbit is inclined to the ecliptic; and if the Moon is in the northern node, the northern horn will pass through spots further east than those through which it passed when the Moon, likewise dichotomous, was at greatest latitude; but if in the southern node, it will pass through spots further west. The opposite is to be understood of the southern horn. So, in figure 6, if for the dichotomous Moon having its greatest latitude the northern horn falls on *Meton* and the southern on *Moretus*, then, for the same Moon placed in the northern node, the northern horn will pass nearly through *Philolaus* and the southern through *Tanner*; while in the southern node the northern horn will pass through the middle of the *Sea of Ice* [maris Glaciei] and the southern a little below *Biancani*. Consequently the line of dichotomy will also pass through different spots lying outside the horns, according as the latitude is greatest, or is indeed none but the Moon is in the northern or the southern node. [Margin: The section of the other phases also varies for the same reason.] There is, however, excepted in dichotomies the spot or small part which is at the centre of the lunar disc: for, libration set

aside, the same lunar disc, and therefore the same centre of the disc, appears to us; nor would there be any other variation here, except a very little from parallax. From this you will gather that no smaller a variation occurs outside the dichotomies, and indeed a far greater one if the effects of librations and latitudes are combined; although we have given examples of this variation, for dichotomies almost alone, in the 40 observations reported above from number 10. Meanwhile we point out that a straight line drawn through the horns of the waxing or waning Moon does not cut the lunar disc in two, as it does when the Moon is full-grown.

SCHOLIA.

Scholia.

[Margin: How our Earth would appear to inhabitants of the Moon.] I. Just as from the Earth we see the phases of the Moon and its spots successively illuminated, so, if anyone were on the Moon, he would see the Earth illuminated by the Sun, so that on the Earth, where there are seas and other waters, large spots would appear, while the mountains, with their ridges lit, and the valleys, shaded behind the backs of the mountains, would appear as small spots, and the plains of the continents as bright parts. Next, the Earth, like another Moon, would appear now full, but then when it is new Moon for us, and now silent and deprived of the direct light of the Sun, when it is full Moon for us; and alternately sickle-shaped and gibbous. In the first lunar quadrature the Earth would appear to him dichotomous, but shining toward the east of the lunar inhabitant, while in the 2nd lunar quadrature it would appear dichotomous and shining toward the west. Since, however, the same hemisphere always faces the Earth, and the Earth is not carried around the Moon as the Moon is around the Earth, not all the inhabitants who might be on the Moon would see the Earth, but only the inhabitants of the hemisphere turned toward us, whereas all the inhabitants of the Earth see the Moon. Moreover, as I indicated in chapter 6, number 9, the Earth seen from the Moon would appear to shine with a secondary light, because of the Sun's light reflected from the Moon onto the Earth. Galileo says so too, in dialogue 1 of the *Systema Mundanum*.

[Margin: How long a day would the inhabitants of the Moon have?] II. The lunar inhabitants would differ from the dwellers on Earth in this too: that, because the same face of the Moon perpetually faces the Earth, they would have a continuous day of nearly 15 of our days. For example, an inhabitant of the upper hemisphere, in the straight line joining the centres of the Earth and the Moon, would have day from the last quadrature to the first following; and for the remaining 15 days, from the first to the second quadrature, perpetual night; and it would be noon for him at new Moon and midnight at full Moon, and the Sun would rise for him at the last quadrature and set at the first. But for the inhabitant of the hemisphere sloping toward us, everything would happen

the other way round. How large our Earth would appear there depends on the lunar distance, and so we shall speak of this in chapter 17.

[Margin: The Galilean libration attacked by Boulliau.] III. Boulliau, in Book 3, chapter 13 of the *Astronomia Philolaica*, rejects the lunar libration introduced by Galileo in the *Dialogues*, that the Moon may keep a certain direction toward the axis of the Earth moved along the annual orb. For let, he says, the annual orb be LIM, in which the Earth is FEHQ, whose axis, around which it revolves daily, is FIH, and let the Moon's orbit be OPN. Then either the Moon's axis must be kept parallel to the axis FH, as is the axis BC, and then either the face of the Moon turned toward us would change every month, or, for the same face always to be shown to us, a periodic revolution of the lunar disc is necessary. For if the Moon is at N, and BC parallel to FH, unless the Moon's globe is turned, the dwellers on Earth will see the part ASC; but when the Moon has advanced from N to O, the part ASC will be hidden and VDC will be seen, which is against the phenomena. Therefore, lest this follow, a revolution of the lunar body in longitude is necessary. But to introduce this is superfluous, since nature delights in the fewest motions and in economy. Or, secondly, the axis of the Moon keeps the same inclination to the axis of the Earth FH, as if the axis is AD, inclined to FH but parallel to the diameter EQ; and then too, according to this inclination, the face of the Moon would turn; or the axis AD must be turned by a rotation, so that, the Moon being at N, the parts ASD are seen there, and then, when it has moved on to O, the parts AVD are seen.

Diagram. A geometric figure in the right column, standing within Scholium III (the column breaks for it after the word *in*, and the sentence resumes below with *quo Terra*). A central circle (the Earth) carries a vertical diameter and an oblique diameter running from upper left to lower right. A shallow arc runs across the figure through the central circle, from lower left to lower right (the annual orb). A larger arc rises from a small circle on the left, passes over the top of the figure to a small circle on the right, and also curves down beneath the central circle, closing below it (the Moon's orbit). The small circle on each side is crossed by intersecting diameters and curved arcs. Labels read:

- A (upper left of the left small circle): point on the left small circle
- B (top of the left small circle): point on the left small circle
- V (top right of the left small circle): point on the left small circle
- O (centre of the left small circle): point on the Moon's orbit
- S (lower left of the left small circle): point on the left small circle
- C (foot of the left small circle; the sort looks small): point on the left small circle
- D (lower right of the left small circle): point on the left small circle
- L (below and to the left of the left small circle): end of the shallow arc
- F (top of the central circle): axis point
- E (upper left of the central circle): end of the oblique diameter
- I (centre of the central circle): centre

- Q (lower right of the central circle): end of the oblique diameter
- H (foot of the central circle): axis point
- A (upper left of the right small circle): point on the right small circle
- B (top of the right small circle): point on the right small circle
- V (top right of the right small circle): point on the right small circle
- N (centre of the right small circle): point on the Moon's orbit
- D (right of the right small circle): point on the right small circle
- S (lower left of the right small circle): point on the right small circle
- C (foot of the right small circle): point on the right small circle
- M (below and to the right of the right small circle): end of the shallow arc
- P (foot of the large arc, below the central circle): point on the Moon's orbit

[Margin: The uncertainty of judicial astrology.] IV. From the variation and libration of the lunar spots, unknown for so many centuries before, no less than from the companions of Jupiter and Saturn, unrecognised before this century of ours, and their motions, or from the alternation of the solar spots, no small argument can be drawn against the certainty of judicial astrology. For it is most probable that from the variation of these too there are different celestial influences on these lower things.

CAPVT X. De loco Lunæ in Vniuerſo.

Chapter 10. On the place of the Moon in the universe.

I. Since astronomy began to hanker after Copernicus [Copernicoturire], the place of the Moon in the universe has not been so certain, if it is referred to the centre of the world; but if to the centre of the Earth, then Pliny the Elder, Book 2, chapter 9, truly calls the Moon *the last of the stars, and the one most familiar to the Earth*. And in the *Dream* Cicero's Scipio is told: *Furthest from heaven, nearest to the Earth.* It is entirely certain to astronomers that of all the planets, let alone the fixed stars, the Moon is nearest to the Earth, and indeed that it holds the lowest heaven, if the Earth is at the centre of the world. This is shown by four arguments, by which the order of the planets in the universe, but above all of the Moon, is confirmed by Copernicus, Book 1, chapter 10; by Johannes de Sacrobosco in the *Sphaera*, chapter 1, and there by his commentators, listed by us in Book 1, in the preface, chapter 1; above all by Clavius, from p. 39 to 72; by Barozzi in the *Cosmographia*, Book 1, from p. 8; by Maurolico, dialogue 1 of the *Cosmographia*, p. 20; by Finé in the *Sphaera*, Book 4, chapter 8; by Biancani, Book 9 of the *Sphaera*, chapter 1; and by the rest who were cited on the constitution of the world system in Book 3, chapter 6.

[Margin: 1st argument for the Moon's nearness to the Earth.] II. The *first* argument is from the shadow. For that star which, at equal altitude above the horizon, ends with its ray a longer right shadow of the same gnomon is nearer to the centre of the gnomon, and so to the Earth, if the gnomon is erected on

the Earth. But the right shadow of the Moon is longer than the shadow of the Sun having the same altitude, and also than the shadow of Jupiter and of Venus (for it is almost impossible to discern the shadows of the other planets); therefore the Moon is lower than these. So in the diagram added here, if the style CR is erected above the horizon ACB, and the Sun S and the Moon L are at the same altitude above the horizon, though at different times, namely on the line SC, the lunar shadow will be CK, much longer than the solar shadow CG; therefore the Sun moves in a higher heaven. The argument must, however, run the contrary way from versed shadows, which are cast by styles fixed in walls: for such shadows of the higher stars are longer than the shadows of the lower.

Diagram. A geometric figure in the left column, with the text of the argument running in a narrow strip to its left. Two concentric-looking semicircles stand on a common base line; the base is the horizon. An upright stands on the base at C. The Sun, drawn as a small rayed face at S, stands on the outer semicircle at upper left; the letter L stands on the inner semicircle, below and to the right of S. Straight lines run down from the upper left through the head of the upright at R to the base at G and at K, and a line runs down to C. Labels read:

- A (left end of the base): end of the outer semicircle
- D (left end of the base, inside A): end of the inner semicircle
- C (base, foot of the upright): foot of the style
- G (base, to the right of C): end of a shadow
- K (base, immediately right of G): end of a shadow
- E (right end of the base, inside B): end of the inner semicircle
- B (right end of the base): end of the outer semicircle
- S (upper left, in the rayed Sun): the Sun
- L (on the inner semicircle, below S): the Moon
- R (head of the upright): head of the style

[Margin: 2nd argument.] The *second* argument is from eclipses. For the Moon alone is eclipsed by the shadow of the Earth; the other planets do not fall into it, but because of their greater distance from the Earth they pass high above it. Next, the Moon hides from us and eclipses not only the Sun but all the other planets and many of the fixed stars, and indeed in all parts of the zodiac; whereas it has never been seen to suffer eclipse by any other star, or to be covered in any part of itself. Therefore the Moon is of all the stars the nearest to the Earth.

[Margin: 3rd argument.] The *third* argument is drawn from the speed of its proper motion. For, as the writers on optics demonstrate with Euclid, of things carried at equal speed, those that are further away appear to move more slowly. But the Moon completes the zodiac most quickly of all the stars, namely in a monthly course, whereas Mercury takes 88 days, Venus 9 months, the Sun one year, Mars about 2 years, Jupiter 12, Saturn 30, the fixed stars nearly 30000. But the theorem of the writers on optics is wrongly applied to this subject: for the

planets are not in fact moved equally and only in appearance unequally. Next, if the daily motion is considered, the Moon returns to the same meridian more slowly than any of the planets; and yet, because of this slowness, the lowest place seems due to it, since of circles described from the same centre and moved by the same motion, those nearer the centre move more slowly, as they traverse a shorter space in equal time. But this example does not suit the Moon either, because it does not return at the same moment to the same meridian, as the points of those circles do, once placed on the same radius, or on a straight line that can be drawn from the centre; and so this argument is topical rather than apodictic. Which authors, further, have assigned the Nete to the Moon, and which the Hypate, in distributing the harmonic intervals, and for what reason, we have already indicated in Book 3, chapter 7, in Scholium 4, but we shall set it out more fittingly in Book 9, section 5, chapter 7.

[Margin: 4th argument.] The *fourth* argument is taken from parallax, for which consult what was said in Book 1, chapter 35, and the figure placed there. For we showed that the star which, other things being equal, undergoes a greater parallax when viewed from the surface of the Earth is nearer to the Earth; and the Moon's horizontal parallax is, in the opinion of all astronomers, of very nearly one degree, whereas the parallaxes of the other planets scarcely reach 6′ each, as will be established from what is to be said in its place; and for the Sun we have already shown it in Book 3, chapter 8.

[Margin: The place of the Moon in the system of Copernicus and of Baliani.] III. In the Copernican system, however, set out by us in Book 3, chapter 6, the Moon is not nearest to the centre of the universe, at which the Sun is there placed; rather, Mercury and Venus are nearer to it. And in the system that D. Giovanni Battista Baliani, patrician of Genoa, was working out so as better to explain the tide of the sea, the Moon had to be at the centre of the world, and the Earth to be turned around it as it stands still, in a monthly revolution. As to what follows from this hypothesis, both in the phases of the Moon and the position of the spots and in the syzygies of the Sun with the Moon, this is not the place to treat it, but rather the book on the systems of the world. For it is enough here to state that of all the stars the Moon is nearest to the centre of the Earth.

CAPVT XI. De Methodo in communi, qua ſine vitioſo circulo, Lunæ Parallaxes, & inde Solis & aliorum Planetarum diſtantię ac Parallaxes inquiruntur.

Chapter 11. On the method in general by which, without a vicious circle, the parallaxes of the Moon, and from them the distances and parallaxes of the Sun and the other planets, are investigated.

[Margin: Doubt about a vicious circle in this analysis.] I. The parallax of the Moon is the foundation of all stellar parallaxes, since on it depends the knowledge of the Moon's distance from the Earth; on the lunar distance, the

distance of the Sun and its parallax, as is clear from the method given in Book 3, chapters 7 and 8; and on the distance of the Sun depend the distances and parallaxes of the other planets, and indeed of the fixed stars, as we shall show in their places. In this analysis, however, one must take care lest a deceptive circle mock astronomy with giddiness or perpetual uncertainty, as someone has indeed feared: because the motions of the stars cannot be known without observation, and parallax is always involved in observations made on the surface of the Earth and concerning stars placed away from the observer's zenith, and very sensibly so in the Moon, because of its nearness to the Earth. Without knowledge of the parallaxes, moreover, the true places of the stars and their true motions, which must be referred to the centre of the world, cannot be distinguished from those apparent to us who observe them on the surface of the Earth. If, therefore, the parallaxes depend on the motions, and the motions on the parallaxes, as known beforehand, we seem to drive and torment astronomers into a vicious circle, as onto the wheel of Ixion. And lest you think that this fear belongs only to newcomers, hear Kepler in a letter to Giovanni Antonio Magini dated 1601 June 1, which Magini himself reproduces in the *Supplement to the Ephemerides*, p. 253. *The theory of the Moon*, says Kepler, *gives Tycho much difficulty. It seems to me that it must be begun from the parallaxes, which occur because of the sensible distance between the centre and the surface of the terrestrial globe. But the doctrine of parallaxes is confounded with the latitudes of the Moon. There would therefore be need of prior knowledge of the latitudes. Each depends on the other.* He then adds three methods, resting content only with the last of them; but they had not then been brought to practice, nor were they later by Magini or Kepler, so far as I know; nor can they easily be brought to practice, as I shall indicate in the following chapter. What Theseus, then, might hold out to us the thread for escaping from this labyrinth? Yet take heart, reader: for here is the thread.

[Margin: The foundations of astronomical observations, and the first step.] II. *First*, finding the meridian line does not depend on parallaxes, as is clear from what was said in Book 1, chapter 10. Once it has been obtained, the altitude of the equator is taken from the two altitudes of a circumpolar star, according to what was said in Book 1, chapter 12, without any inconvenience from parallax. For the fixed stars have no sensible parallax, since the distance of the pole star from the pole has been found to be the same at the same time by observers at very different altitudes of the pole, for example by Tycho in Denmark and by others in Italy; and I now find it as far from the pole as the observation made by Tycho requires, as I shall say in the book on the fixed stars. This would not happen if it had a sensible parallax, for the difference of parallaxes at different altitudes would bring about a different distance of the star from the pole. Besides, there are various ways of discerning whether a phenomenon is subject to sensible parallax (on these, see the book on new phenomena) that do not depend on prior knowledge of the parallax.

[Margin: Step 2.] *Second*, from the Sun's meridian altitude taken on the day of the summer solstice, when it no longer increases, and compared with the altitude of the equator, one obtains the Sun's greatest declination, or the apparent obliquity of the ecliptic, which suffices for the purpose for the time being. From the Sun's meridian altitude taken on the day of an equinox, and from the apparent obliquity of the ecliptic, the apparent equinox is derived by the method given in Book 3, chapter 14. From two equinoxes separated by a very long interval of time, and from the Sun's place between two equinoxes, according to what was said in Book 3, chapters 15, 17 and 24, one derives both the quantity of the equinoctial year, and from it the Sun's mean motion, and the Sun's apparent apogee, and from it the prosthaphaeresis, by which the Sun's mean place is reduced to the true place without any error that would disturb our business in the meantime, even if merely the apparent equinoxes and the apparent apogee have been used. For in this way one knows in what degree of the ecliptic the Sun is at any given time, even though the exact minutes are not yet established.

[Margin: Step 3.] *Third*, from the beginning and end of a lunar eclipse its middle and the moment of full Moon are discerned; and from the degree of the ecliptic known for that moment, in which the Sun is, the opposite degree, in which the Moon is, is recognised. By comparing eclipses observed in antiquity by the Chaldeans and Egyptians with more recent ones, the Moon's mean motion, of anomaly and of latitude, is investigated by the method to be given below; and in this, because of the very long interval of time, no notable error in the Moon's revolutions can arise. From the true place, known through eclipses of the Moon or through the distance from known fixed stars of the Moon placed in the nonagesimal, the equations are derived, that is, the differences between the mean place and the other [medium vtrumq. locum] [recte: *medium verumq. locum*, "the mean and the true place", per the book's errata].

[Margin: Step 4.] *Fourth*, the Moon's greatest latitude, by which it departs from the ecliptic, is taken as having been observed somewhere when the Moon was at or near the observer's zenith, as once happened for Ptolemy at Alexandria when the Moon was at the beginning of Cancer; or as observed from eclipses of the Moon, which is done independently of the Moon's parallax. Then, once the Moon's altitude has been observed with instruments, and the Moon's place and its latitude have been computed by tables from the motion of latitude and the angle of greatest latitude, one learns how great its true altitude ought to be at such a horizon and such a time. The difference between the true and the observed altitude therefore reveals the parallax of the Moon.

[Margin: Step 5.] *Fifth*, from the Moon's parallax its distance from the Earth is derived, by the problem given in Book 3, chapter 7; and when the Moon's altitudes have been observed at different seasons of the year, its various parallaxes and distances are derived. From these the distance of the Sun is then derived by one of the methods given in Book 3, chapter 7, and when this has been found, the parallax of the Sun, according to what was said in the same place, chapter 8.

Once the Sun's parallax has been found, its motions are corrected; and, going back over the steps, all the observations treated from number 2 here to this number 4 are revised, and the true obliquity of the ecliptic, the true equinoxes, the true place of the Sun at the moment of an eclipsed full Moon, and from it the true place of the Moon, are deduced, according as the method used in these observations is more or less accurate.

III. By this method, after the observations of so many centuries, astronomy has at last advanced so far that we are now certain that the Moon's least distance from the Earth exceeds 30 semidiameters of the Earth and does not exceed 80; indeed, if we rely on the observations of this and the preceding century, that it does not exceed 70 and does not fall short of 50, and that its horizontal parallax is not less than 50′ and not greater than 70′. As for the distance of the Sun from the Earth, it is neither less than 650 semidiameters of the Earth, with a horizontal parallax of at most 5′, nor greater than 16,500 semidiameters of the Earth, with a least parallax of 14″. Astronomy acknowledges, and glories in the fact, that it has advanced far enough in so deep an investigation: for by setting up its calculations within these limits it has up to this day foretold to mortals the motions of the planets, and especially the eclipses of the Moon and the Sun, with a certainty such as it seemed unable even to hope for from so many windings, and such as suffices for human use in this life. Thus it is evident to astronomy itself, a posteriori, that it has not laboured in vain in going round through a vicious circle. Yet it labours still to attain greater precision and subtlety; and what chiefly stands in the way of this is certainly not ignorance of the most exact parallaxes, but the multitude of observations and motions to be reconciled, whose errors, small one by one, nevertheless turn out rather large when taken together. Still, it was worthwhile to know this very thing, so that it should not be unknown how far the hopes and efforts of astronomy can extend. Meanwhile we owe a very great deal to Ptolemy, who observed the Moon's greatest latitude for us, without which the inquiry into parallaxes is undertaken in vain. The rest depends chiefly on the true longitude, known with the help of eclipses, or from the Moon's distance from the Sun or from fixed stars of known longitude when the Moon is in the nonagesimal degree of the ecliptic, where it has no parallax of longitude.

SCHOLION.

Scholium.

[Margin: The back-to-front method of Hipparchus.] We have said that one must begin from the parallax of the Moon, so that from it its distance from the Earth may be determined, through this the distance of the Sun, and from that the parallax of the Sun, following, that is, Ptolemy in Book 5 of the *Almagest*, chapter 11, and the greatest part of astronomers. Yet Ptolemy relates in the same place that Hipparchus tried to investigate first the distance of the Sun from the Earth, and from it the distance of the Moon. Having obtained the

Sun's distance as if by conjectures, first supposing a very small solar parallax, then now a greater one, now none that is sensible, and weighing a certain eclipse, he derived from it various and inconstant distances of the Moon. But these were mere conjectures, exposed to fallacies or to misgiving, since about the Sun it is altogether doubtful not only how much parallax it has, but even whether it has any at all, as Ptolemy says in the same place.

CAPVT XII. De Obſeruanda Latitudine Lunæ maxima in gratiam Parallaxium, cæterisq. latitudinibus ex illa eliciendis: Et de Opinionibus Aſtronomorum circa hanc Latitudinem.

Chapter 12. On observing the Moon's greatest latitude for the sake of the parallaxes, and on deriving the other latitudes from it; and on the opinions of astronomers about this latitude.

[Margin: What the Moon's latitude is.] I. The inquiry into latitude in Ptolemy, Book 5, chapter 12, rightly comes before the inquiry into parallaxes. The latitude of the Moon is the arc of a great circle drawn through the centre of the Moon and the poles of the ecliptic, intercepted between the ecliptic and the centre of the Moon. This arc, like every circle of latitude, makes right angles with the ecliptic. [Margin: And the greatest latitude.] The Moon's greatest latitude, therefore, is the Moon's greatest distance from the ecliptic, reckoned on the arc just mentioned, and measuring the angle at which the Moon's orbit is inclined to the ecliptic. [Margin: What the nodes are, and how many.] For the Moon does not always travel along the ecliptic, but along another circle cutting the ecliptic in two opposite points. One of these is called the Northern Node, or the Ascending, or the Carrying-up [Euehens] Node; in Ptolemy [Greek: σύνδεσμος ἀναβιβάζων (syndesmos anabibazōn, "ascending node")]; in Arabic the Dragon's Head. When the Moon begins to approach it, receding from the opposite node, it is said to ascend, and for brevity this node is indicated by the mark ☊. The other is called the Southern Node, or the Carrying-down [Deuehens] Node; in Ptolemy [Greek: σύνδεσμος καταβιβάζων (syndesmos katabibazōn, "descending node")]; in Arabic the Dragon's Tail. The Moon, on approaching it, is said to de- scend, and it is marked thus: ☋. These nodes are not fixed, but move toward the preceding signs, westward, by 3′ 11″ each day, as we shall show later. At these nodes the Moon has no latitude; at a distance from them of a whole quadrant, or 90°, it has its greatest latitude, and these points are called limits, or bellies of the Dragon. For the lunar orbit AEBD, cutting the ecliptic ACBF at the Southern Node A and the Northern Node B, and having its greatest latitude at the points EC and DF, forms as it were two snakes, with the head at B, the tail at A, and the swelling of the belly at E and F. Hence, when these nodes are joined with the nodes of the ecliptic and the equator, that is, at the beginning of Aries and Libra, the limits of greatest latitude are at the beginning of Cancer and Capricorn. Just as the place of the nodes on the ecliptic can be known from the motion of latitude, gathered from

eclipses independently of parallax, so the place of the limits can be known, since it lies 90° from the place of the nodes; and therefore also when the greatest latitude will fall at the beginning of Cancer and Capricorn.

Diagram. Woodcut set into the left column at the right of the text: two circles of about equal size, slightly displaced, crossing one another at left and right, showing the lunar orbit crossing the ecliptic.

Primus Modus obſeruandi Latitudinem Lunæ.

The first method of observing the Moon's latitude.

II. The first method is through the Moon's meridian altitude observed when the Moon is at the observer's zenith, or as near it as possible, so that it has no parallax or almost none, and when at the same time it has its greatest latitude at the beginning of Cancer and Capricorn, that is, has its nodes at the equinoctial sections. For then the same meridian becomes not only the circle of declination and of altitude, but also the circle of latitude and the solstitial colure, as is certain from the doctrine of the primum mobile. Now if the latitude is northern, subtract from the lunar altitude the sum made up of the altitude of the equator and the distance of the tropic from the equator; if the latitude is southern, subtract the lunar altitude from that sum. The remainder will be the Moon's greatest latitude. This method is given by Ptolemy, Book 5, chapter 12, by Regiomontanus in the *Epitome of the Almagest*, Book 5, Proposition 14, and by Copernicus, Book 4, chapter 15.

EXEMPLVM Ptolemaicum.

Ptolemy's example.

[Margin: Ptolemy, Book 5, chapter 12.] For the sake of the parallaxes Ptolemy built an instrument of three four-sided rulers, which he therefore called parallactic, although it serves for taking the altitude of any star, as will be clear from our *Liber Organicus*. Using this instrument at Alexandria, where, on his own testimony, the altitude of the equator is 59° 2′, he observed the Moon's meridian altitude as 87° 53′, when it was established from the tables of the lunar motions that the Moon had its greatest latitude, a northern one, at the beginning of Cancer. The distance of the tropic from the equator, as he judged from his own observation and that of Eratosthenes, was 23° 51′ 20″. The sum of this and the altitude of the equator was therefore 82° 53′ 20″. When this was taken from the Moon's observed altitude of 87° 53′, there remained the Moon's greatest latitude of 4° 59′ 40″. He considered this accurate enough, because the

Moon was very near the zenith and only 2° 7′ away from it, where the lunar parallax is less than 3′; and he set it at a round 5°.

All astronomers down to Tycho acquiesced in this, together with al-Battānī, Jābir ibn Aflaḥ, Alfonso, Peuerbach, Copernicus and Reinhold, who fixed the Moon's greatest latitude at 5° without carrying out any similar observation, because they were not at a suitable horizon, one at which the Moon would ever be little distant from the zenith and free of notable parallax, but confirmed it in some fashion from eclipses.

Secundus Modus.

The second method.

[Margin: Inhabitants of the torrid zone, or near the tropics, are suited to this.] III. Let the Moon's distance from two fixed stars of known longitude and latitude be observed by inhabitants who at times have the Moon at or very close to the zenith, but at the same moment, by four observers, two using one sextant and two the other. For from these distances the latitude and longitude of the lunar body can be found by the common problems of the primum mobile. But that moment of time must be observed as well, so that, once it has been converted into equal time, the place of the nodes may be investigated by tables, and from it the Moon's distance in longitude from the nearer node. If this is 90°, the Moon's latitude found above will be the greatest; if it is less than 90°, then with this distance as a base, and with the latitude found, in a spherical triangle, the angle opposite the latitude found must be sought by the common rules of triangles, for it will be the measure of the greatest latitude.

Tertius Modus.

The third method.

[Margin: By an eclipse of 6 digits.] IV. The third method requires a lunar eclipse of exactly six digits, out of the twelve of the lunar diameter, which rarely occurs. Let the moment of the beginning and end of the eclipse be observed exactly, so that, half the difference being added to the beginning itself, the moment of the greatest and middle eclipse may be established. For that moment, gather from the tables the place of the nearer node and the place of the centre of the Earth's umbra, which is always 180° from the place of the Sun. Finally, let the semidiameter of the Earth's umbra at the place of the Moon's passage be known, either from tables or from an observation made at the time. With these things set down, let the portion of the ecliptic be AC, and the cen-

Diagram. Woodcut across the right column, interrupting the sentence. A nearly horizontal line runs from A at left to C at right. A large circle, centred at about B on that line, represents the umbra. From C a second straight line slopes down to the left through P, M and F to D. Three small equal circles stand on this sloping line, centred at P (right), M (middle, its upper part inside the large circle and hatched) and F (left). Straight lines run from the point at B

to M and toward O and L; short perpendiculars drop from G toward F, from E toward M and from I toward P.

- A (left end of the horizontal line)
- G (on the horizontal line, inside the large circle, left)
- B (on the horizontal line, centre of the large circle, per the prose)
- E (on the horizontal line, immediately right of B)
- I (on the horizontal line, right, above the small circle P)
- C (right end, where the two straight lines meet: the node, per the prose)
- L (on the line from B toward P)
- O (at the left, where the large circle meets the circle about F)
- M (centre of the middle small circle, the Moon at mid-eclipse, per the prose)
- P (centre of the right small circle)
- F (centre of the left small circle)
- D (left end of the sloping line)

tre of the umbra B; let the Moon's orbit, touching the periphery of the umbra at M, be CMD; from the centre M let the lunar disc be described, whose semidiameter, that is, six digits, is eclipsed at the height of the eclipse; and let the semidiameter of the umbra, BM, be drawn to the centre of the Moon and the point of contact. The triangle CBM will then be right-angled at M. In it, therefore, given the side BM, which is the semidiameter of the umbra, and the base BC, the distance of the node C from the centre of the umbra B, you will find by the rules of trigonometry the angle C, which measures the Moon's greatest latitude. Nor does ignorance of the parallax do harm here: since the centre of the umbra B is at the same distance from the Earth as the centre of the Moon M, they have equal parallax, and so the semidiameter BM is not diminished. It should also be noted from Kepler, *Astronomia Optica*, chapter II, Problem 6, that the eclipsed digits are more easily discerned when they are exactly 6 than when they are more or fewer.

EXEMPLVM. Ex Noſtra Obſeruatione.

An example from our own observation.

[Margin: Eclipse of 6 digits.] In the year 1643 September 27, on the following night, I observed at Bologna, from the altitude of Aquila at the end and using the oscillations of a pendulum from the beginning, the start of a lunar eclipse at $6^h\ 18^m\ 15^s$ after noon and its end at $8^h\ 43^m\ 30^s$; the middle was therefore at $7^h\ 30^m\ 52^s$. The digits at the height of the eclipse were, through telescopes and also with the naked eye, by the agreement of all the witnesses, exactly 6, which is also the number Lansbergen's tables require. The semidiameter of the umbra, observed by the method to be given below on eclipses, and from the distances of the luminaries, was 48′. The Sun's place at mid-eclipse was ♎ 4° 29′ 34″; therefore the place of the centre B was ♈ 4° 29′ 34″. The place of the northern node was ♍ 25° 16′ 28″, and that of the southern node C ♓ 25°

16′ 28″; therefore the distance of the centre, or BC, was 9° 13′ 6″. Let us now use the figure given above, just as if the southern part of the Moon had been eclipsed, for the calculation will come to the same thing. In triangle BMC, therefore, right-angled at M, from the base BC of 9° 13′ 6″ and the side BM of 48 [Gr.48.][27], there results the angle C of 5° 0′ 3″.

Quartus Modus.

The fourth method.

[Margin: Other eclipses suited to this.] V. The remaining eclipses of the Moon, however, serve this procedure, if the moments of beginning and end are observed exactly, so that the middle may be established; if the apparent semidiameters of the Earth's umbra and of the Moon at this time are observed or given; and if the Moon's latitude is of the same kind from the beginning to the end of the eclipse. For in the same figure let the Moon at the beginning of the eclipse be at P, touching the periphery of the umbra at L, and at the end at F, touching it at O. By Euclid, Book 3, proposition 12, the straight line connecting the centres of the umbra and of the lunar disc, such as BP and BF, will pass through the points of contact L and O. Hence, when the known semidiameters of the umbra and the Moon are added together, the straight lines BP and BF will be known; and within the few hours the eclipse lasts these do not vary sensibly. The triangle FBP is therefore isosceles, and the straight line BM, bisecting FP at M, will be perpendicular to the Moon's orbit and will make right angles at M, by the converse of proposition 10 of Book 1 of the *Elements*; and triangle MBP will be right-angled at M. In it the base BP is known, namely the sum of the semidiameters of the umbra and the Moon, and also the side MP, because it corresponds to the Moon's hourly motion from the beginning to the middle of the eclipse, known from tables. So by trigonometry the side BM becomes known. Again, in triangle CBM, right-angled at M, the side BM is now known; and from the moment of mid-eclipse and the tables of the Moon and Sun the place of the umbra B and of the nearer node C, that is, the base BC, is known. So by the rules of spherical and right-angled triangles the angle C, measuring the Moon's greatest latitude, will not remain hidden. In the same way different eclipses can be weighed, and it can be discerned whether the data agree among themselves and with the latitude. I admit, however, that an estimate of the umbra made by eye is unreliable, as Kepler notes at the front of the ephemeris for the year 1619.

I pass over the remaining methods, which presuppose that the Moon's parallax is known, because in this place we are investigating the latitude in order to learn through it the parallaxes, still unknown.

[27] the page sets this side with the degree abbreviation; the same semidiameter is stated just above as 48′

Data Latitudine Maxima Lunæ, reliquas eius latitudines inueſtigare ad quamcunque diſtantiam eius à Nodo.

Given the Moon's greatest latitude, to investigate its other latitudes at any distance of it from the node.

VI. Let A be the node at which the Moon's orbit intersects the ecliptic; let AC be a quadrant of the ecliptic and AD a quadrant of the lunar orbit; and let DC be the arc of greatest latitude, making a right angle with the ecliptic at C. This arc is what angle A measures, and the angle has as many degrees as the arc DC. Let the Moon be, not at D, the limit of greatest latitude, but at E, and from this point let the arc of latitude EB be drawn perpendicular to the ecliptic. This produces the spherical triangle ABE, right-angled at B, in which the angle A is given, being as great as the greatest latitude. If, then, the base AE is given, namely the Moon's distance from the nearer [ptopiore] [recte: propiore] node on its own orbit, or is supposed given, the side EB, namely the Moon's latitude belonging to it at point E, can be found by the rules of trigonometry; and likewise for the others.

Diagram. Woodcut set into the left column at the right of the text: a curved triangle with a cross-arc. An upper arc runs from D at left through E to A at right; a lower arc runs from C at the foot up through B to A; a straight-drawn arc DC closes the left side, and a second arc runs from E down to B.

- D (upper left): limit of greatest latitude, per the prose
- E (above the upper arc): the Moon's place, per the prose
- A (right): the node, per the prose
- B (on the lower arc, where the arc from E meets it): per the prose, foot of the arc of latitude EB
- C (foot): on the ecliptic, per the prose

Opiniones Aſtronomorum, de Maxima Lunæ Latitudine.

Opinions of astronomers on the Moon's greatest latitude.

[Margin: The opinion of the Tychonians.] VII. I have already reported Ptolemy's opinion and its foundation at number 2, in the example, and added that all astronomers down to Tycho judged that the Moon's greatest latitude is always 5°, both in ☌ and ☍ and in □. No wonder they acquiesced in it, since they saw that it satisfies the phenomena of eclipses very nearly. Tycho, however, in volume 1 of the *Progymnasmata*, p. 126, and in the *Letters*, p. 140, agreeing with Rothmann, asserts that up to his own time the Moon's greatest latitude was wrongly thought to be invariably 5°; for it was evident to him from his own most diligent observations that the Moon's greatest latitude at new and full Moons is indeed very nearly 5°, that is, 4° 58′ 30″, but at the quadratures [Quadris] 5° 17′ 16″. Tycho was endorsed by Longomontanus in the *Astronomia Danica*, Book 1 of the *Theorica*, chapter 7; by Magini in the *Supplement to the Ephemerides*, Canon 8; by Nicolaus Mulerius in the *Isagoge* to the *Tabulae Frisicae*, part 2, chapter 6; and by Boulliau in *Astronomia Philolaica*,

Book 3, chapters 12 and 16, who considers it a matter of scruple to depart from the Tychonic latitude, since he has quite often found by experience that *in applications of the Moon to the fixed stars it agrees exactly with the sky*. Lansbergen too dissents very little, in chapter 5 of the *Theoricae* and in precept 9, setting the Moon's greatest latitude at the syzygies [Copulis] at 5° and at the quadratures at 5° 16′, confirming this by no particular observation. Tycho, on p. 114, gives four observations of the lunar latitude taken at Uraniborg, not indeed of the greatest latitude, but ones by which his table and hypothesis of the Moon's latitude can be confirmed; these, however, presuppose that the Moon's parallax is already known.

[Margin: The opinion of Kepler.] VIII. Kepler, moreover, at the front of his *Ephemerides* from number 21 to 24, and in the Rudolphine Tables, chapter 27, retains the Moon's greatest latitude of 5° at other syzygies, but at quadratures 5° 18′. In eclipses of the Sun and Moon, however, he sets the angle of greatest latitude at 5° 18′, constant for almost the whole of that month in which the Sun walks through the places of the nodes, as if the inclination of the lunar eccentric to the ecliptic stayed through that whole month and were as great as at the quadratures. But when the nodes are in quadrature, he sets the greatest latitude at 5°, as great as at non-eclipsing syzygies; and he says he is compelled to this variation both by the form of his physical hypothesis and by eclipses. Yet he adds there and in precept 128 that he has relapsed into the Tychonic equipollence, and that by as much as he increased the latitude in eclipses he diminished the annual prosthaphaeresis of the nodes, which for Tycho is monthly; and that therefore as great a latitude of the Moon is derived from them on his hypothesis as on the Tychonic. However, how much the Rudolphine Tables disagree with eclipses is now acknowledged among recent astronomers; and no wonder, since Kepler indulged his own ingenuity more than the sky, and the mysteries of his own ideas more than inviolate observations. He also notes that Ptolemy and Tycho kept the Moon's greatest latitude at the syzygies equal to the equation at 90° of anomaly.

[Margin: The opinion of Godefridus, and ours.] IX. Govaert Wendelen, in the *Idea of the Atlantic Tables*, p. 30, says that the Moon's greatest latitude at the syzygies is most precisely 5° 0′; but what he himself or van Langren thinks of it outside the syzygies is not yet known. For our part, from many eclipses weighed by the problem treated in methods 3 and 4, as will be clear from volume 3 of the *New Almagest*, it is established that even at eclipsing syzygies the Moon's greatest latitude is so close to 5° that an excess or shortfall of a few minutes, let alone many, cannot be proven by any observation, and it can be kept unchanged with the slightest little correction of the semidiameters and motions. On the quadratures, see Scholia 1 and 3.

LATITVDO LVNAE MAXIMA.

The Moon's greatest latitude.

SCHOLIA.

Scholia.

I. Anyone who knows the parallactic rulers [Regulas Parallacticas] and how they are used from experience will recognise how easy it is to err with them by several minutes, especially when the star to be observed is very near the zenith. For the eye to be properly applied to the pinnules [pinnacidijs], one must have the head tilted back, and in fact lie with the whole body; otherwise the eye usually judges the altitude greater than it should. Since, therefore, Ptolemy observed the Moon very near the zenith with this instrument, it is very probable that he assigned it a somewhat greater altitude, or a smaller distance from the zenith, and thus a greater latitude than he would otherwise have given. See what we shall say in the *Liber Organicus* of volume 2 of the *New Almagest*, on the parallactic rulers, and meanwhile what Tycho says about them in the *Mechanica Astronomica*. Relying meanwhile on this probability, I have cut off two minutes and corrected the Moon's latitude, of which I shall speak in Scholium 3, so that it is 5° 18′ at □.

II. Tycho (volume 1 of the *Progymnasmata*, p. 127) and Longomontanus (*Theorica*, Book 1, ch. 7) judge that Ptolemy observed the Moon's greatest latitude as 5° when the Moon was at the beginning of Cancer in such a way that it was also in quadrature aspect to the Sun. This is not improbable, for Ptolemy (Book 5, ch. 13) states that he observed the Moon near the beginning of Capricorn crossing the meridian at sunset, when the Sun was at 5° of Libra, and so very nearly at □ itself, and he says that the Moon's latitude was 4° 59′. Just as it was here almost 5° and at greatest latitude, so it seems to have been when, at the beginning of Cancer, it was seen to have a latitude of 5°. Tycho and Longomontanus add, however, that in this century the greatest latitude of ☾ is 5° 17′ ½ at □, but that the 5° Ptolemy found at those points arose because

the obliquity of the ecliptic was then greater, and 23° 51′ 20″. For had it been, as now, 23° 30′ or 31′, then, added to the altitude of the equator, which at Alexandria is 59° 2′, the meridian altitude of the tropic of ♋ would have been 82° 32′ or 33′; and this, subtracted from the observed altitude of the Moon, 87° 53′, would have left a latitude of 5° 21′ or 20′, about as much as Tycho at □ and Rothmann found.

But how is it probable that at the syzygies [Copulis] the Moon has always kept its greatest latitude of 5°, yet at □ has increased it by just as much as the obliquity of the ecliptic decreases? Either, on the course of its orbit, it has regard to the ecliptic only, and so ought to have kept the same inclination to it at the syzygies as at the quadratures [Quadris]; or it has regard to the equator, and only incidentally to the ecliptic, and so, as the declination of the ecliptic decreased, it ought nevertheless to have kept its own greatest declination constantly, and thus, the latitude at the quadratures being incidentally increased by this, it ought to have increased the latitude at the syzygies too. Although Kepler grants this in part, Tycho and Longomontanus deny it. Should we then rather say what I shall shortly say in Scholium 3?

III. If the obliquity of the ecliptic has always been the same as it is now, 23° 30′, which I showed in Book 3, ch. 27 to be far more probable, then certainly the Moon's greatest latitude observed by Ptolemy at □ must either be corrected, so that it was about 5° 20′, or, because of what was said in Scholium 1, 5° 18′; or else his observation, as regards the altitude of the Moon, must be suspected of error, for the reason indicated in Scholium 1. But if the obliquity of the ecliptic was then 23° 30′ and the greatest latitude at □ 5° 20′, it follows from Ptolemy's other observation that the Moon's parallax is 1° 48′, as I shall show in the next chapter at the end of number 2, and this seems quite absurd. So let the astronomers see what solution they can apply to this knot. For I have not yet been able to observe the Moon's latitude at the quadratures independently of parallax, which, being unknown, is assumed here. For at Bologna the Moon is always far from my zenith, and at □ it has never crossed the meridian at the moment when, according to the ephemerides, it was at the node. Nor do I think this opportunity was ever offered to Tycho himself, whether you run through the ephemerides from the year 1570 to 1601 or what Kepler writes to Magini in the year 1601, to be reported shortly in ch. 13, no. 10. And in the Rudolphine Tables, ch. 27, he too says of this matter: "But the matter is not yet clear in every respect."

CAPVT XIII. De Diſtantijs Lunæ ex Parallaxibus, & de Parallaxibus ex obſeruatione inueſtigandis.

Chapter 13. On finding the Moon's distances from its parallaxes, and its parallaxes from observation.

I. Let the reader recall what I said about parallaxes in general in Book 1, ch. 35, or about the Sun's parallaxes in Book 3, ch. 8. For it follows from what was

said there that the measure of a star's horizontal parallax is the angle B, if the star is at B, on the boundary of the physical horizon AB, which is parallel to the rational horizon HR; and, when the straight line HB is drawn from the Earth's centre H, the triangle HAB arises, right-angled at A. In that triangle, therefore, given the parallactic angle B and from it AHB, as its complement to a right angle, and the opposite side AH, taken as one semidiameter of the Earth, the base HB, that is, the star's distance from the Earth's centre in parts of which AH is one, is easily obtained by the rules for right-angled plane triangles. In brief: if the secant of angle AHB is divided by the radius, or whole sine, or if you look up the residual of the logarithm of angle B, you will have the base HB, or its logarithm.

Diagram. Woodcut set into the right column at the right of the text. A quadrant has its right angle at H (lower left), with one radius rising to V at the top and the other running along the foot to R at the right; an arc runs from V through S and B to R. A stands on the vertical radius HV, and from it a smaller arc descends to C on the foot line HR. Straight lines join H to S and H to B, and A to S and A to B.

- V (top of the vertical radius): the point directly overhead
- S (on the great arc, upper right): the star when its parallax is not horizontal
- B (on the great arc, right): the star on the physical horizon
- A (on the vertical radius): the observer on the Earth's surface
- H (lower left): the Earth's centre
- C (below the foot line, at the foot of the smaller arc): not cited in the prose
- R (lower right): end of the rational horizon HR

However, if the parallax is not horizontal, as with the angle S, then, when the straight lines HS and AS are drawn from the Earth's centre H and from the surface A, since the star's apparent distance from the zenith is given, namely the angle VAS, its complement to two right angles is also given, and so the angle HAS, together with the parallactic angle S corresponding to that distance, and AH as one semidiameter. In the triangle AHS the side HS can therefore be found, which is the star's distance from the Earth's centre. In brief: divide the sine of angle VAS, or of the apparent distance from the zenith, by the sine of the parallactic angle S; or add together the logarithm of angle VAS and the residual of the logarithm of the parallactic angle S. The first gives you the side HS, the second its logarithm. For example, if to an apparent distance of the Moon from the zenith VAS of 50° 55′ there corresponds a parallax S of 1° 7′, as Ptolemy holds, the logarithm of 50° 55′, which is 988999, added to the residual of the logarithm of 1° 7′, which is 171023, gives the logarithm 160022, discarding, as is customary, the redundant unit on the left. With this logarithm you will find in the tables that HS is 39 58′ in parts of which AH is one. You will find the same if you divide the sine of the angle of 50° 55′, which is 77623, by the sine of the angle of 1° 7′, 1949, even though Ptolemy, by a longer calculation, arrives at 39 45′.

Primus Modus obſeruandi Parallaxes Lunæ.

First method of observing the Moon's parallaxes.

II. This first method is taught and illustrated by their own examples by Ptolemy (*Magna Syntaxis*, Book 5, ch. 13), Copernicus (Book 4, ch. 16), Tycho (volume 1 of the *Progymnasmata*, p. 459), and Lansbergen (in the *Thesaurus observationum*, class 5 of lunar observations, and in the *Uranometria*, from p. 3 to p. 11); and by another's example by Regiomontanus (*Epitome of the Almagest*, Book 5, prop. 15) and Daniel Santbech (*de obſeruat.*, prop. 15).

First gather from the tables the time at which the Moon, visible at night or even by day, will be at the beginning of Cancer or Capricorn, or as near to it as possible; for at the tropics the difference of declination is imperceptible within a few hours, and when the Moon is at its meridian altitude, the meridian will be the circle of both declination and latitude. At that time, therefore, observe the Moon's meridian altitude, together with the time. When this has been equated, gather from the lunar motions, by tables or by the problems of the primum mobile, the Moon's latitude and also the Moon's longitude on the ecliptic; and from a table of declinations, the true declination of the Moon's place. If that declination is of the same kind as the latitude, add them; if of a different kind, subtract the latitude from the declination; the sum or the remainder will be the Moon's true declination. Then compare the Moon's observed altitude with the altitude of the equator. If they are equal, the Moon will have no apparent declination; if it is greater than the altitude of the equator, the apparent declination will be northern; if less, it will be southern, among northern peoples. Finally, compare the Moon's apparent declination with its true declination, for their difference will be the parallax of altitude. Using the same observation, however, you can find the Moon's true altitude from its true declination, added to the altitude of the equator if it is northern, subtracted if it is southern; or, subtracting a northern declination or adding a southern one to the altitude of the pole itself, you can find the Moon's true distance from the zenith; and by comparing the true altitude with the apparent, or the true distance from the zenith with the apparent or observed, you can find the parallax in the circle of altitude. Tycho uses the comparison of declinations, Ptolemy and Copernicus that of distances from the zenith, and Lansbergen that of altitudes, but these problems are equivalent to one another. The Moon must, however, be beyond the danger of sensible refraction, and higher than 45° or at least 40°.

EXEMPLVM Ptolemaicum.

Ptolemy's example.

Ptolemy, as he himself relates in Book 5, ch. 13, in the 20th year of the Emperor Hadrian and the year 883 of Nabonassar, on the 13th of the month of Mechir, that is, in the year of Christ 135 October 1, at the apparent hour of equal hours $5^{h}\ 50^{m}$ after noon at Alexandria, observed with the parallactic rulers, the

Sun already setting, the Moon's distance from the zenith on the meridian as 50° 55′. The apparent time reduced to equal time was 5^h 20^m p.m. For that moment he computed from his tables the Moon's place as ♑ 3° 10′; its mean anomaly as 262° 20′, its equated anomaly as 269° 46′; its distance from the northern limit as 2° 6′; its true and northern latitude as 4° 59′; and the true declination of the Moon's true place as 23° 49′ south. Subtracting from this the Moon's true latitude left the Moon's true southern declination as 18° 50′. He added this to the altitude of the pole at Alexandria, 30° 58′, and the Moon's true distance from the zenith came to 49° 48′. But the apparent or observed distance was 50° 55′. The parallax of altitude was therefore 1° 7′, appropriate to the Moon at an anomaly of 269° and nearly at quadrature, for the Sun was then at ♎ 5° 28′. From this parallax he gathered the Moon's distance from the Earth's centre as about 39 45′ semidiameters. However, Ptolemy derived the Moon's latitude from a greatest latitude at the quadratures assumed to be 5°, and the declination of the Moon's place from an assumed declination of the tropic of 23° 51′ 20″. But if, from what was said in the preceding chapter, Scholium 3, it is more probable that the greatest latitude at the quadratures was 5° 20′ and the tropic's distance from the equator 23° 30′, then certainly, at the time of this observation of Ptolemy's, the Moon's northern latitude was 5° 19′ and the declination of degree 3 of ♑ was 23° 28′. The Moon's true southern declination was therefore 18° 9′, the Moon's true distance from the zenith 49° 7′, and the parallax 1° 48′. This has seemed far too great and absurd to everyone, because it would show the Moon's diameter at the quadratures almost twice as great as practitioners have found it down to these times.

Secundus Modus.

Second method.

[Margin: 2. The method of Daniel Santbech.] III. Observe, says Daniel Santbech (book *De observatione*, prop. 15), when the Moon is at the beginning of Cancer or Capricorn and is crossing the meridian together with some star of known declination, the distance between this star and the Moon; this will be done more exactly if at the same moment one observer takes the altitude of the Moon and the other that of the star. For from the star's right ascension you will know the moment of apparent time; and when this has been converted to equal time, you will gather from the tables of the Moon its longitude and latitude, and from them its true declination, and from this the difference between its declination and the star's. Comparing this with the distance taken between them, or with the difference of altitudes, you will gather the parallax of altitude from the difference between these, provided that here too the Moon has been higher than about 45°, so that it is beyond the hazard of sensible refractions. The declination, moreover, is known from the longitude and latitude if the declination of the Moon's place on the ecliptic is known, as we said in the first method.

Tertius Modus.

Third method.

[Margin: 3. Method by observing the time and the Moon's meridian altitude.] IV. In whatever degree of the ecliptic the Moon may be, observe its meridian altitude and the exact moment of time, for here the most precise is required, so that when it has been equated you may gather from the lunar tables its true longitude and latitude. Then, from the tables of declinations of Regiomontanus, or of Magini in the *Directiones* of the primum mobile, which they constructed for each degree of longitude and latitude, look up the Moon's true declination, and from that and the altitude of the equator the true altitude, namely by adding the Moon's declination to the altitude of the equator if the declination is towards your pole, or subtracting it if towards the other. Finally, when the observed altitude has been subtracted from the Moon's true altitude, gather the parallax of altitude. If you lack the tables already mentioned, consult our own or others' problems of the primum mobile, which teach how to find a star's declination from its given longitude and latitude, together with the distance between the poles of the equator and the ecliptic.

Quartus Modus.

Fourth method.

[Margin: 4. Method of al-Battānī and Tycho, by observing the Moon in the nonagesimal.] V. By the example of Tycho (volume 1 of the *Progymnasmata*, p. 461) and the precept of al-Battānī (ch. 40): observe when the Moon is in the nonagesimal degree of the ecliptic counted from the horizon. You will learn this from the erection of the horns, if it is horned, or even gibbous or dichotomous; or from the problem given in this book, ch. 4, Problem 9. Then observe the Moon's apparent latitude, as well as its longitude, which will then be apparent and true at once, and the moment of time; and for that moment, once equated, gather the Moon's true latitude from the tables. For by comparing the true latitude with the apparent, you will detect the parallax not only of latitude but also of altitude, since the circle of latitude passing through the Moon's centre and the nonagesimal of the ecliptic then becomes a vertical circle, or circle of altitude. The latitude and longitude of ☾ are observed, moreover, either with zodiacal armillaries, as I shall teach in the *Liber Organicus*, or by taking the apparent distance from two fixed stars of well-known longitude and latitude, by the common problems of the primum mobile.

Quintus Modus.

Fifth method.

[Margin: 5. Our method, likewise by the Moon in the nonagesimal.] VI. Observe, when the Moon is in the nonagesimal degree of the ecliptic, the exact time and the apparent altitude. When the time has been equated, gather for

that moment from the tables the Moon's true longitude and latitude; and from the right ascension of midheaven, the culminating point of the ecliptic, for the difference in longitude between this and the Moon's place will show the arc of the ecliptic intercepted between the meridian and the nonagesimal. From the table of the angle of the ecliptic and the meridian, you will gather the angle appropriate to the culminating point of the ecliptic, opposite the arc by which the nonagesimal is distant from the zenith. For if, by the rules of right-angled spherical triangles, with the arc of the ecliptic already mentioned and the angle adjacent to it, you find the side opposite it, you will have the distance of the nonagesimal from the zenith, whose complement to 90° is the altitude of the nonagesimal. To this, therefore, add the Moon's northern latitude, or subtract its southern latitude, and the Moon's true altitude will be known; by comparing this with the apparent or observed altitude, you will discern the parallax of altitude, which in this case is also that of latitude. But you can learn the distance of the nonagesimal from the zenith in another way, through its own table, whose use we shall teach, God willing, in the precepts on solar eclipses. If you do not want to depend on tables for the motion in longitude, take at the same moment the distance of the Moon, situated in the nonagesimal, from two fixed stars of known longitude, so as to gather from it the Moon's longitude, which will be true and apparent at once.

You can achieve the same in another way, if a fixed star is then in the same vertical as the Moon when the Moon is in the nonagesimal, and the altitude of each is taken beyond the refractions. For if the latitudes of the Moon and the fixed star are of the same character, the lesser subtracted from the lesser [minor de minore; recte: maiore] will give the difference of latitude, and this, compared with the difference of altitude, will give the parallax. But if they are of different character, the difference of the altitudes taken, subtracted from the sum of the latitudes, will give the parallax, which in both cases is that of latitude and of altitude at once. If because of twilight the star cannot be seen at the time when the Moon is in the nonagesimal, take the azimuth of the Moon together with its altitude and observe the moment of time; and from an Aratean globe [Globo Arateo], first roughly, then by the problems of the primum mobile, find which star must have been in such an azimuth at that moment, and what altitude it must have had there, and carry out the rest as above.

In the methods already mentioned you see a dependence on knowledge of the latitude, or of the Moon's latitude and declination together. Let us now try methods that do not depend on the latitude, or even on the declination.

Sextus Modus.

Sixth method.

[Margin: 6. Our method.] VII. Gather from the tables of the motion of longitude and latitude when the Moon will cross the meridian lacking all latitude, that is, being at one or other of the nodes; and, for that time, the

culminating point of the ecliptic, for that is the very point at which the Moon's centre will be. The declination of this point will be known from the table of declinations of the ecliptic. If you add it to the altitude of the equator when the declination is northern, or subtract it when southern (for I am speaking with northern peoples), the Moon's true altitude will be known. Therefore, if you have observed the apparent meridian altitude and subtracted it from the true, the parallax of altitude will be known. But when will all these things coincide, so that at the time the Moon crosses the meridian it lacks all latitude? Perhaps never in your whole lifetime.

Septimus Modus.

Seventh method.

[Margin: 7. Our method.] VIII. Gather from the lunar tables when the Moon will cross the meridian at a time when it is visible, and will be at one or other of its nodes and at the same time at the node of the ecliptic with the equator, that is, at the beginning of ♈ or ♎. For then it will lack all latitude and declination, and its true altitude will be equal to the altitude of the equator. The Moon's meridian altitude, then observed and compared with the true altitude, that is, with the altitude of the equator, will show the parallax of altitude. But when will these four things coincide? Perhaps never for you, or for many generations of observers. Far less can it be hoped that this should happen not just once, but with the Moon both at apogee and at perigee, and this both at ☌ and at □, so that astronomy may be freed from all doubt about the Moon's parallaxes.

Octauus Modus.

Eighth method.

[Margin: 8. Method of Hájek and Digges.] IX. In Tycho (volume 1 of the *Progymnasmata*, pp. 666 and 668), and indicated by Longomontanus (*Sphaerica*, Book 2, ch. 10, problem 2), there is a general twofold problem of Tadeáš Hájek and Thomas Digges [Thomæ Diggeſei] for finding the parallaxes of any phenomenon. In one of them it is required that the phenomenon be in the same vertical as two known fixed stars, that its apparent distance from each of the fixed stars be taken, and that the azimuth, or the distance of that vertical from the meridian towards the east, be noted; then, when the phenomenon with the fixed stars has been carried by the motion of the primum mobile to a western azimuth equal to the eastern azimuth, that its apparent distance from the same fixed stars be taken again, and the altitude of either of the fixed stars. But as Tycho warns, and Digges does not deny, this can hardly be carried out without error: both because azimuths are hard to observe exactly, unless you use my thread triangle [triangulo filari], discussed in the *Liber Organicus*, and wait for the star at its plane; and because of the slenderness of the sides and angles that occurs in the second observation, since the phenomenon moves little away

from the vertical of the fixed stars within the same night. The second, however, requires the phenomenon's apparent distance in the same vertical with two fixed stars; but in the second observation, with no account taken of verticals, its apparent distance from the same fixed stars and the altitude of either of the fixed stars. Yet this too is liable to error because of the slenderness of the angles, besides the fact that the Moon's centre is found only with great difficulty in the same vertical as two fixed stars, so that the instruments are then set in a suitable position. I have therefore thought it right here to indicate the problem, not to explain it; we shall, however, explain it in the *Liber Opticus*, in the section on parallaxes.

Nonus Modus.

Ninth method.

[Margin: 9. Kepler's method.] X. Lastly, I should like to report the very words of Kepler from his letter to Giovanni Antonio Magini, dated at Graz in Styria, 1601 June 1 [Kal. Iunij], which Magini himself reports in the *Supplement to the Ephemerides*, p. 253. At the end of this letter he says: *"The theory of the Moon causes Tycho much difficulty. It seems to me that it should begin from the parallaxes, which arise because of the sensible distance between the centre and the surface of the terrestrial globe. But the theory of parallaxes is confused with the Moon's latitudes. So prior knowledge of the latitudes would be needed. Each depends on the other. I have therefore considered how parallax might be investigated by observing without knowledge of the latitude. Two methods occurred to me. One, if on the same day the Moon were observed once high and once lower, yet beyond the limit of the refractions, when it is about the limits, where the latitude changes little within two hours. It is also expedient to do this at the beginning of Cancer, where the declination too changes little. But when on the same day after its meridian altitude the Moon becomes sensibly lower, it acquires a parallax in longitude, which must be known beforehand, since that is what is being sought. The other method: that at distinct times the Moon be observed when it is in the nonagesimal degree, at the same limit, at the same distance from the Sun, once higher and once lower. But these three conditions rarely coincide. Add that for each single minute in this observation of altitude an error of one semidiameter of the Earth is committed, and few of these are contained in the eccentricity of the Moon's path. So, in the third place, I take refuge in this: I beg you to observe the Moon as often as you can in the nonagesimal degree, and to share your observations, together with the most exact altitude of the pole at Bologna, with us in Germany. I shall see to it that you have our observations in turn. Thus it will happen that the Moon is sometimes observed at the same time in both places, and so its altitudes at various places of the anomaly will become known; for Bohemia and a good part of Italy are on the same meridian."*

But oh, how uncertain and exposed to an error of several minutes is this very third method! How crude a conception of a confused and entangled mind, which could not be brought to birth in any practice! And so, up to the year

1601, in which Tycho died, there existed in Tycho's journals no observation of lunar parallaxes independent of knowledge of the latitude. I should gladly know, then, by what reasoning he found the greatest latitude at the quadratures to be greater than the latitude at the syzygies by about a third of a degree, for parallaxes derived from the latitude of the syzygies cannot reveal a different greatest latitude.

CAPVT XIV. Referuntur ſelectæ obſeruationes Parallaxium Lunarium, & opiniones inde ortæ Aſtronomorum de Parallaxi Horizontali & Diſtantia Lunæ à Terra in Copulis & in Quadraturis.

Chapter 14. Selected observations of lunar parallaxes are reported, and the opinions of astronomers arising from them on the horizontal parallax and the Moon's distance from the Earth at the syzygies and at the quadratures.

[Margin: 1. The opinion of Hipparchus.] I. With the opinions that are not founded on observations set aside to the scholia that follow, Hipparchus comes first. As Ptolemy reports in part (*Almagest*, Book 5, ch. 11) and Theon in part (in his commentary at the same place), Hipparchus, supposing the Sun's sensible parallax now to be nil, now greater or smaller, tried by certain conjectures taken from eclipses to hunt down the Moon's distances, and from them its parallaxes. For that reason he derived them as varied and inconsistent, and sometimes the Moon's least distance as 71 and its greatest as 83 semidiameters of the Earth, and at other times the former as 62 and the latter as 72½, with an apparent diameter of 35′ at perigee and 30′ at apogee. On Posidonius and other ancients, see Scholium 3.

[Margin: 2. Ptolemy's method and opinion.] II. Ptolemy, for his part, in Book 4, ch. 6 and 10, gathers from eclipses, by the method we shall give in ch. 21, no. 7, that the epicycle's semidiameter is 5 13′ or 5 14′, in units of which the distance of the eccentric's apogee from the Earth's centre is 60. Then, in Book 5, ch. 4, using the already mentioned semidiameter of the epicycle and the greatest equation at the quadratures, 7° 40′, which he had found in ch. 3 from the Moon's true motions as observed and compared with its mean motions, he gathers an eccentricity of 10 19′ and a semidiameter of the eccentric of 49 41′, in units of which the distance of the eccentric's apogee from the centre is 60. Afterwards, in Book 5, ch. 13, relying on the observation I reported in ch. 13, no. 2, in the example, he gathers the Moon's parallax at quadrature as 1° 7′, corresponding to an altitude of 39° 5′ and a mean lunar anomaly of 262° 20′. From this, in the same ch. 13, he gathers the Moon's distance from the Earth's centre at that time as 39 45′ semidiameters of the Earth; the Moon's mean distance at conjunction and opposition, or the distance of the eccentric's apogee from the Earth's centre, as 59 terrestrial semidiameters; the Moon's mean distance at quadrature as 38 43′ semidiameters of the Earth; [Margin: Semidiameter of the epicycle.] and the epicycle's semidiameter as 5 10′ terrestrial

semidiameters. Therefore in ch. 15, by adding the epicycle's semidiameter to the Moon's mean distance from the Earth, [Margin: Distances of the Moon from the Earth.] he establishes the distance of the Moon at apogee from the Earth at conjunction and opposition as 64 10′ semidiameters, which at the quadratures is 43 53′ semidiameters. But by subtracting the epicycle's semidiameter from the Moon's mean distance, the distance of the Moon at perigee comes out as 53 50′ semidiameters at conjunction and opposition, and 33 33′ semidiameters at quadrature. By keeping to the rule of proportions, moreover, the eccentricity is gathered as 10 8′ 41″ semidiameters of the Earth. For if a mean distance of the Moon at the syzygies of 60 units gives an eccentricity of 10 19′ units, then certainly the same distance of 59′ [recte: 59] semidiameters of the Earth [Margin: Eccentricity of the Moon.] gives an eccentricity of 10 8′ 41″ terrestrial semidiameters, that is, almost 10 9′. When the eccentricity is therefore taken away from the Moon's mean distance at the syzygies, [Margin: Semidiameter of the eccentric.] there remains a semidiameter of the eccentric of 48 51′ terrestrial semidiameters. Since the occasion arose, it was worthwhile to set these out here together, as they will serve us elsewhere.

Now, since Ptolemy gives the distance of the Moon at apogee as 64 10′ semidiameters of the Earth at the syzygies, and its visual diameter as 31′ 20″, and from this in Book 5, ch. 14 gathers that the Moon's true diameter is to the Earth's diameter as 16½ to 60; and since he gives the distance of the Moon at perigee at the quadratures as 33 33′ semidiameters of the Earth, it follows by our problem in Book 3, ch. 11, no. 4 that the apparent diameter of the Moon at perigee at quadrature is 56′ 22″. That is nearly twice as great as that of the Moon at apogee at the syzygies, which is evidently contrary to experience. For not Gemma Frisius alone testifies in his *Radius Astronomicus* that he observed, on 1542 December 15, shortly after the quadrature, the Moon's apparent diameter as 30′, at which time according to Ptolemy it should have been at least 50′; many others too have observed a far smaller diameter of the Moon at every quadrature, and for that reason have repudiated Ptolemy's hypothesis on this point: above all Regiomontanus, Book 5 in the *Epitome of the Almagest*, prop. 22; Copernicus, Book 4, ch. 16; and Tycho, vol. 1 of the *Progymnasmata*, p. 118. Nor did Ptolemy confirm so great a diameter by his own observations; otherwise Copernicus would have said that it was so great once but had diminished in the lapse of centuries, and would have devised his own anomaly for it.

[Margin: 3. The opinion of al-Battānī, Alfonso and Peuerbach.] III. Al-Battānī, ch. 39 and 40, follows Ptolemy in all the lunar distances, but diminishes the diameter of the Moon at apogee, though only slightly, so that at perigee at the quadratures a far greater one results than the experience even of someone observing it rather crudely will allow. Nor did the Alphonsines and Peuerbach, in his *Theoricae*, and al-Farghānī, *Differentia* 21, depart from this.

[Margin: 4. The opinion of Copernicus.] IV. Copernicus, Book 4, ch. 16 and 17, derived his parallaxes and distances from two observations, using method 1 of Chapter 13; they are set out below.

EXEMPLA II. Et Obſeruationes Copernici in Quadrato.

Two examples, and observations of Copernicus at quadrature.

[Margin: Moon at apogee.] In the year 1522 September 27, at 5^h 40^m after noon, but 5^h 24^m equated, the Moon's distance from the zenith, observed with the parallactic rulers at Frombork, was 82° 50′. At that time, he says, the true place of the Sun was ♎ 13° 29′ and of the Moon ♑ 12° 33′. The equated anomaly of ☾ was 358° 40′; the southern latitude 4° 47′; the declination of the Moon's place 22° 54′ south; therefore the true declination of ☾ was 27° 41′. The distance of the equator from the zenith, or the altitude of the north pole, was 54° 19′; therefore the Moon's true distance from the zenith was 82°, but its apparent distance was 82° 50′. Therefore the parallax was 50′.

But in the year 1524 August 7, at 6^h, the Moon's distance from the zenith observed at the same place was 81° 55′. The Sun's place was ♌ 24° 14′; the Moon's ♐ 9° 39′; the equated anomaly 239° 40′; the southern latitude 4° 41′; the declination of the Moon's place 21° 55′ south; the Moon's true declination 26° 36′ south; the altitude of the north pole 54° 19′. Therefore the Moon's true distance from the zenith was 80° 55′, but its apparent distance was 81° 55′. Therefore the parallax was 1° 0′.

[Margin: Copernicus's errors in parallaxes.] In these observations there lies at least a threefold error. For the altitude of the pole at Frombork was found by Tycho, through Elias Olai [Elias Olsen Morsing], to be 54° 22¼′, as Tycho relates in vol. 1 of the *Progymnasmata*, p. 34, and in the *Epistolae Astronomicae*, p. 74. And the greatest declination of the ecliptic was not 23° 28′, as Copernicus supposes, but 23° 30′, and so the declination of the Moon's place was 22° 58′ in the first observation and 21° 52′ in the second. And because of the omitted refraction, the distance from the zenith must be corrected so that it was 83° 3′, and the later one 82° 8′. Therefore the parallax was 56′ in the first case and 65′ in the second. But if, as is more probable, the Moon's greatest latitude at quadrature is not 5°, as Copernicus thinks, but 5° 17½′, as Tycho holds, or 18′, each parallax must be diminished by about 16′. Besides which, the Moon was not in such a position that the circle of altitude and the circle of latitude were the same.

Nor does it stand in the way that Copernicus, in Book 4, ch. 27, observed at Bologna in the year 1497 March 9 [7.Idus Martij], at the 5th hour of the night, the Moon eclipsing the southern eye of Taurus, and from this tries to confirm his parallaxes. For, as Tycho points out in vol. 1 of the *Progymnasmata*, p. 245, he used a southern latitude for this star of 5° 10′, whereas it is 5° and nearly 30′; and the Moon was at quadrature, where according to him the greatest latitude is 5°, whereas it is 5° 17½′, that is, greater by almost as much as the latitude of Aldebaran is. The Moon could therefore occult Aldebaran in such a way as to be nearer the southern horn by about a third of the lunar diameter, as Copernicus relates, adding that the Moon then stood 84° from the zenith, and yet omitting refraction. Therefore, from this and similar observations it

cannot be determinately gathered whether the parallax or the latitude is to be increased, but only one or the other.

[Margin: 5. Magini's opinion.] V. Giovanni Antonio Magini, in his *Theoricae Planetarum*, Book 1, from p. 57 to p. 69, takes the measure of the Moon's distances and parallaxes from Copernicus, and so, even though he substitutes an eccentric for the eccentrepicycle, as we shall say later, he labours under the same faults in this matter as Copernicus. But in the *Supplement to the Ephemerides* he builds his parallactic tables and distances on Tychonic foundations. Let us therefore consult Tycho.

[Margin: 6. Tycho's opinion.] VI. Tycho, then, in vol. 1 of the *Progymnasmata*, p. 119, sets out a small table of the lunar parallaxes, both Ptolemy's and Copernicus's and his own, and adds to it two observations at the quadratures, one with the Moon at apogee, the other at perigee, made at Uraniborg, with the days noted in the Old Style. They are these.

Obſeruationes 2. Tychonis in Quadrato.

Two observations of Tycho at quadrature.

[Margin: Moon at perigee.] In the year 1592 August 19, at $18^{h}\ 8^{m}$ p.m., the observed latitude of ☾ was 34′ south, but the true latitude was 1° 12′ 10″. The parallax was therefore 38′ 10″, the Sun's place being ♍ 6° 44′ 18″, the Moon's ♊ 9° 40′, and the equated anomaly 5^{s} 27° 31′ 47″.

[Margin: Moon at apogee.] In the year 1597 March 15, at $5^{h}\ 36^{m}$ p.m., the Moon's meridian altitude was observed as 62° 24′ and its apparent latitude as 4° 48′ north, but the true latitude was 5° 14′ 50″; for the Sun's place was ♈ 5° 7′ 26″, the Moon's ♋ 2° 10′, and its equated anomaly 0^{s} 20° 1′ 27″. Therefore the parallax was 26′ 50″.

After these, on p. 459, he adds six observations of the Moon at quadrature: three at the meridian altitude around the tropics, where the declination does not vary, and three when the Moon was at the nonagesimal of the ecliptic, where the parallax of longitude ceases. They are as follows.

Obſeruationes 3. Tychonis Lunæ in Quadrato in Meridiano prope Tropicos.

Three observations by Tycho of the Moon at quadrature, on the meridian near the tropics.

[Margin: Moon near apogee.] In the year 1583 October 12, at $5^{h}\ 19^{m}$ p.m., the greatest apparent altitude of the Moon's upper limb on the meridian was 13° 38′. Take away the Moon's semidiameter, then 15′, and the altitude of the centre is 13° 23′; and with the refraction of 8′ removed, 13° 15′ remains. This, subtracted from the altitude of the equator, leaves the Moon's apparent declination as 20° 50′. The Moon's place was ♑ 15° 40′ and its true latitude

2° 42′ north; therefore the true declination was 19° 57′. Therefore the parallax was 54′, greater by 1½′ than the canon of Copernicus gives.

In the year 1587 August 4, at 9^h p.m., the meridian altitude of the upper limb of ☾ was observed as 15° 20′ and of the lower limb as 14° 46′; therefore the apparent diameter was 34′ and the apparent altitude of the centre 15° 3′, but with refraction removed, 14° 57′. This, subtracted from the altitude of the equator, gives the apparent declination as 19° 8′. The Moon's place was ♑ 7° 50′ and its latitude 5° 12½′ north; therefore the true declination was 18° 5′ and the parallax 63′, greater than the Copernican by 1′ 30″.

In the year 1587 August 18, at 7^h 26^m before noon, the apparent altitude of the Moon's upper horn on the meridian was 52° and of the lower 51° 29′ 30″; therefore the diameter was 30′ 30″ and the apparent altitude of the centre 51° 44′ 45″. Take from this the altitude of the equator, and there remains the Moon's apparent declination, 17° 39′ 30″. The Moon's longitude was ♊ 27° 30′ and its latitude 5° 14½′ south. Therefore the parallax was 33½′, greater than the Copernican by 30″, because the true declination was 18° 13′.

There follow three other observations of the Moon standing in the nonagesimal degree of the ecliptic from the horizon, where the apparent and the true longitude are the same.

Obſeruationes 3. Tychonis Lunæ in Quadrato in Nonageſimo.

Three observations by Tycho of the Moon at quadrature, at the nonagesimal.

In the year 1586 September 23, at 3^h 9^m after midnight, with the Moon at the nonagesimal of the ecliptic, the apparent latitude was 4° 39½′ south, but the true latitude was 4° 1′; the apparent altitude of the centre was 49½° and the observed diameter 32½′; and so the parallax was 38½′, greater than the Copernican by 30″.

In the same year, October 24, at 6^h 12^m after midnight, when the Moon was at the nonagesimal and in ♋ 27° 5′, the apparent latitude was 5° 50′, but the true latitude was 5° 9′; the apparent altitude was about 49° and the observed diameter 33′; therefore the parallax was 41′, agreeing with the Copernican to the very minute.

On the following day, October 28, at 7^h 29^m after midnight, the Moon was at the nonagesimal and in ♌ 11° 10′; the apparent diameter was about 34′; the apparent altitude very nearly 45°; the true latitude 4° 45′ south, but the apparent latitude 5° 30′. Therefore the parallax was 45′, agreeing scrupulously with the Copernican.

Anyone might wonder, however, why Tycho produces no observations of parallaxes at full Moons. But I wonder more how, on pp. 115 and 119, he rejects the Copernican parallaxes and dissents from them, and yet, because of the agreement of his own with the Copernican ones, says on p. 462: [Margin: Tycho's disagreement with himself.] *"I have now reviewed six particular observations, made with my own instruments, from which I investigated the Moon's*

parallax; and since this agrees as closely as possible with those that the reasonings of Copernicus require at a like altitude, it is consistent that the Moon's parallaxes come out in this way, and consequently that its distance from the Earth, established above, is not unsuitable." But this is surely to dissent from himself. For parallaxes of the Moon cannot be suitable that rest on false Copernican observations and that at quadrature are derived from the assumption of a greatest latitude of 5°, which you think false.

[Margin: 7. The opinion of Longomontanus and Kepler.] VII. Longomontanus, in Book 1 of the *Theorica*, ch. 8 and 9, professes that he follows Tycho. Therefore what we have said about Tycho holds for him too; he does, however, apply a very small correction to these things. But I wish he had published the observations, or stated the reasons for this correction, so that they could be weighed.

[Margin: Kepler's 1st opinion.] Kepler, in the foundations of the *Ephemerides*, p. 5, says that for Tycho the Moon's eccentricity is greatest at the quadratures, 7248, and least at the syzygies; but that for himself, from the form of the physical hypothesis of which I shall speak in ch. 27, the eccentricity is greatest at the syzygies, 6543, and least at the quadratures, 4362, in units of which the radius of the orbit is 100000. But on p. 10 he concludes, from Brahean observations corrected by eclipses, that the Moon's distance from the Earth's centre at the syzygies is about 63 terrestrial semidiameters at apogee, a little more than 55 semidiameters at perigee, and therefore 59 as the mean. From this he concludes that at the syzygies the parallax at apogee is 54′ 41″ and at perigee 62′ 20″. But from these parallaxes there follows an apogee distance of 62 52′ semidiameters of the Earth and a perigee distance of 55 8′.

After this, in the *Epitome of Copernican Astronomy*, p. 482, he says it was fitting that the proportion of the bodies of the Earth and the Moon should be related to the proportion of the Moon's interval and the Earth's semidiameter just as the proportion of the body of the Sun and the Earth was related to the proportion of the solar interval and the Earth's semidiameter; and that from this it follows that, just as the body of the whole Earth is contained in the body of the Sun as many times as the Earth's semidiameter is in the interval or semidiameter of the Sun's orb, so the body of the Moon is contained in the body of the Earth as many times as the semidiameter is contained in the distance or semidiameter of the lunar heaven; and that the semidiameter of the lunar orbit is a mean proportional between the distance of the Sun and the Earth's semidiameter. [Margin: 2nd opinion.] And on pp. 483 and 776 he says that the distance of the Moon at apogee is 59 terrestrial semidiameters and at perigee 54, about as much as Tycho had found at quadrature.

Then on pp. 614 and 820, as also in the Rudolphine Tables, ch. 26, 28 and 31, he affirms that, after observing eclipses and comparing them with parallaxes, and from the proportion of the bodies a priori, on which see p. 482, he found the same distances of the Moon and the same parallaxes at the syzygies and at the quadratures, apogee with apogee and perigee with perigee everywhere

equal, and that its intervals do not vary by reason of the phases; and that the real eccentricity is always 4362, in units of which the mean distance and radius of the orb is 100000. Hence it comes about that for him the distance at apogee is 104362 units, and this is 59 terrestrial semidiameters; therefore at perigee it is 95638 units, or 53 56′ semidiameters, and the mean, which is 100000, becomes 56 28′ semidiameters of the Earth. [Margin: 3rd opinion.] Finally, in the Rudolphine Tables, p. 98, he sets the Moon's horizontal parallax at the syzygies as 58′ 22″ at apogee and 63′ 41″ at perigee. From these, trigonometry gives the distance at apogee as 57 54′ semidiameters of the Earth, at perigee 54 0′, and the mean 55 57′.

[Margin: 8. Lansbergen's opinion.] VIII. Philips van Lansbergen, in Class 5 of the lunar observations and in the *Uranometria* from p. 3, adduces chiefly three observations made at Goes on the meridian near the beginning of ♋, from which he derives his parallaxes, taking the greatest latitude of ☾ as 5° at the syzygies and 5° 16′ at quadrature. They are these.

Obſeruationes 3. Lansbergij Lunæ prope initium Cancri.

Three observations by Lansbergen of the Moon near the beginning of Cancer.

In the year 1600 March 11, at 6^h p.m., the apparent meridian altitude was 63° 51′; the place of ☾ was ♋ 1° 14′; the anomaly 8^s 12° 9′; the latitude 2° 19′ north; the declination 25° 49′ north; the altitude of the equator 38° 29′. Therefore the true altitude of ☾ was 64° 17′ and the parallax 26½′.

[Margin: Moon at opposition, at perigee.] In the year 1601 November 29, at 12^h 15^m p.m., the Moon's apparent altitude was 61° 25′. At that time the Moon's place was ♊ 21° 28′; the anomaly 5^s 27° 27′; the latitude 13′ north; the declination 23° 26′ north; the altitude of the equator 38° 29′. Therefore the Moon's true altitude was 61° 55′ and the parallax 30½′.

[Margin: Quadrature, Moon near perigee.] In the year 1602 September 26, at 16^h 59^m p.m., the Moon's apparent altitude was 59° 39′. The Moon's place was ♊ 27° 25′; the anomaly 5^s 10° 27′; the latitude 1° 45′ south; the declination 21° 43′ north; the altitude of the equator 38° 29′. Therefore the Moon's true altitude was 60° 12′ and the parallax 33½′.

He adds 17 other observations of the Moon in conjunction with the fixed stars, and from his own parallax concludes that Copernicus erred, but Tycho more. But I have more than once insisted that from these applications of the Moon a parallax of determinate measure is not gathered or confirmed, unless the latitude is established independently of parallax; and Lansbergen could not establish this in that climate outside eclipses, unless he appeals to Ptolemy's observations. Moreover, I miss from Lansbergen observations of the full Moon at apogee and of the dichotomous Moon likewise at apogee, so that the parallaxes appropriate to these places might be more certain.

[Margin: 9. The opinion of Wendelen and Kircher.] IX. Govaert Wendelen has so far published no observations on this matter, but in the *Idea of the Atlantic*

Tables he nevertheless brings forward his opinion, which in the table below I shall show along with others. Nor does Athanasius Kircher, in vol. 2 of the *Ars Magna*, Book 9, Problem 9, set down any observation, but he nevertheless gives distances, which you may see in our table at the end of the chapter.

[Margin: 10. Boulliau's opinion.] X. Ismaël Boulliau, in Book 4 of the *Astronomia Philolaica*, supposes from eclipses that the diameter of the Sun at apogee is smaller than the diameter of the Moon at perigee, but the diameter of the Sun at perigee greater than the diameter of the Moon at apogee; and that the Moon's diameters can be known exactly from the Moon's motions in eclipses, because the Moon's motion is known exactly enough, as is also the diameter of the shadow. And from these he examines several distances of the Moon, in order to find the one that of all disagrees least with these diameters. At the quadratures, however, he hunts down the Moon's distance from the form of the ellipse that he employs in the theory of the Moon; for at the quadratures the umbilicus of this ellipse is taken to recede from the Earth by as much as it is itself distant from the centre of the ellipse. But those proportions of the semidiameters could be preserved with the distances altered proportionally. So, in order to have one determinate distance and parallax from which to gather the others, he adduces a single observation of the Moon in the same azimuth as the star preceding the foot of the leading Twin, than which the lower limb of the Moon, in great part eclipsed, appeared higher by 8′. The year was 1638, December 20, and the hour, from the altitude of the Heart of Hydra, $13^{h}\ 40^{m}$ p.m. From this he gathers the altitude of the former star as 56° 42′ and its southern latitude, from Tycho, as 28° 25′, and the Moon's apparent altitude as 57° 7′, whereas from the given latitude and place it ought to have been 57° 40′; therefore the parallax was 37′. And so the parallax for the syzygies, since it is gathered from the latitude, which can be known without parallax, seems more certain; but the one established for the quadratures from the form of the ellipse rather than from observations is not equally certain.

[Margin: 11. Our observations and opinion.] XI. We, for our part, among the many observations that we made at Bologna on this matter, and that, God granting, we shall report in the third volume of the *New Almagest*, have here selected a few, which we trust most, as also the Sun's meridian altitudes taken at the preceding noon. They are as follows.

Obſeruationes 3. Noſtræ in Oppoſit. Lunæ.

Our three observations of the Moon at opposition.

Prima Obſeruatio.

First observation.

[Margin: Moon at apogee.] In the year 1645 May 10, in the following night, from the altitude of Spica in the west, the time at which the Moon's centre passed through the midheaven [M.C.] was $11^{h}\ 53^{m}\ 52^{s}$ p.m., but the equated

time $11^h\ 44^m$. At that time the true place of ☾ on the ecliptic was 22° 30′ 58″; the equated anomaly 0^s 4° 24′ 6″; the true latitude 4° 58′ 22″ north; the declination, from Regiomontanus, 13° 37′ 53″ south; the distance of the equator from the zenith 44° 29′ 30″. Therefore the true distance of ☾ from the zenith was 58° 7′, but the apparent distance, with refraction removed, was 58° 53′ [recte: 58° 53′ 37″, per the book's errata]. Therefore the parallax was 44′ 37″; the distance from the Earth's centre 64 13′ semidiameters of the Earth; and the horizontal parallax 53′ 44″.

Secunda Obſeruatio.

Second observation.

[Margin: Moon at apogee.] In the year 1646 June 27, in the following night, from the distance of Aquila, in the east, from the zenith, the time at which the Moon's centre crossed the meridian was $11^h\ 53^m\ 47^s$ p.m., but the equated time $11^h\ 55^m\ 35^s$. At that time the Moon's place was ♑ 4° 52′ 40″; the equated anomaly 11^s 25° 14′ 27″; the true latitude 2° 16′ 55″ north; the true declination 21° 8′ 5″ south; the distance of the equator from the zenith 44° 29′ 30″. Therefore the Moon's true distance was 65° 37′ 55″, but the distance observed on the meridian was 66° 24′ [recte: 66° 24′ 20″, per the book's errata], and because of refraction 66° 26′ 42″. Therefore the parallax was 49′ 7″, and hence the Moon's distance from the Earth's centre 64 10′ semidiameters of the Earth and the horizontal parallax 53′ 35″. But at the apogee itself the former is 64 15′ semidiameters and the latter 53′ 30″.

Tertia Obſeruatio.

Third observation.

[Margin: Moon at perigee, at opposition.] In the year 1648 March 8, from the altitude of Spica in the east, the time at which the Moon's centre passed across the meridian was, in equated time, $11^h\ 56^m$ p.m. At that time the Moon's place on the ecliptic was ♍ 13° 13′; the equated anomaly 5^s 24° 40′; the latitude 4° 48′ 13″ north; the declination 11° 9′ north; the distance of the equator from the zenith 44° 29′ 30″. Therefore the Moon's true distance from the zenith was 33° 20′ 30″, but the apparent and observed distance was 33° 55′ 30″. Therefore the parallax was 35′, and the distance from the centre of the Earth 54 0′ terrestrial semidiameters, and the horizontal parallax 63′ 43″. But at the perigee itself the former is 53 45′ semidiameters and the latter 63′ 55″.

Obſeruationes 3. Noſtræ in Quadrato Lunæ.

Our three observations of the Moon at quadrature.

Prima Obſeruatio.

First observation.

[Margin: Moon at apogee, at quadrature.] In the year 1646 October 16, from the altitude of Aquila in the west, the time at which the Moon's centre passed across the meridian was $6^h\ 15^m\ 48^s$ p.m., but the equated time $6^h\ 8^m\ 52^s$. At that time the Moon's place on the ecliptic was ♍ 23° 20′; the equated anomaly 0^s 1° 45′ 3″; the latitude 16′ 45″ north. Therefore the declination was 21° 12′ 55″ south. The distance of the equator from the zenith was 44° 29½′. Therefore the Moon's true distance from the zenith was 65° 42′ 25″. But the apparent distance was 66° 26′, and with refraction added 66° 29′ 55″. Accordingly the parallax was 47′ 30″ and the Moon's distance from the Earth's centre 66½ terrestrial semidiameters. Or, correcting it from the following still more refined observation, the distance of ☾ at apogee at quadrature becomes 66⅔ terrestrial semidiameters.

Secunda Obſeruatio.

Second observation.

[Margin: Moon at apogee, at quadrature.] Then in the year 1648 June 13, in the morning, the Moon's centre crossed the midheaven at the apparent time $18^h\ 16^m\ 8^s$ after noon of the 12th, as appeared from the corrected altitude of the Sun. At that time the Moon's apparent distance from the zenith was 52° 50′, but with refraction added it was 52° 50′ 30″. Therefore, when the distance of the equator from the zenith, which at Bologna is 44° 29′ 30″, is subtracted, there remains the Moon's apparent southern declination, 8° 21′. The equated time was $18^h\ 13^m$. At that moment the Sun's place was ♊ 22° 42′ 26″ and the Moon's on the ecliptic ♓ 22° 57′ 5″, its co-equated anomaly 11^s 23° 16′ 30″, and the Moon's southern latitude 5° 17′ 50″. Therefore, by the tables of Regiomontanus, the Moon's true southern declination was 7° 39′ 30″, but the apparent declination was 8° 21′; therefore the parallax was 41′ 29″, corresponding to the Moon's apparent distance from the zenith of 52° 50′ 30″, and hence the Moon's distance from the Earth's centre was 66 42′ terrestrial semidiameters. The quadrature had occurred at $17^h\ 45^m$. The phase of dichotomy, however, when the extremes of the doubtful time were computed and the intermediate one chosen, was at $18^h\ 43^m\ 30^s$, at which moment the Moon was 30′ 15″ on the ecliptic from the place of quadrature. And so, in Book 3, ch. 7, no. 11, using the angle S of the figure set out there in no. 9, and with the Moon's distance found as 66 42′ semidiameters, I derived the Sun's distance, nearly at apogee, as 7572 terrestrial semidiameters.

Tertia Obſeruatio.

Third observation.

[Margin: Moon at perigee, at quadrature.] In the year 1646 March 23, the Moon's centre crossed the midheaven at $5^h\ 30^m\ 36^s$ p.m., as was established from the corrected altitude of the Sun. At that time the apparent distance of the lunar centre from the zenith was 24° 56′ 30″. This, subtracted from the distance of

the equator, 44° 29′ 30″, leaves the Moon's northern and apparent declination, 19° 33′. At that equated moment the Moon's true longitude on the ecliptic was ♊ 26° 10′, the equated anomaly 5ˢ 26° 50′, and the true southern latitude 3° 26′. Therefore, by Regiomontanus's table, the Moon's true northern declination was 20° 1′ 10″, but the apparent declination was 19° 33′. Accordingly the parallax of altitude was 28′ 10″, which, with the Moon's apparent distance from the zenith of 24° 56′ 30″, gives the Moon's distance from the Earth's centre as 51 30′ terrestrial semidiameters. From these and similar observations we establish, at the quadratures, the apogee distance of ☾ as 66 42′ semidiameters and at the perigee itself as 51 28′, so that the mean is 59 0′, such as we found from the syzygies. To this distance there corresponds a horizontal parallax of 66 56′.

It remains for us to set before you, from the authors reviewed above, a synopsis of the lunar horizontal parallaxes and distances, in which three classes of opinions may be seen: for some put the greatest distance of ☾ from the Earth at conjunction and opposition and the least at quadrature; others the greatest and least at conjunction and opposition and the mean at quadrature; and others the greatest and least at quadrature and the mean at conjunction and opposition. Namely:

Distance of ☾:

- Greatest at conjunction and opposition, least at quadrature: Ptolemy, al-Battānī, al-Farghānī.
- Greatest and least at conjunction and opposition, mean at quadrature: Kepler formerly, but later he made them both equal.
- Greatest and least at quadrature, mean at conjunction and opposition: Copernicus, Magini, Tycho, Lansbergen, Longomontanus, Boulliau, ourselves.

Distance of the Moon from the centre of the Earth in semidiameters of the Earth, and horizontal parallax. Left half of the table: in the syzygies, or at ☌ and ☍. Right half: in the quadratures, □. Distances are given in semidiameters and minutes.

[Note set inside the table, in the lower right:] On the opinion of Pythagoras, Eratosthenes, Posidonius and Mario Bettini, see Scholia 2 and 3. On the proportions of the lunar orbs, see below, from chapter 23 to chapter 25. As for Don Vicenç Mut, who writes to me that he is certain that the distance of ☾ at apogee is about 62 semidiameters of the Earth, I shall see to that when his most learned letter on the Alphonsine motion comes out.

SCHOLIA.

Scholia.

[Margin: The variation of the lunar distances is most certain.]

I. Although it may be questioned whether the Sun varies its distance from the Earth, there can be no doubt as regards both luminaries, both because of the plain variation in the Moon's apparent diameter and in her parallaxes, and because the differing magnitudes of eclipses require this variation. That is why Pliny the Elder (Book 2, chapter 9) rightly says of the Moon: "And then she is both low and lofty, and not even this in one way, but at times brought close to the heaven, at times touching the mountains, now raised into the north, now thrust down into the south." And in chapter 16 he confirms the same variation from the swifter motion of a planet at perigee, saying: "It is likewise acknowledged that the motion increases so long as they are in the vicinity of

the Earth, a principle most strongly confirmed by the elevations of the Moon." In vain, therefore, does Girolamo Fracastoro (*Homocentrica* Book 3, chapter 23) try to transfer the parallax and the variation of lunar distance onto another circle, which would vary the Moon's latitudes and declinations while the same distance is kept.

[Margin: The Moon's distance in Father Bettini is too great, and that of the fixed stars too small.]

II. It is clear from what has been said that the lunar distance, which Father Mario Bettini (*Apiarium* 10, Progymnasma 1, proposition 3) raised, from the intervals of his monochord, as far as 382 terrestrial semidiameters, far exceeds every measure of the astronomers, and cannot be reconciled with the distances deduced from the Moon's parallaxes. Yet he himself gives and approves this method of deducing them, in volume 2 of the *Aerarium Philosophicum*, p. 73, and in *Apiarium* 8, Progymnasma 3, proposition 9, and Progymnasma, proposition 4. For from his distance there would follow a parallax of only 10½′. What is worse, it would follow that the Moon could never be eclipsed by the Earth's shadow, since no astronomer extends the Earth's shadow beyond 282 semidiameters of the Earth, as is clear from what was said in Book 3, chapter 11, Problem 8; whereas the same author (*Apiarium* 8, Progymnasma 2, proposition 5) maintains, and rightly, that she suffers that eclipse from no other source than the Earth's shadow. Indeed, the whole Sun would never be eclipsed by the Moon, although he grants (*Apiarium* 8, Progymnasma 2, proposition 10) that the whole of it can be covered by her.

Nor does his lunar distance agree with the Sun's distance of 1144 terrestrial semidiameters, which the same author (*Apiarium* 10, Progymnasma 1, proposition 3) established from harmonic intervals; or with the distance derived from Aristarchus's problem applied to the lunar distance (and this method the same Father gives in volume 1 of the *Aerarium*, p. 629). For when the Moon shines on us half-lit, she is evidently elongated from the Sun by less than 87°, or from the moment of quadrature by less than 6^h. But let us suppose (as Aristarchus supposed, for ample safety against the Pythagorean intervals of the luminaries) that the Moon is then 87° from the Sun. By the third problem given in Book 3, chapter 7, if the Moon is 382 semidiameters of the Earth from the Earth, it follows by trigonometric necessity that the Sun is 7299 semidiameters of the Earth from the Earth. This is indeed not altogether false, but it is nevertheless against the distance of the Sun asserted by Father Bettini. Still, he must be pardoned what Pythagoras is pardoned, because they looked only to pure harmonic proportions, so as to show what intervals of the stars followed from them. Thus the same Father, in the same place, puts the distance of the fixed stars at only 2290 semidiameters of the Earth, from which there follows a parallax of 1½′, against all astronomers. Nor indeed does a harmony in which sense and reason do not agree suit Mercury or Apollo, as Ptolemy warns (*Harmonics* Book 1).

[Margin: The opinion of Pythagoras, Eratosthenes and Posidonius.]

III. As for the ancients, I have already pointed out their errors in lunar distances, whether of defect or of excess, in Book 3, chapter 7, Scholium 1. There, from Plutarch (*De placitis philosophorum* Book 2, chapter 31), Pliny the Elder (Book 2, chapters 21 and 23) and Censorinus (chapter 11), I showed that Pythagoras once put 120,000 stadia from the Earth to the Moon, that is 15,000 Italian miles, which scarcely make four semidiameters of the Earth; but that Eratosthenes put 780,000 stadia from us to the Moon, or 97,500 Italian miles, which scarcely reach 25 semidiameters of the Earth. Posidonius therefore, according to the same Pliny the Elder, did better and put 2,000,400 stadia; but of such stadia he gave the Earth's semidiameter 38,182, and so he put the distance from the Earth to the Moon at 52 15/38 semidiameters of the Earth. But Petosiris and Nechepso childishly narrowed this distance to 1980 stadia, on the testimony of Pliny the Elder (Book 2, chapter 23).

[Margin: The variety of parallactic tables, and their authors.]

IV. Once the horizontal parallax has been established for the Moon at apogee and at perigee, both in the syzygies and in the quadratures, several further parallactic tables must be constructed. One sets, against the individual signs and degrees of the anomaly, either the Moon's distance from the Earth or the horizontal parallax proper to that place of the anomaly. Another sets at its head the lunar distances from the Earth, or at least the horizontal parallaxes, and beneath them other parallaxes proper to each degree of the Moon's altitude above the horizon: altitude, I mean, both true and apparent, since it is expedient that this table be double, although we can use a simple one, according to what was said in Book 3, chapter 8, number 7. For these, use the problems given in the same chapter 8. Such tables are given by Ptolemy (Book 5, chapter 18); Copernicus (Book 4, chapter 24); Erasmus Reinhold in the Prutenic Tables, p. 120; Magini in the *Second Mobile*, p. 678, and in the *Supplement to the Ephemerides*, p. 292; Tycho, volume 1 of the *Progymnasmata*, pp. 119, 120; Longomontanus, *Theorica* Book 1, chapter 8, p. 279; Kepler in the *Astronomia Optica*, p. 424; Nicolaus Mulerius in the *Tabulae Frisicae*, p. 421; Lansbergen in his tables, p. 47; Boulliau in his tables, p. 173; and Vincenzo Renieri in his tables, p. 333.

Besides these, there exist tables for the parallax of longitude and latitude, for several degrees of the height of the pole, or several climates. Theon of Alexandria constructed such tables, on the testimony of al-Battānī (chapter 40); and following him the Alphonsine Tables, p. 112; Erasmus Reinhold in the Prutenic Tables, p. 98; and following him Magini in the *Second Mobile*, p. 691, and Lansbergen, from p. 51 to p. 93.

But instead of tables that show the parallaxes of latitude and longitude, one may use Kepler's parallactic table, which Boulliau and Renieri copied out, as noted above, or the solu- tion of a triangle, which we treat in the problems of the primum mobile, Book 10, and in the rules for eclipses; Ptolemy (Book 5, chapter 19); Regiomontanus (*Epitome* Book 5, from proposition 26 to proposition 32); Copernicus (Book 4, chapter 26); Daniel Santbech (*De observat.*,

p. 93); Tycho (volume 1, p. 133); Longomontanus (*Theorica* Book 1, chapter 8, p. 282); Mulerius in the *Tabulae Frisicae*, p. 435; Erasmus Reinhold on Georg Peuerbach's *Theoricae*, p. 193; and Francesco Barozzi in the *Cosmographia*, p. 303.

CAPVT XV.

Chapter 15.

De Refractionibus & Elliptica Lunæ Figura in Horizonte.

On refractions and the elliptical figure of the Moon on the horizon.

I. We dealt with the Sun's refractions in Book 3, chapter 9; but most of what was said there is common to the Moon's refractions. We therefore send the reader back to that place, since we also pointed out there the tables of lunar refractions and their authors. And although I have a great many observations of both luminaries for refractions, taken at different times of the year, I reserve a more subtle examination of them for the Optical Book, for the most just reasons. For in the meantime Tycho's table, which we shall give at the end of this volume, is not unsuitable. So that the present chapter may not be too short, I shall add a few things on the quasi-elliptical figure which the Moon herself takes on at the horizon at full Moon.

[Margin: The Moon an ellipse.]

II. The full Moon, then, rising or setting at the horizon, shows an egg-shaped figure, but at times more pointed than the Sun, almost as you see in the figure attached here. The cause is the same as that of the solar ellipse, already set out in Book 3, chapter 2.

Diagram. An oval, pointed at its left and right ends, set into the left column. A horizontal diameter joins the two points and a vertical diameter crosses it at the centre. Labels read:

- A (left point): end of the long diameter
- B (right point): other end of the long diameter
- C (top, outside the outline): upper end of the short diameter
- G (bottom, outside the outline): lower end of the short diameter
- D (just above the crossing, right of the vertical): no function stated in this passage
- K (inside, upper left): no function stated in this passage
- L (inside, upper right): no function stated in this passage

Labels not read: none.

Take now, from our Georges Fournier (*Hydrographia* Book 13, chapter 2), the measures of the Moon's apparent diameter observed by Pierre Gassendi in 1634, at the full Moons of October and December. Ours do not much conflict with them,

Month	Altitude of ☾, apparent	Diameter AB	Diameter CG
October	4′ 40″	37′ 40″	34′ 0″
	5′ 15″	37′ 15″	35′ 0″
	7′ 0″	37′ 0″	36′ 0″
December	0′ 0″	37′ 0″	29′ 48″

since at times, with the Moon at perigee about the equinoxes, using a sextant, we saw the diameter AB span 38′ or even 40′. Nor can this be ascribed to dilation of the pupil, since one observer was looking at one edge and another at the other.

CAPVT XVI.

Chapter 16.

De Magnitudine Apparenti Lunæ.

On the apparent magnitude of the Moon.

I. Almost everything we said about the apparent diameter of the Sun in Book 3, chapter 10, holds for the diameter of the Moon, except that in the Moon the change of diameter and of distances is more evident. But from the shadow, or from her image received through a hole onto a board parallel to the hole, the measure of this diameter is less evident. Of the six principal methods of observing the diameters of the luminaries, which I described in that same place, the 1st, 2nd, 3rd and 4th therefore suit the Moon better.

[Margin: A method of observing the Moon's diameter by eclipses.]

There remains, however, a threefold special method of investigating the Moon's diameter from eclipses. The first is the one handed down, together with examples, by Ptolemy (Book 5, chapter 14), al-Battānī (chapter 30), Regiomontanus (*Epitome of the Almagest* Book 5, propositions 18 and 19), Copernicus (Book 4, chapters 18 and 19) and Biancani (*Sphaera* Book 9, chapter 8); and I shall bring it forward shortly in reporting the Ptolemaic and Copernican opinion, because it is based on the Moon's latitude and the digits obscured. The second is based on the Moon's hourly motion and the time of incidence, of which I shall speak in number 14. And the third lies in comparing the lunar diameter with the interval between fixed stars, of which I shall speak in number 9.

[Margin: 1. Ptolemy's opinion.]

II. Ptolemy, then (Book 5, chapter 14), rejects the diameter gathered from a time counted by water-clocks, or by Hipparchus's dioptra. By the dioptra, however, he says, the visual diameter of the Sun and the Moon at ☌ and at apogee was found equal to the Sun's, "without any sensible difference that need concern us." He relates that in the year 127 of Nabonassar, on the 27th day of the month Athyr, in the following night, at the 5th temporal hour, at Babylon, the Moon began to be eclipsed, and that at the height of the eclipse a quarter

of the lunar diameter was eclipsed, towards the south. Supposing the Sun then to be at ♈ 27° 5′, he gathers that the middle of the eclipse was at 5^h 50^m equal time after midnight at Babylon, but at 5^h at Alexandria, and in equated time 4^h 45^m; and that accordingly the Moon's mean motion was ♎ 25° 32′, but her true motion 27° 5′, her anomaly 340° 7′, her distance from the node 9° 20′, and so her latitude north 48′ 30″.

Next, in the year 7 of Cambyses, or 225 of Nabonassar, on Phamenoth 17, in the following night, 1^h before midnight at Babylon, but at Alexandria 1^h 50^m equal, and equated 2^h 10^m, the Moon was eclipsed at the middle, and indeed by half of herself, towards the north. From this, supposing the Sun at ♋ 18° 14′, he deduces the Moon's mean place at ♑ 20° 22′, but her true place 18° 14′, her anomaly 28° 54′, her distance from the node 7° 48′, and her latitude south 40′ 40″. Since, therefore, in both cases the Moon was near apogee, from which she stood only 20° in the earlier eclipse and 29° in the later, he gathers the apparent diameter of the Moon at apogee as 31′ 20″, and so that of the Sun as well; and that of the shadow as 40′ 40″, at the place of the transit of the Moon at apogee.

Diagram. A large hatched disc, set into the right column, with a vertical line through its centre running out to a small circle overlapping its top edge and another overlapping its bottom edge. Labels read:

- E (left, outside the disc): point on the shadow's disc
- L (right, outside the disc): point on the shadow's disc
- B (top, inside the upper small circle): centre of the Moon at the first position
- K (on the vertical, within the disc, below B): end of the Moon's semidiameter BK
- ring at the centre of the disc, on the vertical: no letter beside it; the text calls the centre O
- P (on the vertical, within the disc, near the bottom): end of the eclipsed part AP
- A (on the vertical, where it meets the bottom edge): end of the shadow's diameter
- D (inside the lower small circle): centre of the Moon at the second position

Labels not read: none.

For let AEBL be the disc of the Earth's shadow, and AB its diameter. Let B be the centre of the Moon, eclipsed to the north by exactly her whole semidiameter BK, but let her be eclipsed to the south by a quarter of herself, AP, with the Moon's centre placed at D. Let the Moon's latitude OB be 40′ 40″, which is equal to the latitude OB; for it is clear that the apparent semidiameter of the Earth's shadow is also that great, at the place of the transit of the Moon having an anomaly of 29°. For in an eclipse of half the Moon the lunar centre touches the periphery of the shadow, and BO is the Moon's latitude. Therefore,

because the anomaly was almost the same in both cases, OA, the semidiameter of the shadow, was 40′ 40″; but the latitude OD was 48′ 30″. So when OA is taken away, AD remains, 7′ 50″; and this was a quarter of the lunar diameter. Therefore, by multiplying by four, the apparent diameter of the Moon, as though at apogee, was 31′ 20″. Ptolemy adds that in many observations of this kind he found these quantities very nearly in agreement, and therefore used them for investigating the distance of the Sun; and that the diameter of the Moon at perigee in the syzygies was 35′ 20″.

[Margin: A method of gathering from one the other quantities of the apparent semidiameter.]

How the Moon's true semidiameter is gathered from the distance of the Moon at apogee found by parallaxes, as stated in chapter 14, and from her apparent semidiameter, and from that the apparent semidiameter for her other distances from the Earth, is clear from what was said in Book 3, chapter 11, numbers 2 and 4, and Copernicus teaches it (Book 4, chapter 22). But you have already seen that in these eclipses the Moon was not strictly at apogee; indeed, she stood almost a whole sign from apogee. Next, that determination of the quarter part eclipsed rests on an estimate by eye, and it is not so certain as is the estimate of half the Moon, or of the whole Moon eclipsed in darkness without duration.

[Margin: Ptolemy's error.]

Moreover, the Sun's anomaly was not the same in both cases, since in the earlier eclipse the Sun stood about its mean distance, and in the later it was nearer apogee. This reasoning of Ptolemy's is therefore rather crude, and without doubt erroneous.

[Margin: Our method is better than Ptolemy's.]

Better for this purpose are two eclipses, in one of which half the Moon, and in the other the whole Moon without duration, is eclipsed, provided that the Sun and the Moon each hold the same anomaly in both cases. For then the Moon's latitude proper to the later eclipse, if subtracted from the latitude of the half eclipse, will reveal the Moon's apparent semidiameter. But in our whole history of eclipses I could find no such comparisons of eclipses.

[Margin: 2. The opinion and error of al-Battānī, Alfonso, Clavius, Peuerbach and Hérigone.]

III. Al-Battānī (chapter 30), from the observation of eclipses, determines the apparent diameter of the Moon at perigee in the syzygies as 35′ 20″, with Ptolemy; but at apogee as 29′ 30″. Accordingly, since he sets the diameter of the Sun at apogee at 31′ 20″, he denies that ☼ at apogee can be wholly covered by ☾ at apogee. The Alphonsine Tables, in their table of semidiameters, p. 115½, and Peuerbach in his tables of eclipses, give the Moon at apogee 29′ 0″ and at perigee 36′ 8″. Clavius, in the *Sphaera*, favours them, as does Hérigone, who gives the former 30′ and the latter 36′. But Lansbergen, in the Prolegomena

to the *Uranometria*, demonstrates from these and from the distances set by al-Battānī that the distance of the Sun at apogee follows as 7936½ semidiameters of the Earth, and greatly conflicts with the distance of ☼ set by al-Battānī.

[Margin: 3. The opinion of Copernicus, Reinhold and Mästlin.]

IV. Copernicus (Book 4, chapter 19), from unnamed eclipses, corrects the Ptolemaic diameters, saying: "We have judged that these should be put in order and emended thus: we set the apparent diameter of the Sun at apogee at 31′ 40″ (for it must in some way be greater now than before Ptolemy); that of the Moon, full or new, and at the highest apse, at 30′; and also the diameter of the shadow, at her very passage through it, at 80 3/5′. For it is fitting that there should be in them a slightly greater ratio than 5 to 13, but as 150 to 403; and that the whole Sun is not covered by the Moon unless she has a distance from the Earth of 62 parts, of which the radius from the centre of the Earth is one. For these, so set down, seem by a certain reason to cohere both with one another and in everything else, and to agree with the apparent eclipses of the Sun and the Moon." Then in chapter 20 he gathers from these assumptions that the Earth's true diameter is to the Moon's true diameter as 7 to 2, or in a triple sesquialter ratio; and from this in chapter 22 he gathers the Moon's apparent diameter proper to the distances we dealt with in chapter 14: namely, for the Moon at perigee in the syzygies 35′ 38″; but in the quadratures at apogee 28′ 45″, and in the quadratures at perigee 36′ 44″. Mästlin subscribes to this, in the appendix to Kepler's *Prodromus*, p. 154, and so does Reinhold in the Prutenic Tables.

[Margin: And the error.]

But Lansbergen, in the Prolegomena to the *Uranometria*, demonstrates from these and other data given by Copernicus a geometric inconsistency in the Copernican hypothesis: for it follows that the distance of the Sun from the Earth is 941 53′ terrestrial semidiameters, which conflicts with Copernicus himself. From this you see what you should think about p. 123 of the Prutenic Tables, where the Moon's diameter is put at 30′ at apogee and 35′ 38″ at perigee, as Magini also once put it in the *Theoricae*.

[Margin: 4. The opinion of Tycho and Mulerius.]

V. Tycho (volume 1 of the *Progymnasmata*, pp. 119 and 135) puts the Moon's diameter in the quadratures at 32′ 32″ at apogee and 36′ at perigee; but for the Moon at ☌ he establishes 25′ 36″ at apogee and 28′ 48″ at perigee, and at ☍ 32′ at apogee and 36′ at perigee. "Since it has been noticed," he says, "at the ecliptic ☌ of the luminaries, that the Moon does not keep the same visible diameter that she has at other times, but that her edges are thinned by the force of the Sun's light, as some optical reason suggests, so that about a fifth part of the Moon is thus lost." Mulerius followed his table in the *Tabulae Frisicae*, p. 426, and so did Origanus in volume 1 of the *Ephemerides*.

[Margin: Tycho's errors here, or his deception.]

Three things tell against this hypothesis of Tycho. First, from these and the distances of the luminaries that he gives, it follows that the angle of the

Earth's shadow is greater than the angle subtending the Sun's apparent diameter, whereas it ought to be less, as Lansbergen demonstrates in the Prolegomena to the *Uranometria*; and Kepler, in the *Ephemerides*, p. 9, admits that from the hypothesis of the Tychonic distances there follows a diameter of 33′ 9″ at apogee and 34′ 48″ at perigee. Second, a total eclipse of the Sun could never occur, since the diameter of the Sun at apogee, that is its least, is 30′, whereas that of the Moon at ☌ at perigee, that is its greatest, is 28′ 48″. And so Tycho, when he had read in Clavius (*Sphaera*, chapter 4) that a total eclipse of the Sun, with duration and dreadful darkness, was observed at Coimbra in 1560, wrote to Clavius that he marvelled that a total eclipse had been seen in Portugal, and nocturnal darkness by day; for his observations do not allow the Sun to be wholly covered by the Moon, however low she may be. So Kepler relates, in the appendix to volume 1 of Tycho's *Progymnasmata*, and in the *Optics*, p. 285. But that Tycho's little table is not to be relied on was shown, Kepler says in the same place, by the solar eclipse of 1601 December 24, shortly after the death of Tycho, who had died on October 24, as Willebrord Snel relates in the *Observationes Bohemicae*; for that eclipse was greater than the Tychonic lunar diameter. And we shall show below, in number 15, that total eclipses of the Sun have appeared more than once.

[Margin: Tychonic observations of the lunar diameter.]

Third, if we weigh Tycho's observations on this point, their uncertainty and deceptiveness will at once be plain. For Kepler says in the *Astronomia Optica*, p. 218: "In Tycho's observations, with five or six men observing the same Moon, according to the sharpness of each one's sight, the reckoning of the diameter grew, wandering, from 31′ to 36′; and in 1591 February 22 the Moon was observed twice at 31′, six times at 32′, seven times at 33′, six times at 34′, once at 36′." And on p. 348 he goes on in these words: "In 1592 June 14, with an eclipse at hand, Brahe's men, measuring the Moon's diameter with the astronomical radius according to Gemma's teaching, reported 32′ or 31½′: the Moon was at apogee. The method is both uncertain, and always presumed to state more than is right." See here what I said against the radius in Book 3, chapter 10, number 3, and shall say more fully in the *Liber Organicus*. Kepler adds in the same place that in 1592 February 12 the diameter of the Moon, when she was not at her lowest, was observed by the same men as 35′; that in 1587 January 6 the diameter of the quarter Moon at apogee, from the altitude of the horns, was found to be 30′; that in 1588 March 2 the difference of declinations between the edges of the Moon, by the armillaries, was found to be 33′, 32⅓′, 31′ and 30¾′; and that this very method is somewhat less certain. Let us therefore dismiss Tycho.

[Margin: 5. Magini's more recent opinion.]

VI. Magini, then, in the *Supplement to the Ephemerides*, Canon 3 on calculating eclipses, admits that Canon 68 for finding the diameters of the luminaries, which he gave in the tables of the *Second Mobiles*, on the hypothesis of Copernicus, does not satisfy the heavenly appearances. He condemns Tycho's hypotheses in

this matter and their follower Origanus; and finally he gives a table according to Kepler's view, in the appendix to Tycho's *Progymnasmata*, in which the apparent diameter of the Moon, new as well as full, is 30′ 30″ at apogee and 34′ 40″ at perigee.

[Margin: 6. Kepler's inconstant opinion.]

VII. Kepler himself, indeed, has shown himself to us more inconstant than the Moon herself. For in the *Astronomia Optica*, p. 344, he says that in 1600 July 25 the ray of the full Moon at mean distance, let through a hole onto paper, was of more than 105½ parts and of fewer than 100, and therefore greater than 29½′ and less than 31′ 12″; but that by this route it is estimated as smaller than is right, because the extremes of the ray, being of very weak light, are not well caught by the eyes. In 1603 January 26, however, he says the ray of the Moon at perigee was greater than 113 particles and less than 120, and therefore greater than 32′ and less than 34′ 18″. On p. 347, from a comparison with the distance of the Pleiades, of which I shall speak in number 9, he gathers the diameter of the Moon, as she heads towards apogee, as 31′ or 32′. And on pp. 348 and 359 he concludes, from the solar eclipse of 1601 December 24 and the image of the lunar shadow measured on paper, that the diameter of the Moon at apogee is not less than 30½′, so that the Moon at apogee cannot wholly cover the Sun at perigee; but that the diameter of the Moon at perigee is still uncertain to him, whether it is 33⅓′, or 34′, or 34⅔′, and whether the mean is 31′ 55″, or 32′ 15″, or 32′ 35″.

But in the foundations of his *Ephemerides* he restricts the Moon's diameter in the syzygies to 30′, and at perigee to 34⅙′. He admits, however, that he did violence to his own observations, so as to indulge his predecessors, who had affirmed that the Moon, carried beneath the Sun, did not cover the whole of it, and so as to concede to Hipparchus that the diameters of the Sun and the Moon at apogee are equal. And so, although he had wished from his own observations to make the Moon's diameter at apogee 30′ 30″, and even 31′, he nevertheless gave up one minute or half a minute, lest under the compulsion of his hypothesis he should extend the Moon's diameter at perigee too far beyond 34′. Yet he frankly adds: "Nor is the matter closed with me by these figures, because I reserve the liberty of increasing it by one minute, if a greater number of observations should seem to require it." [Margin: David Fabricius's opinion on an increase of the lunar diameter.] Now David Fabricius, because of air or thicker aether surrounding the Moon (which we discussed in chapter 2), held that the lunar diameter in eclipses of the Moon appears greater by 4′ or 5′, and that the duration of the eclipse therefore comes out longer; but in eclipses of the Sun smaller, because of refractions of the Sun's rays occurring in the Moon's atmosphere. Kepler opposes him in the same *Ephemerides*, p. 9. For although he concedes something to this air, it is not so much, nor the whole of this effect. Other causes, he says, contribute to it: namely the deception of sight, which enlarges the image of white and bright things, as he has said in *Astronomia Optica*, p. 286; the diameter of the Moon, which is in reality at times

smaller than the Sun's; and the increase in the duration of an eclipse from the penumbra.

Lastly, in the Rudolphine Tables, precept 131, he says that if the difference of the coequated anomaly is increased by a sixtieth part of itself, the Moon's parallax results; but if that same sixtieth is added to half of the parallax, the Moon's apparent diameter results. In precept 147, however, he refers the reader to the table of semidiameters which he gives on p. 98, where the Moon's semidiameter in the syzygies is 15′ at apogee and 16′ 22″ at perigee. At the foot of that table he appends these words: "Although the Moon's diameter has been deduced very neatly by a demonstration from archetypal causes, observations nevertheless everywhere call for a larger one: perhaps because the height of the lunar air is so great that the demonstrated solidity of the globe is increased by it, all round, by 1′ or 1½′, or even by a larger amount according to the diversity of physical causes." And a little later: "The Moon at the vertical can also appear ½′ greater than on the horizon." So Kepler wavers between observations and the ideas of his hypotheses. In the *Epitome of Astronomy*, too, p. 861, he sets the semidiameter of ☾ at 15′ at apogee and 16′ 22″ at perigee. And on p. 893, so as not to be forced to contract the Moon's diameter, as the annular eclipse of the Sun seen by Clavius in 1567 would require, he shifts the cause of the phenomenon either onto the inflamed substance of a thicker aether around the Sun, or onto circumlunar air refracting the Sun's rays.

[Margin: 7. Longomontanus's opinion.]

VIII. Longomontanus, in *Astronomia Danica*, *Theorica* Book 1, chapter 9, on account of Tycho's observations gives the Moon at apogee in ☌, and taken by itself in ☌, a semidiameter of 16′ at a distance of 57 semidiameters of the Earth 38′. Therefore, for the Moon at perigee, at a distance of 54 semidiameters 23′, he is forced to give a semidiameter of 17′, two minutes smaller than Tycho's. "For although," he says, "it appears greater at full Moon, this nevertheless happens to it incidentally, because of the refraction of the lunar rays in the thick air around the Earth, especially near the horizon." Because of this refraction he thinks that the Sun's diameter too is enlarged, by the refracted solar rays and by optical dilation, and that therefore the Moon's diameter at ecliptic new Moons appears smaller by a fifth of itself and more. This, he holds, is established by the eclipses from 1589 to 1597 observed with a visual instrument; by the bright ring of 1½ digits around the Moon, observed by M. Andrea Fossio [Anders Foss] in the eclipse of the Sun of 1601 December 24 at Bergen in Norway; and by the eclipse of the Sun of 1608 August 10, which at Copenhagen, with parallax allowed for, ought to have been of at least one digit, and yet none was seen, he says, because of the already mentioned refraction, greater there than in Bohemia, where the air is purer. And therefore, he says, the eclipse of the Sun of 1600 June 30, which ought to have appeared scarcely 4 digits, was greater than 5½ digits. But the chief reason why, in an eclipse of the Sun, the Sun's diameter appears greater relative to the Moon, he says, is the diffusion of the Sun's light through the air around the cone of the lunar shadow, from

rays reflected from the Earth. For when the Moon's shadow is diminished and diluted, the edges of the Sun, which are seen under the angle of the shadow, must appear under a greater angle, and dilated. So too in a lunar eclipse the Moon's diameter appears greater, not only by the force of the refraction of the lunar rays that occurs in the thick air around the Earth, but also because the Earth's shadow is diminished by the rays of the Sun refracted in the same air. For these reasons, on p. 301, he sets out a small table for correcting the semidiameters of the luminaries by an optical equation, greater, however, in eclipses than outside them; and it is given below.

Optical equation of the lunar semidiameter, for the polar altitudes listed below: to be subtracted in ☌; to be added in ☍.

Degrees of polar altitude	20	30	40	46	50	53	56	59	62	65	69	74
In eclipses	0″	10″	30″	40″	50″	2′	3½′	4½′	5¼′	5¾′	6′	6⅓′
Outside eclipses	0″	6″	20″	30″	34″	1⅓′	2⅓′	3′	3½′	3⅚′	4′	4⅕′

[Margin: Objections against Longomontanus.]

Against this doctrine of Longomontanus many things occur to me. First, if the Sun's rays are refracted in our air in such a way that they show a greater diameter of the Sun (about which, however, there is doubt from what was said in Book 3, chapter 10, Scholium 3), then it is not the Moon's semidiameter that should be diminished, but the Sun's that should be increased, and indeed outside the syzygies too: for that refraction is not tied to the syzygies of the luminaries. Secondly, the bright ring appears around the Moon in an eclipse of the Sun even when the Sun stands far from the horizon, at an altitude of 40° or 45°, where by Tycho's rule sensible refractions cease. In the eclipse of ☼ of 1567 April 9, observed with a bright ring by Clavius at Rome near noon, the Sun stood 55° above the Roman horizon. Thirdly, when the luminaries are on the horizon or close to it, their apparent diameter in a vertical circle is far smaller than the diameter transverse and parallel to the horizon, as is clear from what was said about the elliptical figure of the Sun in Book 3, chapter 2, and of the Moon in this Book, chapter 15. Therefore Longomontanus's equation ought not to have been applied indiscriminately to the diameter of the luminaries taken in any direction. Fourthly, when the visual diameter of the Moon is in itself greater than the diameter of the Sun, as is often the case in Longomontanus's view (for the Sun's semidiameter is 15′ at apogee and 16′ at perigee, but the Moon's 16′ at apogee and 17′ at perigee), a total eclipse of the Sun can occur, such that none of its rays reach us, whether direct or refracted in our air. Therefore the Sun will not then appear greater, or, if it does, that will rather be because of refraction occurring in the circumlunar air. Fifthly, the Sun's rays reflected from the Earth towards the Moon do indeed dilute and attenuate the Moon's shadow around the edges, but nevertheless they do not change the angle under which we see the Sun's edges, since we do not see those edges by those rays reflected elsewhere than to our eye.

[Margin: 8. Lansbergen's opinion.]

IX. Philips van Lansbergen, on p. 37, determines the Moon's apparent semidiameter in the syzygies as 15′ at apogee and 17′ 49″ at perigee, which he confirms in the *Thesaurus* of lunar observations, Class 4, and in the *Uranometria*, Book 1, Element 10, by this method. For he says that the semidiameter of the Moon at apogee in the syzygies, set at 15′ by Copernicus, agrees exactly with the sky and with observations. From this, and from the distance of the Moon at apogee, he infers that the Moon's true semidiameter is to the Earth's semidiameter as 16 8/10 to 60. From the true semidiameter, and from other distances corresponding to the anomaly, he deduces the other apparent semidiameters by trigonometry. He then confirms these from a threefold observation made by the Braheans [Braheanis] on 1588 March 2, 1591 February 22 and 1592 February 12, in which the Moon's apparent diameter was seen, in the first observation by armillary spheres, at about 33′; in the second by quadrants, at 33′, a middle value chosen between the extremes; and in the third by the radius, at 35′. Likewise from a double observation by Kepler, of 1598 March 29 and 1598 June 17: in the first of these he saw the Moon's diameter a little smaller than the distance of the western stars in the quadrilateral of the Pleiades, which for Tycho is 31′; in the second, equal to the distance of the two bright stars in the quadrilateral of the Pleiades, which is 32′, as Kepler reports in *Astronomia Optica*, p. 347.

[Margin: Doubts about this opinion.]

But Kepler himself admits there that he trusts observations of eclipses more than an ocular estimate of this interval compared with the Moon's diameter. The observation made by the Braheans by the radius, moreover, is unreliable, and the one made by them by quadrants or by armillary spheres is inconsistent, as we said in no. 5. Nor is the middle value chosen by Lansbergen from those extremes necessarily truer, since one of the extremes could have been true and the others false. Whether this diameter actually satisfies eclipses is something we must weigh more fully in volume 3 of the *New Almagest*, in the book on eclipses, and touch on below, in nos. 15 and 16.

[Margin: 9. Boulliau's opinion and method.]

X. Ismaël Boulliau, in Book 4 of the *Astronomia Philolaica*, chapter 1, investigates the Moon's semidiameter by means of the eclipse of 1638 December 21. He reports that the observed time of incidence, that is, from the true beginning of the eclipse to total obscuration, was $1^h\ 1^m\ 30^s$. The Moon's coequated anomaly was 118° 29′ 31″; therefore the hourly motion was 33′; therefore the Moon, in the time of incidence, traverses 33′ 48″ in the zodiac. So great, then, was the Moon's diameter, since it was entirely obscured. [Margin: But uncertain.] But the time of that incidence, as I have it in my history of eclipses, was observed differently by others: namely at Frenequere [Franeker] by Phocylides, $1^h\ 3^m\ 30^s$; at Digne by Gassendi, $1^h\ 1^m$; at Herk [Hercij] by Wendelen, 58^m; at Brussels by van Langren, $57^m\ 41^s$. The Moon's diameter would therefore be 34′ 55″ for Phocylides and 31′ 44″ for van Langren. This method is therefore unreliable,

especially since they do not agree on the hourly motion (for see no. 14), whether this diversity arises from the eyes and diligence of the observers, or from instruments or calculations, or from air refracting the Sun's rays and affecting the penumbra and the shadow of the Earth with differing quantity. Yet he rightly adds that the semidiameters of the luminaries must be reconciled so that the Sun at apogee appears smaller than the Moon at perigee, and can undergo a central eclipse with duration; while the Sun at perigee appears greater than the Moon at apogee, as eclipses attest. Finally, on p. 196, from the proportion of the distances, he determines the Moon's semidiameter in the syzygies as 15′ 35″ at apogee and 17′ 0″ at perigee, but in □ as 14′ 58″ at apogee and 18′ 2″ at perigee. His tables he gives on p. 138.

[Margin: A second example from another eclipse.]

But let us try some eclipse on whose incidence the observers agreed. Out of the whole history of eclipses, then, a single one occurs, that of 1631 November 8, whose incidence Gassendi, Hortensius and van Langren, in widely separated places, observed with remarkable agreement as 66^{m} of time. The anomaly of ☾ was almost 2°, so that it was very close to apogee; but the hourly motion of the Moon from the Sun varies among astronomers, and so the Moon's apparent diameter derived from it varies, as can be seen in the following small table. But I used the true hourly motion of the Moon, with the true hourly motion of the Sun at that time subtracted from it. How much greater, then, will the diversity be if eclipses are used in which the observers agree neither on the interval of incidence nor on the hourly motion?

Time of incidence 66^{m}. Anomaly of ☾ 2°.

Authors	Hourly motion of ☾ from ☼	Apparent diameter of ☾
Copernicus	26′ 36″	29′ 16″
Tycho	27′ 40″	30′ 0″
Kepler	27′ 13″	29′ 48″
Lansbergen	27′ 18″	29′ 50″
Wendelen	27′ 0″	29′ 42″
Boulliau	27′ 10″	29′ 47″
Ourselves	26′ 48″	29′ 28″

[Margin: 10. Gassendi's opinion, and a deceptive procedure.]

XI. Pierre Gassendi, in the book on the apparent magnitude of the low and the high Sun, letter 2, in the *Institutio Astronomica*, Book 2, chapter 9, and in the *Life of Peiresc*, reports that the Moon's apparent diameter was observed as 26′ 36″ at apogee and 31′ 6″ at perigee, by the shadow of a small plate cast onto a second small plate parallel to the first and at a known distance. But on the uncertainty of this kind of procedure see what I said in Book 3, chapter 10, no. 9.

[Margin: 11. Wendelen's opinion.]

XII. Govaert Wendelen, in the *Idea of the Atlantic Tables*, adducing no individual observation but only from eclipses he has weighed, sets the diameter

of the Moon at apogee at 28′ 40″ on the horizon and 29′ 10″ at the zenith, and at perigee at 32′ 42″ on the horizon and 33′ 18″ at the zenith. On p. 5 he suspects that its diameter is increased by the circumlunar air: for this, he says, is perhaps as thick as the air around the Earth, and so the beginnings of eclipses appear earlier, and the ends later, by almost 1^m of time. [Margin: What does van Langren say here?] But Michael Florent van Langren, royal cosmographer, in a letter to me from Brussels of 1647 July 6, writes that he observed the Moon's diameter on many days indeed, but above all that of the Moon at apogee at the full Moons of 1646 May 29, June 27 and July 27, and at perigee in ♌ on 1647 January 20 and February 18; and that the apogee diameter was to the perigee diameter as 68404 to 78146, that is, as 30 to 34 19/68. But he has not yet disclosed how great it is in definite terms.

[Margin: And that of Athanasius Kircher.]

Lastly, Athanasius Kircher, in volume 2 of the *Ars Magna*, Book 9, Problem 9, gives the Moon's diameter as 29′ 22″ at apogee and 34′ 40″ at perigee.

Noſtræ Obſeruationes ſelectæ, & Primum Fundamentum de apparenti Diametro Lunæ.

Our selected observations, and the First Foundation concerning the apparent diameter of the Moon.

[Margin: Our method for refining the Moon's diameter.]

XIII. Since I saw that among astronomers the Moon's diameter in the syzygies is admitted as never greater than 37′ or smaller than 26⅗′, I left untried none of the methods indicated in Book 3, chapter 10, and in this chapter, and to be explained in the *Liber Organicus*, by which I might come as close to the exact measure of this diameter as is permitted to a mortal. Next I went through the eclipses of the Moon and the Sun, of which I have a most carefully assembled history, so that the diameter sketched from other observations should not conflict with any of those eclipses recorded a little more accurately. And finally I bound the distances of the Moon and the Sun, and the rest that follows from them, to the lunar diameter by a geometrical tie, so that no inelegance or geometrical error [ageometria] arising from them could undermine our hypothesis. At the horizon I used, besides sextants, with which it often appeared 40′ across, a tube without lenses, whose opening at a fixed length takes in 45′ of the sky; and at times this scarcely took in the full Moon, so great was the transverse diameter of the ellipse. Further, in deriving the diameter from the time of transit through the M. C., counted by the oscillations of the pendulum, we took account of the Moon's declination and of the ratio of the parallel on which the Moon stood to the equator. Here then are a few out of many, from which the First Foundation of the lunar diameter has been laid, after a fashion. For the Moon, full and at apogee, carefully observed on 1643 February 3, 1644 June 27, and 1647 June 27 and August 22, when it was only 4° or 5° from apogee, showed us an apparent diameter of 29′ or 28½′. But at perigee, on

1643 August 29 and September 27, the apparent diameter was 34′ at the most, and generally less, except for observations by the astronomical radius, which at times gave it as nearly 36′ at perigee. But we are certain that the radius always exceeds by 1′ and more; and so attention had rather to be paid to the times of the pendulum and to the altitudes of the edges, or to the distances of the edges, taken by two persons with a special instrument in the manner of a sextant. In the quadratures, the diameter for me was between 28′ and 27′ with the Moon at apogee, and between 35′ and 34′ at perigee, but always evidently greater here than at apogee full Moons. [Margin: The awkward hypothesis of some astronomers.] But these must be reconciled more accurately by geometry from the distances, so that we do not commit the fault of Ptolemy, Copernicus and Kepler, of which I shall speak in chapter 18, no. 8 [?].

2. Fundamentum Diametri Lunaris ex meo motu Horario.

2. Foundation of the lunar diameter from my hourly motion.

[Margin: Ratio of the Moon's hourly motion to its diameter.]

XIV. The true hourly motion of the Moon is sufficiently known to us from our tables, from the comparison of the motion of two neighbouring days and its difference divided by 24, and at perigee it is 35′ 30″. Astronomers have observed, as Magini attests in the *Theoricae Planetarum*, Book 2, chapter 25, that the Moon's hourly motion is to its visual diameter as 48 to 47, or rather, from Copernicus and Magini, at perigee approximately as 2255 to 2138. It follows that the Moon's apparent diameter is nearly 33′ 15/23, or certainly 33′ 30″. But since at apogee they set it as 29 to 30, from which a Moon's diameter greater than 29 would come out for me, while very many observations require a smaller one at apogee, it was therefore not permissible to follow that apogee proportion. The first to note the proportion of the hourly motion to the lunar diameter as 48 to 47 was al-Battānī, chapters 30 and 43, whom Peuerbach nearly followed in the *Theoricae Planetarum*, and there Reinhold, p. 206. Regiomontanus, in the *Epitome of the Almagest*, Book 5, proposition 21; Barozzi in the *Cosmographia*, p. 341.

3. Fundamentum ex Conſenſu Diametrorum Solis & Lunæ cum Eclipſibus Solis Totalibus.

3. Foundation from the agreement of the diameters of the Sun and the Moon with total eclipses of the Sun.

XV. Tycho, and with him Mulerius, denied total eclipses of the Sun. This is clear from the table of semidiameters drawn up for ecliptic new Moons, in which the Moon's semidiameter, however close to perigee, is always set by them as smaller than the Sun's apparent semidiameter; from the Appendix to the *Progymnasmata*; and from the testimony of Kepler in *Astronomia Optica*, from p. 285. There he also affirms that what gave Tycho occasion to contract the Moon's diameter at new Moons in this way was the optical enlargement of

the solar diameter, or dilation of the solar rays, in eclipses of the Sun, whether you look at the Sun directly at the time, or by reflection on paper or on a small plate that receives the ray and image of the Sun let in through a hole. For in both cases the Sun's diameter appears greater, and the Moon's smaller, than the hypothesis, resting on other foundations, otherwise demonstrates. However, Kepler rightly warns in the same place that the edges of bright things, especially in darkness, or next to dim or black things, are dilated in the eye, because they prevail in moving the sight, and either overwhelm or blunt the image of darker or black things, as he had taught in chapter 5 of his *Optics* from the structure of the eye and from experiments. [Margin: Tycho's manifold deception regarding the semidiameters of the luminaries.] We too touched on these things in chapter 6, no. 3. He adds that because of this deception of sight, which is inconsistent according to the varying structure of the eye and the state of the air, the table of semidiameters of the luminaries should not be altered, nor should one depart from the table that is demonstrated from what truly occurs. Furthermore, when the Sun is not seen, as in a total eclipse of it, that optical enlargement has no place, for things that appear enlarged are presupposed to be seen. Therefore Tycho ought not to have contracted the Moon's diameter universally at every new Moon. The reason why the Moon's semidiameter derived from ecliptic new Moons observed by reflection on a small plate came out smaller than it should, and the Sun's greater, was that the semidiameter of the hole or small window admitting the rays was not subtracted from the semidiameter of the base of the cone of rays, nor added to the portion of the Moon obscuring the Sun's disc, just as if the rays had entered through an indivisible hole, although in fact it was quite wide. So it should have been subtracted there and added here, as Kepler teaches in *Astronomia Optica*, chapter 11, Problems 2, 7, 8 and 9. Otherwise, in a ray or image received in this way, the Moon's diameter appears smaller than outside in the sky, the digits eclipsed fewer than in the sky, and the horns of the eclipse blunter than in the sky, as he had demonstrated in chapter 2, propositions 10, 11 and 12. On this procedure we too shall speak in Book 5, chapter 17, Problem 2. Lastly, Tycho's error is plainly refuted not only by the single total eclipse of the Sun seen by Clavius in 1560, but by several total eclipses which Kepler brings forward in the same place, and of which we treat in Book 5, chapters 19 and 20, where we shall confirm total eclipses of the Sun by examples and by the authority of astronomers, and distinguish the certain from the uncertain. Among these, from those chapters 19 and 20, I have selected the 12 more certain eclipses, leaving out the doubtful ones or those of doubtful date. The astronomer ought to have these before his eyes in reconciling the diameters of the luminaries, but especially the twelfth, because it was indeed total, but without sensible duration, observed at Naples, as we shall relate in Book 5, chapters 19 and 20. For there is greater danger of erring in this one and in those similar to it, nos. 4 and 6, if indeed the Moon's diameter is set sensibly greater or smaller than the Sun's; so that in the place of a central eclipse it comes out either total with notable duration, or annular.

The error, though, appears more evidently in those tables which make annular eclipses of the Sun out of total ones with duration, or total ones with duration out of annular ones, against the bare and sincere history of observations. The remaining eclipses are not so suitable for testing astronomical tables, because if an eclipse is said to have been observed in a given place as of 8 digits, and the tables allow it only 7 or 6½ digits, it will be easy for the author of the tables to condemn the observation and make it out to be deceptive.

[Margin: Total eclipses of the Sun.]

More certain total eclipses of the Sun, selected from the history of observations.

4. Fundamentum ex Conſenſu Diametrorum Lunæ ac Solis cum Eclipſibus Solis Annularibus.

4. Foundation from the agreement of the diameters of the Moon and the Sun with annular eclipses of the Sun.

XVI. That annular eclipses of the Sun, namely those in which a ring of the Sun's disc appears bright all round the Moon, do sometimes occur, I have already indicated by examples and authorities of astronomers in chapter 6, no. 4, and shall show more clearly in Book 5, chapters 19 and 20, nos. 4 and 5. From this I select the following four, more certain than the others and of more certain date, so that I may also conform the semidiameters of the luminaries to them.

[Margin: Annular eclipses of the Sun.]

5. Fundamentum ex Conſenſu Semidiametrorum Lunæ cum Semidiametro Solis & Vmbræ Terreſtris in Eclipſibus Lunæ ſelectis.

5. Foundation from the agreement of the semidiameters of the Moon with the semidiameter of the Sun and of the Earth's shadow, in selected eclipses of the Moon.

[Margin: How great the semidiameter of the shadow is.]

XVII. I shall demonstrate in Book 5, chapter 4, that the apparent semidiameter of the Earth's shadow at the place of the Moon's transit, joined to the apparent semidiameter of the Sun, is equal to the sum of the horizontal parallaxes of the Sun and the Moon. Now we have established above, from the firmest foundations, both the semidiameters of the Sun (Book 3, chapter 10) and the parallaxes of the luminaries, and so their distances (Book 3, chapters 7 and 8, and this Book 4, chapter 14). The semidiameter of the Earth's shadow therefore now depends on a necessary predetermination. With these, moreover, the Moon's apparent semidiameter must cohere by a geometrical tie, above all in those eclipses of the Moon in which astronomical tables are given no field to roam, and the goal of truth, standing as it were in an indivisible point, must be confined to a very narrow gap. Such are those observed as exactly total without any sensible duration, or very nearly total, without a barely perceptible remainder of the lunar disc, or those that appeared of only one digit or less, or those, finally, that appeared as none or as insensible, although the ephemerides of the calculations promised them as sensible. Among these, in order to examine my semidiameters and those of others, I have selected the following six from the history of which I shall speak in chapters 20 and 21, leaving out older ones of 2 digits, which some think are not to be trusted as the more recent ones are. I know that account must be taken here too of latitude and of the Moon's motions, but the chief elements are the semidiameters.

Eclipses of the Moon selected from observations for testing the astronomical tables.

5	1626	August	7	None or imperceptible
6	1636	February	20	2⅓ digits

Statuitur Semidiameter Lunæ Apparens.

The apparent semidiameter of the Moon is established.

XVIII. Kepler rightly says in the *Optics*, p. 212, that the investigation of the diameter of the luminaries is the foundation which those who undertake the restoration of astronomy must lay first. It is unbelievable, however, how hard it is to reconcile these diameters with the difference of the parallaxes and

distances, which have a necessary connection with them, and with the more certain observations, and, whenever tables were to be formed and reformed, to make all of this cohere by a geometrical tie, both internally and with what has been observed. Therefore, from several full Moons I observed, the diameters of the Moon that stayed with me as more certain than others were 28′ at apogee, at most 33½ at perigee, and about 30½ at mean distance. From these, and from the distances of the Moon, above all the mean distance of 59 Earth semidiameters, the perigee distance of 53 45′ and the apogee distance of 64 15′, and from the resulting eccentricity of 5 10′ in the syzygies, I found the true semidiameter of the Moon to be 26⅕ of the parts of which the Earth's semidiameter is 100. From this, for the other degrees of anomaly, I determined by analysis of triangles the lunar distances according to what was said in chapter 15, and from these the apparent semidiameters of the Moon corresponding to them, as you will see in our tables. From those tables I have selected the following, for the eclipses listed above. Since our hypothesis agrees wonderfully with these, I thought I should rest on it for the present, especially since, after toiling through many labours, I have found that this table could indeed be constructed somewhat differently, but hardly in such a way as not to offend against certain more evident observations, handed down on more reliable authority.

	Order of eclipse	Equated anomaly of ☼	Equated anomaly of ☾	Apparent diameter of ☼	Apparent diameter of ☾
☼ Total	1	0ˢ 0°	5ˢ 8°	30′ 50″	33′ 10″
	2	2ˢ 14°	6ˢ 21°	31′ 28″	33′ 10″

	7	2ˢ 18°	6ˢ 17°	31′ 38″	33′ 16″
	8	3ˢ 20°	6ˢ 9°	32′ 14″	33′ 24″
	9	11ˢ 21°	5ˢ 26°	30′ 50″	33′ 28″
	10	10ˢ 0°	5ˢ 16°	15′ 40″	16′ 39″
	11	1ˢ 4°	4ˢ 10°	31′ 0″	32′ 12″
	12	3ˢ 12°	4ˢ 14°	32′ 6″	32′ 22″
☼ An-nular	1	1ˢ 16°	9ˢ 26°	31′ 8″	29′ 16″
	2	2ˢ 9°	3ˢ 10°	31′ 28″	30′ 54″
	3	3ˢ 22°	4ˢ 10°	32′ 16″	32′ 12″
	4	5ˢ 26°	0ˢ 7°	33′ 8″	28′ 4″
		Equated anomaly of ☼	**Equated anomaly of ☾**	**Apparent semidiameter of the corrected shadow**	**Apparent semidiameter of the Moon**
☾ Eclipses	1	6ˢ 14°	6ˢ 9°	47′ 31″	16′ 42″
	2	7ˢ 25°	1ˢ 10°	38′ 33″	14′ 13″

Order of eclipse	Equated anomaly of ☼	Equated anomaly of ☾	Apparent diameter of ☼	Apparent diameter of ☾
3	11^{s} 27°	0^{s} 16°	38′ 50″	14′ 3″
4	8^{s} 26°	1^{s} 20°	39′ 31″	14′ 24″
5	1^{s} 10°	4^{s} 4°	46′ 5″	16′ 0″
6	7^{s} 24°	9^{s} 23°	40′ 22″	14′ 42″

Consult now the diameters in the tables of other astronomers, which, to make this evident, we shall set out at the end of Book 5 for the already-mentioned degrees of anomaly. You will see that none of the total eclipses is produced by Tycho or by Mulerius, and that numbers 3, 4, 9 and 12 are not produced by Lansbergen, who therefore, to excuse his tables, pretends that the Sun has drawn in its rays: an unheard-of prodigy, and more poetic than astronomical or optical. Of the annular eclipses, Ptolemy delivers none, and Longomontanus almost none, and those only by accident; number 1 is not delivered by Kepler and Wendelen; nor number 2 by Alfonso, Copernicus, Kepler, Boulliau and Wendelen; nor number 3 by Copernicus, Kepler, Boulliau and Wendelen. But they excuse their tables on this point. Kepler does so in the *Optics*, p. 301, attributing that bright ring to air, or to ether, set alight by contact with the neighbouring Sun and shining round about, or else to the circumlunar air or lunar atmosphere, which refracts the Sun's rays as our atmosphere does, and so enlarges the Sun's margins. This is also admitted by Fabricius in Kepler, in the foundation of the *Ephemerides*, p. 22; by Wendelen in the *Eclipses*, p. 5; by Boulliau, p. 210, or Book 4, chapter 5; by Bettini in *Apiarium* 8, *Progymnasma* 2, proposition 10; and by van Langren in a letter sent to me.

[Margin: Errors, or uncertain and forced evasions[28], of certain astronomers.]

Longomontanus, for his part, attributes it both to the air around the Earth, which refracts the Sun's rays and optically enlarges its limbs, above all near the horizon, and to the Sun's rays reflected from the Earth towards the Moon, which diminish the shadow of the Moon, under whose angle we then see the Sun. For otherwise he, like Bettini too, makes the Moon's diameter always larger than the solar one. But since these phenomena can be saved while the other things demonstrated about the Sun and the Moon are also preserved, I did not want to build my hypothesis on uncertain and inconstant causes. This is especially so since inflamed air does not produce a bright ring but suffuses a wide space around the Moon with twilight glow; and telescopes do not plainly reveal air around the Moon, nor is that air to be judged of such density and depth as to produce so great a refraction of the solar rays. What Longomontanus devises, moreover, has either been sufficiently rejected at number 8 or at chapter 6, number 4, or has no force where annular eclipses appear far from the horizon. That Lansbergen extends the diameter of the Sun to 36′ is against the most evident observations. There are also other eclipses of the Sun, either total or

[28]the page prints *effigia*; read as *effugia*

very nearly total, which our tables present far more consistently than those of others, as can be seen in Book 5, chapter 20, and at the end of Book 5, where we shall set out a table of semidiameters, both ours and those of other astronomers, so that, once the quantity of these eclipses has been examined in that chapter 20, the observation can be compared with their hypothesis. There it is truly astonishing that Kepler, in the *Astronomia Optica*, p. 294, contends against the Prutenic Tables that the eclipse of the Sun in the year of the 10th consulship of Constantius and the 3rd of Julian, which Marcellinus records and describes, was total, and yet admits that the Moon was then at apogee, whereas from Kepler's own table this eclipse is partial and annular, as I shall say in Book 5, chapter 19, at the year 360, and in chapter 20, after the eighth eclipse.

Finally, the lunar eclipses I listed above are represented consistently by hardly any tables except Wendelen's. David Fabricius, as Kepler reports in the *Ephemerides*, pp. 9 and 22, says that in the eclipse of ☾ of the year 1613, October 28, a digit seemed to the naked eye to be missing, and by telescope nothing; and that therefore, because of the circumlunar air, the diameter of ☾ is increased to the naked eye by 4′ or 5′, and that eclipses of ☾ seem to begin sooner and end later than they really do and than they do by telescope. Kepler rejects this: for if that air were so dense that it stopped the light of ☼ and could be seen with the naked eye, it would be seen much better by telescope. Likewise Fabricius says that in the smallest eclipses the darkened limb of ☾ is not discerned by the naked eye, and is discerned by telescope. But if the eye sees the eclipsed air of ☾, it will see much more readily both the air and the darkened small part of ☾. The reason why something not seen by the eye is seen by telescope is that the telescope optically enlarges things otherwise invisible. Granted, Kepler may say that it is an optical enlargement of bright objects, beside which dark ones vanish and do not impress a distinct image of themselves on the eye, because the image of the bright objects predominates, as he had taught in the *Optics*, chapter 5. But now let there be a table of opinions on the diameter of ☾ at apogee and perigee.

[Margin: Kepler's objection is refuted.]

But Kepler presses us hard. In the foundation of his *Ephemerides*, p. 9, he adjusted his diameters so as to hold to Hipparchus, who from observation makes the diameters of the Sun and of the Moon at apogee equal. Our hypothesis does not hold this, nor indeed does that of any of the astronomers, apart from Ptolemy and Kepler, as is clear to anyone comparing the preceding table with the table of Book 3, chapter 10. But Ptolemy, in Book 5 of the *Almagest*, chapters 11 and 14, describes Hipparchus to us as doubtful and changeable about the Sun's distance, and therefore also about its diameter and parallaxes, and he confesses that he himself was not so certain and accurate about the Sun's diameter either. For he says in chapter 14: *We too constructed the dioptra with the four-cubit rule which Hipparchus described, and, observing with it, we found that the Sun's diameter is contained everywhere under very nearly the same angle, with no perceptible difference worth troubling about produced by its distances; but we found that the Moon's is contained by the same angle as the Sun's only when, at oppositions, it is farthest from the Earth, etc.* So we should not stand by this. Nor has any eclipse of the Sun so far been produced in which the Moon at apogee has wholly covered the Sun, likewise at apogee. Neither can proposition 8 of Aristarchus be admitted, in whose exposition he says it is manifest that the Sun is wholly eclipsed, but with no delay in the eclipse, if he means this universally and at any distance of the luminaries.

SCHOLIA.

Scholia.

I. In Book 3, chapter 10, Scholium 2, I said that a change in the Sun's distance and apparent diameter cannot be evidently demonstrated from eclipses. For if someone supposes its semidiameter to be perpetually 16′ 10″, not only the

remaining eclipses but also, which seems more difficult, the total and annular eclipses of the Sun will stand, provided one retains the semidiameter of the Moon established by us, as will be clear to anyone contemplating the last column of the earlier small table set before number 18. For the lunar semidiameter will always be larger than the solar, as total eclipses of the Sun require, and smaller, as annular eclipses demand. And conversely, the apparent semidiameters of the Sun could indeed be so fitted that the Moon's semidiameter was always the same, and with the Sun's semidiameter varied, the eclipses would nonetheless be preserved. But this conflicts with the most evident difference of the lunar distances from the Earth, which has been detected from the difference of the notable parallaxes by us and by the others who practise this art faithfully. As for the difference of the solar distances, however, it is not so manifest from observations, because it could be put down to an error of observations, or of causes partly optical and partly physical.

[Margin: The variation of the apparent diameter is more certain in the Moon than in the Sun.]

Therefore, although it is almost beyond doubt for me that the distance of the Sun varies, and so its apparent diameter, yet if invariability of these were to be ascribed to one or other of the luminaries, we are certain that it cannot be attributed to the Moon, but only to the Sun.

II. It was said in chapter 15 that, because of refraction, the diameter of the Moon observed on the horizon is sometimes 38′ and nearly 40′, but the other 36′. From the varied constitution of the vapours of the horizon, therefore, the diameters can vary, and hence the measure of eclipses.

CAPVT XVII.

Chapter 17.

De Vera Magnitudine Lunæ ad Terram Solemq. collata, Portione Lunæ viſa à nobis, illuminata à Sole, deq. Portione & Diametro apparenti Terræ ex Luna ſpectatæ, ac tandem de Vmbra Lunari.

On the true size of the Moon compared with the Earth and the Sun; on the portion of the Moon seen by us and illuminated by the Sun; on the portion and apparent diameter of the Earth as seen from the Moon; and finally on the lunar shadow.

I. In this chapter we take up these problems, because they spring up for us from the distance of the Moon and its apparent semidiameter, now established. For the following propositions, then, let this be the figure, in which the Sun is EMF and the Moon ABCD; and let the extreme rays of the Sun, touching it and the Moon, be EAG and FCG, meeting at G and enclosing the lunar shadow AGC. Let the straight line KHG be drawn through the centres of the luminaries to the apex of this shadow, and from their centres let radii be drawn

to the points of contact of the rays, namely KE and KF in the Sun and HA, HC in the Moon. For there, with the tangent rays, by 16 of the third book of Euclid, they will make right angles at E, A, and so on. When the straight line HL is drawn from the centre of the Moon parallel to GAE, by 29 and 33 of the first book of Euclid it will make the angle AHI and the angles at L on either side right angles, and EL equal to AH, the Moon's semidiameter; and it will make the external angle LHK equal to the internal and opposite angle EGK, that is, to the half-angle of the cone of the lunar shadow, since KG falls on the parallels EG and LH. With these set down, let the following hold.

Diagram. A geometric figure of the Sun, the Moon and the Moon's shadow, set in the right column beside the text. The Sun stands at the top as a shallow bowl, an arc below a nearly straight upper line, with two lines running down from K to E and to F; two straight lines descend from E and F, touch a small circle (the Moon) at A and C, and converge at the apex G at the foot. A vertical line runs from K at the top through M, B, H and D down to G. Inside the Moon's circle, radii run from the centre H to A and C. A slanting line runs from L down to the Moon's circle by I, towards H.

- K (top centre, on the upper line): K
- E (upper left end of the Sun): E
- F (upper right end of the Sun): F
- L (within the Sun, left of the vertical): L
- M (on the Sun's lower arc, on the vertical): M
- I (just above the Moon's circle, left of the vertical): I
- B (top of the Moon's circle, on the vertical): B
- H (centre of the Moon's circle): H
- A (left of the Moon's circle): A
- C (right of the Moon's circle): C
- D (bottom of the Moon's circle, on the vertical): D

PROBLEMA I.

Problem 1.

Diametrum Veram Lunæ & inde Circumferentiam, Aream circuli in Luna maximi, & Soliditatem Lunaris globi inueſtigare.

To find the true diameter of the Moon, and from it the circumference, the area of the Moon's greatest circle, and the solidity of the lunar globe.

II. In the preceding figure let the base HG be given, the distance of the Moon from the centre of the Earth, and the angle AGH, subtending the apparent semidiameter of the Moon as seen from that same centre. [Margin: Summary of the rule.] For since the triangle AGH is right-angled at A, by what was said in number 1, if one makes as the radius to the distance of the Moon, so

the sine of the apparent semidiameter to another term, the true semidiameter of the Moon will be known in the parts in which the distance HG was given. Alternatively, the logarithm of the distance added to the logarithm of the apparent semidiameter will make up the logarithm of the true semidiameter, and by doubling this you will have the diameter. If one makes as 100 to 314, so the diameter to another term, the circumference will be known. A quarter of this, multiplied by the diameter, will give the area of the Moon's greatest circle in square measures, while the whole circumference multiplied by the diameter will give the convex surface in square measures. Finally, the tripled ratio of the terrestrial diameter to the true diameter of the Moon will give the solidity of the Moon, according to what was said in Book 1, chapters 4 and 6. Now, on the occasion offered in this Book 4, chapter 16, from the Moon's apparent semidiameter of 16′ 24″ at a distance of 54 58′ Earth semidiameters, we find the true semidiameter of the Moon to that of the Earth, and so the diameter of the one to the diameter of the other, to be as 26⅕ to 100. Nothing else remains, then, except by this method to deduce the size of the Moon according to the various astronomers, from the lunar distances given in chapter 14 and the apparent diameters given in chapter 16. Here, then, is the fruit of this treatise in the following table, which is to be compared with the magnitudes of the Sun given in Book 3, chapter 11. I have also added, from Aristarchus's little book *On the Sizes and Distances of the Three Bodies*, the measures from his proposition 18, in which, given certain premises, he concludes: *The Earth is to the Moon in a greater proportion than 1259712 to 79507, and in a lesser than 216000 to 6859.* For the rest, see the Scholia.

PROBLEMA II.

Problem 2.

Lunæ Magnitudinem in Stadijs, Milliaribus, aut Leucis exhibere.

To express the size of the Moon in stadia, miles or leagues.

III. This depends on the preceding problem and on what was said about the diameter of the Earth in Book 2, chapter 7, for by using the rule of proportions this problem is easily solved. [Margin: The opinion of Tycho.] Meanwhile Tycho, in volume 1 of the *Progymnasmata*, p. 474, with the terrestrial diameter set at 1720 German miles, gives the diameter of the Moon 495 German miles. [Margin: The opinion of Galileo and Biancani.] But Galileo in the *Sidereus Nuncius*, p. 13, and with him Biancani in Book 9 of the *Sphere*, chapter 9, taking from Copernicus the Moon's diameter to the terrestrial as 2 to 7, assign to the lunar diameter 2000 Italian miles, because evidently they reckon the diameter of the Earth to contain 7000 Italian miles. [Margin: The opinion of Athanasius Kircher.] But Athanasius Kircher, in his *Magnes*, p. 561, gives the lunar diameter 2281 Italian miles; and so others in other ways. [Margin: Our view.] For our part, since in Book 2, chapter 7, we found 8278 modern Bolognese miles in the Earth's diameter, and since for us the true diameter of the Moon is to the terrestrial as 26⅕ to 100, we certainly recognize in the Moon's diameter 2168 84/100 Bolognese miles. Again, therefore, as 100 to 314, so 2168 84/100 to 6750 16/100, the Bolognese miles contained in the circumference of the Moon. Now in chapter 8 of this book, in Scholium 2, we set out the height of certain lunar mountains on the Copernican hypothesis, which assumes the lunar diameter to be to the terrestrial as 2 to 7, because we had not yet established our own measure of this proportion. Now, however, we establish it as 26⅕ to 100. [Margin: The height of the lunar mountains corrected.] So the heights must be somewhat corrected of the mountain Piccolomini, which we there set at 9 Bolognese miles high, and of Saints Michael and Xavier, which we set at 12, with the diameter of the Moon set at 2265 Bolognese miles. But for us it is 2168⅖. Therefore the mountain Piccolomini is only 8 14/25 Bolognese miles high, and Saints Michael and Xavier 11½.

PROBLEMA III.

Problem 3.

Quota Pars Lunæ videatur à terreſtribus ſpectatoribus.

What part of the Moon is seen by terrestrial observers.

IV. In the following figure, the portion ADC of the lunar hemisphere seen from the eye at G falls short of a perfect hemisphere by an arc as great as the angle AGC, which subtends the Moon's apparent diameter, as we showed in a similar case for the Sun in Book 3, chapter 11, number 3. So, given the Moon's anomaly, and its apparent diameter found by means of it, when this is subtracted from the hemisphere's arc of 180°, there will remain the arc ADC seen from the eye at G. From the table of chapter 16, then, here for you is this portion as seen by us in the syzygies.

Diagram. The same kind of figure as on the preceding page, set in the right column beside the text: the Sun at the top as a shallow bowl under a nearly straight upper line, two straight lines descending from E and F past the small circle of the Moon at A and C to the apex G at the foot, and a vertical line from K through M, B, H and D down to G. Inside the Moon's circle, radii run from H to A and C. A slanting line runs from L down towards the Moon's circle by I.

- K (top centre, on the upper line): K
- E (upper left end of the Sun): E
- F (upper right end of the Sun): F
- L (within the Sun, left of the vertical): L
- M (on the Sun's lower arc, on the vertical): M
- I (just above the Moon's circle, left of the vertical): I
- B (top of the Moon's circle, on the vertical): B
- H (centre of the Moon's circle): H
- A (left of the Moon's circle): A
- C (right of the Moon's circle): C
- D (bottom of the Moon's circle, on the vertical): D
- G (apex, at the foot): G

[Margin: Arc of the Moon seen by us in the syzygies.]

Portion of the Moon seen by us in ☌ and ☍ is 179° and in addition:

PROBLEMA IV.

Problem 4.

Quota pars Lunæ vltra hemiſphęrium illuminetur à Solis radijs irrefractis.

How much of the Moon beyond a hemisphere is illuminated by the Sun's unrefracted rays.

[Margin: Why the Problem is restricted to unrefracted rays.]

V. We limit the Problem to unrefracted rays because, if the Moon has around it an air or aether of its own that is denser, and of such density as to be fit for a sensible refraction of the Sun's rays, there is no doubt that much more of the Moon is lit by refracted rays than by unrefracted ones; and indeed more by as much as the horizontal refraction doubled, as we said in a similar case about the Earth illuminated by the Sun in Book 3, chapter 11, Problem 4, and shall show in Book 5, chapter 5, Problem 7. But this refraction at the Moon has not yet been established by any certain experiment or argument. Speaking, then, of the Sun's rays that touch the Moon unrefracted: it was shown in the preceding figure that AH equals EL and that triangle HLK is right-angled at L. So if the Moon's true semidiameter AH, which is supposed known from the first Problem, is subtracted from the Sun's true semidiameter EK, known from Book 3, chapter 11, and from the table of Problem 1, the remaining side LK will be known. And if from the Sun's distance, known from Book 3, chapter 7, the Moon's distance at new Moons, known from chapter 14 of this Book, is subtracted, or conversely if the Sun's distance is added to the Moon's at ☌, the distance HK between the luminaries will be known. Therefore, with base HK and side LK, you will find the angle LHK by means of trigonometry; this angle measures the arc IB. This arc, added to the quadrant AI (since in section 1 we showed that angle AHI is right, and therefore that arc AI is 90°), will make up the arc BA, whose double is the arc ABC of the Moon illuminated by the Sun's unrefracted rays.

[Margin: Short form of the rule.]

In brief, therefore: multiply side LK by the radius and divide the total by the base KH, for the quotient will be the sine of angle LHK; or, to the logarithm

of side LK add the residual of the logarithm of base KH, and the logarithm of angle LHK will result. But if you use the semidiameters of the table placed at the end of Problem 1, in which the Earth's semidiameter is supposed to be 100, you must first multiply the distance between the Sun and the Moon by 100.

[Margin: Authors on this Problem.]

Ibn al-Haytham in *De Crepusculis*, prop. 5, Witelo in Book 10, prop. 59, and Magini in the *Primum Mobile*, Book 11, prop. 28, set out this Problem in general or applying it to the Earth illuminated by the Sun. It is applied to the Moon, however, by Reinhold on Peuerbach's *Theoricae*, p. 165, and by Kepler in the *Astronomia Optica*, from p. 230. But Reinhold takes the diameters and distances of the luminaries from Ptolemy, deducing from them the arc ABC as 181° 45′, and so the angle KHL as 52′ 30″, which is too large, as will soon appear from Kepler's calculations and our own [Epilogiſmis]. Kepler therefore says that on the Ptolemaic hypothesis, when each luminary at apogee is seen under the same angle, the arc ABC ought to have come out at 180° 31′ 20″ in ☌ and 180° 28′ 12″ in ☍. We, however, taking the true distances and semidiameters from Book 3, chapters 7 and 11, and from Book 4, this chapter and chapter 14, have drawn up the following table.

[Margin: How this Problem is to be solved at the Moon's quadrature.]

Furthermore, at the quadratures the distance of the Moon from the Sun is very nearly as great as that of the Sun from the Earth. For in the figure placed in Book 3, chapter 7, Problem 3, triangle SKT is sensibly isosceles, and KS is as great as TS, because angle KTS differs little from the right angle TKS, and differs from it by only 30′, as we said there, and indeed by only 15′ if we believe Wendelen. He thinks that, because of the refraction of the Sun's rays in the lunar air, the Moon's apparent dichotomy is hastened in the first quadrature and delayed in the second by 15′ of the zodiac, that is, in time by about 30^{m}. But if that were so, the horizontal refraction of the Sun's rays in the lunar air would be very nearly 15′, as we shall demonstrate in the book on optics.

Arc beyond the quadrant of the lunar hemisphere illuminated by the Sun's unrefracted rays; when doubled, it gives the portion illuminated by them beyond a hemisphere.

PROBLEMA V.

Problem 5.

Semiangulum & Angulum Coni Vmbræ Lunaris à radijs Solis irrefractis comprehenſæ inquirere.

To find the half-angle and the angle of the cone of the lunar shadow comprehended by the Sun's unrefracted rays.

VI. In section 1 we showed that angle KHL is equal to angle AGH, which is the half-angle of the cone of the lunar shadow, and we have already taught how to find it in Problem 4. Indeed, for the syzygies and quadratures of the Moon we have already found it, at the extreme and mean distances. So consult Problem 4 and its table: the angle of the cone of the lunar shadow is thus as great as the portion of the ☾ beyond a hemisphere illuminated by the unrefracted rays of the ☼.

PROBLEMA VI.

Problem 6.

Axem Vmbræ Lunaris à Solis radijs irrefractis comprehenſæ metiri.

To measure the axis of the lunar shadow comprehended by the Sun's unrefracted rays.

VII. In the preceding figure triangle AGH is right-angled at A, and in it there is given from Problem 1 the side AH, the Moon's true semidiameter in parts of which the Earth's semidiameter is one; and by Problem 5 the angle AGH is given, and from it the angle AHG. Therefore, by analysis of this triangle, you will find the base HG, which is the very height or axis of the lunar shadow. So make: as the radius to side AHG, so the secant of the angle [recte: *AH, ita ſec. ang. AHG*, "to side AH, so the secant of the angle AHG", per the book's errata] to another, and you will have the base HG. Or join the logarithm of side AH to the residual of the logarithm of angle AGH, and the logarithm of the base GH will result. Or, since triangles LHK and EGK are proportional, because the angles at E and L are right and K is common, and LHK is equal to angle EGK: make as KL to KH, so KE to KG; and when KH is taken away, the axis HG of the lunar shadow will remain. Take, therefore, this small table for the Moon's syzygies; for the axis of this shadow at the quadratures is roughly midway between the extreme axes of the syzygies.

Axis or length of the lunar shadow, from unrefracted rays.

Ourselves	60	53	59⅓	53 26/33	59⅔	56 26/33

[Margin: Conflict of Tycho and Kepler with each one's own hypothesis.]

From the preceding table you will gather that the lunar shadow of Tycho and of Kepler does not cohere with the semidiameters of the luminaries at apogee; for then the lunar shadow is longer than the distance of the Moon from the centre of the Earth, as is clear from the distances given in chapter 14. Therefore the whole Sun ought then to be able to be darkened for us by the Moon, with duration, in an eclipse. But Tycho nowhere admits total eclipses of the Sun, while Kepler makes the semidiameters of the luminaries at apogee equal, and so admits a total eclipse there, without any duration.

[Margin: Usefulness of this Problem in eclipses of the Sun.]

From this same small table, and from the Problem on which it rests, and from the distances given in chapter 14, you will gather how far the Moon's shadow reaches at ecliptic new Moons: whether exactly to the Earth, so that the eclipse of the Sun is total without duration; or beyond the Earth, so that the eclipse of the Sun is total with duration; or whether its apex stops short of the Earth, so that a central eclipse of the Sun is nevertheless partial, a bright ring being left all around, free of the eclipse. But more fully on this in Book 5, chapter 9, where we also treat the tract of the Earth occupied by this shadow.

PROBLEMA VII.

Problem 7.

Quanta ſit Diameter Terræ apparens oculo in Luna conſtituto; & Quanta Terræ portio de hemiſphærio videatur ab eodem oculo.

How great the apparent diameter of the Earth is to an eye placed on the Moon; and how great a portion of the Earth's hemisphere is seen by the same eye.

VIII. In Book 2, chapter 6, Scholium 5, it was said that from a distance of 60 Earth semidiameters the Earth is seen under an angle of 1° 55′. But if you want to be more accurate, use the figure of section 1 here, and imagine the eye at G and the Earth at H. For since, in triangle AGH, right-angled at A, the Earth's semidiameter is supposed given as one, and the Moon's distance from the Earth GH in Earth semidiameters, the angle AGH will also be given. When this is doubled, the angle AGC will be known, under which the Earth H can be seen from the Moon G, and which measures the apparent diameter of the Earth seen from there. And since the angles at A and C are right, and in triangle AGH there are two right angles by Euclid I.32, if from the remaining right angle you subtract the angle AGH just found, the angle AHD will be known, which measures the arc AD. When this is doubled, the arc ADC will be known, which is the part of the terrestrial hemisphere seen by the eye at G. For me, from the distances of the Moon established in chapter 14, the angle AGC and the arc ADC stand, for the syzygies and quadratures, as you see in the following small table. Kepler, however, in the Rudolphine Tables, precept 149, and in the *Epitome of Copernican Astronomy*, p. 874, says that this is obtained if from the Moon's horizontal parallax you subtract one and a half times the parallax of the Sun; for this, he says, gives the Earth's semidiameter seen from the Moon.

☾	Diameter of the Earth seen from the Moon	Portion of the Earth's hemisphere seen from the Moon
In ☌ and ☍: Apogee	1° 47′ 0″	178° 13′ 0″
In ☌ and ☍: Perigee	2° 7′ 50″	177° 52′ 10″
In □: Apogee	1° 43′ 16″	178° 16′ 44″
In □: Perigee	2° 13′ 54″	177° 46′ 6″

PROBLEMA VIII.

Problem 8.

Quanta portio Hemiſphærij Terreſtris illuminetur à Lunæ Plenæ radijs irrefractis, aut etiam refractis.

How great a portion of the terrestrial hemisphere is illuminated by the unrefracted, or also the refracted, rays of the full Moon.

IX. With Witelo, Book 2, proposition 28, Pisanus [John Pecham] in the *Perspectiva communis*, prop. 24, Maurolico in the *Photismi*, theorem 17, and the other writers on optics, I suppose that the Moon, being a sphere smaller than the globe of the Earth, illuminates less than a whole hemisphere of the Earth, however full of light it may be. How great this portion is you will learn from the figure of section 1, by imagining the Moon at H and the Earth at K, and the portion of the Moon illuminated by the Sun through unrefracted rays to be ABC, from all of whose points rays are reflected to the Earth. So, when the Moon's true semidiameter AH, known by Problem 1, is taken from the Earth's true semidiameter EK, the side LK of triangle LHK, right-angled at L, will be left known; and in this triangle the distance KH of the Moon and Earth is supposed given. Therefore, as above in Problem 4, the angle LHK will become known, whose complement to a right angle, by Euclid I.32, is the angle LKB, that is, EKM, which measures the arc EM. And when the arc EM is doubled, the arc EMF of the Earth illuminated by the full Moon will be known, but imagining the rays to be unrefracted. But if you add to this arc the doubled horizontal refraction of the Moon, the arc illuminated by refracted rays will be known, in line with what is to be said in Book 5, chapter 5, Problem 7, on the refracted rays of the Sun, which can be applied to this problem without sensible dissimilarity. So, taking the Moon's horizontal refraction from Tycho as 33′, here is a sample of the Problem from our hypotheses. After this, as we did for the Sun in Book 3, chapter 11, we shall collect in one place the theorems worth knowing that can be gathered from the Problems already mentioned.

Portion of the Earth illuminated by the Moon in non-ecliptic ☌.

☾	With unrefracted rays	With refracted rays
☾ Apogee	178° 41′ 2″	179° 47′ 2″
☾ Perigee	178° 25′ 46″	179° 31′ 46″

THEOREMATA

Theorems.

Ex Lunæ Diſtantia, & vera Diametro ſequentia.

Following from the distance and true diameter of the Moon.

1. Theorem. When the Moon appears larger and nearer to us, we in fact see less of it; but when it appears smaller, more: from Problem 3 and its table.
2. Th. As great a portion of the lunar hemisphere is hidden from us as the Moon's diameter apparent to us: from Problem 3.
3. Th. The angle of the cone of the lunar shadow is as great as the portion of the Moon beyond a hemisphere illuminated by the Sun's unrefracted rays, and conversely: from Problem 4.

4. Th. When the Moon shines more for us, namely at full Moon, it is less illuminated by the Sun, both intensively and extensively. As to extension, this is clear from the table of Problem 4; as to intensity, from the greater distance of the Moon from the Sun in ☍ than in ☌, since rays further from their origin are weaker.
5. Th. The circle separating the illuminated part of the Moon from the dark part is hardly sensibly distant from a great circle of the Moon. For from Problem 4 it is gathered that the arc beyond the quadrant illuminated by the Sun on one side is about 16′ if unrefracted rays are used, or 32′ if refracted, that is, a quarter or a half of a degree, of which there are 180 in the arc of the lunar hemisphere. But Aristarchus, in the book on the distances and sizes of the Earth and the luminaries, prop. 4, says: "The circle in the Moon that divides the dark from the bright does not differ sensibly from the great circle in it", because from his hypotheses he concludes that the arc by which this circle is distant from the great circle is less than the 3960th part of a right angle, and so like a point.
6. Th. The portion of the Earth's hemisphere viewed from the Moon is as great as the complement to two right angles of the apparent diameter of the Earth viewed from the Moon, and this is as great as the doubled horizontal parallax of the Moon: from Problem 7.

SCHOLIA.

Scholia.

[Margin: The prudence of Aristarchus.]

I. From the diversity of opinions about the size of the Moon compared with the Sun and with the Earth, which we set out in the table of Problem 1, it appears how prudently Aristarchus, in his little book on their sizes and distances, did not dare to define them, but thought it enough to confine them between certain extremes, in order to refute the Pythagoreans, who, devoted to certain harmonic proportions, had wrongly established the intervals of the luminaries.

[Margin: The opinion of Thales on the bulk of the Moon.]

Before him, however, Thales of Miletus, as Laërtius reports, had said that the orb of the Moon is the 720th part of the size of the Sun. We, however, although we do not deny that God, Best and Greatest [D.O.M.], constructed the heavens above all with a certain supreme symmetry, nevertheless admit that this symmetry is still unknown to us. For although the distance and size of the Moon compared with the Earth are known more certainly from parallaxes and the apparent diameter, the distances and parallaxes of the Sun and the other planets are not so certainly established, and so we can form a conjecture about their size only within certain limits. So about these too we must press home that saying of Pliny the Elder, Book 2, chapter 23: "These things are undiscovered

and inextricable", and, as he says in the same place, "it is not right to hope that the measure of the heavens and the world should come at once to the fingers."

[Margin: What the true praise of God by astronomers is.]

And so the true commendation of Divine Wisdom by astronomers is at last the one that arises not from defining these measures and from proportions that smile on us, but from the candid confession of our ignorance, which lowers its fasces and its pride before God, who through his Ecclesiasticus, chapter 1, said, not ὑπερβολικῶς [Greek: hyperbolikōs, "hyperbolically"] but ἀληθῶς [Greek: alēthōs, "truly"]: "The height of heaven, and the breadth of the earth, and the depth of the abyss, who has measured?" Notwithstanding all this, the proportions in which Tycho, Kepler and certain others took excessive delight must be reviewed.

[Margin: Tycho's foundation and opinion on the size of the luminaries.]

II. So Tycho, in volume 1 of the *Progymnasmata*, p. 474, establishes that the Moon's diameter is contained 18 times in the Sun's diameter, because of the agreement between the diameter of the lunar heaven and the diameter of the solar heaven. For he thinks that the distance of the Moon at apogee is contained in the distance of the Sun at apogee very nearly 18 times, provided that the Sun's distance is taken as 1190 Earth semidiameters, and the Moon's not as 68 according to Copernicus or 64 according to Ptolemy but as a mean, limiting the opinions of both craftsmen, for 66 is contained in 1188 18 times. With these laid down, he adds: "A beautiful and elegant symmetry indeed, and not considered until now by anyone, so far as I know."

[Margin: Tycho's empty boast and the conflict of his hypotheses.]

But Tycho did not then remember that this symmetry conflicts with his own hypotheses; for on page 119 he had established the Moon's greatest distance from the Earth as 60⅗ Earth semidiameters, and the Sun's greatest distance as 1180, as I reported in Book 3, chapter 7. But 60⅗ is contained in 1180 19 7/12 times. So that proportion vanishes.

[Margin: Kepler's foundations on the same subject, and his inconstant opinion.]

III. Similarly, Kepler, in the foundation of the *Ephemerides*, p. 2, defined the distance of the Sun at apogee as 1800 Earth semidiameters, so that this round number would be about thirtyfold the distance of the Moon from the Earth, which is about 60 Earth semidiameters; and so the proportion of the intervals of the Sun and the Earth would be the same as that of the revolutions of the Earth and the Moon around the same centre, as it were, of the Earth. But in the *Epitome of Copernican Astronomy*, as I said in chapter 14, section 7, he wants the distance of the Moon at apogee to be 59 Earth semidiameters, so as to be the mean proportional between the Earth's semidiameter and the semidiameter of the great orb, that is, the distance of the Sun from the Earth; and in the same place, p. 479, he wants the Moon's apogee diameter to be the 720th part of its orb, so that it can cover the Sun without duration. He then says: "Therefore, as the body of the Earth is contained in the body of the

Sun as many times as the Earth's semidiameter is contained in the distance or semidiameter of the solar orb, so the body of the Moon is contained in the body of the Earth as many times as the Earth's semidiameter is contained in the distance or semidiameter of the lunar orb. Hence it comes about that the distance of the Moon at apogee from the Earth is a mean proportional between the distance of the Sun and the Earth and the Earth's semidiameter. Therefore the square root of the Sun's interval of 3469⅓ is about 59; when the cube of the Earth's semidiameter is divided by this, and the cube root of the quotient is taken, the true semidiameter of the Moon results, as 1 to 59 to the Earth; so the Sun," says Kepler, "contains the Moon more than 200000 times." And so Kepler sometimes uses a solar interval of 3469⅓ and sometimes 1180; on this inconstancy or variation I have already spoken in Book 3, chapter 8. What follows concerning their size from the intervals of the luminaries deduced by Father Bettini from harmonic proportions there is no need to weigh here, and I have sufficiently refuted it in chapter 14, in the Scholia.

CAPVT XVIII.

Chapter 18.

De Lunæ Motibus, ac de Diurni Motus Velocitate.

On the motions of the Moon, and on the speed of the diurnal motion.

[Margin: The 15 motions of the Moon are enumerated.]

I. There are fifteen names of motions, or respects, or motions of the Moon, although not all really distinct, nor certain among all authors, by which the multiform Providence of God has commanded it to be driven around the Earth: namely, the Diurnal, to the west, which is also that of the primum mobile; the Monthly motion in Longitude, to the east; the Elongation from the Sun; the motion in Latitude; the motion of the Nodes; the motion of the Apogee; the motion of the Deferents of the Aux; the motion of the simple, or free, or Periodic Anomaly; that of the compound, or monthly, or Synodic Anomaly; that of the Variation or Reflection; that of the Anomaly of Latitude and of the Nodes; that of the Centre of the Eccentric, or of the Eccentricity; that of Altitude; that of Rotation; and that of Libration. So that with every right Pliny the Elder, Book 2, chapter 9, although unaware of all these motions, said: "The last star surpasses all in wonder, the one most familiar to the Earth, and devised by Nature as a remedy for darkness: the Moon. With this multiform winding she has tortured the minds of those who contemplate her, and who resent that the nearest star should be the one most unknown." The motions listed, then, must be explained briefly, since they will often come up. Their measures must first be stated here approximately, and then the technique set out by which astronomers reached an exact knowledge of them and bound them by fixed laws of numbers and hypotheses.

[Margin: 1. Diurnal motion of the Moon.]

II. The Moon's *first* motion is the diurnal one. From east toward west, and from there back again to the east, it appears to revolve in 24 hours, or rather in nearly 25, on the hypothesis of a stationary Earth; or it is the motion by which, travelling westward, the Moon returns from a given meridian to the same meridian after nearly 25 hours. For in this motion the Moon is the slowest of all the stars and does not keep pace with the motion of the primum mobile in 24 hours. If, tonight, at the first hour after sunset, you observe the Moon on the meridian, crossing Mid-heaven together with Spica or some other fixed star, then on the following night you will see that, although Spica has already returned to the meridian, the Moon has not yet returned but stands about 13° 10′ 35″ east of it, to which 48^{m} of time correspond on the equator. The Moon therefore appears to strive against the motion of the primum mobile and, by another motion of its own, to advance about 13° 10′ 35″ each day, and so not to return to the same meridian or horizon until after about 24^{h} 48^{m}. This, certainly, is the reason why in many places the flow and ebb of the sea repeat their alternations each day about an hour later than the day before.

[Margin: 2 and 3. Motions of the Moon in the zodiac, and from the Sun.]

III. The Moon's *second* motion is its proper motion in longitude beneath the zodiac. It shows itself in the fact that each day, as I have just said, the Moon appears farther east by 13° 10′ 35″, a mean motion between the shortest and the slowest. By this motion it completes the zodiac in about 27^{d} 7^{h} 43^{m} 7^{s}. But since the Sun moves eastward each day along the ecliptic by 59′ 8″ 20‴, if you subtract this from the Moon's mean motion in longitude there remains the Moon's *third* motion, its mean motion from the Sun, which Ptolemy in his tables calls the Distance of the Moon from the Sun, and others the Elongation of the Moon from the Sun. There remains, I say, a daily motion of 12° 11′ 26″ 41‴.

[Margin: 4. Motion of the Moon's Nodes.]

IV. The Moon's *fourth* motion is that of the Nodes of the lunar orbit against the order of the signs [in antecedentia]. For the lunar orbit is inclined to the plane of the ecliptic at an angle of 5° at new and full Moons, or of 5° 18′ at the quadratures, as was said in chapter 12. This greatest latitude is called the Limit [Limes], or by the Arabs the Bellies of the Dragons [Ventres Draconum], from their likeness to the snakes which the circumference of the lunar ecliptic forms with the circumference of the lunar orbit; and one is northern, the other southern. The points at which there is no latitude and at which the lunar orbit cuts the ecliptic, diametrically opposite each other, are called the Nodes. One of these is called Northern and Ascending, because the Moon, crossing it by its proper motion, becomes northern; and as it heads toward it from the southern Limit and passes through it as far as the northern Limit, it grows higher each day for us who are northern, and ascends toward our pole and zenith. From this ascent Ptolemy calls this Node [Greek: συνδεσμός ἀναβιβάζων (syndesmos anabibazōn, "ascending node")] and the Arabs the Dragon's Head [Caput Draconis], and it is marked with this character: ☊. The other Node is called

Southern and Descending; for Ptolemy it is [Greek: συνδεσμός καταβιβάζων (syndesmos katabibazōn, "descending node")], for the Arabs the Dragon's Tail [Cauda Draconis], and its sign is ☋. In the ephemerides, moreover, both for the Moon and for the other planets, the letters SA indicate Northern [Septentrionalis] Ascending latitude, in which the planet is between the northern Node and the northern limit; SD, Northern Descending latitude, namely from the northern limit to the southern Node; MD, Southern [Meridionalis] Descending latitude, that is, from the southern Node to the southern limit; and MA, Southern Ascending latitude, namely from the southern limit as far as the northern Node. These lunar Nodes, near which eclipses occur, have been observed to retrogress against the order of the signs, as is shown by eclipses which, other things being equal, occur beneath places of the ecliptic farther west than before. The mean motion of the lunar Nodes is toward the preceding signs, its daily amount about 3′ 10″ 38‴, so that they complete their period beneath the ecliptic in about 18 Egyptian years $228^{d}\ 3^{h}\ 50^{m}$, as Kepler holds in the *Epitome of Copernican Astronomy*, p. 788; or, as Copernicus has it, in $6798^{d}\ 3^{h}\ 49^{m}$; or in 18 years $223^{d}\ 6^{h}\ 12^{m}$, as Magini has it in his *Theoricae Planetarum*; and Antonín Maria Šírek nearly the same, Book 4, chapter 2, Member 4. Others believed this motion to be uniform; but Tycho found it irregular outside the syzygies, as he himself attests in volume 1 of the *Progymnasmata*, p. 115. He is followed by Longomontanus, *Theorica*, Book 1, chapter 7; Kepler in the Ephemerides, number 6, in the *Epitome of Copernican Astronomy*, p. 820, and in the Rudolphine Tables, chapter 27; Mulerius in the *Tabulae Frisicae*, p. 415; Magini in the *Supplement to the Ephemerides*, Canon 7; Boulliau, Book 3 of his *Astronomy*, chapter 13; and in part Lansbergen in his Tables, precept 9.

[Margin: 5. Motion of the Moon's Anomaly of the Nodes.]

From this, therefore, arises the *fifth* motion, namely that of the Anomaly of the Nodes, which is monthly according to Tycho but semiannual according to Kepler. In the other planets, however, the motion of the Nodes is in the order of the signs.

[Margin: 6. Motion of the Moon in latitude.]

V. The *sixth* motion is the motion of latitude, or in latitude. It is made up of the Moon's motion in longitude along its own orbit [Greek: εἰσ τά ἐπόμενα (eis ta epomena, "toward what follows")], that is, in the order of the signs [in Consequentia], and of the motion of the Nodes [Greek: εἰς τά προηγούμενα (eis ta proēgoumena, "toward what precedes")], namely against the order of the signs [in Antecedentia]. On account of this, the Moon acquires its greatest latitude with respect to the ecliptic at ever different places of its orbit. Adding together, then, the Moon's mean daily motions in longitude, about 13° 10′ 35″, and of the Node ☊, about 3′ 10″ 38‴, the mean daily motion of latitude comes to about 13° 13′ 45″ 38‴, so that one period, which from the Dragons already mentioned Wendelen calls the Draconic Orbit [Orbis Draconticus], is completed in very nearly $27^{d}\ 5^{h}\ 6^{m}$. By this motion, then, the Moon each day

moves away from the Nodes in the order of the signs, even though Ptolemy and Copernicus preferred to count the motion of latitude from the northern limit rather than from the northern Node.

[Margin: 7. Motion of the Anomaly of latitude.]

Since, however, this motion is compounded of the motion in longitude toward the east, which for everyone is genuinely anomalous, and of the motion of the Nodes toward the west, which on Tycho's view is anomalous, there arises from this the *seventh* motion, that of the Anomaly of latitude.

[Margin: 8. Motion of the Moon's simple Anomaly.]

VI. The *eighth* motion is that of the Moon's simple Anomaly or Irregularity, which Ptolemy calls the First inequality, the Alphonsines and Prutenics the Periodic, and Kepler the Free [Soluta], that is, not tied to the Moon's phases. For it has been observed that, even leaving parallaxes out of account, the Moon does not return to new and full Moons at the same interval of time, and that true synodic months are now longer, amounting to nearly 30 days, and now shorter, as I shall say in the next chapter, number 1, where the synodic month is treated. So too it is established that the return to the same star, observed when the Moon is at the nonagesimal degree of the ecliptic reckoned from the ascending point of the ecliptic, that is, when it has no parallax of motion in longitude, is completed not in equal but in unequal intervals of time. It was further observed that when the Moon is at apogee and farthest from the Earth, as the parallaxes of altitude have shown, it is slowest, and at perigee fastest. Then, by observing the return from apogee to apogee, that is, from the point of greatest slowness to the point of greatest slowness, or from perigee to perigee, and by comparing many eclipses, Hipparchus and the other astronomers found that this period, taking the mean between the longest and the shortest, is completed in about $27^{d}\ 13^{h}\ 18^{m}\ 35^{s}$, and that this is the anomalistic month; so that each day the Moon by this motion, whether on Ptolemy's epicycle or on an arc of some other equivalent circle or quasi-circle, completes $13^{\circ}\ 3'\ 35''\ 56'''$. How, by the force of an epicycle or eccentric, a planet's motion which is regular in itself can appear unequal to us, and how by the same means the mean motion is reduced to the true and apparent one, is clear from what was said of the Sun's epicycle or eccentric in Book 3, from chapter 19 on, from where the diagrams may be repeated. Finally, it has been observed that in the syzygies, that is, in ☌ and ☍, the Moon undergoes this one simple inequality, and that nothing is needed but a single simple prosthaphaeresis or equation to make the Moon's mean motion agree with the apparent and true one. This equation Ptolemy calls Epicyclic, others the equation of the First and simple inequality, and Kepler the equation of the free Moon; at its greatest it does not exceed 5°.

[Margin: 9. Motion of the Moon's composite Anomaly.]

VII. The *ninth* motion is that of the composite Anomaly, which some call Eccentric or Synodic and Kepler the Monthly Temporary [Menstruam temporaneam], because it depends on the phases of the Moon, which make up the month, and on the varying elongation of the Moon from the Sun. For it

has been observed that the Moon's place outside the syzygies (derived from observation, and also outside the parallaxes of longitude, as when the Moon is observed at the nonagesimal, by taking its distance from fixed stars of known longitude) does not agree with the Moon's place deduced for that moment from the tables and, by the first equation, equated, but that a further, second equation is needed, which in the perigean quadratures is at times nearly 2° 40′ by itself, and 7° 40′ when compounded with the simple one. From this, therefore, astronomers recognized that outside the syzygies the Moon undergoes a double and composite Anomaly or inequality in its motions.

[Margin: 10. Motion of the Variation.]

VIII. The *tenth* motion is, as Tycho puts it on p. 126, the motion of the *Variation*; or, as Kepler puts it in the *Epitome*, the motion of the *perpetual monthly Anomaly*; while Boulliau, Book 3, chapter 13, calls it that of the *Reflection*. For Tycho states that the Moon, stripped of the first and second inequalities, with its place outside the syzygies equated not only by the simple but also by the composite equation, does not agree with its apparent and true place, even when this is observed beyond the risk of parallax in longitude, as when the Moon is observed at the nonagesimal. It therefore undergoes a third inequality or Variation and needs a third prosthaphaeresis, which taken by itself reaches, at its greatest, 41′ 30″, or, as Kepler says, 51′ or 49′. Longomontanus agrees with Tycho, *Theorica*, Book 1, chapter 6, that it is greatest at the places midway between the quadratures and the syzygies, that is, in the octants, namely at 45°, 135°, 225° and 315°, counted in the order of the signs from the preceding conjunction of the Moon with the Sun. But Kepler and Boulliau do not agree on the manner and measure of this Variation and Equation. Kepler, however, called this Equation the Perpetual Monthly, because it returns every month and is of the same quantity in any month; whereas the second Equation, discussed in the preceding number, according to the opinion he finally chose in the *Epitome* and in the Rudolphine Tables, does not return every month and is not the same, but decreases over about 6 or 7 months until it vanishes, and increases again over as many months until it reaches its greatest. For this reason he called that one the Temporary Monthly. Boulliau, for his part, saw that this very Variation is variable, now much less than 40′ and now much greater.

[Margin: 11. Motion in altitude.]

IX. The *eleventh* motion is the motion in altitude, by which the Moon is now higher and now lower, either because of the Eccentricity, or because of the Epicycle, or the eccentric of the Eccentric, or a simple elliptical eccentric, according to the different hypotheses of astronomers. For from the Moon's parallaxes in altitude, in accordance with what was said in chapter 14, it is evident that the Moon stands at different distances from the centre of the Earth at different times.

[Margin: Error of Girolamo Fracastoro and Amicus.]

This is not inferred only from its greater or lesser apparent diameter, or from a hypothesis that feigns epicycles or eccentrics in order to account for

the inequalities of the motions, as Girolamo Fracastoro, Amicus [Giovanni Battista Amico] and others thought, against whom we spoke in Book 3, chapter 7. They therefore tried in vain to explain this appearance by variety of vapours, or by different parts of the heavens that are more or less diaphanous, while keeping the same distance of the planets from the centre of the Earth. For the evident variety of the lunar parallaxes shows the variety of the lunar distances.

[Margin: 12. Motion concerning the apogee.]

X. The *twelfth* motion is the Motion of the lunar Apogee. For the true place on the ecliptic beneath which the Moon is found by observation when it is at apogee is ever different toward the east, and it has therefore been observed that its apogee advances in the order of the signs, slowly indeed but nonetheless evidently, by very nearly 6′ 41″ each day, so that, according to Kepler's *Epitome of Copernican Astronomy*, Wendelen in the 4th *Lampas*, and common opinion, it completes its period in about 8 Egyptian years $311^{d}\ 5½^{h}$.

[Margin: Christmann's error.]

Since Jacob Christmann thought that this time approached half the period of the lunar Nodes, he ventured in his *Theorica* of the Moon to make this motion commensurable with the motion of the Nodes. Longomontanus censures this error, *Theorica*, Book 1, chapter 7, p. 269, and rightly: for the doubled motion of the Apogee is 17 Egyptian years $277^{d}\ 12^{h}$, and falls short of the period of the Nodes by $315^{d}\ 15^{h}\ 50^{m}$; and that much time is required for the Moon's Node to return to the same place on the ecliptic to which the Moon's Apogee has already returned twice, after both Node and Apogee began their motion from the same point of the zodiac, whether the motion of the Apogee then arises from a motion of the Epicycle slower than the motion of the Eccentric, or from some other source. Kepler, however, with a great many others, in Book 6 of the *Epitome of Copernican Astronomy*, holds that the motion of the lunar Apogee is uniform and regular in itself. This motion in the Ptolemaic form they call the motion of the Apogee of the Epicycle, or of the true Apogee, and Kepler that of the Apogee of the free Moon.

[Margin: 13. Motion of the monthly Apogee.]

XI. The *thirteenth* motion is the motion of the Apogee of the Eccentric in the Ptolemaic form, or of the Deferents of the Aux of the Eccentric, or, as some have it, of the monthly Apogee, or, as others have it, the motion of the Centre of the Eccentric; and this motion is against the order of the signs. Not everyone gives it the same measure, however, because of the variety of hypotheses. Some, with Magini, say that its period is completed in 31 days $19^{h}\ 29^{m}\ 52^{s}$; others in 32 days $3^{h}\ 4^{m}\ 38^{s}\ 31‴$. For they derive it by subtracting the Sun's daily motion from the Moon's daily elongation from the Sun; others again, with Boulliau, Book 3, derive it by subtracting the daily motion of latitude from the doubled motion of the Moon from the Sun.

[Margin: 14. Motion of Rotation.]

XII. The *fourteenth* motion is the motion of the Rotation of the Moon about the centre of its own body. This is not the one invented by Berossus, so that the Moon should turn its self-luminous hemisphere toward us at full Moon and away from us at new Moon; for we rejected that one, because of the phases of the lunar spots, in chapter 9, number 2. So too we rejected the total Rotation introduced by Francesco Fontana, by which the southern spots become northern, on which see the same place, number 1. It is rather the one which, in the hypothesis that uses epicycles carrying the Moon, is necessary to keep the same face of the Moon turned toward us through the whole month, on which see the same place, number 2. To defend this phase, and to avoid harming his magnetic fibres and their inclination, Kepler, in the *Epitome of Copernican Astronomy*, p. 613, did not hesitate to suggest a certain motion of the Moon's inner globe, different from and really distinct from the outer crust of the lunar surface, like that of a kernel from its rind, so that the rind should preserve the position of the spots and the kernel follow the motion of the fibres. So fertile in daring is this man's ingenuity.

[Margin: 15. Motion of Libration.]

XIII. The *fifteenth* motion is the motion of Libration, whether to explain the motion of some Anomaly or, rather, to uphold the varying distance of the lunar spots from the limbs, on which see what was said in chapter 9, number 5.

De Velocitate motus Diurni Lunæ.

On the speed of the Moon's diurnal motion.

XIV. To express the speed of the Moon's diurnal motion toward the west, we suppose that each day, in 24 hours of the primum mobile, it runs through 346° 49′ 25″, since it falls short of 360° by 13° 10′ 35″, which it travels by its proper motion in longitude toward the east. So in one hour it runs through 14° 27′ 4″, and in one minute 14′ 27″ of its heaven, whose daily circuit varies with the varying distance of the Moon from the Earth. Secondly, therefore, we suppose from chapter 14 that the Moon's greatest distance, in apogean □ [quadrature], is 66 semidiameters of the Earth; its least, in perigean □, 52 semidiameters of the Earth and 10′; and its mean, 59 semidiameters of the Earth and 5′. Doubling this gives the varying diameter of the lunar heaven, which, by what was said in Book 1, chapter 4, is to the circumference as 100 to 314. From this, then, we shall infer how many diameters of the Earth the Moon runs through in one hour and how many in one minute of an hour. These diameters we shall resolve into Italian Bolognese miles, of which there are 8278 in the Earth's diameter, as we showed in Book 2, chapter 7. If you multiply the number of these miles by 90 and divide the sum by 72, you will have the Italian Roman miles in use under Augustus and Vespasian, for 90 of those equal 72 modern Bolognese, as we showed in the same chapter 7.

[Margin: Method of deriving the Moon's diurnal speed.]

So that beginners may have one example of the method, let the Moon's greatest distance from the centre of the Earth, in □, be 66 semidiameters of the Earth, and let the Moon be on the equator; the diameter of the lunar heaven is therefore 66 diameters of the Earth. Now as 100 is to 314, so 66 is to 207 24/100 diameters contained in the circumference of the lunar heaven, which circumference consists of 360°, or 1296000″. Therefore, if 360° contain 207 24/100 terrestrial diameters, then 346° 49′ 25″, which we said the Moon completes by its mean motion in 24 hours, contain 199 10/13 diameters. Dividing these by 24 gives to one hour 8⅓ diameters, which the Moon runs through in one equal hour. Multiplying the diameters already mentioned by 8278 Bolognese miles, then, we shall have the miles corresponding to the Moon's daily and hourly motion; dividing these by 60, we shall have the miles matching one minute; and dividing these further by 60, we shall have the miles corresponding to one second of an hour, which is nearly equal to one pulse-beat of a human artery. Let the following table therefore stand.

LVNÆ VELOCITAS IN DIVRNO VERSVS OCCIDENTEM MOTV.

The Moon's speed in its diurnal motion toward the west.

In □	Moon's distance from the centre of the Earth: semidiameters of the Earth	Circumference of the lunar heaven: diameters of the Earth	Moon's motion in one day: diameters of the Earth	Moon's motion in one day: Italian miles	Moon's motion in one hour: diameters of the Earth	Moon's motion in one hour: Italian miles	In 1 minute: Italian miles	In 1 second: Italian miles
Greatest	66 0	207 14	199 10/13	1652734	8 1/3	68864	1142 0	19 1/8
Mean	59 5	185 30	176 6/7	1460431	7 1/3	60851 1/2	1042 1/5	16 4/5
Least	52 10	164 36	160 0	1324480	6 2/3	55186 1/3	920 0	15 1/3

SCHOLIA.

Scholia.

[Margin: Biancani's method for the Moon's diurnal speed, less exact.]

I. Biancani, Book 9 of the *Sphaera*, chapter 2, multiplies the 21600 miles of the Earth's circumference by the Tychonic mean distance of the Moon from the Earth, 56 semidiameters of the Earth, and derives a circumference of the lunar heaven of 1200600 miles, the 24th part of which, namely 50400, he takes to be the Moon's hourly motion. But what the Moon takes away from the 360° by its proper motion should have been subtracted.

II. Kepler, in the book *De Stella Nova*, chapter 16, since he assigned the diurnal motion toward the west not to the Moon but to the Earth, could not cite the speed of this motion. Instead he took up the other daily motion, namely

that of longitude toward the east, which is much slower than the diurnal motion toward the west: for by the latter the Moon runs through 346° 49′ 25″ each day in mean motion, whereas by its proper motion toward the east it completes each day, in mean motion, only 13° 10′ 35″. He did this to show that according to the hypothesis of Copernicus any planet is the faster the nearer it is to the Sun.

[Margin: The speed of the planets in the hypothesis of Copernicus.]

For in that hypothesis, in one hour ♄ travels through nearly 300 German miles, ♃ 400, ♂ 600, the centre of the Earth 740, ♀ 800, ☿ 1000.

[Margin: The speed of the Earth in the same.]

But since the Earth rolls eastward not only annually around the Sun but also daily around its own centre, the parts of its surface lying beneath the equator complete 240 German miles in one hour by their lasting [diutino] motion. If you add these to the miles traversed from the centre in the meantime, the sum is 980, which a city located on the equator traverses in one hour of midnight; but if you subtract those from these, there remain 500 miles, which such a city completes in one hour of midday.

[Margin: The speed of the Moon in the hypothesis of Copernicus.]

The Moon, however, around the centre of the Earth, when it is 60 terrestrial semidiameters distant from it, passes through 476 German miles in one hour by its proper motion toward the east. If you add these to the miles of the Earth's centre, the journey of the full Moon through the aethereal air in one hour is 1216 German miles; but if you subtract them, there remains for the new Moon an hourly journey of 264 miles. For at full Moon it is like a planet direct around the Earth, tending in the same direction as the centre of the Earth; at new Moon it is carried in the opposite direction, like a retrograde one. So Kepler. Yet far greater, and nearly fifteenfold, is the Moon's speed in the common hypothesis, which assigns the diurnal motion to the Moon; for in it, in one hour, at its mean distance from the Earth, the Moon completes 60851½ of our Italian miles, that is, 15212 German.

[Margin: Hérigone's method for the speed of the Moon.]

III. Pierre Hérigone, in volume 5 of his *Cursus Mathematicus*, p. 583, investigates the Moon's speed differently. He says that, since the Earth's semidiameter is to the semidiameter of the lunar orbit as 1 to 56, and the Moon runs through its orbit once while the Earth completes about 28 daily revolutions around its centre, the ratio of the Earth's motion around its centre to the Moon's proper motion in the order of the signs is as 28 to 56, that is, as 1 to 2; and that it follows from this that in one minute of an hour the Moon completes 30 Italian miles around the Earth. Of these miles he holds that 60 are contained in one degree of a great circle of the Earth, and 21600 in the whole circle. Dividing these by 24 yields 900 for one hour, and subdividing these by 60 yields for one minute the 15 Italian miles which the Earth runs through. So if the Moon does double, it runs through 30 Italian miles in one minute around the Earth. Although it is always moved with the centre of the Earth in the order of the

signs, with respect to someone viewing from the Sun, yet since the Earth by its annual motion completes 47 Italian miles in each minute, if these are added to the Moon's motion around the Earth at full Moons they make 77; but if they are subtracted at new Moons, there remain 17 Italian miles, which, all things reckoned, the Moon completes in one minute. But Hérigone on p. 581 had supposed a distance of the Earth from the Sun of 1142 terrestrial semidiameters, which for me is much larger.

[Margin: Galileo's opinion on the cause of the tides.]

Opportunely, moreover, he relates that, according to Galileo, from the annual motion of the Earth around the Sun and its motion around its own centre, of which the former is to the latter as 47 to 15, there arises the flow and ebb of the sea, just as from the unequal motion of a vessel the water runs now to one end of the vessel, now to the other.

[Margin: The inequality of the Moon's motion, from Geminus.]

IV. The Moon's motion is so unequal that, according to Geminus, *Elements of Astronomy*, chapter 15, its least daily motion in the zodiac is 11° 6′ 11″ 35‴ and its greatest 15° 11′ 35″. For he follows the measure of the motions deduced from the Chaldean period, of which we shall speak in chapter 19. But see what we shall say about the variation of the synodic month in the next chapter, number 1, from the opinion of Tycho, following which Kepler, in the *Epitome of Copernican Astronomy*, p. 815, has this on the variety of the Moon's motion:

[Margin: The harmonic inequality of the Moon's motion, from Kepler.]

"The hourly motion of the Moon from the equinox," he says, "in the syzygies is made 29′ 41″ at apogee and 38′ 32″ at perigee; in the quadratures, 29′ 35″ at apogee and 35′ 11″ at perigee. But with the Anomaly increased by the Variation, in the syzygies it is 29′ 50″ at apogee and 38′ 45″ at perigee; in the quadratures, 29′ 26″ at apogee and 34′ 39″ at perigee. And when the Sun's mean hourly motion of 2′ 27″ is taken away, the motion of the Moon from the Sun at perigee in syzygy is 36′ 5″, and at apogee in quadrature 27′ 8″; between these there is precisely a diatessaron, that is, the ratio of 3 to 4. So the Moon's motion from the Sun at apogee in syzygy becomes 27′ 14″, and at perigee in quadrature 32′ 44″; between these there is precisely a minor third [tertia mollis], that is, the ratio of 5 to 6. So too between the purely syzygial motions there is a diatessaron, and between the purely quadrature motions a lesser ditone [Ditonus minor]. The difference of the syzygies from the quadratures gives a minor tone." You will understand these things better from our Book 9, of the Systems, where the Harmonic System is treated.

CAPVT XIX.

Chapter 19.

De Menſibus, Anniſq. Lunaribus, Epactis & Cyclis magnis Luniſolaribus, Primoq. Artificio inueſtigandi per hos Cyclos motus Lunæ.

On lunar months and years, epacts and the great lunisolar cycles, and on the first technique for investigating the Moon's motions by these cycles.

I. The month [Mensis] is in Greek [Greek: μήν μηνός (mēn, mēnos, "month")], and from this the Moon is called [Greek: μήνη (mēnē, "moon")], because, just as the Sun was the cause of distinguishing years, so the Moon was the cause of distinguishing months, by its revolution back to the Sun after traversing the zodiac. One kind of month is Political or Civil; another, Astronomical. The Astronomical is either Periodic, or Synodic, or of Illumination; to which could be added the Anomalistic, Apogistic and Draconic month.

[Margin: The Civil month.]

The *Civil* month is a period of 30 natural days or thereabouts: 30, indeed, among the Persians of old and the Egyptians and certain Greeks before Solon, but variable among the Romans under Romulus, Numa and Julius Caesar; and these months were rather midway between solar and lunar ones. For those who have used and still use purely lunar months, such as the Hebrews and most others, employed them alternately of 30 days, which we call [Greek: πλήζους [recte: πλήρους, per the book's errata] (plērous, "full")], that is, Full, and of 29, which we call [Greek: κοίλους (koilous, "hollow")], namely Hollow. But we say more on these in the Chronological Book, where we also treat of both Common and Intercalary months.

[Margin: The Periodic month.]

The *Periodic* month, or month of traversal, which Kepler calls the physicians' Critical month, is one by the Moon of the zodiac, or of its own orbit equivalent to the zodiac as it traverses it: a revolution from one point of the zodiac or orbit back to that same point. For in Greek [Greek: περίοδος (periodos, "a going round")] means a going round. If you consider the motions as they truly appear to us, this month is unequal; but if you consider the mean motion between the slowest and the fastest, it is supposed equal, and is called the Mean Periodic Month [Mensis Periodicus Medius]. The Mean month is about $27^{d}\ 7^{h}\ 43^{m}\ 7^{s}$.

[Margin: The Synodic month.]

The *Synodic* month, that is, the Conjunctive month, is one revolution of the Moon to conjunction with the Sun, or meeting with the Sun; for in Greek [Greek: σύνοδος (synodos, "meeting")] means conjunction and meeting, or coming together. This month is longer than the Periodic because the Moon, setting out from a new Moon and a conjunction with the Sun made, for example, at the beginning of Aries, and having traversed the zodiac by mean motion in $27^{d}\ 7^{h}\ 43^{m}$, does not find the Sun at the same point of the zodiac but advanced farther toward the east. So, to be conjoined with it again, the Moon must still traverse nearly one sign, which the Sun has meanwhile completed,

before it overtakes the Sun, which all this while is still advancing. This month is also called a Lunation [Lunatio]: True if you consider the true motions, Mean if the mean ones. [Margin: The mean, longest and shortest lunation.] The Mean Lunation is about $29^{d}\ 12^{h}\ 44^{m}\ 3^{s}$. The longest, however, is for Ptolemy $30^{d}\ 3^{h}\ 14^{m}\ 3^{s}$, for Tycho $30^{d}\ 1^{h}\ 24^{m}\ 3^{s}$; the shortest for Ptolemy $28^{d}\ 22^{h}\ 14^{m}\ 3^{s}$, for Tycho $28^{d}\ 23^{h}\ 24^{m}\ 3^{s}$. For Kepler, in the *Epitome of Copernican Astronomy*, p. 790, with the Sun at perigee or fastest and the Moon at apogee or slowest, the month is longest, $29^{d}\ 19^{h}\ 47^{m}$; but with the Sun at apogee and the Moon at perigee the month is shortest, $29^{d}\ 6^{h}\ 42^{m}$.

The month of *Illumination* is the time from the Moon's first phase, or evening appearance after new Moon, to its last morning appearance before the following new Moon; for the remaining time, which slips by between these two phases, is called the interlunium. Between these phases there intervene interlunia sometimes of 2, 4 or 6 days, and so the month of illumination is sometimes 27½ days, or 25½ days, and very rarely 23½ days. But see what we said about these phases in chapter 3, from no. 4 to no. 10, and in chapter 4, no. 10.

[Margin: The Anomalistic month.]

The *Anomalistic* month is the time in which the Moon on the epicycle, according to Ptolemy, moves from its greatest slowness through mean speed to its greatest speed, and returns from the apogee of the epicycle to the same apogee. By the mean motions this time is about $27^{d}\ 13^{h}\ 18^{m}\ 34^{s}$.

[Margin: The Apogistic month.]

The *Apogistic* month, if one may so speak, is the time in which the orb carrying the apogee of the lunar eccentric completes its period against the order of the signs [in præcedentia Signorum]: namely, about $32^{d}\ 3^{h}\ 4^{m}\ 24^{s}$.

[Margin: The Draconic month.]

The *Draconic* month, or month of Latitude, is the time in which the Moon completes its period in the motion of latitude: namely, about $27^{d}\ 5^{h}\ 5^{m}\ 36^{s}$. I mean the motion compounded of the Moon's motion in the zodiac in the order of the signs and of the motion of the Nodes against the order of the signs.

[Margin: What the lunar year is, and of how many kinds.]

II. The *lunar year* is either Common, or Embolismaean, that is, Embolismic or intercalary. The former consists of 12 lunar months, the latter of 13. The civil Common year is of 354 days, not of 355 as once among the Greeks and the less advanced Romans; the Embolismic, of 384 days. Astronomically, however, the mean lunar year, if Common, is about $354^{d}\ 8^{h}\ 48^{m}\ 38^{s}\ 12'''$; if Embolismic, $383^{d}\ 21^{h}\ 41^{m}\ 18^{s}\ 24'''$.

[Margin: What an epact is.]

Epacts, in Greek [Greek: ἐπακταὶ ἡμέραι (epaktai hēmerai, "added days")], from the verb [Greek: ἐπάγω (epagō, "I bring in")], which means I introduce, I take on, I add, are the days to be added to the common lunar year so that it is made equal to the solar year. In civil reckoning these are usually 11 days and sometimes 12, rarely 10 or 13, as may be seen in the Calendar of Clavius,

chapter 12, no. 13. Astronomically, however, according to the mean motions, they vary with the varying opinion about each of the two years. For now it is enough to know that in the Rudolphine Tables they are $10^{d}\ 15^{h}\ 11^{m}\ 21^{s}\ 49'''\ 53''''$, but in the Prutenic Tables, as given by Clavius, $10^{d}\ 15^{h}\ 11^{m}\ 21^{s}\ 52'''\ 24''''$. When their accumulated sum after 3 years exceeds the quantity of the synodic lunar month, one month is thrown out and the remainder is retained as the epact of the following year, while the preceding year consists of 13 lunations. On this, however, there is more in the Ecclesiastical Computus.

III. The lunisolar cycle can be taken in two ways. *First*, for the period produced by multiplying the Cycle of the Moon by the Cycle of the Sun, in the sense used by the calendar computists. For them the Cycle of the Moon is a period of 19 years, serving the golden number and, through it, the finding of new Moons. The Cycle of the Sun is the cycle of weekdays [feriarum] recurring through the weeks of the Julian year. If the year were always Common, of 365 days, this cycle would be of 7 years; but because of the leap years [Biſſextiles] it is of 28 years, after which the weekdays return to the same day of the year, and the same Dominical letter returns. So when 28 is multiplied by 19, the result is 532 years, after which it was believed that new and full Moons return not only to the same day of the year but also to the same weekday. [Margin: The period of Victorinus and Dionysius, of 532 years.] Such was the Cycle devised by Victorinus of Capua and begun from the Baptism of Christ. It was restored, however, by Dionysius, surnamed Exiguus (the Small), but Great in wisdom and uprightness of character, as his contemporary Cassiodorus affirms; and it was begun from the Incarnation of the Lord, in order to abolish the custom of numbering years from the beginning of the reign of the most impious tyrant Diocletian. There is more on this period in Scaliger, *De emendatione temporum*, Book 2, p. 157, and Book 4, p. 300, and in Pétau, *De doctrina temporum*, Book 6. [Margin: The Julian period, of 7980 years.] Similar to it is the Julian Period, introduced by the same Scaliger (p. 2 of the Prolegomena to *De emendatione temporum*). It is produced by multiplying the Dionysian period of 532 years by the 15 indictions, and is of 7980 years. In the Chronological Book we show that it is not so very suitable for recording dates, much less necessary, as Scaliger asserts, or very useful, as Pétau affirms in the *Rationarium temporum*, Part 2, Book 1, chapter 4.

[Margin: The second meaning of the lunisolar cycle.]

Second, the lunisolar cycle is taken for a period of years at whose end the syzygies of the luminaries, namely new and full Moons, return to the same hour and moment of the hour of the same day, say the first day of January; granted that some require for this that they return to the same point of the zodiac, and a restitution [Greek: ἀποκατάστασιν (apokatastasin, "restitution")], that is, a revolution, not only of the luminaries but of all the celestial phenomena. This is by no means necessary; indeed it is perhaps not even possible in mathematical rigour, because of that incommensurability in the celestial motions which we suspect, together with Kepler at the end of the *Prodromus* or *Mysterium*

Cosmographicum, Boulliau, Book 2, chapter 3, and others. In this second sense, then, but restricted to the restitution of the syzygies to the same time of year, we here take lunisolar cycles, because astronomers and computists used them to investigate, as best they could, the measure of the solar and lunar year, and from that of the months and the other motions, as we shall shortly relate.

Cyclorum Lunisolarium aut Periodorum enarratio.

An account of the lunisolar cycles or periods.

[Margin: The cycle of Cleostratus, Harpalus and Eudoxus, of 8 years.]

IV. The first period was that of Cleostratus of Tenedos, and then of Harpalus, consisting of 8 solar years and therefore called the octaëteris [Greek: ὀγδοετήρις (ogdoetēris, "eight-year period")]. On it see Censorinus, *De Die Natali*, chapter 6; Macrobius, *Saturnalia*, Book 1, chapter 13; Scaliger, *De emendatione temporum*, Book 2, p. 64. For although there was previously in use the Trieteris, of 2 full years but 3 when the terms are counted, in which the year had alternately 12 and 13 months; and although, when the error had been recognised, a Tetraeteris was then made, of 4 whole years but 5 when the terms are counted, and therefore called the Penteteris; yet the Octaëteris seemed more correct, which, if you count the terms, was an enneateris, that is, of 9 years. So Cleostratus, thinking with many others that the lunar year is of 354 days and the solar of 365¼, judged that eight lunar years, with as many solar excesses, namely 2922 days, complete 99 lunations. He began this period, in civil reckoning, from the winter solstice. [Margin: The month of Cleostratus.] But since the lunar month is about 29 days and 12¾ hours, and Cleostratus had taken it as only 29½ days, as is plain to anyone who divides 2922 days by 99 lunations, it came about that Cleostratus's new Moons fell ahead after 8 years by 6 hours. And when at length they fell ahead by two days, while the true new Moons lagged by as many days, Harpalus, correcting Cleostratus's Octaëteris, made it of 2924 days. [Margin: The month of Harpalus.] When this is divided by 99, the lunar month comes out as 29 days and 12 84/99 hours, or $50^{m}\ 54^{s}\ 33'''$. But when 2924 is divided by 8, the solar year comes out too large: $365^{d}\ 12^{h}$, or, as the codex of Censorinus has it, chapter 7, $365^{d}\ 13^{h}$. Scaliger, however, makes the Harpalean syzygy

29 days and 12 28/33 hours, or about 51^{m}. [Margin: The month of Eudoxus.] This was later found to be too large by Eudoxus of Cnidus, who compared it with eclipses observed by the Egyptians. So, as Geminus reports in chapter 6, and Diogenes Laertius, he introduced another Octaëteris, of 2923½ days. Dividing this by 99 lunations gives one lunation of $29^{d}\ 12^{h}\ 43^{m}\ 38^{s}\ 11'''$; but dividing 2923½ by 8 gives a year of $365^{d}\ 13½^{h}$. But let us leave these Octaëterides aside, and also those of Nauselis, Doxitheus and Menesistratus, on which see Censorinus, chapter 6; for none of them was suited to restoring the new Moons to their original positions.

[Margin: The cycle of Meton, of 19 years, or of Philippus and Euctemon.]

V. The *second* period, of 19 years, was that of Meton. On it see Theophrastus in his book on Prognostics; Censorinus, chapter 6; Diodorus Siculus, Books 2 and 12; Tzetzes, Book 12 of the *Variae historiae*; Aelian, *De varia historia*, Books 10 and 13; Manutius, Question 6, by letter, which concerns Meton's Great Year; Giraldi, in his book on years, p. 20; Scaliger, *De emendatione temporum*, Book 2, p. 72, Book 4, p. 292, and Book 5, p. 410; Clavius, chapter 8 of the Calendar; and Pétau, *De doctrina temporum*, Book 2, from chapter 11 on, and in the *Uranologion*, Book 6, chapter 10. A trace of this cycle does seem to have existed long before in Magna Graecia, since Livy relates that Numa so adjusted lunar years to the Sun that, when the 19th year was complete and the twentieth beginning, *the days would coincide at the same turning-point of the Sun from which they had set out, the full spans of all the years being accomplished*. And in his *Elements of Astronomy*, chapter 6, Geminus attributes the discovery of this cycle to Euctemon and Philippus. Yet the others just cited, and Festus Auicenus [Rufius Festus Avienus], soon to be cited, ascribe it to Meton. So Meton of Athens, son of Pausanias and in astrology a pupil of Phaenus, himself most celebrated for his prognostics, for the drawing and levelling of waters, whose springs he conducted to Athens, and for the heliotrope, or sundial, which he dedicated there in the forum, devised or restored the cycle of 19 years. It was therefore called [Greek: δεκαιννεατήρις (dekainneatēris, "nineteen-year period")] or [Greek: ἐννεαδεκατήρις (enneadekatēris, "nineteen-year period")], that is, the Decennoval Cycle. In it, as Censorinus and Geminus attest, intercalation was made seven times, and it contained 6940 days, as the corrected codex of Censorinus has it in Manutius, Scaliger and Pétau; for the corrupt one has six thousand CCCCXL, when DCCCCXL should have been written. In these days Meton thought that 235 lunations, of which 110 are Hollow and 125 Full, and 19 years of the Sun, are completed with no minutes of an hour over or short. [Margin: How long Meton's year and month are.] So Geminus says that the year was fixed by Philippus and Euctemon at 365 5/19 days, and Censorinus, chapter 7, says it was fixed by Meton at *365 days with five nineteenth parts of a day*, which comes to the same thing, namely $365^{d}\ 6^{h}\ 18^{m}\ 56^{s}\ 51'''$. Dividing the 6940 days by the 235 lunations gives one lunation of $29^{d}\ 12^{h}\ 47^{m}\ 26^{s}\ 48'''\ 30''''\ 38'''''\ 18''''''$, whatever others may gather [Greek: ἀλογιστικῶς (alogistikōs, "without reckoning")] from the data given by Meton. But 19 Julian years contain only $6939^{d}\ 18^{h}$. In these, as Clavius computes in chapter 8 of the Calendar, there occur by the Prutenic reckoning 235 mean lunations, but these take up only $6939^{d}\ 16^{h}\ 32^{m}\ 27^{s}\ 18'''$. So the new Moons precede the end of the 19 Julian years by $1^{h}\ 27^{m}\ 32^{s}\ 41'''$. If instead you use equinoctial years, each of which for me is $365^{d}\ 5^{h}\ 48^{m}\ 40^{s}$, 19 years make $6939^{d}\ 14^{h}\ 24^{m}\ 40^{s}$, and so the mean new Moons follow later by $2^{h}\ 7^{m}\ 47^{s}\ 18'''$. [Margin: The defect of the Metonic cycle.] Either way, therefore, the cycle of Meton was defective, although, because of its civil use, it was held in such esteem that its number was called Golden. [Margin: The cycle of Rabbi Adda.] Rabbi Adda, however,

corrected it in the Hebrew Calendar. For he took a cycle of 6939 days, 16 hours and 595 parts [punctorum], that is, $33^m\ 3^s\ 20'''$. Divided by 19 years, this gives a year of $365^d\ 5^h\ 55^m\ 25^s\ 26'''\ 20''''$; but divided by 235 lunations, it gives one lunation of $29^d\ 12^h\ 44^m\ 3^s\ 20'''$. As for true lunations, let the following table serve as a sample of this falseness, drawn from observed lunar eclipses reduced to the meridian of Bologna according to the difference of longitude established in our Geographical Book.

CYCLORVM METONICORVM EX VERIS PLENILVNIIS EXAMEN.

Examination of the Metonic cycles from true full Moons.

[Margin: Eclipses of the Metonic cycle.]

Year of Christ	Month and day	Mid-point of the lunar eclipse, after noon	Time	But at Bologna	Interval between the eclipses in Julian years	Difference from the completed 19th year
1584	November 17	Tycho, at Uraniborg	$13^h\ 9^m$	$13^h\ 9^m$

Year of Christ	Month and day	Mid-point of the lunar eclipse, after noon	Time	But at Bologna	Interval between the eclipses in Julian years	Difference from the completed 19th year
1623	April 14	Hortensius, at Leiden	$10^h\ 52^m$	$11^h\ 24^m$		
1642	April 14	We, at Bologna	$14^h\ 44^m$	$14^h\ 44^m$	19 yr $0^d\ 3^h\ 20^m$	$3^h\ 20^m$

[Margin: The beginning of the Metonic cycle.]

As for the beginning of this cycle: since Euctemon and Meton observed solstices, but [Greek: ὁλοσχερῶς (holoscherōs, "roughly")], that is, less exactly, as Hipparchus attests in Ptolemy, *Almagest*, Book 3, chapter 2, it is no wonder if Meton began the epoch and start of his cycle in year 4 of Olympiad 86, from the 13th day of the Athenian month Scirrhophorion, as Diodorus Siculus relates, Book 12. That is, in the year 432 before Christ, on June 27, when the mean solstice occurred, and on the 28th the true solstice followed, as the Emendator of Times, cited above, and Pétau in the *Uranologion* point out. Ptolemy, moreover, agrees wonderfully with this mark of time and with Diodorus, in Book 3, chapter 2, where he relates that a solstice was observed by Euctemon and Meton in year 316 of Nabonassar, on the 21st of the Egyptian month Phamenoth, in the morning. That is, as is clear from our Chronological Book, in the year 432 before Christ, on June 27, weekday 1. From this you will note in passing that the order of the golden number introduced by Meton was afterwards interrupted, and is not the same as that later used by St Cyril of Alexandria, Dionysius Exiguus, Bede and the Roman Church in its Calendar. For going back through the Golden Numbers of the Roman Calendar, the golden number in that year 432 before Christ would have been 7, whereas for Meton it was 1.

The last new Moon [Neomenia], moreover, then fell on June 15, and the first of Hecatombaeon on July 15. The Greeks generally began their year at the summer solstice, and so Meton began his cycle from there. Festus Avienus also touches on this, after first praising Harpalus, in these verses:

> For that [?] which holds that the Sun is rolled through the aether
> for nine winters, so that the Moon's former interval may return,
> Harpalus brings it back more swiftly to its seats and its ancient
> moments. To his numbers Meton, by Cecropian art, is said to have
> added long decades again, and he took root in men's minds. Skilful
> Greece grasped the matter at once, and sent the discovery on down
> the long years. But Meton took his first beginnings from the year
> when Phoebus was scorching Cancer with his ruddy star, when the
> sea carried far off the belt of Orion, and when Sirius was blazing
> with its dark-blue star.

[Margin: The Chaldaean period, of 12 and 18 years, but when tripled, 54.]

VI. The *third* period was the Chaldaean: not that [Greek: δωδεκαετήρις (dōdekaetēris, "twelve-year period")] of 12 years which, as Censorinus says in chapter 6, the Chaldaeans kept *adapted not to the courses of the Sun and Moon*

but to other observations, because they said that in it the weather and the yields of crops, and likewise barrenness and diseases, come round. It was rather the one of which Geminus treats, *Elements of Astronomy*, chapter 6, Ptolemy, *Magna Constructio*, Book 4, and Boulliau, *Astronomy*, Book 3, chapter 2. It consisted of 6585 days and 8 hours, that is, 18 Egyptian years $15^{d}\ 8^{h}$, but 18 Julian years $11^{d}\ 8^{h}$. For they thought that in it there were completed 223 lunations, 241 periodic months together with 10° 40′, 239 revolutions of anomaly and 242 periods of latitude. So that they might nevertheless have a period without a fraction of a day, they tripled this and made it of 19756 days, in which there are 54 Egyptian years 46 days, but 54 Julian years and 34 days; periodic months, as the Chaldaeans thought, 723, and 32° besides; synodic months 669; anomalistic 717; of latitude 726. Now if you divide the 19756 days by the 669 months, one month comes out as 29 days and 13 63/669 hours. [Margin: The defect of this period.] Hipparchus saw that this conflicts with all observations of eclipses, and so he turned to devising other periods, as will be said a little below. Certainly, as Boulliau too notes, Book 3, chapter 2, from the total lunar eclipse observed by Tycho at Uraniborg in 1577 September 26, at $13^{h}\ 3^{m}$ after noon, to the total eclipse observed by him at the same place in 1595 October 7, at $20^{h}\ 29^{m}$ after noon, there are not $6585^{d}\ 8^{h}$, as the first period of the Chaldaeans requires, but $6585^{d}\ 7^{h}\ 26^{m}$. Again, from the total eclipse observed by him at Uraniborg in 1588 March 12, new style, at $15^{h}\ 2^{m}$ after noon, to the total eclipse observed by us at Bologna, and correspondingly at Uraniborg, in 1642 April 14, at $14^{h}\ 44^{m}$ after noon, there are not 19756 days, as the Chaldaeans thought, but $19755^{d}\ 23^{h}\ 42^{m}$.

[Margin: The opinion of Geminus.]

Geminus, however, notwithstanding these things, in the *Elements of Astronomy*, chapter 15, relying on the Chaldaean period of 19756 days, with 669 lunations, 717 circles of anomaly, and 723 circles of longitude or of the zodiac and 32° completed in that interval, gathers the synodic month as about 29½ 1/33 days and the periodic as 27 1/18 days, and the Moon's mean daily motion as 13° 10′ 35″, its greatest as 15° 11′ 35″ and its least as 11° 6′ 12″, as is found in Pétau, *Uranologion*, p. 64. [Margin: The Chaldaean month and that of Geminus.] But Boulliau shows that the text of Geminus is erroneous and that the periodic month must be restored as $27^{d}\ 13^{h}\ 20^{m}$. The synodic month, on dividing 19766 days by 669 lunations, comes out as $29^{d}\ 13^{h}\ 5^{m}\ 39^{s}\ 24'''\ 11''''$. Yet it is surprising that Geminus, himself a Rhodian, who flourished in the time of Cicero and was thus later than Hipparchus of Rhodes, as Pétau shows, did not know of, or ignored, the correction Hipparchus applied to the Chaldaean period.

[Margin: The cycle of Philolaus and Oenopides, of 59 years.]

VII. The *fourth* period was that of Philolaus the Pythagorean, and of Oenopides of Chios, of 59 years. But Philolaus, as Censorinus relates, chapters 6 and 7, introduced 21 intercalary months and made the solar year of 364½ days. Therefore, says the Emendator of Times, Book 2, p. 166, he took the lunar

month, roughly in the civil manner, as of 29½ days, which doubled makes 59 days. So he assigned as many years to his period, and 21505½ days; for when these are divided by 59, there results a year of 364½ days. His lunar year was of 354 days, and there were 729 lunations in this period. But Oenopides of Chios, whose cycle, as Aelian affirms in Book 10 of the [Greek: ποικίλης (poikilēs, "varied")], that is, of the *De varia historia*, was publicly displayed at the Olympic Games, retained indeed the cycle of 59 years. But the solar year, as Censorinus records, chapter 7, he defined as 365 days and the fifty-ninth part of 22 days, that is, 8 56/59 hours. So this period exceeds 59 Julian years by an excess of 7 days and 6 hours. Now multiply 365 days by 59 and add 22 days to the sum: this period then comes to 21557 days, containing 730 lunations. [Margin: The month of Oenopides.] When those days are divided by these, one lunation comes out as $29^{d}\ 12^{h}\ 43^{m}\ 24^{s}$. This is that fifty-nine-year period which Plutarch touches on in *De placitis philosophorum*, Book 2, chapter 32.

[Margin: The period of Calippus, of 76 years.]

VIII. The *fifth* period, by far the most celebrated of those before it, was that of Callippus of Cyzicus, mentioned by Geminus, *Elements of Astronomy*, chapter 6; Ptolemy, *Almagest*, Book 4, chapter 9; Censorinus, *De Die Natali*, chapters 6 and 7; Regiomontanus, in the *Epitome*, Book 4, Proposition 3; Copernicus, Book 4, chapter 4; Scaliger, *De emendatione temporum*, Book 2, from p. 81 on; Clavius in the Calendar, chapter 8; Pétau, *De doctrina temporum*, Book 2, from chapter 16 on, and Book 10, chapter 37; and Boulliau, Book 2, chapter 2. For Callippus judged from eclipses that, when Meton's cycle is quadrupled, that is, taken as 76 years, the new Moons come one day ahead, because Meton's solar year was too large, being 27760 days in 76 years. So, one day being taken away and 27759 days divided by 76, he obtained a solar year of 365¼ days. Geminus and Ptolemy also attest this, and by them the text of Censorinus must be corrected, which in chapter 7 has 365 days, with the quarter omitted. And so in 76 years 19 intercalary days were required, as many as there were years in the simple cycle of Meton. Again, because in 76 years 235 lunations taken four times, that is 940, were completed exactly, as he thought, provided that the days of the period were only 27759, he divided these by 940 and found the synodic lunar month to be about $29^{d}\ 12^{h}\ 44^{m}\ 12^{s}\ 45'''\ 57''''\ 26'''''\ 49''''''$. [Margin: The month of Calippus.] Geminus and Censorinus add that of the 940 months 28 in that period were intercalary; on this intercalation Scaliger says more, and learnedly. This year of $365^{d}\ 6^{h}$, moreover, was favoured by Archimedes, Geminus, Sosigenes and nearly by Aristarchus, who, however, as Censorinus attests, added to it the 1532nd part of a day. But the excessive quantity of the year at length revealed a defect in the year and in the lunar month derived from it.

[Margin: The defect of this period, and its beginning.]

As for the epoch [Greek: ἐποχὴν (epochēn, "epoch")] and beginning of the Calippic period, it is established from Ptolemy, Book 3, chapter 2, Book 4, chapter 11, Book 6, chapter 5, and Book 7, chapter 3, that it was begun in

the year 330 before Christ, which followed the victory of Alexander the Great over Darius at Arbela; begun, I say, on June 28, the solstice having preceded on the 27th, this 28th day being the new Moon of Hecatombaeon among the Athenians, as Scaliger, Pétau and Boulliau agree. This period may then have spread among the people and passed into civil use, as Scaliger thinks, or it may have remained only with the learned, as Pétau contends. Certainly Diodorus Siculus, Book 22, writes that in his time the cycle of Meton was in use.

[Margin: The cycle of Democritus, of 82 years.]

IX. The *sixth* period was that of Democritus of Abdera, whose work is entitled in Laertius *The Great Year*, *Astronomy* and *Parapegma*. A parapegma, as Vitruvius indicates, Book 9, chapter 7, is a catalogue of predictions and prognostics compiled chiefly from the risings and settings of the stars. The period of Democritus, in Censorinus, chapter 6, was of 82 years with 28 intercalaries. From this Scaliger, *De emendatione temporum*, Book 2, p. 167, concludes that for him the lunar year was of 355 days, the solar of 365¼ days and the lunation $29^{d}\ 14^{h}$, both of which exceed the truth. [Margin: The month of Democritus.] Next to this was that Hebrew period of 84 years, which Guldin, in the Calendar, Book 5, chapter 13, gathers from Munsterus [Sebastian Münster] and from Pétau's notes on Epiphanius, heresy 51. It was far from the truth, since in 84 Julian years the epacts are about $28^{d}\ 5^{h}\ 52^{m}\ 53^{s}$, which lack more than 30 hours of a whole lunation.

[Margin: The period of Gamaliel, of 247 years.]

X. The *seventh* period, in Paulus of Fossombrone [Paul of Middelburg], Book 8 of the *Summa*, was that of Gamaliel, of 247 years, in which the mean new Moons are restored very nearly to their original place. For the epacts of 247 years, by the Rudolphine Tables, are only $1^{h}\ 1^{m}\ 2^{s}\ 53'''\ 39''''$. Further, in 247 years 3055 lunations are completed; and in 247 Julian years, which were already in use in Gamaliel's time, there are 90216 days and 18 hours. [Margin: The month of Gamaliel.] Dividing these by 3055 gives a lunar month of $29^{d}\ 12^{h}\ 44^{m}\ 4^{s}\ 20'''$, closer to the truth.

[Margin: The first period of Hipparchus, of 304 years.]

XI. The *eighth* period, now, was that of Hipparchus, but threefold; the first indeed more civil, the others astronomical. On the first, see Ptolemy, *Magna Syntaxis*, Book 4, chapter 2; Censori- nus, chapter 6; Regiomontanus in the *Epitome*, Book 4, Proposition 3; Copernicus, Book 4, chapter 4; Scaliger, *De emendatione temporum*, Book 2, p. 108; and Clavius in the Calendar, chapter 8. Hipparchus flourished about 200 years after Callippus, and in those years, from observations of eclipses, he noted that the Moon was already running ahead of the Calippic new Moons by 16 hours; and therefore by a whole day, or 24 hours, in 300 years, which contain very nearly four periods of Callippus, amounting to 304 years. He therefore thought that one day should be taken away from them, so as to have a juster measure of the year and a more exact restitution of the lunisolar cycle. Accordingly, a three-hundredth part of a day was to be removed from the Calippic year of 365¼ days, and he noticed

from observing the equinoxes that this did not conflict with their revolutions. Now the three-hundredth part of a day is $4^{m}\ 48^{s}$; taken from 365 days and 6 hours, it leaves the Hipparchan year received by Ptolemy, $365^{d}\ 5^{h}\ 55^{m}\ 12^{s}$. And so from four Calippic periods (which would have been 111036 days) he took away one day, so that there were 111035 days. Dividing these by 3760 lunations, he obtained one synodic lunar month of $29^{d}\ 12^{h}\ 44^{m}\ 41^{s}\ 6'''$. In this period, moreover, as Censorinus says, there was intercalation 112 times. Clavius, however, maintains that for the new Moons to come ahead by one whole day requires not 300 or 304 years but 312½, evidently because he uses a smaller year. But Copernicus had noticed that the revolution of the Moon with respect to the Sun occurs only when the year is of such a size that a three-hundredth particle of a day must be taken from the Calippic and Julian year; for he thought that the quantity of the year varied.

[Margin: Praise of Hipparchus.]

[Margin: And a period of about 345 or 441 years.]

Since, however, this period of 304 years did not restore the conjunctions of the luminaries very exactly, and much less the revolutions of anomaly and latitude, that towering man, to whom those two things never commended enough to any astronomer, Labour and Truth, were dear (for Ptolemy calls him [Greek: φιλόπονον καὶ φιλαλήθη (philoponon kai philalēthē, "labour-loving and truth-loving")] and Pliny the Elder a sharer in nature's counsels), compared with one another many eclipses formerly observed by the Chaldeans and Egyptians along with those he had observed himself. He noticed that in 344 Julian years, 363 days and 1 hour, that is, in 126007 days and 1 hour, 4267 synodic months are completed, 4612 periodic months less 7° 30′, and 4573 revolutions of simple anomaly; but that the restitution [apocatastasim] of latitude is not restored except in 5458 lunations, at which point 5923 revolutions of latitude are complete. Therefore, in the matter of the Moon, the revolutions of solar years must be set aside; and these four periods, namely of synodic and periodic months, of anomaly and of latitude, have not yet been made commensurable by so great an interval of time that all would be exactly restored in one and the same interval. Ptolemy, Book 4, chapter 2, judges this matter difficult, but Scaliger, Book 4, p. 288, [Greek: ἀδύνατον (adynaton, "impossible")]. [Margin: The month of Hipparchus.] Further, dividing 126007 days and 1 hour by 4267 gives a synodic month of $29^{d}\ 12^{h}\ 44^{m}\ 3^{s}\ 15'''\ 44''''\ 39'''''\ 4'''''''$.

[Margin: Viète's period of 3400 years.]

XII. The *ninth* period was that of François Viète, in Proposition 31 of his Calendar, which he falsely calls Gregorian, since it was not approved by Gregory. This period is of 3400 Julian years, or 1241850 days, containing 42053 synodic months, in which he affirms that the revolutions of both luminaries are exactly restored. Clavius, however, in the Calendar, chapter 24, denies that this can happen unless the synodic month is $29^{d}\ 12^{h}\ 44^{m}\ 3^{s}\ 10'''\ 43''''$; which Viète has not yet demonstrated, though he does admit that the lunar month is of 29 12313/42053 days. But Clavius too grants that this period comes very close

to the truth, and Kepler, in the Rudolphine Tables, Precept 135, thinks that it falls short of exact restitution by only $1^m\ 19^s$, and therefore strongly commends it. More than 200000 years would therefore be required before this period could be convicted from observations of a defect of one hour. But just as it cannot yet be demonstrated that this period is false, so, to speak with Boulliau, Book 2, chapter 3, who has ever demonstrated that the motions of the Sun and Moon are fully commensurable? [Margin: The month of Viète and of Kepler.] Now in 3400 years there are 42053 lunations. When 1241850 days are divided by these, according to Viète, Viète's lunar month comes to $29^d\ 12^h\ 44^m\ 3^s\ 11'''$; but by my reckoning to $29^d\ 12^h\ 44^m\ 3^s\ 10'''\ 43''''\ 50'''''\ 41''''''\ 25''''''\ 43''''''''$. If, however, you divide 1241850 days and $1^m\ 19^s$ by the same number, according to Kepler, the lunar month will be $29^d\ 12^h\ 44^m\ 3^s\ 10'''\ 43''''\ 57'''''\ 26''''''\ 40''''''$; and yet in the Rudolphine table of syzygies he gives $29^d\ 12^h\ 44^m\ 3^s\ 10'''\ 51''''$. Viète, however, adds in Proposition 35 that the greatest period of the lunar restitution is of 165580000 Gregorian years, which is less than the same number of Julian years by 3400 Julian years.

SCHOLION.

Scholium.

Do not look here for other cycles, as though they had been passed over unadvisedly or omitted through forgetfulness. For these are either certain Great Years for some other end than restoring the conjunctions of the Moon and the Sun to the same time, or else civil or rather ecclesiastical cycles, set up for feast days and festivals, or for restoring, after a fashion, new Moons and especially the Paschal ones, such as those of Anatolius, Theophilus, Cyril, Victorinus, Dionysius Exiguus, Bede and countless others, some of whom I indicated in Book 3, chapter 14, Scholia 3 and 4. It will be enough, then, to have recorded the nine already mentioned.

CAPVT XX.

Chapter 20.

De Secundo Artificio, quo Aſtronomi Reuolutiones & inde Motus Lunæ inueſtigarunt.

On the second technique by which astronomers have investigated the revolutions and, from them, the motions of the Moon.

I. SINCE it is clear from what was said in the preceding chapter that it is vain to investigate the restitution of the Moon's meetings with the Sun to the same moment of the year from cycles of the Moon and the Sun together, or from a commensuration of the lunar year and month together with the solar year, the care of the solar year must meanwhile be set aside, for we have already investigated its quantity better from the equinoxes, in Book 3, chapter

15. Just as there, then, from two observed equinoxes separated by a very long interval, but reduced to equal time and, from a moderate knowledge of the solar apogee, converted into mean equinoxes, we investigated the measure of the tropical year; so now, from two observed lunar syzygies, that is ☌ or ☍, separated by the longest possible stretch of time, but reduced to equal time and, from a moderate knowledge of the anomaly of the luminaries, brought back to mean syzygies, we must investigate the measure of the lunar month and of the other revolutions of the Moon. Ptolemy presents this technique in Book 4 of the *Magna Constructio*, from chapter 1; Regiomontanus there in the *Epitome*, Book 4, from Proposition 4; Biancani in the *Sphere*, Book 9, chapter 2; and Boulliau, Book 3 of his *Astronomy*, from chapter 2 to chapter 7. The remaining astronomers pass over it, except Copernicus, who deals with the third technique, of which I shall speak in chapter 22. No one, however, has set out this whole method clearly and in order, as we would wish, and so we shall present it distinctly in the following precepts.

[Margin: Precept 1.]

II. *First*, from observations of eclipses one must choose two eclipses of the Moon separated by the longest possible interval of time, so that an error, if one creeps in, spread over very many years, becomes insensible; and so that, on the contrary, an error arising in a small interval is not multiplied over a large interval and, from insensible, made enormous and manifest, as Ptolemy warns, Book 3, chapter 2, and Book 4, chapter 1. I said eclipses of the Moon because, since the Moon is then truly deprived of the light received from the Sun, eclipses of this kind occur in the same way on all horizons, as regards the duration and quantity of the eclipsed part, and toward the same regions of the world; nor is any other difference found in them than the count of time arising from the difference of geographical longitude, or from the distance of the meridians. Therefore, at the middle of a lunar eclipse, which can be known from its beginning and end without sensible error, the Moon is diametrically opposite the Sun and 180° from it in the zodiac, and the Sun's place at the stated time can be known quite exactly from the tables established in Book 3, and that either independently of parallax, which cannot be known without the Moon, or dependently on a parallax known in some fashion, though not exquisitely (for that is not required here). So, by the addition or subtraction of 180° from the Sun's place in the zodiac, the true place of the Moon in the zodiac can be known at once, and no parallax of the Moon intervenes to disturb this business.

But if eclipses of the Sun were chosen, or if two places of the Moon had to be gathered from its approach to fixed stars, or from its distance from two fixed stars, or from the Sun on one side and one of the fixed stars on the other, or from azimuths and from right ascension and declination observed and seen, it would be necessary to disentangle the Moon's parallaxes in longitude and latitude. These differ on different horizons at the same time; they make the same eclipse of the Sun greater and longer in some places, smaller and shorter in others, and nil elsewhere; they introduce into its beginning and end another

difference beyond the one that arises from the distance of the meridians; and finally they make the visible place differ greatly from the true one. So Ptolemy, Book 4, chapter 1, rightly preferred lunar eclipses in this practical procedure, because of their uniformity everywhere on Earth. For, as is said in the same place, [Greek: Τὸ τεταγμένον, καὶ τὸ ὅμιον [?], τῶν ἀτάκτων καὶ ἀνομίων ἀναγκαῖον ἂν εἴη πρωυποκεῖσθαι], that is: *What is ordered and alike must necessarily be put before what is disordered and unlike.* In addition, outside the syzygies the Moon is subject to two or three inequalities or anomalies, indicated in chapter 19, whereas at the syzygies it undergoes only a simple and single inequality.

[Margin: Precept 2.]

III. *Second*, as Ptolemy prescribes, Book 4, chapter 2, two eclipses of the Moon must be chosen in both of which the Moon is in the same degree of its simple anomaly and the Sun in the same degree, but of its own anomaly; this, however, he admits is very difficult to find. But at least the Moon should be in the same degree of anomaly, or equally distant in the order of the signs from the point of greatest or least slowness. This can be known from the durations of eclipses and the hourly motion, and from lunar tables constructed from them and adequately proved by their truth in predicting eclipses without enormous error. But the best eclipses, as Regiomontanus advises, Proposition 5, would be those in both of which the Moon was slowest, that is, at the apogee, or fastest, that is, at the perigee of the epicycle. And since the Moon in overtaking the Sun depends on the varying speed of the motion not only of itself but also of the Sun, I said accordingly that it was more prudent that the Sun too should occupy the same degree of its anomaly in both eclipses. Two other eclipses of the Moon can also be chosen for proof, which show the greatest inequality and yet do not contain whole revolutions of anomaly: for instance, if in the first interval it began from the apogee and did not end in the perigee, while in the other interval of eclipses it entered from the perigee and did not end in the apogee.

In this or in the preceding precept, however, there is no need for those two eclipses to have occurred in the same degree of the zodiac, provided the other conditions are present.

[Margin: Threefold Precept 3.]

IV. *Third*, the apparent time of the observed lunar eclipses must be converted into equal time, according to the precepts of Book 3, chapter 31. Next, from astronomical tables, which through smaller cycles and smaller intervals of time are supposed to have the motion of the Moon's anomaly and the equations of the first inequality known in some fashion and, as I said, to have been already proved by a tolerable prediction of eclipses, the apparent eclipse full Moons must be converted into mean ones, by adding the equation where otherwise it would have been subtracted and subtracting it where it would have been added. And finally, if the eclipses were not observed under the same meridian, their mean time must be reduced to the same meridian, according to the difference

of geographical longitude, known from another eclipse observed at the same time in both places, or from the distance of the places, or from some other source.

[Margin: Precept 4.]

V. *Fourth*, the interval of time, equated as above, must be resolved into days; and from this must be found the number of whole revolutions of the Moon completed in it, namely of lunar synodic and periodic months, and also of simple anomaly and of latitude. Hipparchus, and others following in his footsteps, have searched these out for us with such certainty, from ephemerides, from smaller cycles and from observations handed down, by comparing the times of greatest, least and middling speed and also of latitude, that there is now no danger of error in one whole monthly revolution.

For Hipparchus, as Ptolemy reports, Book 3, chapter 2, and Book 4, chapter 2, from the Chaldean period of 18 years and, tripled, of 54 years, from the Calippic period of 76 years and, this quadrupled, of 304 years, was certain that in 19 Julian years, that is, in 6939 days and 18 hours, 235 lunations and a very little more are completed; and in 54 years, or 19756 days, 669 lunations; and in 76 years, or 27759 days, only 940 whole lunations and somewhat more; and in 304 years, or 111035 days, 3760 lunations are completed, with almost no sensible remainder, as we also said in chapter 20, numbers 5, 6, 8 and 11. But from a deeper comparison of eclipses he saw that in the 54 years of the Chaldean period there are not exactly completed 669 lunations, nor 723 periodic months with 32°, nor 717 anomalistic circuits, nor 726 circuits of latitude, as the Chaldeans had thought; but that in 344 Julian years and 1 hour, or 126007 days and 1 hour, there are exactly completed 4267 lunations, 4612 zodiacs less 7½°, and 4573 revolutions of anomaly; but that the revolutions of latitude are not restored except in 5458 lunar months, or 441 Egyptian years $213^{d}\ 23^{h}\ 23^{m}$, at which point 5923 draconic circuits are completed. Having examined these things, I say, he left us this rule: we are to multiply the days elapsed in the interval between the eclipses by 4267, and divide the sum by 126007, to have the number of lunations. These, moreover, are to the revolutions of anomaly as 4267 to 4573, and to the revolutions of latitude as 5458 to 5923. And Hipparchus set the mean synodic month at very nearly $29^{d}\ 31'\ 50''\ 8'''\ 9''''\ 20'''''$.

[Margin: Hipparchus's slight error in the Moon's anomaly and latitude.]

Ptolemy, however, Book 4, chapters 2 and 3, affirms that the proportions already mentioned are correct as regards synodic months, without danger of sensible error; but that in the revolutions of anomaly and latitude Hipparchus erred by some sensible error; and that this became known to him by a simple method, of which we shall speak in chapter 22. But this method cannot be taught unless the mean motions of the Moon, investigated by the rules already mentioned, and then corrected or to be corrected in the manner still to be taught, are set out first. He adds that as 4267 is to 4573, so 251 is to 269, and that we can therefore use these smaller numbers.

[Margin: Wendelen's rule.]

Govaert Wendelen, moreover, an outstanding investigator of lunar secrets, after long reflections over very many years, affirms in the *Idea of the Atlantic Tables* that in precisely 79736 days, which are 2184 Egyptian years with 166 days, exactly 27000 lunations are completed; and that in 16831 synodic lunar months are completed 18038 eccentric circuits, that is, as Ptolemy would say, epicycles or circles of anomaly; but in 6890 synodic months, 7477 draconic circuits, or circuits of latitude. In this reckoning he agrees with Hipparchus, both as to whole anomalies, since by Hipparchus's rule 18038 anomalistic circuits are completed in 16831 months, and in the circuits of latitude, since according to Hipparchus 7477 draconic circuits correspond to 6890 months.

[Margin: Boulliau's rule.]

Ismaël Boulliau, an astronomer of deep inquiry, in Book 3 of his *Astronomy*, chapters 3 and 4, from several but smaller intervals of eclipses, limited on either side, shows that in 18 years etc., that is, in $6585^{d}\ 11^{h}\ 8^{m}$, 223 months are completed, 241 zodiacs and 239 circuits of anomaly, and that the Moon's apogee completes the zodiac twice in this time. Next, advancing to greater intervals of eclipses, he shows that in $652685^{d}\ 3^{h}\ 51^{m}$ there are completed 22102 months, 23885 zodiacs less $3^{\circ}\ 3'\ 58''$, and 23661 anomalies, while the Moon's apogee meanwhile completes the zodiac 198 times. Likewise, that in $652863^{d}\ 9^{h}\ 31^{m}$, 22108 months are completed. But in chapter 6, true eclipse full Moons having been reduced to mean ones, he teaches that in $736404^{d}\ 16^{h}\ 20^{m}\ 5^{s}$ there are completed 26725 anomalies and a further $114^{\circ}\ 35'\ 34''$; but in $76404^{d}\ 9^{h}\ 1^{m}\ 29^{s}$, 24937 months.

[Margin: On Mulerius's table of syzygies.]

Nicolaus Mulerius, in the *Tabulae Frisicae*, constructed for us a table for finding the number of lunations or syzygies for given Julian years. In it, I believe rather through the fault of copyists or printers, there are some errors; so in its place we shall substitute another, made from the Rudolphine epacts, and we shall give it at the end of this work as an aid for beginners, so that for given Julian years the mean lunations completed in them can be summed, together with the remaining epacts.

[Margin: Precept 5.]

VI. *Fifth*, then, divide the days of the interval between the lunar eclipses mentioned above by the lunations, or by the revolutions of anomaly or of latitude found by means of Precept 4, and the result will be the time corresponding to one mean lunation, or one anomalistic revolution, or one draconic circuit, or circuit of latitude. The remaining part of the precept, on the daily motions, will be given more conveniently below, from number XII.

It is a pleasure now, with three lunar eclipses from our His- tory of Eclipses, selected as examples, to illustrate the precepts already mentioned and, by the same effort, to lay the foundation of our hypothesis on the lunar motions. For no other such observed eclipses exist so far that are better suited to this purpose.

EXEMPLVM I.

Example 1.

[Margin: First eclipse.]

VII. The Chaldeans at Babylon, as Ptolemy reports, Book 4, chapter 11, observed a lunar eclipse in the year 336 of Nabonassar, which was the year 383 before Christ, on day 26 of Thoth, namely December 22 completed, at 19^h 20^m after noon; but at Alexandria at 18^h 30^m. Therefore, as I shall show in the Geographical Book, at Uraniborg and Bologna it was at 16^h 47^m, but in equated time at 16^h 37^m 52^s. For the Sun was in ♐ 26° 35′, its anomaly 203° 40′. The Moon's true place was ♊ 26° 35′, its anomaly 230°; and the mean motion of the Sun was ♐ 25° 49′, of the Moon ♊ 22° 45′, and the difference from the true opposition 3° 4′, to which, from the Moon's mean motion from the Sun, correspond 6^h 4^m. So the mean opposition preceded the true one, and it occurred at 10^h 34^m.

[Margin: Second eclipse.]

Next, in 1628, on January 20 in the New Style, but on day 10 in the Old, an eclipse of the Moon was observed, as I have it in the Letters of Gassendi and as Wendelen reports, at Aix [Aquis Sextijs] by Pierre Gassendi at 9^h $36½^m$ after noon, although Wendelen draws it to 9^h 26^m, because he thinks that Brussels and Aix are under the same meridian, while at Brussels he observed the end 10^m later than Gassendi. But by my reckoning, from my Geographical Book, Brussels is farther west than Aix by 4^m of time, and Aix farther west than Bologna by 29^m. Keeping therefore to the observation of Gassendi, whom I have found very accurate from other eclipses observed by him and by us, the middle of the eclipse at Bologna was at 10^h $5½^m$, but in equated time at 10^h $14½^m$. For the Sun was at the very beginning of ♒, at 36′ of it, and its anomaly 203° 30′. The Moon was in ♌ at minute 36′, and its equated anomaly was 231° 4′. The mean motion of the Sun was ♑ 29° 48′, and of the Moon ♋ 26° 52′. It therefore fell short of the place of opposition by 2° 56′, to which, from the Moon's mean elongation from the Sun, correspond 5^h 47^m. So the true opposition followed the mean one, and the mean one was at Bologna at 4^h $27½^m$ in equal time.

[Margin: The interval of time between these eclipses.]

Now, from the time of the first mean eclipse full Moon to the end of the year there are 8^d 13^h 26^m; from there to the beginning of the years of Christ there are 382 whole years; and from there to the time of the second, but mean, eclipse full Moon there are 1627 whole years 10^d 4^h $27½^m$. Added together, these make 2009 Julian years 18^d 17^h 53^m 30^s. Now 2009 multiplied by the 365 days of a common year makes 733285 days. Again, dividing 2009 by 4 gives the leap years in that number of years, and so 502 days. When these, along with 18^d 17^h $53½^m$, are added to the 733285 days, the whole interval of the eclipses comes to 733805^d 17^h 53^m 30^s. So, multiplying these, according to Hipparchus's rules,

of which see Precept 4, by 4267, and dividing the sum by 126007 days, we find 24849 mean lunations; and multiplying these by 269 and dividing the sum by 251, we find 26631 revolutions of anomaly, though these are to be brought back under the geometer's file below, in the next chapter.

[Margin: Finding the mean synodic month.]

Further, when 733805 days are divided by 24849 lunations, the result is 29^{d} 12^{h} 44^{m} 0^{s} $32'''$ $36''''$ $26'''''$. When the 17^{h} 53^{m} 30^{s} that remained are resolved into $3864600'''$ of time, and these are divided by 24849 lunations, the result is 2^{s} $36'''$ $21''''$ $43'''''$ $12''''''$. When all are added together, then, one mean lunation, or one synodic month, comes to 29^{d} 12^{h} 44^{m} 3^{s} $8'''$ $57''''$ $43'''''$ $12''''''$.

Likewise, when 733805 days and 17^{h} $53½^{m}$ are divided by 26631 anomalies, one revolution of simple anomaly comes to 27^{d} 13^{h} 18^{m} 34^{s} $25'''$ $21''''$ $43'''''$ $12''''''$. This comparison of eclipses is outstanding, because the Sun's anomaly was the same in both, the Moon's anomaly in both was very nearly in the same degree, and the interval is very large: conditions that I have not been able to find so exquisite in any other comparison of eclipses, as will be clear from the last table of the next chapter.

EXEMPLVM II.

Example 2.

[Margin: The first eclipse, Hipparchus's.]

VIII. In the year 548 of Nabonassar, as Ptolemy, Book 4, chapter 11, reports from Hipparchus, which was the year 200 before Christ, a total eclipse of the Moon was observed at Alexandria on day 9 of Mechir, that is, March 19, at 13^{h} 20^{m} p.m. At Bologna it was 11^{h} 37^{m}, but in equated time 11^{h} 38^{m}. For the Sun was in ♓ 25° 10′, its anomaly 289° 5′, and its mean place ♓ 23° 18′. The Moon's equated anomaly was 103° 42′, and its mean place ♎ 0° 31′. So the mean eclipse preceded the true one by 7° 13′, that is, by 14^{h} 14^{m}, and it occurred on day 18 at 21^{h} 24^{m}.

[Margin: The second eclipse, observed by us.]

In the year of Christ 1642, on April 14, but on the 4th in the Old Style, we, with many others at Bologna, observed a total eclipse of the Moon, from the altitudes of Spica and Aquila; the times of its duration were also counted by the oscillations of the pendulum, on which see Book 2, chapter 20; and the penumbra was separated, and the beginning of the spurious eclipse from the legitimate one, by means of a very clear telescope. The middle was exactly at 14^{h} 45^{m} p.m. There is no eclipse of which I have so many observations made in different places, for it was observed in 15 widely separated cities in Europe, and by distinguished men, for the most part very skilled in astronomy, as I shall relate in the History of Eclipses. The equated time was 14^{h} 38^{m}, for the Sun was in ♈ 25° 13′, its equated anomaly 288°, and its mean motion ♈ 23° 21′. The Moon's equated anomaly was 103° 47′, and its mean place ♏ 0° 4′.

So the mean opposition preceded the true one by 6° 43′, or 13^{h} 16^{m}; the mean full Moon therefore occurred at 1^{h} 22^{m}. And in both eclipses the anomaly of the Sun and that of the Moon were the same, so that this pairing too is very valuable.

The interval of time between the two mean oppositions was 1841 Julian years 16^{d} 3^{h} 58^{m}, or 672441^{d} 3^{h} 58^{m}, in which, by Precept 4, 22771 whole syzygies and 24404 anomalies were accomplished. When 672441^{d} 3^{h} 58^{m} are divided by 22771, then, the mean synodic month comes to 29^{d} 12^{h} 44^{m} 3^{s} 21‴ 23⁗ 30⁗′, and one anomaly to 27^{d} 13^{h} 18^{m} 32^{s} 35‴. So that you may see how much it matters that the Moon's anomaly should be the same and the interval of time as great as possible, do not be reluctant to bear with a third example.

EXEMPLVM III.

Example 3.

[Margin: The first and most ancient of all observations of an eclipse.]

IX. Ptolemy, Book 4, chapter 6, relates from Hipparchus that an eclipse of the Moon was observed by the Chaldeans at Babylon in the first year of Mardocempadus and the 27th of Nabonassar, which was 721 before Christ, on day 29 of the month of Thoth, that is, March 19, and that the Moon began to be eclipsed after its rising, a good hour having passed. From the duration he gathers that the middle of the eclipse was 2^{h} 30^{m} before midnight, but at Alexandria 3^{h} 20^{m}, that is, 8^{h} 40^{m} after noon; therefore at Bologna 6^{h} 57^{m}, but in equated time 7^{h}. For the true place of the Sun was ♓ 23° 30′, its mean place 21° 9′, and its anomaly 295°. The Moon's mean place was ♍ 27° 59′, and its equated anomaly 66°. So the mean opposition preceded the true one by 6° 20′, or 12^{h} 30^{m}, and it occurred on day 18 at 18^{h} 30^{m} p.m.

[Margin: The second eclipse, observed by Wendelen.]

In the year of Christ 1621, an eclipse of the Moon was observed by Govaert Wendelen at Bethasiis in Belgium on November 28 at 15^{h} p.m. So at Bologna it was 15^{h} 22^{m}, but in equated time 15^{h} 13^{m}; for the true place of the Sun was in ♐ 7° 9′, its mean place ♐ 8° 10′, and its anomaly 151° 10′. The Moon's mean place was ♊ 11° 51′, and its equated anomaly 67° 36′. So the mean opposition preceded the true one by 3° 41′, namely by 7^{h} 14^{m}, and it occurred at 8^{h} 8^{m} p.m.

The interval was 2341 Julian years 244^{d} 13^{h} 38^{m}, or 855294^{d} 13^{h} 38^{m}. By Precept 4, then, there are 28963 lunations and 31040 anomalies. When 855294^{d} 13^{h} 38^{m} are divided by 28963, one mean lunation comes to 29^{d} 12^{h} 44^{m} 3^{s} 25‴ 51⁗ 25⁗′ 18⁗′′, and one revolution of anomaly to 27^{d} 13^{h} 18^{m} 36^{s} 12‴.

CAPVT XXI.

Chapter 21.

De Tertio Artificio, quo Motus Lunæ in Longitudinem eiusque prima Inæqualitas demonstratur, eaque occasione Semidiameter Epicycli inueſtigatur.

On the third technique, by which the Moon's motion in longitude and its first inequality are demonstrated, and on that occasion the semidiameter of the epicycle is investigated.

I. THIS technique is presented by Ptolemy, Book 4, chapters 6 and 7; by Copernicus, Book 4, chapters 4, 5 and 6; and by Boulliau, Book 3 of his *Astronomy*, from chapter 3 to chapter 7. In it the tables of the Moon's mean motion are assumed to have been constructed first, from the synodic and anomalistic month already known beforehand, by the technique treated in chapter 20. Next, three ancient eclipses of the Moon are employed. These are arranged on a circle, and from the true and mean motions of the luminaries the eccentricity of the Moon, or the semidiameter of the epicycle, is investigated, and from that the anomaly, the equation, and the difference between the true and mean place of the Moon. The very same is done by means of another three, more recent, eclipses of the Moon. Finally, by comparing the ancient anomaly with the recent one, it is gathered whether the Moon's mean motion, as held in the tables, agrees with those equations, or instead falls short or exceeds; and by spreading the shortfall or excess over the time between the ancient and the recent eclipse, the tables of the motion of anomaly are corrected. In the same way, by comparing the true places of the Moon, the synodic month is corrected, and from it the mean motion of the Moon's elongation from the Sun and in the zodiac, if need be.

[Margin: Three earlier eclipses examined by Ptolemy.]

II. Now Ptolemy first takes three eclipses observed at Babylon by the Chaldeans. The *first* was in year 1 of Mardocempadus, with day 29 of Thoth completed, at $9^h\ 30^m$ p.m., but at Alexandria $8^h\ 40^m$, with the Sun in ♓ and the Moon in ♍ 24° 30′. The *second* was in year 2 of Mardocempadus, on day 18 of Thoth, at $11^h\ 10^m$ p.m. at Alexandria, with the Sun in ♓ and the Moon in ♍ 13° 45′. The *third* was in the same year 2 of Mardocempadus, on day 15 of Phamenoth, at $7^h\ 40^m$ p.m. at Alexandria, with the Sun in ♍ and the Moon in ♓ 3° 15′. With these laid down, he gathers from them that the semidiameter of the epicycle, or the eccentricity, is very nearly 5 13′ in parts of which the radius of the eccentric carrying the epicycle is 60; that in the second of these eclipses the Moon's mean place was at ♍ 14° 44′, and therefore the equation to be subtracted 59′, since the true place was 13° 45′; and that the anomaly, or distance from the apogee of the epicycle, was 12° 24′. The first of these eclipses was total, the second of 3 digits from the south, the third of more than 6 digits from the north.

[Margin: Three other eclipses examined by Ptolemy.]

III. Again, he selects three other eclipses, observed by himself at Alexandria with the greatest accuracy. The *first* was in year 17 of the Emperor Hadrian, with day 20 of Payni completed, at $11^h\ 15^m$ p.m., with the Sun in ♉ and the

Moon in ♏ 13° 15′; and it was eclipsed totally. The *second* was in year 19 of Hadrian, with day 2 of Choeac completed, at 11^{h} p.m., with the Sun in ♎ and the Moon in ♈ 25° 10′; and three-quarters of the lunar disc, or 9 digits, was eclipsed from the north. The *third* was in year 20 of Hadrian, with day 19 of Pharmuti completed, at 16^{h} p.m., with the Sun in ♓ and the Moon in ♍ 14° 12′; and half of the Moon was eclipsed from the north.

[Margin: How large the semidiameter of the Moon's epicycle is.]

From these he gathers that the eccentricity, or the semidiameter of the epicycle, is 5 14′ in parts of which the radius carrying the epicycle is 60, or 8722 parts of which that radius is 100000; that in the second of the recent eclipses the Moon's mean place was in ♈ 29° 30′, and so the equation to be subtracted 4° 20′, since the true place was 25° 10′, just as the Sun's true place at the middle of the second eclipse was ♎ 25° 10′; and that the anomaly was 64° 38′.

[Margin: Correction of Hipparchus's lunar motion, made by Ptolemy.]

IV. Having done this, Ptolemy, chapter 7, reasons as follows. At the moment of the second ancient eclipse full Moon, the Moon's mean place was ♍ 14° 44′ and its anomaly 12° 24′; at the moment of the second recent eclipse full Moon, its mean place was ♈ 29° 30′ and its anomaly 64° 38′. It is clear, then, that in the time between these two eclipses, whole circuits set aside, the Moon advanced by its mean motion in longitude 224° 46′, the distance from ♍ 14° 44′ to ♈ 29° 30′, but on the circle of anomaly 52° 14′, the distance from degree 12° 24′ of anomaly to degree 64° 38′. Now the time between the second of the ancient and the second of the recent eclipses, but equated and converted from apparent to equal, was 854 Egyptian years 73^{d} 23^{h} 20^{m}, or 311783^{d} 23^{h} 20^{m}. To this time, according to Hipparchus's tables compiled from the synodic month, by accumulating the daily motion, which in them is 13° 10′ 34″ 58‴ 53⁗ 30⁗′ 30⁗′′, there correspond 224° 46′, the whole zodiacs traversed by the Moon being set aside. He therefore concludes that the synodic month, and the Moon's mean motion in the zodiac and in elongation from the Sun, as found by Hipparchus and distributed by Ptolemy himself into tables, are correct. On the other hand, to the same time, according to Hipparchus's tables of the daily motion of the lunar anomaly, which was 13° 3′ 53″ 56‴ 29⁗ 38⁗′ 38⁗′′, there correspond, the whole circles of anomaly being discarded, 52° 31′; whereas, from what was demonstrated by the two trios of eclipses, only 52° 14′ should correspond. Hipparchus's anomalistic motion therefore exceeds by 17′ in 311783^{d} 23^{h} 20^{m}. In one day, then, it exceeds by 11⁗ 46⁗′ 39⁗′′. So the exact daily mean motion of anomaly is 13° 3′ 53″ 56‴ 17⁗ 51⁗′ 59⁗′′.

[Margin: Three other eclipses observed by Copernicus.]

V. Nicolaus Copernicus, for his part, Book 4, chapter 5, takes the three eclipses observed by Ptolemy that were discussed in number 3, and reduces their time to the meridian of Frombork and Kraków, which he judges to be one hour west of Alexandria. He then selects three other eclipses of the Moon observed by himself at Frombork. The *first* was in the year of Christ 1511,

with October 6 past, and its middle, or eclipse full Moon, was at $0^h\ 35^m$ after midnight, with the Sun in ♎ and the Moon in ♈ 22° 25′; and it was eclipsed totally. The *second* was in the year of Christ 1522, with 5 days of September elapsed, at $1^h\ 20^m$ after midnight, with the Sun in ♍ and the Moon in ♓ 22° 12′; and it was again eclipsed totally. The *third* was in the year 1523, with 25 days of August past, at $4^h\ 25^m$ after midnight, with the Sun in ♍ and the Moon in ♓ 11° 21′; and the Moon was eclipsed totally.

[Margin: How large the semidiameter of the Moon's epicycle is.]

From these, and from the mean motions of the luminaries, taken from tables made according to Ptolemy's motion of the Moon, he gathers that at the moment of the second of his eclipses the semidiameter of the epicycle was 8604 parts of which the semidiameter of the deferent carrying the epicycle is 100000; the Moon's mean place in ♓ 26° 50′; its subtractive equation 4° 38′, since the true place was in ♓ 22° 12′; its anomaly 74° 27′; and the Moon's mean elongation from the Sun 182° 51′. Copernicus's comparisons are, moreover, far better than Ptolemy's, because the Moon was in almost the same anomaly and the Sun in the same anomaly.

[Margin: Correction of Ptolemy's lunar motion, by Copernicus.]

VI. After this, Copernicus, chapter 6, continues as follows. In the second Ptolemaic eclipse, the mean distance of the Moon from the Sun was 182° 47′ and the anomaly 64° 38′; in the second of the recent eclipses, the Moon's mean elongation from the Sun was 182° 50′ and the anomaly 74° 27′. The time between these eclipses, reduced from apparent to equal, was 1388 Egyptian years $302^d\ 3^h\ 34^m$, or $506922^d\ 3^h\ 34^m$. To this time there correspond, according to Ptolemy's tables, beyond 17165 whole lunations, 358° 38′, and of anomaly, whole circles being discarded, 9° 11′. But in fact 17166 months and 0° 4′ were completed; and of anomaly, whole circles being discarded, 9° 49′ were completed. So Ptolemy's motion falls short on both counts in 506922 days: by 26′ as to the elongation from the Sun, and by 38′ as to the anomaly. Distributing these over $506922^d\ 3^h\ 34^m$, I find that to Ptolemy's daily motion of the Moon's mean elongation from the Sun, which is 12° 11′ 26″ 41‴ 20⁗ 17⁗′ 59⁗′′, there must be added 11⁗ 4⁗′ 43⁗′′, so that the daily elongation is 12° 11′ 26″ 41‴ 31⁗ 22⁗′ 42⁗′′; which, however, the Prutenic Tables put at 12° 11′ 26″ 41‴ 29⁗ 57⁗′ 50⁗′′. And to the daily mean motion of anomaly, which for Ptolemy is 13° 3′ 53″ 56‴ 17⁗ 51⁗′ 59⁗′′, there must be added 16⁗ 11⁗′ 30⁗′′, so that it is 13° 3′ 53″ 56‴ 34⁗ 3⁗′ 29⁗′′; which, however, the Prutenic Tables, by I know not what reckonings [Epilogiſmis], put at 13° 3′ 53″ 56‴ 23⁗ 57⁗′ 41⁗′′.

VII. It remains for us to give, by one example, the method by which Ptolemy investigated the semidiameter of the epicycle and the anomaly of the Moon by means of three lunar eclipses. For this we shall choose, from the 9 eclipses, the three in the middle, namely Ptolemy's own. In the first interval of these, as is clear from what was said in number 3, the Moon, having completed whole circles, traversed a further 161° 55′, the distance from ♏ 13° 15′ to ♈

25° 10′; in the second interval, after whole circles, it completed 139° 2′, the distance from ♈ 25° 10′ to ♍ 14° 12′. To the equated time of the former interval, which is $531^{d}\ 23^{h}\ 39^{m}$, there corresponds, from the earlier tables of Hipparchus and Ptolemy, after whole circles are discarded, a mean motion of the Moon in the zodiac of 169° 37′, and of anomaly 110° 21′. To the equated time of the latter interval, namely $502^{d}\ 5^{h}\ 30^{m}$, there corresponds a mean motion of the Moon in the zodiac of 137° 34′, and of anomaly 81° 36′, whole circles being discarded. Now compare the true places of the Moon, known from the true places of the Sun, with the mean ones, and you will see that to the anomaly of 110° 21′ there correspond 7° 42′, to be subtracted from the mean motion, but to the anomaly of 81° 36′ there correspond 1° 21′, to be added to the mean motion of the Moon in the zodiac. Keep these aside.

With these laid down, let ABC be the epicycle of the Moon, on which the first Ptolemaic eclipse is at point A, the second at B, the third at C, and let the Moon's passage in this order be understood as toward the preceding signs. Let arc AB be 110° 21′ and BC 81° 36′; for the complement to the circle, arc CEA, will be 168° 3′. To this is due an additive equation of 6° 21′, so that from this and the equation due to arc BC, which was 1° 21′, there comes a total additive equation of 7° 42′ due to arc BCA, as great as was the subtractive equation of arc AB in the former interval. Now since the apogee of the epicycle is not in BC or AEC, as these call for an additive prosthaphaeresis and are less than a semicircle, it must be in arc ALB (since in the lunar theory the body of the Moon is taken to move toward the preceding signs on the circumference of the epicycle, and so the equation of the first inequality is additive in the lower part of the epicycle but subtractive in the upper), and the perigee in arc AEB. So let D be the centre of the ecliptic, about which the centre K of the epicycle moves uniformly; from D let the straight lines DA, DB, DC be drawn to the three places of the eclipses, and let these be connected by the straight lines EB, EC and CB; and finally let EZ be drawn perpendicular to DB, EI perpendicular to DC, and CT perpendicular to EB.

For angle ADB, that is EDZ, will be 7° 42′, since it subtends the subtractive equation due to arc AB; and since the angle at Z is a right angle, the ratio of DE to EZ will be known in the right triangle EDZ.

Diagram. Geometric figure set into the left column, with the text running in a narrow measure beside it. A circle, the lunar epicycle, stands above a long narrow fan of straight lines that converge at the point D at the foot. One line rises from D through M and K to L at the top of the circle. Other lines rise from D to A (upper left on the circle), passing through E (lower left on the circle), and to B (upper right on the circle). A further line from D rises near C and I. Inside the circle, K is joined to A and to S (left on the circle) through N; E is joined to B through T and to C; T is joined to C; C is joined to B; a short line runs from E past I to Z, outside the circle at lower right. Labels read (13): L, A, B, S, N, K, T, E, M, C, I, Z, D. Labels not read: none. C is set small, above I.

- L (top of circle): apogee of the epicycle
- A (upper left on circle): place of the first eclipse
- B (upper right on circle): place of the second eclipse
- C (lower right on circle, small): place of the third eclipse
- E (lower left on circle): point where DA cuts the circle
- M (bottom of the circle, on DL): perigee of the epicycle
- K (centre of the circle): centre of the epicycle
- D (foot of the figure): centre of the ecliptic
- S (left on circle), N (on KS), T (on EB), I (on EZ), Z (outside the circle, lower right): construction points

So too in triangle BEZ, EBZ is known; for AEB, by proposition 20 of the third book of Euclid, is half the angle at the centre K subtending AB, of 110° 21′, and is therefore 55° 10½′; and AEB, by 32 of the first book, equals the two interior and opposite angles, namely angle EDB, which is 7° 42′; so EBD is 47° 28′ 30″. In triangle EZB, then, right-angled at Z, the ratio of BE to EZ will be known; but the ratio of DE to EZ was known, so the ratio of DE to EB will be known. Similarly, in triangle EDI, right-angled at I, because angle EDI is known, at 6° 21′, the ratio of DE to EI will be known. Now angle BEC is known, being, by 20 of the third book, half the angle at the centre K subtending arc CB, which was 81° 36′; so BEC is 40° 48′. Together with AEB this makes AEC 95° 58½′, to which, by 32 of the first book, EDC, of 6° 21′, and ECD are together equal; so ECD is 89° 37½′. In triangle CEI, therefore, right-angled at I, angle CEI is 6° 21′. So the ratio of EC to EI will become known. But the ratio of DE to EI was already known, so the ratio of DE to EC will be known. Again, in triangle ECT, right-angled at T, angle TEC is known, at 40° 48′, and so ECT is 49° 12′. So the ratio of ET and of TC to EC will be known, EC being already known in the parts in which DE was already known; and so the remaining TB, out of the whole EB now known, will become evident; and from TC and TB known, CB will be known. Now from arc CB, of 81° 36′, the chord CB is known in parts of which the radius of the epicycle is, for example, 100000; so in the same kind of parts the chord EC will be known. Hence arc EC will be known, and from this the whole arc ECB; and since ALB is known, the remaining arc AE will be known, which Ptolemy finds to be 95° 16′ 50″. From this it was clear that the centre K of the epicycle falls in the segment ABE; so, when the straight line DMKL is drawn, M comes out as the perigee and L as the apogee of the epicycle. Further, by means of the chord EC or BC, the ratio of DE to the chord EA will be known, and so the whole DEA in parts of the semidiameter of the epicycle, and DE in the same parts. But by Corollary 1 of 36 of the third book of Euclid, and 6 of the second, the rectangle formed from AD and DE, together with the square of the semidiameter of the epicycle, is equal to the square of KD; so the ratio of LK, the semidiameter of the epicycle, to KD, the semidiameter of the deferent carrying the epicycle, will be known. Ptolemy finds it to be 5 14′ in parts of which DK is 60.

VIII. As for the anomaly in the second eclipse, let KNS be drawn perpendicular to DEA, and the straight line AK. For since the ratio of DE to EA was known, and EA is bisected by KS, and so NE is half of AE, the ratio of ND to DK will be known; hence angle DKN will be known, and its arc MES, and so the whole of MSA, and therefore also AL, the remainder to the semicircle, which is the anomaly in the first eclipse. AB was already known, so arc LB will be known, namely the Moon's anomaly in the second eclipse, and LBC in the third. Ptolemy finds AL to be 45° 43′, LB 64° 38′ and LBC 146° 14′.

[Margin: Tycho's judgement on this technique of Ptolemy and Copernicus.]

IX. But Tycho, volume 1 of the *Progymnasmata*, page 114, affirms that eclipses derived from the Ptolemaic and Copernican motions sometimes depart from the truth by more than a whole hour, and that three eclipses are not enough to establish the Moon's motions; rather, more eclipses and many other phenomena of the Moon must be examined. Yet he brings out no examination of these. He only indicates the times of 21 eclipses of the Moon and 8 of the Sun observed by himself, and their magnitude; and then he adds the daily and annual motion of the Moon derived from them, keeping back the technique by which he investigated it. But that error of a whole hour can be attributed in part to the uncertain distance of the meridians and to the fallibility of observations; for before the use of the telescope, some wrongly took the penumbra and the spurious beginning of an eclipse for the shadow and the genuine beginning, and Tycho himself or the Tychonians erred in something similar, as Govaert Wendelen has shown in the eclipses listed below. In these, because of προσκοτίαν [Greek: proskotian, "adumbration"], or ἐπισκοτίαν [Greek: episkotian, "overshadowing"], that is, the sootiness and appendage of shade that usually hastens the beginning of lunar eclipses and delays their end, the Tychonians recorded the eclipse full Moons otherwise than a truer calculation requires.

Eclipsium Lunæ Tychonicarum Dissidium à Vendelini Calculo.

Disagreement of the Tychonic eclipses of the Moon with Wendelen's calculation.

Years of Christ	Month	Day	Apparent time recorded at Uraniborg by the Tychonians, hours p.m.	Time from Wendelen's calculation	Difference
1573	Dec.	8	$8^h\ 3^m$	$7^h\ 50^m$	13^m
1177	April	2	$8^h\ 50^m$	$8^h\ 25^m$	25^m
1577	Sept.	26	$13^h\ 3^m$	$13^h\ 17^m$	14^m
1580	Jan.	31	$10^h\ 10^m$	$10^h\ 30^m$	20^m
1581	Jan.	19	$9^h\ 57^m$	$10^h\ 6^m$	9^m
1581	July	15	$16^h\ 57^m$	$16^h\ 45^m$	12^m
1584	Nov.	17	$13^h\ 12^m$	$12^h\ 50^m$	22^m
1592	June	24	$10^h\ 16^m$	$10^h\ 31^m$	15^m
1592	Dec.	18	$7^h\ 41^m$	$7^h\ 21^m$	20^m
1595	April	23	$16^h\ 36^m$	$16^h\ 13^m$	23^m
1596	April	12	$9^h\ 29^m$	$8^h\ 46^m$	43^m

Moreover, the middle of the eclipse of the year 1581 July 15 Tycho puts in the *Epistles* at $13^h\ 6^m$, but in the Catalogue, volume 1 of the *Progymnasmata* at $13^h\ 12^m$.

[Margin: Tycho's sometimes doubtful reliability, and the error of the tables.]

And in the eclipse of the year 1596 April 12, Tycho, as Wendelen says, writes his own refutation. For he admits that the middle of the eclipse was not visible, and the middle seems to have been determined from the mere observed beginning and then from the Tychonic tables, rather than from observation. For that reason Pétau could find it from no tables in such a way as to come closer to the Tychonic determination. But Kepler too, in the *Ephemerides*, page 11, has this: *Simon Marius writes, in his Prognostication for the year 1617, that some notable defect remains in Tycho's lunar reckonings* [Lunaribus]*, not only in the time but also in the magnitude of eclipses. He proves it from the observation of the solar eclipse of 1614 October 3, which both occurred earlier and became larger. The same was observed by me at Linz, and the same at Venice and Munich.*

[Margin: Longomontanus's judgement on the technique of Ptolemy and Copernicus.]

X. Longomontanus, Book 1 of the *Theorica*, chapter 2, in the commentary on the Moon, and chapter 6, affirms that with Herculean labour he toiled alongside Tycho for a whole seven years on the theory of the ☾, and completed it in the year 1600, so that it holds good for all ages. He too, however, criticises Ptolemy and Copernicus, because in hunting down the eccentricity and the semidiameter of the epicycle, and from these the anomaly and the lunar motions, by means of trios of eclipses, they erred in connecting the motions of the Moon, the Sun and the fixed stars, and neglected the equant circle in the Moon. He brings forward three eclipses of the Assyrians, three of Hipparchus and three of Ptolemy, and then 23 eclipses of the Moon observed at Uraniborg or Copenhagen. But more than once he reports their observed time differently from Tycho, which leads Wendelen to be suspicious of his reliability. Computing their places from the mean equinox, using his own equations but omitting the equation of time that arises from the obliquity of the zodiac to the equator, he gathers the Moon's mean motions, but chiefly from Hipparchus's eclipse of the year 548 of Nabonassar. Finally, in chapter 6, he concludes from the examination of ancient and recent eclipses that the Prutenic Tables err by almost nothing sensible in the motion of longitude and of anomaly, and that the Prutenic Canon should therefore be used almost whole.

[Margin: Lansbergen's attempt.]

XI. Lansbergen, in the *Thesaurus observationum*, class 1 of the lunar observations, having examined 38 eclipses of the Moon, sees that their observations agree with his tables; and so he concludes that his tables hold good for all ages, and that the motions of the Moon derived from so many eclipses are correct. But in truth, in his eclipse 10, the middle of the eclipse at Alexandria, recorded by Ptolemy as $8^h\ 24^m$, comes out from Lansbergen's tables as $8^h\ 51^m$. But he thinks that Ptolemy's text is corrupt. And in eclipse 7 he relates from Ptolemy,

Book 4, chapter 9, that the middle of the eclipse observed at Babylon was one hour before midnight,

[Margin: The doubtful reliability of the same man.]

whereas Ptolemy says twice that it was observed at Babylon half an hour before midnight, and at Alexandria one hour and a third of an hour. And in eclipse 16 he puts the hour of the observation at $11^h\ 6^m$, whereas Regiomontanus puts it at $11^h\ 14^m$. Justly, then, Johannes Phocylides [Holwarda], in his πανσελήνω [Greek: panselēnō, "full Moon"], convicts him of doubtful reliability, because of another unreliable account similar to this one; on it see Boulliau, Book 3, chapter 7.

[Margin: Lansbergen's deceitful technique.]

But recognise the man's plainly artless technique, ἄτεχνον [Greek: atechnon, "without art"], and a cunning rather detected by us. Lansbergen saw that the observed times of seven eclipses disagreed with his tables; these are eclipses 18, 23, 25, 27, 35, 36 and 37 in his own order. So that this disagreement should not rebound into the fallibility either of the observations or of his tables, he devises a certain second equation in lunar eclipses, which rests on no theory at all and has no consistency. Not content with this, in the precepts, Precept 8, he makes this equation universal and decrees that it be applied to the mean time whenever eclipses have occurred in the same parts of the zodiac, as if that position by itself produced this variation. Here these words must be noted: *But the cause of the discrepancy is not any error in the equation of days, but comes from the Moon, and is still hidden. Until, therefore, it is brought to light, a second equation of time must be established from observations of eclipses. We have observed, moreover, that when either luminary is eclipsed at the beginning of Aries,* 30^m *must be added to the mean time*, etc. But if there were no deception in the observations or the tables, this equation could have been gathered from the agreement of other observations with Lansbergen's tables; so it should first have been demonstrated that there is no deception underlying either. Then why did he not use a similar equation in eclipses 7, 10 and 16, discussed above, but instead showed us either a corrupt text or his own good faith corrupted in reporting the time?

[Margin: Boulliau's attempt on this matter.]

XII. Ismaël Boulliau, Book 3 of the *Astronomia Philolaica*, from chapter 3 to chapter 7, investigates the synodic and the anomalistic month, partly by the method given in chapter 20 and partly by means of several eclipses arranged on a circle. He does not use the technique of Ptolemy or Copernicus described from number 1 to number 8, but a method of Viète's very like it, discussed under the eccentricity and apogee of the Sun, Book 3, chapter 24. He employs now 3, now 4 eclipses, and intervals of years now small, now large, but chiefly of 1788 Egyptian years $65^d\ 3^h\ 51^m$, between two eclipses recorded on the one side by Hipparchus and on the other by Tycho. Not resting on these, he adduces 19 ancient eclipses and 34 recent ones and, attending to the difference between their observed place and the place computed from tables, he uses a double supposition: one that assumes the motions of the Moon already investigated by

him in chapter 6, the other that subtracts 5′ from the Moon's longitude and 30′ from its anomaly. Yet he does not dare to attribute so much to his tables as to say that they hold good for all ages. He does suspect, however, that Ptolemy may have altered the times of the eclipses and drawn them to fit his hypotheses, or that the ancients sometimes recorded their times with too little accuracy.

[Margin: What Wendelen did on this matter!]

This perhaps was the reason why Wendelen used only recent eclipses in the *Idea of the Atlantic Tables*, since these were usually observed more accurately, at least after the use of the telescope; unless perhaps in the *Apotelesmata* of eclipses that he promises there he has also used ancient eclipses.

XIII. For my part, after a long suspension of judgement, arising from the suspicion of deception in observations of eclipses before the use of the telescope, and from the diversity of opinions on the difference of meridians, on the places of the fixed stars, and on the calculations by which the times of eclipses are derived, I have decided to bring all eclipses back to calculation according to the hypotheses of all the tables. This will be done, God willing, in volume 3 of the *Almagest*, so that from the comparison of these and of other phases of the Moon it may appear which are the best of all, and what more probable correction can be applied. Meanwhile, from the 86 eclipses that I shall list shortly, I have selected 40, that is, 20 pairs, which I have weighed by the method and technique given in chapter 21, and some also by the Ptolemaic and Copernican method. In these I applied the usual equation of time and the difference of meridians established in my Geographical Book, which I have judged should be set before the eclipses to be listed, assuming from the same book that the meridian of Bologna and of Uraniborg is the same, with no evidently sensible difference.

Differentia Temporis, qua loca infraſcripta ſunt Vraniburgo, & Bononia OR, vel OC. ideſt Orientaliora, vel Occidentaliora

Difference of time by which the places written below are OR or OC from Uraniborg and Bologna, that is, more eastern or more western.

31

Among the eclipses already mentioned, the pairs [bigæ] set out below seemed to us the best and the principal ones for investigating the motion of longitude and of anomaly, because of their outstanding distance apart and the nearer equality of the Moon's anomaly and, for the most part, of the Sun's. God willing, we shall give an examination of these and of the rest according to the tables of all the astronomers in the third volume of the *Almagestum Novum*,

[31] observers and places stand as printed; the identifications that follow are editorial and not on the page. *Griembergerus* is Christoph Grienberger; *Vendelinus* Govaert Wendelen; *Gaſſendus* Pierre Gassendi; *Galterius* Joseph Gaultier de la Valette; *Hortenſius* Martinus Hortensius; *Michaël Flor. Langren.* and *Langrenus* Michael Florent van Langren; *Bullialdus* Ismaël Boulliau; *Mydorgius*, *P. Auxon* and *P. Andreas Arzet* are not identified here. *PP. Soc. although we have already weighed very many of them in this way, so that the Moon's motions are almost established for us.

Further, from all of these, but chiefly from the first, I set the mean synodic month at $29^{d}\ 12^{h}\ 44^{m}\ 3^{s}\ 10'''$. This is almost midway between Tycho's on the one hand and Lansbergen's and Wendelen's on the other, and comes very close to the Prutenic and the Rudolphine.

[Margin: Mean synodic month.]

The anomalistic month, on the other hand, I set at $27^{d}\ 13^{h}\ 18^{m}\ 34^{s}\ 30'''$. For, having chiefly consulted three eclipses observed by us in the years 1642 and 1643, I found that at the equated time of the eclipse of 1643 September 27, which at Bologna was $7^{h}\ 29^{m}\ 25^{s}$ after noon, the Moon's anomaly was not 194° 51′, as I had gathered from the tables I had adopted, but 195° 10′. For this reason I judged that the motions of anomaly should be corrected from here.

[Margin: Mean anomalistic month.]

CAPVT XXII.

De Inueſtigando Motu Latitudinis Lunæ ac Nodorum.

Chapter 22. On investigating the motion of the Moon's latitude and of the nodes.

[Margin: Hipparchus's opinion on the restitution of the Moon's latitude.]

I. Hipparchus judged that the restitution [apocataſtaſis] of the Moon's latitude is completed only in 5458 synodic months, or 441 Egyptian years $213^{d}\ 23^{h}\ 23^{m}$, and that 5923 draconic orbits [orbes Dracontici] are then completed. Therefore, if any other number of lunations is multiplied by 5923 and the sum divided by 5458, one will have the number of whole draconic orbits, or revolutions of latitude, though not of the remainder of the motion of latitude accomplished beyond them. But Govaert Wendelen, in the *Idea of the Atlantic Tables*, affirms that 7477 draconic orbits are completed in 6890 synodic months. In this he follows Hipparchus's ratio as regards whole circuits: for as 5458 is to 5923, so is 6890 to 7477. But since Hipparchus relied on proportions that were not very exact, as Ptolemy teaches in Book 4, at the end of chapter 2 and the beginning of chapter 9, let us rather listen to Ptolemy.

[Margin: Ptolemy's method for the Moon's latitude, and his opinion.]

II. Accordingly Ptolemy, in Book 4, chapter 2, lays down that two lunar eclipses are to be chosen in each of which the Moon had either no latitude, while nonetheless standing at the same node, or an equal latitude of the same kind, that is, towards the same quarter of the world; that, if possible, she was ascending in both or descending in both, and at the same degree of anomaly, or at least with the luminaries at the same distance from the Earth; and that the size of the eclipsed part lay towards the same quarter. Accordingly, in chapter 9, he chose two eclipses. The first was observed at Babylon in the 31st year of Darius I, the 3rd day of Tybi having elapsed, half an hour before midnight, but at Alexandria at hour 1⅓, when 2 digits were eclipsed from the south: namely in the year 491 before Christ, April 25, the Sun's anomaly being 237° and the Moon's 102° or 100⅓°. The second was observed by Ptolemy himself

at Alexandria in the 9th year of Hadrian, the 17th day of Pachon having passed, $3^h\ 36^m$ before midnight at Alexandria, and again 2 digits were eclipsed from the south: namely in the year of Christ 125, April 5, when the Sun's anomaly was 306° but the Moon's 252°. So the Moon stood 102° from apogee in the first and 108° in the second, and thus at very nearly equal distance from the Earth and near the same node, although Ptolemy puts the distance in the first at 100° 19′. Therefore, according to the anomaly of the earlier eclipse, the Moon's true motion was less than its mean motion by 5°; according to the anomaly of the second, the true motion was greater than the mean by 4° 53′. Accordingly, in the elapsed time, which was 615 Egyptian years $133^d\ 21^h\ 50^m$, the Moon's true motion in latitude completed whole circles, but the mean motion fell short of completing the last revolution by 9° 53′. According to Hipparchus's mean motion of anomaly, however, it would fall short by 10° 2′, that is, with an excess of 9′. So, dividing 9′ by the elapsed days, which were 224609, gives 8‴ 39⁗ 18⁗⁗. Added to Hipparchus's mean daily motion of latitude, which was 13° 13′ 45″ 39‴ 40‴ 17⁗ 19⁗⁗, these make the exact motion 13° 13′ 45″ 39‴ 48‴ 56⁗ 37⁗⁗.

[Margin: Copernicus's method and opinion.]

III. Copernicus, in Book 4, chapter 13, having said that several circumstances are required for defining the motion of the Moon's latitude, namely two lunar eclipses alike and equal in every respect, and that it is therefore harder to find, and that two eclipses agreeing in these conditions are rarely found, adds: *To us, certainly, they have not occurred at present.* He is therefore forced to use another method, namely two eclipses that took place around opposite nodes but were alike as regards the other conditions. The first, as it stands in Claudius Ptolemy, Book 6, chapter 5, was in the 7th year of Ptolemy Philometor, which was year 150 of Alexander the Great, the 27th day of Phamenoth having passed: namely in the year 174 before Christ, April 30, at $14^h\ 20^m$ after noon at Alexandria, but at Kraków, as Copernicus judges, at $13^h\ 20^m$. At that time at most 7 digits were eclipsed from the north, around the descending node. The second was observed by Copernicus himself under the meridian of Kraków in the year of Christ 1509, June 2, at $11^h\ 36^m$ after noon, and very nearly 8 digits were eclipsed from the south, around the ascending node. Using equated time, Copernicus computes the Moon's mean anomaly in the first eclipse as 163° 33′ and the equation as 1° 23′, by which the Moon's true place was less than its mean place; in the second eclipse, the mean anomaly as 159° 55′ and the equation as 1° 44′, *by which the equal motion was less than the apparent*. Those are Copernicus's words, but the good old man certainly erred: for if the anomaly was 159° 55′, the equation is to be subtracted from the mean motion, and the mean is greater than the true. The Sun, moreover, stood 29° from apogee in the first and 13° in the second. And since the second eclipse was greater by one digit, that is by 2′ 30″, he concludes that the Moon in the second [secunda; recte: prima?] eclipse was farther from the north node by about 30′ than she was from the

south node in the second eclipse, and so that the true motion of latitude, after the completed revolutions, was 179° 30′. The difference of the equations was 21′, so the mean motion of latitude after whole orbits was 179° 51′. The time between the eclipses already mentioned was 1683 years 88^{d} 22^{h} 35^{m}, in which, after 2577 completed revolutions of latitude, 179° 51′ remain. This agrees with the numbers Copernicus set down towards the end of chapter 4, where he had said that the mean motion of latitude according to Hipparchus is, annually, after 13 whole revolutions, 148° 42′ 46″ 20‴ 3⁗, and daily 13° 13′ 45″ 39‴ 40⁗; but that the annual exceeds by 1″ 2‴ 42⁗, and so is 148° 42′ 45″ 17‴ 21⁗, although the Prutenic Tables have it somewhat differently.

[Margin: Longomontanus's opinion.]

IV. By what reasoning the Tychonians emended the Prutenic Tables at this point, however, is not yet clear. For Longomontanus, in Book 1 of the *Theorica*, chapter 6, speaks very obscurely on this matter, in these words: *We use the Prutenic Canon in full for the Moon's longitude and anomaly. As regards the argument, or motion, of latitude, I indeed see, from the comparison of the second of the three most ancient eclipses, which occurred at Babylon in the year 720 before Christ, as also from other particular ancient ones, that something must here be taken away from the Prutenic Tables, about 7′, so that that most ancient eclipse which I have just named may agree closely in magnitude with the one of Lord Tycho made in the year 1578 after Christ, on 15 September, provided that the size of the Earth's shadow and of the Moon in the following ones is duly proportioned. But in Tycho's earlier restitution, which was carried out at Prague, I remember that 12′ were added to the Prutenic motion of latitude. Nor can anyone doubt that everything concerning the Moon's latitude was then in sufficiently good order, since we very frequently tested it with new observations even outside eclipses: both for the variation of latitude found around the quadratures, and in investigating parallax from the Moon's meridian altitude in each Tropic, and finally in the sextile and trine aspect with the Sun, where the variation of the motion of the nodes is found greatest on either side. For this reason, if from the year before Christ, as I said, 720, up to the completed year 1584 after the birth of Christ, to which the earlier particular restitution of the Moon refers, I distribute the said combined emendation of the mean motion of latitude, that is 19′, over the 2305 equal years between, then 29‴ 39⁗ fall to each common year in correcting the Prutenic Tables.* I, however, doubt how 7′ to be taken away from the Prutenic motion of latitude and 12′ to be added can make a combined emendation of 19′. Nor does the comparison of those eclipses seem well suited to establishing the motion of latitude: for in the earlier, of the year 720 before Christ, March 8, the Sun's anomaly was 162°, the Moon's 12°, and 3 digits were eclipsed from the south; whereas in the later, of 1578 September 15, the Sun's anomaly was 61°, the Moon's 317°, and the digits 2½.

[Margin: What Tycho and Kepler hold on the motion of the nodes and of latitude.]

V. But not even Tycho himself, in volume 1 of the *Progymnasmata*, page 127, makes clear how he found the mean motion of latitude and of the nodes to vary

insensibly in the syzygies [Copulis] and quadratures [Quadris], yet to grow to as much as 1° 45′ in the intermediate places. He must be believed until his observations are published and we weigh our own, set up for this purpose, in volume 3 of the *Almagest*. Meanwhile Kepler, in the *Ephemerides*, pages 7 and 8, admits that he has kept the retrograde motion of the nodes uniform, with the ancients, lest with this new little observation he should fix a new cross for the astrologers, who hold that great power resides in these nodes. Thanks must nevertheless be given to Origanus, because in his *Ephemerides* this Tychonic libration of the nodes, by which their mean mo- tion is made anomalous, he has put to use. But neither of them has disclosed to us the foundations on which he defined the motion of latitude in his Tables, just as the Alphonsines did not in former times, nor Wendelen later.

[Margin: Boulliau's method and opinion.]

VI. Boulliau, for his part, in his *Astronomia Philolaica*, Book 3, having noted in chapter 2, from Ptolemy, that the revolutions of latitude do not return with the months unless there comes about an [Greek: ἀνταπόδοσις (antapodosis, "correspondence", "return in kind")] of eclipses — that is, unless a likeness of eclipses occurs from the first interval to the later one, or unless the eclipses are equal in quantity of obscuration and in duration, and have the same latitude, and of the same kind — later, in chapter 8, first uses two eclipses. One is of 1462 June 11, observed by Regiomontanus at Viterbo, of 7 digits, near the south node, with lunar anomaly 273°. The other was observed by Tycho in 1592 June 24, of 8 digits, near the south node, with lunar anomaly 35°. From these he gathers 7 revolutions of the nodes, lacking 4° 57′ 11″, in an interval of 130 Egyptian years $35^{d}\ 19^{h}\ 36^{m}$. Next he chooses two others with a greater interval. The *first* is the very one Longomontanus used, namely the second of the Babylonian eclipses in Ptolemy, Book 4, chapter 6. It was in 720 before Christ March 8, at 12^{h} p.m. at Babylon, or as Ptolemy has it [Greek: κατ' ἀυτὸ τὸ μεσονύκτιον (kat' auto to mesonyktion, "at midnight itself")], but at Uraniborg $9^{h}\ 58^{m}$, as Boulliau has it; of 3 digits from the south, when the Sun's anomaly was 219°, the Moon's 13°, and the distance from the north node 9° 30′ 34″. The *second* was in 1634 March 14, at $9^{h}\ 20^{m}$ at Uraniborg, of 11 digits from the south, when the Sun's anomaly was 257°, the Moon's 38°, and the distance from the north node 5° 30′ 48″. Gassendi, however, who observed this eclipse at Digne, puts it at 10¼ digits. Having related these things, Boulliau divides the 2354 Egyptian years $218^{d}\ 23^{h}\ 22^{m}$ of the interval between these eclipses by the interval of the two preceding ones, namely by 130 years $35^{d}\ 19^{h}\ 36^{m}$. From this he gathers 18 periods consisting of seven revolutions of the nodes each, that is 126 revolutions, less some degrees, and in addition 12 years 23 days $2^{h}\ 16^{m}\ 30^{s}$. And he at once concludes thus: *There are therefore 126 zodiacs 151° 36′ 31″, or 12 second sexagesimals and 38 first sexagesimals of degrees, together with 31° 36′ 31″. But of days there are 3 third sexagesimals, 58 second and 43 first, together with 48^{d} 58′ 25″. Therefore, dividing the sexagesimals of degrees by the sexagesimals of days, we*

shall gather the daily motion of the nodes toward the preceding signs as 0° 3′ 10″ 38‴ 25⁗ 3⁗′ 12⁗′′ 7⁗′′′ 26⁗′′′′ 35⁗′′′′′. And adding the Moon's daily motion from the equinox, we shall have the Moon's daily motion from the node as 13° 13′ 45″ 39‴ 38⁗ 5⁗′ 39⁗′′ 35⁗′′′ 17⁗′′′′ 3⁗′′′′′, and the year as 4ˢ 28° 42′ 46″ 6‴ 44⁗ 25⁗′ 49⁗′′ 38⁗′′′ 45⁗′′′′ 15⁗′′′′′. But neither was the comparison of these eclipses suitable enough, because of the inequality of the anomalies and of the digits. Granted that from this he has fished out rather the motion of the nodes, and from that the motion of latitude, and that his effort deserves praise. And from this one may recognise that 7 revolutions of the nodes toward the preceding signs are completed in about 47486 days, but in 859429 days, 126 revolutions and about 152° besides.

[Margin: Our method and opinion.]

VII. We, however, by the singular favour of God, Best and Greatest, have observed one eclipse entirely similar to a very ancient eclipse, and one to be preferred, for establishing the motion of latitude, to all those observed up to now, at least those that survive. The *first* of the ancient eclipses, then, in Ptolemy, Book 4, chapter 6, is the third observed at Babylon by the Chaldaeans in year 2 of Mardocempadus and 28 of Nabonassar, when day 15 of Phamenoth had been completed, or in the year 720 before Christ, when September 1 had been completed. The Moon began to be eclipsed after its rising, and half of the lunar disc was eclipsed from the north. So Ptolemy gathers from the duration of the eclipse that the middle of the eclipse was at Alexandria at $7^h\ 40^m$ after noon, granted that Longomontanus computes $7^h\ 50^m$ from the Prutenic Tables. It was therefore, according to what is said in my *Geographical Book*, at $5^h\ 57^m$ at Bologna, but in equated time $6^h\ 5^m$. For the Sun's true place was ♍ 0° 26′ and its mean place ♍ 2° 24′, because its anomaly was 93° 10′; the Moon's mean place was ♓ 2° 7′ and its simple anomaly 158° 20′. So the mean full Moon followed the true one by 34^m of time, and was at Bologna at $6^h\ 39^m$.

The *second* eclipse, observed by us and by many others, was at Bologna in the year of Christ 1643, September 27, but 17 in the old style, at $7^h\ 30^m\ 52^s$ at the height of the eclipse, which was likewise of 6 digits to the north; but the equated time was $7^h\ 29^m\ 25^s$. For the Sun's anomaly was 89° 5′ 40″, its true place in ♎ 4° 29′ 34″, and its mean place 6° 27′ 52″. The Moon's simple anomaly was 195° 10′ and its mean place ♈ 3° 9′ 4″. Therefore the mean full Moon followed the true one by $6^h\ 2^m\ 6^s$, and was at Bologna at $13^h\ 31^m\ 31^s$.

[Margin: Observers of this eclipse.]

This same eclipse of 6 digits was also observed by Wendelen at Antwerp, by Boulliau at Paris, by Gassendi at Succij [?], by Hevelius at Danzig, by the most illustrious D. Giulio Giustiniani at Venice, by D. Vicenç Mut in Majorca, and by Father Io. Bapt. Zuppo [Giovanni Battista Zupi] at Naples, as I shall relate in the History of Eclipses. In both eclipses, then, half of the lunar disc was eclipsed to the north near the south node; the estimate of 6 digits is by far the most certain of all partial eclipses, as Kepler too notes in the *Optics*; the

Sun was at the same degree of anomaly; and the interval is the greatest. This comparison therefore surpasses all others. And although in the second eclipse the Moon was a very little higher, and therefore a little nearer the south node, than in the earlier eclipse, it was nevertheless at very nearly the same distance from the Earth, since it was 160° from the apogee in the first and 165° in the second.

The interval of time between the mean full Moons was 2362 Julian years 16^{d} 6^{h} 42^{m} 31^{s}, or 862736^{d} 6^{h} 42^{m} 31^{s}. In this time, by Precept 5 of chapter 21, there came about 29215 equal lunations or syzygies. Therefore, according to the same precept, when 29215 is multiplied by 5923 and the product divided by 5458, there result 31704 whole draconic circuits [Orbes Dracontici], or revolutions of latitude. Dividing the interval between the eclipses, or 862736^{d} 6^{h} 42^{m} 31^{s}, by these, I find that one mean month of latitude comes to 27^{d} 5^{h} 5^{m} 36^{s} $0'''$ $55''''$. Nor is any other elaborate labour [periergia] needed, since we have obtained two such eclipses, alike in every respect, of the kind astronomers once wished for in vain, God reserving them for us, or us for them.

CAPVT XXIII.

De modo colligendi reliquos Lunæ Motus, ex Menſtruis ipſius reuolutionibus: cum Synopſi Opinionum de Lunæ Motibus.

Chapter 23. On the way of deriving the Moon's remaining motions from its monthly revolutions; with a synopsis of opinions on the Moon's motions.

[Margin: The lunar year and the epact.]

I. The common and mean lunar year is easily obtained from the mean synodic month multiplied by 12. If you add one month more to it, the result will be the embolismic lunar year [Annus lunaris Emboliſmicus], that is, one of 13 months. The remainder, however, by which the common lunar year falls short of completing the civil solar year of 365 days will give the epact of one common year. And in this way the epacts of several years are accumulated, taking account of leap years, yet so that the synodic month is cast out of the accumulated sum as often as it is contained in it, and the remainder is kept as the epact.

[Margin: The periodic month.]

II. You will derive the periodic month from the synodic month as follows. To the Sun's mean motion corresponding to the synodic month add the zodiac, or 360°; for this is the space that the Moon, having traversed the zodiac, runs through in a synodic month. Then divide by this sum the amount produced by multiplying the synodic month by the zodiac, that is by 360°, and you will have the time corresponding to the periodic month. But it is better first to resolve all these amounts into the smallest fractions of one kind, for example into thirds. The anomalistic and draconic months, however, have already been derived from what was said in chapters 21 and 22.

EXEMPLVM.

Example.

For me the synodic month is $29^d\ 12^h\ 44^m\ 3^s\ 10'''$; or, resolved into thirds of time, it is 153086590‴. In that time, by my mean motion of the Sun, on which see Book 3, chapter 17, the Sun's motion is 29° 6′ 24″ 17‴. To this I add 360°; the sum is 389° 6′ 24″ 17‴, which resolved into thirds is 84047057‴. And the zodiac, 360°, resolved into thirds is 77760000‴. When 153086590‴ is multiplied by these, the amount is 1190 401323840000‴. When this is divided by 84047057‴, the periodic month results as 141635098‴ 836/840, that is, $27^d\ 7^h\ 43^m\ 4^s\ 58'''\ 59''''\ 45'''''$.

[Margin: The Moon's daily motion in the zodiac.]

III. You will find the Moon's daily mean, or equal, motion in the zodiac as follows. To the Sun's mean motion corresponding to the synodic month add 360°. Multiply this sum, resolved into fractions, say thirds, by the fractions of time of one day resolved, say thirds; and divide the product by the fractions of the synodic month, likewise thirds. There will result the fractions that the Moon completes in the zodiac in one natural day by its mean motion, and these you will reduce to degrees by dividing by sexagesimals.

EXEMPLVM.

Example.

The sum of 360° and the motion the Sun makes in one synodic month, resolved into thirds, is, by what was said in precept 2, 84047057‴. And 1 day, resolved into thirds, is 5184000‴. When these numbers are multiplied together, the amount is 435699943488000‴. When these are divided by the thirds of one synodic month resolved, 153086590‴, the Moon's mean daily motion in the zodiac results as 2846101‴ 466/1531. When these are divided and subdivided by 60, the same motion comes out as 13° 10′ 35″ 1‴ 18'''' 16'''''.

[Margin: The Moon's daily motion from the Sun.]

IV. You will have the daily elongation, or distance, of the Moon from the Sun according to the mean motions of both bodies if you subtract the Sun's daily mean motion from the Moon's daily mean motion in the zodiac.

EXEMPLVM.

Example.

For me the Sun's daily mean motion is 59′ 8″ 19‴ 51'''' 46''''' 20'''''', and the Moon's daily motion in the zodiac, from what was just said, is 13° 10′ 35″ 1‴ 18'''' 16'''''. When the former is subtracted from the latter, there remains the Moon's daily mean motion from the Sun, 12° 11′ 26″ 41‴ 26'''' 29''''' 40''''''.*

[Margin: Daily motion of the anomaly.]

V. You will have the daily motion of the simple anomaly if you multiply the circle of 360°, first resolved into fractions, by the fractions of time of one day,

and divide the product by the anomalistic month, first resolved into fractions of the same kind as those of the day and of the resolved circle.

EXEMPLVM.

Example.

360° resolved into thirds are 77760000‴, and one day resolved into thirds of time is 5184000‴. When these are multiplied together, the amount is 403108440000000‴. And the anomalistic month for me, from what was said at the end of chapter 21, is 27^{d} 13^{h} 18^{m} 34^{s} 30‴, that is, 142842870‴. Dividing the above-mentioned amount by these, there results the daily mean motion of the anomaly, 13° 3′ 53″ 56‴ 30⁗.

[Margin: Daily motion of latitude.]

VI. You will get the daily mean motion of latitude if you divide the amount produced by multiplying the circle of 360° by the fractions of the day resolved, by the draconic month, first resolving all of these into fractions of the same kind.

EXEMPLVM.

Example.

The amount from multiplying the thirds of one day by the thirds of one circle, from what was just said, is 403108440000000‴. And the month of latitude, or draconic month, for me, from what was said in chapter 22, section 7, is 27^{d} 5^{h} 5^{m} 36^{s} 0‴ 55⁗, that is, 14068161‴ [recte: 14106816‴?]. Dividing the above-mentioned amount by these, there remains the Moon's daily mean motion in latitude, 13° 13′ 45″ 29‴ 28⁗.

[Margin: Daily motion of the node ☊.]

VII. You will get the daily motion of the lunar nodes toward the preceding signs if you subtract the Moon's daily mean motion in the zodiac from its mean motion in latitude.

EXEMPLVM.

Example.

From my daily motion of latitude, 13° 13′ 45″ 29‴ 28⁗, take away my daily motion of the Moon in the zodiac, 13° 10′ 35″ 1‴ 18⁗ 16⁗⁗, there remains the daily motion of the node ☊, as also of ♈, toward the preceding signs, 3′ 10″ 38‴ 9⁗ 44⁗⁗.

[Margin: Daily motion of the mean apogee.]

VIII. You will get the daily mean motion of the mean apogee from the line of the Sun's mean place, that is, toward the preceding signs — which is the same as the motion of the centre of the eccentric toward the preceding signs according to Ptolemy and his followers — by subtracting the Sun's daily mean motion from the daily mean elongation from the Sun; granted that Boulliau thinks it is obtained by subtracting the daily motion of latitude from the doubled motion of the Moon from the Sun.

EXEMPLVM.

Example.

From my daily lunar elongation from the Sun, which is 12° 11′ 22″ [recte: 26″?] 41‴ 26⁗ 35⁗′ 40⁗′′, subtract my daily motion of the Sun, 59′ 8″ 19‴ 51⁗ 46⁗′ 20⁗′′, and there remains the daily motion of the mean apogee, 11° 12′ 18″ 21‴ 34⁗ 49⁗′ 20⁗′′.

[Margin: Daily motion of the apogee under the zodiac.]

IX. You will have the daily motion of the apogee in the zodiac by subtracting the daily motion of the simple anomaly from the Moon's daily motion in the zodiac.

EXEMPLVM.

Example.

I take my daily motion of the anomaly, 13° 3′ 53″ 56‴ 30⁗, away from my daily motion of the Moon in the zodiac, which is 13° 10′ 35″ 1‴ 18⁗ 16⁗′, and there remains the daily motion of the apogee in the zodiac, 6′ 41″ 4‴ 48⁗ 16⁗′.

[Margin: Hourly and minute motion.]

X. You will have any hourly motion by dividing the daily motion by 24, and the motion of one minute by subdividing the hourly motion by 60, and so on. Yet you will have the hourly motion more easily if you add together double the daily motion and half the daily motion, but change the titles of degrees into minutes and of minutes into seconds. You will note this device in the Alphonsine and Prutenic Tables, in Arabic form.

EXEMPLVM.

Example.

For me the Moon's daily motion in the zodiac is 13° 10′ 35″ 1‴ 18⁗ 16⁗′. Its double is 26° 21′ 10″ 2‴ 36⁗ 32⁗′, and its half 6° 35′ 17″ 30‴ 39⁗ 8⁗′. The sum of the double and the half is 32° 56′ 27″ 33‴ 15⁗ 40⁗′. Therefore the Moon's hourly motion in the zodiac is 32′ 56″ 27‴ 33⁗ 15⁗′ 40⁗′.

[Margin: Investigation of the lunar months from the daily motion.]

XI. Finally, since in the tables of many astronomers the daily motion is given but the month is lacking, you will derive the synodic, or periodic, or anomalistic, or draconic month from it by dividing the circle of 360° by the daily motion; but to derive the synodic month you must first increase the circle by the Sun's daily motion. Remember, however, that the annual motion is not exactly contained in the hourly motion given in the tables written below, because of some further fractions omitted or reduced to the preceding ones; so an error not to be despised could be committed in the sum of many years. It is better, therefore, to multiply the daily motion by 365 days so as to have the annual motion. The lunar year can also be derived from the more accurate

epacts of certain authors, by subtracting them from 365 days; and when the lunar year is divided by 12, the synodic month can be derived.

XII. It remains for us to bring into tables the opinions of the more distinguished astronomers on the lunar motions. The foundation of these tables is either the synodic, periodic, anomalistic and draconic month in the authors treated from chapter 19 to chapter 21 inclusive, to whom, for the synodic month, add the Prutenic Tables, page 84½; Clavius, chapters 8 and 28 of the *Calendar*; Kepler in the Rudolphine Tables, page 99; Lansbergen in his Tables, page 36; Mulerius in the *Tabulae Frisicae*, page 344; Magini in the *Theoricae Planetarum*, Book 1, and in the *Canon of the Second Mobile*. Or their foundation is the lunar year, which is derived from the epact of one year subtracted from 365 days; these epacts, as far as fourths, are shown by Clavius, chapter 28 of the *Calendar*, and by Kepler in the Rudolphine Tables, page 99. Or finally the foundation is the Moon's daily motion, which is given by Ptolemy, Book 4 of the *Almagest*, chapter 3; the Alphonsine Tables, pages 60, 65, 92 and 100; Reinhold in the Prutenic Tables, the tables from page 45 to page 48; Tycho, *Progymnasmata*, volume 1, page 113; Longomontanus, *Theorica*, Book 1, chapters 2 and 6; Kepler in the Rudolphine Tables, pages 47, 88 and 94; Lansbergen in the *Treasury of Observations*, page 95, and in his tables from page 23 to page 25; Wendelen in the *Idea of the Atlantic Tables*, page 29; Boulliau, *Astronomia Philolaica*, Book 3, chapters 6 and 7; Vincenzo Renieri in the lunar *Tabulae Mediceae*; and Antonín Maria Šírek, or de Rheita, in his *Radius Sidereomysticus*, Book 3. From these let there be

CAPVT XXIV.

De Conſtituendis Epochis Lunarium Motuum.

Chapter 24. On establishing the epochs of the lunar motions.

[32] In the rows for Alfonso, Tycho and We, for the present, the page sets no 48 after the 8 hours, so that each row's figures stand one place to the left of their neighbours and the last places are filled with 0. Twelve times the month of the same row in Table 3 runs 8 hours, 48, then the figures printed here. The figures are given as printed.

[Margin: Authors who treat this subject.]

I. We must recall here what we said about the epochs and roots [Radicibus] of the celestial motions in general, on the occasion of the solar roots, in Book 3, chapter 33. Keeping to that, we shall set the lunar epochs for the meridian of Bologna, beginning the year from noon of the last day of December, and in these matters we shall use the device that Ptolemy teaches in Book 4, chapters 8 and 9, Copernicus in Book 4, chapters 7 and 14, and Boulliau in Book 3, chapter 9.

[Margin: Root of the Moon's longitude from Aries.]

II. *First*, we shall establish the root of the Moon's longitude from the equinox as follows. In chapter 22, section 7, we had the eclipse full Moon at Bologna in 1643, on September 17 Old Style but September 27 in the Gregorian style, at equal time $7^{h}\ 29^{m}\ 25^{s}$ p.m.; and at that moment the Moon's place, as regards mean motion in the zodiac, ♈ 2° 50′, and the mean motion of the anomaly 195° 10′, as we said there and also at the end of chapter 22. Therefore, according to the mean motion we established in chapter 23, at noon of the last day of December, on which the year 1643 was completed, the Moon's mean motion was $5^{s}\ 20°\ 28′\ 23″\ 53‴$. For from the equated time of the full Moon to the end of the year 1643 there were $94^{d}\ 16^{h}\ 30^{m}\ 35^{s}$. To these corresponds a mean motion of $5^{s}\ 17°\ 38′\ 23″\ 53‴$, whole circles being cast out; and this, added to the mean motion the Moon then had, namely 2° 50′, makes a motion of $5^{s}\ 20°\ 28′\ 23″\ 53‴$.

[Margin: Root of the Moon's anomaly.]

III. *Second*, by our tables a motion of the anomaly of $5^{s}\ 7°\ 5′\ 26″\ 18‴$ belongs to the already mentioned interval of $94^{d}\ 16^{h}\ 30^{m}\ 35^{s}$. If this motion is added to the motion the Moon had at the equal time of the full Moon, namely, as we said, 195° 10′, there results at the end of the year 1643 a motion of the anomaly of $11^{s}\ 22°\ 15′\ 26″\ 18‴$.

[Margin: Root of the motion of the node.]

VI. [recte: IV.] Finally, at the same equal time of the eclipse full Moon of 1643 September 27, the Sun's anomaly was 89° 5′ 40″, and the Moon's 195° 10′ but, equated, 196° 30′ 3″. The apparent semidiameter of the Earth's shadow was exactly 48′, according to the distances of the luminaries we have now established. And since the eclipse was of exactly 6 digits, the Moon's true latitude was therefore as great as the semidiameter of the Earth's shadow at mid-eclipse. The angle opposite this at the south node, that is, the Moon's greatest latitude, is 5°, according to what was said in chapter 12. Therefore the distance of the true centre of the shadow from the more westerly south node was, by the rules of trigonometry, 9° 13′ 6″, and accordingly the distance of the Sun's true place from the north node was as great. But the Sun's place, according to the true place, was ♎ 4° 29′ 34″; therefore the place of the north node ☊ was in ♍ 25° 16′ 28″. From then to the end of the year 1643 there are, as I said, $94^{d}\ 16^{h}\ 30^{m}\ 35^{s}$, to which, of the mean motion of the north node ☊ toward the preceding signs, 5° 0′ 50″ correspond. Therefore, when these are

subtracted from the place of the node, the root of the node ☊ at the end of the year 1643 was 5ˢ 20° 15′ 38″. Going back from here, then, to the beginning of the first year of the Christian era, and to other years backward and forward, we have put the roots of the lunar motions into the tables.

CAPVT XXV.

De Secunda Lunæ Inæqualitate, & de Hypothesi, qua Ptolemæus hanc & primam Inæqualitatem explicauit.

Chapter 25. On the Moon's second inequality, and on the hypothesis by which Ptolemy explained this and the first inequality.

[Margin: Ptolemy's progress in each inequality.]

I. In Book 4 of the *Almagest* Ptolemy had set out the Moon's first inequality, had noticed it alone at new and full Moons, and had found that a single equation was therefore then needed to convert the Moon's mean motion into the true, or the true into the mean. In chapter 10 he accordingly fixed the greatest epicyclic equation at 5° 1′, subtractive at 96° of anomaly and additive at 264°, using here, that is, a semidiameter of the epicycle of 5° 14′ of which the radius of the Moon's eccentric orb is 49° 41′, as he had gathered from sets of three eclipses in chapter 6.

[Margin: Hipparchus's errors in this matter.]

Next, in chapter 11, he relates that Hipparchus, using the epicycle hypothesis on sets of three eclipses, found the semidiameter of the epicycle to the semidiameter of the deferent of the epicycle to be as 4° 46′ to 60°, or as 247½ to 3122, with a greatest equation of 4° 34′; but that, using the eccentric hypothesis, he found the eccentricity to be 6° 15′ of which the radius of the eccentric is 60°, or 327⅚ parts of which the same radius is 3144, with a greatest equation of 5° 49′, although equal results ought to have been gathered from either hypothesis. But Ptolemy shows that Hipparchus went somewhat astray in computing and equating the interval of time between the eclipses, and that the discrepancy arose from this, not from any fallacy of the hypotheses.

[Margin: The way in which the Moon's second inequality was detected.]

II. With this done he passes to Book 5, and in chapter 1 describes the astrolabe made of armillary rings, which we too shall describe in volume 2, in the *Liber Organicus*. In chapters 2 and 3 he draws on the observations of Hipparchus and on his own, in which he observed with the armillary rings the distances of the Moon from the Sun, especially when the Moon stood at the nonagesimal degree of the ecliptic and so lacked all parallax of longitude. He relates that from the Sun's known place he often observed the Moon's true place in this way, both at the quadratures and outside them. And in gathering from the tables already constructed the Moon's true motion, equated, for the moment of the observation, he found that at the syzygies ☌ and ☍ the simple equation spoken of above was indeed enough to obtain a true place agreeing with the observed one; but that outside the syzygies another equation was needed besides this

one, and that this one was greatest at the quadratures, when the equation of the first inequality was greatest in them, and that it reached 7° 40′. So the second inequality grows from new Moon to the first quadrature, then shrinks as far as full Moon; and from full Moon it grows again as far as the second quadrature, then shrinks as far as the next new Moon. From this he concludes that the period of the second inequality is completed twice in each month.

To explain both inequalities, then, he assigned the first to the epicycle, on whose circumference the Moon is carried in its upper part toward the preceding signs and in its lower part toward the following signs; and the second to the eccentric that carries the epicycle, so that after the syzygies the centre of the epicycle approaches the centre of the world more and more, according to the proportions he determines in chapter 4.

[Margin: Authors following or expounding Ptolemy's hypothesis.]

A great many embraced this hypothesis, down to Copernicus. It must therefore be made clear with an accompanying figure, not least so that it may smooth our way to understanding the hypotheses of others. Those who treat of it are: Ptolemy in Book 5, from chapter 2 to 10; Proclus in the *Hypotyposes*; al-Battānī in chapter 30; Jābir ibn Aflaḥ in Book 4 of the *Astronomy*; Regiomontanus in the *Epitome of the Almagest*, Book 5, from proposition 4 to 13; Georg Peuerbach in the *Theorica Lunae*, and on it Giovanni Battista Capuano, Campanus of Novara, Erasmus Oswald Schreckenfuchs, Pedro Nunes, Erasmus Reinhold and Christian Wurstisen. Likewise Jean Fernel in Book 1 of the *Cosmotheoria*, chapter 4; Francesco Maurolico in Dialogue 3 of the *Cosmographia*, from page 79; Alessandro Piccolomini in the *Theoricae Planetarum*, Book 1, from chapter 11; Clavius at the end of the *Sphere*; Francesco Barozzi in Book 4 of the *Cosmographia*, from page 250; Biancani in Book 9 of the *Sphere*, chapter 2; Joseph Lange in the *Elementa Astron.*, part 2, chapter 10; Pierre Hérigone in volume 5 of the *Cursus Mathematicus*, from page 514; Andrea Argoli in the *Pandosion*, chapter 40, and in the *Ephemerides*, Book 1, chapter 9; Pierre Gassendi in Book 2 of the *Institutio Astronomica*, chapter 2; and Boulliau in Book 3 of his *Astronomia*, chapter 6. All of these, like the Alphonsines, follow the Ptolemaic hypothesis with a very few figures corrected, except Biancani, Lange, Hérigone, Gassendi and Boulliau, who merely explain it so as to lead beginners by the hand into astronomy. Let there be, then,

Ptolemaicæ Hypotheſis Schema cum Proportionibus Orbium.

The scheme of the Ptolemaic hypothesis, with the proportions of the orbs.

III. In chapter 14, section 2, we obtained the Moon's distances in terrestrial semidiameters. We shall now reduce them to parts of which the semidiameter, or radius, of the eccentric is 100000, and in this kind of parts we shall have the proportion of the Moon's orbs; for otherwise you will find them badly corrupted

in other authors, through a fault either of calculation or of the printing. Here they are, then, in a small table.

PTOLEMAICAE HYPOTHESIS SYNOPSIS

Synopsis of the Ptolemaic hypothesis.

Intervals	Lines	To a radius of the orb of 100000	Semidiameters of the Earth
Semidiameter of the eccentric	I D	100000	48 51′
Semidiameter of the epicycle	B D	10576	5 10′
Semidiameter of the small circle, and eccentricity	A I	20766	10 92′
Distance in ☌ ☍, greatest	A B	131352	64 10′
Distance in ☌ ☍, mean	A D	120766	59 0′
Distance in ☌ ☍, least	A F	110190	5[?] 50′
Distance in □, greatest	A p	89814	[?]3 53′
Distance in □, mean	A b	79234	38 43′
Distance in □, least	A K	68662	33 33′
Greatest equation in ☌ ☍	G A D	5° 1′	
Greatest equation in □	m A Z	7° 40′	

33

With these things assumed, let A be the centre of the Earth, from which the Moon's ecliptic ♈ ♋ ♎ ♑ is to be described, which, carrying the other, lower orbs with it, moves the nodes of the Moon's path toward the preceding signs. Let BAC be the line of the mean syzygies, that is, of the mean new Moon and full Moon, and ♎ ♈ the line of the mean quadratures. This is set down by way of example, granted that the latter do not always occur under ♎ or ♈, nor the former under ♋ or ♑. Beneath the ecliptic let there be understood the orb that carries the aux [Augem] of the eccentric, in whose plane lie the planes of all the remaining orbs, these being inclined to the ecliptic at 5°; and let its semidiameter be AB. Next, from A, the centre of the world, let the small circle IXβY be described, carrying the centre of the eccentric toward the preceding signs, and let its semidiameter AI be the Moon's eccentricity.

First, then, with the centre taken on the line of the syzygies and on the circumference of the already mentioned small circle, that is, at the point I, and with the interval of the semidiameter ID, which is to be 48 56′ semidiameters of the Earth, let the eccentric D p f b D be described, with f as its perigee and D as its apogee. From D as a centre let the epicycle BGFH be described, with DB as its semidiameter. And from the centre of the world let two straight lines Aθ and Ax be drawn as far as the ecliptic, touching the epicycle at G and H.

Second, let the centre of the eccentric, I, be moved toward the preceding signs through a half-quadrant as far as M. With the centre made at M, and with

[33] The figure 92 in the row of the small circle stands as printed, although it cannot be a number of minutes.

the interval ML, equal to the semidiameter ID, let there be described another, not so much eccentric as position of the eccentric, namely L ε *e* N H L, with L as its apogee. From L let a straight line be drawn through M to O, the point opposite the centre M itself. Meanwhile the centre of the epicycle will have advanced toward the east, that is, toward the following signs, by as much as the centre of the eccentric, M, and the apogee, L, have receded toward the preceding signs from the line of the mean syzygies, so that the centre of the epicycle is at N. From N let the epicycle PR be described, equal to the first. Through its centre N let the line ONQ be drawn from the point O, for it will be the line of the mean apogee of the epicycle, namely of the point Q; and from A, the centre of the world, the line AP, the line of the true apogee of the epicycle, which, produced as far as the ecliptic, is the line of the Moon's mean place. And if the Moon is at R, having meanwhile completed about a half-quadrant of the epicycle, PR, let the straight line ARS be drawn through the centre of the Moon's body, for it will be the line of the Moon's true place.

Third, let the centre of the eccentric have reached X, the quadrant IX being completed; and from the centre X, with the interval as above, let the third position of the eccentric be described, namely a γ E V F a. Let the aux of the eccentric be at a, and the point opposite the aux at V; and to this V let the centre of the epicycle have meanwhile come, having completed about a quadrant of elongation from the line of the mean syzygies. And from the centre V let an epicycle be described equal to the earlier ones.

Fourth, let the centre of the eccentric have reached β, the semicircle I X β being completed, and let its apogee be at Φ and its perigee at u. From β let an eccentric be described equal to the earlier ones, namely Φ δ p u b γ Φ; and from the centre Φ let an epicycle be described equal to the earlier ones, for the centre of the epicycle will have come to Φ, having completed a semicircle of elongation from the line of the syzygies.

Fifth and last, let the centre of the eccentric have come from β to Y, and the apogee of the eccentric to π. From Y let an eccentric be described equal to the earlier ones, namely π P R m n ε δ π; and let its perigee be Z, to which the centre of the epicycle, Z, will have come. From Z let the epicycle λ m b n be described, whose tangents drawn from the centre of the world to the ecliptic are to be A m μ and A n ξ. These could indeed have been drawn also to the points of contact e h of the epicycle, as could several other positions of the eccentric; but to avoid a tangle of lines let us be content with those already mentioned.

Diagram. Ptolemaic scheme of the Moon's orbs, set in the left column. An outer circle, the Moon's ecliptic, is marked at its four quarters with ♋ at the top, ♈ at the right, ♎ at the bottom and ♎ at the left, this last set sideways. A vertical and a horizontal diameter cross at the centre A, around which is a small circle. Solid and dotted circles, the successive positions of the eccentric, surround the centre, and five small epicycles stand on them: at the top, at the

upper left, at the left, at the right and at the bottom. Straight lines run from the centre to the outer circle. Labels read:

- θ, x (top, on the outer circle, either side of ♋): ends of the tangents from A
- ♋ (top), ♈ (right), ♑ (bottom), ♎ (left, sideways): the signs at the quarters
- B, D, F (top epicycle, on the vertical line): its top, centre and foot
- G, H (either side of the top epicycle): points of tangency
- T, S (upper left, on the outer circle): ends of the lines AP and ARS produced
- P, R, Q, N (upper-left epicycle): true apogee, Moon, mean apogee, centre
- u (on the vertical line below the top epicycle)
- I (on the vertical line above A, on the small circle)
- L (upper right): apogee of the second position of the eccentric
- μ (right, on the outer circle): end of the tangent A m μ
- m, n (top and foot of the right epicycle)
- λ, Z (inside the right epicycle; the Z is a Z with a stroke)
- b (right side of the right epicycle)
- a (right, within the outer circle)
- M, X (right of the centre, on the small circle)
- Y, A (at the centre; Y left of A)
- o (small, lower left of the centre)
- β (below the centre, on the small circle's foot)
- f (on the vertical line below β)
- ξ (lower right, on the outer circle, sideways): end of the tangent A n ξ
- ε, γ (lower right, on the eccentrics)
- E (on the vertical line above the bottom epicycle)
- Φ, C (inside the bottom epicycle)
- h, V, K (left epicycle: above it, inside it and at its right side)
- π, p (left, on the dotted circle and the next circle)
- [?] (a sort like a 5 beneath p)
- e (below the left epicycle)
- δ (lower left, on a dotted circle, sideways)

De Quatuor Lunæ Orbibus, & totidem præcipuis Motibus per eos factis.

On the Moon's four orbs, and the same number of principal motions produced by them.

IV. There are, then, four orbs of the Moon's heaven according to Ptolemy, Alfonso, Peuerbach and the others mentioned in section 2: namely the ecliptic, the deferent or deferents of the aux of the eccentric, the eccentric, and the epicycle; and the same number of principal motions are produced by them.

[Margin: 1. The Moon's orb and the motion in it.]

The *first* orb is the Moon's ecliptic, which moves toward the preceding signs and carries westward the nodes of the Moon's path, that is, of the plane in which the remaining lower orbs lie. For Ptolemy it completes 3′ 10″ 41‴ 15⁗ 26⁗′ 7⁗′′ daily and 19° 20′ 0″ 58‴ 53⁗ 48⁗′ 35⁗′′ yearly, so that it finishes its whole period beneath the ecliptic of the highest heaven in about 18 Julian years 7 months 12 days, or $6798^{d}\ 3^{h}\ 49^{m}\ 40^{s}\ 16'''$. There are those who call this orb the Moon's equant.

[Margin: 2. The orb and motion of the apogee of the eccentric.]

The *second* orb is the deferent of the apogee of the eccentric. In place of it, it is enough to attend to the motion of the centre of the eccentric about the centre A, made on the circumference of the small circle Iβ, since that centre moves with the same kind and quantity of motion as the apogee of the eccentric, namely toward the preceding signs from I toward M. This motion is regular about the centre of the world. Its recession from the line of the syzygies BC, or from the line of the Sun's mean motion, toward the preceding signs is as great as the mean elongation of the centre of the epicycle from the same line toward the following signs. For that reason most authors gather the motion of the aux of the eccentric from the motion of the Moon from the Sun, by subtracting the Sun's mean motion from it: thus Wurstisen, Clavius, Barozzi and Gassendi, who accordingly put its daily motion at 11° 12′ and say that its period is completed in $32^{d}\ 3^{h}\ 5^{m}$. Lange, however, puts it at 11° 12′ 18″ 21‴ 52⁗ and the period at $32^{d}\ 3^{h}\ 4^{m}\ 38^{s}\ 51'''$. But subtracting the Sun's daily motion from the Moon's daily elongation from the Sun, there remains, according to Ptolemy, a daily mean motion of this apogee of 11° 12′ 18″ 24‴ 7⁗ 5⁗′ 28⁗′′. Boulliau, however, thinks it is gathered by subtracting the mean motion of latitude from the doubled motion of the Moon from the Sun, by which reckoning the daily motion of this apogee would be, for Ptolemy, 11° 9′ 7″ 42‴ 51⁗ 39⁗′ 21⁗′′.

[Margin: Motion of the mean apogee of the epicycle.]

Moreover, by force of this motion there is a shift in the point on the small circle Iβ opposite the centre of the eccentric, from which point a line drawn through the centre of the epicycle to the circumference of the epicycle determines the point of the mean apogee of the epicycle itself. Therefore this apogee also shifts: toward the preceding signs as long as the centre of the epicycle is in the first and fourth quadrants of the eccentric, and toward the following signs as long as it is in the 2nd and 3rd quadrants. Reinhold on page 73 and Wurstisen on page 97 make this clear with accompanying diagrams, which are by no means necessary here.

[Margin: 3. The orb and motion of the eccentric.]

The *third* orb is the eccentric, which carries the centre of the epicycle toward the following signs, receding from the line of the mean syzygies, or from the line of the Sun's mean motion, by as much as the apogee and centre of the eccentric recede from the same line toward the preceding signs. This motion is irregular over the centre of the eccentric, but its mean daily amount is 13° 3′ 52″, and it completes its course in $27^{d}\ 13^{h}\ 13^{m}$. Over the centre of the world, or

of the zodiac, A, however, it is regular, and its mean daily amount is 13° 10′ 34″ 58‴ 35⁗ 30′′′′′ 30′′′′′′, and it completes the periodic month in about 27^{d} 7^{h} 43^{m} 7^{s}. If you take the Sun's daily motion from this, there remains the elongation of the Moon, or rather of the centre of the epicycle, from the Sun, daily and mean, of 12° 11′ 26″ 41‴ 20⁗ 17′′′′′ 59′′′′′′, and it completes the synodic month in about 29^{d} 12^{h} 44^{m} 3^{s}. But if to the daily motion of the centre of the epicycle in the zodiac you add the daily motion of the node ☊ toward the preceding signs, the motion of this centre becomes the motion of latitude. Its daily amount is 13° 13′ 45″ 39‴ 48⁗ 56′′′′′ 37′′′′′′, and it completes its period, or draconic circuit [orbem Draconticum], in 27^{d} 5^{h} 5^{m} 36^{s}, according to the Ptolemaic figures. The nearer the centre of the epicycle is to the aux of the eccentric, the faster it moves; and the farther from it, the slower.

[Margin: 4. The orb and motion of the Moon on the epicycle.]

The *fourth* orb is the epicycle, whose centre is on the circumference of the eccentric and whose plane is in the plane of the eccentric. On the circumference of the epicycle is the centre of the Moon's body, which, by the motion of the epicycle, moves in the lower part, as HFG, toward the following signs, from H to F, and so on. The Moon therefore moves faster at that time, because this motion is joined to the motion of the centre of the epicycle going toward the east. But in the upper part of the epicycle, as GBH, it moves against the succession of the signs, and so the Moon's motion is then slower. This motion is counted from the mean apogee: for example, at the mean syzygies from B toward H. With respect to the true apogee and the centre of the epicycle it is irregular, but with respect to the mean apogee it is regular, and it is called the motion of the argument, or of the anomaly. Its daily amount is 13° 3′ 53″ 56‴ 17⁗ 51′′′′′ 59′′′′′′, and it completes its course in 27^{d} 13^{h} 18^{m} 34^{s}. Since, then, the Moon's motion is very swift, the Moon cannot be called stationary; and since the Moon's motion on the epicycle is less than the motion of the centre of the epicycle in the zodiac, it cannot be called retrograde, but always direct.

[Margin: Motion of the true apogee.]

Moreover, since the motion of the eccentric is swifter than the motion of the epicycle, the true apogee of the epicycle advances toward the following signs and completes its course in 8½ years. For its daily motion is 6′ 41″, and it is obtained by subtracting the motion of the anomaly, or of the epicycle, from the motion of the Moon in the zodiac.

COROLLARIA.

Corollaries.

Ex Lunæ Motibus prædictis & Orbium descriptione.

From the already mentioned motions of the Moon and the description of the orbs.

[Margin: 1st Corollary.]

V. From what was said in numbers 3 and 4 it follows, *first*, that twice in every month the centre of the epicycle is at the apogee of the eccentric, namely at every mean ☌ new Moon and ☍ full Moon: for example, once at D and again at Φ; and twice at the perigee of the eccentric, as about the first quadrature at V and about the second □ at Z. Indeed, it is from these distances that the motion of the apogee of the eccentric has been detected.

[Margin: 2nd Corollary.]

Second, at every mean ☌ and ☍ the line of the mean motion and that of the motion of the apogee of the eccentric coincide, and the same line is the line of the mean conjunction or opposition, namely BAC.

[Margin: 3rd Corollary.]

Third, at every mean ☌ and ☍, and also at every mean □ quadrature, the line of the apogees of the eccentric, or of the epicycle, both true and mean, is one and the same.

[Margin: 4th Corollary.]

Fourth, at mean new Moons and full Moons, no equation is needed if the Moon is at the apogee of the epicycle, as at B or at C, that is, if its mean argument or anomaly is nil, or if it is at the perigee of the epicycle, as at F or at E, that is, if its anomaly is exactly 6^{s} or 180°; instead, the mean motion and place coincide with the true. But if it is at the points of contact, as at H, that is, if it has an anomaly of 96° according to *Ptolemy*, the maximum equation of the first inequality is needed, to be subtracted from the mean motion; for *Ptolemy* this is 5° 1′. At the point G, however, that is, at an anomaly of 264°, it is to be added to the mean motion, so that the true motion may be had. Elsewhere this equation is smaller, but in the first semicircle of the anomaly, as in BHF, it is to be subtracted, and in the second, FGB, to be added to the mean motion, so that the true or apparent motion may be had.

[Margin: 5th Corollary, and the way of deriving the maximum equation and its place.]

Fifth, the maximum equation of the simple inequality, that is, the epicyclic equation, is derived in triangle AGD, right-angled at the contact G, with the following given or already found: the semidiameter of the epicycle GD, the semidiameter of the eccentric DI, and its eccentricity IA, and hence the whole of AD as base. For from these, by the rules of trigonometry, one derives the angle of the maximum equation, GAD, whose complement to a right angle is angle ADG, equal to angle ADH. This angle, then, subtracted from the 180° of the semicircle BHF, gives the place of the anomaly H, where the maximum subtractive equation occurs; added to the same semicircle, it gives the point G, of the maximum additive equation.

[Margin: 6th Corollary.]

Sixth, outside the mean syzygies a double equation is often needed, one of the epicycle and the other of the eccentric. Thus if the Moon is at R, the anomaly QR must be equated by adding the arc PQ, so that the true anomaly

may be had, that is, the anomaly computed from the true apogee P; therefore the angle PNQ will be needed.

[Margin: Maximum equation about the quadratures.]

In the quadratures, however, if the Moon were at the apogee or perigee of the epicycle, no equation would be needed, as if it were at ρ, b, K, λ. But if it is at the contacts of the tangents to the epicycle, as at *m* or at *n*, the equation is at its maximum, 7° 40′ for *Ptolemy*.

[Margin: 7th Corollary.]

Seventh, if a new Moon occurs at the apogee of the epicycle, as at B, the first quadrature will occur about the end of the first quadrant, as at *h*; the full Moon about the perigee of the epicycle, as at E; and the second quadrature about the end of the third quadrant of the epicycle, as at *m*. But if the new Moon occurs at the perigee of the epicycle, as at F, the first quadrature will occur at the end of the third quadrant, as at *e*; the full Moon at the apogee of the epicycle, as at C; and the other quadrature at the end of the first quadrant, as at *n*. Now if the new Moon occurs at the end of quadrant 1, at H, or of quadrant 3, at G, the first quadrature will occur in the one case at the perigee K, in the other at the apogee ρ; the full Moon in the one case at the end of quadrant 3, in the other at the end of quadrant 1; and the second quadrature in the one case at the apogee *b*, in the other at the perigee λ. From these it is easy to understand the positions of the other syzygies and quadratures on the circumference of the epicycle.

[Margin: 8th Corollary.]

Eighth, throughout the month both the centre of the epicycle and the Moon describe by their motion not a circle but a certain egg-shaped and almost elliptical line, as can be seen in the following figure, in which the line PCHDP represents the line described by the centre of the epicycle. Its greater semidiameter PT consists of the semidiameter of the eccentric and the eccentricity; its lesser, TC, of the remainder of the semidiameter of the eccentric after the eccentricity has first been taken from it. The former is therefore 59 0′ semidiameters of the Earth, the latter 38 43′ semidiameters of the Earth. Similar to this is the line described by the centre of the Moon's body, but now wider, now narrower, according as it is nearer to or farther from the apogee of the epicycle at the syzygies and quadratures. Reinhold set out this egg-shaped figure at the end of Peuerbach's *Theoricae*.

Diagram. At the head of the right column, standing inside the sentence above: a large outer circle (the eccentric's path) with a vertical diameter from A at the top to S at the bottom and a horizontal diameter from Z at the left to V at the right, their intersection near T. Four small epicycles stand on an inner egg-shaped line taller than it is wide: one at the top with centre P, one at the bottom with centre H, one at the left with centre C, one at the right with centre D. A straight line runs up from the area of T to M at the upper rim, passing near B.

- A (top, outside the circle)
- M (top, to the right of A, at the end of the slanted line)

- P (in the upper epicycle, right of the vertical)
- B (in the upper epicycle, at its right edge)
- ☍ (in the upper epicycle, to the left of P)
- L (left of the vertical, below the upper epicycle)
- □ (in the left epicycle, above the horizontal)

Summa Definitionum ac Regularum ad Lunæ Theoricam Ptolemaicam, & præcipuè ad Prosthaphæreses spectantium.

Summary of the definitions and rules pertaining to the Ptolemaic theory of the Moon, and especially to the prosthaphaereses.

[Margin: True place.]

[Margin: Line of the true place.]

VI. The Moon's *true place* [Locus Verus] in the zodiac is the point of the zodiac on which falls a straight line drawn from the centre of the zodiac, that is, of the Earth, through the centre of the Moon's body: as, in the earlier figure, the point S, on which ARS falls if the Moon is at R. And this line is called the line of the true, or apparent, place.

[Margin: Mean place.]

The Moon's *mean place* [Locus Medius] is the point of the zodiac on which falls a straight line drawn from the centre of the Earth through the centre of the epicycle: as the point T, on which A N T falls if the centre of the epicycle is at N. And that line is called the *line of the mean place or motion.*

[Margin: Mean longitude.]

Mean longitude [Longitudo Media] is sometimes taken for the mean or middling distance of the Moon from the Earth, and sometimes for the point of the epicycle or eccentric at which it stands a quadrant away from the apogee of the epicycle or eccentric, that is, half of the greatest and semicircular distance: as are 90° and 270° of anomaly.

[Margin: True apogee of the epicycle.]

The *true apogee of the epicycle* is the point on the circumference of the epicycle most distant from the centre of the Earth, as B or C. But by an extended use of the name, any point of the epicycle on which falls a straight line drawn from the centre of the Earth through the centre of the epicycle is also called a true apogee: as the point P, on which ANP falls; that line is accordingly called the *line of the true apogee*.

[Margin: Mean apogee of the epicycle.]

The *mean apogee of the epicycle* is the point on the circumference of the epicycle on which falls a straight line drawn through the centre of the epicycle from the point opposite the centre of the eccentric and as far from the centre of the Earth as the centre of the eccentric is from the same centre of the Earth: as is the point Q, on which the straight line ONQ falls, with the centre of the epicycle placed at N and that of the eccentric at M. And this is called the *line of the mean apogee*.

[Margin: True apogee of the eccentric.]

The *true apogee of the eccentric* is the point on the circumference of the eccentric on which falls the straight line drawn through the centre of the eccentric from the centre of the world.

[Margin: True anomaly.]

The Moon's *true argument* or *anomaly* is the Moon's distance from the true apogee, computed on the circumference of the epicycle to the right, that is, westward: thus if the Moon is at R, its true anomaly will be the arc PR.

[Margin: Mean anomaly.]

The *mean argument*, or *mean anomaly of the orb*, is the Moon's distance from the mean apogee of the epicycle, computed on the circumference of the epicycle westward: as is the arc QR.

[Margin: Centre of the Moon.]

The *centre of the Moon*, or *anomaly of the eccentric*, or, as Peuerbach puts it, *double longitude*, is the arc of the zodiac intercepted between the line of the apogee of the eccentric and the line of the mean place or of the true apogee of the epicycle, but counted from the line of the aux of the eccentric in the order of the signs: as is the arc TBL, with the aux of the eccentric placed at L and the epicycle at N. This arc is obtained by doubling the Moon's mean elongation from the Sun;

and therefore it is usually called the doubled longitude of ☾ from ☉; and it is called the centre because from it the place of the centre of the eccentric is derived.

[Margin: Epicyclic equation.]

The *equation of the argument* [Aequatio Argumenti], or epicyclic equation, or equation of the first inequality, is the arc of the zodiac between the line of mean motion and the line of true motion. It is nil if the Moon is at the apogee or perigee of the epicycle, as at B or F; it is at its maximum if the Moon is at the contacts of the lines tangent to the epicycle and drawn out from the centre of the Earth, as if it is at H or at G, at *m* or at *n*. At the syzygies it is 5° 1′, in □

7° 40′. It is obtained in the same way as the Sun's equation in the hypothesis of the epicycle, as in triangle DGA, right-angled at G, given AD and GD and the complement of the anomaly to, or its excess over, 180°.

[Margin: Eccentric equation and its method.]

The *equation of the centre* [Aequatio Centri], or eccentric equation, is the arc of the epicycle intercepted between its true and its mean apogee, as the arc PQ. It is so called because it is obtained from the centre of the Moon, that is, from the doubled mean elongation of the Moon from the Sun. For the arc PQ, for example, is as great as the angle N subtending it, which by 15 of Book 1 of *Euclid* equals the angle ONA. This angle becomes known in the same triangle, because in it are given the eccentricity AO and the side ON, which in this case is equal to the line drawn from M to N, that is, the semidiameter of the eccentric; and the angle OAN is the complement, to two right angles, of the angle NAL, which measures the doubled distance of the Moon from the Sun. The maximum equation of the centre, however, does not occur at the Moon's mean longitudes but a little below them, as *Peuerbach, Maurolico*, and the others above teach; that is, about the sextile and trine, or, as *Nunes* shows with *Ptolemy* at p. 224, at the point of the eccentric distant from its aux by 114° 3′ 55″; and the maximum equation itself is 13° 8′ 7″.

[Margin: Where the maximum equation of the centre occurs and how great it is.]

But because *Giovanni Battista Capuano* and certain others thought that the maximum equation occurs when the centre of the epicycle is on the line that meets the line of the apogee of the eccentric orthogonally at the opposite point, that is, when the line of the mean apogee makes right angles with the line of the apogee of the eccentric, as if NO were to fall orthogonally on OL, *Pedro Nunes* above, p. 213, and *Reinhold*, p. 74, therefore demonstrate that this is false and that this equation becomes greater below that point. Conversely, this equation is nil when the centre of the epicycle is at the apogee of the eccentric, D or Φ, or at its perigee, V or Z.

[Margin: Use of both equations.]

Now the epicyclic equation is added to the mean motion, so that the true motion may be had, if the anomaly is greater than 6^s; it is subtracted if less. But the eccentric equation is added to the mean anomaly if the centre is less than 6^s; it is subtracted if greater.

[Margin: Diversity of the diameter.]

The *diversity of the diameter* [Diuersitas Diametri] of the epicycle is the arc of the zodiac by which the perigean equation of the epicycle exceeds the apogean epicyclic equation. Thus in the earlier figure, with the centre of the epicycle placed at the perigee of the eccentric Z, the arc corresponding to the maximum equation is μ ♈ or ♈ ξ; with it placed at the apogee D, the arc is θ B or B *x*. Therefore the excess by which μ ♈ exceeds θ B is called the diversity of the diameter; for it is as great as the portion by which the arc μ ξ, subtending the diameter *m n*, exceeds the arc θ *x*, subtending the diameter GH.

[Margin: Proportional minutes.]

Proportional minutes [Scrupula proportionalia] are the sixtieth parts of the diversity of the diameter by which the true argument, or true anomaly, is equated. For these minutes are set against the signs and degrees of the centre, and by means of the true argument the diversity of the diameter is taken from the table. If the minutes are 60, the diversity is added whole to the equation of the argument; if they are fewer than 60, a part proportional to them is added, and thus the true equation of the argument is had for such a position of the epicycle. By means of this, the composite equation of the Moon is then drawn from its own table. For others, however, with whom the eccentricity varies, these minutes are the difference between the longest line of the apogee and the shortest line of the perigee, that is, the eccentricity divided into 60 parts.

[Margin: Method of calculation.]

The method of calculating longitude is this. From the tables one takes the Moon's mean longitude from ♈, its distance from the Sun, and the anomaly of the orb; and the distance from the Sun is doubled, so that the anomaly of the eccentric, or of the centre, may be had. With this, one looks up in the tables the equation of the centre, together with the proportional minutes. This equation is added to or subtracted from the anomaly of the orb, and the equated anomaly of the orb is had. With this, one looks up in the tables the equation of the orb with its excess, which would be taken whole if those minutes were 60; but if they are fewer, a part proportional to them is taken from the excess and is always added to the equation of the orb, so as to make the absolute equation. For this, added to or taken from the mean longitude, gives the Moon's true longitude from the equinox.

CAPVT XXVI.

Chapter 26.

De Lunari Hypothesi Copernici, Magini, Tychonis, & Longomontani.

On the lunar hypothesis of Copernicus, Magini, Tycho and Longomontanus.

[Margin: Absurdity of the Ptolemaic hypothesis.]

I. Copernicus, Book 4, chapter 2, rejects the Ptolemaic hypothesis about the Moon for three reasons. The first is that he holds it absurd that the celestial motions should be unequal in themselves and with respect to their own centres, as is the motion of the Moon on the epicycle, which according to *Ptolemy* is unequal about the centre of the epicycle, and that they should beg their equality from another's centre, namely from the centre of the Earth. The second is the enormous size of the Ptolemaic parallaxes at the quadratures, which by what was said in chapter 14 is 103′ at perigee, that is, almost twice as great as that of the Moon at apogee in the syzygies, although *Copernicus* affirms that these differ very little or not at all from one another. The third is the likewise

enormous apparent size of the Moon at perigee in ☐: at a distance, that is, of 33 33′ semidiameters of the Earth, by what was said in chapter 16, its diameter would appear to be 55′, nearly twice as great as in the apogean syzygies, where for *Ptolemy* it is 31′ 20″. *Copernicus* says that this is contrary to the evidence of the phenomena.

[Margin: Objections to Copernicus on behalf of Ptolemy.]

II. But someone could adduce on behalf of *Ptolemy*, against Copernicus, the change in the Moon's eccentricity, which would have grown smaller with time. For that enormity of the visible diameter and of the parallaxes of the Moon at perigee in ☐ arises from its excessive closeness to the Earth, which could be corrected so as to fit these centuries of ours if the eccentricity were reduced: as if, in the first figure of chapter 25, no. 3, the semidiameter A X of the small circle became shorter, and the eccentric were described from the point X with the interval XV; then certainly V, the centre of the Moon's epicycle, and K, the perigee of the epicycle, would be moved away from the centre of the Earth, A. That is, unless someone wanted to call in the contraction of the semidiameter of the epicycle as part of this correction. As for the Moon's moving equally about another's centre, those more recent astronomers who have admitted the equant circle, not only for the five minor planets but also for the Sun, as we said in Book 3, chapter 22, think this not at all absurd. Copernicus certainly seems hardly consistent with himself in this, since he invented a diminution of the eccentricity in the Sun, as was said in Book 3, chapter 26, and did not devise the like for the Moon. Nevertheless, let us meanwhile hear him, in chapters 3, 8 and 9; *Mästlin* in the Appendix to Kepler's *Prodromus*, p. 151; and *Magini* in the first *Theorica* of the Moon and in the *Canon of the Second Mobiles*, who with Copernicus substitute the hypothesis set out below for the Ptolemaic one.

Copernicæ Hypothesis Synopsis

Synopsis of the Copernican hypothesis.

For the distances see ch. 14	Lines or angles	To the radius of the concentric orb, 100000	Earth semidiameters, 1
Semidiameter of the concentric	A C	100000	60 19
Semidiameter of the epicycle, greater	C E	10970	6 36
Semidiameter of the epicycle, lesser	P E	2370	1 26
Distance at ♂ and ☍, max.	A N	108600	65 30
Distance at ♂ and ☍, mean	A C	100000	60 19
Distance at ♂ and ☍, min.	A O	91400	55 9
Distance at ☐, max.	A P	113340	68 20
Distance at ☐, mean	A C	100000	60 19
Distance at ☐, min.	A Q	86660	52 17
Equation at ♂ ☍	G A I	5° 0′	

For the distances see ch. 14	Lines or angles	To the radius of the concentric orb, 100000	Earth semidiameters, 1
Maximum at ☐	C A D	7° 40′	

III. With these things supposed, from A, the centre of the Earth, let a portion of an orb or circle concentric with the Earth, BCD, be described at an in- terval AC, of 100000 parts, and from the centre C the greater epicycle EHGF, with semidiameter CE of 10970 parts, carrying the lesser epicycle P S N, whose semidiameter PE is of 2370 parts. Let the epicycles I K L M, and OTQ, and R D, etc., be equal to this one, so that the lesser epicycle with its apogee P describes the circle P L Q D P, and with its perigee N the circle N I O. And let straight lines be drawn from the centre of the Earth A: one, A I, tangent to the epicycle O Q at T, or to the circle N O at I; the other, A D, tangent to the epicycle R D at D, or to P Q at D.

[Margin: Method of deriving the proportion of the epicycles.]

For it has been observed that when the Moon is half-lit, that is, placed at the quadratures and at the nonagesimal, where the parallax of longitude ceases, its observed or apparent place, when it differs most from the Moon's mean place as derived from the tables of equal motions, differs by 7° 40′; and that this maximum prosthaphaeresis occurs when in ☐ the Moon has an anomaly of about 3^{s} or 9^{s}; whereas in ☌ and ☍ the maximum prosthaphaeresis needed to reduce the mean place to the true and observed place is 5° 0′. With A I drawn, then, tangent to the circle N O at I, the triangle A I C is, by 16 of Book 3 of *Euclid*, right-angled at I. Therefore, given A C, 100000, and the angle C A I, 5°, trigonometry yields C I, of 860 [recte: 8600] parts, to which CN is equal. And with AD drawn, tangent to the circle PQ at D, in the triangle CAD, right-angled at D, from the base AC, 100000, and the angle CAD, 7° 40′, one derives CD, of 13340 parts, to which CP is equal. With CN taken from CP, therefore, NP remains, of 4740 parts, and half of it, that is, the semidiameter of the lesser epicycle, PE or NE, is of 2370 parts; and with NE added to NC, the semidiameter of the greater epicycle, CE, comes to 10970 parts.

[Margin: Form of the lunar motions.]

Now let the centre C of the greater epicycle move in the order of the signs toward B, with the Moon's equal motion in the zodiac; if you take from this the mean motion of the Sun, the mean motion of the Moon from the Sun remains. Meanwhile let the centre E of the lesser epicycle move against the order of the signs, the motion being counted from E toward F, with the motion of the mean anomaly, which is of course the distance of the centre of the lesser epicycle, computed from the apogee E of the greater epicycle. And finally let the body of the Moon move on the circumference of the lesser epicycle against the order of the signs from N through S to P, counting from N the double motion of the Moon from the Sun; that is, under this rule, that when the line AC is the line of the Sun's mean motion, the Moon at mean ☌ and ☍ is at the perigee N of the lesser epicycle, and in ☐ is at its apogee P. For in this way

it will come about that the Moon runs through the small epicycle twice in a month, in which time the centre C will have returned once to the Sun; and the new and full Moon will appear to describe the smallest circle N I O, but at the quadratures the largest, P L Q D, and therefore to undergo in the former case smaller, in the latter larger differences of the parallaxes, of the visual diameters, and of the prosthaphaereses. And with these things laid down, and with their motions supposed, on which see chapter 23, *Copernicus* holds that all the lunar appearances agree with this hypothesis.

Diagram. In the left column, with the narrowed text running down its left side: the greater epicycle's circle centred at C, carrying around it four small epicycles at top, left, bottom and right, enclosed by a larger circle through P at the top and Q at the bottom, with an inner circle about C through N and O. A long vertical line runs from P at the top through C to A at the foot, and two lines run down from the circles to meet at A. Point C stands near the centre; a slanted line passes through C from upper right to lower left.

- P (top, outside the circle)
- E (in the upper epicycle, right of the vertical)
- S (right edge of the upper epicycle)
- N (below the upper epicycle, on the inner circle)
- K (at the top of the left epicycle)
- R (at the top of the right epicycle)
- C (centre)
- B (far left, outside the circle)
- L (next to B, on the left edge of the left epicycle)
- H (in the left epicycle)
- I (inside, at the right edge of the left epicycle)
- F (in the right epicycle, a drawn line running through the sort)
- D (far right, outside the circle)
- M (below the left epicycle)
- O (on the vertical, above the lower epicycle)
- T (in the lower epicycle, left of the vertical)
- G (in the lower epicycle, right of the vertical)
- Q (below the lower epicycle)
- A (at the foot, where the lines meet)

[Margin: Investigation of the equations.]

IV. Further, in chapter 9 he investigates the equations, and the difference by which the Moon appears to move unequally from the apogee of the lesser epicycle, by this method. In this second figure let the greater epicycle be AB, and let the lesser, with centre E, have withdrawn from the highest apsis A against the order of the signs by any arc AE; and let the Moon be at M or L, the contacts of the lines C M or CL. For since the angles M and L, by 16 of Book 3 of *Euclid*, are right, and CE is of 10970 parts of which M E or LE is 2370, the angle ECL follows as 12° 28′, namely the maximum difference by which the Moon varies from the highest apsis F of the lesser epicycle. This, he

says, occurs when the Moon in its mean motion is distant from the mean place of the Sun by 38° 46′, and by as much on either side of the mean opposition.

Diagram. In the right column, with the narrowed text running down its left side: a circle centred at C, the greater epicycle, with A at the top and B at the bottom, joined by a vertical line that continues down to D. Three small circles stand on its circumference, at upper left, upper right and lower right. Lines radiate from C to points on the small circles, and two long lines run from the left and right small circles down to meet at D.

- G (top left, at the top of the upper-left small circle)
- A (top, outside the circle)
- M (left of the upper-right small circle's centre)
- E (centre of the upper-right small circle)
- F (top right, at the edge of the upper-right small circle)
- E (centre of the upper-left small circle)
- I (below the upper-left small circle, right of the line to D)
- L (lower edge of the upper-right small circle)
- C (centre)
- P (in the lower-right small circle)
- N (right edge of the lower-right small circle)
- K (below N, at the same edge)
- B (bottom of the circle, outside)
- D (at the foot, where the lines meet)

With this done, in chapter 10 he gives the way of demonstrating the apparent motion geometrically, from the mean motion given for a given time, together with the canon of the lunar prosthaphaereses and their foundations. For in the second figure let the Moon be at G, and let the arc IG, or angle C E G, be known from the doubled motion of the Moon from the Sun. Then in the triangle CEG, given the angle just mentioned and the sides CE, 10970, and EG, 2370, the angle ECG and the side GC will be found by the rules of triangles. Now let the anomaly APBE be given, and hence its complement E A, that is, the angle ECA, which, subtracted from the semicircle AEB, leaves the angle ECD. To this, ECG added will give the angle GCD, in the triangle GCD, in which GC has been found and DC, 100000, is given. Therefore by trigonometry the angle GDC will not remain hidden, namely the prosthaphaeresis to be added to the mean motion of the Moon from the Sun; just as, with the angle ECG taken from the angle ECA, there remains the true distance of the Moon from the apogee of the first epicycle, G C A, and thus the equated anomaly. But if the Moon were at K, with mean anomaly AP, and with the arc KN known from the double motion of the Moon from the Sun, that is, the angle KPN, and its complement to two right angles, C PK, then certainly in the triangle CPK, in which CP is of 10970 parts and PK of 2370, the side CK would become known, and the angle KCP, to be added to the mean anomaly so that it would be equated, DCK. With this, and with the sides CK, just found, and CD, of 100000 parts, the angle CDK would become known, which is the

prosthaphaeresis to be subtracted from the mean elongation of the Moon from the Sun, so that the true elongation may be known. I pass over the way of finding the Moon's motion by tables, on which see *Copernicus*, Book 4, chapter 12, *Reinhold* in the precepts of the Prutenic Tables, and ourselves in the practical part at the end of this work. From this he deduces the maximum equation of the first inequality as 4° 56′ 19″ at the 95th and 265th degree of anomaly, and the maximum equation of the second inequality as 7° 40′ at 98° and 262° of anomaly.

[Margin: Fallacy of the Copernican hypothesis.]

But since the Copernican parallaxes of the Moon are fallacious, as we said in chapter 14, no. 4, it is no wonder if, both for this reason and from mean motions not so exactly established, this hypothesis strays somewhat from the phenomena. Besides this, it follows from it that the lunar spots would appear to us at the perigee of the lesser epicycle and be hidden at the apogee, unless the epicycles mentioned are transformed into eccentrics; which *Copernicus*, Book 4, chapter 3, concedes can be done. *Kepler* adds, in the Rudolphine Tables, p. 57, and in the *Epitome of Astronomy*, p. 674, that from these two epicycles it follows that the planet wanders outward around the mean longitudes and is twisted into various bends, whereas observations attest that in those places it enters toward the sides and contracts its distances.

V. Accordingly *Giovanni Antonio Magini*, Book 1 of the *Theoricae*, from p. 70, having seen that it follows from Copernicus's epicycles that the lunar spots would be hidden from us at the apogee of the first epicycle, which *Averroes* had long ago objected to the Ptolemaic epicycle, transformed the Copernican hypothesis into eccentrics, one in particular being carried on the circumference of a hypocycle, that is, a small circle placed near the Earth, yet making the centre of the Earth and of the ecliptic one and the same; and he used solid orbs, while retaining almost the Copernican numbers and intervals. The synopsis of his hypothesis is set out below.

Maginicæ Hypotheseos Synopsis

Synopsis of Magini's Hypothesis

Interval	Lines	In parts of an orb radius of 100000	Semidiameters of the Earth, 1
Semidiameter of the eccentric	C G	100000	60 19
Semidiameter of the small circle	B C	2375	1 26
Eccentricity, greatest	A C	13330	8 2
Eccentricity, least	A D	8580	5 10
Distance at conjunction and opposition, greatest	A H	108580	65 29
Distance at conjunction and opposition, mean	A M	100000	60 19
Distance at conjunction and opposition, least	A F	91420	55 9
Distance at quadrature, greatest	A G	113330	68 21
Distance at quadrature, mean		100000	60 19

Interval	Lines	In parts of an orb radius of 100000	Semidiameters of the Earth, 1
Distance at quadrature, least	A E	86670	52 17

[Margin: Six orbs in Magini's lunar theory.] In the lunar heaven, then, six orbs must be conceived. One, the highest, lies in the plane of the ecliptic GPT, described from A, the centre of the Earth. It carries the nodes of the lunar orbit against the order of the signs by 3′ 10″ 47‴ daily and by 19° 20′ 33″ 44‴ yearly, and completes its circuit in 18 Egyptian years $223^{d}\ 6^{h}\ 12^{m}$. The others, carried round by the highest, must be conceived in a plane inclined to the ecliptic by 5°, which is the Moon's greatest latitude. Among these, the two immediately below the ecliptic carry the mean apogee of the eccentric in the order of the signs, from the first star of Aries, by 6′ 40″ 56‴ 28⁗ daily and by 40° 39′ 3″ 32‴ yearly, and they complete their course in 8 Egyptian years $312^{d}\ 9^{h}\ 27^{m}\ 46^{s}$.

[Margin: The mean apogee of the eccentric and its motion.] The mean apogee is the point in the highest lunar heaven determined by the line drawn from the centre of the world A through the centre B of the small circle carrying the eccentric: for example G, if the centre of the eccentric is at C; or the point X, if the centre of the eccentric is at V.

[Margin: The motion of the anomaly of the apogee and eccentricity.] Below these are the fourth and fifth orbs, namely those of the anomaly of the apogee and of the eccentricity. They move in the order of the signs with the doubled motion of the Moon from the Sun, 24° 22′ 53″ 23‴ daily, and complete their circuit in $24^{d}\ 18^{h}\ 22^{m}\ 1^{s}$. This motion takes place about the centre B of the small circle CD and is counted from its perigee D, or at any rate from the perigee F of the eccentric HMFZ. By the force of this double motion the centre of the eccentric is restored to the perigee D twice in one synodic month. Some call this motion the centre of the Moon; *Copernicus* and the *Alphonsines*, the doubled distance of the Moon from the Sun; *Magini*, the anomaly of the apogee and eccentricity. It is counted as far as the line drawn from the centre B through the centre of the eccentric, as is the line BVL in the following figure, if the centre of the eccentric is at V.

Finally the sixth orb, which carries the body of the Moon against the order of the signs, is the eccentric, whose mean daily motion is 11° 18′ 59″ 27‴, and it completes a circle in $31^{d}\ 19^{h}\ 29^{m}\ 12^{s}$. This motion takes place about a moving centre on the periphery of the small circle CVD, and is counted from the mean apogee of the orbs of the anomaly, which is defined by the straight line drawn from the centre B through the centre of the eccentric, as is the line BVL.

Diagram. Magini's lunar hypothesis, in the left column. A large outer circle carries G at the top and T at the bottom, joined by a vertical diameter through A. On that diameter from the top stand G, R, H, C, B, D, A, E, F, T. A small circle round B passes through C and D. Two eccentric circles stand inside the outer circle, one with its top at G and its foot at E, the other with its top at H

and its foot at F; a further arc runs from the region of X and K down past L to S. A horizontal line joins I, C and Y; another joins M and D and runs on to the letter beside L. A line runs from B through V to L. Lines radiate from D, C and A to the upper left, ending on the outer circle at the labels there, and a line runs from A through the region of D and V up through K to X.

- G (top of outer circle); T (foot of outer circle)
- X, K (upper right, on the line to the outer circle)
- R, H, C, B, D, E, F (on the vertical diameter, in that order downward, with A between D and E)
- A (on the vertical diameter)
- V (right of D, on the small circle)
- I (left end of the upper horizontal); Y (right end of the same)
- M (left end of the lower horizontal); L (right, on the outer region)
- Z (immediately left of L, with a slanting foot)
- S (lower right); Θ (left of the vertical, above F)
- on the outer circle at upper left, in order from the left: a glyph like a turned 9, read as Q [?]; P; N; O
- inside the outer circle at upper left: ε (below N O); δ (below P)

VI. Therefore, on the line of apsides TG, bisected at A, the centre of the world, let the ecliptic GT be described, and at the interval AB, of 10955 parts of which CG, the radius of the eccentric, is 100000, let the centre B be taken, and with the semidiameter BC of 2375 parts let the small circle CVD be described. On its periphery, for the mean conjunctions and oppositions, let the centre of the eccentric be at D, and let the eccentric be HMFZ, with its apogee at H and its perigee at F, and the points of mean longitude M, Z, determined by the straight line MDZ, perpendicular to GT. And let us suppose that at that time the Moon is not at H, where the true and mean motions agree, but at δ. For the line Dδ Q, drawn from the centre of the eccentric through the body of the Moon, will be the line of mean motion, and the mean place will be at Q; but the line Aδ P, drawn through the Moon's centre from the centre of the Earth, will be the line of true motion, the true place will be at P, and the equation to be subtracted will be the angle AδD.

Now for the mean quadratures let the centre of the eccentric be at C, and the eccentric be GIEY; and let the Moon be not on the line GT, where the equations cease, but at ε. For the line of mean motion will be CεN, and of true motion AεO, and the equation to be subtracted the angle AεC; and the points of mean longitude will be I and Y, determined by the line ICY. In the other semicircle of the eccentric, however, the equations would be additive.

The greatest equations occur a little below the points of mean longitude. The equation of the first inequality, 4° 56′ 19″, occurs at conjunction and opposition, a little below the points M and Z, that is, with the Moon distant from the apogee of the eccentric by the arc HM or HZ of 98°, and with the centre of the eccentric placed at D; and the base of the angle of the equation is the least eccentricity AD, of 8580 parts. But the greatest equation of the

composite or second inequality, 7° 40′, occurs at quadrature, with the Moon placed below the mean longitudes I or Y, distant from the apogee G by the arc GI or GY of 95°, and with the centre of the eccentric placed at C; and the base of this greatest equation is the greatest eccentricity AC, of 13330 parts. The rest will be understood from what has been said. This hypothesis, if the Copernican numbers on which it rests are corrected and it is freed from the entanglements of solid orbs, is not unfitting.

Tychonis & Longomontani Hypothesis.

The Hypothesis of Tycho and Longomontanus.

VII. *Tycho Brahe*, with *Longomontanus* assisting him, saw that the eccentricity and the semidiameter of the Ptolemaic epicycle were too great, that the semidiameters of the Copernican epicycles were too great, and likewise the Moon's distances arising from them. He therefore adopted an eccentric with Ptolemy and two epicycles with Copernicus, but reduced the measures of both in proportion to the lunar distances he had observed, as was said in chapter 14. And since, besides the first and second inequality of the lunar motion, he had observed a certain third variation from the syzygies to the quadratures, and indeed greatest in the octants, he added a small circle of libration and hammered out a new hypothesis. It is explained by *Tycho* himself, volume 1 of the *Progymnasmata*, p. 116; by *Longomontanus*, Book 1 of the *Theorica*, chapter 6; by *Kepler*, before the *Ephemerides*, pp. 3 and 5, and in the Rudolphine Tables, pp. 79 and 82; and by *Nicolaus Mulerius*, in the *Isagoge* to the *Tabulae Frisicae*, part 2, chapter 3. Its measures are as follows, with the semidiameters of the Earth added from our chapter 14.

Tychonicæ Hypotheseos Synopsis

Synopsis of Tycho's Hypothesis

Intervals	Lines	In parts of a radius of 100000	Semidiameters of the Earth, 1
Semidiameter of the eccentric	A I	100000	56 30
Greatest eccentricity	A D	4348	2 28
Semidiameter of the small circle	A C	2174	1 14
Semidiameter of the greater epicycle	I L	5800	3 17
Semidiameter of the lesser epicycle	M L	2900	1 38½
Distance at conjunction and opposition, with the centre of the eccentric at A: greatest	A M	102900	58 8
The same: mean	A I	100000	56 30
The same: least	A X	97100	54 52
Distance at quadrature			
Greatest, at the apogee of the eccentric and at the perigee of the lesser epicycle		107248	60 36
Mean, as above		100000	56 30
Least, at the perigee of the eccentric and the apogee of the lesser epicycle, with the centre of the eccentric at D		92752	52 24

Intervals	Lines	In parts of a radius of 100000	Semidiameters of the Earth, 1
Greatest equation at conjunction and opposition		4° 58′ 27″	
Greatest equation at quadrature		7° 28′ 0″	

[Margin: Tycho's device in this theory.] The reason for these proportions is as follows. *Ptolemy*, Book 4, chapter 6, investigating the semidiameter of the epicycle through sets of three eclipses, had found it to be 5° 14′, of which the radius of the orb, but of the orb concentric with the world, is 60; that is, 8696 parts, of which the radius of the orb is 100000. *Tycho* bisected this quantity and took its half, 4348, for the diameter of the small circle AD and for the greatest eccentricity. He also divided the Ptolemaic epicycle into two epicycles, of which the greater should have a semidiameter twice as great as the semidiameter of the lesser, the semidiameter of the former being 5797⅓ parts and of the latter 2898⅔. In these, however, he chose round numbers: 5800 for the one, 2900 for the other. Using the quantity 8700, not as the sine of the greatest equation, as happens in the eccentric hypothesis, but as the tangent, he found the greatest equation at the syzygies to be 4° 58′ 22″ at 90° of anomaly. This he chose to make equal to the greatest latitude at the syzygies, just as the ancients, equating longitude with latitude, had made each of them 5°; but at an anomaly of 92° he made it 4° 58′ 27″. Bisecting this, he made the greatest equation to be added to it at quadrature 2° 29′ 13″, so that the whole was 7° 27′ 40″, or 7° 28′. Such, evidently, is the device by which *Tycho* and *Longomontanus*, attending also to the parallaxes and distances discussed in chapter 14, built up the lunar theory for us.

VIII. Let this, then, be the scheme, at least for the syzygies. In it let A, the centre of the Earth and of the world, and indeed, at the true syzygies, at which there is no eccentricity, be the same as the centre of the circle ITBV, at other times eccentric, now concentric. Let its diameter IB be the line of the true syzygies and quadratures. Let it be extended to P; and with the centre taken at I, let the greater epicycle LFEG be described at the interval IL, of 5800 parts of which the radius AI is 100000. With the centre taken at L on its periphery, at the interval PL of 2900 parts, let the lesser epicycle PNMO be described. For L will be the apogee of the greater epicycle and E its perigee, while P will be the apogee of the lesser and M its perigee.

Diagram. Tycho's lunar scheme at the syzygies, set in the left column with the text running narrow beside it. A large circle has a vertical diameter running through it from a small circle at the top down to B at the foot. Across the top of the large circle, centred on its upper point, is the greater epicycle; above that, centred on the greater epicycle's top, the lesser epicycle. A very small circle with R to its left and S to its right surrounds the point I on the large circle's top. Inside the large circle, on the diameter above A, is a small circle with H at its left, K at its right and C within it.

- P (top of the lesser epicycle); L (its centre); N (its left); O (its right)
- M (foot of the lesser epicycle, inside the greater)
- R (left of the very small circle); I (its centre); S (right of it)
- F (left, where the greater epicycle meets the large circle); G (right, the same)
- E, D (on the diameter, in that order downward, below the greater epicycle)
- H (left of the inner small circle); C (its centre); K (right of it)
- A (on the diameter, at the foot of the inner small circle)
- T (left, inside the large circle); V (right, inside the large circle)
- B (foot of the large circle)

[Margin: Motion of the centre of the eccentric.] Finally, taking the semidiameter AC of 2174 parts, let the small circle of the eccentricity AKDH be described. On its periphery let the centre of the eccentric move in the order of the signs, its motion beginning from A towards K, with the doubled motion of the Moon from the true place of the Sun, but with the Moon's motion equated by the prosthaphaeresis of the prior inequality; so that at every true full Moon and new Moon the centre of the eccentric is at A, the centre of the world, and at every true quadrature it is at D; and twice in a month the centre of the eccentric runs through the circumference of this small circle.

[Margin: Line of the mean and true apogee.] At the syzygies let the one line BI be that of the mean and true apogee; outside them, let the line of the mean apogee be the one that passes through the centre of the eccentric parallel to the diameter AD of the small circle, and that of the true apogee the one through the centres of the Earth and of the eccentric. Therefore anyone who wants to draw the figure for himself for the quadratures must, with the centre taken at D and the semidiameter AB, describe the eccentric, on whose periphery the centre of the greater epicycle is towards L for the Moon at apogee and towards B for the Moon at perigee; and he must draw the two epicycles, as above, on either side.

[Margin: Motion of the epicycles.] Further, let the centre I of the greater epicycle move in the order of the signs towards T, its motion beginning from the mean apogee, such as the point I or another on which the line of the mean apogee falls; let it move, I say, with the mean motion of the simple anomaly, discussed in chapter 23. Meanwhile let the centre L of the lesser epicycle likewise move with the motion of the simple anomaly, but against the order of the signs, from L to G, this motion always beginning from the point on the periphery of the greater epicycle on which falls the straight line drawn from the centre of the eccentric through the centre of the greater epicycle; and let it complete its motion in $27^{d}\ 13^{h}\ 18^{m}\ 35^{s}$.

[Margin: Motion of the Moon.] Finally, let the body of the Moon on the circumference of the lesser epicycle, that is, by the motion of that epicycle, move in the order of the signs from M to O, with a motion twice as great as the motion of the epicycles singly, or with the doubled motion of the simple

anomaly, so that it completes its period in $13^{d}\ 18^{h}\ 39^{m}\ 17^{s}\ 30'''$. This motion always begins from the point of the periphery of the lesser epicycle nearest the centre of the greater epicycle; for example, in our scheme, from the point M. The straight line drawn from the centre of the greater through the centre of the lesser epicycle either coincides, as in our scheme, or, outside conjunction, opposition and quadrature, is parallel to the diameter AD. Hence it happens that when the centre L is midway between L and E, that is, at F or at G, the Moon is at P, the apogee of the lesser epicycle. Whenever the centre of the greater epicycle is at the apogee I, that is, when the motion of the anomaly is 0^{s}, the Moon is at M, the perigee of the lesser epicycle; but if the anomaly is 6^{s} and the centre of the greater epicycle is at the perigee of the eccentric, the Moon is at the apogee of the lesser epicycle, and in both places it lacks all prosthaphaeresis. When, however, the centre of the greater epicycle is towards T or V, that is, when the anomaly is 3^{s} or 9^{s}, the Moon is at the mean distances from the apogee of the lesser epicycle, as at N or O; and so at the points of contact, at which the equations become greatest.

IX. [Margin: Small circle of libration for the third variation.] To save the third inequality, or Variation, which is nil at conjunction, opposition and quadrature and greatest in the octants, let there be a small circle RS, though it is rather to be conceived in the surface of the sphere of the fixed stars, as *Kepler* notes in the *Epitome of Astronomy*, p. 812. On its diameter let the centre I of the greater epicycle librate to and fro with a motion analogous to circular motions, as we saw done in Copernicus in Book 3, chapter 29. This motion is to be commensurable with the doubled true distance of the Moon from the Sun, and it is to produce a prosthaphaeresis, to be added, from conjunction and opposition as far as quadrature, but subtracted, from quadrature to conjunction and opposition, to the Moon's mean longitude from the Sun, so that the true place of the centre I of the greater epicycle may be established. The greatest variation is to be $40'\ 30''$, added in the first and third octant after conjunction, subtracted in the second and fourth octant. And so at the syzygies the centre of the greater epicycle will be at I, and in the sextile and trine aspects at R and at S. See, however, another scheme in chapter 29, no. 2.

Kepler notes, in the *Epitome of Astronomy*, p. 812, that the portion of $40'\ 30''$, taken as the whole sine, that answers to the sine of the doubled elongation from the Sun, already equated, is the Variation that applies. Moreover, says *Longomontanus*, just as the anomaly of the eccentric, accounted for by the small circle DHAK, depends on the distance of the Sun and Moon from the Earth, through a power flowing out of the epicycle of the Sun which varies the Moon's motion under the greatest angle of vision, so the third Variation comes from the Sun, according to the Moon's varying disposition towards it and towards the Earth. For while the Moon is joined to the Sun or opposed to it, greater efficacy is assigned to the Earth, as the primary centre of the lunar orbit, because of the solar rays falling on the Earth and reflecting themselves, together with the motive force, from it jointly and directly to I, the common centre of the

Moon's epicyclic system, which for that reason moves more hastily in the order of the signs. Around the quadratures, however, it moves more slackly, because the power of the solar rays is dissipated in the greatest obliquity of aspect. So far *Longomontanus*.

[Margin: A method of deriving the Moon's motions from this hypothesis.] Since the form of lunar calculation in this hypothesis is somewhat intricate, although *Magini* made it easier through his tables in the *Supplement to the Ephemerides*, and *Renieri* after him in the *Tabulae Mediceae*, I should still like to take from Tycho himself the geometric method of deriving the lunar motions from it.

EXEMPLVM.

Example.

X. *Let there be given: the Sun's mean place, 5^{s} 5° 50′ 21″, and its true place, in Virgo 4° 5′ 12″; the Moon's mean longitude from the Sun, 9^{s} 25° 13′ 13″; and its mean anomaly, 45° 37′ 29″. Now, as in the following figure, let the small circle AKD be described, whose semidiameter AC is 2174 parts, of which the radius of the eccentric OF is 100000. And since the doubled longitude of the Moon from the Sun is about 230°, if it is counted from A through K, the centre of the eccentric will fall at O, from which describe the eccentric FIB. The straight line FB, drawn through O, will mark the mean apogee at F, just as the straight line drawn through the centres AO, that is, AOE, will mark the true apogee at E. So count from F, in the order of the signs, the arc FI of the mean anomaly, 45° 37′ 29″; and from I describe the first epicycle, whose semidiameter IL is 5800 parts, of which OF is 100000. Having drawn a straight line from O through I as far as G, count against the order of the signs from G towards L the arc GL, likewise of 45° 37′ 29″; and from L describe the second epicycle, whose semidiameter LM is 2900 parts, of which IG is 5800.*

Diagram. The worked example of Tycho's lunar hypothesis, in the left column. A large circle with F at the top and B at the foot is joined by a vertical line through O. In its lower right part a small circle carries D at its top, K at its right, A at its foot and H at its left, with C at its centre and O on its upper left. At the upper left, on the large circle, stands a very small circle round I, with S and R on it; round I is a larger circle carrying G at its far left; on that circle, above, is a further circle round L, with M at its top, T at its upper right and N at its foot. Straight lines run from T to O and from T to A; from G through I to O; from A through O to E on the large circle; and from C to O, to H and to A.

- F (top of large circle); E (on the large circle, left of F); B (foot of large circle)
- M (top of upper epicycle); L (its centre); T (its upper right); N (its foot)
- G (far left of the greater epicycle)
- I (centre of the very small circle); S (right of it); R (lower left of it)

- D (top of the small circle); O (its upper left); C (its centre); K (its right); H (its left); A (its foot)

Extend ILM and count from N, in the order of the signs, the arc NT of the doubled anomaly, namely 91° 14′ 58″; for the Moon will be at T. To it draw the semidiameter LT, and connect the centre I with the Moon T by the straight line IT. For in the triangle ILT the sides IL, 5800, and LT, 2900, are given, and the angle NLT, 91° 14′ 58″; therefore by trigonometry you will derive the angle TIL, 26° 18′ 43″, and the side IT, of 6541 parts. Next draw from the Moon T the straight lines to the centres of the eccentric and of the Earth, namely TO and TA; for in the triangle TIO are given OI, of 100000 parts, TI, found to be 6541, and the angle TIO, 108° 3′ 48″, since it is the complement of the angles LIT, found to be 26° 18′ 43″, and GIL, which measures the arc GL of 45° 37′ 29″. So from the laws of triangles the angle TOI becomes known, 3° 29′ 16″, which is the epicyclic equation, together with the side OT, of 102217 parts, of which OF is 100000.

Now add the Sun's mean place to the mean longitude from the Sun, and the Moon's mean longitude from the vernal equinox becomes 3^s 1° 3′ 34″. When the epicyclic equation is subtracted from this, the Moon's equated longitude from the equinox remains 2^s 27° 34′ 18″. And when the same equation is subtracted from the anomaly itself, the equated anomaly remains 42° 8′ 13″. After this, from the Moon's longitude from Aries, epicyclically equated, subtract the Sun's true place, and the Moon's true longitude from the Sun is left, 9^s 23° 29′ 6″. Its double, a whole circle being cast out, is 7^s 16° 58′ 12″. So, this arc being counted from A through K and D, and the 6^s of the semicircle AKD being cast out, the arc DO remains, 46° 58′ 12″. Therefore, the semidiameter of the small circle CO being drawn, the isosceles triangle OCA is formed, in which the angle OCA, the complement of the angle OCD, that is, of the arc DO, is 133° 1′ 48″; and the angle at the circumference, namely OAD, is by the 20th of the third book of Euclid *half the angle OCD, and is 23° 29′ 6″. This, evidently, is the angle of the second anomalistic equation, to which, by the 28th of the first book of* Euclid*, the angle EOF is equal; it is to be subtracted from the coequated anomaly TOF, which was 42° 8′ 13″, and the anomaly equated a second time remains 18° 39′ 7″. This, subtracted from the semicircle, leaves the angle TOA, 161° 20′ 53″.*

Further, the side of the eccentricity OA is investigated as follows. Since the arc OHA was found above to be 133° 1′ 48″, its half is the arc AH, 66° 30′ 54″, and the right sine of this is 9171634. So as the radius is to this sine, so is the semidiameter of the small circle AC, of 2174 parts, to 1994 parts, whose double gives the chord AO, of 3988 parts, of which OF is 100000, namely the eccentricity. Thus in the triangle TOA are given the sides OA, 3988, and OT, already found above, 102217, and the angle TOA was 161° 20′ 53″. Therefore by the analysis of triangles there will be given TA, the distance of the Moon from the Earth, and in addition the angle ATO, 41′ 22″, which is the equation of the eccentricity, to be subtracted from the coequated longitude of the Moon from Aries; and the Moon's nearly true place remains 2^s 26° 52′ 56″.

Finally, since the motion of libration, commensurable with the double distance of the luminaries and beginning to be counted from its own apogee in the contrary

direction, that is, in the order of the signs with respect to the first epicycle, is 7ˢ 16° 58′ 12″, and the sine of its excess beyond the semicircle is 7309965: therefore, as the whole sine 10000000 is to 7309965, so the greatest Variation, or the semidiameter of the small circle RS, 40′ 30″, is to the Variation 29′ 36″, to be subtracted from the Moon's last place, so that the Moon's exact place remains in Gemini 26° 23′ 20″ on its orbit. But from this hypothesis, as from the Copernican, it follows that the lunar spots are seen at perigee and hidden from us at apogee, unless those who use an epicycle give the Moon a motion of rotation about its centre, which, however, Tycho *denies, volume 1, p. 742.*

CAPVT XXVII.

Chapter 27.

De Lunari Hypothesi Ioannis Kepleri, P. Alberti Curtij, Fabricij, Bullialdi, Lansbergij, Vendelini, & Recentiorum.

On the Lunar Hypothesis of Johannes Kepler, Father Albert Curtz, Fabricius, Boulliau, Lansbergen, Wendelen, and More Recent Authors.

I. *Kepler* had indeed decided, in his *Commentaries on Mars*, published in 1608, and in the first part of the *Epitome of Copernican Astronomy*, published in 1616, that the causes of the inequality of the celestial motions are not to be sought a priori from mere geometry and the bare lines of circles, whether these were concentrics with epicycles or eccentrics; but that they are physical, and that either all or part of that inequality is real, and not merely optical, that is, apparent to one viewing the motions from a centre other than their own. This physical cause, he held, is the Sun with respect to Saturn, Jupiter, Mars, Venus, Mercury and the Earth, and with respect to the Moon the Earth itself, through a power received from the Sun. [Margin: Kepler's variations in constructing the lunar hypothesis.] By these the planet in motion would be moved according to the disposition of magnetic fibres and according to the ratios of the balance and the lever, from which the path of the moved planet would turn out elliptical, as I shall say more clearly in the Scholia of this chapter.

But because of the manifold anomaly of the Moon he still used a double eccentric, with the distances of the Moon at apogee at opposition and conjunction different from the distances at quadrature; and a double eccentricity from the centre of the Earth. One of these, depending on the magnetic fibres of the Moon, was free of the Moon's phases and independent. The other depended on the shape of the illumination and its comparison with the magnetic fibres; it would arise twice each year and die away again, and its apogee, if it began from new Moon, would die away at full Moon, but if it began at full Moon, would finally die away, after 6 months, at new Moon; and so it was tied to the phases. On this pattern he composed the *Ephemerides* for 1617 and 1619, as is clear from their short prefaces to the reader.

But as one day teaches another, when he came to the *Ephemeris* for 1618 he noticed that among the physical causes the illumination could be placed, not of the Moon, but of the Earth, and that the two real and physical eccentricities could, without great inconvenience, be fused into one geometric eccentricity, whose apogee would have an unequal motion and whose eccentricity would vary through the year. On this pattern he computed the single *Ephemeris* for 1618, as is clear from his letter to the reader prefixed to that *Ephemeris*.

Finally, in 1620 April, from a deeper study of the physical causes, he chose a hypothesis in which there is a single orbit, that of an eccentric ellipse, and a single real eccentricity; and so the Moon's distances from the Earth are equal both at the syzygies and at the quadratures, namely apogee distances to apogee distances and perigee to perigee, and so on, as is clear from the *Epitome of Copernican Astronomy*, in the preface to Book 5 and pp. 614 and 820, and from the Rudolphine Tables, p. 79. So anyone who wants to understand this last hypothesis must consult the second part of the *Epitome of Astronomy*, published in 1621, Book 4, from pp. 549 and 609, and Book 6, the whole of its part 4, and also chapters 20, 25 and 26 of the Rudolphine Tables, besides what he teaches in Book 5 of the *Epitome* as common to the Moon and all the planets. As for what concerns the physical causes of accelerated or retarded motion, namely the magnetic fibres, the lever and the balance, partly common to the other planets and partly proper to the Moon, we shall set these aside for the Scholia of this chapter and refute them in part; or, as regards the motion in latitude, for the Scholia of Chapter 29. The rest, which concerns the geometrical or arithmetical computation of the Moon's motion in longitude, we shall set out here not a little more clearly and distinctly than the author himself.

[Margin: The Moon's threefold anomaly.]

II. In Kepler's hypothesis there is a threefold inequality or anomaly of the Moon, and therefore a threefold equation.

[Margin: 1. Free.]

He calls the first *Free* [Soluta], that is, not tied to the variety of the phases and of the Moon's elongation from the Sun; others call it the first and simple anomaly, and the Ptolemaics the epicyclic. But in this theory it arises from the invariable and real eccentricity of the Moon's elliptical orbit from the centre of the Earth.

[Margin: 2. Temporary Monthly anomaly.]

The second is called *Temporary Monthly* [Menstrua Temporanea], because it is tied to the variety of the phases that return through the month and make it up, yet in such a way that it neither returns nor is of the same quantity in every month. It depends both on the line of syzygies, which leaves the Moon's apogee, and on a variable eccentricity: not indeed a real one, that is, of the centre of the eccentric orbit from the centre of the Earth, but that of a certain monthly point, and of the semicircle of the whole orbit, from the plane of the circle of illumination, by which the Earth is illuminated by the Sun and which separates the diurnal hemisphere from the nocturnal.

[Margin: Variable eccentricity.]

This eccentricity, with its anomaly, decreases from greatest to least, indeed to none, over 6 months, and over about another six increases from none to greatest.

[Margin: Period of this anomaly.]

For that reason it is not semi-monthly, nor does it return twice in any month, as in Tycho; it has a half-yearly growth and a half-yearly decline, and so it is annual, and twice a year it dies and rises again. For when the Moon's apogee is at the quadratures, the equations for the whole month are simple, such as they are in the Free anomaly; and there is no eccentricity of the monthly or equating [Æquatorij] point, since the line of the apogee lies in the plane of the Earth's circle of illumination.

[Margin: Empty month.]

Kepler calls that month *Empty* [Vacuus], that is, lacking the monthly equation. But in the following month, when the Sun's quadrature has left the apogee (which is slower than the Sun, since it completes in the order of the signs no more than 6′ 41″ 4‴ a day), some eccentricity of the monthly point begins, and some small perceptible monthly equation, even if the Moon were at the mean apogee, where by the laws of the Free anomaly it ought to lack all equation. As the months succeed one another, the eccentricity of the monthly or equating point grows, and with it the monthly equation, until the line of syzygies, namely when the seventh month from the extinction of the eccentricity has begun, has reached the apogee. In that month the equations become greatest and join themselves to the equations of the Free anomaly, so that at last, at one and the same moment, namely at the Moon's quadratures, both become greatest.

[Margin: Full month.]

And that month is called *Full* [Plenus]. From there they decrease again through as many degrees.

[Margin: Monthly apogee.]

Just as a second eccentricity, called monthly, is given for this anomaly, so also a second apogee and perigee, called monthly, which is always near the Sun's apogee or perigee and on a line parallel to the line of syzygies. This, moreover, is the equation that Ptolemy called the Nod [Annutum] or [Greek: πρόσνευσιν (prosneusin, "inclination")] of the epicycle; the Arabs, the parallax of the epicycle; Copernicus, the prosthaphaeresis of the eccentricity of the second epicycle; and Tycho, the prosthaphaeresis of the eccentricity, all supposing in their hypotheses something optical and geometrical. For Kepler, however, it is purely physical and comes from purely physical causes, as he himself notes on p. 803 of the *Epitome*.

[Margin: 3. Anomaly.]

The *third* inequality and anomaly, which the older authors included in the second and confused with it, is called by Tycho the *Variation*, but by Kepler the *Perpetual Monthly* [Menstrua perpetua], because it returns every month and

is of the same quantity at the same distances of the Moon from the Sun and from the Earth. So it is called monthly on two grounds: because it returns the same every month, and because it is tied to the phases that make up the month. For it depends on the line of syzygies, indeed, but not on the variable eccentricity. It is nil at the syzygies and quadratures, and greatest at the octants, that is, at degrees 45, 135, 225 and 315, counted in the order of the signs from the conjunction of the Moon with the Sun. Because of it the Moon becomes slow twice in the month, namely at each quadrature, and fast twice, namely at each syzygy, and it is the faster the nearer it is to the syzygies.

The place of the Moon equated by the first equation, that of the Free anomaly, is therefore called the true place of the Moon at the syzygies; but outside them it is called the feigned place, or the place first equated. If the Temporary Monthly equation is added to it, it is called the nearly true place, or the place second equated. If finally the Perpetual Monthly equation is added, it is called the true and absolute place of the Moon. But what has been said in summary will be better grasped in the figures that follow. Before them, however, we shall set out in our usual way the measures of the distances and of the greatest equations. For the distances, though, see what was said in chapter 14, number 7.

TRIVM KEPLERI HYPOTHESIVM SYNOPSIS.

Synopsis of Kepler's Three Hypotheses.

Source	Distances	Lines	Radius 100000	Earth's semidiameters, ′
From the *Ephemerides*	Eccentricity, greatest, at conjunction and opposition	☩	6543	3 52′
From the *Ephemerides*	Eccentricity, least, at quadrature	☩	4362	2 36′
From the *Ephemerides*	Distance from the centre of the Earth, at conjunction and opposition, greatest	☩	106543	62 52′
From the *Ephemerides*	Distance from the centre of the Earth, at conjunction and opposition, least	☩	93457	55 8′
From the *Ephemerides*	Distance from the centre of the Earth, at quadrature, greatest	☩	104362	61 36′
From the *Ephemerides*	Distance from the centre of the Earth, at quadrature, least	☩	95638	56 24′
From the *Ephemerides*	Distance from the centre of the Earth, mean	☩	100000	59 0′
In the *Epitome of Astronomy* and the Rudolphine Tables, chapters 25 and 26	Perpetual eccentricity	A B	4362	2 32′
In the *Epitome of Astronomy* and the Rudolphine Tables, chapters 25 and 26	Semidiameter of the ellipse, greater	B D	100000	56 28′
In the *Epitome of Astronomy* and the Rudolphine Tables, chapters 25 and 26	Semidiameter of the ellipse, lesser	B E	99810	
In the *Epitome of Astronomy* and the Rudolphine Tables, chapters 25 and 26	Distance from the centre of the Earth, both at conjunction and opposition and at quadrature, greatest	A P	104362	59 0′

Source	Distances	Lines	Radius 100000	Earth's semidiameters, ′
In the *Epitome of Astronomy* and the Rudolphine Tables, chapters 25 and 26	Distance from the centre of the Earth, both at conjunction and opposition and at quadrature, mean	A E	100000	56 28′
In the *Epitome of Astronomy* and the Rudolphine Tables, chapters 25 and 26	Distance from the centre of the Earth, both at conjunction and opposition and at quadrature, least	A R	95638	53 56′
From the Rudolphine Tables, p. 98	Eccentricity	A B	3486	1 57′
From the Rudolphine Tables, p. 98	Distance from the centre of the Earth, both at conjunction and opposition and at quadrature, greatest	A P	103486	57 54′
From the Rudolphine Tables, p. 98	Distance from the centre of the Earth, both at conjunction and opposition and at quadrature, mean	A E	100000	55 57′
From the Rudolphine Tables, p. 98	Distance from the centre of the Earth, both at conjunction and opposition and at quadrature, least	A R	96514	54 0′

Greatest equation of the Free anomaly, 5° 0′. Of the Temporary Monthly, taken separately from the Free, 2° 30′; compounded with it, 7° 30′. Greatest Variation, 51′ or 49′.

III. Let this now be the first scheme, in which the line of apsides is PR, that is, of the apogee P and the perigee R; and let the semidiameter BP be of 100000 parts, of which AB, the real eccentricity of the centre B from A, the centre of the Earth, is 4362. From B let the circle PDRC be described, and through its centre B let another diameter DC be drawn at right angles. Let A be one of the two points of comparison [ex comparatione], that is, one of the foci or umbilici of the ellipse to be inscribed in the circle already mentioned; the other equally distant from the centre B, be S. For by what Apollonius demonstrated in the *Conics*, if from A or S two points E, V are taken on the diameter DC, at a distance from A or S equal to the semidiameter BP of the circle, the elliptical section will pass through those points; and EV will be the minor diameter, or latus rectum, of the ellipse, and PR the transverse side, or major diameter, or axis. In numbers, you will have BE if from the square of the semidiameter BP, that is AE, you take away the square of the eccentricity AB, assumed as the distance of one focus from the centre of the ellipse: for the square root of the remainder will give the quantity EB, which in this theory is 99810 parts, of which DB is 100000 and DE is 190. To find other points through which the elliptical circumference must pass, let perpendiculars to PR, such as GF and NQ, be drawn from any number of points you please on the circular periphery, say from G and N; with respect to the circle these are called sines, but with respect to the ellipse ordinates [Ordinatim applicatę]. But let the arc which those points bound be given, such as the arc PG, or that of its complement to the semicircle, such as NR. For if you make, as the whole sine DB is to the

minor semidiameter of the ellipse EB, so the sine GF of the given arc GP to HF, or so the sine NQ of the arc NR to OQ, you will have, by what Apollonius demonstrated, the points H and O through which the ellipse passes; and so for the other points. In this way the ellipse PHEMORTKVP can be described.

[Margin: Error in the circle commonly used in place of the ellipse.]

For although Kepler, in chapter 25 of the Rudolphine Tables and on p. 800 of the *Epitome*, says that such great subtlety is not necessary, and therefore uses perfect circles there, asserting that no error greater than 17″ can be committed in the Moon's place, he nevertheless adds the equations he constructed from the elliptical form; and it is better to become used to this from the beginning, if you wish to know exactly the foundations of the Rudolphine calculation. Therefore, with the line of apsides laid down as PR, EV is the line of mean longitudes; and whenever

Diagram. Kepler's lunar ellipse inscribed in a circle, standing in the left column. An outer circle and, just inside it, an ellipse share the vertical line of apsides from P at the top to R at the bottom; the horizontal diameter DC runs through the circle's centre B. A small circle centred on A, the centre of the Earth, passes through B at its top. Two horizontal lines cross the figure below DC, one through A from M to T, and one through Q from N and O to Y. Further lines join A and B to the points G and H at upper left, A to D and E at left, and A to K and L at right; a dotted line runs from B through the small circle towards Y; a line runs from O through A towards K, and through the small circle at Z.

Labels read (all as printed, on the figure):

- P (top): apogee
- G, H (upper left): G on the circle, H on the ellipse
- F (on PR, level with H): foot of the perpendicular
- S (on PR, between F and B): the other focus
- B (centre of the circle)
- D, E (left end of the horizontal diameter): D on the circle, E on the ellipse
- V, C (right end of the horizontal diameter): V on the ellipse, C on the circle
- K, L (right, below C): K on the ellipse, L on the circle
- I (on PR, between B and A)
- A (centre of the Earth)
- M (left), T (right): ends of the line through A
- Z (on the small circle, lower left of A)
- O, N (lower left): O on the ellipse, N on the circle
- Q (on PR, foot of the small circle)
- Y (lower right)
- R (bottom): perigee

Labels not read: none noticed. Show-through from the facing leaf's table lies under the lower half of the figure and was not read as part of it.

the Moon is at apogee P or perigee R, there is no need of an equation; rather, the true place of the lunar apogee or perigee is also the Moon's true place in the zodiac. But whenever it is at the points E or V, the distance EA, etc., of the Moon from the centre of the Earth A is mean, and equal to the major semidiameter BP, and there the physical equation of the eccentric anomaly is greatest. Its measure is the area of the triangle EAB, based on the whole eccentricity AB and having its vertex at the centre of the planet placed at E, reduced to parts of which the area of the whole ellipse is 360°; or the area of the companion triangle DAB, because of its equipollence, of which shortly. In other positions, however, as if the Moon is at H, to which the point G of the circle corresponds, when these points are joined to the centres of the Earth A and of the eccentric B, two equating triangles [Triangula Aequatoria] arise: one, a segment of the elliptical plane, namely HAB, based on the eccentricity AB and having its vertex at the Moon H; the other, a segment of the circular plane, namely GAB, likewise based on AB but ending at G, which nevertheless is equipollent to the triangle HAB, as we shall say. So the physical equation is the area of the triangles already mentioned, and Kepler here uses it alone; the optical equation, however, would be the angle H or G, if it had any use. Moreover, the line EV, passing through the centre of the ellipse, that is its minor diameter, is called by Kepler [Greek: διάκεντρος (diakentros, "through the centre")], or Diacentra; but the line MT parallel to it, passing through the centre A, at which he places the Sun in the hypothesis of the other planets, is called [Greek: διήλιος (diēlios, "through the Sun")], or Dihelia; here, however, since A is the centre of the Earth, it can be called [Greek: διάγειος (diageios, "through the Earth")], or Diagea.

IV. Now let the centre of the eccentric B move in the order of the signs, from B to Z, on the circumference of the small circle BZQ described around the centre of the Earth A at the distance of the eccentricity AB, carrying the apogee P forward, likewise in the order of the signs, with an equal daily motion of 6′ 41″ 4‴, so that it completes its period in 8 Egyptian years $311^{d}\ 6^{h}$. This is granted even though, with respect to the Sun, which moves faster, it may be imagined to move retrograde, and the line of syzygies, in which the Sun lies, overtakes the Moon's apogee after approximately 13½ months. The Moon itself recedes from the apogee P in the order of the signs, and moves on the elliptical periphery PHEO, etc., unequally, by reason of its curvature and of its varying distance from the centre A; although it may be imagined to move equally on the periphery of the circle PGDN, and to advance daily with the simple motion of the eccentric anomaly by 13° 3′ 54″, so that it completes its period in $27^{d}\ 13^{h}\ 18^{m}\ 35^{s}$.

[Margin: What the eccentric anomaly is.]

So let the Moon be at H. The eccentric anomaly will be the arc PH, or by equivalence and denomination the arc PG, which is measured by the angle GBP, namely the one counted in the order of the signs from the apogee P, or line of apsides, up to the place of the Moon, so long as it does not exceed a

semicircle. For if it does exceed one, as if the Moon is at Y, its excess above the semicircle is applied, namely the arc RY; or if it is beyond V, its complement to the circle. The measure of this anomaly is potentially contained in the elliptical area BHP, or by equivalence in the circular area BGP, reduced to degrees, etc.; and it is the one that in the Rudolphine Tables, p. 80, stands in the first column in whole numbers of degrees. The area of the equating triangle HAB, or by equivalence the area GAB, reduced to degrees or minutes, of which the whole area of the ellipse or circle is 360°, is the one that in the same column of the Rudolphine Tables is set, with its minutes, beneath the eccentric anomaly. Added to the eccentric anomaly, it makes up the value of the whole area AHP or AGP, that is, the mean anomaly, which in this hypothesis is the sum of the eccentric anomaly and the physical equation.

[Margin: Coequated anomaly.]

The coequated anomaly, on the other hand, is the angle at the Earth (in the other planets, however, at the Sun) A, made by the line of apsides and by the line drawn through the body and apparent place of the planet in its own orbit, or its complement to 4 right angles. This angle subtends the arc of the zodiac to which the lines already mentioned are understood to be produced, and in which this anomaly is properly counted, beginning from the line of apsides: as in our example, with the Moon placed at H, it is the angle HAP; but with the Moon placed at K, it would be the angle KAP. It shows the planet's true distance from the apogee, and it is the one that in the Rudolphine Table, p. 80, stands in the third column. Its difference from the mean anomaly is the equation, to be subtracted from the mean anomaly itself in the first semicircle PDR and added to it in the second, RCP, so that the planet's true distance from the apogee may be established. So if the true place of the apogee in the zodiac is known, the planet's true place from the equinox in its own orbit will also be known from this; or if the planet's mean place from the equinox was already known, then by adding or subtracting the equation already mentioned, the planet's true place becomes known; and for the Moon this holds at the syzygies, for outside them it will be the feigned place, and only first equated.

V. Three elements therefore [printed ego; recte: ergo] are needed to investigate the equation, in this hypothesis common at least to the Moon's Free anomaly and to the other planets. The *first* is the eccentric anomaly, or arc PG, and this is obtained by subtracting the planet's mean motion from the motion of the apogee already set up in the tables; and it is always as great as the area BGP (for we have already placed the Moon at H) in parts of which the whole area of the circle is 360; so it becomes known with no further device. The *second* is the physical equation of the eccentric anomaly, whose measure is the area of the triangle HAB or GAB. For this we need the eccentricity AB, as given, and the sine of the eccentric anomaly, namely the sine GF of the arc PG; for this sine gives the height of the triangle GAB over the line PAR, and this height is less than the whole sine DB, that is, than the height of the greatest equating triangle. So since they stand on the same base, the triangle

GAB is smaller and is contained in the triangle DAB. Let there therefore be taken within DAB itself the right-angled triangle EAB over BA, equal to GAB; and let EAB be such, with EB assumed by fiction not as the semidiameter of the ellipse but as a line equal

[Margin: Method of finding the physical equation, and by it the mean anomaly.]

to the sine GF. For if the sine GF, that is EB, is multiplied by half the eccentricity AB, the area of the triangle EAB, that is of GAB, will be known. This is reduced to degrees, of which the area of the whole circle is 360, if it is multiplied by 360 and the result is divided by the area of the whole circle; with the radius BD set at 100000 parts, this area is for Kepler 31415926536. He himself, however, on p. 686 of the *Epitome* uses this shortcut. First he finds the area of the greatest triangle DAB by multiplying half the eccentricity by the whole sine; this half in the Moon is 2181, and so the result is 218100000, namely the area of the triangle DAB. This he multiplies by 360°, resolved into seconds, 1296000″, and divides the result by the area of the whole circle, that is by 31415926536; and he finds the greatest physical equation of the eccentric anomaly, that is, the value of the greatest triangle DAB, to be 2° 29′ 57″. Then this value, first resolved into seconds, 8997″, he multiplies by the sine GF of the given arc PG, and divides the result by the whole sine. For the quotient gives the value of the triangle GAH [recte: GAB], that is the physical equation, to be added to the eccentric anomaly in the first semicircle PDR and subtracted in the second, RCP, so as to have the value of the whole area, namely GAP, that is the mean anomaly. So the number of seconds, 8997″, will always be useful.

The *third* is the angle GAP, or HAP, for which we need either the sides of the right-angled triangle, namely GAF, or the base GA, that is the planet's distance from A, and one of the sides. But the distance itself is gathered in two ways. The first of these is by the sides themselves about the right angle: for in the triangle GFA, right-angled at F, there is given BF, the second sine of the given arc PG, which, joined to the eccentricity AB, makes the side AF; with this and with the first sine GF of the same arc PG you will find trigonometrically the distance GA, in parts of which the sides GF and FA are known. But if you wish to work more accurately, first make, as DB the whole sine is to EB the minor semidiameter of the ellipse, so GF the sine of the arc PG to HF; with this side and AF you will find the most exact distance HA. But if the planet were below the Diacentra EV, yet above the Dihelia or Diagea MAT, say at K, the distance KA is to be sought in the right-angled triangle KIA, in which the side AI is obtained by subtracting from the eccentricity AB the second sine BI of the arc RL, known from the eccentric anomaly; and the side IL is the first sine of the same arc, which, if it is made to KI as DB to EB, will give the other side IK. If finally the planet is below the Dihelia or Diagea, as at O, the distance OA will be investigated in the right-angled triangle OQA, in which, from the sine NQ of the arc NR, which completes the anomaly PDN, the side

AQ will become known as above, by subtracting the eccentricity AB from BQ, the second sine of the arc NR.

[Margin: What Libration is, and the method of finding the planet's distance.]

Now the difference between the mean distance AE and any other, say AH or AO, Kepler on p. 679 of the *Epitome* calls the Libration, because, as in the motion of scale-pans, it is slow at the beginning and at the end, when the planet is most distant from A or nearest to it, but fast in the middle. By means of it, on p. 682, he seeks the planet's distance; for he says that when the second sine BF of the given arc PG is multiplied by the eccentricity AB and the result is divided by the whole sine, the Libration comes out, to be added to the mean distance in the upper semicircle, which is above the Diacentra, but to be taken away in the lower, so as to have the planet's distance from A. With the planet's distance obtained, then, as the base of a right-angled triangle, namely GA of the triangle GAF, and with one of the sides, namely GF or FA, the angle at A, namely the coequated anomaly, is easily found by trigonometry. Kepler, however, on p. 690 of the *Epitome* uses the base GA and the side FA, found as above; this he multiplies by the whole sine, and when the result is divided by the distance GA, the quotient gives the sine of the angle FGA, whose complement to a right angle is the angle GAF, that is the planet's coequated anomaly. Its difference from the mean anomaly is the equation of the place or mean motion of the planet, computed from the equinox. Without this, however, if the true place of the apogee is known, the coequated anomaly itself, that is the planet's true distance from the apogee, will show the planet's true place, by adding it to the place of the apogee. And what has been said so far applies to the five minor planets and to the Moon as Free, or indeed as Monthly but enjoying the greatest eccentricity, that is, when the centre of the eccentric B is on the line of syzygies: for these the scheme of number III serves.

VI. But if the centre of the eccentric, because of the faster motion of the Sun than of the lunar apogee, has receded from the line of syzygies, then, in order that the Monthly eccentricity and its variation, and the monthly point, and the monthly apogee, and the manner of the monthly equation may be understood, let there be a second scheme, in which A is the centre of the Earth; B the centre of the eccentric PDRC; PR the line of apsides of the Moon as Free, on which let P be the apogee and R

Diagram. The second scheme of Kepler's lunar hypothesis, standing at the head of the right column. A large circle carries H and M at the top, P at upper right, D at upper left, O at left, Q at right, S and T at the ends of a horizontal line lower down, R at lower left, K and N at the bottom and C at lower right. A small circle at the centre, about A, has its lower half hatched. A middle circle about A passes through B at its upper right. Two near-vertical lines run down from H and from M; the horizontal line OQ passes through G and B, and the line ST through X, A and I. Oblique lines join P through B and A towards R, D through B towards C, and O and D to points near A and C. A short dotted vertical line drops from near L to X.

Labels read (as printed, on the figure):
- H, M (top)
- D (upper left), E and F (on the short line running right from D)
- P (upper right)
- V, B, L (on or near the middle circle, upper part)
- O (left), G (on the line from O), Q (right)
- S (left), β (between S and X), X, A (centre), I, T (right)
- an R-shaped sort (a small bowl at the top and a long leg sweeping down to the right), right of I [?]
- a looped sort (a closed loop at lower left rising to an open hook at the top), below right of I [?]
- C (lower right)
- a sort in the shape of the sign of Aries (♈) on the middle circle, lower left, and Y on the vertical line below A
- R (lower left), K and N (bottom)

Labels not read: none noticed; show-through from the facing leaf lies behind the figure and was not read as part of it. The two flagged sorts are given as seen; the prose of this page names only one Y.

the perigee; and let DBC, drawn at right angles to it through B, be the line of mean longitudes. Let the hemisphere of the Earth in which A stands be nocturnal, and the rest diurnal; and let XI be the diameter of the circle of illumination separating these hemispheres. Produced to the periphery of the eccentric, it becomes the line ST; and let it be called the line of terrestrial illumination.

[Margin: What the line of illumination is.]

To this let OBQ be drawn parallel through the centre of the eccentric, and let it be called the boundary of the new and variable eccentricity. The line HAK, perpendicular to both and drawn through the centre of the Earth, serves as the line of syzygies, in which the Sun is at H, where conjunction occurs, and its opposite K, at which the Moon's opposition occurs; and the same line is the line of the monthly apogee, on which are the monthly eccentricity and the centre of the new eccentricity, deputy of the centre of the Earth, or the monthly equating point.

[Margin: Which is the monthly eccentricity, and what it is.]

In this scheme, however, the temporary monthly eccentricity is AG, and its centre is G. This eccentricity is not that of the centre of the eccentric B, that is AB, always the same; it is that of the whole semicircle of the eccentric divided in two by the line OGQ, that is, by the parallel to the line of illumination drawn through the centre of the eccentric. For the distance of this semicircle from the plane of the circle of illumination is called the Monthly and variable eccentricity, according to the variation in quantity of the line GA.

[Margin: What the monthly apogee is, and which is its line.]

Just as the perpetual eccentricity AB, produced beyond the centre B to the periphery of the eccentric, marks on it the point P, the apogee of the Free

anomaly, whose opposite R is the perigee, so the monthly eccentricity AG, produced beyond G, the centre of the monthly eccentricity, to the periphery, marks at H the monthly apogee, whose opposite K is the monthly perigee; and the line AH is called the line of the monthly apogee. It is always in the greater part of the eccentric divided by the line of illumination; but the line AK is the line of the monthly perigee, and it is in the lesser part of the eccentric.

VII. Eight cases must be noted, however, for which Kepler gives eight schemes in chapter 25 of the Rudolphine Tables; but for us these two will suffice. Of these eight cases, four are more notable, because of the four cardinal points of this eccentricity and monthly anomaly.

[Margin: When and where the Full month and the greatest monthly equation occur.]

For if the centre of the eccentric B is on the line of syzygies, so that PR, which is the line of apsides of the Free anomaly, becomes the line of syzygies and coincides with HK, with the centre B situated either at V or at Y, then the line of mean longitudes is parallel to the line of illumination, as in the earlier scheme, and the greatest eccentricity is the line AV or AY, and therefore equal to the Free eccentricity AB, that is of 4362 parts, of which BP is 100000. And then the month is called Full, because then the physical equation is the greatest among the monthly ones, and the same point performs a double office, namely of the centre of the eccentric and of the monthly equating point; and AV or AY that of a double eccentricity. But of these two cases, either the centre B is at V, and then the new Moon occurs in both apogees at P, coinciding with H, and the full Moon in the perigee at R, coinciding with K, without any sensible equation; and the quadratures occur in the mean longitudes at D and C of the earlier scheme, coinciding with OQ as regards the mean quadratures, for the true ones occur on the line of illumination MT of the earlier scheme, or at ST of the later. At these quadratures occurs the greatest equation of both the Free and the monthly anomaly, and the value of the greatest equating triangle ADB of the earlier scheme is doubled. The equation of the Free anomaly, compounded of the physical and the optical, is 5°, and the physical by itself is 2° 30′; so that when this is compounded, the greatest equation then becomes 7° 30′. The same things happen if the centre B is at Y, but then the new Moon occurs in the perigee of both the Free and the monthly anomaly, and the full Moon in both apogees. These are the two cases of the Full month, because in that month twice, namely at the quadratures, at the mean longitudes, the greatest equations of all occur; and throughout that month the monthly equations, compared with the monthly equations of other months, are greatest, inasmuch as throughout that month the Moon's apogee does not move perceptibly away from the line of syzygies except after many days.

[Margin: When and where the Empty month and zero eccentricity occur.]

VIII. If, on the other hand, the centre B comes to Z or β, the points of the line of illumination, so that the line of illumination ST becomes the line of apsides RP of the Free anomaly and divides the eccentric in two, then the line that

ought to be the limit of the monthly eccentricity, such as OGQ drawn through the centre of the eccentric, is not merely parallel to the line of illumination ST but actually coincides with it. There is therefore no eccentricity, since the monthly point G is extinguished in the centre of the Earth A; and then, though only at the one moment at which this happens, the month is empty of all monthly equation, even at the quadratures, because these occur on the line of illumination. One of the quadratures falls in the apogee, the other in the perigee, while the syzygies occur at the mean longitudes.

[Margin: Where the Variation is greatest, where it is zero?]

But both in these two cases and in the two earlier ones, the third anomaly, which is called the Variation, is not extinguished unless the Moon is placed in the syzygies or in the quadratures; it is greatest in the octants. The remaining four cases occur when there is some monthly equation and eccentricity intermediate between none and the greatest: for instance if the centre of the eccentric is at B or at δ, where the apogee P of the Free anomaly precedes the monthly apogee H, or at L or γ, where it follows. Now although the Moon runs through the whole periphery of the eccentric in any month, the Sun, or the line of syzygies, does not move away from the apogee of the Free anomaly so as to return to the same place except in almost 13½ months. In this chart the line of syzygies HK is imagined as immobile, on which supposition the motion of the centre of the eccentric and of the apogee of the Free anomaly must be imagined as retrograde. But if the line of syzygies is supposed to move in the order of the signs with the Sun, it will spend 6¼ months going from V, the point of greatest eccentricity, to β, the point of no eccentricity, and then as many months to Y, the other point of greatest eccentricity; and so the anomaly from V to β is half-yearly, and from V to Y about annual.

Diagram. The lunar eccentric with its monthly eccentricity, set in the left column. A large outer circle (the eccentric) has its centre at B. The vertical line HK passes through H at the top, E, V, G, the Earth's centre A and Y to K at the foot; a parallel vertical MN passes through B and I. A horizontal OQ runs through B, and a horizontal ST through A, carrying β, X, A, I and Z. A middle circle about A carries V at its top, L upper left, B upper right, β at left, Z at right, γ lower left, δ lower right and Y at its foot. A small circle about A, half hatched, stands for the Earth. Straight lines join D to F (horizontally, crossing HK at E), P through B and A to R, and various points to C at lower right and to D; a dotted vertical drops from the line through L towards ST.

- H (top, left of centre) · M (top, right of H)
- E, F (on the horizontal from D, upper centre)
- D (outer circle, upper left) · P (outer circle, upper right)
- V, G (on the vertical through A) · B (centre of the outer circle) · L (middle circle, upper left)
- O, Q (ends of the horizontal through B) · S, T (ends of the horizontal through A)
- β, X, A, I, Z (on ST; the last is cut as ζ or an italic Z)

- γ, δ (middle circle, lower part; δ is a looped sort) · Y (foot of the vertical through A)

IX. Let us now come to those monthly equations that are not the greatest, which are purely physical, for the greatest monthly equation is equal to the greatest physical equation of the Free anomaly, that is 2° 30′.

[Margin: Method of finding the monthly equation.]

Let it be, as in our scheme, that the centre of the eccentric is at B, and the rest as above, so that the eccentricity is AG, and the distance of the Sun, as of the monthly apogee H, from the apogee P of the Free anomaly, reckoned in the order of the signs on the ecliptic, is the angle HAP, since the ecliptic is understood to be described from the centre of the Earth. But so that it may be reckoned on the periphery of the lunar eccentric, let a straight line MN be drawn through its centre B, parallel to HK; for by Euclid I.29 the angle MBP will be equal to the angle HAP, and therefore the arc MP, measured by the angle MBP, will be the distance of the Sun from the apogee of the Free anomaly, but numbered on the Moon's eccentric. From this, moreover, there will arise BI, equal to the monthly eccentricity AG. Now let the Moon be at D, and AD the line of the Moon's first-equated place; for by the steps of the following precepts you will arrive at the monthly equation for that moment [Æquationem menstruam temporaneam], and at the Moon's nearly true place.

[Margin: 1st precept: on the anomaly of the eccentric and the monthly argument.]

First. Find the place of the apogee P of the Free Moon, the place of the Sun, set at H or at K, and the Moon's place at D, first-equated with the equated anomaly according to the precepts given in no. 5. In this way the anomaly of the eccentric, or arc DP, will be known, and also the distance of the Sun, or of the opposite place H, from the apogee of the Free anomaly, namely arc MP, which the angle MBP, equal to angle HAP, measures. When this distance is subtracted from the anomaly of the eccentric, the monthly argument remains, namely arc DM; for the monthly argument of longitude is the arc between the Moon's first-equated place and the parallel to the line of the monthly apogee, drawn out towards the same side on which the monthly apogee lies. *So let DMP, for example, be 81° 42′ 24″ and MP 36°; for when the latter is subtracted from the former, there will remain DM, the monthly argument, 45° 42′ 24″. The anomaly first equated, moreover, will be 77° 18′ 30″; and let the Moon's apogee be at 24° Aries and the Sun at the beginning of Gemini.*

[Margin: 2nd precept: on the monthly eccentricity.]

Second. In the right-angled triangle GAB, find the monthly eccentricity AG by means of trigonometry: for in it the base AB is given, namely the whole eccentricity, of 4362 parts, and the angle GAB, equal to the angle MBP, and as

large as the distance of the Sun from the apogee of the Free anomaly, already known by precept 1. *In our example this was 36°. With these given, AG comes out as 3529 parts, of which AB is 4362, or BP 100000; and BI is also that much.*

[Margin: 3rd precept: on the area of the greatest triangle of such a month.]

Third. When IQ or IO has been drawn, there arises the greatest equating triangle of that month and moment, BIQ or BIO. You will find its area if you multiply half the monthly eccentricity, taken on the line BI, by the whole sine BQ. *In our example, half of the monthly eccentricity BI, of 3529 parts, is 1764½, and this multiplied by 100000 makes the area of the greatest triangle in such a month 176450000 square parts.*

[Margin: 4th precept: on the area of the greatest triangle in the Full month.]

Fourth. Have to hand the area of the greatest triangle in the Full month, such as is the triangle DBA in the earlier scheme, for it will always be useful in the other cases. *It is of 218100000 parts; for half the whole eccentricity AB, which is 2181, multiplied into the whole sine 100000, amounts to such an area.* Let this area now be valued at 60 minutes.

[Margin: 5th precept: on the monthly minutes.]

Fifth. Multiply by 60 the area of the greatest triangle treated in precept 3, and divide the result by the area of the greatest triangle in the Full month, and the monthly minutes of longitude [Scrupula menstrua longitudinis] will come out. *So in our example the area 176450000 multiplied by 60 makes 10587000000; and when this is divided by the area 218100000, there remain monthly minutes 48′ 33″.*

[Margin: 6th precept: on the area of the monthly equating triangle and its value.]

Sixth. Since the Moon is at D, drop the perpendicular DF from it to the diameter of the eccentric; this will be the sine of the monthly argument treated in precept 1. Look up its sine in the tables of sines. Then join the Moon D by straight lines to the four points A, G, I, B; for there will arise the triangle of the physical monthly equation, containing that equation in its area, which will be DAG, being based on the monthly eccentricity AG. But because the area of this triangle cannot be found by means of the sine DF, and one would need to know its portion DE, the companion triangle DBI is taken, which here is somewhat larger. Find its area, and its value in minutes proportional to the area of the greatest triangle in this month, as follows. Multiply the sine DF of the monthly argument by the monthly minutes treated in precept 5, reduced to seconds, and divide the result by the whole sine, and there will remain the proportional minutes of the equating triangle DBI. Then multiply these by the greatest physical equation of the Full month, which is 2° 30′, and divide the result by the value of the greatest triangle in the Full month, reckoned as 60, first reducing both this and the 2° 30′ to seconds; for the quotient will give the area and value sought, namely the physical monthly equation, which must however be corrected, as below, by the exempt particle [particulam exortem]. *So in our example the monthly argument was 45° 42′ 24″, whose sine 71577, multiplied*

by the monthly minutes 48′ 33″, that is by 2913″, makes 20850380l. When this is divided by 100000, there remain minutes 2085″. These multiplied by 2° 30′, that is by 9000″, make 18765000″; and when this is divided by 60′, that is by 3600″, there remain 5212″, that is 1° 26′ 52″. This, then, is the monthly equation, but it needs a slight correction.

[Margin: 7th precept: on the correction of the equation by the exempt particle.]

Seventh. Correct the monthly equation found in precept 6 by the exempt particle and its value, which is nothing other than the difference between the companion triangle, here DBI, and the truly equating triangle DAG. This is to be subtracted when the latter is smaller than the companion triangle, that is, when the Moon is in the semicircle in which the perigee of the Free anomaly lies, as in our case, in which the Moon D is in the semicircle MDN, in which R, the perigee of the Free anomaly, lies. For the semicircle is here bounded by the line parallel to the line of syzygies HK. But the value of the exempt particle must be added when the companion triangle is smaller than the truly equating triangle, that is, when the Moon is in the monthly semicircle in which the apogee of the Free anomaly lies: as if the Moon were at C, the truly equating triangle would be CAG, greater than the companion triangle CBI, and in the semicircle MCN would lie the apogee P of the Free anomaly.

Now the exempt particle can be found in many ways, but for brevity it is convenient to take in its place the uncia, or twelfth part, of the Variation, of which I shall speak shortly, to which it is very nearly equal, as Kepler says on p. 805 of the *Epitome of Copernican Astronomy*; especially since it could also be omitted because of its smallness, as is noted in the same place. For if the greatest Variation does not, for Kepler, exceed 5l′ or 49′, then the exempt particle, a twelfth of it, certainly does not exceed 4′ 15″ or 4′ 5″, and will very often be less.

[Margin: 8th precept: on the anomaly second coequated, and the Moon's nearly true place.]

Eighth. Add the monthly equation treated in precept 7 to the anomaly first coequated in the semicircle HDK, reckoned from the monthly apogee in the order of the signs; but in the other semicircle KCH, if the Moon were at C, subtract it. The anomaly second coequated will come out, or the distance of the Moon D from the apogee of the Free anomaly; and from its place in the zodiac you will learn the Moon's second-equated place, or nearly true place, and also its nearly true elongation from the Sun H. *So in our example of precept 1 the anomaly first equated was 77° 18′ 30″; if you add to this the equation of 1° 26′ 52″, treated in precept 6, the anomaly second equated becomes 78° 45′ 22″. And the Moon's apogee was at 24° Aries and the Sun at the beginning of Gemini. Therefore the nearly true place of the Moon D is Cancer 12° 45′ 22″, and the nearly true elongation from the Sun 42° 45′ 22″.*

[Margin: 9th precept: on the Variation and its use.]

Ninth. Find the Variation, or perpetual monthly equation, by multiplying the sine of the doubled nearly true elongation of the Moon from the Sun by the

greatest Variation, either Tycho's 40′ 30″ or Kepler's 51′ or 49′, and dividing the result by the whole sine. *So since the elongation by precept 8 was 42° 45′ 22″, doubled it is 85° 30′ 44″, whose sine is 99693; this multiplied by 51 gives 5084343. When this is divided by 100000, there remain 50′ 84/100, or 50′ 45″, for the Variation.* This Variation is added when the Moon is in the first or in the third quadrant, numbered in the order of the signs from the preceding new Moon, but in the second and fourth it is subtracted from the Moon's nearly true place, and the Moon's absolute and third-equated place results; if, however, you have subtracted the twelfth part of the Variation, which here is 4′ 15″, as the exempt particle, from the monthly equation for that moment, according to what was said in precept 7. *So from the Moon's nearly true place, which was Cancer 12° 45′ 22″, with 4′ 15″ subtracted but 50′ 45″ added, that is with 46′ 30″ added, the Moon's absolute place becomes Cancer 13° 31′ 52″.*

[Margin: Properties of the ellipse.]

X. Moreover, since in the above precepts Kepler relies on certain properties of the elliptical plane, partly demonstrated by Apollonius in the *Conics* and partly by himself in Book 5 of the *Epitome of Copernican Astronomy*, and indicated in chapter 20 of the Rudolphine Tables, it will not be out of place here to indicate them summarily, repeating here the figure of no. 3 and the explanation given there. They are these.

[Margin: 1st property of the ellipse.]

1. *If an ellipse is inscribed in a circle, the elliptical periphery cuts in the same ratio the ordinates applied to the major diameter of the ellipse and drawn from the periphery of the circle;* therefore, as DB is to EB, so is GF to HF, and NQ to OQ, and LI to KI, etc.

[Margin: 2nd property.]

2. *The major semidiameter of an ellipse, drawn from the extremities of the ellipse's minor diameter to the major diameter, marks on it by comparison two points equally distant from the centre of the ellipse, which are now called the foci or umbilici of the ellipse.* So if from E or V you draw to A or to S a straight line EA or VA, equal to BP, A and S will be the foci of the ellipse PERVP, and AB will be equal to SB.

[Margin: 3rd property.]

3. *Any two straight lines drawn from one point of the elliptical circumference to the foci of the ellipse are, taken together, equal to the major diameter of the ellipse; and to the same are equal two lines drawn from one of the foci to points of the ellipse opposite through the centre.* Thus the straight lines drawn from H to S and to A, and likewise the straight lines drawn from A to H and to the opposite point Y, are equal to the diameter PR; for H and Y are opposite through the centre, since the straight line HY, drawn to those points, passes through the centre B.

[Margin: 4th property.]

4. *If the planet's eccentricity is equal to the distance of either focus from the centre of the ellipse, the planet's path on the circumference of the ellipse will agree*

with the observed intervals and motions. For if the eccentricity is equal to the distance AB, its greatest distance from the centre A will be the line AP, with the apogee or aphelion at P; its least AR, with the perigee or perihelion at R; their difference AB; and the mean distance AE, at the points a quadrant distant from the extremes P and R. It is established, moreover, that at these points a quadrant distant from the highest and lowest apsis the planets are at a mean distance from the centre A, namely from the Earth in the case of the Moon and from the Sun in the case of the other planets, and that there they take on the greatest equations of their motions.

[Margin: 5th property.]

5. *The eccentricity of the centre of the ellipse from the foci is the mean proportional between the major diameter and the excess of the major diameter of the ellipse over the minor.* Kepler, p. 662 of the *Epitome*. So here AB is the mean proportional between DC and DE doubled. But the minor semidiameter EB is more easily had in numbers, if the square of the given eccentricity AB is taken from the square of the major semidiameter AE; for there will remain a square whose root will be EB.

[Margin: 6th property.]

6. *Ordinates applied to the major diameter of the ellipse cut both the ellipse and the circle circumscribed about it into proportional arcs and areas.* Kepler, p. 663 of the *Epitome*. Thus as the arc PG is to the arc GD, so is PH to HE; and as PG is to PH, so is GD to HE; likewise as GH is to HF, so is the area of the segment PGF to the area of the segment PHF; and as BD is to EB, so is the area of the quadrant PBD to the area of the elliptical quadrant PBE, and the area of the semicircle PDRBP to the area of the semi-ellipse PERBP. From this he concludes that the most exact measure of a planet's delay in elliptical arcs lies in the area of the elliptical segment comprised by the arc of the ellipse traversed and by the straight lines drawn to the extremes of this arc from the centre that moves the planet, that is, from the Earth A, which moves the Moon, or from the Sun A, which moves the other planets; and so the planet's delay in the arc PH is measured by the area of the segment HAP.

Diagram. The ellipse inscribed in its circumscribed circle, set in the right column. The vertical major axis PR runs through P at the top, F, S, B, I, A and Q to R at the foot, with the centre of the circle at B. A horizontal through B runs from D on the circle through E on the ellipse to V on the ellipse and C on the circle. Horizontal ordinates cross the axis: G on the circle and H on the ellipse above F; N on the circle and O on the ellipse below, at Q; and on the right K on the ellipse and L on the circle, level with I. A small circle or oval surrounds A. Lines radiate from A, among them to H, to E, to L, to T on the right, to M and O on the left and to Y at lower right; a dotted line runs from B through to Y, and four lines run down from G and H towards B and A.

- P (top) · R (foot)

- G, H (upper left, on circle and ellipse) · F, S (on the axis, upper part)
- D, E (left end of the horizontal through B) · B (centre) · V, C (right end of the same)
- I (on the axis below B) · K, L (right, level with I)
- M (left, level with A) · A (axis) · T (right, just below L)
- a sort like Z or ζ, left of the axis below A · O, N (lower left) · Q (on the axis) · Y (lower right)

Labels not read: none noticed. M, T and the Z-like sort stand on the block and are not cited in the text of this page.

[Margin: 7th property.]

7. *The plane of the circle circumscribing the ellipse, together with its areas, is equivalent to the plane of the ellipse and its areas, in measuring the delays of the planet in the arcs completed.* Kepler, p. 671 of the *Epitome*. For by property 6, as the area PDR is to the area PER, so is the area PGA to the area PHA, or PDA to PEA; and by permutation, as PER is to PHA or to PEA, so is PDR to PGA or PDA. And as the semiperiodic time which the planet spends on the semicircumference PER is to the time it spends on PH or on PE, so is the area PER to the area PHA or PEA. Therefore, as the half-time of the arc PER is to the time of the arc PH or PE, so is the area PDR to the area PGA or PDA. In these segments of the circular plane, therefore, there is an exact measure of the planet's delay in the arcs of the ellipse; and those segments become known by means of sines, as we taught above in the precepts.

Indicatur Hypothesis P. Alberti Curtij Societatis Iesu.

The hypothesis of Father Albert Curtz of the Society of Jesus is indicated.

XI. Kepler himself indicates this hypothesis in chapter 25 of the Rudolphine Tables in these words: *There arises also a fifth hypothesis, that of Father Albert Curtz, S.J., my Uranian friend, one of the most beautiful ingenuity, which, while it leaves me the balance for forming the elliptical path, nevertheless snatches away the lever; that is, it transfers the area of the triangle to the Ptolemaic equating point, one of the foci of the ellipse, around which the mean anomaly is ordered by equal angles; but which in its effect on longitude, which we are considering here, coincides entirely with the Ptolemaic equant.* It therefore doubles the eccentricity AB, so that AS in the preceding scheme is of 8724 parts, of which AB is 4362 and BP 100000. You have a specimen of this equant in Book 3, chapters 22 and 23.

Indicatur Hypothesis Dauidis Fabricij.

The hypothesis of David Fabricius is indicated.

XII. The same Kepler touches on this one also in a few words in the *Epitome of Copernican Astronomy*, p. 673, and in chapter 20 of the Rudolphine Tables, where he admits that the elliptical orbit of a planet can be produced by a composition of circles, and that Fabricius attempted this using the Ptolemaic

apparatus, namely by the motion of a small circle, regular around a centre not its own, that is, in reality unequal; or rather by two small circles, which would make the centre of the eccentric librate on the transverse or shorter diameter of the ellipse, and with a single libration indeed, but one requiring contrary motions of two equal circles; and that at the same time he so made the apsides librate that, by a count begun from the highest apsis and carried to the body of the planet, he measured the time on the periphery of the eccentric. But Kepler adds that he obtained neither pure uniformity of the motions nor complete precision, nor any saving of labour, and that he renounced physical causes of the motions.

Ismaelis Bullialdi Hypothesis.

The hypothesis of Ismaël Boulliau.

XIII. The ingenuity of this author can be seen in this hypothesis of the Moon, which he attempts to explain in Book 3 of the *Astronomia Philolaica*, especially in chapters 1, 10, 11, 12 and 14. It has two parts: one deals with the suppositions of the lunar motions and their threefold inequality and measure, the other with the exposition of the scheme by which the Moon, carried in an ellipse by the Earth's annual motion, undergoes those three anomalies. The first and simple one he calls *Periodic*, depending on the line of apsides and the Moon's departure from it. This anomaly is completed in about $27^{d}\ 13^{h}\ 12^{m}$, and for Boulliau it is partly optical, arising from the real eccentricity of the centre of the ellipse from the centre of the Earth, and partly physical, because of the unequal and real delays or accelerations of the motion made in equal arcs of the elliptical periphery, a periphery which he had shown in Book 1, chapter 20, to be equivalent to infinitely many equating small circles. The second he calls *Synodic*, depending on the Moon's digression from the synodic line or line of syzygies, which of course passes through the centres of the Sun and the Earth. The third, Tycho's *Variation*, he himself calls the *Reflection of the Apogee*. The first, indeed, has its origin from the Moon's own periodic motion and the position of the apogee under the zodiac; the second and third he calls monthly, and he attributes their cause to the translation of the lunar system, carried out by the Earth as it moves with annual motion in its ellipse, by virtue of which the centre of the lunar ellipse acquires a new and real eccentricity; and for that reason the second and third inequality is immediately optical, but mediately from a physical cause. So, to set out this hypothesis more clearly, we shall first state the suppositions and measures, and then present the schemes and their function in these anomalies.

[Margin: Suppositions of the first inequality.]

XIV. As for the first. As observations establish, the Moon in every true syzygy needs no equation; but in every mean syzygy it needs a single and simple equation, unless it is in the apogee or perigee, or on the line of apsides: for then it lacks every inequality, first as well as second and third, and the mean

and true place coincide. In the month in which the new or full Moon occurs on the line of apsides, the quadratures occur in the mean longitudes, or at about degrees 90 and 270 of the Periodic anomaly, and in such quadratures occur the greatest equations of the first inequality; and they are, by themselves, 5° 0′. But if the new and full Moon occur in the mean longitudes, or near 90° and 270° of the periodic anomaly, the quadratures occur on the line of apsides, one in the apogee and the other in the perigee, or very nearly; and the Moon then lacks sensible periodic inequality indeed, but not all synodic inequality, and sometimes needs some monthly equation. The beginning of the Periodic anomaly is the Moon's apogee, and from there to the perigee, throughout the first semicircle, its prosthaphaereses are subtractive; but from the perigee to the apogee, in the second semicircle, they are additive, if you wish to derive the true and apparent motion from the mean.

[Margin: Suppositions of the 2nd inequality.]

As for the second inequality, as is evident from observations: when the new or full Moon occurs in the apogee or perigee, or at 0° or 180° of the Periodic anomaly, or when the synodic line agrees with the line of apsides, at that moment there is indeed no first or second inequality; yet in that month the quadratures occur at the mean longitudes, or at degrees 90 and 270 of the Periodic anomaly, and at these quadratures occur the greatest equations, both Periodic, 5°, and Synodic, 2° 30′, so that compounded they are 7° 30′. For the Moon's place then observed does not agree with the place derived from the tables, even when corrected by the equation of 5°, but differs from it by 2° 30′. Boulliau confirms this by an observation of the Moon in conjunction with Aldebaran near quadrature and at degree 261° 11′ of the anomaly, from which greatest equation he also derives the eccentricity of the lunar orbit as of 4362 parts, as we shall say later. On the other hand, when the synodic line falls in the mean longitudes, or when the new and full Moon occur one at 90° and the other at 270° of the Periodic anomaly, and thus the quadratures occur at the apogee and perigee, throughout that month there is almost no second inequality, but still some, and greater and greater in the succeeding months. Moreover, the beginning of the second inequality, from which it begins to grow, is the mean longitude with which the synodic line lies, or 270° of the Periodic anomaly: for as the synodic line recedes from there, the second inequality begins to grow, and it grows until the synodic line reaches the apogee; and from there it decreases to 90° of the Periodic anomaly, where it is extinguished. In this semicircle of the monthly anomaly, from conjunction to opposition, the monthly equation is subtractive. Then from degree 90 the second inequality begins to grow again up to the perigee of the Periodic anomaly, with which the synodic line is joined; and from there it decreases to 270°, where it vanishes again. In this semicircle of the monthly anomaly, from conjunction to opposition, the monthly equation is additive. Hence it comes about that in every true syzygy both equations are nil; in quadrature they are greatest; and in the first quadrant of the Periodic anomaly both are

subtractive, and in the 3rd both additive; but in the 2nd the first is subtractive and the second additive; in the 4th the first additive, the second subtractive. Now since the Moon completes a synodic month in about $29^{d}\ 12^{h}\ 44^{m}$, and daily is elongated from the Sun by mean motion 12° 11′ 26″ 41½‴, while it moves from its apogee daily by mean motion 13° 3′ 54″, and the Moon's motion exceeds the motion of the line of syzygies daily by 52′ 27″, it is elongated from that same line by just as much:

and therefore, when the synodic line falls on the first of the mean longitudes, there are almost no additive equations of the second inequality; but on the second of the mean longitudes, no subtractive ones.

[Margin: Suppositions of the 3rd inequality.]

As for the third inequality, although Boulliau in the end subscribes to Tycho, and for the time being, until a greater light shines from experiment, admits that the greatest Variation is 40′ 30″, and that it reaches that size in the octants, in such a way that from the new Moon to the first quadrature and from the full Moon to the second quadrature it is to be added to the Moon's mean motion, but from the first quadrature to opposition and from quadrature 2 to conjunction it is to be subtracted, he nevertheless calls it into doubt because of 24 observations made in the octants counted from conjunction, when the Moon stood 90° on either side of the Periodic apogee. For he found that it is neither always greatest precisely in the octants, nor always 40′ 30″, but sometimes nearly 57′ and sometimes only 23′; from this he conjectures that the Tychonists, being in doubt, chose the middle value, namely 40′ 30″. Whether this Variation itself is anomalous, however, and undergoes some fourth inequality, he does not determine. But he admits that he tried without success to refer this apparent anomaly of the Variation to the motion of libration, by which the lunar spots appear now nearer to, now farther from, the edge: say the *Caspian* to the western edge and the *Lake of Posidonius* [Lacus Possidonij] to the eastern. And he urges those who possess the journals of the Tychonic observations to compare a great many observations made on successive days, and so to see whether this inequality lasts through some months, and when it recurs. Finally, to Wendelen's assertion that *the Moon's equations in the octants are equal to one another both above and below the mean longitudes*, he says that some of his own observations agree, provided however that the equation of natural days is admitted, which Wendelen does not admit.

XV. Now let us come to the diagrams of Boulliau's theory, first setting out, from our chapter 14 and from what he posits in Book 3, the measures of the distances, as in the following small table.

BVLLIALDICÆ HYPOTHESEOS SYNOPSIS.

Synopsis of Boulliau's hypothesis.

Distances	Lines	Radius 100000	Semidiameters of the Earth
Semidiameter of the ellipse: major	AC	100000	59 5′

Distances	Lines	Radius 100000	Semidiameters of the Earth
Semidiameter of the ellipse: minor	BC	99810	58 55′
Eccentricity from the Earth: greatest, in fig. 2	TXC	8724	5 10′
Eccentricity from the Earth: least, in fig. 1	TC	4362	2 35′
Distance from the centre of the Earth at conjunction and opposition: greatest	TA	104362	61 40′
Distance from the centre of the Earth at conjunction and opposition: mean	TB	100000	59 5′
Distance from the centre of the Earth at conjunction and opposition: least	TP	95638	56 30′
Distance from the centre of the Earth at quadrature: greatest	TVA	108724	64 15′
Distance from the centre of the Earth at quadrature: mean		100000	59 5′
Distance from the centre of the Earth at quadrature: least	TP	91276	53 55′

Greatest equation: Periodic 5°; Synodic 2° 30′; compound 7° 30′. Variation or Reflection: mean 40′ 30″; greatest 57′; least 24′, in the limits.

Let there now be two figures, the former for the syzygies, the latter for the quadratures, for from these the rest can be understood. In them let AP be the line of apsides and axis, or major diameter of the ellipse, of 200000 parts, in which A is the apogee and P the perigee; and let BD be the Diacentra [Diacentros], or minor diameter of the ellipse, whose half BC is 99810 of the parts of which AC is 100000. Let C be the centre of the ellipse and V the umbilicus, and let their distance CV be of 4362 parts. But let T be the centre of the Earth, with which the umbilicus is united in the syzygies; and therefore let VC be the least eccentricity, 4362. In such a case let the line of the mean longitudes, or the parallel to the Diacentra drawn through the umbilicus, namely MVN, coincide with the Diagea FTG, which of course is parallel to the Diacentra and drawn through the centre of the Earth. For thus in the syzygies the line BT or DT will be the mean longitude, taken for the Moon's mean distance from the Earth, as being drawn from the umbilicus V, placed at T, to the ends of the Diacentra; and both BT and DT will be of 100000 parts. And then also the points B and D will be mean longitudes, taken for the Moon's mean distance from the apogee in the orbit; and the arc ALB will be 90°, and ABPD 270°. In the quadratures, however, as you see in the latter figure, the umbilicus V does indeed lie on the line of apsides, but most distant from T, the centre of the Earth; and let VT, the distance of the umbilicus from the centre of the Earth, be as great as VC, the distance of the umbilicus from the centre of the ellipse; and so let VT be of 4362 parts, but the whole CVT double, namely 8724.

Diagram. The first of two figures set side by side at the head of the right column, the one the text assigns to the syzygies: an ellipse, pointed at top and bottom as drawn, with the vertical axis AP and the horizontal minor diameter BD crossing at C. A small circle lies below C on the axis, with its horizontal diameter HK and its centre I; the horizontal FG runs through its lowest point. Straight lines join L to C and L to T, and B and D to T. Two dotted lines run from the axis at T toward the lower right edge of the ellipse.

- A (top end of the axis)
- L (on the upper left of the ellipse)
- B (left end of the minor diameter)
- C (centre, above the crossing)
- D (right end of the minor diameter)
- H, I, K (left point, centre and right point of the small circle)
- F, G (left and right ends of the lower horizontal)
- M, T, V, N (along the lower horizontal, inside the ellipse, in that order from the left)
- P (bottom end of the axis)
- Z (on the lower right of the ellipse)

Diagram. The second figure, the one the text assigns to the quadratures: the same ellipse, with the horizontal BD through C, a shorter horizontal MN through V, and the lower horizontal FG. The small circle now stands with its top at V, its centre at I, its horizontal diameter HK and its lowest point on FG at T. A solid vertical runs from A to P through C; a second solid near-vertical runs down the left of it from S to Y, and a dotted line runs between them from E at the top to Q at the bottom. A straight line runs from R on the upper right through the top of the small circle down to F.

- S, E, A (at the top of the ellipse, in that order from the left)
- R (on the upper right of the ellipse)
- B, D (left and right ends of the upper horizontal)
- C (centre, on the upper horizontal)
- V, X (side by side at the top of the small circle)
- M, N (left and right ends of the second horizontal)
- H, I, K (left point, centre and right point of the small circle)
- T (below the small circle)
- F, G (left and right ends of the lower horizontal)
- Y, P, Q (at the foot of the ellipse, in that order from the left; the Q carries a long tail)

Therefore if the Moon, when it is joined to or opposed to the Sun, is at A or at P, no equation is needed, and in that month the quadratures occur at B and D, where the equations are greatest. But if in the mean syzygies the Moon is off the line of apsides, as at L, only a simple equation is needed; and the line of mean motion will be CL, while that of the true or apparent motion, to an eye at T, will be TL; and the optical part of this equation will be the angle VLC, as arising from the eccentricity TC. It differs from the physical part, since the Moon in equal times does not traverse equal arcs of the elliptical periphery with respect to the centre C of the ellipse, although it may traverse equal arcs of the circle circumscribing the ellipse.

Now if the Earth did not move with an annual motion, says Boulliau, this simple ellipse would suffice, as in the first figure, and no other second inequality, let alone a third, would be seen in it. But because the Earth too moves in its own ellipse, or annual orb, toward the east, the centre of the lunar system also,

which is the very centre of the Earth, is carried away from its own proper and connatural seat; and it no longer has a simple relation to the centre of the World and to the Sun, as it does in the syzygies, in which it stands on the same straight line with them, say on AIP or on LTZ. Instead it acquires a varied position, and the evection of the apogee occurs. For the umbilicus V moves on the periphery of the small circle from T toward K, with double the Moon's motion from the Sun, so that twice a month the umbilicus is united with the centre of the Earth, namely at conjunction and opposition, because twice a month the greatest monthly equations occur, in the quadratures. From this arises a real change of the eccentricity, which cannot come about by an approach of the centre of the ellipse to the centre of the Earth, since otherwise at times, off the line of apsides, the whole first inequality would perish, which is false. Nor can it come about by a libration on the straight line TIC, on which the umbilicus would librate, because, as Boulliau demonstrates in Book 3, chapter 1, it would at times happen that the second equation in that arc of the anomaly would be additive, say in the last quadrant, in which nevertheless, as we supposed from the observations at no. 14, it must be subtractive. Nor, finally, does this libration occur on the transverse line HK; otherwise, when a quadrature occurred at the mean longitudes there would be no monthly inequality, but when it occurred on the line of apsides it would be greatest, whereas it is established from observations that it is greatest at the former and nil at the latter. It remains, therefore, that the umbilicus of the ellipse moves on the small circle already mentioned, with double the Moon's motion from the Sun, in such a way that from the syzygy, where the umbilicus was at T, to the first quadrature, V comes through K to X, the semicircle of the small circle being completed; from the quadrature, V then descends through H to the centre of the Earth T, where the other syzygy occurs, and so one period of the small circle has now been completed once; and again from T, through K, it comes to X, where the second quadrature occurs, and finally from X, through H, it descends to T, where a new lunation begins.

XVI. Boulliau continues, and says that the Earth by its annual translation imprints on the whole lunar system a motion by which the centre of the ellipse C, following the motion of the umbilicus V, and with these the apogee A, is carried outside the place that by its nature it would keep in a lunar system not translated; and the Earth throws it away from itself, moving the perigee P toward itself. And from this motion, by means of the small circle already mentioned, arises the second inequality; and the apogee in the quadratures is at its greatest evections, and remains longer in them, at almost the same rate, because then the body of the Moon is on the periphery of the annual orb, or very near it, and moves with the same motion about the centre of the universe H as the centre of the Earth does. But in the syzygies the evections of the apogee grow or shrink most quickly, because the body of the Moon recedes furthest from the annual orb, and after conjunction strives against the motion of the centre of the Earth, heading toward the opposite quarter of the World; but from the full Moon on it goes along with it.

[Margin: Cause of the third inequality.]

The third inequality, or Variation, arises from the same translation; for it too is monthly, and is completed twice in a month's revolution. Thus, while the whole line ACVP, which passes through the centre of the ellipse, the umbilici and the apogee, is carried from the parallel position in which it would naturally rest if the Earth stood still, and does not remain in the parallel position SY which it held in the syzygies, the apogee by a certain natural appetite turns back toward the line of its natural position; and there fight against each other, on one side the love of rest in that line, on the other the translation impressed from outside. Therefore the place of the apogee settles midway between those parallel lines AP and SY, namely at E; and because this turning of the apogee occurs about the umbilicus V, as the centre of this turning, the perigee too is reflected to the opposite point at Q. Since, then, the motion of the evection, from new Moon to first quadrature and from full Moon to second quadrature, carries the apogee in the order of the signs from A toward E while the umbilicus moves through the semicircle TKX, the Moon seems to be advanced; for as the apogee advances, to which it is bound as to the limit of its motion, it too must be advanced. But while the umbilicus runs through the other semicircle, namely from the quadratures to the syzygies, the apogee is reflected against the order of the signs, and so the Moon is drawn back against the order of the signs, and a retardation of its motion occurs. Finally, in the octants, when the umbilicus is at K or at H, the greatest evection or reflection occurs, or what for Tycho is the Variation [Varietas]. And although on this sheet the small circle is represented as unmoved, it must nevertheless be conceived as moved, since its centre I is carried along with the Earth T.

[Margin: A supposititious confirmation of the Copernican system.]

With these supposed as certain, Boulliau in Book 3, chapter 1 confirms Copernicus's hypothesis, because from it there follows that this motion is impressed on the lunar system by the Earth, as being translated by an annual motion, but that a like motion is not impressed on the planetary system by the Sun, as not being translated; whereas in Tycho's hypothesis the Earth, though at rest, displaces the lunar system from its place, and yet the translated Sun does not displace the planetary system: statements which he thinks are made less coherently.

Gotifredi Vendelini Hypothesis, & ferè Leandri Bandtij Abbatis.

The hypothesis of Govaert Wendelen, and nearly that of Abbot Leander Bandtius [?].

XVII. The *Apotelesmata* of this outstanding astronomer have not yet appeared, and he has not brought to light his whole theory of the Moon; he hesitates, though now close to seventy, while I and others urge him in vain to publish it. But the part that touches the syzygies he has indicated, for the sake of eclipses, in two small works which he himself most generously sent me as a gift.

One is titled *Lampas Arcanorum Caelestium* [ARCANORVM CÆLESTIVM LAMPAS] [Greek: ΤΕΤΡΑΛΥΧΝΟΣ (tetralychnos, "with four lamps")]; the other, *Lunar Eclipses of Govaert Wendelen, Luminarcanus* [GOTIFREDI VVENDELINI LVMINARCANI ECLIPSES LVNARES], observed from the year 1573 to 1643, on which the Atlantic Tables are built, and their Idea is set out. In these he has most elegantly wrapped four doctrines in as many verses:

1. *In the heavens tomorrow's sum is equal to today's.* [In Cœlis par est hodiernæ crastina summæ.]
2. *An equal Oscillation moves the Moon at its highest and its lowest.* [Par summam atq. imam ciet Oscillatio Lunam.]
3. *A sextantal ratio gives the law to the apsides.* [Apsidibus ratio dat Sextantaria legem.]
4. *The Moon will triple the Year's turns at the Sun's apsis.* [Luna vices Anni triplicabit ad Apsida Solis.]

The sense of the first is that all natural days are equal to one another, and so there is no need of an equation of them. This he strives to confirm from observations of eclipses, which mostly favour this position remarkably; on this subject we said not a little in Book 3, chapters 31 and 32. The sense of the second verse is that the Moon's prosthaphaereses are oscillatory. For just as a pendulum drawn out of the perpendicular line and released to itself swings to and fro with equal librations, or with vibrations isochronous to sense, as we showed in Book 2, chapter 20, so the Moon's equations at a number of degrees equidistant both from the apogee and from the perigee are equal. For example, let the Earth be G, and ABC the path of the centre of the lunar body, which is B, describing by its mean motion the circle eccentric to the Earth. But the lunar body does not describe about B the epicycle HF, as in the Ptolemaic theory; instead it oscillates, or librates, from E to D through F, and in turn from D to E through F; hence the equations are equal at an equal distance from the line GFB. They would not be so if the Moon ran round through the upper space DHE of the epicycle. So writes Leander Bandtius [?], Abbot *Disimbergensis* [?] in Flanders, to my friend Uranicus [?], who communicated these things to me; and with such a diagram he sets out his opinion, which he strengthens by Govaert's authority.

Diagram. Set into the right column, with the text running down its left side. A circle centred at B, its vertical diameter running from H through B to F and continuing down as a solid line to a small round body at the foot of the figure. A shallow arc crosses the circle through B from A on the left to C on the right. Short dotted lines join B to D and to E on the circle. Two longer dotted lines run from D and from E down to the small body, whose interior is hatched and which carries the letter G.

- H (top of the circle)
- B (centre of the circle)
- A (left end of the arc, outside the circle)
- D (on the circle, left, just below the arc)

- E (on the circle, right, just below the arc)
- C (right end of the arc, outside the circle; heavily inked)
- F (just below the circle, on the vertical)
- G (inside the small body at the foot)

[Margin: Boulliau's vain attempt against Wendelen.]

Wendelen continues, and says that it has hitherto been believed that the lunar equation at 45° and 315° of anomaly is 3° 20′, but at 135° and 225° of anomaly 3° 46′. He himself, however, affirms that at all these four points of the anomaly, since the former stand equally distant from the apogee and the latter from the perigee, it is the same and precisely 3° 32′, which he contends is confirmed by an epilogism [Epilogismo] of eclipses; while at 90° and 270° the greatest equation is 5°. He is speaking, moreover, of the Periodic equations; for on the monthly ones he has not yet published his opinion, although Boulliau in Book 3, chapter 15 transfers his view to the monthly ones as well, and indeed in the octants, and in the same place tries to overturn it, saying that in this hypothesis of Wendelen's there must necessarily be no eccentricity with respect to the Earth, and no epicycle substituted for the eccentricity. For if an eccentricity is posited, the equating angles subtending it, and equally distant, one from the apogee and the other from the perigee, will not be equal; but if an epicycle, then under the same equating angle there will not be contained equal arcs of the epicycle, intercepted by the line of the true place and of the apsides, but the arc in the upper part of the epicycle will be greater than in the lower. But if Wendelen does not use the upper portion of the epicycle, as Abbot Leander indicates, or uses no epicycle, but a pure libration in the eccentric, then the weapon hurled from the upper arc of the epicycle, or from the pure eccentric, is aimed in vain. For the monthly equation, however, Wendelen employs an eccentricity, which he certainly states expressly as of 654465 parts, of which the radius of the eccentric is 10000000, but invariable and perpetually constant; and he says that to it there corresponds the greatest compound equation, 7° 30′, and that it is to the Sun's eccentricity, 174500, as 15 to 4; and that the Moon's apogee, most manifestly of all, advances, completing a period in about 3231^{d} 5^{h} 30^{m}. But whether, with the eccentricity posited as invariable, he posits the Moon's apogeal distance from the Earth as equal both in the syzygies [Copulis] and in the quadratures [Quadris] is not yet clear; and so I adjourn the verdict [amplius pronuncio] and await the publication of this whole theory. It only remains that, beyond the rule of the lunar motions that I gave from Wendelen in chapter 20, you should survey, from what was said in chapter 14 and from Wendelen's small works, the measures set out below.

Vendelini Hypotheseos Semisynopsis.

Half-synopsis of Wendelen's hypothesis.

	Radius 10000000	Semidiameters of the Earth
Semidiameter of the eccentric	10000000	60 0′

	Radius 10000000	Semidiameters of the Earth
Perpetual eccentricity	654465	3 55⅗′
Distance from the centre of the Earth at conjunction and opposition: greatest	10654465	63 55′
Distance from the centre of the Earth at conjunction and opposition: mean	10000000	60 0′
Distance from the centre of the Earth at conjunction and opposition: least	9345535	56 4⅖′

Greatest Periodic equation 5°; Synodic, together with it, 7° 30′.

Philippi Lansbergij Hypothesis.

The hypothesis of Philips van Lansbergen.

[Margin: The device of Lansbergen's hypothesis.]

XVIII. Lansbergen set out his lunar hypothesis briefly in the *Theoricae motuum caelestium* [Theoricis motuum Cælestium], chapter 3, in Book 1 of the *Uranometria*, and in the *Treasury of Observations*, pp. 95, 98 and 107. If considered more attentively, it seems to be built out of the Copernican hypothesis as transformed by Magini, and out of Tycho's small circle of libration. For the semidiameters of the Copernican epicycles, 10970 and 2370, melted into one, make Lansbergen's greatest eccentricity, 13340; and the semidiameter of the smaller epicycle, 2370, makes for Lansbergen the semidiameter of the hypocycle carrying the eccentric, even though he corrected and contracted the distances from the Earth. But why he gives the librating small circle a semidiameter of 7000 he nowhere explains. Let us first set out, in our usual way, the measures of this hypothesis, for which recall the lunar distances given in chapter 14.

LANSBERGIANAE HYPOTHESEOS SYNOPSIS.

Synopsis of Lansbergen's hypothesis.

Distances	Lines	Parts of the radius 100000	Semidiameters of the Earth
Semidiameter of the eccentric	MK	100000	59 5′
Semidiameter of the small circle	NI	2370	1 24′
Diameter of the same	PN	4740	2 48′
Eccentricity: greatest	AP	13340	7 53′
Eccentricity: least	AN	8600	5 5′
Semidiameter of the libration	DG	7000	4 8′
Distance from the centre of the Earth at conjunction and opposition: greatest	AN, with MK	108600	64 10′
Distance from the centre of the Earth at conjunction and opposition: mean	MK	100000	59 5′
Distance from the centre of the Earth at conjunction and opposition: least	NA taken from ML	91400	54 0′
Distance, etc., at quadrature: greatest	AP, with MK	113340	66 58′

Distances	Lines	Parts of the radius 100000	Semidiameters of the Earth
Distance, etc., at quadrature: mean	MK	100000	59 5′
Distance, etc., at quadrature: least	PA taken from ML	86660	51 12′

Greatest equation at conjunction and opposition 4° 58′ 44″; at quadrature 7° 40′.

Let A, then, be the centre of the Earth, and the greatest eccentricity AP of 13340 parts of which the radius of the orbit, MK or MD, is 100000, and the least, AN, 8600, and their difference the diameter of the small circle, PN, 4740. When this is bisected at I, with the semidiameter PI, 2370, let the small circle of the eccentricity PMNV be described, on which let the centre of the eccentric move in the order of the signs, beginning from N toward V, with the doubled motion of the Moon from the Sun, which is called the motion of the anomaly of the centre, and is daily 24° 22′ 53″ 22‴ 55⁗ 0⁗′ 20⁗′′. In accord with this motion let the Moon's apogee be continually shifted, so that in the mean syzygies the centre is at N, but in the mean quadratures at P. Outside these, however, it is elsewhere, say at M.

Diagram. Set into the left column, with the text running down its left side. A large circle, crossed by a vertical CE and a horizontal running from H on the left to B on the right; a diagonal runs from K at the upper left to L at the lower right, crossing the others near M. On the right of centre a small circle stands on the horizontal, with a short vertical through its top P, its centre I and N below. On the left a second small circle straddles the large circle's edge, with the horizontal passing through it.

- K (upper left of the large circle, end of the diagonal)
- C (top of the vertical)
- G, H, R (top, left and bottom of the left-hand small circle)
- D (inside the left-hand small circle, where the large circle crosses the horizontal)
- F (right of the left-hand small circle, on the horizontal)
- M (near the crossing of the lines)
- P, I, N (top, centre and below the right-hand small circle)
- V (right of I, at the right edge of the right-hand small circle)
- B (right end of the horizontal)
- A (on the diagonal, below N)
- E (foot of the vertical)
- L (lower right, end of the diagonal)

Therefore from the centre M let the eccentric KDLB be described, on which the Moon is elongated from the Sun in the order of the signs daily by 12° 11′ 26″ 41‴ 27⁗ 30⁗′ 10⁗′′; and parallel to the line AIP let the line CME be drawn, passing through M, the centre of the eccentric. For C will be the line of the mean apogee, which advances in the order of the signs about the centre A, in the order of the signs, daily by 6′ 41″ 3‴ 57⁗ 56⁗′ 24⁗′′. But the line drawn

through A, the centre of the Earth, and M, the centre of the eccentric, namely KL, marks the true apogee K and the perigee L; this advances in the order of the signs in accord with the motion of the centre of the eccentric. Besides these motions, the Moon's eccentric librates with a double libration: one from west to east and back, on the diameter GDR of the small circle GHRF, by force of which the Moon, placed on the eccentric, is carried now to R, now to G; and the motion of this anomaly is fourfold of the Moon's mean motion from the Sun, and is counted on the small circle already mentioned from H to G, against the order of the signs. The semidiameter of this small circle, namely DG, is of 7000 parts of which MK is 100000; or it is 4° 1′ 10″ of which the Moon's orbit BCDE is 360°. The other libration occurs from south to north at the centre A, and differs in no way from the libration of the obliquity of the zodiac.

Given, therefore, the Moon's equal motions, their equations and apparent motions are gathered from this, unless the line of the mean apogee and that of the true coincide together with the line of the syzygies or quadratures; for then no equation is needed. For there are gathered, for the given time, but equated, the mean motions of the Moon and the Sun and of the Moon from the equinox, together with the mean anomaly of the orbit.

EXEMPLVM.

Example.

XIX. For the sake of example, let the Sun's mean motion be 5^s 5° 36′ 2″; the Moon's mean motion from the Sun 9^s 25° 3′ 1″, and from Aries 3^s 0° 39′ 3″; and the mean anomaly of its orbit 1^s 17° 4′ 4″. Therefore in the following figure, having described the small circle of the anomaly of the centre NVPM, whose semidiameter IP is to be of 2370 parts, and PN 4740, let this be produced as far as A, so that NA is of 8600 parts of which the radius of the eccentric, soon to be described, is 100000. Then let the doubled motion of the Moon from the Sun, which, a whole circle being cast away, is 7^s 20° 6′ 2″, or 230° 6′ 2″, be counted from N through V toward M; and so let MP be 50° 6′ 2″; and let the centre of the eccentric be at M, through which and through A let the line of the true apogee K be drawn, which is KL; and through M let CE be drawn, parallel to PA itself, so that the mean apogee is at C. From it the arc CD of the mean anomaly of the orbit, counted in the order of the signs, namely 47° 4′ 4″, marks the Moon's mean place at D: from which let the small circle HGR be described, with semidiameter HD of 7000 parts of which MC is 100000. On it let the doubled motion of the anomaly of the centre, that is, the quadrupled motion of the Moon from the Sun, which, whole circles being cast away, is 100° 12′ 4″, be counted from H toward G as far as F. Therefore, with the quadrant HG subtracted, GF remains, 10° 12′ 4″. Its second sine DQ is of 98420 parts of which HD is 100000; but in parts of which HD is 7000, DQ is 6889. To this corresponds the arc DQ, 3° 57′. Subtracted from the arc DC of the mean anomaly of the orbit, which was 47° 4′ 4″, it leaves the arc CQ of

the coequated anomaly, 43° 7′ 4″. Its sine QB is 68348 and its second sine BM 72996, in parts of which MQ is 100000.

Now the arc MP was 50° 6′ 2″. Its sine MT is 76716 and its second sine TI 64145, in parts of which the radius IP is 100000. Therefore in parts of which PI is 2370, TI will be 1520 and MT 1818, and the whole TNA 12490. Now add BS, equal to MT, of 1818 parts; add it, I say, to the sine QB, and the whole QS becomes 70166. Likewise add AT to the second sine MB, that is, to its equal ST, and the whole AS becomes 85486. Therefore in the triangle ASQ, right-angled at S, the sides QS and AS are given, and hence the angle QAS, 39° 22′ 42″. Its difference from the angle QMC of the coequated anomaly, 43° 7′ 4″, is 3° 44′ 22″, namely the equation to be subtracted from the Moon's mean motion, which was 3^{s} 0° 39′ 3″. And so the Moon's true place, reckoned from the mean equinox, is 2^{s} 26° 54′ 41″. If, following Lansbergen, the additive prosthaphaeresis of the equinoxes, 15′ 58″, is added to this, the Moon's true place counted from the true equinox becomes Gemini 27° 10′ 39″.

But if you want to know the true place of the true apogee, use the triangle MTA, right-angled at T, in which, as appeared above, AT 12490 and MT 1818 are given; therefore the angle MAT is 8° 17′. Its difference from the angle QAS, already found above to be 39° 22′ 42″, is 31° 5′ 42″. Subtract this from the Moon's true motion, and there will remain the true place of the apogee K, in Taurus 26° 4′ 57″.

This hypothesis is certainly the simplest of the rest, and it does not overturn the position of the lunar spots, as the Copernican and the Tychonic do.

Diagram. Set in the left column, between line and line. A large circle with a small circle on its periphery at the upper left and a second small circle inside it at the lower right. Straight lines run from K and from C down through M, reaching the foot of the large circle at L and E as drawn; lines run from the small circle at the upper left to M and to A. Dotted lines run from the upper-left small circle horizontally through B to S, and from S vertically down to T.

- C (top of the large circle)
- K (upper left of C, on the large circle)
- H (left point of the upper-left small circle)
- G (top of the upper-left small circle)
- Q (inside the upper-left small circle, above D; the letter carries a tail)
- D (inside the upper-left small circle)
- F (right side of the upper-left small circle)
- R (below the upper-left small circle, where it meets the large circle)
- B, S (on the dotted horizontal, B left of S)
- P (top of the inner small circle)
- M (left of the inner small circle)
- T, I (inside the inner small circle, T above I)
- V (right of the inner small circle)
- N (foot of the inner small circle)
- A (below N)

• E, L (at the foot of the large circle, E left of L)

Diagram. Set in the right column, between line and line. An outer circle, a second circle slightly displaced from it, and a small circle near the middle. The horizontal EC and the vertical DF cross in the small circle; a second horizontal IM and a second vertical KL cross at B. A line runs from R through N to the centre region, and a line from P through the small circle to Q. A crescent-and-circle sign stands at N. Zodiac signs stand beside the four ends of the outer circle's diameters.

• D (top of the outer circle), with the sign of Cancer
• C (right end of the outer circle's horizontal), with the sign of Aries
• F (foot of the outer circle), with the sign of Capricorn
• E (left end of the outer circle's horizontal), with the sign of Libra
• R (upper left, beyond the outer circle)
• N (upper left, on the second circle)
• K (top of the second vertical)
• L (foot of the second vertical)
• I, M (left and right ends of the second horizontal)
• P (upper right, on the second circle)
• Q (lower left, on the second circle; the letter carries a tail)
• H (upper right of the small circle)
• A (inside the small circle, above the second horizontal)
• B (left point of the small circle, on the second horizontal)
• G (below the small circle)

Antonij Mariæ Schyrlæi de Rheita Hypothesis.

The hypothesis of Antonín Maria Šírek of Rheita.

XX. This author indicates his lunar theory in the book entitled *Radius Sidereomysticus*, Book 3, from chapter 2, or p. 151. Let A be the centre of the Earth, from which let the upper ecliptic [Ecliptica suprema] CDEF be described, whose beginning from Aries is at C. Around the same centre A let the small circle BGH be described, whose semidiameter AB, that is, the constant and perpetual eccentricity of the Moon, is of 1000 parts of which BK, the semidiameter of the eccentric, is 10000. For thus AB will be as great as the semidiameter of the solar globe. Let the centre of the eccentric, B, move in the order of the signs from B toward G, H, etc., by about 6′ 30″ daily. From B, at the distance BK of 10000 parts, let the Moon's ecliptic, or its eccentric KILM, be described; let the line of apsides be drawn through the centres A and B, and let Q be the apogee and P the perigee, which are to move with the motion of the centre B. Again, let the straight line IBM be drawn through B, parallel to the diameter EAC of the upper ecliptic, which is to be the line of the equinoxes, and likewise KBL, parallel to the line DAF of the solstices; and let the Moon's body move in its own ecliptic in the order of the signs, with a mean daily motion of 13° 10′ 35″.

This motion is to be counted not from C, the beginning of the upper ecliptic, but from M, the moving and librating beginning of the lunar ecliptic, because of the motion of the centre B. Let the motion of the apogee also be counted from M, through N, toward Q, in the order of the signs. Now let the Moon be at N, distant from the beginning M by the arc MKN, known from the tables of mean motion in the zodiac. Through it let the line of mean motion BN be drawn from the centre of the eccentric B, and the line ANR of true motion as far as the upper ecliptic; and let the motion of the apogee Q from the beginning M be counted by the arc MNQ. For when the motion MN, measured by the angle NBM, is taken from the arc and motion MNQ, there will remain the known arc NIQ, measured by the angle NBQ, whose complement to two right angles will be the angle NBA in the triangle NBA, in which, besides the angle mentioned, the eccentricity AB, 1000, and the radius BN, 10000, are given. Therefore by solving this triangle the angle N becomes known, that is, the prosthaphaeresis to be added to the mean motion when the Moon is in the semicircle ascending from the perigee P to the apogee Q, as in our case; but in the other semicircle QMP it is to be subtracted, so that the Moon's true place becomes known in that part of the zodiac in which the plane of the lunar orbit lies.

Šírek adds that the semidiameter of the ecliptic is of 3389830 parts of which the radius of the lunar orbit is 10000, or that it is of 100000 parts of which the latter is 295; and that others need epicycles or equations because they have not determined the correct eccentricity. And in Book 4, chapter 2, section 4, he adds that the 29½ days of the lunar month give us the Moon's mean distance from the Earth, namely 29½ diameters of the Earth, that is, 59 terrestrial semidiameters. From this, however, it follows that when the triangle NAB is right-angled, the equation is greatest, 5° 44′ 30″, and that the apogeal distance is equal both in the quadratures and in conjunction and opposition. This runs against the diversity of the parallaxes observed by us. Nor does there appear any excess of the equation outside the syzygies over the Moon's equations in the syzygies; nor will it ever show in the syzygies an equation of 5° 44½′. And so this hypothesis does not satisfy the phenomena. Let a synopsis of its distances nevertheless stand in the accompanying table.

Antonij Mariæ Rheitensis Hypothesis.

The hypothesis of Antonín Maria Šírek.

Distances	Lines	Radius 10000	Semidiameters of the Earth
Eccentricity	AB	1000	5 54′
Semidiameter of the eccentric	BP	10000	59 0′
Moon's distance from the centre of the Earth, both in conjunction and opposition and in quadrature: greatest	AQ	11000	64 54′
Moon's distance from the centre of the Earth, both in conjunction and opposition and in quadrature: mean	AN	10000	59 0′

Distances	Lines	Radius 10000	Semidiameters of the Earth
Moon's distance from the centre of the Earth, both in conjunction and opposition and in quadrature: least	AP	9000	53 6′
Greatest equation	5° 44′ 30″		

SCHOLIA.

Scholia.

[Margin: Rotation of the Sun and of others about their own centre.]

I. Since Kepler holds that the Moon is moved in a circuit by the Earth in almost the same way as the primary planets by the Sun, and derives much from their theory into the lunar theory, his universal principles must be touched on here and applied to the Moon's hypothesis. First, then, in the *Ephemerides* and in the Rudolphine Tables, but especially in the *Commentaries on Mars* and in the *Epitome of Copernican Astronomy*, Book 4, from p. 513, he teaches that the Sun is at the centre of the World, and is moved by no other motion than a rotation of 25 or 26 days about its own axis and centre, in the plane of the ecliptic, toward the east. He confirms this rotation, as we do in Book 3, chapter 4, from the sunspots, which are faster and larger around the middle of the Sun's disc, but more contracted and slower around the edges. Hence he thinks it probable, on p. 549, that all the primary planets, or at least those that have secondaries around them, are moved by rotation about their own centre, and indeed toward the east: namely Saturn and Jupiter, which their satellites surround, and the Earth, around which the Moon runs as its attendant and secondary planet.

[Margin: Periods of the planets.]

Moreover, he teaches that the Sun is a source no less of motion than of light, heat and life, and that from the centre of its body, animated by a material soul and kept in perpetual rotation, it emits a certain image [speciem], or a power and quality very like the magnetic, and diffuses it in every direction through the ethereal air, thinned in a uniformly difform way; and that this power, together with the Sun, turns with an equal rotation, and in the same direction, that is, toward the east, seizes the planets and drags them around. For thus a physical cause is provided for why the planets more remote from the Sun complete their periods more slowly, namely: Saturn in 29 Egyptian years $174^{d}\ 4^{h}\ 58^{m}\ 25^{s}\ 30'''$; Jupiter in 11 years $317^{d}\ 14^{h}\ 49^{m}\ 31^{s}\ 56'''$; Mars in 1 year $321^{d}\ 23^{h}\ 31^{m}\ 56^{s}\ 49'''$; the Earth in $365^{d}\ 5^{h}\ 49^{m}\ 15^{s}\ 48'''$; Venus in $224^{d}\ 17^{h}\ 53^{m}\ 2^{s}\ 14'''$; and Mercury in $87^{d}\ 23^{h}\ 15^{m}\ 36^{s}$; and also why the same planet is carried faster the nearer it comes to the Sun, and slower the more remote it is, since the Sun's power of course prevails more where it is stronger than where, because of the distance, it is weaker and thinner. Yet he thinks that each planet's passive inertia toward the motion of translation also contributes in its own measure to this diversity of motion, and by force of it their period is longer than the Sun's rotation.

II. To explain, and as it were to give shape to, this magnetic motion: just as in our magnet there is a double face and force extending along the same length, one by which it draws and attracts to itself the friendly face of another magnet, the other by which it repels the hostile face, so in the planets moved by the Sun there is a double power or disposition extended along straight lines, which he calls magnetic fibres [fibras magneticas]. One is friendly to the Sun's centre, namely the one that at the beginning of the World was turned toward the Sun, and which the Sun would at length have united to itself by continued motion, if it did not itself rotate and if the resistance of those fibres did not stand in the way while they strive for parallelism. The other is akin to the surface of the Sun but hostile to its centre, namely the one that was then turned away from the Sun toward the fixed stars. Therefore the Sun's power, falling perpendicularly on the fibres already mentioned, that is, on a position of the planets neither friendly nor hostile to the Sun's centre, neither attracts them nor repels them, but holds them, and so seized carries them around.

Meanwhile those fibres, because of an innate appetite for facing the same quarter, toward the east or the west, in which they were once placed, strive to keep their parallelism while they are moved by the Sun. And so the one end, the Sun-seeking [Solipeta], comes nearer the Sun, and the hostile one farther away; and thus the Sun can more easily draw the planet to itself, on that side, from the circumference of a perfect circle, until it inclines the fibre to a position tending directly toward the Sun.

[Margin: Reinhold ahead of Kepler in scenting out the elliptical path of the planets.]

From there, however, with the fibre resisting, its position is at length restored to parallelism; and from this arises the elliptical circumference, or oval path of the planet, such as Reinhold had described much earlier in the last lunar hypothesis, to say nothing of the hypothesis of Mercury, at the end of Peuerbach's *Theoricae*.

III. For the clarity of what has been said, let the following diagram stand, somewhat elucidated, from Kepler's *Epitome of Copernican Astronomy*, pp. 587, 596 and 654. In it let Cβ be the diameter of the eccentric, A on it the centre of the Sun, and B the centre of the eccentric. Let some planet be at aphelion C, and let its magnetic fibre be represented by the little arrow GF in its natural position, which the fibre itself and the whole body of the planet, compacted of such fibres, loves; and on the fibre let F be the end friendly to the Sun, or Sun-seeking, and G the Sun-fleeing [Solifuga]. Let the Sun's power fall along the straight line AC, perpendicular to the fibre GF; for at the beginning of this motion it will neither draw nor repel the planet, because of the equal distance of the ends G and F from the Sun. Let the planet then be drawn toward the east to H. For there, if the planet's fibre did not strive for a position parallel to the straight line GF, it would be in the position LK; but because it does strive for it, it inclines of its own balancing into the line HO. But because the end K comes nearer the Sun than it was at F, the Sun inclines it still more, into the position MN, and at the same time it is drawn inward; and so the centre of the

planet H departs somewhat from the perfection of the circular path, and is bent into the elliptical one.

Diagram. Set in the right half of the right column, with the text running down its left. A vertical straight line from C at the top to β at the foot, with a curved path bulging to the left between them. Five small circles stand on the path, each crossed by a short arrowed line: at the top C, at the upper left H, at the left D, at the lower left T, and at the foot β. A small rayed Sun with a face and the letter A stands on the vertical, below B. Solid lines run from the circle at H to O and from the circle at D to B, and a line runs from the circle at T to Y. Dotted lines run from N to P and from N to B, from R to A, and from V to Y.

- C (inside the top circle, on the vertical)
- G, F (left and right ends of the arrow through the top circle)
- K (on the path, upper right of the circle at H)
- H (inside the circle at the upper left)
- M (left end of the upper arrow)
- L (at the lower left of the circle at H, set on a slant)
- N (at the point of the arrow through H)
- O, P, B (on the vertical, in that order downward)
- D (inside the circle at the left)
- Q (at the far left of the circle at D, set sideways)
- a sign resembling Ω, above and to the right of the circle at D [?]
- R (at the lower right of the circle at D)
- A (in the rayed Sun)
- X (left end of the arrow through the circle at T)
- T (inside the circle at the lower left)
- V (at the point of that arrow)
- Y (on the vertical, in the circle at the foot)
- β (inside the circle at the foot)

When it has come to the mean longitude at D, let the fibre QR tend directly toward the Sun, and there let it depart most from the circular periphery, so that DB is the transverse semidiameter of the ellipse, and AD is equal to the major semidiameter BC. Then let the fibre gradually begin to be restored to its parallelism; at T let it take up the position XV, and finally at the perigee β let it be perfectly restored to its position and be parallel to GF. And by a similar libration, arising from the power of the Sun, which moves but repels the hostile part, and from the strength of the fibre struggling for parallelism, let the other semicircle be completed.

[Margin: Physical cause of unequal motion in the planets.]

For in this way the elliptical path of the planet will come about with the properties of the ellipse preserved, and a physical cause can be provided for why the planet, in equal times, moves more slowly at the greater distances, and why the motion is accelerated in the semicircle of the orbit that contains the perigee; and the inequality of the planets' motion is not all optical, or apparent

to us who are placed outside the centre of the celestial motions, as Aristotle and Copernicus contend, but part of it is physical, and comes from a real acceleration and retardation, from the Sun's physical motion and the balancing of the fibres; if these did not strive for parallelism, the motion would be perfectly circular. And without the superfluous apparatus of eccentrics and epicycles, the inequality will be produced by one most simple elliptical periphery. And if these two powers, of the Sun and of the fibres, do not perfectly compensate each other, the parallelism is restored not exactly at the apogee C but beyond it; and so the planets' apogee will appear to advance gradually.

[Margin: The ratios of the lever and the balance are included in the motion of the planets.]

IV. Now since the libration by which the Sun moves the planets comes about, according to Kepler, by the ratios of the balance and the lever, and is measured from the ratios of the balance, let there be supposed a steelyard from whose shorter arm a heavier weight hangs, and from whose longer arm a lighter weight in equilibrium with it; and as the longer arm on that side is to the heavier weight on this side, so, by permutation, is the shorter arm on this side to the lighter weight on that side. Then let the heavier weight and its power be imagined to be at the yoke [iugo] of the steelyard; for there it will have greater force to raise a weight that is less distant on the other arm than the same weight at a greater distance, for the reasons already known in the lever. Let the Sun, then, says Kepler in the *Epitome of Copernican Astronomy*, p. 579, be placed at A, as at the yoke; for it will have more strength to move a nearer planet P from its place than a more remote one C.

Again, since the raising of one pan in a balance and the lowering of the other is measured by the second sine of the angle that the arms of the balance make with the perpendicular line of the handle passing through the point of the yoke, or the centre of the balance, as Kepler shows in the same place, p. 650, and as is easily evident: for the raising of the lighter pan at the end of the arm, or viewed on the diameter of the balance, is as great as the second sine of the angle already mentioned, as will be evident, in the motion of the pans, to anyone who describes the balance in a circle made by its arms. Since, I say, the sine already mentioned is the measure of the motion of the pans, so the measure of the libration, by which the planets' fibres are inclined from their parallelism, is the sine of the angle that the line of the fibre makes at the centre of the planet with the perpendicular drawn to the major diameter of the ellipse. For that reason he teaches that the ratios of the balance are included in this libration. And so in the preceding figure the fibre QR, like the arm of a balance, is inclined below the perpendicular DB by the arc δR, or by the angle ADB, which measures that arc, whose sine is the sine of the angle already mentioned. He shows moreover (Kepler, on p. 596), that as AD (which, with the Sun placed at A, one of the foci, in the ellipse, is equal to the mean distance or semidiameter BC) is to BA, the eccentricity or half the libration, which is the measure of the angle ADB, so is the planet's semidiameter DR, taken as the

whole sine, to the sine of the angle of greatest inclination δDR; and likewise, as the sine HO of the arc CH completed by the planet is to the whole sine DB, so is the angle NHO to the angle RDδ. Then, from p. 654, he shows that the sine of the arc of the orbit completed by the planet is the sine of the libration, and thus that the sine HO of the arc HC is the measure of the libration. And on p. 656, using Pappus's demonstration in Book 5 of the *Collection*, prop. 36, and citing his own attempt in *Mars*, chapter 57, he shows that the measure of the libration accomplished, begun from the apogee C, is the versed sine [Sinum Versum] of the arc completed on the orbit. For as the whole diameter Cβ is to the whole libration of the semicircle, or the semidiameter BC to half the libration reckoned by the eccentricity AB, so is the versed sine of any arc on the orbit, say OC of the arc CH, to the part of the libration accomplished. From this it follows that, just as the motion of the pans in a balance is fast in the middle and slow at the extremes, so the planet's motion undergoes smaller differences near the apogee and perigee, but larger ones at the mean longitude.

[Margin: Application of what has been said to the Moon's hypothesis.]

V. Now what the Sun is to the primary planets, the Earth is to the Moon. For the Earth, turned toward the east by a daily rotation about its own axis, propagates from itself the magnetic power received from the Sun; and this power inclines to itself the friendly part of the lunar fibres and repels the hostile part, while the fibres meanwhile strive to keep themselves in a parallel position toward the same parts of the World. From this arises an ellipse, in one of whose foci is the centre of the Earth. For this, on p. 610, he shows this figure, in which the centre of the Earth, A, A, etc., is moved around the Sun by an annual motion toward the east through the great orb [Orbem magnum]; and the body of the Earth is turned about its own centre A by a daily rotation, likewise toward the east, carrying the Moon with it in the same direction. The Moon's fibres, indicated by an arrow, have the part akin and friendly to the Earth at BCDEFGHIKL, and the opposite part, as at MNOP, is hostile to the Earth. Let the Moon at BL be at the middle place between apogee and perigee, but at EFI a little before apogee and at HK a little before perigee; and let the Moon appear to the Earth new at C, full at B, E, H, and dichotomised at D.

Diagram. Set in the left column, between line and line. A rayed Sun with a face stands in the middle. Around it a curved line passes through six positions of the Earth, each a circle lettered A, half hatched, with a larger circle around it; on or beside each larger circle stands a small Moon, half hatched, crossed by a short arrow. Two of the larger circles carry two Moons.

- A (six times, inside each Earth)
- G, F (at the heads of the arrows through the two Moons at the upper left; no letter read at the tail of the arrow at G)
- M, E (tail and head of the arrow through the Moon at the upper right)
- C (head of the arrow through the lower Moon of that circle; no letter read at its tail)
- R (above the Moon just left of the Sun)

- I (head of the arrow through that Moon)
- a letter at the tail of the arrow through the Moon at the far left, reading O
- D (head of that arrow)
- N, B (tail and head of the arrow through the Moon at the right)
- H (head of the arrow through the Moon at the lower left; no letter read at its tail)
- L (head of the arrow through the Moon at the lower right; no letter read at its tail)
- P, K (tail and head of the arrow through the Moon at the foot)

Therefore while the Moon goes around the Earth, its mover, in the circle MC, DI, etc., always keeping the same periodic eccentricity, it acquires the first, free anomaly [Anomaliam Solutam] by reason of this eccentricity, because of which it becomes now apogeal, now perigeal. And if its apogee falls in the syzygies, then the magnetic image or power of the Earth, diffused into a larger orb and thinned by a uniformly difform decrease, is weakened; at perigee, on the contrary, it is stronger; and there it retards the motion, here it accelerates it. But if the Moon's apogee falls in the quadratures, it behaves in a middle way, feeling neither loss nor gain of the Earth's moving power or the Sun's promoting power. The second and third monthly anomaly it acquires from the varied relation of the eccentric to the lunar phases, and from the varied eccentricity of the semicircle of the eccentric, with respect to the circle of illumination on the Earth that divides day from night; and because it becomes accidentally now nearer to the Sun, now farther from it, it is also advanced by the Sun in a varied way by means of the illumination. And the Moon's apogee stays in the same sign through almost the whole year, and the fibres PK, etc., remain almost parallel to themselves through the whole circuit. But the Earth, with the Moon's heaven, passes from sign to sign each month. Hence it happens that the fibres are applied differently at different times to the circles of illumination, both lunar and terrestrial, made by the Sun, as you see in the arc RI, by which the end I of the fibre declines from the circle of illumination R.

[Margin: Monthly anomaly of the Moon from the Sun's illumination.]

VI. To explain better the monthly anomaly arising from the Sun's illumination, Kepler in the *Epitome of Copernican Astronomy*, pp. 560, 616 and 791, uses the following figure, in which BA is the Earth; the full Moon is at DC, the new at GH; the first quadrature at KI, the second at EF; the first octant from the new Moon is N, where the Moon is 45° from the Sun and appears horned; the second octant O, in which it is 135° from the Sun and appears gibbous; the third octant L, in which it is 225° from the preceding conjunction with the Sun but 135° from the following one, and appears gibbous; and finally the fourth octant M, in which it is 315° from the preceding conjunction with the Sun but 45° from the following one, and appears horned.

Diagram. Set in the right column, between line and line. A large central circle, its upper half hatched, is the Earth, with a vertical line through it from

the top of the figure to the foot. Around it runs a ring on which stand eight small circles, each with its upper half hatched and a stroke through it: at the top, the upper left and upper right, the left and right, the lower left and lower right, and the foot.

- D, C (left and right of the circle at the top)
- L (in the circle at the upper left)
- O (in the circle at the upper right)
- E (above the circle at the left)
- Q (on its side, at the far left of that circle)
- T (inside that circle)
- P (to the right of that circle)
- F (below that circle)
- B, A (left and right ends of the Earth's horizontal)
- R (to the left of the circle at the right)
- K (above the circle at the right)
- V (inside that circle)
- S (to the right of that circle)
- I (below that circle)
- M (in the circle at the lower left)
- N (in the circle at the lower right)
- G, H (left and right of the circle at the foot)

Tycho further observed that the Moon's mean motion, stripped of that second anomaly which exists in all planets because of the eccentricity of the orbit, has another one, and is always faster in the syzygies DC or GH and slower in the quadratures EF, IK than the reasoning of the eccentricity allows, whether the Moon is situated at the apogee, at the perigee, or at any other place on its eccentric. This anomaly, therefore, cannot be ascribed to the eccentricity. But neither can it be ascribed to the image or power of the Earth, turned by the terrestrial rotation through the annual orb LMNO; for at an equal distance of the Moon from the Earth its speed is uniform, both in the syzygies and in the quadratures. This anomaly therefore comes from elsewhere, from a cause connected with the Moon's phases; and these are produced by the Sun. The Sun therefore assists the Moon's motion around the Earth; just as elsewhere it was said, according to Kepler's view, that the Sun, by illuminating the terrestrial globe, spurs on by its own rotation the daily turning of the Earth, to such a degree that the Earth, which of itself would make only the 360 days of the archetypal year, nevertheless produces a year of 365¼ days. Therefore, while the Sun by its whirling spurs on the whirling of the Earth that moves the Moon, it spurs on the Moon as well.

For although, both in the syzygies and in the quadratures, half of the terrestrial and of the lunar globe is illuminated by the Sun, yet the Moon's illumination, which is bounded at the surface of the lunar globe, namely the part of the circle of illumination, as CD, GH, etc., is applied in a different way to the image of the Earth, or the magnetic power, turned through the circle

LMNO. For in the syzygies DC and GH, the image of the light and the image of the Earth are applied by contact, so that the portion DC or GH coincides through the whole arc DC or GH with the circle of illumination DC or GH; and because of this conjunction the Earth's power is greatly strengthened by the light, and accelerates the Moon's motion. But in the quadratures, the circle of illumination PQ or RS cuts the arc of terrestrial power EF in the single point T, or KI in V, at right angles. It is no wonder, therefore, if the application of light to the terrestrial power, at one point and almost nil, in no way strengthens the Earth's faculty and in no way accelerates the Moon. In other places, where this application and section occurs at oblique angles and imperfectly, there is some acceleration, but not so great. Since, however, the Earth's image, turned in the order of the signs and spurred on in that direction by the Sun's rotation, always moves the Moon in the order of the signs, whereas the force of the light can spur it even against the order of the signs, with respect to the centre of the Sun at new Moons, the illumination therefore strengthens the image of the terrestrial power separately, and without regard to the quarter in which the terrestrial power is directed.

Kepler next teaches, in the same place, from pp. 564 and 616: if the Moon were not advanced by the illuminating Sun, the lunar year would coincide with the Sun's sidereal year, and the Moon in it would re- turn to the Sun exactly twelve times. But because it is accelerated, after 12 synodic months completed in the sidereal year it also runs through 132° 45′, which, distributed through the second and the monthly equations, produce the greatest Variation in the octants, 51′. But if that increment is reduced to 127° 10′, which the Moon makes in order to arrive after 12 lunations at its initial place among the fixed stars, from which the Sun is distant after 360 days, the greatest Variation will be 49′. You will note also that when the apogee is in the quadrature EF and the perigee in the quadrature IK, and that month lacks a synodic equation, the parts of the luminary acceleration are equal in both syzygies, because of the Moon's equal distance from the Earth. In the following months, however, because of the inequality of the distances in the syzygies — as if the apogee should be at L and the perigee at N — some monthly equation arises, and throughout that month it is greatest in the quadratures. [Margin: The greatest size of the Variation.]

VII.

[Margin: A refutation of the objection from the lunar spots against the position of the fibres.]

Two more of the countless fictions of the Keplerian hypothesis remain to be pointed out, from p. 613 of the *Epitome*, where he says that it is not necessary for the Moon's magnetic fibres to be directed straight toward the Earth at the two opposite times of the period. It is enough that at those moments they should at least be inclined toward the Earth on alternate sides, and that this position of the fibres should stay parallel throughout the Moon's circuit; for in this way it can happen that now one face of the fibre and now the opposite one nods closer to the Earth. This inclination, if it is small, cannot be observed

by us on the lunar disc, because of the slightness of the new spots at the edges of the Moon. If it is somewhat larger, this alternation can be attributed to an interior globe of the Moon, enclosed within the crust of the lunar surface like a kernel and having a rotation different from the rotation of the crust. So it can happen that the outer shell always turns the same spots toward the Earth, and yet the magnetic fibres of the inner globe nod toward the Earth with their sides turned to it alternately. This astronomer of most audacious ingenuity has dared to imagine a kernel of the same kind in the Earth too.

[Margin: A second eccentricity, and a difference of distances tied to the phases, is rejected.]

To establish that the second inequality does not come from any second eccentricity, he says on p. 614 that this second eccentricity conflicts with the observed parallaxes, when the study of eclipses is added, along with the reasoning, taken a priori, from the proportion of the bodies to their distances. Therefore, although he thought otherwise elsewhere, he has at last found that the lunar distances do not change by reason of the phases, and that the distance is not tied to the phases in such a way that the greatest in the syzygies is less than the greatest in the quadratures, or the reverse. On the contrary, the apogeal distance at conjunction and opposition [☌ ☍] is equal to the apogeal at quadrature [□], and the perigeal to the perigeal. He confirms this further from the fact that the astronomers who made this change tied to the phases nevertheless found it smaller and smaller all the time. For Ptolemy had made it enormous. When Regiomontanus had censured it, Copernicus corrected and halved it, and transposed it from the form of an eccentric into the form of a second epicycle. Tycho, reducing it again, assigned part of it to the equating small circle, with a motion double that of the Moon from the Sun. Kepler at last removed this change of distances tied to the phases, and transformed the change from apogee to perigee from a monthly into an annual one, and from the half-monthly change of a semicircle into a half-yearly one. But let this be enough and more than enough of Kepler's fictions; yet I have only pointed them out, so as not to be prolix to no purpose.

VIII.

[Margin: Kepler's hypothesis is disapproved.]

For on many grounds I do not approve of Kepler's hypothesis, however great the engines of ingenuity that prop it up. First, because it does not represent the lunar motions, as we have found in observations of more recent eclipses and in the Rudolphine calculation applied to some ancient eclipses. Second, because the equality of the parallaxes and of the lunar distances in the syzygies and in the quadratures alike goes against observations most evident to me, let alone those of Tycho, of Copernicus and of very many others, since the distance is sensibly greater and the parallax smaller at apogees in quadrature than at apogees in conjunction and opposition; and conversely, the distance is smaller and the parallax greater at perigees in quadrature than at perigees in conjunction and opposition. But the man, inclined to fictions and to daring, and impatient of

observing, misuses Tycho's observations, to the point that he does not fear to drag them by force to the ideas and mysteries not of the heavens but of his own ingenuity, believing that these could not be convicted of falsity by any observer in future.

[Margin: A contradiction in Kepler's hypothesis.]

And surely whom would that inconstancy in the lunar parallaxes, which I reported in chapter 14, number 7, and in the preceding chapter toward the end, number 2, not strike with a huge suspicion of violated astronomical good faith? In the Rudolphine work itself, chapter 25, does he not set the real eccentricity at 4362 parts, of which the radius is 100000? From this follows a distance of the Moon at apogee of 104362 parts and at perigee of 95638. And yet in the tables on p. 98 he sets the Moon's horizontal parallax at apogee at 58′ 22″ and at perigee at 63′ 41″. From these there follows a distance from the Earth, in semidiameters of the Earth, at apogee of 57 54′, at perigee of 54 0′, and a mean of 55 57′. So if for Kepler this mean distance equals the radius 100000, then certainly the greatest is 103486 and the least 96514, and thus the eccentricity is 3486; and yet he has gathered the lunar equations from 4362 parts of eccentricity.

Third, an inclination of the lunar fibres so great that at the mean longitudes they tend toward the Earth conflicts with the phenomena of the spots. And as for the remedy for this, discussed in Scholium 7 and begged from a kernel of the lunar globe, there is no one who does not see how forcibly, not to say how hot-headedly, it has been hunted up.

[Margin: The complications and troubles of calculation in the Keplerian hypothesis.]

Fourth, because while Kepler parades the simplicity of a single elliptical eccentric, with a small circle carrying its centre around, and sings a triumph over vanquished epicycles, equants and doubled eccentrics — as may be seen in the Rudolphine Tables, chapters 20 and 26, and in the Letter to the Reader prefixed to Book 5 of the *Epitome of Astronomy* — in reality he falls into more complications, of many triangles, of equants and of the exempt particle [particulæ exsortis]. So much so, that he himself says in the Rudolphine Tables, chapter 26: "It is rather the purpose of the present work, by explaining the diagrams, to lay the foundations of the calculation, lest, if these are not known, the labour of calculation should become less pleasant, tedious enough in itself because of the remarkable variety of cautions brought forth by this hypothesis, not newly laid down but offered freely by Nature." And at the foot of the same chapter, in precept 125: "But since the equation of light is not extracted exactly enough for the taste of the curious, let them therefore take on themselves the labour, surely not a little troublesome, of extracting from the table the monthly minutes [Scrupula menstrua] and the Exempt [Exsortem], and of forming the equation by means of them." What if everything had to be worked out by geometrical niceties [apices Geometricos], without the help of tables?

Fifth, the application of the light that strengthens the Earth's image is nil in the quadratures for this reason, that it takes place at a point. But it takes place at

a point no less in every other position in which the plane of the circle separating the illuminated part of the Moon from the dark part cuts the circumference of the lunar orbit; for granted that it cuts at oblique angles, it still cuts at no more than a point. Therefore it cannot aid the Earth's image outside the syzygies, contrary to what Kepler lays down. Re-read what was said in Scholium 6, and you will grasp the force of our objection. So much for the things proper to the Moon.

IX.

Against the general hypothesis, common to the Moon and the other planets, not a few things tell. First, the annual and diurnal motion of the Earth, and the Sun's rest at the centre of the world from every motion τῆς φορᾶς [Greek: τῆς φορᾶς (tēs phoras, "of conveyance")], that is, of translation; many things to be adduced in Book 9 forbid me to subscribe to this. And as regards the Moon, I think it absurd that the Moon is placed among the secondary planets, as Kepler places it so as not to disturb the order of his system. Second, that in seeking physical causes he begs them from the likeness of the magnet, the balance and the lever — things surely too material and gross. And he is wholly taken up with seeking the efficient cause, when he ought to have sought the final cause, if he could; a cause that Aristotle, in *Physics* 2, recognises as the most physical of all [Greek: φυσικοτάτην (physikotatēn, "most physical")]. For the planets do not move along such a path, at such distances from the Sun and from the Earth, and with such a difference of speed and slowness, for this reason: that the Earth or the Sun strives to carry them along with itself or even to unite them to itself, and that they, in order to preserve the position of their fibres, partly resist this seizure and union. Nor is this a cause sufficient to settle our intellect. Rather, Divine Providence without doubt had certain ends in these motions, and architectonic and lofty ones at that, far nobler than to show us the magnetic librations of bodies. Yet Kepler conceals these, while he so binds the planets to material necessity and to the blind striving of these motions, like millstones to a mill, as to banish from them every mind that orders and directs these motions, and with arguments surely frivolous to proscribe the Intelligences from the motion of the heavenly bodies, as I shall show in Book 9.

X.

But Kepler nevertheless admits, in Book 4 of the *Epitome*, p. 516, that the consideration of the celestial harmonies, treated in the last chapter of Book 5 of the *Harmonics*, suggests conjectures about a moving Intelligence of the heavenly bodies. Even so, all that Keplerian harmony rests on the musical scale, neatly fitted to our ears, or on the distances of the 5 regular bodies, or on certain round numbers, which he counts as ideal and archetypal for this reason, either because they are round, or because they contain certain ratios purely mathematical, or at most harmonic, but with a harmony tied to our hearing. So the year, if you listen to him, ought to have been of 360 days and the month of 30 days, and the distances of the planets to the proportions flattering our imagination or pleasing to our hearing ought to have been

adjusted. [Margin: Kepler's inconstancy once more.] Hence it came about that he fell into plainly conflicting opinions. In the *Ephemerides*, p. 2, he defined the distance of the Sun from the Earth as 1800 Earth semidiameters, so that it would be thirty times the lunar distance of nearly 60 semidiameters, just as the Moon's monthly revolution around the centre of the Earth is thirty times the Earth's daily revolution around that same centre of its own. But in the *Epitome of Astronomy*, Book 4, from p. 478, and Book 6, p. 776, he makes the distance of the Sun 3469 Earth semidiameters and that of the Moon 59, so that it may be the mean proportional between the Earth's semidiameter and the distance of the Sun. But more against this harmony in Book 9, on the Harmonic System. Meanwhile I say that the harmony of that divine Harmonizer [Harmostæ] and the geometry of that supreme Demiurge are far too sublime to need measuring by the scale of Guidi Aretini [Guido d'Arezzo], or by the compasses and rule of Archimedes or of Euclid; and that God, Best and Greatest [D.O.M.], had other ends. Such indeed He had when He distributed the fixed stars, not into regular small plots bounded by figures, say of a quadrangle, a pentagon or a hexagon (which would of course have pleased Kepler's ideas uniquely). And if the year, for example, for an end that pleased God, is of 31574925 seconds, as Tycho holds, this number, or another closer to it but more exact, is round and perfect to the divine mind; or else it is to be reduced to further and more exact minutiae, so that it may be rounder.

[Margin: Kepler censured by Boulliau.]

Moreover, lest anyone should think that Kepler is censured on this point by me alone, or undeservedly, let him hear Boulliau, who says this in Book 3, chapter 14, of his *Astronomy*: "Hence I cannot wonder enough at Kepler's intemperance [Greek: ἀκολασίαν (akolasian, "intemperance")], by which, driven as if by the violence of some stormy spirit, he boldly departs from the authority of observations and passes over to the archetypal ratios of a cosmic music that he devises. As though what he has imagined for himself could command the bodies of the world, so that they should keep to it. Cosmic music is to be understood from the motions and their properties; those motions are not to be ordered from our musical ratios. For the symphonies of those motions admit other compressions [Greek: καταπυκνώσεις (katapyknōseis, "compressions")], condensations, intensifications and relaxations, different from ours." He rightly said "is to be understood"; for it is not to be perceived by the senses, or judged by the laws of sense.

CAPVT XXVIII:

Chapter 28

Anacephaleosis Præcedentium Hypotheseon; Iudicium de illis, & Indicium de Nostra.

A recapitulation of the foregoing hypotheses; a judgment on them, and an indication of our own.

I.

[Margin: The hypothesis of Ptolemy.]

So the diversity of the lunar distances and motions has driven astronomers into so many and so varied hypotheses. Ptolemy explained the first inequality by the Moon's motion on an epicycle, and the second by the motion of the epicycle's centre on an eccentric and its approach to the Earth and recession from it. But he moved the centre of the eccentric on a circle described around the Earth, using always the same eccentricity; and the sum of the semidiameters of the epicycle and of the eccentric [recte: of the hypocycle, per the book's errata][34] was for him 31342 parts, of which the radius of the eccentric was 100000. This hypothesis was worked by the Arabs, and also by Gherardo Cremonensi [Gherardo da Cremona], Sacrobosco and Peuerbach, into the matter and solidity of several partial orbs. But since the semidiameters already mentioned were found to be enormous, and no observations ever showed the lunar diameter, parallax and distance twice as great at perigee as at apogee, as the Ptolemaic hypothesis nevertheless required, this hypothesis was rejected by Regiomontanus; but he put no other in its place.

[Margin: The hypothesis of Copernicus.]

Copernicus therefore, rejecting the eccentricity, chose a concentric with an epicycle on an epicycle [Epicepicyclo]. He distributed the first inequality to the first epicycle and the second to the second, and restricted the aggregate of both semidiameters to 13340 parts, which is nearly half of the Ptolemaic aggregate.

[Margin: The hypothesis of Tycho and Longomontanus.]

Tycho, with the help of Longomontanus, kept the two epicycles of Copernicus on a concentric for the syzygies, and on an eccentric outside them, moving its centre on an equating hypocycle, and assigning the greatest eccentricity to the quadratures and none to the syzygies. He added besides, for the third inequality, the Libration outside the lunar system. The aggregate of the semidiameters of the epicycles and of the greatest eccentricity is for him 13048 parts, although in his hypothesis these three quantities never concur to make up the difference of the greatest distance from the least.

[Margin: The hypothesis of Magini and Lansbergen.]

Magini and Lansbergen, rejecting the epicycles, used a mere eccentric; but in place of the epicycle carrying the Moon they substituted a hypocycle, or small circle carrying the eccentric. This small circle does not reach the centre of the Earth with its periphery, as in Tycho, but stands wholly distant from it; and so it varies the eccentricity from the least to the greatest, which for Magini is

[34] in this copy a hand has struck through the printed Eccētrici and written Hypocycl· in the margin beside it

13330 parts and for Lansbergen 13340, so that he may keep close to Copernicus. But Lansbergen, for the Tychonic third variation and for other reasons, adds a small circle on whose diameter, not on whose periphery, the Moon is librated.

[Margin: The hypothesis of Wendelen, Leander and Šírek.]

Wendelen, Leander and Antonín Maria Šírek, also using an eccentric without an epicycle, nevertheless keep the eccentricity unvaried, and so describe a small circle carrying the eccentric around the Earth. But the first two try to uphold the lunar inequalities by oscillating librations from east to west and back, and the last by a double ecliptic, of which the lunar one is carried by the force of that small circle. The eccentricity is for Wendelen 6545 parts and for Šírek 10000, of which the radius of the eccentric is 100000.

[Margin: The hypothesis of Kepler.]

Kepler, having rejected the eccenter of the eccentric, or the difference of real eccentricity, let alone the epicycles, moves the Moon, as he does the other planets, on a simple eccentric but of elliptical periphery, whose centre is carried on the periphery of a small circle described around the Earth with a semidiameter of constant eccentricity of 4362 parts. He does not acknowledge an apogeal distance in the syzygies different from the apogeal in the quadratures, as he does not acknowledge a perigeal different from the perigeal. In place of equant circles, however, he uses areas of triangles based on an eccentricity not real but fictitious. And acknowledging the Moon's second and third inequality as physical and real, he refers it to the differing illumination by the Sun and to the application of light with the Earth's magnetic force moving the Moon.

[Margin: The hypothesis of Boulliau.]

Boulliau, finally, himself also using an ellipse, nevertheless admits a change of the real eccentricity, and for this he uses a small circle passing with its periphery through the centre of the Earth and carrying not the centre of the elliptical orbit but the umbilicus or focus of the ellipse. For it the least eccentricity is 4362 parts and the greatest 8724, of which the radius, or greater semidiameter of the ellipse, is 100000. The second and third inequality he ascribes to the Earth, carried by an annual motion and impressing on the whole lunar system a motion by which it thrusts the apogee away from itself and draws the perigee to itself, and produces a varying real eccentricity, etc. The hypotheses of the others are not yet fully established.

II.

[Margin: Objections against epicycles.]

What displeases me in the hypotheses already mentioned, so that I acquiesce in none of them, I think should be briefly indicated. The Ptolemaic, Copernican and Tychonic epicycles do not preserve the same face of the Moon toward us, nor the same position of the spots. On them the Moon's body moves in such a way that the spot Caspia, for example, which appears near the western limb in the first phases, would have to appear on the eastern edge when the Moon is already full, and from full Moon to interlunium none of those spots that we see on it ought to appear. This false supposition, manifestly contrary

to the phenomena of the spots both old and new, we can indeed remedy by a monthly motion of rotation, by which the Moon's globe, turned the contrary way around the centre of its own body, would keep the same face of the lunar disc toward us. But if no necessity presses from elsewhere, motions are not to be multiplied. Moreover, the Copernican and Tychonic epicycles twist the planet into excessively winding bends, contrary to one another; and the planet, or its mover, in a free and fluid heaven without solid orbs, as Tycho holds, must look to the fictitious centres of several circles, and those perpetually shifting. For while the Moon moves itself, or its mover moves it on the last epicycle, it must meanwhile move it toward that part toward which the centre of the smaller epicycle is imagined to move, and at the same time direct this very motion to where the centre of the greater epicycle is imagined to turn. And in this very act it must attend, in the Tychonic hypothesis, to the fictitious motion on the hypocycle near the Earth, and in these things must make use of the fiction of one of these motions in the contra- ry direction. Not to repeat here what we said about the measure of the distances a little earlier against Ptolemy, and in chapter 14 against him and Tycho: for in the former the difference of the apogeal distances from the perigeal is too great, in the latter too small, and it goes against observations of parallaxes carried out by us with the greatest good faith and diligence.

[Margin: What is to be said against the hypocycles of some?]

But the hypocycles described around the Earth in place of epicycles by Kepler, by Šírek and perhaps by Wendelen, in order to keep the Moon's eccentricity always the same in imitation of Ptolemy, go against the evident difference of distances between apogees in the syzygies and apogees in the quadratures. For the latter are greater than the former by an excess of two semidiameters of the Earth, and the perigees less than the perigees. Therefore, since this difference is not compensated by Ptolemy's epicycle or by something else equivalent, such as a libration of the planet upward or downward, the fallacy of the hypothesis is not avoided.

[Margin: Objections against eccentrics.]

So the eccentric of Magini and Lansbergen, which varies the eccentricity and carries the body of the Moon directly, avoids all the inconveniences already mentioned. But since these men and all who use an eccentric set another centre different from the centre of the Earth, in order to uphold the real equality not only of the distances but also, and above all, of the motions, in itself and with respect to their own centre, they imagine some point or other in the universe, displaying no other prerogative, whose good or dignity should prevail, and to which the motion of the planets should rather be ordered; and with respect to which they are to be said to move in themselves and primarily with an equal motion, but accidentally to move unequally with respect to the centre of the Earth. For that point, as was said in chapters 25, 26 and 27, is distant from the centre of the Earth, in Earth semidiameters: for Ptolemy, 10⅙; for Magini and Lansbergen, sometimes 5⅙ and sometimes 8; for Tycho at quadrature and for

Kepler, always 2½ very nearly; for Boulliau, at least 2⅗ and at most 5⅙; for Wendelen, always 3 11/12; for Šírek, always 5 11/12; and among those who vary the eccentricity it has an inconstant distance. Where in the world, then, is this point, so noble that it demands to be regarded in itself and primarily by the planet's mover? In the elementary sphere? (For this must be said, if you deny that the heaven of the Moon extends beyond the perigeal distance of the lunar body.) Then either in the air or in the fire, since it is outside the terraqueous globe. So a reason must be given why the Moon should move in itself and equally in relation to the air or the fire and some point of it, but accidentally and unequally in relation to the earth and the water. No such reason, I believe, can be devised with sufficient probability. For if you say that the air and the fire have a greater kinship, both in place and in quality, with the Moon, which is on the border of celestial and elementary bodies, many will not agree, who assert rather that it is another Earth, or more like the terraqueous globe; on them see chapter 2. Nor indeed do any living creatures live, or any meteorological effects occur, in that part of the air, let alone of the elementary fire, in which the centre of the eccentric lies, on account of which the lunar motion should have been directed there. I confess that I tried to set one of these points on the surface of the Earth and another on the surface of the elementary sphere, and that I imagined many other similar things; but in vain, because the measure of the distances, perceived by me through observations of parallaxes, could not in good faith be adapted to these fictions. But you will say that this centre was set there for the reason that the motion of a celestial body had to be uniform and equal, and it cannot be defended as such unless the centre of this motion is far distant from that centre in which the same motion appears unequal. Yet here, from this very invented position of the centre, something is already assumed which is both disputed among astronomers and which I shall show below, with greater probability, to be false. This argument holds in its own measure against epicycles, devised so that the physical and real equality of planetary motion should be safe on every side, and against that part of the elliptical orbit with respect to which some physical equality of motion at least, if not all of it, is sought. For in so far as Kepler and Boulliau acknowledge a physical inequality in this motion, they do not fear the blow of this argument.

[Margin: Objections against the elliptical orbit.]

What then do we find lacking in their form? Namely, that they should give a reason why the planet had to move in an ellipse, and in its motions had to regard only one of the two foci, or umbilici, the other being neglected and empty, and why it should besides regard the centre of the ellipse, however far that may be from the Earth, and though it has no character of good in the universe for which it should have been regarded; a reason, moreover, that does not already suppose that the motion must take place in an ellipse, or assume other uncertain things as certain. Add to this that in Boulliau's form the Earth is often outside both umbilici of the ellipse, and so three points must frequently be regarded: namely the centre of the Earth, the centre of the ellipse, and one

of the umbilici. Nor is there any need for me to press again here either the motions of the Earth, on which those forms rest, or the equality of the distances in the syzygies and quadratures, assumed by Kepler falsely and against the good faith of the observations; or the mystical trifles of the magnetic fibres and of the terrestrial crust and kernel, invented by Kepler to prop up his hypothesis; for enough has been said of these in the Scholia of the preceding chapter.

III.

[Margin: The heavenly motions are physically unequal, and a moving Intelligence regulates them.]

Since, therefore, we cannot avoid the inequality of distances that is manifest in the planets' approach to the Earth and in their recession, and the senses clearly perceive that the motions of the planets are not equal in all their parts, and no reason a priori, whether efficient or final, stands against this inequality, we shall acknowledge a physical inequality in them. And, with very wise men, we shall attribute the immediate efficient cause of this motion to Intelligences rather than to blind nature, because it is the work of a Mind that knows the end and the idea of that inequality. But because this controversy about the inequality of the heavenly motions, about their hypothesis and their moving cause, is universal, it will be treated by us more fully and more opportunely in Book 9, which is on systems and hypotheses; there we shall also blunt the frigid arguments that Kepler devised against moving Intelligences.

IV.

Now, however, for custom and for I know not what necessity of founding the calculation of the planets on some geometrical figure, and until the observations of Tycho are published — whose edition our Father Albert Curtz directs by order of the Emperor — so that from these, and from those of others and our own, made at very many eccentric places of the Moon, a more accurate form may be set out in volume 3 of the *Almagest*, we propose the following very simple hypothesis. We propose it not as true and such as shines forth in the mind of the Intelligence moving the Moon, but such as we judge suitable, so that from the fiction of an equal motion with respect to the centre of the eccentric we may, for a given variation of the real eccentricity, try out the equations to be applied to the mean motion, so that the true motion, or one very nearly true, may result. But the measures must first be set out, for which one must recall what we established in chapter 14.

[Margin: Kepler too, in the *Ephemerides*, no. 20, admits that from the parallaxes observed by Tycho the greatest equation in the syzygies comes out as 5° 1′; although, not trusting this subtlety and serving his own novelties, he sets it at 5° 0′.]

NOSTRAE FICTAE HYPOTHESIS SYNOPSIS.

Synopsis of our fictitious hypothesis.

A, centre of the Earth; B, centre of the eccentric at ♂ ☍; G, centre of the eccentric at □	Letters of the lines	Distances, to radius 100000	Distances, in semidiameters of the Earth	Horizontal parallax
Semidiameter of the eccentric	B C	100000	59 0′	
Eccentricity, greatest, at □	A G	13053	7 42′	
Eccentricity, least, at ☍ & ♂	A B	8745	5 10′	
Diameter	B G	4308	2 33′	
Distance of the Moon from the centre of the Earth at ♂ & ☍, greatest	A C	108745	64 15′	53′ 30″
Same, mean	A O	100000	59 0′	58′ 16″
Same, least	A D	91255	53 45′	63′ 55″

RESIDVVM TABVLAE PRAECEDENTIS.

The remainder of the preceding table.

A, centre of the Earth; B, centre of the eccentric at ♂ ☍; G, centre of the eccentric at □	Letters of the lines	Distances, to radius 100000	Distances, in semidiameters of the Earth	Horizontal parallax
Distance of the Moon etc. at □, greatest	A H	113053	66 42′	51′ 32″
Same, mean	A Q	100000	59 0′	58′ 16″
Same, least	A K	86947	51 20′	66′ 56″

Greatest equation at ♂ & ☍: the angle AFB, 5° 1′, at the point F, and at the arc of anomaly CNF, of 95° 1′, to which corresponds the arc CFV, 264° 59′; since AB is 8745, the sine of the arc FN is 5° 1′.

Greatest equation at □: the angle APG, 7° 30′, at the point P, where the anomaly HNKP is 262° 30′, to which corresponds the arc 97° 30′, where the equation is equal; since AG is 13053, the sine of the arc MP is of 7° 30′.

[Margin: Explanation of the figure for the conjunctions and oppositions.] Let A, then, be the centre of the Earth and B the centre of the eccentric in the syzygies, so that BC is the semidiameter of the eccentric, of 100000 parts, and AB the least eccentricity, of 8745 such parts. Let the eccentric CFDE be described from B, and let C be the apogee, with AC the Moon's greatest distance from the centre of the Earth in the syzygies, and D the perigee, with AD the least distance in the syzygies. Now let a perpendicular be drawn to A from the periphery of the eccentric, namely FA, and let it be joined to B. For in the triangle ABF, right-angled at A, the angle F will be the greatest equation, since the angle F is the greatest of all those having their vertex on the periphery of this circle and subtending the eccentricity AB as their base. This greatest equation occurs in the syzygies when the Moon is at F, a point below the mean longitude, that is, at the end of the arc of anomaly CNF, 95° 1′. For since AB is 8745 of the parts of which BC, that is, the whole sine, is 100000, this same AB is the sine of the arc NF, of 5° 1′. The mean longitude taken as the planet's mean distance from the apogee C is the arc CN, of 90°. But the mean longitude taken as the planet's mean distance from the centre of the Earth, A,

is the line AO; for it the point O is sometimes taken, that is, the place at which the planet holds its mean distance from the Earth. This point is below N and above F, and it is the point from which the perpendicular OI is drawn from the periphery to the line of apsides, falling at half the eccentricity and ending at I. For when O, A and B are joined, two equal triangles arise, in which BO, drawn from the centre of the eccentric, is equal to OA itself; and hence OA is equal to the radius BO, or BC, which is the mean distance between the greatest, AC, and the least, AD. For it is false, and contrary to observations, that the greatest equation occurs at the points of the mean longitudes, except in the sense on which see Book 3, Chapter 20. Finally, if we imagine the Moon to be at F, BF will be the line of the mean place and AF that of the true place, and the anomaly will be the arc CNF.

Diagram. A geometric figure set within the left column: two large overlapping circles of equal size, one drawn around G and one around B, cut by a vertical line of apsides running from H at the top to D at the foot. A small circle lies on that line between G and B, with T inside it and R just to its right. From the left periphery, broken and dotted lines run to B and to A; a solid line runs from F through to B; a horizontal solid line runs from F through A to P; a short solid line runs from O to I on the vertical. On the right, a dashed line runs from G to M, a dotted line from G to Q, a solid line from G to P, and a dashed line from A up to Q.

- H (top of the vertical, on the upper circle): apogee of the eccentric drawn around G
- C (on the vertical, below H, on the lower circle): apogee of the eccentric drawn around B
- G (on the vertical, top of the small circle): centre of the eccentric at the quadratures
- T (inside the small circle): not explained in the text of this page
- R (right of the small circle): on the small circle BRG
- B (on the vertical, foot of the small circle): centre of the eccentric at the syzygies
- I (on the vertical, below B): foot of the perpendicular OI
- A (on the vertical, below I): centre of the Earth
- K (on the vertical, on the upper circle's foot): perigee of the eccentric drawn around G
- D (foot of the vertical, on the lower circle): perigee of the eccentric drawn around B
- M, Q, V (right periphery, descending); P (right, on the horizontal through A)
- N, O, F (left periphery, descending); S (lower left, right of F, on the horizontal)
- E (lower right periphery)

Labels read: H, C, G, M, Q, T, R, N, B, I, O, F, S, A, P, V, E, K, D. Labels not read: none.

Let the centre of the eccentric now be at G for the quadratures, so that AG, the greatest eccentricity, is 13053 of the parts of which the radius GH is 100000. [Margin: Explanation of the figure for the quadratures.] From G let the eccentric HSKM be described, and let H be the apogee, with AH the greatest distance from the centre of the Earth, and K the perigee, with AK the least distance. Then, when the perpendicular PA has been drawn to A and P has been joined to G, the right triangle GAP will result, in which the angle P, subtending the greatest eccentricity AG, 13053, will be the greatest equation, 7° 30′ — and not 7° 40′, as those would have it who, with Copernicus, set the greatest eccentricity in the syzygies, that is, the sum of the semidiameters of the epicycles, at about 13340. But the distances we have observed in the apogee and perigee quadratures by no means allow this. Here too the equations occur at the point P, or at the point corresponding to it on the left, where the arc MP is computed from the eccentricity AG and its sine as 7° 30′. But the mean longitude taken as the mean distance is AQ, and the point Q that ends it is below M by the arc MQ, which is 3° 44′ 30″, as its sine shows, that is, half the eccentricity AG, which is 6526 of the parts of which the radius GH is 100000.

Just as no equation is needed when the Moon is on the line of apsides, that is, in the apogee or perigee of the eccentric, and this whether in the syzygies or quadratures or outside them, so the greatest equations occur a little below the mean longitudes. Therefore, in the month in which the new Moon falls in the apogee C, the first quadrature will occur at the point S with the greatest subtractive equation, and the full Moon nearly in the perigee D, and the second quadrature at P with the greatest additive equation. But if the new Moon occurs in the perigee D, the first quadrature will occur at P with the greatest additive equation, the full Moon nearly in the apogee C, and the second quadrature at S with the greatest subtractive equation. Conversely, if the first quadrature occurs in the apogee H, the second will occur in the perigee K with almost no equation; but the full Moon will occur at F, with the greatest syzygial equation to be subtracted, and the new Moon at V, with the greatest equation to be added. In turn, if the first quadrature occurs in the perigee K, the second will be in the apogee H, the full Moon at V with the greatest equation to be added, and the new Moon at F, nearly with the greatest equation to be subtracted. For this is what the observations require; and from them we have also learned that when the doubled distance of the once-equated Moon from the Sun is 180°, the centre is at G and it is the time of quadrature, and that in the mean longitudes the greatest equations are as great as we have said.

V. [Margin: Explanation of the hypothesis outside the syzygies and quadratures.] For the hypothesis outside the syzygies we must recall what is certain so far, from our own observations and those of others, about the mixing of the second inequality with the first, and what was already sufficiently indicated, with Boulliau, in the preceding chapter, no. 14. We note, however, that it is not necessary to imagine the centre of the eccentric as moved on the small circle BRG; it is enough that it be carried up or down from the point B to the

point G — not, indeed, along the same straight line in the world, since the line of apsides DH must be conceived as moving continually eastward, and so the centre of the eccentric must change its position by an oblique ascent and descent. For while the Intelligence describing a spiral line with a slower motion than the motion of the primum mobile, seems to us to retard the planet toward the east, it at the same time, in measuring the distances, observes or is imagined to observe a centre of the eccentric that is always further and further to the east. Yet at any given moment we can employ this centre as though it were then unmoved and, letting fall a perpendicular from it to the centre of the Earth, measure the eccentricity. Nor indeed is it necessary for us to use the sines of the arcs of the small circle BRG in order to measure the appendix to be added to the least eccentricity AB, namely the appendix BT, even granting that for this we use the doubled motion of the Moon from the Sun. Instead we have so far used another, easier method, by which we have been accustomed to derive equations agreeing with the observations. We therefore propose it, until, from a sufficient number of observations — a number that an unseasonable sky has not rarely cut short — something can be perfected more exactly by the astronomical file. We suppose, moreover, that the Moon's monthly motion is tied to the true rather than to the mean motion of the Sun; that this too was observed by Tycho you will learn from the Appendix to volume I of the *Progymnasmata*.

Diagram. A geometric figure set within the left column: a large circle, the Sun's circle, drawn around A, with a smaller circle, the Moon's eccentric, inside it, drawn around B. A vertical line runs from T at the top to Z at the foot, through G, Q, B, C, A and P. Two further straight lines cross at A, one from H to K and one from F to N. A dotted horizontal line joins D to E through B. From L on the inner circle, and from M on it, straight lines run to A, to B and to C.

- T (top of the outer circle), Z (foot of the outer circle), on the vertical
- H (upper left), N (lower left), F (upper right), K (lower right), on the outer circle
- ♈ (on the outer circle at its rightmost point)
- ♎ (on the outer circle at its leftmost point, opposite ♈)
- G (top of the inner circle), P (foot of the inner circle), on the vertical
- Q, B, C (on the vertical, descending, between G and A); A (the crossing of the lines)
- L (upper left on the inner circle), M (lower right on the inner circle)
- S (where HK cuts the inner circle, upper left), I (where FN cuts it, upper right)
- R (where FN cuts it, lower left), V (where HK cuts it, lower right)
- D (left end of the dotted line), E (right end of the dotted line)

Labels read: T, G, H, L, S, Q, B, D, E, I, F, C, A, M, V, R, P, N, K, Z, ♈, ♎. Labels not read: none.

Let the line of apsides be GAP, movable toward the east, on which lie A, the centre of the Earth and of the world, and the least eccentricity AC, of 8745 parts, and the greatest, AQ, of 13053 of the parts of which the radius of the eccentric, BG, is 100000. Now, however, let the centre of the near-circular spiral be at B, from which the circle GDPE will be described; and so let the temporary or monthly eccentricity be AB and the appendix of the eccentricity be BC, always to be added to the least eccentricity AC if you wish to know the momentary eccentricity AB. Now let the Moon be at L or M, and let these places be joined by three straight lines each: to A, the centre of the Earth; to C, the centre of the other eccentric, used for the Moon in the syzygies; and to B, the centre of the present eccentric. For two triangles of equation will arise. One is LAC or MAC, which in this figure does not indeed contain the exact equation of the first inequality, because the centre of this eccentric is not at C; yet it indicates that equation, so that the imagination may be helped and so that the drawing of the other eccentric, on which the Moon in fact is not now, may not lead us into another, greater deception. The other triangle is LCB or MCB, in which the angle at L or M is the exact measure of the monthly equation considered separately from the first. The angle L in the triangle LBC therefore becomes known by trigonometry, given now the radius BL, 100000, the appendix of the eccentricity B[?][35], and the sum of the angles BLC and BCL. By Euclid 1.32 this sum is as great as the external angle LBG, that is, as great as the anomaly of the once-coequated Moon, counted from the apogee G in the order of the signs. Likewise when the Moon is at M, in the triangle MCB there must be given the radius BM, 100000, the appendix of the eccentricity BC, and the sum of the angles BCM and BMC; when the anomaly is greater than a semicircle, this sum is equal to the complement of the anomaly to the circle, namely the angle GBM. Next, the angle found at L or M, that is, the monthly equation, is added to or subtracted from the place of the once-equated Moon, so that the Moon's true place, or its twice-equated place, results. Here, however, we must repeat the rules of addition or subtraction, gathered from observations of the Moon's true place; and they are those written below.

VI. [Margin: Figure for the rules of monthly addition or subtraction.] Describe the Sun's circle THNZKF from the centre of the world A, and draw through A, in any way, the synodic lines HAK, or NAF, or TAZ, cutting the Moon's eccentric at the points S, V, R, I, G, P; if the Moon were at these points, there would be either a new Moon or a full Moon. Finally, when the line of the lunar apsides GAP has been cut in two and at right angles at B, let the points D and E be marked. For, as we said in the preceding chapter, no. 14, the periodic anomaly, or first inequality, begins from the apogee G, and from there it grows up to the first mean longitude near D, where it becomes greatest; from there it decreases as far as the perigee P, where it vanishes, and the equations are subtractive in the semicircle GDP. (For to avoid confusion we

[35] the second letter is blotted on the page, a C-shaped bowl with a dark mark inside it, unlike the G set two lines below; the parallel sentence for M reads BC

here employ this eccentric just as if it were the one that serves the Moon when set in the syzygies, and as if it should be described from the centre C.) From there it begins to grow as far as E, the second longitude, where it is greatest, and from there it decreases as far as G, where it vanishes; and in the semicircle PEG the equations of the first inequality are additive. But the second anomaly, or monthly inequality, begins from the mean longitudes of the periodic anomaly, namely from the points E and D, of which E is at the 270th degree counted from G through DP, and D at the 90th. Now if the synodic line is joined with the line of the lunar apsides and the Sun is at T or at Z, when the Moon, joined or opposed to it, is at G or at P, there is no first inequality; but in that month, as we have said, the quadratures will occur at the mean longitudes D and E. And therefore, when the synodic line falls on the periodic apogee G or perigee P, we have said that the monthly inequality becomes greatest in that month. The monthly inequality therefore begins to grow from the point E, on which the synodic line falls, and it grows as far as G and decreases again as far as D. And if the synodic line falls within this earlier semicircle of the monthly anomaly, namely the one containing the periodic apogee G — as if the Sun is at F and the synodic line AF falls on I, or if the Sun is at H and the synodic AH falls on S — the monthly equations from ♂ to ♌ are to be subtracted, but from ♌ to ♂ added, to the once-equated place of the Moon. Conversely, if the synodic line falls in the later semicircle of the monthly anomaly, the one containing the periodic perigee P — as if the Sun is at N and the synodic line AN falls on R, or the Sun is at K and the synodic line AK falls on V — then the monthly equations from ♂ to ♌ are to be added, and from ♌ to ♂ subtracted. For example, if the Moon is at L and the Sun at F, the Moon will be in the earlier semicircle of the month, that is, it will have departed from a new Moon made near F, and will be tending toward a full Moon to be made a little beyond N, and the synodic line will fall on I, a point of the earlier semicircle of the monthly anomaly. Therefore the monthly equation will have to be subtracted. With these things set down, let the whole progress of the calculation now follow.

VII. [Margin: Precept 1. Method of finding the true place of the Moon.] *First.* For the given time, gather from our tables the true place of the Sun, the once-equated place of the Moon, and the once-equated anomaly of the Moon. Subtract the true place of the Sun from the Moon's once-equated place, taking a whole circle if necessary, so as to have the elongation of the Moon from the Sun; and finally double this. If so doubled it does not exceed 180°, use it; if it does exceed, use its complement to 360°. In either case let it be called the anomaly of the eccentricity.

[Margin: Precept 2.] *Second.* Multiply the anomaly of the eccentricity by the whole difference of the eccentricities, CQ, namely by 4308, and divide the sum by 180. For the quotient will be the appendix of the eccentricity, as CB; added to the least eccentricity AC, it will make up the temporary or monthly eccentricity AB. And this same appendix added to the radius, 100000, will make

the sum of the sides, and subtracted from the same it will make the difference of the sides; these are the two data required for solving the equating triangle.

[Margin: Precept 3.] *Third.* Take the once-equated anomaly of the Moon if it does not exceed 180°, or its complement to 360° if it does exceed 180°, and divide it in two; for its half is the half-sum of the angles adjacent to the base of the equating triangle. With this, and with the sum and difference of the sides mentioned in Precept 2, find the angle opposite the appendix of the eccentricity; for that will be the monthly equation. Therefore, if you wish to proceed by sines and tangents, multiply the tangent of the half-sum of the angles by the difference of the sides; and the sum, divided by the sum of the sides, will give the tangent of the angle always to be subtracted from the half-sum of the angles; for the remainder will be the monthly equation. [Margin: A short way of solving the triangle of equation.] But if you use the short way of logarithms, add together the mesologarithm of the half-sum of the angles, the logarithm of the difference of the sides, and the residual of the logarithm of the sum of the sides. For the sum, with unity taken away from the left, will be the mesologarithm of the angle to be subtracted from the half-sum of the angles, and the remainder will be the monthly equation.

[Margin: Precept 4.] *Fourth.* Subtract the once-equated anomaly from the once-equated place of the Moon, taking a whole circle if this is necessary for the subtraction, and you will have the place of the lunar apogee. Subtract this from the true place of the Sun, and you will have the longitude of the Sun from the Moon's apogee. If this is less than 90° or greater than 270°, the synodic line will be in the first semicircle of the monthly anomaly; but if it is greater than 90°, yet less than 270, it will be in the second.

[Margin: Precept 5.] *Fifth.* Finally, if the synodic line is in the first semicircle of the monthly anomaly and the Moon is tending from new Moon to full Moon, subtract the monthly equation from the Moon's already once-equated place; but if it is tending from full Moon to new Moon, add it. Conversely, if the synodic line is in the second semicircle, add it from ♂ to ♌ and subtract it from ♌ to ♂; and you will have the true place of the Moon, twice equated. But if you wish to know the Moon's distance from the centre of the Earth, you must, in the triangle resting on the eccentricity, seek the base or third side, namely the side LA in the triangle ALB, given the radius LB, the monthly eccentricity BA, known from Precept 2, and the complement of the coequated anomaly to a semicircle, or its excess if it should exceed one. But an example will make the precept clear.

EXEMPLVM.

Example.

VIII. In the year 1641, at noon on February 13, the motions of the ☾ and the ☉ stand as follows from our tables.

	Value
☉ True place	10ˢ 24° 19′ 14″
☾ Place once equated	0ˢ 6° 19′ 6″
☾ Anomaly once equated	10ˢ 5° 12′ 44″
☾ elongation from ☉	1ˢ 11° 59′ 52″
Doubled	2ˢ 23° 59′ 44″
or	83° 59′ 44″

Since, then, the doubled elongation of the Moon from the Sun does not exceed 180°, when 83° 59′ 44″, or 84°, is multiplied by 4308, the sum is 361872. When this is divided by 180, there remains the appendix of the eccentricity, CB, of 2010 parts. When this is subtracted from the radius BM, 100000 (for we imagine the Moon to be at M), there remains the difference of the side CB from the side BM, 97990; and when it is added to the radius, the sum of these sides results, of 102010 parts. Now the complement of the once-equated anomaly to the circle was 54° 47′ 16″, namely the angle MBG, which is equal to the angles BCM and BMC taken together, and their half-sum is 27° 23′ 38″, whose tangent is 51822. This tangent, then, being multiplied by the difference of the sides, 97990, and the sum divided by the sum of the sides, 102010, there will remain 49786, the tangent of the angle of 26° 28′. Subtracted from the half-sum, 27° 23′ 38″, this leaves the monthly equation, 55′ 38″.

Now when the equated anomaly of the Moon is subtracted from the once-equated place of the Moon, there is left the place of the lunar apogee, 2ˢ 1° 0′ 22″. Subtracted from the true place of the Sun, K, this leaves the arc GLRV, the distance of the Sun from the Moon's apogee, 8ˢ 23° 18′ 52″, or 263° 18′ 52″. So the synodic line was in the later semicircle of the monthly anomaly, that is, within the arc DPE, and the Moon was tending from new Moon to full Moon, as is clear from its elongation from the Sun, and it was near the first octant. The monthly equation of the Moon, 55′ 38″, must therefore be added to the once-equated place of the Moon, 0ˢ 6° 19′ 6″, and the true place of the Moon becomes 0ˢ, that is ♈, 7° 14′ 44″.

But by Tycho's calculation at Bologna it was ♈ 7° 18′; for Argoli it is ♈ 6° 24′, for Lansbergen ♈ 6° 14′, for Copernicus ♈ 5° 52′. Nor is this surprising, for sometimes the difference in the twice-equated lunar place among these authors and others rises to a whole degree. So our calculation ought not to seem false to anyone because it sometimes differs by several minutes from the place given by others; rather, the sky is to be consulted, and from observations the hypotheses are to be corrected, whether those of others or our own. As for that Variation which Kepler (Book 6 of the *Epitome*, p. 816, and in the Rudolphine Tables, p. 83, col. 2) and Boulliau (Book 3, Chapter 14), the former from Tychonic observations, the latter from his own and those of others, teach to be an anomaly, and to be now 50′ ½, now 30′ ½, now midway between these: it is not yet so known to me that it can be bound to fixed laws.

CAPVT XXIX.

Chapter 29.

De Theorica Latitudinis Lunæ.

On the theory of the Moon's latitude.

I. In Chapter 12 it was said what the Moon's greatest latitude is and how great, both in the syzygies, 5°, and in the quadratures, 5° 18′; and the way of finding these by observations was given there. In Chapters 22 and 23, moreover, we taught the way of determining the mean or true motion of the lunar nodes against the order of the signs [in antecedentia], which, added to the Moon's mean motion in the zodiac in the order of the signs [in consequentia], constitutes the mean motion of latitude; we determined this too in the same place, and the period of this motion in Chapter 18. Nothing else remains, then, but to set out the theory of this motion. [Margin: The ancients' hypothesis on the Moon's latitude.] Now Ptolemy in Book 4, al-Battānī in Chapter 38, Peuerbach in the *Theorica* of the Moon and his commentators there, Copernicus in Book 4, Chapters 4, 23 and 24, Magini in the *Theoricae Planetarum*, Book 2, Chapter 2, and Barozzi in Book 4 of the *Cosmographia*, p. 243, were not much concerned about this part of the hypothesis, since they supposed with Ptolemy that the Moon's greatest latitude is perpetually and invariably 5°. So it was enough for them to suppose that the plane of the lunar orbit, together with the plane of the epicycle or epicycles, is inclined to the plane of the ecliptic at an angle of 5°, and that these planes cut one another in a diameter passing through the centre of the world. Those who posited solid orbs added that the axis of the lunar orb intersects the axis of the ecliptic at the centre of the world, with an angle of intersection of 5°, so that the poles of the lunar orb are 5° from the poles of the ecliptic, and that these poles are on the periphery of the circle passing through the limits, that is, on that circle of latitude whose arc intercepted by the Moon's orbit and the ecliptic is the greatest latitude. Copernicus and Lansbergen, however, chose to count latitude from these limits rather than from the nodes. In the hypothesis of these authors, moreover, the equations of the motion of latitude are not different from the equations of the motion of longitude, but are the very ones, of exactly the same quantity and character, by which the motion of longitude is equated, since this motion is included in the motion of latitude and the motion of the nodes in itself is, with them, always uniform.

II. [Margin: The anomaly of the motion of latitude and of the nodes, detected by Tycho.] Tycho, however, as he himself affirms in volume 1 of the *Progymnasmata*, p. 127, and after him Longomontanus (*Theorica*, Book 1, Chapter 7) and Mulerius (*Isagoge* to the *Tabulae Frisicae*, p. 415), Origanus (second part of the *Ephemerides*, Chapter 4) and Magini (*Supplement to the Ephemerides*, canon 7), affirms from his observations that in the syzygies, and nearly in the quadratures, the motion of the nodes does not need any equation, and that the

greatest latitude of the lunar orbit is perpetually 4° 58′ 30″; but that outside the syzygies the motion of the nodes is unequal and therefore needs an equation, which sometimes grows to 1° 46′; and hence that from this motion the latitude of the Moon, since it is further from the nodes than the motion of the ancients would allow, can turn out about 10′ greater than usual; and that the greatest latitude of the lunar orbit in the quadratures is 5° 17′ 30″. This is to be believed on his word in the meantime, until his observations come to light, whose edition, as I have said more than once, is in the charge of Father Albert Curtz of our Society, by order of the Emperor. On this assumption, Tycho and Longomontanus there account for this anomaly with the following figure. From B, the pole of the ecliptic CFDG, let the ecliptic be described, which the semicircle of latitude CBD cuts at right angles at C and D; on whose periphery, here along a straight line as represented, let A be the pole of the lunar orbit KFHG, distant from the pole B by 5° 8′ — that is, by as much as the mean inclination of this orbit to the ecliptic, or the Moon's mean latitude if it is at K, measured by the arc CK; and the nodes will then be at F and G. Again, from A let the small circle EMZI be described, whose semidiameter AE is 9′ 30″.

Diagram. In the left column: a large circle with concentric-looking eccentric arcs. The vertical diameter runs from C at the top through B and A down to D, with H just below D outside the circle. Near the centre, about A on the vertical line below B, stands a small circle with a horizontal diameter. Three arcs cross the upper part of the vertical at R–L–S, X–K–d and N–Y–O, and curve down to the rim on both sides. Labels read on the plate:

- C (top of the vertical): the point where the semicircle of latitude meets the ecliptic
- R, L, S (upper arc, from left to right across the vertical)
- X, d (next arc, left and right of the vertical)
- K (on the vertical, below L)
- N, Y, O (next arc, from left to right across the vertical)
- B (on the vertical): the pole of the ecliptic
- T (left) and V (right): rim points at the height of the small circle's upper part
- F and P (left rim, side by side)
- G and Q (right rim, G above Q)
- I (top of the small circle), E (its left end), A (its centre), Z (its right end), M (its foot, on the vertical)
- D (foot of the vertical), H (below it)

This is the small circle of the third anomaly, or Variation, and also of the anomaly of latitude and of the nodes. On its periphery the pole of the lunar orbit moves in the order of the signs [in consequentia] from I to E, with a motion double the Moon's elongation from the Sun, so that at new and full Moons this pole is at I. From I the lunar orbit TRSV is understood to be described, with the nodes at T and V, and with the smallest angle of inclination, CTR, or the smallest latitude, 4° 58′ 30″. At that time there is no Variation in the

motion of longitude, and no anomaly of the motion of latitude and of the nodes. Conversely, when the pole of the lunar orbit is at M, which happens at the quadratures, the orbit is PYQ, etc., with the nodes at P and Q, and the inclination CPY and the latitude CY at their greatest, 5° 17′ 30″. Then too there is no Variation and no inequality of the nodes, because the arc CBAMD, etc., is continuous. In octants 1 and 3, however, the pole is at E, and in octants 2 and 4 at Z; and there the greatest Variation occurs (which can, however, be accounted for by a libration along the diameter EZ alone), together with the greatest anomaly of the nodes. Now let arcs of circles of latitude, RBZ and SBE, be conceived, cutting the arc CD at the pole B: for the spherical angle ABZ will be the measure of the equation of the nodes, since it is equal to the angle XBK, just as ABE is equal to the angle dBK. In the triangles ABZ and ABE, moreover, the side BA, 5° 8′, is always given, and the side AZ or AE, 9′ 30″; and the angle BAZ or BAE that they comprehend is known from the doubled motion of the Moon from the Sun, for it is equal to this elongation if that is not greater than 180°, as with BAE; but if it is greater, the angle is equal to its complement to the circle, as is the angle BAZ. This anomaly is counted from I, where the pole is at conjunction [☌], towards E, etc.; and the prosthaphaeresis is subtractive from the motion of the nodes in the first semicircle of the doubled elongation, IEM, but additive in the second, MZI.

[Margin: Verdict on this hypothesis.] III. In this hypothesis, then, the Variation and the anomaly of latitude and of the nodes are monthly. But this hypothesis, as Tycho meant it, is indeed a fiction, made as a geometrical model for calculation on paper and a foundation for the imagination, as Kepler admits in the *Epitome of Copernican Astronomy*, p. 817; it is not, however, real. For Tycho himself did not later admit solid orbs, nor did he hold that the planets are moved by the motion of the whole machinery of their heaven, but rather that they move freely in a fluid aether, by the force of some physical cause; and so the motion already mentioned, on that small circle devised about the poles of the ecliptic, is not real. For us, however, all this is accomplished by an Intelligence that leads the Moon round in spirals, bending it from the ecliptic and intersecting the ecliptic in different ways and at different places, accelerating and retarding its motion as harmony requires — not the harmony of the ears, which Kepler pursued all too clumsily, by an analogy utterly [Greek: ἄλογον (alogon, "irrational, without ratio")] from the divine plan, but the harmony of minds, which Divine Providence has fixed in advance according to the alternation of effects, and whose idea it willed to shine forth from its archetype in the mind of the Intelligence that moves the lunar globe.

[Margin: Kepler's hypothesis on the Moon's latitude.] IV. Kepler, however, in the foundations of his *Ephemerides*, from no. 20 on, in the *Epitome of Copernican Astronomy*, Book 6, pp. 620, 788, 797 and 817, and in the Rudolphine Tables, Chapters 25 and 27, partly adheres to Tycho and partly departs widely from him. But later he relapses into Tycho's view, by an inconstancy or a craftiness that is certainly remarkable, though familiar to this mind, so that he

may not either bring forth nothing new, or have the offspring of his novelty found illegitimate through disagreement with the phenomena. Accordingly he grants Tycho that the Moon's greatest latitude at the quadratures is 5° 17′ 30″, or in round figures 5° 18′; that in the other syzygies, those without eclipses, the smallest latitude is 4° 58′ ½, or rather, in round figures, 5°; and that when the Moon's nodes are in the octants it has a small latitude. But in most respects he disagrees as regards the form of the hypothesis, even granted that as regards the effect of the calculation, as will be said later, he differs from Tycho imperceptibly. He says, then, that after Tycho's death he discovered from eclipses of the Sun and Moon that the angle of latitude is greatest, 5° 18′, throughout the whole month in which the Sun or the Earth's shadow passes the places of the nodes; that in the following months, he says, this angle diminishes until at the syzygies it comes to 5° 0′; and that this anomaly is annual, not monthly, and is restored twice in one year. Accordingly Tycho, from the eclipse syzygies, releases the Moon from a small angle of inclination to the greatest at the quadratures, so that this increase is nil at the end, greatest at the beginning but slow, and steep in the middle; and the nodes reciprocate twice in any month, turning from direct to retrograde. Kepler, by contrast, from the eclipse syzygies releases the Moon at a large angle of inclination, which it keeps throughout the eclipse month, so that when the node is at quadrature, the Moon runs out on a straight, not a bent, path to the syzygies at a small angle of 5°, and acquires a latitude equal to this at the syzygies; and the change is slow only when the increments of latitude are greatest, and fastest when they vanish; nor do the nodes ever become direct, but rather resemble stationary bodies twice in the year, and their inequality is semi-annual. Moreover he advanced the places of the nodes 25′ beyond what Tycho's calculation gives for these times. But in order that, with a large angle of inclination posited, constant from the syzygies to the quadratures, the latitude should not be greater than Tycho's observations allow when the Moon has its nodes in the octants, he introduced — after many perplexities and great errors, as he admits in Chapter 27 of the Rudolphine Tables — an annual libration and prosthaphaeresis of the nodes, so that this should take away as much as the large angle had added in the eclipse latitudes. And although in the *Ephemerides* he had set up a libration of the limits on an axis released from the Sun, that is, on the line connecting the nodes and the centre of the Earth, yet in the *Epitome of Copernican Astronomy*, pp. 794, 818 and 821, he set up a libration of the monthly limit on an axis and line tied to the line of the syzygies. And finally, forced to choose a middle way, he introduced a double prosthaphaeresis of the node, three-monthly rather than annual, which would be of very small quantity when the node is near the Sun; but when the node is in the octants, and 45° from the Sun on one side or the other, it would be equal to Tycho's monthly equation. Yet in that Chapter 27 he professes that these matters are not yet clear in every respect.

[Margin: The physical cause of this hypothesis.] V. As for the physical cause of the varying latitude, Kepler in Book 4 of the *Epitome of Copernican*

Astronomy, p. 620, assigns it to the light of the Sun and its application to the Moon's fibres, but to the fibres of latitude. For just as our stomach has three positions of fibres, for attracting, retaining and expelling, so it is no wonder if in the Moon there are two kinds of fibres, of which one kind strives to keep the same position, parallel to itself, as regards longitude in the universe, and the other the same position as regards latitude. When, therefore, the light, which has a certain breadth [latitudinem] since it is a surface, is fitted to the fibres of latitude, it increases the latitude; otherwise it does not increase it. [Margin: A fictitious scheme of the same.] As for the hypothesis devised to help the imagination, recall here the Keplerian Sun set out in Chapter 27, no. 6, and imagine a plane drawn through the points A and G, oblique at 5° to the plane of the ecliptic, on a line passing through the centre of the Earth, A, and the places of the nodes; in which plane let the line of the syzygies be HGAK, on which the Moon's eccentric PDRC is inclined to the plane I spoke of earlier — not always, however, but according to these laws. If S and T are the places of the quadratures among the fixed stars, and the limits of the Free anomaly are on the line HGAK, then the plane of the eccentric is united with the former plane, with no inclination between them, though their common inclination to the plane of the ecliptic is kept. But when the limit of the Free anomaly, the northern one for example, begins to digress from H, the place of opposition, towards the quadrature K, and has come, say, to D, then as the sine of the angle HAP is to the sine of the right angle HAT, so let the portion of the northward libration, by which the monthly limit K librates, be to the whole libration or inclination of the planes, which is 18′. This whole inclination occurs in the month in which the northern limit of the Free anomaly comes to T, the place of the quadrature. Hence the northern limit of the Free anomaly rises northward from the former plane until it falls on the quadrature K, and from there gradually inclines back towards the former plane; and finally, on coming to K, it recedes into that plane itself. But when the northern limit of the Free anomaly passes the point K, towards T, the semicircle HCK becomes southern with respect to the monthly latitude.

VI. The method of calculation by which one arrives at the monthly equation of latitude, moreover, is this. First, with the Sun's distance from the north node, the minutes of latitude are sought, that is, the sine of the complement or of the excess, to or beyond one or three quadrants, of the Sun's distance from the Moon's node ☊, reduced to astronomical minutes of which the whole sine is worth 60. Second, by the monthly argument, that is, by the distance of the Moon's true and finally equated place from the Sun's true place, the monthly latitude is taken out, namely the arc of a great circle under the ecliptic, whose plane, passing through the centres of the Earth and the Moon, stands erect at right angles on the plane inclined at a constant angle of 5° to the plane of the ecliptic; it is, I say, the arc intercepted between this plane, when extended, and the place under which the centre of the lunar body lies. Third, the monthly latitude is multiplied by the minutes of latitude, for from this the appropriate

portion of latitude is obtained. But see the precepts of the Rudolphine Tables, Chapter 27, on which we treat in the practical part. Whether, moreover, the nodes have as much power as the astrologers imagine is disputed by Kepler in the foundation of the *Ephemerides*, no. 25; consult him.

[Margin: Lansbergen's scheme.] VII. Lansbergen's theory for the latitude and the motion of the nodes, given by him in Chapter 5 of his *Theoricae*, is as follows. From A, the centre of the world, let a circle of latitude be understood to be described, of which, for brevity's sake, we here mark only the arcs QG and DR; let it be at right angles to the plane of the ecliptic, marked here by the straight line CAB. And let the limits of the smallest latitude be F and E, and those of the greatest G and D, joined by straight lines; for the angle CAF will be the smallest inclination of the lunar orbit to the plane of the ecliptic, and CF the smallest latitude, 5°, at the syzygies; but the angle CAG and the arc CG will be the greatest, at the quadratures, 5° 16′. Therefore the mean, that is the arc CI, will be 5° 8′, and the difference between them 16′, half of which is the arc FI, 8′. With this interval let the small circle HFKG be described, the circle of the anomaly of the obliquity of the lunar orbit, which is as great as the anomaly of the centre, that is, as great as the doubled distance of the Moon from the Sun, and is counted from F through K, G, H, in the order of the signs. The libration of the lunar orbit in latitude itself takes place along the diameter FG, reciprocally, and is restored twice in a month.

Diagram. Set into the left column, with the text running in a narrow measure beside it on the left. From A, low in the figure, straight lines rise to an upper arc and descend to a lower arc, the two arcs being opposite ends of a circle of latitude. At the upper right on the arc stands a small circle with a diameter through its centre. Lines rise from A to P and C on the left of the fan, and a dotted line rises from A through O towards the small circle; below A the lines descend, one of them dotted, to D, N, E and B on the lower arc. Labels read on the plate:

- Q (far left end of the upper arc), C (on the upper arc), F (left rim of the small circle)
- H and M (above the small circle), I (its centre), L (within it, to the right of I), G (its right rim), K (its foot)
- P (on the left of the fan, below the upper arc), O (on the right of the fan, level with P)
- A (the crossing point of the lines)
- D, N, E, B (along the lower arc from left to right), R (right end of the lower arc)

[Margin: Method of geometrical and logistic calculation for the latitude.] VIII. With these premises, let the Moon's southern latitude observed by Tycho be 5° 13′, in 1587 August 17, Old Style, at the hour p.m. $19^{h}\ 24^{m}$ at Uraniborg — but, as examined, $19^{h}\ 18^{m}$ — and at Goes $18^{h}\ 33^{m}$. At that time the Sun's mean motion from Lansbergen's tables was 155° 36′ 2″. The Moon's mean elongation from the Sun was 295° 3′ 1″, which, doubled, is 590° 6′ 2″. When a circle of

360° is discarded, then, there remains the anomaly of the centre, and also of the obliquity of the lunar orbit, 230° 6′ 2″. The mean motion of latitude was then 180° 35′ 9″, and the subtractive prosthaphaeresis of the orb 3° 44′ 18″; therefore the true motion of latitude was 176° 50′ 51″. So, drawing the intersecting line NM, which marks at L the latitude CL that we are seeking, let 230° 6′ 2″ be counted from F through K; for when the semicircle FKG of 180° is discarded, there remains the arc GM, 50° 6′ 2″, whose second sine, namely LI, is 64145 of the parts of which IF is 100000. But of the units of which IF is 8′, LI is 5′ 1/10, and LF 13′ 1/10. And when the smallest latitude is added, the southern latitude CL becomes 5° 13 1/10′, which is very nearly what Tycho observed. But it can be corrected as below.

For let the plane of the lunar orbit at that time be marked by the intersecting line NAOM, which we may use as if it were a semicircle; and let N be the northern limit of the temporary latitude and M the southern, with the south node at A; and let the motion of latitude, 176° 50′ 51″, be counted from N as far as O. For when 90°, that is the arc NA, are discarded, there remains the arc AO, that is, the Moon's distance from the south node, 86° 51′. So a perpendicular arc is dropped from O to P. [Margin: Finding the places of the nodes.] For since in the spherical triangle APO, right-angled at P, the angle at A is given, 5° 13 1/10′, and the base AO, 86° 51′, the side OP, that is the Moon's latitude, will be found to be very nearly 5° 13′. And since the motion of latitude counted from N, then the northern limit, was 176° 50′ 51″, if you add to it 90° against the order of the signs [in præcedentia], you will find the motion of latitude counted from A, but from the north node, 266° 50′ 51″. If you take this from the Moon's motion, which was then ♊ 27° 11′, there will remain the true place of the Dragon's Head in ♎ 0° 20′, and of the Dragon's Tail in ♈ 0° 20′. [Margin: The hypothesis of Pierre Hérigone.] Hérigone, moreover, in volume 5 of his *Cursus Mathematicus*, follows Lansbergen's hypothesis in this theory, as can be seen on p. 588.

IX. Ismaël Boulliau, in Book 3 of the *Astronomia Philolaica*, Chapter 13, pressing his own opinion — which should be recalled here from our Chapter 27, from no. 13 — affirms that if the Moon were not moved with an annual motion around the Earth, the nodes would advance in the order of the signs; but that if, carried along by the Earth with the annual motion alone, it had not been raised up month by month, there would be no reciprocation of the nodes such as Tycho observed. But since the Moon is carried off by the motion of the Earth with its whole system towards the east, and the Moon's apogee is advanced in the same direction, nature has provided that the lunar system should be drawn back towards the west by certain restraints, so to speak. Because of the evection, moreover, a reciprocal libration of the nodes follows each month: for when the Moon's ellipse is displaced, the northern part is raised further to the north, and the Moon's latitude increases from the syzygies to the quadratures, and decreases from the quadratures to the syzygies. Meanwhile, from ☌ to the first quadrature, and from ☍ to the second, the nodes are dislocated, and the Moon, ascending from the syzygies to the quadratures, is lifted towards the north; and

so the node moves faster against the order of the signs, and its greatest speed comes in the octants. From the quadratures to the syzygies, however, the north node passes to the south and the southern to the north, and over the same time the node's motion is faster in the order of the signs.

Now let the annual orb be ABC, with the Earth at B, carrying the Moon around the Sun; let the circle KAL be in the plane of the annual orb, and let the Moon's orbit be HOFZ, with the north node ☊ and the south node ☋, and the southern semicircle ☋F☊. At the syzygies the nodes are carried against the order of the signs with a simple and uniform motion from ☊ to F; but outside the syzygies a synodic motion supervenes on them, while each month the umbilicus B is carried out through the small circle BDEG; and to this motion the raising of the node ☊ and the lowering of the node ☋ are commensurate. At the syzygies, indeed, the umbilicus B is joined to the Earth; but when the umbilicus has moved away from B through the quadrant BD, that is, by the double motion of the Moon from the Sun, and so with the Moon placed at 45° from ☌, or in the first octant, the node ☊ recedes to R and ☋ to O; and at these points occurs the greatest equation of the nodes, additive to the retrograde motion, and the retrogradation is increased for those nodes; but from there to the first quadrature, with the umbilicus now brought to E, the node that was at R tends to the mean place ☊, and the other node returns from O to ☋; and at these points no equation occurs. From the first quadrature to the second octant the umbilicus is at G, and the node ☊ recedes from its mean place in the order of the signs towards Z, and the node ☋ to C, where the subtractive equation is greatest. When the umbilicus is again brought to B, at the other syzygy, the nodes return to their mean places, and all their equation ceases. From there a second revolution takes place through the circle BDEG, and this anomaly returns twice in the whole month. The inclination of the planes, however, librates by another law, since it increases from the syzygies to the quadratures but decreases from the quadratures to the syzygies. This libration of the nodes, says Boulliau, seems similar to the swinging of pendulums nodding this way and that while they are being transported.

Diagram. Set into the left column, with the text running in a narrow measure beside it on the left. A circle with a vertical diameter, inside it a second, displaced circle, and at the centre a small circle standing on an arc that crosses the figure from lower left to the right and runs out beyond the rim. Labels read on the plate:

- H (above the top, outside), L (below the foot, outside), F (on the vertical, near the foot)
- K (on the vertical, upper part), E (on the vertical, at the top of the small circle), B (on the vertical, at the foot of the small circle)
- G (left of the small circle), D (right of the small circle)
- O (upper left rim), Z (upper right rim)
- ☋ (left rim), ☊ (right rim)

- C (on the crossing arc, left), R (on the crossing arc, right), A (at the arc's right end, outside the rim)

[Margin: Tycho praised, and soon unpraised, by Boulliau.] He adds that from his own observations of the Moon applied to the fixed stars it is established to him that Tycho's latitude of the Moon agrees exactly with the heavens, and therefore that he has changed nothing as regards this measure; but that the form of the Tychonic hypothesis is not so consistent with itself, since the Tychonic Moon, though not transported by the Earth nor impelled by a Sun that moves the Earth, nevertheless suffers so many varieties of motion in longitude and latitude that have a relation to the Earth and the Sun; whereas the other planets, by contrast, suffer nothing of the kind from the Sun, although it is moved, neither in longitude nor in latitude. [Margin: A weak confirmation of the Earth's motion.] For it seems that one should rather say that the body that induces these varieties, namely the Earth, moves; and that the body that does not induce them, namely the Sun, does not move with a motion of translation. But do you not see, Boulliau, that it follows from this that, since the Moon undergoes these varieties with respect not only to the Earth but also to the Sun, and in them follows its elongation from the Sun, not only the Earth but also the Sun should be transported; or, if only one of these is transported, that the translation of the Sun and the rest of the Earth suffice? Secondly, it is assumed here that these varieties come from the Earth or from the Sun as from an external cause physically moving the Moon; but this has not yet been shown; and it suffices that the Earth and the Sun should be the terms of the relation that the Moon's mover, whatever that is, has in moving the Moon.

[Margin: Solid orbs denied.] Boulliau says in that Chapter 13 that it is indeed remarkable in the system of the heavenly bodies that, although it does not consist of solid orbs or material circles, but the planets move freely without these machines, they nevertheless move according to fixed and immutable laws just as if they were moved by the force of material circles, and describe ellipses around scalene cones, conceivable by the intellect.

[Margin: An indication of our hypothesis.] X. For my part, I have already said that the physical efficient cause of these motions is a moving Intelligence, in whose mind there are images divinely infused and formed from the divine archetype, which, according to the harmony of the effects to be produced in sublunary things, fixed in advance by Divine Providence, represent the admirable modes and alternations of these motions; and that to carry out and direct these motions the angels do not need our regular figures, but restore the planet to its due places according to rhythms and numbers in the most perfect order. If anyone nevertheless needs some scheme, let him by all means use the small circles or librations that Tycho, or Lansbergen, or Boulliau used. I, however, have no need to distribute this anomaly according to the sines of arcs in small circles assumed for the purpose. For example, in Lansbergen's scheme set out at no. VII, I use the diameter FG, as I did in the preceding chapter in investigating the eccentricity, and from it the monthly equation. Counting the

doubled motion of the Moon from the Sun from F through K, if it does not exceed 180°, I use those degrees; but if they exceed it, I use their complement to the whole circle; and I multiply those degrees, or this complement, by the difference of the extreme latitudes, namely by 18′, divide the sum by 180°, and add the quotient to the smallest latitude, so that the true latitude results. In this way too, I see, the librations of the nodes and the Variation can be dealt with.

EXEMPLVM.

Example.

Let the example be the same one that Lansbergen used; for in it the doubled elongation of the Moon from the Sun was 230° 6′ 2″. The complement of this to the circle is 129° 53′ 58″, that is, very nearly 130°; when these are multiplied by 18′, the sum is 2340; and when this is divided by 180, there remain 13′, namely the portion LF of the diameter, which, added to the arc CF, or the smallest latitude, 5°, makes the latitude CL 5° 13′, exactly what Tycho then observed.

CAPVT XXX.

Chapter 30.

De Reductione Lunæ ad Eclipticam.

On the reduction of the Moon to the ecliptic.

I. Since the Moon's orbit, or the path along which it moves in longitude, is inclined to the ecliptic, it follows that the place of the Moon, when it is outside the nodes or limits, is not the same in the ecliptic as it is in the orbit; nor are there as many degrees and minutes from the node or limit to the point of the ecliptic determined by the circle drawn through the poles of the ecliptic and through the centre of the lunar body, as there are in the lunar orbit, if they are counted from the same node or limit up to the point of the orbit through which the circle already mentioned passes, which is called the circle of latitude. From tables or geometrical hypotheses, however, the Moon's longitude in its own orbit is first collected. It must then be reduced to the ecliptic, so that we may have its place in the ecliptic or according to the ecliptic. This is commonly done by means of the spherical triangle ADC, in which let AED be a quadrant of the ecliptic, and ABC a quadrant of the lunar orbit[36]; and let the portion of the circle of latitude, drawn through the poles of the ecliptic orthogonally to the ecliptic, be CD, if the Moon is at D, one of the limits. For then the Moon's place in the ecliptic, namely the point C, is the same as that at D, the point of the orbit; that is, the arc AD is as great as AC. But let the Moon be at E, and let the portion of the circle of latitude be EB, making a right angle at B but an oblique one at E. For, given the base AE, that is, the Moon's distance in its

[36]the rest of the paragraph, and the figure, treat AED as the lunar orbit and ABC as the ecliptic; the two arcs appear to be interchanged in the print

orbit from the nearer node A, and given the angle A, the side AB, that is, the Moon's distance from the nearer node computed in the ecliptic, is easily found by trigonometry. And by this device the Table of Reduction is constructed.

Diagram. Set into the right column, with the text running in a narrow measure beside it on the left. A spherical triangle: an upper arc from D on the left through E to A on the right; a lower arc from A through B down to C; a side from D to C; and a short arc from E down to B. Labels read on the plate:

- D (left), E (top of the upper arc), A (right, in a larger sort), B (on the lower arc), C (foot)

Tycho, however, in volume 1 of the *Progymnasmata*, p. 118, used for the angle A the mean inclination, 5° 8′, because in this way an error beyond half a minute is never committed. It is better, however, to use the Moon's true latitude, in the way that Lansbergen, in the figure of no. 7, having drawn the arc OP at right angles at P, the point of the ecliptic, from O, the point of the lunar orbit, uses the latitude OP and the Moon's distance AO to investigate the arc of the ecliptic AP. But Boulliau, in Book 3, Chapter 16, though he knew this, nevertheless kept Tycho's little table of this reduction unvaried, as did Magini in the *Supplement to the Ephemerides*, Canon 9; and Lansbergen finally transcribed it into his own *Canones*, p. 30.

II. The reduction of the Moon to the ecliptic, moreover, is at most about 7′, and it is to be subtracted if the argument of latitude is signs 0, 1, 2, 6, 7, 8; in the others it is to be added to the Moon's place in the orbit; but the contrary must be done if the reduction is to be made from the ecliptic to the orbit. Nor is this equation to be neglected, since otherwise in applications to the fixed stars a notable error can be committed, when the Moon's place, observed by instruments in the ecliptic, is brought back to the place in the lunar orbit. Moreover, according to Kepler it is a little greater in the eclipse syzygies, because the angle of inclination of the Moon's path is then 5° 18′; the same author also notes this in the Rudolphine Tables, precept 130.

LIBRI QVARTI FINIS.

End of Book 4.

LIBER QVINTVS DE LVNÆ ET SOLIS ECLIPSIBVS.

Book Five. On the Eclipses of the Moon and the Sun.

CAPVT I.

Chapter 1.

De Nomine, & falſis Eclipſium cauſis ac ſpeciebus, in omnibus Sideribus: Deque in his detegendis, illiſq. prædicendis Aſtronomorum Præſtantia.

On the name, and on the false causes and the kinds of eclipses, in all the heavenly bodies; and on the excellence of astronomers in detecting and predicting them.

[Margin: The names of an eclipse.]

I. We now enter the darkness of eclipses, than which, nevertheless, nothing in the whole theatre of astronomy is more illustrious, and nothing more sublime than the contemplation of them. *Eclipsis* is a Greek word: from ἐκλείπω [Greek: ekleipō, "I fail"], that is, *deficio*, comes ἔκλειψις [Greek: ekleipsis, "eclipse"], namely a failing [deliquium] or defection [defectio]. So the sick who, deprived of the vital spirit, seem to suffer a swoon of the soul and a faintness very like the death agony are said to have fallen into ἔκλιψιν [recte: ἔκλειψιν] [Greek: ekleipsin, accusative of the same word]. Therefore the Moon, when at the full it falls into the shadow of the Earth and grows pale, deprived of the Sun's life-giving rays, and the Sun in its turn, when through the interposition of the Moon, failing not for itself but for us, it seems to be darkened, are both said to fail and to suffer eclipse, or a failing, deficiency and defection [deliquium, defectum, & defectionem]. For Pliny the Elder uses these names along with Cicero; and in Pliny the Elder and in Tacitus the shadow of the Earth darkening the Moon is called *hebetatrix* [the dimmer]. Long ago, however, Anaxagoras called eclipses simply σκιὰς [Greek: skias, "shadows"], that is, shadows; Plutarch and Ptolemy called them ἐπισκοτήσεις [Greek: episkotēseis, "darkenings"], that is, obscurations; and the Latin poets after Virgil called them the labours of the Moon and of the Sun. For what Lucretius had said in bk. 5:

> Likewise also the failings of the Sun, and the hidings of the Moon,

Virgil expressed more elegantly in *Georgics*, bk. 2, thus:

> But as for me, first of all may the Muses, sweet before all things,
> Whose sacred emblems I bear, struck by a mighty love, Receive me,
> and show me the paths of the sky and the stars, The Sun's various
> failings and the Moon's labours.

[Margin: Barozzi, in correcting Virgil, himself needs correcting.]

The last of these lines Barocius [Francesco Barozzi] (bk. 4 of the *Cosmographia*, p. 328) to no purpose brought out inverted, thus:

> Defectus Lunæ varios, Soliſq. labores. [The Moon's various failings,
> and the Sun's labours.]

His reason is that the same Virgil said in *Aeneid* 1:

> Hic canit errantem Lunam, Soliſq. labores, [Here he sings the
> wandering Moon and the Sun's labours,]

and that the Sun does not truly fail, or is not truly deprived of light, as the Moon is in an eclipse. But the Sun does not truly labour any more than it truly fails; and Barozzi has surely fallen into an eclipse of memory, since he ought to have remembered that in Pliny the Elder and Tacitus, not to mention the poets, the eclipse of the Moon is everywhere expressed by the name of labour, and its failing by the verb *laborare*, as we shall presently see.

[Margin: Why the name of labour was transferred to the eclipse of the Moon.]

[Margin: Fictions of Stesichorus, Pindar and other poets about the cause of eclipses of the Sun and Moon.]

II. For, as Pliny the Elder testifies (bk. 2, chap. 12), there was an ancient error in the wretched mind of men, which at the failings of the stars dreaded crimes or some death of the heavenly bodies. It is evident that the sublime mouths of the poets Stesichorus and Pindar were in this fear at an eclipse of the Sun; and that in the case of the Moon mortals laid the blame on sorcery and for that reason came to its aid with a discordant din. The idea, of course, was that the Moon failed because, by the magic incantations of witches, above all Thessalian ones, with a bronze rhombus wound round with threads and whirled in a circle like a top, it was compelled to come down to earth and to froth onto the herbs with some virulent dew or other, which the sorceresses needed as something of immediate effect for whatever they wished. The Moon, it was held, usually struggled against being called down from the sky, but was at last overcome by the chants, unless it were deafened to the witches' chants by the ringing of bronze and a disorderly din, and the noisy superstition of mortals came to the aid of the Moon labouring in that struggle; and this superstition persists to this very day among certain barbarians. It will not be out of place to confirm this by the testimony of poets and historians, as well as the other opinion, about the failing of the Sun on account of men's crimes. There is that well-turned line of Virgil, *Eclogue* 8:

> Songs can even draw the Moon down from the sky.

Ovid, *Amores* 1, elegy 8, on the old woman Dipsas:

> She knows well what a herb can do, what threads set whirling on the twisted rhombus, What the venom of a mare in heat avails. When she has wished, the clouds mass over the whole sky; When she has wished, again the day shines in the world.

And in the same place, bk. 2:

> Songs draw down the horns of the blood-red Moon.

And *Metamorphoses* 12:

> His mother was Mycale, who, it was agreed, had often by her chanting Drawn down the horns of the resisting Moon.

And in the *Epistle of Hypsipyle*:

> She strives to draw the resisting Moon down from her course,

and *Metamorphoses* 4:

> Or beneath a glowing whiteness, When the bronzes sound in vain in aid of the Moon.

Of this redness the same Ovid says in the *Amores*:

> As roses gleam when mixed among their lilies, Or when the Moon labours with her enchanted horses.

So in *Metamorphoses* 7 that sorceress boasts:

> You too, Moon, I draw down, although the Temesan Bronzes lessen your labours.

And another, in Petronius, in the *Satyrica*:

> Why should I speak of lighter things? The image of the Moon descends, Drawn down by my songs.

And Medea in Seneca, Act 4:

> I see the swift chariot of Trivia, Not the one she drives all night, bright with full face, But the one she drives, ghastly with mournful face, When, harried by Thessalian threats, She skirts the sky on a closer rein. So, pale as you are, pour your sad light With your torch through the air; Terrify the peoples with a new horror, And in your aid, Dictynna, Let the costly bronzes of Corinth sound.

Tibullus, bk. 1, elegy 8:

> Song also tries to draw the Moon down from her chariot, And will do it, if the struck bronzes do not sound.

Lucan, bk. 6:

> And, pressed down by chant, she suffers such great labours Until, closer now, she froths onto the herbs beneath.

And shortly after:

> —— she supplies lunar venom in plenty.

Martial too (bk. 9, epigram 22), with a shameful grief, mourns the death of Philaenis, the most ancient of bawds and witches:

> What woman now will know how to draw down the Moon with a Thessalian rhombus, What woman, etc.?

[Margin: A witty passage of Martial, and of Juvenal.]

But more wittily, of a certain eloquent man, one accustomed to report whatever went on in the world (bk. 12, epigram 46):

> He will say how many hands of the world are beating bronzes When the Moon, cut by the Colchian rhombus, takes a beating.

But more sharply Juvenal, *Satire* 6, on a garrulous little woman:

> —— Such a torrent of words falls That you would say so many basins and bells Were being struck at once. Now let no one tire out trumpets and bronzes: One woman alone will be able to come to the aid of the labouring Moon.

[Margin: Seneca: an ingenious fiction.]

But Seneca more ingeniously still brings on the Chorus in Act 2, applying a very recent failing of the Moon, whether real or invented, to the beauty of Hippolytus, by whose beauty Diana, turned to a blush as if by a magic incantation, checked her course:

> The star born after the ancient Arcadians Will not be able to turn her white chariot. And lately she blushed, though no dirtier cloud Stood in the way of her bright face; But we, anxious at the troubled light, Thinking her drawn by Thessalian songs, Gave out our ringings. You had been the labour, You the cause of the delay.

This fiction is surely far more generous than the one that Ludouicus Viues [Juan Luis Vives], hostile to a city of the Swiss and to some magistrate or other (rather, I do know him, but I do not want him named, since he was slandered unjustly), made up: namely, that the man was so stupid that when a donkey-driver blamed the failing of the Moon on his little donkey, which had

swallowed with a brisk draught the Moon shining back from the bottom of a trough, he went so far in believing him that he went out of the city wanting to look into the matter, had the wretched little donkey cut open with more than triumviral scourges and made to vomit up the Moon; and that, the Moon meanwhile having been restored to its former splendour, he returned to the city full of self-congratulation. It should then have been added, so that this splendid fiction might not lack its tail, that a law was passed forbidding beasts of burden in future to drink water under the open sky at full Moon. But enough now of trifles, and of the wrinkles with which I fear the brows of the sterner sort are furrowed; let us smooth them again with a little flower or two from the Christian poets.

Papinius Statius, *Thebaid* 6:

> ..... whenever from the stunned stars The Sun's darkened sister is torn away; far off the nations Clash their aiding bronzes and fear in vain; but the victorious Thessalian woman Laughs at the panting team when her song is heard.

And Petrus Apollonius, *On the Destruction of Jerusalem*, bk. 1:

> ..... A mingled Shout goes up to the stars, as great as when peoples striving to help the frightened Moon Redouble it with ringings of sharp bronze, And strive that the Thessalian song may not reach The goddess's deafened ears.

Now to other writers, leaving the poets for a while.

[Margin: The superstition of the ancients, mixed in with little tales.]

III. St Basil (*Hexaemeron*, homily 6) relates that ridiculous little stories of old women are going around, who say that the Moon, "by μαγγανείαις [Greek: manganeiais, "trickeries, sorceries"]", that is, by sorceries, is "moved from its own seat and drawn down to earth"; and Apuleius, bk. 1, reports that "by a magic whispering the Sun is checked, the Moon made to froth", etc. Caesarius too, in dialogue 3, ridiculing the superstition of the ancients, says: "The Moon, although she does not let herself down, nevertheless burns with grief, shudders, hides herself by putting on a cloud, and, following her brother's example, disdains to lavish her splendour on the unworthy, etc. How do some say that the Moon is pulled from the sky by incantations and conjuring tricks? Certainly the greatest part of the human race, persuaded and preoccupied by the report of this thing, think by beating iron and bronze to free her from her error by the din, as if she had gone out of her power." There survives by St Maximus, bishop of Turin, a homily entitled *On the Failing of the Moon*, which contains this: "When I asked what this shouting meant, they told me that your outcry was coming to the help of the labouring Moon, and was aiding her failing with its shouts." But this abuse was far older. For Livy relates in bk. 26: "The unwarlike multitude of the Campanians, stationed on the walls, raised a shout with such a clash of bronze as usually happens on a silent night at a failing of the Moon." There is a remarkable passage on this subject in Tacitus, bk. 1 of the *Annals*, where he relates that the Pannonian legions, on hearing of the death of

Augustus and the succession of Tiberius, turned to mutiny, and that Drusus, sent there, barely escaped the fury of the threatening men. He then adds:

[Margin: An eclipse of the Moon, opportune for quelling a mutiny.]

"Chance softened a night that was threatening and about to break out into crime: for the Moon, in a suddenly clear sky, was seen to grow faint. The soldier, ignorant of the reason, took this as an omen of the present state of things, likening the failing of the star to his own labours, and thinking that what they were carrying out would turn out well if the brightness and clarity of the goddess were restored. So they made a din with the sound of bronze and the blended noise of trumpets and horns; as she grew brighter or darker, they rejoiced or grieved. But after clouds rose and blocked the view, and she was believed buried in darkness, they lamented, as minds once struck are easily moved to superstition, that eternal labour was portended for them, and that the gods turned away from their crimes. Caesar, thinking that advantage must be taken of this inclination and that what chance had offered must be turned to wisdom, orders the tents to be visited." And a little later: "There lasted too the dread of heavenly anger, and that not in vain did the stars grow dim against the impious, and the storms rush down," etc.

[Margin: An eclipse of the Moon predicted by Sulpicius Gallus.]

Let Plutarch follow this, who reports the following in his *Life of Aemilius Paulus*: "That night, when after dinner the soldiers had given themselves over to sleep, suddenly the Moon, while it was shining with full light and high in the sky, was darkened, and having lost its light passed, covered over with various colours, into darkness. When the Roman soldiers, according to their custom, tried to call back its splendour by the ringing of struck bronze, and raised many lights with kindled torches towards the sky, nothing of the kind was done by the Macedonians; instead, horror and stupor pervaded the camp, and the common talk murmured that the king's destruction was portended by that prodigy. Aemilius, however, although he was not altogether ignorant of the ecliptic alternations by which the Moon, carried round, falls at fixed times into the shadow of the Earth and stays hidden until, having passed beyond the shadow, it is again lit by the Sun, nevertheless, being a religious man and an augur, as soon as he saw the Moon purged of darkness, sacrificed eleven calves to it."

Christophorus Borus [Cristoforo Borri] also relates, in his report of the year 1620 on the kingdom of Cochinchina, sent to Urban VIII, that on the night following December 8 the prince of Caciani rushed out into the open with a great part of the city and, with drums and trumpets ready, waited in vain for a lunar eclipse predicted by that ruler's astrologers, who erred by one day; for it occurred on the night of the 9th, as the mathematicians of our Society had determined. Then indeed, with a frantic din, the cry went up that they should bring help to the Moon. For some Arabs hold that the Moon then either slips into the sleeve of Muhammad or is swallowed by the celestial Dragon, the little tale taking its occasion from the nodes and limits of the Moon's path, which

they have called the heads and tail and bellies of the Dragon. Levinus Hulsius also reports (chap. 30 of the *Dutch Voyages*) that in the year 1599 an eclipse of the Moon on August 6 was seen by the inhabitants of the Moluccas, Tidore and Ternate, and by the Dutch there, at about 8^{h} in the evening, and was received with a huge din of cymbals and bells.

[Margin: The supposed cause of solar eclipses.]

IV. It was a very ancient opinion that the Sun suffers eclipses by day because, with its eyes turned elsewhere, it recoils in horror from the crimes of mortals and from some monstrous deed, either already committed or soon to be perpetrated; and this opinion was not rarely succeeded by the fear, arising from these eclipses, of the imminent end of the world. Well known is that passage of Seneca in Act 4, on Thyestes, as he feeds on the flesh of his own children at an unspeakable banquet and insults the Sun itself as it draws in its rays:

> O long-suffering Phoebus, though you have fled backward And
> removed the day, broken off in mid-sky, You have set too late, etc.

After this the Chorus, having lengthily lamented the failing of the Sun, ends in these complaints:

> Have we, out of so great a people, seemed Worthy to be crushed
> by the world With its hinge overturned? On us the last Age has
> come. O we, born to a hard Lot, whether, wretched, we have lost
> The Sun or driven it away: Let complaints depart, go away, fear:
> He is greedy of life who does not wish, When the world perishes
> with him, to die.

As if to say that, when the Sun is dying and threatening the destruction of the world, no one should take his own death hard. Pliny the Elder made the same point in passing about the failing of both luminaries (bk. 2, chap. 12), saying: "For who, seeing these things and the appointed labours of the stars (since it has pleased us to call them so), would not, being born mortal, pardon his own necessity?"

What Virgil sang in *Georgics* 2 about the Sun darkened after Caesar's death seems to point here:

> He too took pity on Rome when Caesar was extinguished, When
> he covered his shining head in dark rust, And the impious ages
> feared eternal night.

But most think that this was not a true eclipse of the Sun but a ball of clouds, seen beneath the Sun for that entire year, as Pliny the Elder relates (bk. 2, chap. 30): "There occur prodigious and longer failings of the Sun, such as when the dictator Caesar was killed and in the Antonian war, with a continuous pallor of almost the whole year." Yet that unforeseen darkening, of which Petronius speaks in the *Satyrica*, does seem to signify an eclipse:

> At once the slaughter of men and the losses to come
> Were revealed by the auspices of the gods: for with bloody mouth
> The disfigured Titan covered his face in gloom.

And Lucan, bk. 1:

> Titan himself, when he bore his head in mid-Olympus, Hid his burning chariot in black gloom, And wrapped the world in darkness, and forced the nations To despair of day.

But Heruartus [Johann Georg Herwart von Hohenburg] (chap. 145 of his *Chronology*) moves that darkening to the beginning of the year under the following consuls, Hirtius and Pansa. On prodigies of this kind, however, and on spurious eclipses, see the Scholia of the following chapter, and below, chap. 20, at the year 43.

[Margin: Opinions of the old philosophers on the cause of eclipses.]

V. Now let us not be reluctant to review, from Plutarch (*De placitis philosophorum*, bk. 2, chaps. 24 and 29), the babbling school of the ancients on the causes of eclipses. Anaximenes thought that the failing of the Moon happens when the mouth of its rim [absidis] is stopped; Berosus, when the extinguished part of it is turned towards us; Heraclitus, when the convexity of its bowl is turned over; certain of the Pythagoreans, by an obstruction of the light by our earth and a reflection from that of the Antichthones. Anaximander said that the failing of the Sun happens when the breathing-hole in the rim of the solar wheel is blocked; Heraclitus, by the turning of the solar bowl, which shines only on its hollow side and is then rolled round upward; Xenophanes, by a real extinction of the Sun, another meanwhile being reborn, for there are, he said, several Moons and Suns over different tracts of the earth. Aristarchus counted the Sun among the fixed stars and said that the Earth turns around the Sun and by its own inclinations and motions shades the Sun for itself.

[Margin: Truer opinions.]

But Plutarch also adds, in the same place, the authors of truer causes, saying: "Plato, Aristotle, the Stoics and the mathematicians agree that failings occur when the Moon runs into the shadow of the Earth, and by the interposition of the Earth between the two heavenly bodies." And in chap. 24 he had said: "Thales was the first to say that the Sun fails when the Moon passes perpendicularly beneath it, since she is by nature opaque like the Earth; and this is seen as in a mirror with a disc placed underneath." The same author, however, in the *Nicias*, gives first place, but among the Athenians, to Anaxagoras:

[Margin: Danger to learned men from the ignorant.]

"For the first who most openly and most freely dared to publish in writing an account of the illumination and shading of the Moon was Anaxagoras, and he no man of old; nor was this then discussed publicly, but secretly and cautiously among a few. For the Athenians did not then tolerate those who professed the nature of things and celestial and sublime matters, as men who tore the divine power apart into absurd causes and necessary affections. Thus Protagoras too was driven into exile, and Anaxagoras, thrown into prison, Pericles barely saved," etc.

VI. The true cause of eclipses, then, which Plutarch has already touched on, is for the Sun the opaque body of the Moon interposed between our sight and the Sun, and for a failing of the Moon the shadow of the Earth interposed

between the Sun and the Moon. "For," says Pliny the Elder (bk. 2, chap. 10), "it is evident that the Sun is hidden by the intervention of the Moon, and the Moon by the interposition of the Earth, and that they repay each other in turn: the Moon by its interposition takes the same rays of the Sun away from the Earth, and the Earth from the Moon. As the Moon passes beneath, sudden darkness is drawn over; and in turn the star grows dim by the other's shadow."

[Margin: Sulpicius Gallus's priority among the Romans in the science of eclipses.]

[Margin: And that of Thales among the Greeks.]

But Pliny the Elder discloses in the same bk. 2, chap. 12, from where the Romans learned these things, saying: "And the first of the Roman race to make public the explanation of both heavenly bodies was Sulpicius Gallus, who was consul with M. Marcellus, but was then a military tribune; he freed the army from anxiety on the day before King Perseus was overcome by Paulus, being brought forward before the assembly by the commander to foretell the eclipse, and soon afterwards also by composing a book. Among the Greeks, however, the first of all to investigate it was Thales of Miletus, in Olympiad 48, year 4, when he predicted the failing of the Sun that took place under King Astyages, in the year 170 of the founding of the City." Now this passage of Pliny the Elder, and Plutarch's account of the eclipse that arose before the defeat of Perseus, which we reported towards the end of no. 3, must be illustrated by the account of Livy (Decade 5, bk. 4), in which he says:

"When the camp had been fortified, C. Sulpicius Gallus, a military tribune of the second legion, who had been praetor the previous year, with the consul's permission called the soldiers to an assembly and announced that on the coming night, so that no one should take it for a portent, the Moon would fail from the second hour to the fourth hour of the night; since this happens in a natural order at fixed times, it can be both known beforehand and predicted. Thus, just as they did not wonder, since the risings and settings of the Sun and Moon are fixed, that the Moon shone now with a full orb, now, when waning, with a slender horn, so they ought not to take it as a prodigy either that she is darkened when hidden by the shadow of the Earth. On the night that was followed by September 4 [pridie nonas Septembris], when the Moon had failed at the stated hour, the wisdom of Gallus seemed almost divine to the Roman soldiers. It moved the Macedonians as a grim prodigy portending the fall of the kingdom and the ruin of the kingdom, and the seers took it no differently; there was shouting and howling in the Macedonian camp until the Moon emerged into her own light."

[Margin: Sulpicius Gallus's prediction of the eclipse was held almost divine.]

VII. And it was truly something divine to bring the so abstruse principles of eclipses, which leave no trace of themselves in the sky and happen so far from our regions, back to laws so fixed that astronomers can foretell all those that have been or will be, and how great their magnitude and duration are, and the moments of their beginning and end. And not undeservedly, says Reinhold

in the *Theoricae* (p. 209), do such things arouse admiration: for the keenness of human ingenuity could never have penetrated to the knowledge of such great matters without God going before, as Plato most weightily says in the *Epinomis*. Nor was Dionysius extravagant in once paying Helicon of Cyzicus a talent for each eclipse properly predicted; nor is it unfitting that even now the ruler of Cochinchina awards a mathematician an entire estate for the same thing. If this generosity resided with other princes, astronomers would not be compelled to degenerate into astrologers, and to recook the very stars into gold for themselves with alchemical industry, or to hunt their living among the beasts of the zodiac with invented predictions. With sounder counsel they would imitate Hipparchus, of whom Pliny the Elder says (bk. 2, chap. 12), after the praises of Thales and Sulpicius Gallus:

[Margin: Encomium of Hipparchus and of astronomers, from eclipses predicted long in advance.]

"After them Hipparchus foretold the course of both heavenly bodies for six hundred years, embracing the months of the nations, and the days and hours, and the sites of places and the villages of peoples, with time as his witness; in no other way than as one sharing in the counsels of nature." Having recalled these things he exclaims: "Mighty men, above the nature of mortals, who discovered the law of such great divinities, and set free the wretched mind of men, etc. Hail to your genius, you interpreters of the sky, you who comprehend the nature of things, by which you have overcome gods and men."

[Margin: St Augustine's most wholesome warning to astronomers.]

But unless astronomers refer the divination and glory of these alternations to the Father of lights, with whom there is no change nor shadow of alteration, there is a danger that they themselves may run into deeper darkness and shadows. Let them therefore listen to Augustine, the summit of theologians, who wholesomely warns them (*Confessions*, bk. 5, from chap. 3, and bk. 7, chap. 6): "Those who know these things exult and are lifted up; and, through impious pride falling back and failing from their own light, they foresee the future failing of the Sun so far ahead, and do not see their own in the present; for they do not ask religiously from where they have the ingenuity with which they ask these things."

SCHOLIA.

Scholia.

[Margin: Do other heavenly bodies suffer eclipses?]

I. This book treats of the failings of the Sun and Moon, as phenomena to be wondered at among those that are manifest. For the eclipses of the other heavenly bodies are either non-existent, or almost daily, or hidden from the common sight of mortals and observable only by the most skilled astronomers with the Belgian spyglass [Specillo Belgico]. To one who asks, then, whether other heavenly bodies have their eclipses, there respond, some one way and

some another: Pliny the Elder (bk. 2, chap. 10); Ptolemy (*Almagest*, bk. 9, chap. 1), and on that passage Regiomontanus in the *Epitome*, prop. 1; Clavius in the *Sphere*, p. 70; Barozzi in the *Cosmographia*, bk. 4, p. 326; Wurstisen on Peuerbach's *Theoricae*, p. 357; and Kepler in the *Optics*, p. 304, and in the *Epitome of Copernican Astronomy*, bk. 6, p. 825. But a distinction is needed, and we must first speak of eclipses made by a shadow, of which kind is the eclipse of the Moon.

[Margin: First reply, on the first kind of eclipses, those from shadows.]

Therefore that statement of Pliny the Elder, that no other heavenly body is darkened in the same way as the Moon, that is, by the shadow of the Earth, since the shadow does not extend beyond 282 terrestrial semidiameters (from what was said in bk. 3, chap. 11, Problem 8), is called into doubt by Kepler on account of the parallaxes of Mars, because of which it does not seem impossible that Mars, opposite the Sun, is grazed by the Earth's shadow. It never, however, reaches Saturn and Jupiter; nor does the Earth ever come between the Sun and Venus or Mercury. So even if the Earth's shadow extended to their heaven, they would still never fall into it, because of their small digressions from the Sun, which do not exceed 50°. The same Kepler adds that it seems fitting that, just as the point of the Moon's shadow ends at the Earth, so the point of Venus's shadow should end at the Moon when near the Sun, and Mercury's at Venus, and the Earth's at Mars, and that of Mars at Jupiter, and that of Jupiter at Saturn. On this matter we cannot decide before we have established their distances, and whether they have their own light; for that is necessary if one is to undergo an eclipse from the shadow of another. But it is now certain that the Satellites of Jupiter frequently suffer eclipses from Jupiter's shadow, and this will be shown below, in bk. 7, when we treat of Jupiter.

[Margin: Second reply, on eclipses from the interposition of a heavenly body.]

II. As for the second kind of eclipses, those that occur when a heavenly body comes between our sight and another body, it is certain that all the fixed stars that lie below the zodiac [infra Zodiacum], and all the planets, can be covered by the Moon, just as the upper planets can be covered by the lower. For astronomers everywhere record conjunctions of this kind that are at the same time occultations. Thus in the year 241 before Christ, September 4, Jupiter as a morning star [Eous] occulted the southern Ass [Aſellum Auſtrinum], according to Ptolemy, bk. 11, chap. 3.

[Margin: Fixed stars occulted by planets.]

And in the year 272 before Christ, January 18, Mars in the morning covered the northern star in the forehead of Scorpius; and on October 12 Venus in the morning covered Vindemiatrix, according to Ptolemy, bk. 10, chaps. 4 and 9. And in the year of Christ 1574, September 16, Mästlin saw Regulus covered by Venus in the morning, and Kepler saw the same in the year 1598, September 25, at 3^h in the morning.

[Margin: Planets occulted by planets.]

Now Jupiter occults Saturn only very rarely, within many centuries; yet Kepler thinks this happened in the year 1464. Proclus, for his part, reports some comet or other covered by Jupiter; on which, Tycho, *Progymnasmata*, vol. 1, p. 619. Furthermore, Mästlin and Kepler saw Jupiter covered by Mars at Tübingen, 1591 January 9: the fiery colour of Mars showed it to be the lower. Proclus reports that Venus was observed running beneath Mars, and Mercury beneath Venus; for Venus and Mercury can occult each other, now the one and now the other being the upper. Mästlin also saw Mars occulted by the whiter Venus in the year 1590, October 3, at 5^{h} in the morning.

[Margin: What of Venus and Mercury with respect to the Sun?]

There remains the controversy over Mercury and Venus: whether they can occult, not indeed the whole of the Sun, but a part of it. Certain more recent authors mentioned in Ptolemy, bk. 9, chap. 1, set these two above the Sun for that reason, as al-Biṭrūjī also did in the case of Venus: because they had never been seen to occult the Sun at their conjunctions. But Ptolemy rejects those authors, because these planets can be conjoined with the Sun and yet, on account of latitude (just as the Moon, on account of latitude, usually does not cover the Sun), or else on account of the smallness of their visible diameter, as Regiomontanus there and Clavius above add, either not cover the Sun or cover it imperceptibly. For if, as al-Battānī and Thābit ibn Qurra hold, the visual diameter of Venus is ten times smaller than the Sun's diameter, that is, of 3′, then the visual circle or disc of Venus will be to the Sun's disc as 1 to 100; since by prop. 20 of the Sixth and prop. 2 of the Twelfth of Euclid, circles are to one another as the squares of their diameters, and the squares of the diameters are in the duplicate ratio of the diameters. Or, as Barozzi says, if Venus and Mercury were to pass beneath the Sun in the same plane with the Sun and our sight, they would still either not appear, on account of their diaphaneity, or would appear as a black point on the Sun. But we have already shown, in the Scholia to bk. 3, chap. 3, that Mercury has been seen under the Sun and has more than once occulted a small part of it. Venus, says Kepler, cannot cover the Sun in this century; yet it could almost 200 years ago and will be able to some day, and the smallness of its diameter will be no obstacle if it is observed with a telescope, since it was no obstacle in the case of Mercury, which is smaller than Venus. From this you see with what limitation we must understand the dissertation of Martinus Hortensius on Mercury seen under the Sun and Venus unseen.

[Margin: Spurious or extraordinary eclipses, especially of the Sun.]

III. Besides the regular or ordinary eclipses of the luminaries, there occur certain spurious, or extraordinary, or prodigious ones, with which astronomy does not concern itself: whether from snows [niuibus] or clouds, or from flocks of birds, or from misty globes accompanying the luminaries beneath them, or from the shadows of comets, or from ashes and smoke belched into the heavens out of volcanoes like Vesuvius [ex Veſuuijs], or finally from a coming-together of spots. Kepler, in the *Optics*, p. 304, surmises a shadow of comets on account of the darkness that lay over the lands in the year 47.

[Margin: Eclipses from ashes.]

As for ashes, Cornelius Gemma relates that in Portugal in the year 1562 the Sun was covered by them. And Dio [Cassius Dio] records such an eclipse of the Sun too, seen at Rome under Domitian, when Vesuvius belched ashes as far as Palestine; and under Titus, for the same cause, the Sun was hidden just as if it had been eclipsed, says Dio. So too Marcellinus [Marcellinus Comes], in the *Chronicle*, relates a night-time darkness by day on account of the ashes and murk of Vesuvius. And because these fires usually come with earthquakes, while the prodigious eclipse of the Sun at the death of Christ came with an earthquake, Kepler, in the *Epitome of Astronomy*, p. 896, does not hesitate to attribute it to ashes of this kind, against the manifest authority of St Dionysius the Areopagite; but on this see below, chap. 19, no. 3, opinion 4.

[Margin: And from misty globes.]

Of dense globes running beneath the luminaries, and as it were clinging to them, several examples survive. Such was that clouding-over for the whole year after the murder of Caesar, which was discussed in the previous chapter, no. 4, even though Ovid, *Metamorphoses* 15, places this failing before Caesar's death. On these eclipses see what I said in bk. 3, chap. 3, Scholium 1; and add to them the darkness lasting many days, of which Trebellius Pollio writes in the *Gallieni*; and the darkness of 18 days in the year 798, so great that ships at sea went astray; and that passage of Tertullian in *Ad Scapulam*: "For that Sun too, in the assembly at Utica, its light almost extinguished, was so great a portent that it could not have suffered this from an ordinary eclipse, being placed in its own exaltation [hypſomate] and domicile." And this of St Jerome to Pammachius: "We split the Church, we who a few months ago, around the days of Pentecost, when the Sun was darkened and the whole world feared that the judge was coming at any moment," etc. Baronius understands this of a prodigious eclipse, under the year 393, and Scaliger agrees with him in the *Prolegomena*, p. 51, since from the year 391 to 395 the Moon's latitude allows no eclipse of the Sun around the days of Pentecost.

CAPVT II.

Chapter II.

De Admiranda DEI Prouidentia in Eclipſibus; Deq. illarum multiplici vſu, Effectibus, & Portentis.

On the wonderful Providence of God in eclipses, and on their manifold use, effects and portents.

I. I do not deny that, for the foolish and for those prone to slander the works of God, the failings of the Moon and Sun could be turned into failures of a Providence not understood: as if eclipses defiled or infested the heavens, or had been established rashly, from uncorrected errors of motion, for the sake of no good. For this is what created, for Anaxagoras when he asserted that the

Moon is shaded by the Earth, that danger among the Athenians which we have already reported from Plutarch's *Nicias*. For they would not tolerate that the Moon, as if it were some divinity, should of necessity suffer the deprivation of its light from our Earth, for absurd causes that had no definite end in view; and Plutarch pointedly notes this there. But in truth they themselves were wrong by the whole width of heaven, while Providence erred not at all. For the supreme Maker of all things had many ends, and excellent ones, in eclipses, and commanded the light of his divine wisdom to shine out of this darkness, as will be clear from their manifold use, shortly to be shown.

[Margin: 2 Corinthians 4.]

[Margin: First end and use of eclipses, theological or moral.]

II. The first end, then, unless I am mistaken, which concerns religion and morals, was that failings of this kind should be proof to us that the Moon and Sun are not divinities, since their light can be either wholly taken away or impeded in its propagation; and that true divinity is to be acknowledged in him alone with whom there is no change, nor shadow of alteration: for God is light, and in him there is no darkness at all.

[Margin: 1 John 1.]

Next, and closest to this, that whoever contemplated these alternations of the luminaries should be reminded again and again of their own mortality, and of the destruction that will at last come to all things, however beautiful. To this purpose is that verse of Ecclesiasticus 17: "What is brighter than the Sun? And this too will fail." Or, if it is permitted to repeat here the words of Pliny the Elder from bk. 2, chap. 12: "Let anyone who sees these things and the appointed labours of the stars (since it has pleased us so to call them), being born a mortal, pardon his own necessity." What if eclipses were also destined for this: that no one should be so bent towards the ground and forever gazing at earthly things, so careless and contemptuous of the heavens, as not to be forced at some time, by the very horror of this unexpected darkness, to raise his eyes; whether, thunderstruck, he merely looked up at the heavens, or also began to surmise and seek out the causes of these darkenings [Greek: ἐπισκοτήσεων (episkotēseōn, "darkenings")] and of the unlooked-for gloom? And those who grasped these causes, and were now able to divine and foretell other similar portents to come, drawn by this particle, or rather participation, of divinity, might be joined by closer reverence and love to God, who foreknows all things to come, and might then be invited to cultivate astronomy further by the good fortune of so great a success. Or at least that from portents of this kind they might dread some huge calamity, the avenger of an offended Deity; and, some day, whether the last day of the World or that night, as soon to fall upon them, or might dread in these shadows its lesson and its shadow.

[Margin: Second end and use of eclipses, astronomical.]

III. After these or other supreme causes and ends, eclipses are more useful to no art than to astronomy, just as nothing demands greater skill than the exact prediction of eclipses. Kepler, in the *Epitome of Astronomy*, p. 900, not inaptly

called eclipses the tutors of astronomers for thoroughly learning the celestial motions. Pliny the Elder, bk. 2, chap. 11, puts it aptly: "This reckoning draws mortal minds up into the heavens and, to those contemplating as if from there, discloses the size of the three greatest things in nature. For the whole Sun could not be taken from the lands by the Moon's coming between, if the Earth were larger than the Moon. From both, the Sun's vastness is disclosed more surely, so that there is no need to search out its extent by the evidence of the eyes and the conjecture of the mind."

[Margin: Pliny the Elder's lapse.]

Here Pliny the Elder must be pardoned the error by which he thought that eclipses of the Sun could be universal for the whole hemisphere of the Earth, and therefore that the entire globe of the Earth could be enclosed within the conical shadow of the Moon's body. If that happened, Pliny the Elder's argument would without doubt establish that the Moon is larger than the Earth. Nor is there any reason for Iacobus Milichius [Jacob Milich], on this passage, to invert the text in order to vindicate Pliny the Elder; for Pliny the Elder continues in the same opinion, saying of the Sun: "The failing of the Moon declares its size by a reckoning beyond doubt, just as, failing itself, it declares the smallness of the Earth." Yet rightly, in chap. 10, after the mention of the Moon made in chap. 9, he adds: "that its own failings and the Sun's, a thing most wonderful in all contemplation and like a portent, are the indicators of their sizes and of the shadow." And indeed it is incredible to say how many things most worth knowing astronomers have attained through the shadows of eclipses, climbing as by ladders into heaven, more happily than by any giant's effort.

> Happy the souls whose care it was first to know these things, and to climb to the homes above. They brought the distant stars close to our eyes, and set the aether beneath their own genius. So is heaven sought: not that Olympus should bear Ossa, and the peak of Pelion touch the stars!

That is how it is. From eclipses of the Moon we have learned the Moon's simple motion and its first inequality, and also the shape of the Earth's shadow; from the Moon's motion, its parallaxes and distances from the Earth; from the Moon's distances, the distances and parallaxes of the Sun; from these, the thickness and height of the Earth's shadow. From eclipses of the Sun, moreover, we have confirmed the Moon's parallaxes and have obtained the measure of the Moon's shadow; further, from the Sun's intervals we have searched out the intervals and parallaxes of the remaining planets; and at last, from the distances of all the planets together with their apparent diameters, we have hunted down by geometrical ingenuity their true and threefold magnitude. For that reason we owe a great part of astronomy, and the most delightful part, to eclipses, or rather to immortal God, their architect. And yet, even if nothing else were learned from it, the theory and practice of foretelling eclipses was to be sought for its own sake, as a most splendid proof of the divine genius in ordering them, and of human genius, not without God, in searching them out.

[Margin: Third end and use of eclipses, geographical.]

IV. Who is so uncultured [Greek: ἄμουσος (amousos, "without the Muses", uncultured)] or so ignorant of geography [Greek: ἀγεόγραφος (ageographos, "ignorant of geography")] as not to know that geography would be maimed and obscure if there were no eclipses? For there was a time when geography, as to the distances of places, teemed with foul errors, because, as Ptolemy says in bk. 1, chap. 3, "mathematical considerations were not yet exactly grasped, nor had many lunar eclipses yet been observed at the same time in different places." For the difference of longitude, or distance between the meridians of widely separated places, can be measured with no other ten-foot rod and no other device than the difference of time at which the same phase of the same eclipse, say the beginning or end of the failing, is observed by two spectators in those separated places; for that difference, converted into degrees of the equator, at once yields the difference of the meridians. Thus, for example, we have recognised that Paris lies further west than our Italian Bologna by exactly 11° reckoned on the equator, because the several phases of the lunar eclipse of the year 1642, April 14, were observed at Paris by Father Georges Fournier, S.J., together with the eminent astronomers Pierre Gassendi and Ismaël Boulliau, 44^{m} of time later than by us at Bologna. So too it has been established that Macau, on the borders of China, lies 15° further west than Nagasaki, the chief city of Japan, from the eclipse of the Moon of the year 1612, November 8. Its beginning was observed at Nagasaki at 9^{h} 30^{m} after noon by that most illustrious and unconquered martyr of Christ, Father Carlo Spinola, and at Macau at 8^{h} 30^{m} by Father Giulio Aleni, S.J., once a pupil of Giovanni Antonio Magini, to whom this observation was written; we found it here at Bologna among his papers. Now 1 hour corresponds to 15°, and 44^{m} of time to 11° on the equator. Therefore by paired observations of eclipses and their not difficult calculation, as with an enormous measuring-rope, or by throwing a very great bridge, we join places far apart from one another and set them in their proper seats on the geographical globe [Glogo] [recte: Globo], the altitude of the pole being known.

Further, whether total eclipses of the Moon are better suited to this business, as Ptolemy, Tycho, Magini and most others have believed; or those of the Sun, as Kepler prefers in the Rudolphine Tables, chaps. 16 and 32, precept 176; or the very frequent eclipses of the satellites of Jupiter, observed with suitable telescopes, as Galileo, Don Vincenzo Renieri and Pierre Hérigone have thought; or finally the illuminations of small spots on the Moon's disc, both in an eclipse and outside one, or observations made suddenly and noted in different places with excellent spyglasses together with the exact moment of time, as that man so dear to me, my friend in things celestial [amicus Vranicus], Michael Florent van Langren, Royal Cosmographer, hopes and is working to do: this controversy we have discussed in our *Geographical Book*, which will be the fourth in the second volume of our *New Almagest*. Meanwhile, all you who take pleasure in geographical maps of the world or in globes, "whom it delights

[viuat] [recte: iuuat] to run over the world with unmoving feet": credit to eclipses, and to the Deity who dispenses them, this most beautiful and most pleasant opportunity. Those maps of yours shine out of this illustrious darkness; with the brushes of such great shadows are terrestrial hemispheres or globes painted. Finally, so that in this point of the universe the points of places may be distinguished for you, the lamps of the world are extinguished again and again. Have we, and our learning, been so close to the heart of God?

[Margin: Fourth end and use of eclipses, chronological.]

V. Now that most ancient witness of the times, bond of the ages, lamp of history and high priest of truth, chronology, would never have escaped from the utterly obscure hiding-places of years otherwise uncertain, had not the luminaries darkened on known days, and the eclipses noted by historians, carried a torch before it. How true this is, and how frequent and immediate a remedy it is for setting the dislocated limbs of chronicles, I have discussed abundantly in the *Chronological Book*, which is the fifth of volume 2 of the *New Almagest*. There too we have exposed the false reasonings of many, and above all of Kepler, who, from eclipses noted around the birth or death of Christ, try to undermine this era of the times, in very common use throughout the Christian world for a thousand years and more. As if the epoch of Christ, the Son of God, and of the sect of Christians so dear to him, had been less a concern to God than that of Iphitus or Nabonassar, in his providence for the years of the Olympiads or of the Egyptians!

[Margin: Note the remarkable argument for divine Providence in preserving and restoring the celestial motions and the series of the times.]

Yet the order of the times mattered so much to God that he willed nothing ever to be taken from their intervals, not even through that prodigy by which, when Christ was about to die, the Moon, retreating from the place of the full Moon, darkened the Sun for three whole hours by passing under its disc. For having performed this obedience, the Moon returned not to its former place but to a place about 1½° further east than the place of the full Moon, as far as it would have advanced in the zodiac during that delay of three hours. Otherwise we could not, by calculating backwards, have recognised the eclipses of 700 years and more before Christ that were observed by the Chaldaeans and recorded in Ptolemy, nor have confirmed them by the moments of the hours handed down; we should have to apply a prosthaphaeresis of three hours in order to reproduce them exactly. From this I likewise gather that the customary series of the times was not interrupted either as a favour to Hezekiah, in whose time the Sun went back on the dial of Ahaz, or at the command of Joshua, "who made the Sun stand still in his days"; rather, whatever had been taken away by that prodigy was restored and made good from heaven. This was also the opinion of St Thomas Aquinas, part 3, question 44, art. 2.

[Margin: Fifth end and use of eclipses, physical.]

VI. I now pass to the physical uses, of which there are doubtless many, though unknown to us. For just as the alternations of winter and of night have

their advantages in nature, so the withdrawal of the Moon's light at that time when, full, it would otherwise have lit the lands, and the blocking of the Sun's rays, appear to serve for tempering or interrupting influences. Nor, if eclipses are harmful to some things, should we believe that they benefit no sublunary nature at all. As for the calamities that most astrologers appear to foretell from the failings of the luminaries, we shall say something in the Scholia.

[Margin: Sixth end and use of eclipses, political.]

VII. There remains the last use of eclipses, the civil use, which has shown itself on various occasions. On these, different people have used or abused them in different ways, through skill or lack of skill, to the happiness or the ruin of the commonwealth. How well Sulpicius Gallus used a lunar eclipse to steady the Roman soldiery, and Drusus to quell a mutiny of the soldiers, we have already related in chap. 1, no. 3, from Tacitus and Plutarch; to these we shall here add similar select cases.

[Margin: An eclipse of the Sun predicted by Thales.]

VIII. The first eclipse of the Sun, then, predicted to the Ionians by Thales of Miletus, was useful not only to him but also to the Medes and Lydians. Of this Pliny the Elder says, bk. 2, chap. 12: "Among the Greeks, moreover, Thales of Miletus was the first of all to investigate it, in the fourth year of the forty-eighth Olympiad, predicting the eclipse of the Sun that occurred under King Alyattes, in the year 170 from the founding of the City." In the life of Thales, Diogenes Laertius has this: "Most think that he was the first to search out the secrets of astrology, and that he foretold eclipses and solstices of the Sun, as Eudemus says in his history of astrology; for which reason he was greatly admired by Xenophanes and Herodotus." And shortly after: "He was also the first to find the Sun's course from solstice to solstice; and the first, as some hold, to say that the Moon's orb, compared with the Sun's size, is a 720th part of it." But to our purpose, Herodotus, bk. 1, relates as follows: "In the sixth year of the war between Cyaxares, king of the Medes, and Alyattes, king of the Lydians, when they were fighting a pitched battle on equal terms, it happened while the battle-lines stood that day was suddenly turned to night. Thales of Miletus had predicted this change of the day to the Ionians, fixing in advance the year in which it occurred. When the Lydians and Medes saw day turning to night, they broke off the fight, and for that reason hurried all the more readily to establish peace between them, the authors of this agreement being Syennesis the Cilician and Labynetus the Babylonian."

[Margin: Peace entered upon between the Medes and Lydians by force of this eclipse.]

We shall say more on this in chap. 19, at the year 581 before Christ.

[Margin: An eclipse of the Sun terrifies Cleombrotus; and another terrifies the ship-captain of Pericles, not Pericles.]

IX. In the year 478 before Christ an eclipse of the Sun, October 2, at 2^{h} after noon at Athens, or another nearer to this one, greatly terrified Cleombrotus while he was fortifying the Isthmus, as Herodotus relates, bk. 9. But another,

in the year 431 before Christ, August 3, at about 6^h after noon at Athens, did not terrify Pericles, because he had learned the causes of eclipses from Anaxagoras. Of this one Plutarch relates, in the *Pericles*, that while Pericles was setting sail for the Peloponnese night was drawn over the sky, and at once the helmsman of the commander's ship was terrified; but Pericles ran up and freed him from his panic terror by wrapping the man's head in the covering of a cloak and asking him whether he feared anything from that cloak. When the man said no, Pericles added that the Sun was covered by the Moon in just this way, and would soon be present again; and that there was no other difference except that the Moon was of course larger than the cloak of Pericles. Of this same eclipse Thucydides, who flourished at that time, speaks in bk. 2, saying: "In the same summer, on the first day of the month, at the new Moon [in Neomenia], the only time at which it is evident that the Sun can fail, the Sun was so darkened after noon that several stars were seen in the sky; and shortly after, when it had taken the shape of a half Moon, it returned to its former shape."

[Margin: An eclipse of the Sun ominous for Pelopidas.]

X. It did not go so well with Pelopidas, who, as Diodorus Siculus relates, bk. 15, in Olympiad 104, that is, in the year 364 or 365 before Christ, fought against Alexander of Pherae. And Plutarch says in the *Pelopidas*: "And now, as the commander was about to set out, the Sun failed, and darkness seized Thebes in the daytime. Then Pelopidas, seeing the crowd disturbed by that portent, was unwilling to compel men who were trembling and had no good hope, or to lead into danger the seven thousand citizens who had offered themselves to him. He therefore gave himself to the Thessalians, with three hundred horsemen following him of their own accord and with mercenary soldiers. Neither the augurs nor his friends approved of that expedition, thinking that this so great a sign had been sent from heaven to so great a man. And indeed the Thessalians did win, but Pelopidas, fighting with unconquered spirit, died pierced by wounds after a very great slaughter of the enemy, and was buried with great honour on a pyre built of soldiers' shields, with the bridles and trappings taken from the horses, so that they too seemed to mourn the death of so outstanding a commander."

[Margin: The dexterity of Agathocles in the use of an eclipse of the Sun.]

XI. I should now like to bring forward the acumen and dexterity of a Sicilian king, namely Agathocles, when he was taking his fleet across to Africa, in the consulship of Gaius Junius and Quintus Aemilius. Justin says, then, in bk. 22: "But the sight of a portent frightened them, because the Sun had failed as they were sailing. The king gave an account of this with no less care than of the war: if it had happened before they set out, it would be believed to be a prodigy against those about to set out; but as it was, because it had happened after they had departed, it portended against those to whom they were going. Further, the failings of natural stars always change the present state of affairs, and it was certain that a change was signified for the flourishing wealth of the Carthaginians and the adverse fortunes of the Sicilians." Of this failing

Diodorus Siculus says: "On the next day there was so great a darkening of the Sun that you would have said it was plainly night, the stars appearing on all sides." Salianus conjectures it to have been in the year of the world 3744, or 310 before Christ, August 15, at $8\frac{1}{4}^{h}$ after midnight at Syracuse, and says it was almost total.

[Margin: The skill of the Emperor Claudius in the use of an eclipse of the Sun.]

XII. Let us now hear Dio, bk. 6, on the Emperor Claudius, in the consulship of Marcus Vinicius and Statilius Corvinus: "Since an eclipse of the Sun was going to occur on his birthday, he feared that some disturbance might arise from it, as certain other prodigies had also happened; so he publicly announced not only that this failing would occur, and both its time and its extent, but also the causes for which it would necessarily come about."

[Margin: The inexperience and timidity of Nicias on account of an eclipse of the Moon.]

XIII. But so that we do not pass over lunar eclipses untouched, we must recall the timidity of Nicias arising from the eclipse of the Moon of the year 413 before Christ, August 27, about midnight at Syracuse. On account of it, says Thucydides, bk. 7, he feared to lead his fleet out of the harbour, created ruin for himself and his men, and exposed himself with his whole army to be killed by the Syracusans. Polybius, bk. 9, Diodorus Siculus, bk. 13, and Plutarch in the *Nicias* concur; Plutarch says: "When everything was ready for departure, and none of the enemy was watching, the Moon failed by night. This cast great terror into Nicias and others who, deceived either by inexperience or by superstition, fear portents of that kind. For it was already then, after a fashion, commonly understood that the Sun's light is sometimes darkened at the time of new Moon, and that the Moon brings this about; but what the matter was, that the Moon, suddenly, when it is shining in full light, should lose it and show various colours, was not easily understood, and was construed as a prodigy by which some great calamity was being foreshown by divine agency." After recounting the inexperience of the Athenians, and the danger of Anaxagoras, who was the first among them to profess openly the true causes of lunar eclipses, he adds:

[Margin: The judgement of Philochorus on the portent of an eclipse.]

"Nicias at that time by chance had no skilled seer with him; for Stilbides, who used to remove much of the superstition, had died shortly before. For, as Philochorus asserts, that sign is by no means bad for men in flight, but very advantageous; for things done in fear require darkness and hiding-places, and light is against them. And in any case the portents that occur about the Sun or Moon are ordered to be guarded against for only three days, as Autoclides relates in his *Exegetics*; but Nicias ordered them to wait for another circuit of the Moon, as though he would not at once see it restored to its brightness after it had passed the place of its opposition to the Sun."

[Margin: The act of Dion, contrary to Nicias.]

Dion, King of Sicily, by contrast, about to sail from Zacynthus against Dionysius, when the Moon had failed and others were turning this into a bad omen, was not ignorant of the cause himself: he pursued the undertaking he had begun, drove out the tyrant, and took possession of Syracuse; for he had been taught by Plato. So Plutarch.

[Margin: Christophorus Columbus used an eclipse of the Moon to good effect.]

XIV. Christophorus Columbus [Cristoforo Colombo] profited not a little from his knowledge of eclipses. For when in the year 1493 he had landed on the island of Jamaica, and the Spanish force there was suffering from want after a mutiny, and no food could be obtained from the Jamaicans, Colombo threatened them with a plague and, as a sign of it, with an eclipse of October 22, shortly to appear. When it occurred, those barbarians vied with one another to bring supplies and threw themselves at his knees to obtain pardon. On this matter one may also see Io. de Roias [Juan de Rojas] in the preface of the *Astrolabe*, addressed to Charles V.

[Margin: The prediction of an eclipse opens a way for the Gospel.]

XV. Let the line be closed by the lunar eclipse of the year 1620, December 9, which the mathematicians of our Society had foretold to the Prince of Caciani [?] in the Kingdom of Cochinchina as going to occur on the night following that day, when his other astrologers maintained that it would occur on the night following the 8th. So when they had waited for it in vain that night, with a great display of drums and trumpets, and it came on the night of the 9th, it is incredible how much those wretched astrologers blushed at this, and how great a splendour of reputation accrued to our men. So much so that (if what Christophorus Borus [Cristoforo Borri] relates in the Relation sent to Urban VIII is true) that ruler, together with many men of letters, embraced our religion. Surely no eclipse of the Moon was ever more fortunate: out of its darkness God willed so much light to shine forth for that people walking in darkness.

SCHOLIA

Scholia.

[Margin: The opinions of astrologers on the significations of eclipses set out.]

I. Astrologers derive not a few things from eclipses for their predictions. For Hermes says in the *Centiloquium*, no. 53: "Many misfortunes come about in the world when there is an eclipse of both luminaries in one month, and especially in those places over which their signification is particular." And Messahallach [Māshāʾallāh], ch. 5, teaches that the signification of a bad or good outcome is to be sought from the degree ascending at the moment of mid-eclipse and from the lord of the ascendant, but that the Part of Fortune is not to be neglected. Ptolemy, however, says in the *Tetrabiblos*, Book 2, ch. 7: "There is no prior or

more powerful cause of such occurrences than the one drawn from the ecliptic syzygies of the Moon and Sun, and from the transits of the stars at their time." He first gives guidance for the regions in which eclipses signify some outcome. He then asserts that the effects of a solar eclipse last as many years as the eclipse lasted hours, but as many months as a lunar eclipse lasted hours. Finally he adds many things on the kind of these outcomes, which Porphyry elucidates, and also Cardano, who says in Book 2, text 21, that the eclipse of the year 1539, which took place in Taurus, a part of his horoscope, brought nothing bad to himself or to Milan, because it did not accord with the city in which he was then living. Yet still more rules on these matters are handed down by Proclus and, following him, by Giuntini, from p. 307 to p. 314. Giuntini brings as an example the birthday of the city of Venice, which was 421 March 25, with the 25th degree of Cancer ascending, and the solar eclipse of the year 1591, which took place in the 26th degree of Cancer. He therefore says, with Luca Gaurico etc., that it portends for the Venetians seditions and many evils for senate and people, betrayals and naval disasters etc., but that their liberty will last until the year 1880.

[Margin: The duration of the Venetian Republic.]

Garsæus [Johannes Garcaeus] too, p. 288, contends that Bohemia is subject to Cancer rather than to Leo, because of the evils that befell it from eclipses taking place in Cancer: namely from the solar eclipses of the years 1424, 1433, 1469 and 1536. He also contends that Nuremberg is subject to Gemini or to Virgo, because it suffered many calamities from solar eclipses occurring in those signs: on 1448 August 29, and in 1551 in the 17th degree of Virgo, and in 1560 in the 8th degree of Virgo, with a plague following. But he had said at p. 57 that an ecliptic place, if it is referred to a nativity chart, always signifies something bad, in whatever part of the sky it may be. Finally Origanus, in vol. 1 of the *Ephemerides*, part 3, ch. 2, having reviewed Ptolemy's rules from Book 2 of his *De Iudicijs*, from ch. 7 on, foretells many good things for mankind from the lunar eclipse of 1607 August 26, with Jupiter as its ruler and Venus as its companion.

But I, though I do not deny that eclipses have great force in either direction, nevertheless judge that much among the astrologers is empty. To show this by at least one example: Ptolemy lays down, Book 2, text 28, that if an eclipse, especially of the Sun, falls on the western horizon, its effects will begin around the last 4 months and will show themselves most in the last third of the whole duration. Yet the plague that in 1630 followed or accompanied the solar eclipse of June 10, which we observed at Forum Naevii [?] [Foro Næuij], had begun to show itself in the month of April, and it raged in June, July and August.

[Margin: The deceptiveness of astrological rules.]

Kepler too, in the *Ephemerides*, p. 7, no. 25, judges that there is no force in the nodes of the lunar orbit; granted that in the *Optics*, p. 407, he agrees with Ptolemy that a greater signification can be sought from the inclinations of eclipses.

II. It is nevertheless a pleasure, as a courtesy to the learned reader, to compile a short chronicle of some eclipses, with the more notable events more closely connected with them, although I am well aware that some eclipses occur in every year, as I shall say in ch. 15, and that there is no year in which some more notable event does not happen.

CHRONICON ALIQVOT ECLIPSIVM

A chronicle of some eclipses.

Ex Aliorum magis quàm Noſtra opinione Aſtrologiæ deſeruiens.

Serving astrology in the opinion of others rather than in our own.

Years before Christ	Date	Entry
754	July 5	But according to the old calendar on April 21: an eclipse of the Sun, on which day the foundations of Rome were laid, if Taruntius Firmanus is to be believed, about whom Plutarch in *Romulus*.
721	March 19	A total eclipse of the Moon, on which Ptolemy, Book 4 *Almagest*, ch. 6. End of the empire of the Assyrians and beginning of the Babylonian, now established.
585	May 28	An eclipse of the Sun predicted by Thales, from which came peace between the Medes and Lydians. Herodotus, Book 1, and Pliny the Elder, Book 2, ch. 12.
523	July 16	An eclipse of the Moon, on which Ptolemy, Book 5, ch. 14. The killing of Cambyses followed. Salianus, Year of the World 3531.
502	November 19	An eclipse of the Moon in Ptolemy, Book 4, ch. 9. Defeat of the Sabines, death of Valerius Poplicola. Salianus, Year of the World 3552.
491	April 25	An eclipse of the Moon, on which Ptolemy, Book 4, ch. 9. A severe famine at Rome, beginning of the Peloponnesian War. Salianus, Year of the World 3563.
463	April 30	An eclipse of the Sun. The Persian war, and the revolt of the Egyptians from the Persians. Eusebius in the *Chronicle*.
431	August 3	A total eclipse of the Sun, on which Thucydides, Book 2, and Plutarch in *Pericles*. A comet, and plague at Athens.
413	August 27	A total eclipse of the Moon. Nicias cut down with his fleet by the Syracusans. Polybius, Book 9; Thucydides, Book 7; Diodorus Siculus, Book 13; Plutarch in *Nicias*.
394	August 14	An eclipse of the Sun. The Persians routed by Conon in a naval battle. Xenophon, Book 4.
364	or 365	A great eclipse of the Sun; Pelopidas killed in battle. Plutarch in *Pelopidas*; Diodorus Siculus, Book 15.
331	September 20	A total eclipse of the Moon, 11 days before Darius was defeated by Alexander the Great. Diodorus Siculus, Book 17; Q. Curtius, Book 4; Arrian, Book 3; Pliny the Elder, Book 2, ch. 70; Plutarch in *Alexander the Great*.
310	August 15	An eclipse of the Sun. Agathocles conquers the Carthaginians, but with ill fortune. Justin, Book 22.
217	February 11	A failure of the Sun. The Romans defeated by Hannibal at Trasimene. Livy, Book 22, and Julius Obsequens in his little book on prodigies.

Years before Christ	Date	Entry
190	March 14	A great eclipse of the Sun. Antiochus routed by Scipio. Livy, Book 37.
168	June 20 [?]	A total eclipse of the Moon. Perseus, King of Macedon, defeated by Paulus Aemilius on the following day. Livy, Book 35; Plutarch in *Paulus Aemilius*.
50	or 49	An eclipse of the Sun. Caesar crosses the Rubicon: beginning of the civil wars. Dio, Book 41.
44	or 43	An eclipse of the Sun after the killing of C. Julius Caesar: the second civil war. Aurelius Victor; Josephus the Hebrew, Book 14 *Antiquities*, ch. 21; and many others.
4	or 1	An eclipse of the Moon before the death of Herod the child-slayer. Josephus, Book 17 *Antiquities*, ch. 8.
Years of Christ		
14	March 28	An eclipse of the Sun. Augustus dies on August 19. A severe famine followed. Dio, Year of the City, ch. 757; Nicephorus, Book 1, ch. 17; St Jerome in the *Chronicle*.
14	September 26	An eclipse of the Moon, by which Drusus quells the mutiny of the Pannonian legions: Tacitus, Book 1 of the *Annals*.

RESIDVVM CHRONICI.

The rest of the chronicle.

Years of Christ	Date	Entry
49	✝	A total eclipse of the Sun, after which, from Lucan and Dio, Book 4, Caesar, having crossed the Rubicon, casts the die and the torch of the civil wars.
59	April 30	An eclipse of the Sun. Pliny the Elder, Book 2, ch. 70, and Tacitus, who places it among the prodigies on account of the murder of Agrippina by Nero.
69	October 18	An eclipse of the Moon. Nero, on account of the killing of the Holy Apostles Peter and Paul, takes his own life. Dio, Book 65.
72	February 9	An eclipse of the Sun, which was followed on day 22 by an eclipse of the Moon. Jerusalem captured by Titus: more than eleven hundred thousand [supra vndecies] Jews slain, 97000 taken captive. Pliny the Elder, Book 2, ch. 13, and Josephus the Hebrew.
95	✝	An eclipse of the Sun. Domitian killed. Philostratus in the *Life of Apollonius*.
97	January 27	An eclipse of the Sun on the day of Nerva's death. Aurelius Victor, Eutropius, and perhaps Plutarch on this one, in the opuscule *On the Face of the Moon*.
192	✝	An eclipse of the Sun before the death of the Emperor Commodus, from Herodian.
237	April 12	A total eclipse of the Sun. A sign that Gordian would not rule long, as Capitolinus says in the *Gordians*. The sixth persecution in the Church.
301	September 2	An eclipse of the Moon. Diocletian's persecution against the Church. See the Acts of St Felix the Martyr in Baronio, year 302, and Scaliger, p. 18, in the Prolegomena to *De emendatione temporum*.
306	July 27	An eclipse of the Sun. Stars seen in the sky. The Emperor Constantius dies. From the ancient *Fasti*.

Years of Christ	Date	Entry
337	✝	An eclipse of the Sun, shortly before the death of Constantine, who died on May 22, the feast of Pentecost. From the *Life of Constantine*.
450	April 27	An eclipse of the Sun, on which St Gregory of Tours, Book 2, ch. 3, speaking of the coming of Attila and of the heresies troubling the Church, where he adds: "Then too the Sun appeared hideous, so that scarcely a third part of it shone out; I believe, indeed, for such great crimes and for the shedding of innocent blood." [Margin: Even saints turn eclipses into a portent.]
605	May 5	An eclipse of the Sun, and after it a plague of 3 months raging most fiercely throughout all Italy. Regino [Regino of Prüm], Book 1 of the *Chronicle*.
813	May 4	An eclipse of the Sun of 10½ digits. Michael Curopalates dies; Leo the Armenian succeeds. Theophanes in the *Miscellanea*.
840	May 2	A dreadful eclipse of the Sun: a month and a half later Louis the Pious dies. *Annales Franc.*
944	✝	An eclipse of the Sun on the sixth weekday. The King of the Saracens defeated by Ramiro [Rhadamiro]. Sigebert [Sigebertus] in the *Chronicle*.
1009	✝	An eclipse of the Sun. Jerusalem captured by the Saracens. Lycosthenes in the *Chronicle*.
1039	May 14	An eclipse of the Sun. The Emperor Henry dies. Ubbo Emmius.
1133	August 2	An eclipse of the Sun with stars appearing. Schism of three antipopes. Dodechinus and Sigebert.
1181	July 15	An eclipse of the Sun. Alexander III and the Emperor Louis Crassus die. Sigebert.
1187	August 29	An eclipse of the Sun. Baldwin, on September 28, by Saladin, and Jerusalem captured: Lycosthenes in the *Chronicle*. Pope Urban dies at Ferrara on October 20 [13. Kal.Nouembr.]. Spondanus [Henri de Sponde] in the *Annals*.
1197	September 4	An eclipse of the Sun with stars visible. The Emperor Henry dies on September 28, excommunicated by Celestine. Gregorius Tholosas, Book 21 *De Rep.*, ch. 7, and Spondanus in the *Annals*.
1239	June 2	An eclipse of the Sun in Gassendi, in the *Life of Peiresc*. War between Gregory and the Emperor Frederick, who is excommunicated.
1307	February 11	An eclipse of the Sun and then of the Moon on February 26. Our people driven from Rhodes by the Saracens. Lycosthenes in the *Chronicle*.
1419	April 5	An eclipse of the Sun. Bohemian disturbances and calamities from Jan Žižka [Io. Zisca]. Origanus in the preface to vol. 3 of the *Ephemerides*.
1448	August 29	An eclipse of the Sun. Wars between Albrecht of Brandenburg and the Emperor: Origanus above. The Venetians defeated: Lycosthenes.
1518	June 17	An eclipse of the Sun, from which the astrologers conjectured the death of the Emperor Ferdinand. Spondanus in the *Epitome* of the *Annals*.
1520	November 20	An eclipse of the Sun. With Luther excommunicated, turmoil in the Church. Selim dies of plague; Suleiman bursts into Hungary: Spondanus and others in the *Annals*. Origanus above.
1540	April 7	An eclipse of the Sun. A great drought: forests burned up by the Sun; many fires. Origanus above.
1560	August 11	A total eclipse of the Sun observed by Clavius at Coimbra. King Francis of France dies of an abscess on December 5. Gustavus, King of Sweden, dies on September 29. The Spanish fleet battered, with 18000 men perishing, and Andrea Doria [Andreas Auria] dies.

Years of Christ	Date	Entry
1598	March 7; August 16; and 31	An eclipse of the Sun, and on August 31, and of the Moon on the 16th. Rains and floods; was it because it took place in Pisces? From this, crops ruined, dearth of corn, buildings submerged with their people. Origanus above and at this year. Ferrara recovered by Clement VIII on the death of Duke Alfonso; Philip, King of Spain, dies on September 13. Theodore, Duke of Muscovy, died. Eclipses had preceded.
		I pass over the eclipses of our own age, for just reasons; for I am now tired of playing too long a game in the uncertain dust of the astrologers.

CAPVT III.

Chapter III.

Definitio, Cauſæ & Species ac Varietates Lunarium Eclipſium.

The definition, causes, species and varieties of lunar eclipses.

[Margin: Definition of an eclipse of the Moon.]

I. An eclipse of the Moon is the privation, in the Moon, of the primary light it has previously received from the Sun, because of the interposition of the terrestrial globe between it and the Sun. So, more or less, Aristotle, 2 *Poster.*, ch. 1; Pliny the Elder, Book 2, ch. 10; Plutarch in *Nicias*; Livy, Book 4, Decade 5; and others, on whose opinions the same Plutarch, ch. 29, and we ourselves in Book 4, ch. 5, where see what is said against Berossus. I have added the word "primary" [Primarij] in the definition, because the Moon in eclipse is not always deprived of secondary light, that is, of rays refracted in the air around the Earth, as we shall show later. To explain the cause of a lunar eclipse, it is usual in *Theoricae* of the planets to set out first a threefold figure of the shadow, from Cleomedes, Book 2; Pliny the Elder, Book 2, ch. 11; Witelo, props. 26, 27, 28; and from the common *Perspectiva*, props. 22, 23, 24.

[Margin: Cylindrical shadow.] [recte: Vmbra Cylindrica; the note prints Vmbra lindrica]

For either the luminous sphere, as in the figure below, AC, is equal to the illuminated sphere GE, and then the shadow that the illuminated sphere casts has a columnar or cylindrical shape; and for this reason it is called in Greek [Greek: κυλινδροειδὴς (kylindroeidēs, "cylinder-shaped")]. Such is the shadow GKEM, but it extends to infinity.

[Margin: Top-shaped or basket-shaped shadow.]

Or the illuminating sphere is smaller than the illuminated sphere, as in the second figure is sphere EG compared with sphere ABC; and then the shadow of the larger sphere imitates the form of a straight top, or of a truncated inverted pyramid, or of a basket, from which it is also called [Greek: καλαθοειδὴς (kalathoeidēs, "basket-shaped")]. Such is the shadow ANPC; but this too is of infinite length. Or finally the illuminating

Diagram. The first figure of the shadow, set at the foot of the right column. Two equal circles stand side by side on one horizontal line, joined by straight tangents above and below. The right half of the right-hand circle is solid black, and a hatched rectangle runs from it to the right.

- A (above the top of the left circle): point on the luminous sphere
- C (below the foot of the left circle): point on the luminous sphere
- D (inside the left circle, left of its centre cross): no text gloss
- B (right edge of the left circle, on the axis): no text gloss
- F (on the axis between the circles): no text gloss
- H (inside the right circle, at its vertical diameter): no text gloss
- G (above the top of the right circle): point on the illuminated sphere and corner of the shadow
- E (below the foot of the right circle): point on the illuminated sphere and corner of the shadow
- K (top right corner of the hatched rectangle): corner of the shadow
- M (bottom right corner of the hatched rectangle): corner of the shadow sphere is larger than the sphere to be illuminated, and the shadow of this sphere has the figure of a turning-post or cone, one indeed finite and ending in the sharpness of a point. Such, in the adjoining scheme, is the shadow EMG of the sphere EG, illuminated by the larger sphere ABC. Hence that shadow is called [Greek: κωνοειδὴς (kōnoeidēs, "cone-shaped")].

[Margin: Conical shadow.]

Diagram. The second and third figures of the shadow, drawn as one block in the upper left column. A large circle stands in the middle. Above it a hatched inverted truncated cone widens upward to a flat top. Below it two straight lines converge from the sides of the circle to a small circle, half black, and under that small circle a hatched cone narrows to a point.

- N (top left corner of the upper hatched band): corner of the shadow
- O (top centre, on the axis): no text gloss
- P (top right corner of the upper hatched band): corner of the shadow
- A (left of the large circle): point on the sphere ABC
- C (right of the large circle): point on the sphere ABC
- R (inside the large circle, left of its centre): no text gloss
- D (inside the large circle, right of its centre): no text gloss
- B (at the foot of the large circle): point on the sphere ABC
- F (on the axis above the small circle): no text gloss
- H (inside the small circle): no text gloss
- E (left of the small circle): point on the sphere EG and corner of the shadow
- G (right of the small circle): point on the sphere EG and corner of the shadow
- M (apex of the lower cone): apex of the shadow

II. It is evident, moreover, from the Sun's distances from the Earth established in Book 3, ch. 7, no. 15, and from the apparent size of the Sun, on which see the same book, ch. 10, that the true size of the Sun is greater than the whole terraqueous globe. So, from what was said in the same place, ch. 11, according to Tycho, who attributes the least to it, the body of the Sun contains the globe of the Earth 140 times; but according to Wendelen, who attributes the most, 262144 times; according to us, for the present, 38600 times; and according to others otherwise.

[Margin: That the Earth's shadow is conical.]

Therefore the shadow of the Earth illuminated by the Sun must be conical, and so finite. This is confirmed even by the fact that Saturn or Jupiter, let alone any of the fixed stars that are in the Zodiac, never suffer an eclipse from the Earth's shadow, however much the Earth is interposed between these stars and the Sun, provided that one holds that they receive their light from the Sun; otherwise let this confirmation be void. In its place let there follow the demonstration given in Book 3, ch. 11, Problem 8, on the axis or length of the Earth's shadow. With the Sun at perigee, no one puts this at less than 213 terrestrial semidiameters and no one at more than 268 semidiameters; with the Sun at apogee, no one puts it at less than 231 semidiameters and no one at more than 282 semidiameters.

[Margin: The increase and decrease of the Earth's shadow with the Sun's recession or approach.]

For it is certain that the shadow of the Earth, and of any smaller globe illuminated by the Sun or by any larger globe, becomes blunter, narrower and shorter as the Sun approaches the Earth; but as the Sun recedes, it becomes sharper and comes out more extended in length and thicker or ampler in breadth. Erasmus Reinhold demonstrates this in Peuerbach's *Theoricae*, p. 208; but it will be readily evident from the mere drawing of the figures, provided that the same size of the Sun and the Earth is kept at any distance.

[Margin: Argument 1 for the cause of a lunar eclipse from the Earth's shadow.]

III. With these foundations laid, we must now demonstrate that the Moon suffers eclipse from the Earth's shadow. First, from the time. For this eclipse never occurs except at full Moon, when the Moon, distant from the Sun in the Zodiac by a whole semicircle, stands diametrically opposite to it, and so is in that tract of the sky into which the shadow of the Earth illuminated by the Sun is cast. So it is in the present diagram, in which the Sun is AB, the Earth CD, the Earth's shadow CFD. For unless the Moon is in that region of its sky which CFD takes in, it is never naturally eclipsed.

Diagram. The Sun, drawn as a rayed disc with a human face, stands at the top. Two straight lines converge from its sides past the Earth to a point at the foot. The Earth is a circle with its lower half solid black, and below it a hatched cone narrows to the point. Four small circles mark places of the Moon: a white one at the left edge of the cone and a dark one inside it on the same level, a

smaller dark one lower down inside it, and a white one outside the cone beside its lower part.

- A (left of the Sun): one side of the Sun
- B (right of the Sun): other side of the Sun
- C (left of the Earth): one side of the Earth
- D (right of the Earth): other side of the Earth
- H (left of the small white circle at the edge of the cone): the Moon on entering the shadow
- G (right of the dark circle inside the cone): the Moon in the shadow
- I (right of the small dark circle lower in the cone): the Moon in the shadow, more remote from the Earth
- K (right of the small white circle outside the cone): the Moon clear of the shadow
- F (below the apex): apex of the Earth's shadow

[Margin: 2nd argument.]

Second, from the distance of the Moon compared with the height of the Earth's shadow. For this, as I said in no. 2, extends to 213 terrestrial semidiameters and more when it is least; whereas the Moon's greatest distance from the Earth does not exceed 70 terrestrial semidiameters, from what was demonstrated in Book 4, ch. 14. So when the Moon at full Moon is on the ecliptic or near one of the nodes, so that the distance of the Moon's centre from the axis of the Earth's shadow, that is, the Moon's latitude, is less than the sum of the semidiameters of the shadow and the Moon, either the whole of it or a part must be darkened by the Earth's shadow, as if it is at G or I. For the axis of this shadow, cast towards the part opposite the Sun, always lies in the ecliptic, as the Sun does; and the Moon has its primary light from the Sun, from what was said in Book 4, ch. 5. If on the contrary the distance already mentioned is equal to that sum or greater than it, as if the Moon is at K, the Moon at full Moon avoids the Earth's shadow and so is not darkened at all. And it is established from observations of nearly 2400 years that the Moon is always eclipsed when that distance is less than that sum, but free of eclipse when it is equal or greater.

[Margin: 3rd argument.]

Third, from the beginning and end of a lunar eclipse. For it always begins to be eclipsed on its eastern side, because with that side it runs into the Earth's shadow, and it begins to emerge from the shadow likewise on its eastern side; so that the last part to be freed from the shadow is the western. For the Sun moves from B to A, and the Earth's shadow from C to D, and the Moon from H to G, all in the order of the signs; but because the Moon is swifter than the Sun and the shadow in apparent motion in longitude, it at length overtakes the shadow. So when the Moon is placed at H, its western part will appear bright and its eastern part darkened; and when it is placed at G, its eastern part will begin to appear.

[Margin: 4th argument.]

Fourth, from the duration of the eclipse, which, other things being equal, is greater when the Moon is nearer the Earth, as if it is in the tract HG, because there it must traverse a larger space of thicker shadow before it escapes the darkening by its motion of elongation from the Sun. On the contrary, it is less when the Moon is more remote from the Earth, as at I, for the opposite reason.

[Margin: 5th argument.]

Fifth, from the shape of the eclipsed part of the Moon. For the darkened part appears as a segment of a black circle, as may be seen in the first of the following schemes and in others to be presented in ch. 6, exactly as the shape of a shadowy cone requires. For this reason the portion of the Moon free from the shadow is sickle-shaped or horned towards the shadow.

Sixth, from the places of the Zodiac in which lunar eclipses occur. For since it is established from the motion of lunar latitude that the places of the nodes, near which eclipses occur because of the small latitude, move continually against the order of the signs, it has also been observed that the places of eclipses follow this motion and retreat against the order of the signs; so that if the eclipse of one year took place at the beginning of Taurus, the eclipse of the following year takes place in Aries, and so on for the rest.

Seventh, from the part and quarter of the Moon in a partial eclipse. For it is always the northern part when the Moon has southern latitude; but it fails in the southern part when it has northern latitude that is less than the sum of the semidiameters of the Moon and the Earth's shadow.

Eighth and finally, from the infallible prediction of lunar eclipses, which, resting on these suppositions and on the comparison of the sum of the semidiameters of the Moon and the shadow with the latitude, has always been found true. It is evident, therefore, physically and astronomically, that no other more fitting cause can be assigned for the Moon's undergoing eclipse than its falling into the Earth's shadow. Cleomedes, Book 2, ch. 5, presents some of these arguments in learned fashion.

[Margin: The species of lunar eclipses.]

IV. Now there are four species of lunar eclipse, indicated by the same number of schemes added here. In these the ecliptic is the line EL; the Moon's path, inclined to the ecliptic and measuring the span of the duration, is BP; the large black circle is the one whose plane cuts the cone of the Earth's shadow at right angles, at the place through which the Moon passes; the other, smaller ones represent the Moon's disc at the beginning, middle and end of the eclip-

Diagram. Caption: *Partial eclipse of the Moon.* A large black circle is crossed by the horizontal line EL. A slanting line runs from B at upper left to P at right, passing through three small white-outlined circles, the middle one overlapping the top of the black circle.

- B (inside the small circle at upper left): beginning of the Moon's path
- G (above the middle small circle): no text gloss
- P (inside the small circle at right): end of the Moon's path
- E (left end of the horizontal line): end of the ecliptic

• L (right end of the horizontal line): end of the ecliptic

Diagram. Caption: *Total eclipse of the Moon without duration.* A large black circle is crossed by the horizontal line EL. A slanting line runs from B to P through three small circles; the middle one lies wholly inside the black circle, and the outer two touch its edge from outside.

• B (inside the small circle at left): beginning of the Moon's path
• P (inside the small circle at right): end of the Moon's path
• E (left end of the horizontal line): end of the ecliptic
• L (right end of the horizontal line): end of the ecliptic se. The first species is the Partial Eclipse [Eclipſis Partialis], as at G, when at the height of the darkening not the whole Moon but only a part of it is eclipsed. This happens when the Moon's true latitude is less than the sum of the semidiameters of the shadow and the Moon, but greater than the excess of the shadow's semidiameter over the Moon's semidiameter.

[Margin: Partial eclipse of the Moon: how great, and when?]

The second species is the Total Eclipse without duration in the shadow [Totalis ſine mora], as in the second scheme. It occurs when the Moon's apparent semidiameter together with its true latitude exactly equals the shadow's semidiameter, or when the Moon's latitude equals the excess of the shadow's semidiameter over the Moon's semidiameter. For then, at the height or middle of the eclipse, the whole Moon is indeed eclipsed, but at the same moment it begins to emerge from the shadow.

[Margin: Total eclipse without duration.]

Diagram. Caption: *Total eclipse of the Moon with duration.* A large black circle stands in the left column beside the narrow text. A line runs from B to P through a small circle lying wholly inside the black circle, nearer the middle; two further small circles, holding B and P, cross its edge, their centres lying just outside it. A second line, EL, crosses the black circle below the first.

• B (inside the small circle at left): beginning of the Moon's path
• P (inside the small circle at right): end of the Moon's path
• E (left end of the lower line): end of the ecliptic
• L (right end of the lower line): end of the ecliptic

Diagram. Caption: *The greatest of total eclipses, or central.* A large black circle is crossed by the horizontal line EL. A slanting line runs from B at lower left to P at upper right through a small circle at the centre of the black circle; two further small circles, holding B and P, touch its edge from outside.

• B (inside the small circle at lower left): beginning of the Moon's path
• P (inside the small circle at upper right): end of the Moon's path
• E (left end of the horizontal line): end of the ecliptic
• L (right end of the horizontal line): end of the ecliptic

The third species is the Total Eclipse with duration [Totalis cum mora], as in the 3rd scheme. It occurs when the Moon's true latitude is less than the excess of the shadow's semidiameter over the Moon's semidiameter.

[Margin: Total eclipse with duration.]

The fourth species is the Central Eclipse [Eclipſis Centralis], which is nevertheless reduced to the Total with duration. It occurs when, at the middle of the eclipse, the Moon has no true latitude but occupies one of the Nodes with its centre, as in the 4th scheme; and this, other things being equal, is the greatest of lunar eclipses.

[Margin: Central eclipse.]

V. The causes, then, that come together to produce the species of lunar eclipses and to vary their magnitude and duration are 4. The first is the height and thickness of the Earth's shadow, which is greater at a greater and less at a lesser distance of the Sun from the Earth; and the greater it is, the greater the quantity and duration of the eclipse it produces. The second is the Moon's apparent semidiameter, which is greater at a lesser and less at a greater distance of the Moon from the Earth; and the greater it is, other things being equal, the smaller the eclipse. The third is the Moon's true latitude: the less it is, the greater the eclipse it produces, and the greater it is, the lesser. The fourth is the Moon's hourly motion from the Sun, which varies because of the varying slowness of the motion of the luminaries; and the slower this motion of the Moon is, the greater, other things being equal, the duration of the lunar eclipse. Now the causes that increase or diminish these four, whether of themselves or incidentally, also increase or diminish the duration and magnitude of eclipses, as we shall indicate in the Scholia.

[Margin: Causes varying the measure of eclipses.]

SCHOLIA.

Scholia.

I. The first cause varying eclipses of the Moon, discussed in no. 5, is itself varied, first, by the varying eccentricity of the Sun, if that is admitted, on which I have said enough in Book 3, Chapter 26: for the greater the eccentricity, the greater the Sun's distance, the thicker the shadow and the greater the eclipses of the Moon.

[Margin: The Sun's eccentricity varies eclipses of the Moon.]

It is varied, second, by the varying shape and size of the terraqueous globe, not so much because of the varying height of mountains as because of the atmosphere, or the denser air surrounding the Earth. The height of this air is usually estimated from twilight, as we said in Book 1, Chapter 31, and it is not thought to exceed 70 Italian miles; indeed, if its measure is derived from the Sun's refracted rays, it contracts to about 24 miles, as Wendelen holds in the preface to the *Idea of the Atlantic Tables*, and very nearly Kepler in the *Optics*, p. 287. The Earth, therefore, being larger than itself because of this crust of thick air, produces a thicker shadow and increases the shadow's apparent semidiameter, so that Wendelen thinks an eclipse of the Moon begins 17^s or 20^s of time sooner and ends later. But if this air has swollen with clouds or vapours, he thinks this increase can be felt up to a full half of a minute of time. He adds

that our air is lowest under the Equator and the Torrid Zone and higher under the Poles, from which the Earth's shape turns out oval, as Clavius too noted in the *Sphere*; and that account should be taken of this at least in total eclipses without duration.

[Margin: The air around the Earth increases the shadow.]

However, since the shadow's semidiameter, as I shall say shortly, is determined by the Sun's unrefracted rays, and so by rays touching not so much the Earth as the thick air, whatever increase arises from that is understood to be already computed in the semidiameter of the shadow that the astronomical tables give. Conversely, if the Sun's apparent diameter is enlarged because of refractions, the shadow contracts, as Longomontanus notes in Book 1 of the *Theorica*, pp. 292 and 293.

II. The second cause, of which no. 5 speaks, namely the Moon's apparent semidiameter, appears to be varied by the denser air or aether around the Moon, of which we spoke in Book 4, Chapter 2. For David Fabricius, in Kepler's *Ephemerides*, pp. 9 and 22, holds that because of this air the Moon's semidiameter is enlarged, the beginning of the eclipse is therefore hastened and its end delayed, and its duration increased, expanding the Moon's diameter on this account to 4′ or 5′. Wendelen, in the preface to the *Eclipses*, p. 5, supposes that from this the duration can be increased by a whole minute and the beginning hastened by half a minute of time. Nor would Galileo deny it, in the *Sidereus Nuncius*, p. 13, since he admits that the orb of this denser substance, when lit by the Sun, presents us with a larger Moon.

[Margin: Whether the air around the Moon increases eclipses.]

But Kepler, in the *Optics*, p. 302, and in the two passages of the *Ephemerides* noted above, denies that the Moon's diameter or the duration of the eclipse is sensibly increased by this. That enlargement, he says, is a deception of sight, to which white and luminous things next to black or dark ones appear larger, because of the confused image at the back of the eye, the bright part prevailing and acting more strongly. A sign of this, he says, is that the Moon seen through the telescope appears either without that air or with air so thin that the measure of eclipses is in no way varied by it; or even, on the testimony of Fabricius himself, who says of the eclipse of 1613 October 28: "Near the end of the eclipse of the Moon, when to the naked eye a digit was judged to be missing, through the telescope the whole Moon appeared illuminated and round." From this he infers the conclusion that Kepler rejects: therefore the limb that seemed to the naked eye to be lacking was the limb of the lunar air above the Moon's body. But in truth, if that air were something real and objectively increased the diameter and duration, the same should have been seen with the telescope, and indeed more clearly and larger, since that is the telescope's proper effect. That phase, therefore, is not in the sky, but in the eye, overwhelmed by the brightness of our air.

III. Although an eclipse of the Moon is said to be Universal, that is, of the same quantity and duration in all the parts of the Earth where it appears, because

it consists in a true privation of the direct light usually received from the Sun, which occurs in the same way everywhere on Earth; and therefore, if an eclipse of the Moon is partial to one spectator, it should be thought partial to any spectator as well; nevertheless Wendelen acutely noted, in the preface to the *Eclipses*, p. 7, as did Father Paolo Casati by his own wit, that in strictness this is not true. For the same eclipse can be observed as Partial by one spectator and as Total by another, since the Moon's limb can be outside the shadow and the angle of contact, towards the north, and yet be hidden from a southern observer far removed from us; and so an eclipse that is Partial to us can appear Total to our Antoeci, and conversely. Wendelen admits, however, that this difference is so insensible that it deserves to be neglected.

[Margin: A paradox about an eclipse of the Moon, Partial to one and Total to another.]

CAPVT IV.

Chapter IV.

De Triplici menſura Vmbræ Terræ à radijs Solis Irrefractis comprehenſæ.

On the threefold measure of the Earth's shadow as bounded by the Sun's unrefracted rays.

I. The threefold measure of this shadow or penumbra consists in the angle of the shadowy cone, in the height or axis of this cone, and in the breadth, or its apparent semidiameter at the place through which the Moon passes at full Moon. And on the angle and semiangle of the cone of the Earth's shadow, and also on its height, with the Sun's unrefracted rays in view, enough has already been said in Book 3, Chapter 11, Problems 5 and 8, where we also reviewed the opinions of others. Our own opinion is that the already mentioned semiangle is 14′ 50″ with the Sun at apogee and 16′ 8″ at perigee; and there is no one from whose hypothesis there follows a value greater than 16′ 8″ or less than 12′ 10″. Here I add only what I forgot there: that Kepler, in the *Epitome of Copernican Astronomy*, p. 861, derives this semiangle by subtracting the Sun's horizontal parallax from the Sun's visual semidiameter, which is very nearly true. In the same place we fixed the axis of the Earth's shadow at 231½ terrestrial semidiameters with the Sun at apogee, but 213 at perigee. Nor is there anyone who makes it greater than 282 semidiameters of the Earth or less than 213.

Here, however, the terrestrial semidiameters are to be understood as those not of the bare Earth, but of the Earth surrounded by that denser air, which the extreme rays of the Sun touch as they go on beyond without refraction, and not those rays that are commonly imagined to touch the Earth itself; for those are neither extreme rays nor unrefracted. Kepler, however, in the passage cited, derives this axis by multiplying the Sun's distance by the true semidiameter of the Earth, and dividing the total by the excess of the Sun's true semidiameter

over the true semidiameter of the Earth. It remains, then, for us now to deliver what we promised there, in no. 10, and to determine the apparent and the true semidiameter of the Earth's shadow at the place of the Moon's transit; and after that we shall also complete the dimensions and properties of the penumbra.

PROBLEMA I.

Problem 1.

Semidiametrum Vmbræ terreſtris ad datam Lunæ per Vmbram tranſeuntis diſtantiam à Terra, inuenire.

To find the semidiameter of the Earth's shadow at a given distance from the Earth of the Moon passing through the shadow.

II. The first method is by a lunar eclipse of exactly six digits, that is, when exactly half of the lunar disc suffers eclipse at the height of the darkening. Ptolemy gives it in Book 5 of the *Almagest*, Chapter 14; Regiomontanus in the same place, prop. 18; Reinhold in Peuerbach's *Theoricae*, p. 209; and Biancani, Book 9 of the *Sphere*, Chapter 8. For this method, in the adjoined figure

[Margin: 1st method, by an eclipse of 6 digits.]

Diagram. An uncaptioned figure in the left column. A straight line runs from A at the left to C at the right, carrying the points G, B, E and I. A large circle is centred on B. A second straight line runs from C down to the left to D, through three small circles with centres P, M and F; the small circle at M, on the edge of the large circle, has its part within the large circle hatched. Straight lines join B to F, to M and to P, and G to F, E to M and I to P.

- A (left end of the upper line): the ecliptic ABC, as the text gives it
- G, I (on the upper line): feet of the latitudes FG and PI
- B (on the upper line): centre of the shadow
- E (on the upper line): foot of the latitude ME
- C (right end of the upper line): the nearer Node
- D (left end of the lower line): the path of the lunar orbit CD
- O, L (where the lines from B meet the large circle, near F and near P): points on the circle of the shadow OML
- M (centre of the middle small circle): the Moon's centre at the height of the eclipse
- P (centre of the right small circle): the Moon's centre at the beginning of the eclipse
- F (centre of the left small circle): the Moon's centre at the end of the eclipse

let the ecliptic be ABC, on which the centre of the shadow is B, from which the circle of the shadow OML is described; and let the path of the lunar orbit be CD. At the height of the eclipse let the Moon's centre M touch the periphery of the shadow, so that exactly half of the lunar diameter is darkened. For when the centres B and M are joined, BM will be the apparent semidiameter of

the shadow, which Ptolemy holds to be sensibly equal to the Moon's latitude. Therefore, for the moment of such a greatest darkening, derive from the tables the Moon's true latitude and the lunar anomaly, to which the Moon's distance from the Earth corresponds; and the shadow's semidiameter will become known for the given anomaly of the Moon and distance from the Earth, for it will be as great as the latitude.

Thus Ptolemy, above, selects an eclipse of half the Moon towards the north, which took place in the year 225 of Nabonassar, or 523 before Christ, on the 17th of Phamenoth going into the 18th, or July 16, and was observed at Babylon 1^h before midnight. For that equated moment he derives the Moon's anomaly as 28° 5′, and its latitude, and so the shadow's semidiameter, as 40′ 40″.

[Margin: An example from Ptolemy.]

Here, however, we are using arcs as if they were straight lines, or chords of the arcs. In strictness, when the Moon's centre touches the periphery of the shadow, the radius MB makes with the chord MC a right angle at M, by 16 of Book 3 of Euclid. So in triangle CBM the angle B cannot be a right angle; nor is BM the arc of the circle of latitude or its chord, since that must make a right angle with the ecliptic; instead it is called the arc through the centres. The arc of latitude, or its chord, is the line ME, which makes a right angle with the ecliptic at E.

III. Our second method, then, by an eclipse of 6 digits, is this: for the moment of the greatest eclipse, let the Moon's true latitude ME be derived from the tables, and the distance of the lunar centre M from the nearer Node C, namely the arc MC. For from these data, in the spherical triangle right-angled at E, the angle C is easily derived; and with it and the arc MC, in the triangle CBM, right-angled at M, you will derive by trigonometry the arc BM, namely the semidiameter of the Earth's shadow.

[Margin: Our 2nd method.]

IV. Our third method works from these data, at the beginning or end of any lunar eclipse whatever: the Moon's visual semidiameter, its latitude, and the distance both of the shadow's centre and of the Moon's centre from the nearer Node, all of which I suppose can be known from tables already corrected. For in the preceding figure let the Moon's centre be at P at the beginning of the eclipse, or at F at the end; let these centres be joined to B, the shadow's centre, by the lines BP and BF; and from the Moon's centres let there be drawn lines orthogonal to the ecliptic AC, representing the Moon's true latitude, and let them be PI and FG.

[Margin: Our 3rd method.]

Therefore, if you use the beginning: in triangle CIP, right-angled at I, in which are given the base PC, namely the distance of the Moon's centre from the neighbouring Node, and PI, the true latitude, derive angle C. With it, in triangle CBP, and with PC, known as above, and BC, the distance of the shadow's centre from Node C, derive the side BP. From it subtract the Moon's semidiameter LP, and the shadow's semidiameter BL will remain. But

if you use the end: in triangle CGF, right-angled at G, from the base FC, namely the Moon's distance from the nearer Node, and the latitude FG, derive angle C. With it, in triangle CBF, and with FC and BC, known as above, derive the side BF. From it take away the Moon's semidiameter FO, and the shadow's semidiameter BO will be known. Martinus Hortensius, however, in the dissertation with Gassendi on Mercury seen in the Sun, uses an eclipse greater than 6 digits and the duration between the two moments at which the Moon's centre touches the periphery of the shadow, and so appears eclipsed by half of itself.

V. The fourth method is by observation, receiving the Moon's image on a white tablet, especially at the height of a partial eclipse, provided the tablet is equidistant from the lunar disc, and marking three points on the periphery of the lunar image and also three points on the periphery of the shadow, as in the following scheme, in which the image of the shadow is ABC and that of the Moon AFC.

[Margin: 4th method, by reflected observation.]

Diagram. An uncaptioned figure at the foot of the right column, beside the narrow text. Two overlapping circles stand one above the other, the upper larger than the lower, on a vertical line running from B at the top to F at the bottom. The arcs of the two circles cross at A on the left and C on the right, and the straight line AC crosses the vertical line. Straight lines join A and C to E on the vertical line, and A and C to I on the vertical line. The upper circle is inscribed with the words VMBRA VEL SOL (shadow or Sun), the lower with the word LVNA (Moon).

- B (top of the vertical line): on the periphery of the shadow's image ABC
- E (on the vertical line, just below the inscription): centre of the shadow's image
- G (on the vertical line, in the common part of the circles, above K): not explained on this page
- K (on the vertical line, at its crossing with AC): not explained on this page
- D (on the vertical line, below K): on the periphery of the shadowy image
- I (on the vertical line, beside LVNA): centre of the Moon's image
- F (foot of the vertical line): on the periphery of the Moon's image AFC
- A (left crossing of the circles): common point of both peripheries
- C (right crossing of the circles): common point of both peripheries

For when the three points A, F, C have been marked on the periphery of the lunar image, and the points A, D, C on the periphery of the shadowy image, the centre of each, E and I, and the semidiameter are easily found with compasses, by the scholium to Book 4, prop. 5 of Euclid; and from that the proportion of the semidiameters, of the shadow AE to the Moon's semidiameter AI. So, once the Moon's semidiameter is known, the shadow's semidiameter will at once be known.

In this way Father Andreas Arzet of the Society of Jesus, in the eclipse of 1630, on the night following November 19, observed that the diameter of the Moon is to the diameter of the shadow as 100 to 266; and in the eclipse of 1632 October 27, that it is to the diameter of the spurious shadow as 100 to 303, but to that of the legitimate shadow as 100 to 261. And Father Georges Fournier, in the eclipse of 1642 April 14, writes that the semidiameter of the Moon to that of the shadow, or 17 to 40, was observed by him, Gassendi and Boulliau. For it is useful to divide the Moon's diameter into as many and as minute particles as possible; and therefore its image is usefully received through the telescope, by which it is amplified with its clarity and distinctness preserved; and before observing the shadow, the diameter and image of the full Moon are usefully received on the tablet, at a distance determined from the telescope, to be kept from then on.

VI. Our fifth method is this: in a lunar eclipse of 6 digits, at the moment when exactly six digits are darkened, the distance between the lunar horns is taken, and shortly before or after the Moon's diameter is observed in the same kind of parts. For let the Moon's disc be DFKG, its centre A, its diameter FAG and its semidiameter FA; and taking the shadow's centre B, let the arc of the shadow CAE be described with the interval AB, passing through the centre A of the lunar disc. The Moon's horns will be C and E, their distance CE and their half-distance CM. Let one of the horns, as C, be joined by straight lines to the centres A and B, by drawing CA and CB. The shadow's semidiameter will be both BA and BC, and so triangle ABC is isosceles, in which the angles at the base, namely CAB and ACB, are equal by 5 of Book 1.

[Margin: Our 5th method, by observation.]

Diagram. An uncaptioned figure in the left column, beside the narrow text. A tall triangle has its apex at B, its two long sides running down to C at the left and E at the right, and a vertical line from B through D and M to A, the centre of a circle with K at its foot. An arc from C through A to E crosses the circle, the straight lines CE and FAG cross it near each other, and straight lines join C and E to A.

- B (apex): centre of the shadow
- D (top of the circle, on the vertical line): on the Moon's disc DFKG
- M (on the vertical line, on CE): midpoint of the distance between the horns
- C (left end of the arc): one horn of the Moon
- E (right end of the arc): the other horn of the Moon
- F (left end of the diameter, just below C): on the Moon's disc
- G (right end of the diameter, just below E): on the Moon's disc
- A (on the vertical line, below M): centre of the lunar disc
- K (foot of the circle): on the Moon's disc

So make: as the observed FA is to the observed CM, so the radius FA, 100000, to CM, the sine of the arc CD, which measures the angle CAD. Since, therefore, in triangle ABC all the angles will be known individually (for CBA

is the complement to two right angles of the equal angles at A and C), and the base AC is known because it equals the semidiameter AF, neither leg, AB or CB, will escape the trigonometer, in parts of the kind in which AF was observed. Accordingly, if AF is known from elsewhere in minutes and seconds, then from the already mentioned proportion the shadow's semidiameter AB will also become known in minutes and seconds. Thus in 1643 September 27, in an eclipse that at its height was of 6 digits, we observed the shadow's semidiameter AB as 48′. By what means small intervals are taken more exactly, not with the astronomical radius, which is deceptive, but with another instrument, we shall show in the *Liber Organicus*.

It is not necessary, however, for the eclipse to be of 6 digits at its height; it is enough if it is of 6 digits at some moment. We must now come to the methods that are connected with the search for the true semidiameter, or that rest on figures serving the investigation of both.

PROBLEMA II.

Problem 2.

Veram ſimul & Apparentem Semidiametrum Vmbræ Terreſtris inueſtigare.

To investigate at once the true and the apparent semidiameter of the Earth's shadow.

VII. The sixth method is used by Ptolemy, Book 5, Chapter 14; Regiomontanus there, prop. 22; al-Battānī, Chapter 30; Copernicus, Book 4, Chapter 19; and Magini, Book 2 of the *Theoricae*, Chapter 24, although they do not use exactly the same method or figure. It is of this kind. Let the Sun be ABC, its centre D and its diameter AC; and the Earth KLM, its centre N; and let the extreme rays of the Sun touching the Earth at K and M be CKS and AMS. So the Earth's shadow is KSM, its axis NS, and the distance of the Sun from the Earth DN, in the same straight line; and on this line let there be the Moon at apogee, EFG, at distance HN from the Earth. Here Ptolemy supposes that the angle subtending the Sun's visual semidiameter, namely CND, is equal to the angle subtending the Moon's apparent semidiameter, namely angle ENH. Now let the line NP, equal to the distance NH, be taken on the axis NS. P will then be the place of the Moon at apogee in the Earth's shadow, and IQ, orthogonal to NS, will be the diameter of the circle of the shadow at the place of transit of the Moon at apogee.

[Margin: 6th method.]

[Margin: Ptolemy's method for investigating the semidiameters and distances of the shadow, the Sun and the Moon.]

First, Ptolemy, from the observation of two eclipses, about which we spoke in Book 4, Chapter 16, derives the visual semidiameter of the Moon at apogee as 15′ 40″. From this and its distance HN, in triangle EHN, right-angled at E, he derives EH, the true semidiameter of the Moon, as 0 17′ 33″ of terrestrial

semidiameters. And from the observation of the same eclipses he had derived the semidiameter of the Earth's shadow at the place of the Moon nearly at apogee as 40′ 40″, by the first method given in Problem 1; and he adds that from many other observations the Moon's semidiameter was found to be to the shadow's semidiameter as 1 to 2⅗, or as 5 to 13. Let it be made, therefore, as 5 to 13, so the Moon's true semidiameter, 17′ 33″, that is 1053″, to the true semidiameter of the shadow, 2737⅘″, or 45′ 37″ 48‴, or as Ptolemy has it, 45′ 38″, of which the Earth's semidiameter is 60′. Next let it be made, as 5 to 13, so 15′ 40″, the Moon's apparent semidiameter, to 40′ 44″, the shadow's apparent semidiameter.

[Margin: The true semidiameter of the Earth's shadow.]

Diagram. A tall uncaptioned figure in the right column, with the narrow text at its left. A vertical axis runs from the apex S down through P, L, N, F, H and B to D and on to the foot of a large circle. From S two long lines descend to C and A, the ends of the horizontal diameter of the large circle at the bottom. Three chords cross between these lines: IQ through P; KM through N, the diameter of a circle with L at its top; and a line from E through H and G to T, with a small circle above it whose top is F. From N two further lines descend to C and A, passing through E and G.

- S (apex): apex of the Earth's shadow
- I, Q (ends of the upper chord): diameter of the circle of the shadow at the place of transit of the Moon at apogee
- P (on the axis, on IQ): place of the Moon at apogee in the shadow
- L (top of the middle circle): on the Earth KLM
- K, M (ends of the chord through N): points where the Sun's extreme rays touch the Earth
- N (on the axis, centre of the middle circle): centre of the Earth
- F (top of the small circle): on the Moon EFG
- E, G (either side of H): on the Moon EFG
- H (on the axis): centre of the Moon
- T (right end of the line through H, on the long line): end of HT
- B (top of the large circle): on the Sun ABC
- C, A (left and right ends of the large circle's horizontal line): on the Sun ABC
- D (on the axis, on CA): centre of the Sun

Ptolemy, however, supposes that the chords AC, EG and KM differ insensibly from the diameters of these circles, because of the great distance of these three bodies from one another. Second, since HT and PQ, parallel to it, are equally distant from NM, therefore HT and PQ together are double NM, which Regiomontanus says is easily evident; and so they are together equal to two NM, semidiameters of the Earth, or 120′. Therefore, since HG is 17′ 33″ and PQ 45′ 38″, that is together 63′ 11″, when these are taken from 120′ there remains GT as 56′ 49″, of which NM is 60′. Now by the second of Book 6 of Euclid, in triangle ANM, the straight line NM is to GT as AN to AG; and NG to AG as

NH to DH. So NM to GT is as ND to DH; and therefore, if ND is 60′, DH will be 56′ 49″ and HN 3′ 11″. And so the proportion is known of HN, namely the distance of the Moon at apogee from the Earth, to the Sun's distance ND. Now HN is 64 10′, of which NM is one; therefore ND, the distance of the Sun at apogee, is almost 1210, of which NM is one. Further, NH is to HG as ND to DA, but NH is to HG as 64 10′ to 0 17′ 33″, and ND is 1210; therefore DA is 5 30′. Finally, NM to PQ is as NS to PS; therefore the proportion is known of NP, the distance of the Moon at apogee, to NS, the axis of the shadow, which he finds to be 268 semidiameters of the Earth. I wanted to set out the whole of Ptolemy's method here from the man himself, because we presented it otherwise, with Lansbergen, in Book 3, Chapter 7, Problem 2.

[Margin: The Sun's distance.]

[Margin: The axis of the shadow.]

Al-Battānī, however, in Chapter 30, although he assumes the same distance of the Moon at apogee and the same visual semidiameter of the Sun as Ptolemy, nevertheless sets the Moon's semidiameter at 14′ 45″ and the shadow's at 38′ 20″. From these he derives the horizontal parallax of the Sun at apogee as 3′, its distance from the Earth as 1146 terrestrial semidiameters, and the shadow's axis as 254 terrestrial semidiameters. But from his data Lansbergen, in the Prolegomena to the *Uranometria*, derives the true semidiameter of the shadow at the place of the Moon at apogee as 42′ 9317350/10000000, of which one semidiameter of the Earth is 60′; and the axis of the shadow as 225 33′ terrestrial semidiameters, and

[Margin: Al-Battānī's opinion, and its inconsistency.]

the Sun's distance 7936½ semidiameters of the Earth, and its horizontal parallax 0′ 26″.

Copernicus, for his part (Book 4, chapters 19 and 23), puts the Moon's distance at apogee at 65½ semidiameters of the Earth, and the apparent semidiameters of the Moon at 15′ 0″, of the shadow at 40′ 18″, and of the Sun at apogee at 15′ 50″. From these he thinks it follows that the axis of the shadow is 265 semidiameters of the Earth, the Sun's distance 1179, and its horizontal parallax 2′ 55″. But Lansbergen, in the same place, derives from Copernicus's earlier data a true semidiameter of the shadow of 46′ 721760/10000000, of which one semidiameter of the Earth is 60′; an axis of the shadow of 282⅛ [?] semidiameters of the Earth; a distance of the Sun of 941 53′; and a horizontal parallax of 3′ 39″. As for the greatest shadow, Copernicus derives 47′ 52″.

[Margin: Copernicus's opinion and its inconsistency.]

Tycho, however, in volume 1 of the *Progymnasmata*, puts the Moon's distance at apogee at 58 8′ semidiameters of the Earth, and the visual semidiameters of the Moon at apogee at 16′ 0″, of the shadow at 43′ 0″, and of the Sun at apogee at 15′ 0″. These do not cohere. For, as Lansbergen shows in the place cited, there follows from them a true semidiameter of the shadow of 43′ 6306944/10000000, of which one semidiameter of the Earth is 60′, and a semi-angle of the cone of the shadow, namely K S N, of 16′ 8″. That is greater than the angle C N D,

which subtends the Sun's apparent semidiameter, set at 15′, whereas by Euclid, Book I, proposition 32, it ought to be smaller.

[Margin: Tycho's opinion and its inconsistency.]

Longomontanus too (Book 1, *Theorica*, chapter 9) puts the Moon's distance at apogee at 57 38′ semidiameters of the Earth, and at apogee the apparent semidiameters of the Sun at 15′, of the Moon at 16′, and of the shadow at 43′. But from these, on Lansbergen's reckoning, there follows a true semidiameter of the shadow of 43′ 2554304/10000000, of which one semidiameter of the Earth is 60′, and a semi-angle of the cone of the shadow of 16′ 37″. That is certainly greater than the apparent semidiameter of the Sun set by him, whereas it ought to be smaller. But here one should recall what we said about this incongruity and conflict of the hypotheses in Book 3, chapter 7, Problem 6, together with Problem 5, where we dealt fully with the semi-angle of the cone of the shadow, and Problem 7, where we dealt fully with the axis of the shadow, the Sun's rays being taken as unrefracted.

[Margin: Longomontanus's opinion and its inconsistency.]

VIII. The seventh method, however, that of Longomontanus (Book 1, *Theorica*, chapter 9), is as follows. In the accompanying diagram let A be the centre of the Earth and B the centre of the Sun, let C M E and D N E be the rays touching both globes, and so let M E N be the shadow of the Earth. With B A E drawn through the centres, let the Sun's distance A B be a mean one, of 1288 semidiameters of the Earth; and with A D drawn, let the Sun's apparent semidiameter, or its measure the angle B A D, be 15′ 30″. First, then, from triangle A B D, right-angled at B, the Sun's true semidiameter is derived as 5 807/1000 terrestrial semidiameters, and C B is of that size. So, with M R drawn parallel to B A, the angles at R will be right, and R B will equal one semidiameter of the Earth, A M. When this is subtracted from B C, there remains C R, 4 807/1000 semidiameters of the Earth. Further, by Euclid, Book VI, proposition 2, as C R, 4 807/1000, is to the Sun's distance R M, 1288, so B C, 5 807/1000, is to B E, 1556. With A B subtracted, therefore, there remains the axis of the shadow A E, 268 terrestrial semidiameters. Next, let A G be the Moon's mean distance, 56 semidiameters of the Earth. When this is subtracted from A E, there remains G E, 212 semidiameters of the Earth. And with P G drawn parallel to M K, it will be that as E A, 268, is to A M, 1, so E G, 212, is to G P, the true semidiameter of the shadow, 47′ 28″, of which one semidiameter of the Earth is 60′. Finally, with A P drawn, there are given in triangle A G P, right-angled at G, the side A G, 56 semidiameters of the Earth, and G P, 0 47′ 28″. Therefore the angle P A G, subtending the shadow's apparent semidiameter, is 48′ 34″.

[Margin: 7th method: Longomontanus's.]

[Margin: Axis of the shadow at the mean distances of the luminaries, according to Longomontanus.]

[Margin: True and apparent semidiameter of the shadow at the mean distances of the luminaries.]

Diagram. A tall narrow figure inset in the left column, beside the narrowed text. At the top a large circle, the Sun, is cut by the horizontal diameter C–D, on which R and B stand. Two long tangents run down from C and D, through M and N on a middle circle, and meet at the apex E. Between the Sun and the middle circle stands a small circle holding F. The middle circle holds T, A and K on the line M–N. Below it a small circle holds G on the line P–L, inside the cone. Straight lines run down from R and B and to the lower points.

- C (left end of the top diameter): point where the ray touches the Sun
- R (on the top diameter, left of centre): foot of M R
- B (on the top diameter, centre): centre of the Sun
- D (right end of the top diameter): point where the ray touches the Sun
- F (inside the small upper circle): no gloss on this page
- M (left of the middle circle): where the ray C M E touches the Earth
- T (inside the middle circle, left): no gloss on this page
- A (inside the middle circle, centre): centre of the Earth
- K (inside the middle circle, right): point on M N used in the text
- N (right of the middle circle): where the ray D N E touches the Earth
- P (left of the lower circle): end of G P
- G (inside the lower circle): the Moon's place on the axis
- L (right of the lower circle): end of G L
- E (apex): end of the shadow

But Longomontanus adds that at a pole-height of 56° this angle, from many observations of lunar eclipses, has been found no greater than 44′ 10″. From this he confirms that the thickness of the air around the horizon, by refracting the Sun's rays, thins the semidiameter of the Earth's shadow, though only moderately; but that perhaps in farthest Norway, Ireland and regions nearer the Pole, because of thicker vapours, it is contracted somewhat more.

[Margin: Breadth of the penumbra.]

By a wholly similar method, varying the distances of the luminaries, he derives a varying axis and a varying semidiameter of the Earth's shadow, as can be seen in the following small table; although afterwards, in the Table of semidiameters, he limits it and sets it differently, as we shall see below in the Synopsis of opinions.

☉ Distance in semidiameters of the Earth	☾ Distance in semidiameters of the Earth	Apparent semidiameter of the shadow
	Apogee 57 38′	46′ 49″
Mean 1288	Mean 56 0	48′ 34″
	Perigee 54 23′	50′ 24″
Apogee 1334	Mean 56 0	49′ 0″
Perigee 1242	Mean 56 0	48′ 4″

But he first sets out the apparent semidiameter of the shadow at the mean distance of the luminaries, from these authors: Ptolemy 44′ 48″, Alfonso 41′, Copernicus 43′ ½, Reinhold 43′ ¾, Tycho 44′ ⅛ [?]. And he adds that the

ancients, measuring the shadow from the Moon's transit, fell short, because they thought the Moon's motion slower. But since the basis of a varied semidiameter of the shadow is uncertain and has not been demonstrated by this author, and since it contains that conflict spoken of above at the end of number 7, we cannot safely follow him.

IX. The eighth *motus* [recte: modus, "method"] is that of Lansbergen, *Uranometria*, Book 2, elements 5, 6 and 7. First, with Hipparchus, Ptolemy, al-Battānī and, as he himself says, Copernicus, he supposes that the Moon's apparent semidiameter is to the apparent semidiameter of the shadow as 5 to 13. He confirms this by observation of the eclipse of 1601 December 9, of 10 digits 56′ according to Kepler but according to himself 10 digits 40′, with the Moon and Sun nearly at perigee, when the Moon's apparent semidiameter was 17′ 49″ and its northern latitude 32′ 32″. So the sum of the two was 50′ 21″, which is how large the shadow's semidiameter would have been if the eclipse had been of 12 digits. But one digit and a third remained unharmed, to which 4′ 2″ of the Moon's diameter correspond. When these are subtracted from 50′ 21″, a semidiameter of the shadow of 46′ 19″ remains. And as 17′ 49″ is to 46′ 19″, so is 5 to 13. From this he derives that the apparent semidiameter of the shadow, with the luminaries at apogee, is 39′. From these, moreover, he derives the axis and the true semidiameter of the Earth's shadow, and the semi-angle of the cone, by the following method.

[Margin: 8th method: Lansbergen's.]

[Margin: Apparent semidiameter of the shadow.]

In the figure immediately above, let A G be the Moon's distance and B A the Sun's, A E the axis of the shadow, A N the semidiameter of the Earth and G L that of the shadow; and let K L be drawn parallel to A G, and A L, so that G A L is the apparent semidiameter of the shadow. First, then, in triangle G A L, right-angled at G, the Moon's distance A G from the centre of the Earth is taken as given, and the angle G A L, the apparent semidiameter of the shadow; therefore G L, the true semidiameter of the shadow, can be found trigonometrically. Second, with G L subtracted from A N, there remains K N, known, in triangle K L N, in which K L too is known, being equal to the lunar distance; therefore the angle K L N can be found, which by Euclid, Book I, proposition 29, equals the interior angle A E N, namely half the angle of the cone of the shadow. Third, as A N, the sine of the angle A E N, is to A E, the second sine of the same angle, so A N, one semidiameter of the Earth, is to A E, the semidiameters of the Earth contained in the axis of the shadow. So at the greatest distance of the luminaries he derives an apparent semidiameter of the shadow of 39′ and a true one of 43′ 67825/100000, of which one semidiameter of the Earth is 60′; a semi-angle of the cone of the shadow of 14′ 34″; and an axis of the shadow of 236 semidiameters of the Earth. We, however, deduced the semi-angle of the cone and the axis of the shadow somewhat differently from the data he gives, in Book 3, chapter 7, numbers 6 and 9. Moreover,

Lansbergen relies on an estimate of the eclipsed digits, which is very deceptive when they are not precisely six.

[Margin: True semidiameter and axis of the shadow.]

[Margin: Lansbergen's flaw.]

X. The ninth method, Boulliau's (*Astronomia Philolaica*, Book 4, chapter 1), relies on the lunar eclipse of 1638 December 21. He puts the time of its incidence [incidentię], accurately observed, at $1^h\ 1^m\ 30^s$, the anomaly at 118° 29′ 31″, and the Moon's hourly motion at 33′, and so the Moon's semidiameter at 16′ 54″; and from the duration of the eclipse he derives an apparent semidiameter of the shadow of 44′ 9″. From another observation taken at that time, of the Moon's altitude compared with the altitude of the leading star in the foot of Gemini, he derives the Moon's parallax, and from it the Moon's distance, 56⅔ terrestrial semidiameters. And yet, without any better-known foundation, feeling his way, he assumes in this eclipse a lunar distance A G of 57 51′ semidiameters and a semidiameter of the shadow G A L of 45′ 4″. From these he derives the true semidiameter of the shadow G L, 45′ 30″, of which A N is 60′. With G L, or A K, subtracted from A N, there remains K N, 14′ 30″. Then in triangle K L N, right-angled at K, from K N just found and K L, equal to the lunar distance, he derives the angle K L N, that is, the semi-angle of the cone equal to it, B E D, 14′ 21″. Next, from the Sun's apparent semidiameter at perigee, B N D, 16′ 45″, which by Euclid, Book I, proposition 32, equals the two angles B E D and E B N, he derives the Sun's parallax at perigee, 2′ 24″, namely by subtracting the angle B E D, 14′ 30″[37], from the angle B N D, 16′ 45″; and the Sun's distance at perigee, 1433 52′ semidiameters of the Earth. But from the Sun's eccentricity, 1784, of which the half of the transverse axis in the ellipse is 100000, he derives the Sun's distance at apogee, 1485 56′ semidiameters of the Earth, its horizontal parallax 2′ 19″ and its apparent semidiameter 16′ 9″; and from these the Sun's mean distance, 1459 54′. The Moon's distance at apogee in the syzygies he derives as 61′ 40″[38] semidiameters of the Earth, and at perigee as 56 30′. Finally he derives the axis of the shadow with the Sun at apogee as 249 52′ semidiameters of the Earth, and at perigee as 237 37′; and the apparent semidiameter of the shadow with the Sun at apogee and the Moon at perigee as 47′ 5″, but with Sun and Moon at apogee as 41′ 51″; and the total variation from the Sun's apogee to its perigee as 35″; and accordingly with the Sun at perigee and the Moon at apogee 41′ 16″, but with Sun and Moon at perigee 46′ 30″. For the rest, this whole machine relies on a semidiameter of the shadow and a lunar distance in that eclipse that are assumed rather than demonstrated, as will be clear to anyone reading the author himself. And I have already said, in Book 4, chapter 16, number 10, that the time of incidence in that eclipse was observed differently by others.

[Margin: 9th method: Boulliau's.]

[Margin: Boulliau's flaw.]

[37]so printed; the same angle stands as 14′ 21″ just above

[38]so printed, with minute and second marks

[Margin: Axis and apparent semidiameter of the shadow.]

XI. The tenth method is ours. It relies on the semi-angle of the cone of the shadow and on the axis of the shadow, already demonstrated in Book 3, chapter 11, Problems 5 and 7, from two very simple elements, namely the Sun's distance and its semidiameter, first the apparent and then the true; from these we derived the following quantities trigonometrically.

[Margin: 10th method: ours.]

☉	Axis of the shadow, in semidiameters of the Earth	Semi-angle of the cone, that is, A E N
At apogee	231½	14′ 50″
At perigee	213 0	16′ 8″

With these set down, and with the lunar distances in the syzygies taken from Book 4, chapter 14, let the Moon's distance A G, in the preceding figure set out at number 8, be at apogee 64 15′ semidiameters of the Earth, and at perigee 53 45′. When these are subtracted from the axis of the shadow A E, the side G E remains known in triangle G E L. With it and the semi-angle of the cone E, the true semidiameter of the shadow G L is derived; and with this and the Moon's distance A G, the angle G A L in the same triangle G A L, which measures the apparent semidiameter of the shadow. Here, then, is the sum of the calculation.

☉	☾	Semidiameters of the Earth: ☾ distance A G	Semidiameters of the Earth: axis of the shadow A E	Semidiameters of the Earth: remainder G E	True semidiameter of the shadow G L, of which A N is 100000	True semidiameter of the shadow G L, of which A N is 60′ 0″	Apparent semidiameter of the shadow G A L

XII. The eleventh method, without geometry, is by the ratio of the Moon's apparent semidiameter to the apparent semidiameter of the Earth's shadow at the place of the Moon's transit. This ratio is as 1 to 2⅗, or as 5 to 13, with the Sun at apogee, as Ptolemy asserts was observed from various eclipses (Book 5, chapter 14), and from him Reinhold on Peuerbach's *Theoricae*, p. 207, Wurstisen in the same place, p. 348, and Barozzi, *Cosmographia*, Book 4, p. 345. But Lansbergen (*Uranometria*, Book 2, element 6) uses this ratio of 5 to 13 also with the Sun nearly at perigee, as we saw at number 9. Copernicus, for his part (Book 4, chapters 19, 21 and 23), says that with the Sun at apogee it is as 150 to 403, but at perigee more than 5 to 13, and that therefore a mean can be chosen. But from the observations of Fathers Arzet and Fournier reported at number 5, the Moon's semidiameter would be to the shadow's semidiameter as 5 to 11 13/17, or as 5 to 13 3/10. For my part, since the Moon's semidiameter for me

is 14′ at apogee and 16′ 45″ at perigee, if I wished to follow Ptolemy's rule it would be: as 5 to 13, so 14′ to the shadow's semidiameter, 36′ 24″, at apogee, and 43′ 33″ at perigee. This differs too much from the semidiameter found by the preceding method at number 11. So if we wish to know the semidiameter of this shadow without geometrical inquiry, we shall rather have recourse to the rule of Kepler and Wendelen, of which presently.

[Margin: 11th method: from Ptolemy, by the ratio of the Moon's semidiameter to the shadow's semidiameter.]

XIII. The twelfth method, then, is Kepler's, in the Rudolphine Tables, precept 148, and in the *Epitome of Copernican Astronomy*, p. 862, where he says: "Gather the horizontal parallaxes of the Sun and Moon into one sum, and from that sum cast off the Sun's apparent semidiameter, and the correct semidiameter of the Earth's shadow will be left." Wendelen approved this precept in the *Idea of the Atlantic Tables*, p. 32, and elegantly enclosed it in the following couplet:

> *Iunge Parallaxes Solis Lunæq. deinde Subtrahe ſemiſſem Solis, ſic noſcitur Vmbra.*
>
> Join the parallaxes of Sun and Moon, then subtract half the Sun: so the shadow is known.

[Margin: 12th method: Kepler's and Wendelen's.]

But since neither of them demonstrated this truly most beautiful rule, the demonstration falls to us, and we easily accomplish it with the help of the following scheme. In the accompanying figure, then, let A B C be the Sun, with its centre at S on the same straight line S V on which lies the centre of the Earth T; and let C H V be the extreme ray of the Sun, touching the Earth at H and serving as the physical horizon with respect to the eye at H. From T let two straight lines be drawn: T R, to the point R, imperceptibly distant from the point C, and T K, to the centre of the Moon, to be conceived at K. For the angle T K H will be the horizontal parallax of the Moon, and T C H that of the Sun: for the parallax of the upper limb at C is as great as that of the centre S when it is at C. Afterwards let R T be produced towards N, and, with K I drawn, let it be the semidiameter of the Earth's shadow at the place of the Moon in its transit,

[Margin: The rule of Kepler and Wendelen is demonstrated.]

Diagram. A tall narrow figure in the right column, beside the narrowed text. At the top S stands at the head of a vertical line running down to V at the foot; straight lines run from S out to A at the left and C at the right, and a further line from S to R, which stands just inside C. A semicircular arc hangs from A to C, its lowest point at B on the vertical. Two long lines run down from A and C and meet at V. Below the arc a small circle holds L, with P on its left and G on its right. Below it a larger circle holds F and T, with H on its right edge. Below the larger circle N stands to the left of the left-hand line, and a short horizontal joins I on the vertical to K on the right-hand line. Further lines run from C and R down through T.

- S (top of the vertical): centre of the Sun

- A (left end of the Sun's arc): the Sun, A B C
- B (lowest point of the arc, on the vertical): the Sun, A B C
- C (right end of the arc): the Sun's limb
- R (just inside C): end of T R, imperceptibly distant from C
- L (inside the small circle): no gloss on this page
- P (left of the small circle): no gloss on this page
- G (right of the small circle): no gloss on this page
- F (inside the larger circle, upper): no gloss on this page
- T (inside the larger circle, on the vertical): centre of the Earth
- H (right edge of the larger circle): where the ray C H V touches the Earth
- N (left, below the larger circle): R T produced runs towards N
- I (on the vertical, low): end of K I
- K (on the right-hand line, low): centre of the Moon
- V (foot, apex): end of the line S V and of the ray C H V

I K, and its measure the angle I T K. For the external angle N T K, by Euclid, Book I, proposition 32, equals the two interior angles of triangle T C K opposite it, at C and K, that is, the horizontal parallaxes of the luminaries taken together. So when the angle N T I is subtracted from N T K, that is, from their sum (N T I being equal, by proposition 15 of Book I, to the angle S T R, which measures the Sun's apparent semidiameter), there remains the known angle I T K, which measures the apparent semidiameter of the Earth's shadow.

That moderate difference, however, between the semidiameter of the shadow derived by this method and the one deduced at number 11, an almost negligible difference, we attribute to that operation, as being more composite than this one; and it matters little which you prefer to follow in tables and in practice. I admit, moreover, that the semidiameter I reported as deduced from observation, in Book 4, chapter 12, number 4, and here at number 6, also differs somewhat from this one. And no wonder: for the horns of the shadow in a partial lunar eclipse, whether observed by direct view or by reflection on a small board, are blunted and show a smaller arc, because the bright part of the Moon prevails, and white and luminous things next to black or shadowy ones appear larger. But at that time I was pressed by the need to investigate the semidiameter of the shadow, so as to find from it the Moon's latitude independently of parallax; now, however, we already take the parallax as known.

Kepler adds, in the place cited above, that this is the demonstrative semidiameter of the shadow, which is often found to be greater than the one Tycho presents in the *Progymnasmata*, shaped from observations of lunar eclipses; but that those observations are deceptive, because of a concurrence of physical causes, which are inconstant. In the Foundations of the Ephemerides, number 29, he teaches that the semidiameter of the shadow follows necessarily from the parallaxes of the luminaries and the semidiameter of the Sun; and that the Tychonic semidiameter of the shadow in the table of the *Progymnasmata* therefore does not cohere by a geometrical bond with the semidiameter of the

☉ and the parallaxes of the luminaries, because Tycho followed observations instead. For Kepler, moreover, the greatest semidiameter of the shadow, with the ☉ at apogee and the ☾ at perigee, is 49′ 41″, and the least, with the ☉ at perigee and the ☾ at apogee, 43′ 52″. For Wendelen the former is 46′ 39″ and the latter 38′ 43″.

[Margin: Tycho's inconsistency.]

[Margin: Semidiameter of the shadow according to Kepler and Wendelen.]

XIV. It is now pleasing to set out in the following table the apparent semidiameter of the shadow, or rather of the penumbra, as comprehended by the Sun's unrefracted rays; and such rays are not those that touch the Earth, for those are refracted, but those that touch the thicker atmosphere around the Earth. The table will have two parts: the first as it stands in the authors; the second contains the semidiameter that follows from the data given by the same authors for the semidiameter of the ☉ (Book 3, chapter 10) and the horizontal parallaxes of the ☉ (Book 3, chapter 8) and the ☾ (Book 4, chapter 14). From these the conflict will appear, great in some cases, and in others none or almost none.

First part of the table: semidiameter of the Earth's shadow at the place of the ☾'s transit, comprehended by the Sun's unrefracted rays, as it stands in the authors. Second part: as it follows from the data given by the authors and the method of number 13.

SCHOLIA.

Scholia.

I. The semidiameter of the Earth's shadow, by the method discussed above at numbers 11 and 13, is the one derived from the Sun's unrefracted rays, as is clear from the demonstrations given there. But the Sun's unrefracted rays are not those that touch the Earth; for those that touch the Earth's globe are refracted on entering the denser air around the Earth. They are rather those that touch the atmosphere, that is, that air so dense that the remaining rays are sensibly refracted on entering and leaving it. The semidiameter of this atmosphere, beyond the semidiameter of the Earth, contains for Kepler as much as the height of the greatest mountains, which in this matter scarcely bears a sensible proportion to the semidiameter of the Earth; and for Kepler it is 2 Italian miles. For Wendelen, in the *Idea of the Atlantic Tables*, p. 6, it is less than 24 miles, since the height of the twilight atmosphere, the whole of which is not suited to sensible refraction, is in his opinion 24 Italian miles above the Earth. Now the Earth's shadow, which is contained by unrefracted rays, is not pure shadow but penumbra, of which I shall speak in the following chapter. Therefore the semidiameter derived here by the preceding method, whether ours or that of Kepler and Wendelen, is not that of the pure terrestrial shadow but of the atmospheric penumbra. And it is this that truly serves for producing and measuring eclipses; and if it had been rightly derived from observations by other astronomers, no other semidiameter than this would have been arrived at, granted that it takes its name from the Earth, which has the largest part in the sphere of the atmosphere. Hence the axis too is that of the penumbra, not of pure shadow, and its measure is to be understood not in semidiameters of the bare Earth, but of the Earth clothed with the air already mentioned. Meanwhile it is worth noting that this semidiameter of the shadow must not be increased by 17″ to obtain the semidiameter of the penumbra, as Wendelen teaches above, p. 5; since the semidiameter of the shadow, as deduced by him from the parallaxes of the luminaries and the Sun's semidiameter, presupposes unrefracted rays, and so is the semidiameter not of the shadow but of the penumbra.

[Margin: It is rather the semidiameter of the penumbra than of the shadow that serves for eclipses.]

[Margin: Wendelen corrected.]

II. In his preface to the *Idea of the Atlantic Tables*, p. 6, Wendelen notes that astronomers, in the quantity of lunar eclipses, treat the Moon as a disc, although it is a globular body and its boss is nearer to us than the rest of the body; and so the shadow there is greater than in the place through which the Moon's great circle passes. Moreover, since over each distance measured in terrestrial semidiameters the shadow's semidiameter varies by a whole minute, as for him it subtends 39′ at apogee and about 47′ at perigee, the shadow is therefore increased at the boss by a quarter of a minute, or 15″, over what it is at the centre of the lunar disc, because that boss is nearer to us than the Moon's centre by a quarter of a terrestrial semidiameter:

[Margin: Wendelen's acute observation on the place of the Moon's transit through the shadow.]

as a result, every eclipse appears there one-tenth of a digit greater than the calculation directed at the Moon's centre allows, and in place of 6 digits, 6 digits 10′ are seen. Moreover, those for whom the Moon stands overhead see the same boss of the Moon that would be seen by people looking from the Earth's centre; but the rest see one boss or another, which Wendelen calls parallactic [Parallacticos]. From this he thinks that a difference of 15″ can arise, so that an eclipse that appears from the vertical as one of 6 digits can appear to northerners as one of 6 digits 10′ and to southerners as one of 5 digits 50′. Combining both differences, therefore, it can rise to a third of a digit, or to 20′, of which one digit contains 60. But it is false that that boss is so much nearer to us, and that so great a difference can arise from it.

For let A be the centre of the Earth EC, and CDFE the frustum of the Earth's shadow, enclosed by the Sun's rays CD and EF, which touch the Moon at G on its entry into the shadow and at M on its exit. From these points let the radii, or semidiameters, GK and ML be drawn to the Moon's centre. From A, through the centres of the Moon, let the arc KL be described, along which the Moon's centre travels, so that NI is the arc of the shadow's diameter that astronomy assumes the Moon to pass through; and through the points G and M, from A, let the arc GM be described, which the Moon traverses from the beginning to the end of the eclipse. Then let the centres A and K be joined by the straight line AK, which is the distance of the Moon's centre, and finally from the point C let the straight line CK be drawn.

Diagram. Set into the left column, with the text running down its left side. A solid black frustum of the Earth's shadow narrows upward from a circle (the Earth) at its base; a vertical line runs through its middle. Two small circles (the Moon) straddle the frustum's sides at left and right, linked by a pair of arcs across the shadow, and a line runs from the base up to the right-hand circle.

- F, B, D (top edge of the frustum, left, centre, right)
- L (centre of the left-hand circle)
- N, I (upper arc inside the shadow, left and right)
- K (centre of the right-hand circle)
- P, H (outside the right-hand circle, right, upper and lower)

- M, G (lower arc inside the shadow, left and right)
- O (small, on the line just below the right-hand circle)
- E, A, C (base: left, centre, right)

The Moon's boss of which Wendelen speaks, therefore, will be the segment GOH; but this does not enter the shadow at the point O but at the point G, which is distant from the point I, assumed by the old astronomy, only by the arc GI. This arc is as large, very nearly, as the angle GKI, namely as large as the angle GCK, which subtends the Moon's apparent semidiameter, and this at the Moon's perigee does not exceed 17′. Therefore the arc GH lies insensibly distant from the arc IKP, since GO is 89° 43′ and GI only 17′. So although the Moon's true semidiameter KO is almost a quarter of the Earth's semidiameter, from what was said in Book 4, chapter 17, and the point O is nearer the centre A than the point K by a quarter of the Earth's semidiameter, nevertheless the point G, at which contact and the beginning of the eclipse occur, is insensibly nearer than the point K, by scarcely a two-hundredth part of the Earth's semidiameter. For the sine of the arc GI, 17′, is 495, which to the whole sine KO, 100000, is less than 1 to 200. Therefore the arc MG too is insensibly greater than the arc NI.

[Margin: Wendelen's subtlety, here too scrupulous, is corrected.]

III. There have been some who believed that if the Earth's shadow were cylindrical or calathoid, the Moon would suffer an eclipse at every full Moon. So teach Cleomedes, Book 2, chapter 5, and Wurstisen on Peuerbach's *Theoricae*, p. 337, and Erasmus Reinhold's teacher Jacob Milich on Book 2 of Pliny the Elder, chapter 11. But they are wrong. For if it were cylindrical, as in the first figure of Chapter 3, its apparent diameter KM would not be greater than twice the horizontal parallax of the Moon at perigee, and this does not exceed 140′. But if it were calathoid, as in the second figure, even if the Sun were a single point M, in which case the breadth of the shadow NOP would be greater, still at the distance DO of the Moon at perigee the apparent semidiameter of the shadow OP, under the angle ODP, would not exceed 1° 58′. For from the distance MD of the Sun at perigee (this is what increases a calathoid shadow), the least among the authors being 1000 of the units of which DC, the Earth's semidiameter, is one, there follows the angle DMC, 3′ 26″. Now add to this 1000 the distance DO of the Moon then at perigee, so that it is only 30 semidiameters of the Earth, and the whole MO is 1030. From this and from the angle OMP, 3′ 26″, you will gather OP as 1 3/100 semidiameters of the Earth; and with this side and the side OD, taken as 30, the angle subtending OP is gathered as 1° 58′. But the Moon at full can have so great a latitude that it exceeds the sum of this semidiameter and the Moon's semidiameter, since it sometimes has a latitude of 5°. Therefore, granted even a shadow as great as this, it would still avoid eclipse; how much more if the shadow were cylindrical, since its semidiameter would not exceed 70′.

[Margin: The error of Cleomedes, Wurstisen, Milich and others concerning a necessary eclipse of the Moon if the shadow were cylindrical or calathoid.]

CAPVT V.

Chapter 5.

De Penumbra Terræ, & varijs Lunæ in Eclipſi, aut prope Eclipſim, Phaſibus aut Coloribus à Refractione radiorum ortis.

On the Earth's penumbra, and on the various phases or colours of the Moon in or near eclipse that arise from the refraction of rays.

I. Since that shadow of the Earth which dulls the Moon is itself dulled by the Sun's refracted rays, and enlarged by the same rays when they are obstructed, or is also diluted by the rays of the Moon, and since from this the various phases and colours of eclipses appear, whatever pertains to this subtlety must be dealt with in this one chapter. And first, the manifold notion of the penumbra as a whole must be explained. For sheer shadow [Mera Vmbra] is the privation of the whole of the primary light, direct as well as reflected and refracted, or blunted and weakened. Penumbra, on the other hand, is the privation sometimes of part of the primary light, sometimes of the whole of the direct, unblunted or unweakened light; yet with some partial primary light, or at least with refracted and therefore blunted and weakened light. Let us be allowed, then, to call the first species of penumbra the image of the shadow [Vmbræ imaginem] or, in contracted form, the *Umbrago* [Vmbraginem]; and the second, the *Penumbra*: although many, with Kepler, call the first the penumbra, in the *Astronomia Optica*, p. 239, or [Greek: λιπαύγειαν (lipaugeian, "failure of light")].

[Margin: The manifold notion of the penumbra.]

II. The umbrago in the Moon, then, is the privation of some primary and direct light otherwise propagated from the Sun, along with some primary and direct light. For let DRP be the Sun, and DFC and PMC its outermost rays touching the Earth, and let VOS be the sheer shadow of the Earth B, and LQZ the Moon's orbit, with the Moon at T before its eastern limb is impaired by any shadow. For although its half-disc IT is lit by all the Sun's rays contained within DR, that is, enclosed within the two ray-cones DFR and TFI, it nevertheless lacks the other rays arising within RP, on the part where it sees less of the Sun, rays it nonetheless enjoyed before it approached the Earth's shadow. It is no wonder, then, that before the genuine and sheer shadow and before the legitimate beginning of the eclipse, the Moon should seem to the unwary to be darkened and suffused with a sort of smoke in its more easterly part IT, especially since that part too, as can be seen in the *Selenographia*, Book 4, Chapter 7, is darker in itself on account of larger and ancient spots, namely the Philippic Ocean [Oceano Philippico], and becomes darker still through the privation of these rays. The more recent and more careful astronomers therefore usually distinguish, at the beginnings of lunar eclipses, this umbrago from the shadow, and the smoke and spurious eclipse from the legitimate one.

Those who do otherwise overshoot enormously, by a quarter of an hour and more, in noting the beginning and end of the eclipse, and lengthen the duration on both sides beyond half an hour, counting that pallor and virtual agony as part of the eclipse and, so to speak, of its death. Indeed, Wendelen, in the preface to his Eclipses, that is, in the *Idea of the Atlantic Tables*, p. 3, judges that this optical enchantment sometimes introduces an error of 30′ on this side and as many on that, so that the duration appears an hour longer to weaker eyes,

[Margin: What the umbrago is, and what its effect is in an eclipse of the Moon.]

[Margin: The beginning of the spurious eclipse, and its twofold cause.]

[Margin: The fallacy of the inexperienced in observing the beginning of a lunar eclipse.]

Diagram. Set into the right column, with the text running down its left side. From a semicircle (the Sun) at the foot, labelled P, R, D, lines rise through a large circle (the Moon's orbit) to the apex C of a narrow black cone (the sheer shadow), with dotted lines marking the rays bounding the lighter zones on either side. Several small circles (the Moon in successive positions) lie along the cone and the orbit, one of them, at X, stippled in part.

- C (apex at the top)
- O (small, inside the cone near the apex, on its axis)
- K, E (small circles against the right side of the cone, upper and lower)
- Y, X (a further small circle to the right, with Y on its left edge and X inside it)
- L (small circle on the left side of the cone, on the orbit)
- I, T, G (on the small circle on the right side of the cone, on the orbit)
- Q, Z (left and right ends of the large circle)
- M, V, B, S, F (along the band at the base of the cone, left to right)
- N (below the band, under the small semicircle at the base of the cone)
- R, P, A, D (the semicircle at the foot: top, left, base centre, right) and bleary ones. For the rest, keen eyes, whether naked or equipped with the telescope, clearly distinguish in the Moon this pallor and first beginning of the shadow from the true shadow. For, as in the Moon X, the true and sheer shadow blackens conspicuously, and like the edge of a horse's hoof begins with a small circular segment to impair the Moon's eastern limb, occupying a very small part of it from the Philippic Shore [Littore Philippico] onward, as you see at Y; whereas that umbrago occupies a large part, and displays no blackness but only pallor and a languid light.

III. The penumbra more strictly taken is the privation of direct and primary light, with some light, but refracted or weakened. For this reason it is subdivided into two species, as it were. The first would hold alone if the Sun's rays passed through the atmosphere, that is, through the thick vapours surrounding the Earth's globe: as in the figure given above, if around the Earth VBS there is a hemisphere of vapours MNF, through which rays contained on this side within DO and DC, and on that side within PO and PC, pass unrefracted as regards

their figure, yet blunted or weakened and enfeebled in their degree of intensity by the denser and more opaque medium, as I assume from my Optical Book, and generate a penumbra enclosed within the rays already mentioned, whose base is MF and whose apex is C, and which clothes the sheer shadow VOS like a crust. If that were to happen, there is no doubt that the Moon would begin to be dimmed by this penumbra, as can be seen at E, before being impaired on its eastern limb by the shadow simply so called, and would emerge from the penumbra later, as at L, than from the sheer shadow. This, however, does not in fact happen, because the Sun's rays in the vapours and in our denser air are not only weakened in intensity and vigour of light but are also refracted, and change the figure of the penumbra, as will be set out in the following figures. Therefore this penumbra in fact, not disjunctively but conjunctively, *is the privation of direct light, with some light both weakened and refracted alike*. Meanwhile, however, three beginnings and three ends of a lunar eclipse, and so three durations, ought to be distinguished here: the first from the umbrago, as at T; the second from the penumbra, as at E or L; the third from the shadow, as at K. This would hold both in observations and in predictions, if the inconstancy of the physical causes, which vary the density and opacity of the atmosphere in height and in degree of intensity, allowed these limits to be defined, and to be determined to these times according to the greater or lesser removal of the luminaries from the horizon and according to the different temper of the air; I see that this has been attempted in vain. Since this is not yet allowed, therefore, we shall be content with that moderate knowledge of the penumbra and more exact knowledge of the shadow which God has granted us. For as to Wendelen's statement above, p. 5, that the semidiameter of the shadow is increased by the penumbra by about 17″, we have rejected it in Scholium 1 of chapter 4.

[Margin: The penumbra: its two species and causes.]

[Margin: A truer definition of the penumbra.]

[Margin: The threefold beginning, end and duration of a lunar eclipse.]

IV. Further, the penumbra produced by the Sun's rays refracted in the air around the Earth produces a redness or other colours in the eclipsed Moon. In order that the penumbra may be distinguished from the sheer shadow, and the measures of each be made known separately, some points must be explained, which Kepler sets out beforehand for this purpose in the *Astronomia Optica*, from p. 269 to 279. With centre A describe the Sun's hemisphere EF, and with centre B the Earth HPQK and the atmosphere RTVS. Let ERD and FSD be the Sun's outermost unrefracted rays, touching the sphere of our air at R and S and bounding the aggregate of penumbra and shadow RDS. Next, let there be the rays ET and FV, which, if the density of the air did not prevent them, would touch the Earth at H and K, go straight on and meet at G, producing the straight shadow HGK of the Earth alone and separating it from the penumbra of the thick air, which would be RDGH on one side and SDGK on the other. But in reality they are refracted at T and at V, and strike the points P and Q

of the Earth. So let there be two other, higher rays, which by the force of refraction can touch the Earth's globe, namely the rays EI and FC; the former at I, the latter at C, are so refracted toward the perpendicular that, touching the Earth at L and M, they make for X and Z, which are points on the air's convex surface. They would meet straight on at N if the second refraction, on leaving the air, did not prevent it, and would produce the sheer shadow of the Earth LNM. But because on exit into the rarer air, according to the laws of refractions treated in the Optical Book, they are refracted away from the perpendicular line that would be drawn from the centre B through the points X and Z, they are therefore bent toward the point O, at which they bound the sheer shadow LXOZM; but the remaining rays, higher than the rays EI and FC yet below the unrefracted rays ER and FS, are similarly refracted by a double refraction, one on entering the denser air and the other on leaving it, there converging toward the perpendicular, here diverging from the perpendicular, but not so as to touch the Earth's globe; and they meet at other points, partly below and partly above O. Therefore, if no refracted rays reached below O, the height of the Earth's sheer shadow would be BO.

[Margin: An account of the penumbra produced by refracted rays.]

Diagram. Heads the right column, interrupting the sentence that runs from the left column's foot. At the top a broad semicircle (the Sun's hemisphere) opens upward; lines from its corners converge downward past a double circle (the Earth inside the atmosphere) and on to a long narrow apex at the foot. Solid lines from X and Z, at the foot of the circles, meet at the point O on the central line; two pairs of dotted lines run on past it and meet lower down, at N and at G.

- A (top centre), E, F (upper corners of the semicircle)
- I, T (upper left of the outer circle)
- V, C (upper right of the outer circle)
- P, B, Q (inside the inner circle: left, centre, right)
- R, H (left edge of the circles, outer and inner)
- L, M (inside the inner circle, lower left and lower right)
- K, S (right edge of the circles, inner and outer)
- X, Z (foot of the outer circle, left and right)
- O, N, G, D (down the central line below the circles, top to bottom; D at the apex)

Lemma ad ſequentia Problemata.

Lemma for the following problems.

V. The lemma is as follows. *The angle formed by a ray of the Sun taken as unrefracted and touching the Earth, and by a ray of the Sun radiating from the same point of the Sun but refracted in the air and touching the Earth, is sensibly equal to the angle of horizontal refraction.* From the centre B let the hemisphere of the Earth MHP be described, and that of the refracting atmosphere AIK, and let the

straight line through the centre dividing the hemispheres be AG, on which let BG be the axis of the shadow, made, or in the manner of the ancients imagined, by the unrefracted ray EG touching the Earth at H, at which point a right angle is made, by III.18, by the tangent and the semidiameter BH. Next let there be another ray FI, which on entering at I, if it were not refracted, would go straight toward R; but let it be refracted at I so that it eventually touches the Earth, as at L, and let IL be the refracted ray, produced as far as N. To the point of contact L let the semidiameter BL be drawn, making with the tangent IL a right angle by Euclid III.18. With these laid down, since the rays EHG and FIR are assumed to issue from the same point of the Sun's limb (although the Sun is not drawn here, as it was in the preceding figure), and their distance SI, because of the slight height of the air suited to the refraction of rays, is small, as I assume from what was said in Book 1, chapter 31, and from what is to be said in the Optical Book, therefore, by what was demonstrated in Book 3, chapter 5, number 6, they are sensibly parallel. For this reason the refracted ray ILN will meet the unrefracted ray EHG at some point, say C, and will make with it angles at the vertex C that are equal, by Euclid I.15. And since IC falls on lines sensibly parallel, the angle ICE will be sensibly equal to the angle of refraction RIC; and to this same angle is equal the angle GCN, which is vertical to the angle ICE: which was to be shown. Further, the refraction of the first ray, among those refracted, that touches the Earth and issues from the Sun's upper limb is as great as the Sun's horizontal refraction, for this refracted ray ILN is the physical horizon of an eye at L, along which the Sun is first seen; and this refraction, ordinarily, from Tycho's observations in Denmark, is 34′. Therefore in the same place the angle GCN is 34′; and the angle of refraction NXO at the exit X is as great as the angle RIC at the entry, by Witelo X.9, so that this too is 34′ by Tycho's reckoning.

Diagram. Set into the left column, with the text running down its left side. A long vertical line on the right carries the letters of the central axis, from A at the top to G at the foot. Two arcs (the atmosphere and the Earth) curve to the left of this axis, and straight and dotted lines, the rays, cross between them near the left limb and converge down on the axis.

- A, M (head of the vertical line, top to bottom)
- F, E (top left, the upper ends of two rays)
- B (on the vertical line, at the middle)
- P, K, O, N, G (down the vertical line below B; G at the foot)
- I (on the outer arc, left)
- S (on the inner arc, near the top of the crossing lines)
- R (on the outer arc, below I)
- H, C, L (at the crossing of the rays near the inner arc)
- T (on the outer arc, below R)
- X (on the outer arc, lower, on a ray running down to the axis)

PROBLEMA I.

Problem 1.

Terræ ſolius meram Vmbram comprehenſam à radijs Solis refractis terramq. tangentibus metiri quoad altitudinem.

To measure, as to its height, the sheer shadow of the Earth alone, enclosed by the Sun's rays refracted and touching the Earth.

VI. In the figure of the preceding lemma, the height of the sheer shadow that we are seeking is the axis BO. Now in the triangle CGN the angle GCN is given by the same lemma, because it is equal to the Sun's horizontal refraction, and according to Tycho it is 34′. The angle CGN is also given, from what was said in Book 3, chapter 11, number 6, because it is the semiangle of the cone of the Earth's shadow made by unrefracted rays, and for Ptolemy, in Kepler, it is 12′ 48″; together with the angle GCN it makes a sum of 46′ 48″. And the external angle LNB, or XNO, is as great as this, by Euclid I.32. In the small triangle XNO, therefore, there is given the angle of refraction at the exit, NXO, 34′, and XNO, 46′ 48″, whose sum is 1° 20′ 48″; to this the external angle XOB is equal, by Euclid I.32. Now let the refracted ray OX be continued toward the atmosphere until at T it makes a right angle with the perpendicular BT drawn to it from the centre of the Earth. For the triangle OTB will be right-angled at T, and in it, besides the right angle T, there is given the angle TOB, 1° 20′ 48″, and the semidiameter TB, taken as one, which is slightly greater than the semidiameter BL of the Earth alone. Therefore the height BO will be 43 of the units of which BT is one. But if you take our semiangle of the shadow's cone CGB, 14′ 50″, with the Sun at apogee, according to what was said in Book 3, chapter 11, number 6, and retain the Tychonic refraction of 34′, BO will come out as 41½ of the units of which BT is one. And if the portion LT of the refracting air is given, then by multiplying it by 41½ and adding the product to the BO that was found, there will remain a more exact measure of BO itself. Now the air suited to refraction is for us at most 25 Italian miles high, but for Kepler much lower. And 41½ multiplied by 25 makes 1037, which is almost a third of the Earth's semidiameter. Therefore OB remains for us 41 5/6 semidiameters of the Earth. We are speaking here, however, of rays not prevented by mountains from passing out, of rays touching the Earth before their exit, and of ordinary refraction. For rays that have passed out but do not touch the Earth fall below O, and so the height of the sheer shadow is less than BO; and it is still less if, as the refraction or the angle of the shadow's cone grows, the angle TOB turns out larger.

[Margin: The height of the sheer terrestrial shadow.]

PROBLEMA II.

Problem 2.

Quantus ſit ſemiangulus coni Vmbræ meræ terreſtris à radijs Solis refractis, & Terram tangentibus comprehenſæ.

How great is the semiangle of the cone of the Earth's sheer shadow, enclosed by the Sun's rays refracted and touching the Earth.

VII. We shall know the angle XOB from what was said in Problem 1. For this angle, as was proved in the course of the demonstration of Problem 1, is composed of the Sun's refraction taken twice and of the semiangle of the shadow made, or imagined, by the Sun's unrefracted rays; and from what Kepler lays down it is 1° 20′ 48″, while from our foundations it is 1° 22′ 50″. Its double therefore gives the Keplerian angle of the sheer shadow as 2° 41′ 36″, and ours as 2° 45′ 40″. In this way, very easily, from the semiangles of the cone of the unrefracted shadow set out in Book 3, chapter 11, number 6, by adding to them the Sun's horizontal refraction doubled, you will gather, in the opinion of others, the semiangle of the sheer shadow; and by doubling it you will have the whole angle.

[Margin: How great is the angle of this cone of sheer shadow?]

PROBLEMA III.

Problem 3.

Quantò plus de Terra illuſtret Sol radijs in aere refractis, quàm radijs, vt veteres putabant non refractis.

How much more of the Earth the Sun lights with rays refracted in the air than with rays not refracted, as the ancients supposed.

VIII. As regards unrefracted rays, we have already completed this problem in Book 3, chapter 11, Problem 4. Using now the figure set out here at number 5, we showed that the part of the hemisphere MHP lit by the unrefracted ray EHG, touching the Earth at H, and by the others contained between this and the central ray AM, is greater than the quadrantal arc MS by as much as the arc SH, measured by the angle SBH; and that to this angle is equal the semiangle of the cone of the shadow made by unrefracted rays, namely the angle HGB. But since the Sun's rays are in reality refracted in our air, if we take the first one that is higher than the ray EG and, once refracted, touches the Earth as soon as may be, say the ray IL, it will certainly touch below H, say at the point L, and still more of the arc MLP is lit, more by as much as the arc HL, measured by the angle HBL. The task now is to find the measure of this angle. I say that it is as great as the horizontal refraction of the Sun's ray, namely, in Tycho's opinion, 34′ in Denmark; which I also asserted in Book 3, chapter 11, Problem 4, with Kepler and very nearly with Bettini, although in the *Apiarium* 8, Progymnasma 2, Proposition 4, having assumed an elevation of the ray that is not at all necessary, he adds a single minute and makes the arc HBL 35′.

Now that assertion is easily demonstrated as follows. The angle ICH is sensibly equal to the angle of horizontal refraction RIC, by our lemma at number 5. But this is equal to the angle HBL. For when a straight line is drawn from B to C, the point at which the rays touching the Earth intersect, namely the unrefracted EHG and the refracted ILN, the trapezium CHBL is divided into two triangles CHB and CLB, right-angled at the contacts H and L. Therefore the four angles of this trapezium taken together are, by Euclid I.32, equal together to four right angles; and to these likewise are equal the four angles at the point C made by the said rays, by Euclid I.13. Taking away, then, the common obtuse angle HCL, there remain the three angles of the trapezium, H and B and L, together equal to the three angles ICG, the obtuse one, and the two acute ones ICH and GCL together. But the two angles ICG and GCL are equal to two right angles by I.13, that is, to the two angles at the contacts H and L. Taking those away on the one side and these on the other, there remains the angle ICH, which is the measure of the Sun's horizontal refraction, equal to the angle HBL: which was to be shown. Therefore, by adding the Sun's horizontal refraction to the arc HS of the ancients, on which see Book 3, chapter 11, Problem 4, the whole arc SL will be produced, which the Sun lights beyond the quadrant. Moreover, Bettini adds above, in a corollary, that the limits of the illuminated Earth do indeed grow from refraction, but the shadow does not decrease, because he thinks that the refracted rays die away in the valleys and strike against the mountains in such a way that none passes out; I shall speak of this at number 11.

PROBLEMA IV.

Problem 4.

Vmbræ & Penumbræ terreſtris ſegmenta varia diſtinguere; eorumq. altitudines.

To distinguish the various segments of the Earth's shadow and penumbra, and their heights.

IX. Let the second figure be this one, in which the straight line from the centre of the Sun through the centre of the Earth to the apex of the penumbra is ABD; the centre of the Earth and of the atmosphere is B; the Earth's circle is HK and the atmosphere's AMG. Let the Sun's extreme rays, which touch the atmosphere and bound the penumbra, be RD and SD. Let the rays next to them, δ[?]M and δ[?]G, fall on the convex surface of the atmosphere and, with the greatest refraction at the points M and G, be refracted to L, so that they are the outermost of the refracted rays touching or nearly touching the atmosphere. From the points L, on emerging, let them be refracted again to O and, intersecting each other there, make for PP, and so enclose the Earth's sheer shadow LOL, whose height or axis is BO, although, to avoid confusion, not all of it is blackened here, but only its portion XOZ. Now let the straight lines BM

and BL be drawn. Next, let there be two other outermost rays of the refracted ones, but touching the Earth, namely EI and FC, refracted on entry at I and C towards the perpendicular and touching the Earth at H, K. Having passed on to X and Z, let them be refracted there on exit away from the perpendicular, making for the point N, and, intersecting each other there, let them continue, X to V and Z to T, so as to enclose the Earth's shadow XNZ, were it not cut short by the rays LOL. Further, let both these and all the other refracted rays contained within the rays EXN and RPD on one side, and within FZN and SPD on the other, refracted by a double refraction, one on entry through the arcs MI and GC, the other on exit from the arcs LX and LZ, all of them, I say, intersect at the nearest points m, m. From there, diverging, let them proceed towards ω ω, between the segments VmP and TmP. Finally, from B to one P let the straight line BP be drawn, and two other straight lines, PP and ωNω.

Diagram. Set into the left column, with the text running down its left side and the figure reaching to the foot of the column. A double circle stands at the top: the outer circle (the atmosphere) carries A at its head and M and G at its left and right limbs; the inner circle (the Earth) has its centre at B. Below the circles a long cone tapers downward to its apex D. Its upper part is solid black as far as O; below that a lattice of fine lines, the refracted rays, crosses and recrosses around the central axis; the lower part is solid black again from T and V down to D. Rays rise from the circle's top to the letters outside it.

- A (head of the outer circle, on the axis)
- R, E (upper left, outside the circle), with a small flag-like sign beside R, read as δ [?]
- F, S (upper right, outside the circle), with the same sign beside S, read as δ [?]
- Φ (on the axis, inside the outer circle below A)
- I, C (on the outer circle, upper left and upper right)
- B (centre, on the axis)
- M, G (left and right limbs of the outer circle)
- H, K (inner circle, left and right)
- L, L (lower arc of the outer circle, left and right)
- Ψ (on the axis, foot of the inner circle)
- X, Z (lower arc, left and right of the axis)
- m, m (boxed in white in the black of the shadow, left and right)
- O (on the axis, foot of the upper black part)
- two small italic signs just below O, left and right of the axis, perhaps Q, Q [?]
- P, P (outer edges of the cone, left and right)
- ω, ω (outer edges, lower, left and right)
- N (on the axis, boxed in white)
- Y, Y (either side of the axis, below N)
- a small open triangle (on the axis, below Y, Y)

- T, V (edges of the cone, left and right, at the head of the lower black part)
- D (apex)

These 9 or 10 segments of the penumbra and shadow then arise, which are solid frusta of the cone MDG. The *first* is XOZ, which however ought to be HXOZK, all black, and this is the Earth's shadow. The *second*, MPQm, and the *third*, GPQm, are sheer shadows, but of the atmosphere, because within them there are no rays either direct or refracted. The *fourth*, QmO on the left, and the *fifth*, QmO on the right, are half-lit segments of the atmospheric penumbra, lit by refracted rays, on the one side by those from the left alone, on the other by those from the right. The *sixth* is OQNQ, a kernel of refracted light and a rhomboid of sorts, in which the refracted rays unite and those from the left grow stronger together with those from the right; this, however, could be subdivided into two segments. The *seventh* is TNQP and the *eighth* VNQP, segments of the atmospheric penumbra that, after passing out of the biconical frustum NQOQ, are lit by refracted rays, on this side those from the left and on that side those from the right, separately. The *ninth*, finally, deprived by these of every ray direct and refracted, is the biconical segment NTDV, sheer shadow, but of the whole atmosphere, consisting of the cones TDV and TNV.

[Margin: The segments of the penumbra and shadow, 9 or 10.]

So the cone that darkens the Moon has nine segments: one the sheer shadow of the Earth; three the sheer shadow of the atmosphere; five the penumbra of the atmosphere, lit by the Sun's refracted rays, which raise the Sun above the horizon when it is really below it, and make day, and which light up towers and trees in such a way that these cast a distinct shadow. What wonder, then, if they can illuminate the Moon, even when it is immersed in the penumbra?

X. As regards the measures of these segments useful for our purpose, Kepler's method, *Astronomia Optica* p. 280, is as follows. Taking the horizontal refraction at the entry points I and C as 34′, it follows by the rules he gives in the same place, chapter 4, number 6, proposition 9, that the refraction DML of the ray δ[?]M of greatest inclination, almost touching the air, is 61′ 30″. Therefore the angle δ[?]ML is 178° 58′ 30″, and so the arc ML, or the angle MBL, is 2° 3′. Kepler confirms this rather obscurely from Euclid III.2, but it is shown more clearly by III.32: for the angle in the alternate segment MAGXL equals the angle that the tangent DM makes with LM, which cuts the circle. But by III.20 the angle at the centre MBL is double the angle at the circumference standing on the arc ML; therefore it is also double the angle DML, to which the angle in the alternate segment has just been shown equal. The semiangle MDB, moreover, is on Ptolemy's value, according to Kepler, with the Sun at apogee, 12′ 48″; and BMD is right, because δ[?]M differs insensibly from the tangent RM and it is just as if it touched, since it is physically next to the tangent. Therefore MBD is 89° 47′ 12″; and when MBL, 2° 3′, is subtracted, LBD will be 87° 44′ 12″, and LBO the same. Now because δ[?]M is taken to touch the circle as far as the senses can tell, the ray LO will also touch the circle

at L, by Witelo X.9; so OLB will be right. But LBO was 87° 44′ 12″; therefore LOB is 2° 15′ 48″, by Euclid I.32. So, all the angles in the triangle LBO being given, and the side LB taken as one semidiameter of the atmosphere, it is found by the rules of triangles that the axis BO is no longer than 25⅔ atmospheric semidiameters; and so great, or no greater, is the height of the sheer terrestrial shadow, if the horizontal refraction of the ray all but touching the atmosphere is 34′. Kepler was therefore right, at p. 269, although he had gathered from the refracted rays touching the Earth that the height of this shadow was 43 semidiameters, to add that it is made shorter by other refracted rays, namely those touching the air. For us, however, BO is 24 semidiameters of the Earth, because the angle MDB is 14′ 50″; indeed it is made shorter by the refracted rays that travel between HX and ML.

[Margin: The height of the sheer shadow, BO.]

Second, the angle DOP, as being equal by I.15 to the angle LOB, was found to be 2° 15′ 48″; and ODP on Ptolemy's reckoning is 12′ 48″. Therefore by Euclid I.32 OPG, the exterior angle equal to those two, is 2° 28′ 36″. But the circumference MLG was 179° 34′ 24″. For, from what we said in Book 3, chapter 11, theorem 4, the arc of the smaller sphere illuminated by the Sun beyond the hemisphere is as great as the angle of the cone of shadow; so when the angle MDG, which for Ptolemy is 25′ 36″, is added to 180°, the arc MAG becomes 180° 25′ 36″, and so MLG 179° 34′ 24″. And when ML, which was 2° 3′, is taken away, LXG remains, 177° 31′ 24″. And since the lines drawn from P, the right-hand one, to G, and to L, the left-hand one, are tan- gents, the arc of the angle GBP will be half the arc LXG, and therefore of 88° 45′ 42″, and BPG will be 1° 14′ 18″. From this, in the right-angled triangle BGP, it is gathered by trigonometry that PG is 46⅓ of the parts of which BG is one. For us, however, for whom the angle BDG is 14′ 50″, GP comes out at only 44½ atmospheric semidiameters.

[Margin: The height of the lateral shadow, GP and MP.]

Third, HΦK had to be 180° 25′ 36″ by what was set down above and from what Kepler established, chapter 6, number 3, if the Sun's rays had arrived without refraction; but an observer at H and K sees the Sun higher than is correct by 34′. The arc HΦK is therefore increased by 1° 8′ and becomes 181° 33′ 36″, and so HΨK is 178° 26′ 24″, half of which, HΨ, that is the angle HBN, is 89° 13′ 12″. When HX∇ is continued, the angle H∇B is concluded to be 46′ 48″; and XNB, the exterior angle, equals that together with the complement of ∇XN, or 34′. So XNB is 1° 20′ 48″. And since NX, continued, cuts BM between M and H, very close to H, it makes little difference whether we take BH as the measure or something a little greater, though much less than BM. Since, then, HBN is 89° 13′ 12″, and BNX, which is now BNH, is 1° 20′ 48″, BHN will be 89° 26′. Therefore, of parts of which BH, or a little more, is one, BN is about 43, on the assumptions Kepler makes in the *Optics*, chapter 6, numbers 3 and 8.

[Margin: The height BN, of the limit N.]

Granted that, forgetting himself, or with the figures wrongly written through a slip of the imagination or of the pen (which happens to great men at times, but is worthy of pardon), he gathers BN as 70 semidiameters in the *Optics*, p. 281. Hence it comes about that on his account, with the horizontal refraction of the refracted ray touching the Earth set at no more than 34′, the Moon, which at full Moon never rises as far as 70 semidiameters of the Earth, is never, not even in the middle of an eclipse, darkened by the sheer shadow of the atmosphere, DN, but only by the penumbra, passing between PP and ω ω. But when it is darkened by the sheer shadow DN, the refraction becomes greater, so that the height BN becomes less than the Moon's distance. So Kepler, p. 282; and from this, as we shall say at number 17, and from what was said in Book 3, chapter 10, last scholium, he gathers that the Sun's horizontal refractions are sometimes and in some places 51′, indeed 60′, indeed more than one degree.

[Margin: Kepler's slip.]

[Margin: A notable corollary.]

But with Kepler's figures and calculation corrected, the Moon in the middle of a total eclipse does in fact enter the sheer shadow of the atmosphere, and the following figure must be substituted for the preceding one. In it the height of the sheer terrestrial shadow is BO, very nearly 26 terrestrial semidiameters; the height of the segments of sheer atmospheric shadow MPI and GPL, namely MP and GP, is about 46 semidiameters of the Earth; the distance of the tip N from the Earth's centre B, that is BN, is about 43 semidiameters of the Earth; and the base TV of the inverted cone TNV is distant from the Earth's centre very nearly 73 semidiameters of the Earth, as I have calculated, using half the angle TNV, given above as 1° 20′ 48″, and half the angle D, 12′ 48″, and ND of 228 semidiameters of the Earth, which is obtained by subtracting BN, 43, from the axis BD, which on Ptolemy's values is 271 with the Sun at apogee, according to what was said in Book 3, chapter 11, number 9; and by solving the triangle DTN. For I found the side TN to be 31 semidiameters of the Earth; so in the triangle TNV the perpendicular from N to the base TV comes out at about 30, and these, added to BN, 43, make 73. Further, the arc AF marks the path of the Moon at apogee, and RS at perigee. So the cone of sheer atmospheric shadow that darkens the Moon in the middle of a total eclipse is TNV, unless the variation in the refractions becomes so enormous that BN exceeds the Moon's distance from the Earth.

Diagram. Set into the left column, with the text running down its left side and the figure reaching to the foot of the column. A ring (the atmosphere) stands at the top, its lower half filled black by the top of a long black cone that tapers down to its apex D. A little below the ring, rays from the ring's two sides cross in a light diamond on the axis; below the diamond the rays spread to the cone's sides, where two arcs cross the cone. Below them the cone is solid black again from T and V to the apex.

- M, G (left and right, on the ring)

- H, K (inside the ring, on the black, left and right)
- B (centre, on the axis)
- O (head of the light diamond, on the axis)
- I, L (inside the diamond, left and right of the axis)
- N (foot of the diamond, on the axis)
- P, P (cone's edges, left and right)
- R, S (the upper arc, left and right)
- A, F (the lower arc, left and right)
- T, V (cone's edges, left and right, at the head of the lower black part)
- D (apex)

Applicatio Doctrinæ de Vmbra & Penumbra ad Eclipſes Lunæ.

The application of the doctrine of the shadow and penumbra to eclipses of the Moon.

PROPOSITIO I.

Proposition 1.

Luna non patitur Eclipſim ab Vmbra mera ſolius Terræ.

The Moon does not suffer eclipse from the sheer shadow of the Earth alone.

XI. This is Kepler's paradox, in the *Astronomia Optica* pp. 268 and 270, and it is proved as follows. At full Moon the Moon is never less distant from the Earth than 52 semidiameters of the Earth, as is clear from what was said in Book 4, chapter 14, and when it is at apogee it is much further; but the height of the sheer shadow of the Earth alone does not exceed about 26 semidiameters of the Earth. Indeed if the Sun's refracted rays between those touching the Earth and those touching the refractive atmosphere combine to cut it short, as they do, it is far smaller, and smaller still if the horizontal refraction is greater than 34′, as is clear from what was said partly in Problem 1, partly in Problem 4, number 10.

[Margin: Kepler's paradox.]

Nor does the authority of the ancient astronomers or cosmographers stand in the way, who attribute the eclipse of the Moon to the terrestrial shadow, as Bettini objects to Kepler, though without naming him, in *Apiarium* 8, Progymnasma 2, Proposition 5. Chief among them are Cleomedes, *Cyclical Theory* Book 2, chapter 5; Pliny the Elder, Book 2, chapters 10, 11, 12; Ptolemy, Book 5, chapter 14, and Theon there; and Plutarch in the little work *On the Face of the Moon* and in the *Nicias*. For they did not distinguish the sheer shadow of the Earth from the penumbra, but by the name of shadow meant the deprivation, caused by the Earth, of the direct and primary sunlight by which the Moon usually shines outside full Moon, or at a full Moon without eclipse. They did not exclude the dense matter around the Earth, which could deprive the Moon

of such light, or else they named that deprivation after the stronger and greater mass of this globe.

[Margin: The first objection of Father Bettini against Kepler is dissolved.]

Nor, likewise, does it stand in the way that the same author objects against him in the same place, Proposition 6, namely that the air capable of refracting the rays of the stars is very low: by his own conjecture in Proposition 3 about 151 paces, and according to Kepler in the *Optics*, pp. 117, 129, 135 and 271, no more than two Italian miles; on this matter see what was said in Book 2, chapter 19. For from this, Bettini judges, it comes about that the rays refracted on entering this air do not pass out of it, but strike against the flanks of mountains or are buried in valleys. Granted that in Proposition 1, number 6, and Proposition 2, number 2, Bettini may have conceded that the Earth's shadow is cut short by them, not absolutely but on condition that the Earth were not rough with mountains and valleys, or that the height of the refractive air were much greater; this is certainly a sharp objection and not to be despised. But it is answered: first, because in our opinion the height of the refractive air is greater, as we indicated in Book 2, chapter 19, and shall teach in the Optical book; next, because many great tracts of the Earth are level expanses of plains and seas, and many are rough with very low hills, so that the greatest part of the rays once refracted can pass out and, refracted again, cut the shadow short. Finally, if none of the refracted rays passes out of the atmosphere, and they neither dilute nor diminish the shadow of this globe, then this shadow is indeed sheer, without any admixture of penumbra, but it is nevertheless the shadow of the whole atmosphere enclosing the Earth, not of the Earth alone.

[Margin: The second objection of the same author is dissolved.]

PROPOSITIO II.

Proposition 2.

Luna Eclipſim patitur ſub initium finemq. Eclipſis à Penūbra Atmoſphæræ; circa medium autem partim ab eadem Penumbra, partim verò ab Atmoſphæra mera Vmbra.

Towards the beginning and end of an eclipse the Moon suffers eclipse from the penumbra of the atmosphere; around the middle, however, partly from the same penumbra, partly from the atmosphere's sheer shadow.

XII. By the name of atmosphere I here understand the terraqueous globe surrounded by air, and distinguished from the aether (whether the aether is pure elemental fire or a heavenly and most fluid substance coming down as far as the air), and I suppose that all this air is denser and more opaque than the aether, but uniformly difformly [vniformiter difformiter], more and more so towards the Earth. And so, although exhalations predominate in its upper part and vapours in its lower, the whole is fit for some refraction, in places scarcely sensible, in others more and more sensible. With this laid down, the

proposition is proved from the history of eclipses and from our figure. For after the umbrago and smoke, on which see number 2, the Moon never begins or ceases to be eclipsed by the eclipsing elementary globe without some light and some colour appearing on the eclipsed segment; and there happens what Galileo, as quoted by Kepler in the *Ephemerides* p. 22, reports of the eclipse of 1610 December 30, observed with the telescope: *The limit of the shadow appeared indistinct, confused and as if clouded over.*

[Margin: The notion of the atmosphere.]

But this, whatever it is, of grudging light, or of colour usually reddish, does not come from the Sun's rays reflected from the Earth on to the Moon, since at full Moon the reflected rays of the Sun make for the opposite part, towards the Sun; nor from rays reflected from any other assignable body. For, granted that, as Barozzi would have it (*Cosmographia* p. 318), they could be reflected from the remaining part of the Moon not yet darkened, yet when it is now wholly darkened they cannot. Nor does it always come from the direct illumination of the planets, which are often in a position and place unsuited to this; nor from the fixed stars, since otherwise they would also illuminate the Moon in the middle of an eclipse, and at an even rate, and on a moonless night we should see the Earth lit by them with a brighter and direct light than we see the Moon by their light reflected from the Moon to us. Nor does it come from sunlight drunk in, as Liceti would have it, and preserved in much the way that the light-drinking [lucibibus] Bologna stone preserves it for some time; for if that were so, a trace of this light would always appear even in the middle of a total eclipse, or it would gradually weaken towards the eclipse's end, whereas rather it grows brighter towards the end. Nor does it come from its own light, which we determined in Book 4, chapter 6, that it does not have; nor, finally, from any other probable cause.

And on the other side it seems not only probable but certain that very many of the Sun's rays pass out of the atmosphere refracted towards the axis of the shadow, and so diminish the shadow and illuminate the region in which the Moon is, already or still suffering eclipse. Now this compound, of the deprivation of primary light arising from the whole eclipsing globe and of refracted and weakened light sent through the vapours and exhalations of the air, is a penumbra, not of the air alone, nor of the terraqueous globe alone, but of the whole atmosphere. For since a penumbra consists of the deprivation of direct and primary light and of positive indirect light, which in our case is refracted, not reflected, both concur in the deprivation of direct light: the terraqueous globe, which by its opacity blocks the passage of all light, and the density and some opacity of the air, which block the direct propagation of light. So, when all the parts of this argument are gathered together, towards the beginning and end of an eclipse the Moon is darkened by the atmosphere's penumbra. Nor, around the horizon, at the entry or exit of the Sun's rays from the atmosphere, are clouds ever so foul as to block all passage entirely to the Sun's rays, since with the Sun above the horizon it never becomes sheer night.

So if clouds do not snatch the sight of the eclipse from us, that shadow which dulls the Moon at the beginning and end, however dark it appears, always, with some small particle of light mixed in, shows us some colour, not purely black, on the eclipsed part of the Moon. And, as Scheiner says: *That rust colour which the Moon shows when it moves around the edges of the terrestrial shadow is nothing other than the Sun's light, with an admixture of terrestrial shadow, that has glided on to it and been sent back to us.* And this is confirmed, because from what was said at the end of number 10 the Moon is always within PT and PV.

Kepler adds, in the *Epitome of Copernican Astronomy* p. 870: *Often too a luminous substance inflamed around the Sun irradiates the outermost limits of the shadow, and so the Moon, although wholly immersed in the shadow, does not seem immersed; see* Astronomia Optica *fol. 301. And Galileo too thinks so; but that appendage of inflamed substance around the Sun not seldom paints itself on paper, when we catch the Sun's image through a hole.*

XIII. The second part of the proposition is shown from the same history of eclipses. For sometimes the Moon, in the middle of a total eclipse, watched with the sky clear around it, so disappears that no trace of it in the sky, no colour of a ruddy, or livid, or pale Moon glimmers through. Sometimes, however, it appears ruddy or pale even in the middle of a total eclipse, and *failing, and yet conspicuous in its failure*, as Pliny the Elder says, Book 2, chapter 9. Sometimes, finally, it disappears entirely for some and not entirely for others, keeping a trace of a faint glow, as I shall shortly relate.

For so that there may be some example of this uncertainty from our own observations: on 1642 April 14, at Bologna, the Moon, already immersed in the penumbra and reddening, shortly after seemed to die and to be withdrawn entirely from our eyes, and for a long time we searched in vain for the place in the sky where it was; then it reddened again, and not very long after emerged gradually from the penumbra. And yet for the whole time of the eclipse the sky seemed clear to us, with the stars glowing all around.

[Margin: The Moon extinguished in the middle of an eclipse, for some.]

The same, as regards the Moon's extinction in the middle, was observed at Prague by Fathers Theodorus Moretus [Theodoor Moretus] and Vuolfangus [?], of the Society of Jesus, and at Paris by Father Georges Fournier, S.J., with D. Pierre Gassendi and Ismaël Boulliau, as I have it from their letters delivered into my hands. Indeed Scheiner says in the *Disquisitiones Mathematicae* p. 59: *It is established that the Moon in the very middle of the terrestrial shadow is entirely deprived of all light and colour.* To others, however, it did not seem entirely extinguished. For the most illustrious D. Giulio Giustiniani writes to D. Fortunio Liceti, and Liceti to me, that it was seen with a tiny portion of reddish glow, like Mars or the nebula of Praesepe; and he adds that the same was seen by Bonuicino [?] and Pieronio [?] at Vienna. At Glacij [Kłodzko] too Father Balthasar Conrad, S.J., and at Nyſſæ [Nysa] Father Scheiner saw a faint glow always clinging to the Moon like a star, but of the rest of the Moon they saw nothing at all.

[Margin: The same not entirely extinguished for others.]

At Pisa, D. Vincenzo Renieri writes to me about this eclipse as follows: *What seems worthy of consideration in a phenomenon of this kind is the total loss, so much so that the Moon was not only entirely stripped of that redness with which it shines in such a case, but the limb of the disc itself did not appear at all, and only a tiny whiteness was seen, from that part of the disc believed to face the south-west* [Notolybicum]. *Let those who think the Moon shines with its own light see here how they can save a phenomenon of this kind.* Wendelen tells it a little differently in the preface to the *Eclipses*: *It sometimes happens that the Moon, once immersed in the shadow, so vanishes that unless carefully sought it cannot be found; which Tycho left in writing about the eclipse of 1588, which very thing happened in 1620, and finally in 1642, in April, we all noted it.* And in Kepler's *Astronomia Optica* p. 277: *On 1588 March 3, at Mulpronnæ [Maulbronn] in Württemberg, I could scarcely make out the Moon with my eyes, through its ashen colour, when it was in the middle of the shadow.* Now the Moon was then at mean distance from the Earth, at 25° Libra; Venus at 20° Aries; Saturn at 20° Pisces and Jupiter at 8° Pisces; that is, in a place most suited to imparting some light to the Moon, which stood almost opposite.

But in the same year, on October 7, in the middle of a total eclipse, we saw the Moon grow pale after it had been red, but not wholly extinguished. It was nearer perigee than apogee, and at 15° Aries; and it could then have been illuminated by Venus, placed at the end of Scorpio. Gassendi saw the same in the eclipse of 1623, in the month of April. And Wendelen adds, in the place above: *When it is now set in the midst of the darkness, it reddens like a glowing coal*; which we too have seen at other times. Nor is what Scheiner pronounced universally above true.

So although, when the Moon shines in the middle of a total eclipse and no planet stands opposite it in a position suited to illuminate it, it seems certain that it is with part of itself in the penumbra and receives secondary light from the Sun's refracted rays, especially if it does not shine in the middle as it does at the edges, and so that it is with part of itself outside, and with the middle of itself inside, the cone TNV; yet when planets suited to illuminate it are present, whether the Moon in the middle of the eclipse is visible to all observers, or only to some, or to none, it is uncertain whether it is in the sheer shadow of the atmosphere and its cone TNV, or within ON, since because of extraordinary refractions it is not impossible that its limit N rises above the Moon's distance from the Earth, to 70 semidiameters, and so it appears glimmering, or, if planets illuminating it are present, it appears to some and not to others, because of a different temper of the air or attention not kept up in observing; or whether, as I said, it is in the lucid segment NQOQ of the penumbra, but does not appear because of small clouds interposed between the Moon and us, or thick vapours around the horizon, at about the same time spread around such a position of the atmosphere that, by an enormous refraction, they at once refract and weaken either the Sun's rays on entering or leaving the atmosphere, or the Moon's rays on entering it, so that the Moon can scarcely, or not even scarcely, be

seen. And I say the same when no planets suited to illuminating the Moon are present and it does not appear; for that total failure need not necessarily be attributed to their absence rather than to other causes. Finally, we have very few observations in which the appearances of the middle of a total eclipse have been accurately noted and committed to record. I do hope that posterity will be more exact in these matters; yet astronomy will always waver here, because of the inconstancy of physical causes.

PROPOSITIO III.

Proposition 3.

Luna in medio Eclipſi totalis poteſt ſed rarò plus ſublucere, quàm ante aut poſt medium; quando autem tota in medio obſcuratur, craſſiorem Vmbram permeat in Apogeo quàm in Perigeo, & meræ Vmbræ conus Lunam obſcurans inuerſo mucrone Terram reſpicit.

In the middle of a total eclipse the Moon can, though rarely, glimmer more than before or after the middle; but when it is wholly darkened in the middle, it passes through a thicker shadow at apogee than at perigee, and the cone of sheer shadow that darkens the Moon faces the Earth with its point inverted.

XIV. Father Bettini touched ingeniously on the foregoing paradoxes, in other words, but from a hypothesis he himself did not absolutely admit, in *Apiarium* 8, Prop. 2, Prop. 2[39], and he deduces them from Kepler's figure and from what was said at numbers 9 and 10. Namely, if the Moon is in the segment NQOQ, whose middle lies beyond 46 and below 70 semidiameters of the Earth, and the Sun's refracted rays from left and right unite in it and illuminate the Moon with doubled light; and if these same rays, at a smaller distance from the Earth, say within OQ, are less spread apart and more united, and because of their smaller distance from their origin more intense, than at a greater distance, say within QN. Conversely, if the Moon is in the atmosphere's sheer shadow TNV, then the nearer it is to the Earth, the nearer it will be to the limit N, and it will enter a smaller part of the shadow at YY than if, being further from the Earth, it comes nearer to the shadow's greater breadth TV.

[Margin: Father Bettini's ingenious paradoxes.]

The former part, however, is deduced from the hypothesis of Kepler's measure, which is nevertheless erroneous, from what was said at the end of number 10. Yet that part can be verified, if the horizontal refraction varies so much that the height BN is greater than the Moon's distance; but that happens very rarely, and almost always, as in our second figure, substituted at the end of number 10, the Moon in the middle of an eclipse is above ON and within the cone TNV.

[39] *Prop.2.* is printed twice; the same work is cited further on this page as *Apiario 8. Prog.2. prop.9.*

The third part of the proposition, on the inverted point, is clear from our figure at the end of number 10.

PROPOSITIO IV.

Proposition 4.

Eclipſium Lunarium Quantitas & Duratio eadem eſt quoad ſenſum, ſiue æſtimetur ex Penumbra Atmoſphæræ, ſiue ex putata à Priſcis mera Vmbra Terræ.

The magnitude and duration of lunar eclipses is the same as far as the senses go, whether it is reckoned from the penumbra of the atmosphere or from what the ancients took to be the sheer shadow of the Earth.

XV. This, of course, is what Kepler meant when he said in the foundations of the *Ephemerides*, number 29: *The business of refractions does indeed cause the redness in the failing Moon, but it does not at all disturb the geometrical figure of the terrestrial shadow*; and in the *Astronomia Optica* p. 268: *That neither eclipses should be cavilled at from refractions, nor refractions from eclipses*; and p. 271, where he teaches that the astronomical calculation will not be disturbed if, in place of the ancients' terrestrial shadow, the penumbra from the air is used. See the reason for this statement in Scholium 1 of chapter 4.

PROPOSITIO V.

Proposition 5.

Poteſt eſſe & videri Eclipſis Lunæ, etiam in medio, quamuis vtrumq. Luminare ſupra Horizontem appareat, & tamen interim alijs apparere infra Horizontem.

An eclipse of the Moon can exist and be seen, even at its middle, although both luminaries appear above the horizon; and yet it can meanwhile appear to others below the horizon.

XVI. Goclenius denied this in *Urania* p. 128, of both luminaries above the horizon; but it seemed not ἀδύνατον [Greek: ἀδύνατον (adynaton, "impossible")] to Pliny the Elder but παράδοξον [Greek: παράδοξον (paradoxon, "paradoxical")], when he says in Book 2,

[Margin: Goclenius's error.]

chapter 13: *And what is most wonderful in this marvel: although it is agreed that the Moon is dulled by the Earth's shadow, this happens to it now from the side of the setting, now from that of the rising. And in what way, since at sunrise that dulling shadow must be under the Earth, did it once happen that the Moon failed at its setting, with both bodies visible above the Earth?*

[Margin: A history of such eclipses.]

Mästlin testifies that something of the kind was seen by him in 1590 July 17, in the *Theses on Eclipses*, thesis 55, and Kepler after him in the *Astronomia Optica* p. 136. Mästlin's words are: *Here at Tübingen, with the Sun's centre emerging above the horizon, we saw the Moon, already failing from the south by several digits, raised almost 2°; and conversely, with the Moon's centre descending to its setting, we noted the Sun's height above its rising as 2°. But the Moon set before it had come to its greatest darkening.* And the Romans will see a similar eclipse in 1668 May 25; on this and similar ones, see what I said against Clavius in Book 2, chapter 2, Scholium 3.

Cleomedes, moreover, in Book 2, chapter 5, which concerns the Moon's eclipse, appears to deny such eclipses absolutely. For he had said: *Some say that eclipses of the Moon have been seen with both luminaries visible above the horizon, which would plainly show that the Moon does not fail because it runs into the Earth's shadow*; and he had refuted the ancient mathematicians who untied this knot by saying that it can happen to an eye raised above the globular Earth; and he had granted them that it can happen if the sight were very high and raised above the Earth's globosity, but by no means if it rests closer to the Earth, as it usually does. Having related this, I say, he adds:

[Margin: Cleomedes's ambiguous judgement on this phenomenon.]

But first those who say this must be met with the point that this story has been made up by certain philosophers and astrologers: for there are extant many eclipses of the Moon, both total and partial, all of which are set down in writing, and no one down to our own times has reported such an eclipse, neither a Chaldean, nor an Egyptian, nor any other mathematician or philosopher; but what is said is invented.

[Margin: Cleomedes's first response.]

Now Kepler in the *Optics* p. 145, and Mästlin with him, judge that it is Pliny the Elder who is here rebuked by Cleomedes without being named. Our Bettini, on the contrary, in *Apiarium* 8, Progymnasma 2, Proposition 9, thinks that Pliny the Elder took this from Cleomedes, and so he wonders that some are so ignorant of chronology as to have thought that Cleomedes took it from Pliny the Elder. But there were two men named Cleomedes: one who flourished under Theodosius the Younger, about the year of the Lord 390, and so later than Pliny the Elder by three centuries; the other who flourished in the century before the birth of CHRIST, shortly after Posidonius, and wrote two books κυκλικῆς θεωρίας μεθεωρῶν [Greek: κυκλικῆς θεωρίας μεθεωρῶν (kyklikēs theōrias meteōrōn, "of the cyclical theory of the heavenly bodies")] [recte: μετεώρων], as well as an *Arithmetic* and a *Harmonics*, as Robertus Balforeus [Robert Balfour] testifies, who translated the first work and elucidated it with scholia; and Biancani after him in the *Chronologia Mathematicorum*. Thus the parachronism [parachronologismus] of Kepler and Mästlin was rightly noted by Father Bettini. And indeed, how could Cleomedes deny that such an eclipse had ever been committed to writing by anyone, if he had known that this one observation was extant in Pliny the Elder? Yet I do not agree with Bettini when he asserts that Pliny the Elder copied from Cleomedes those words *and*

in what way … once; for Cleomedes does not say that it once happened, and indeed he denies that any such thing is read anywhere in the history of eclipses.

[Margin: The parachronism of Kepler and Mästlin, rightly noted by Bettini, though not without a blemish of his own.]

Cleomedes, however, goes on, also on the hypothesis of such an eclipse having been seen or being yet to be seen. He responds, secondly, that it can happen either because of an image of the Sun reflected from a thicker cloud to our sight, or because of our visual rays in moist and more humid air, which nevertheless present to us above the horizon a Sun placed below the horizon. Here, in the second part of his response, as if stammering, he touches on the true cause; for his own words are: *Further, the ray poured out from the eyes, having met moist and more humid air, can also* κατακλᾶθαι [Greek: κατακλᾶθαι (kataklasthai, "to be broken" — the text's own gloss follows)] [recte: κατακλᾶσθαι]*, that is, be broken, and reach the Sun, already hidden under the horizon: for we have observed something similar in a gold ring put into an empty vessel, which from a moderate distance is not seen, but from the same distance appears if the vessel is filled with water, etc.* In this, however, Cleomedes errs: he both defends vision by the emission of rays, and thinks it necessary that the air at the horizon be sprinkled with abundant moisture, whereas the greater density of our air alone is enough. Yet his response is approved by Milich on Book 2 of Pliny the Elder, chapter 13; by Io. Pisanus [John Peckham], *Perspective* Book 3, propositions 5 and 7; and by Stöffler on Proclus, p. 63½.

[Margin: The second response of Cleomedes, of Milich, of Pisanus, of Stöffler.]

XVII. The true cause of this phenomenon, therefore, especially as regards the beginning of a morning lunar eclipse or the end of an evening one, can in part be the one which the ancients in Cleomedes, the mathematicians, pointed out: namely the raising of the eye above the ground, whether on a hill or in a tower or some other lookout; for from there it can see the Sun, even though the Sun is placed below the horizon, as is gathered from what was said in Book 2, chapter 10. But the principal cause, and one that always intervenes, is the refraction of the rays, solar on the one side and lunar on the other, which visibly lifts the luminaries above the horizon, although one of them, or even both, is really situated below it, as Kepler teaches above. He adds that the refraction by whose force Mästlin saw such an eclipse in Swabia was greater than 1° in each of the luminaries, since it raised the luminaries into his view in spite of the mountains besetting the horizon of Tübingen.

[Margin: The second cause of this phenomenon.]

In that Proposition 9, Bettini also ingeniously adds that the same lunar eclipse can be seen by some above the horizon, and by others below the horizon of the former but above their own (add: and by others on the horizon), and this at the same moment of time, namely by the force of a refraction that raises the luminaries for each of them towards his own zenith. So in the following

figure, in which let the Earth's centre be M, and the astronomical horizon AMB, serving both the inhabitant HI and his antipode KL.

[Margin: Bettini's ingenious observation.]

Diagram. Set in the left column. At the left, three circles stand one above another, touching: the upper labelled C, the middle A, the lower D; a curved line runs through C and D, passing the junctions with A. In the middle is the Earth, with a centre M, its left half showing land and dotted water, its right half hatched. A straight line runs from A through M to a point B at the far right, and two tangent lines run from the region of A's contact points past the top and bottom of the Earth, converging on B to form the hatched cone of the shadow. Around that cone stand, on a second curved line, a circle E above and a circle F below, with a smaller circle G on the axis between them, overlapping both.

- Upper left circle: C
- Middle left circle: A
- Lower left circle: D
- Top of the Earth: H I
- Centre of the Earth: M
- Bottom of the Earth: K L
- Upper right circle: E
- Circle on the axis: G
- Lower right circle: F
- Far right, apex: B

For although the Sun be at A, for example, and the Moon at G, already eclipsed by the shadow or penumbra IBL, yet by the benefit of refraction the eye H or I will be able to see the Sun at C and the eclipsed Moon at E, at the same moment at which the eye K or L sees the Sun at D and the eclipsed Moon at F. Indeed, even while the eye H sees the luminaries on the horizon, the other eye I will be able to see one of them above it. Indeed, what is more wonderful, all those whose horizons intersect at the same point where the failing Moon stands will be able to see their own distinct image of the luminaries, and one real eclipse can be multiplied into almost infinite apparent ones, in diverse images, by the force of refraction, because horizons of this kind are infinite, or finite without limit.

[Margin: Infinite eclipses of the Moon from one.]

XVIII. The assertion of Father Bettini, however, which is found on this occasion in the corollary of that Proposition 9, must be corrected. For he affirms that at the time such an eclipse appears (the one discussed above with Pliny the Elder) the luminaries are on the horizon, and that therefore, once their apparent altitude has been observed by instrument and the horizontal parallax added to it, the measure of the horizontal refraction is at once obtained. This would indeed be true if it were known that at that moment the true place of the luminaries is on the astronomical horizon; but this is not always certain independently of refraction, and indeed it is mostly certain that the luminaries

are already either below or above the horizon. For when the Sun appears on the physical horizon, it is below the astronomical one, since these horizons are apart only by the arc of the horizontal parallax, which in the Sun is not 4′, whereas refraction raises it about 34′. Hence, for it to be on the astronomical horizon when it appears above the physical one, it must be seen raised about 30′ above the physical one; and this can be concluded with determinacy only if its horizontal refraction is known and presupposed beforehand. The Moon, because of its greater parallax, is subject to a greater variation in this; but more on these matters in the Optical Book.

[Margin: Bettini's fallacious way of measuring refraction from such eclipses.]

SCHOLIA.

Scholia.

I. The matters concerning the Moon's own light, asserted by some on account of the light and redness it has in its eclipses, have already been sufficiently discussed in Book 3, chapter 6, from number 11, although in this chapter, at number 12, we have touched on most of the arguments on this subject. On the colours of the eclipsed Moon, however, we said some things incidentally in Book 3, chapter 6, near the end, where we reported the false causes of these colours advanced by certain people, and conjectured the true one to lie in the diverse vapours of the atmosphere, more or less dense and opaque, and in a threefold refraction in them: namely of the Sun's rays once on entering the atmosphere and again on leaving it, and a third time of those same rays reflected from the Moon to us and refracted on their return through the atmosphere.

[Margin: Whether the Moon has its own light.]

[Margin: The cause of the diversity of colours in an eclipse of the Moon.]

Sometimes the variety of these colours is so great that Kepler, in the *Astronomia Optica* pp. 274 and 282, thinks they resemble the colours of the rainbow. For Cornelius Gemma, in Book 2 of the *Cosmocritice* p. 64, relates of the eclipse of 1569 March 3: *In the morning at the third hour Phoebe suffered a horrible eclipse, marked by dreadful colours. First it shone dusky, then blood-red, soon also crimson, and green, and livid, and finally misshapen with an incredible variety.* And Apollonides in Plutarch, in the little work *On the Face in the Orb of the Moon*: *Since therefore we see the Moon take on so many colours in the shadow, those people are not right to seize on the ember-colour.* And in the *Aemilius Paulus* Plutarch says that the Moon, overlaid with various colours, went off into darkness.

[Margin: The variety of these colours.]

Mostly, however, either the pale or the red predominates in it. Hence Frodoard says in his *Chronicle* for the year 926: *On April 1 [Cal.April.] the Moon suffered eclipse and was turned to pallor, with a small part of its light left, as though it were a second-day Moon; and so, with dawn already beginning, it was changed entirely into a blood colour.* There is also extant in the *Acts of the Holy Martyrs* this passage about St Felix, an African bishop who with his companions gained

martyrdom in Campania because he refused to hand over the divine books, that is, sacred Scripture, and to obey Diocletian's edict in this: *And he was led to the place of his passion, when the Moon itself also was turned to blood, on August 30 [die tertio Kal.Sept.].* Scaliger, however, in the prolegomena to the *De emendatione temporum* p. 18, because he assigns this eclipse to the year of CHRIST 301, September 3 [3.Nonas Septembris], thinks that August 30 [3. Kal. Septembris] was the day on which Felix was led to the place of his passion, but that the eclipse that followed is described soon after.

[Margin: The red colour is the more frequent in these eclipses.]

So Cardano, Book 3 of *De subtilitate*: *It is agreed that in the greatest eclipses the Moon reddens like a sort of ember of fire.* Scheiner, in the *Disquisitiones* number 26, calls this colour rust-red. The poets chime in here, speaking of the colours of the failing Moon. Ovid, *Amores* 2:

Songs draw down the horns of the blood-red Moon.

Seneca in the *Hippolytus*, Act 2, Chorus: *And lately it reddened.* For the rest see chapter 1, number 2. Lucan, Book 6:

and serene Phoebe, Not otherwise beset by the dreadful poisons of words, Grew pale, and burned with black and earthly fires.

That is, from the Earth's penumbra.

II. Besides the phases discussed so far, there are at times notable *Hapsi*, that is, small clouds or spots hanging under the Moon, arising when it is already darkened, and suspended beneath it. Mästlin saw one of this kind on the evening of 1605 April 3, in the eclipse of that year. For he says in the *Theses* on eclipses, thesis 152, that he saw on the Moon's body, towards the north, a blackening spot darker than the rest of the body, and of the colour of glowing iron; perhaps it was the lake of Panciroli, on which I spoke in the *Selenography*, Book 4, chapter 7. Wendelen, for his part, in the preface to the *Eclipses* p. 3, says that he has often seen small clouds hanging under the Moon while it was still set in darkness, as if heavy with much water, which at times, because of their shape arched in the manner of the shadow, can imitate the beginning and end of an eclipse produced by the true penumbra. Thus in the year 1638, although he was certain from the better tables and the remaining phases that the whole eclipse had ended at $4^{h}\ 8^{m}$ after midnight, yet because of an arched small cloud clinging to or accompanying the Moon, it was seen to last until $4^{h}\ 40^{m}$. Therefore Tycho and the ancients must be pardoned if, in noting the beginnings and ends of eclipses, they sometimes go enormously astray, deceived either by the umbrago, or by these Hapsi, or by suffusions of the eyes, especially since the telescope had not yet been discovered.

[Margin: A false and spurious penumbra from Hapsi and arched small clouds.]

III. As for the astrological judgements to be made from the colours of eclipses, they rest rather on conjectures and on a certain remote analogy. So Ptolemy, in Book 2 of the *Quadripartitum*, chapter 9, t. 51, 52, 53, and after him Origanus in the *Introduction to the Ephemerides*, part 3, chapter 2, teach that a black and

somewhat livid colour signifies Saturnine effects; white, Jovial; ruddy, Martial; yellow, those of Venus; variegated, Mercurial. But neither are the astronomical judgements on the future colours of eclipses any more certain, although some have handed down rules of some kind or other, among them Apollonides in Plutarch, in the little work *On the Face in the Orb of the Moon*: *We see the Moon in eclipse take on now one colour, now another, which the mathematicians distinguish by the reckoning of the time as follows: if towards eve-*

[Margin: The fallacious prejudgements, astrological on the effects of colours, and astronomical on the future colours of eclipses.]

ning the Moon fails, it is horribly foul; if at midnight, it becomes crimson and red; towards dawn it puts on a fierce and dark blue face. But the Alphonsines, following Io. de Linerijs [Jean de Lignières] or following the Arabs, Apian in the *Astronomicum Caesareum* statement 27, Magini in Canons 73 and 89 of the *Secunda Mobilia*, and Renieri in the *Tabulae Mediceae*, second edition, p. 355, set out small tables that do not answer to experience.

IV. Just as in a Moon that is not full the section between the part lit for us and the dark part is winding, because of the roughness of the Moon's valleys and mountains, so in partial lunar eclipses the borders of the penumbra and of the bright part appear roughened and broken, whether you look through the telescope or receive its image on paper. Kepler shows something of the kind in the *Optics* p. 247 and in the *Dissertatio cum Nuncio Sidereo* p. 6½. He thinks the cause of this phase is that, at the border of the eclipse, some parts of the Moon take up the weakened ray of the Sun more strongly, others more weakly, and send back the Sun's direct ray, and indeed also the ray refracted in the penumbra; and so in the darkened part that redness appears blacker in some places than in others, as can be seen in the figure of the eclipse of 1602 December 31, 6^{h}, observed on paper, which Kepler has in the *Optics* p. 247.

[Margin: The roughness and inequality of the penumbra.]

Wendelen, however, in the preface to the *Eclipses* p. 6, attributes this jagged edge and fringed border of partial eclipses to vapours that are lower under the Torrid Zone and higher under the Poles. So it comes about that the convexity of the atmosphere is itself also unequal and has its own valleys and mountains, so to speak, and so the rays, refracted at its surface by a double or triple refraction, produce this inequality at the border of the penumbra. For my part I judge that both causes, each in its own measure, contribute to this. Now follows the table mentioned at the end of number III.

[Margin: The twofold cause of this.]

COLORES ECLIPSIVM.

The colours of eclipses.

In an eclipse of the Sun		In an eclipse of the Moon				
Distance of the Sun from the Dragon's Head or Tail	**Colours**	**Moon's latitude**	**Colours**	**Argument of latitude**	**Colours**	**Argument of latitude**

CAPVT VI.

Chapter 6.

De Lunarium Eclipſium Terminis, Magnitudine, Duratione, & Medio; vbi & de Horario motu Luminarium.

On the limits, magnitude, duration and middle of lunar eclipses; where also on the hourly motion of the luminaries.

PROBLEMA I.

Problem 1.

Terminos Eclipſis Lunę determinare.

To determine the limits of a lunar eclipse.

I. The limit [Terminus] of a lunar eclipse is the distance of the Moon's centre from the nearer of the nodes, beyond which an eclipse of the Moon is naturally impossible, and within which it is either necessary or at least possible. And so these limits are subdivided into possible and necessary. Their determination depends on three elements: the apparent semidiameter of the Moon, the apparent semidiameter of the shadow of the Earth or rather of the atmosphere, and the true latitude of the Moon. For if the latitude is not less than the sum of the apparent semidiameters of the Moon and of the shadow or penumbra, an eclipse is not possible. Therefore, to have the limits of a possible eclipse, we must take the greatest semidiameter of each, namely of the Moon at perigee and of the shadow or penumbra with the Sun at apogee. For their sum will give the side EB in the spherical triangle ABE, right-angled at E, in which the angle at the node A is supposed given, measuring the Moon's greatest latitude in the syzygies. By the rules of triangles the base BA will then be found, namely the distance from the nearer node A within which an eclipse of the Moon will be possible, and beyond which it will not.

[Margin: How the possible limits are found.]

To have the limits of a necessary eclipse, on the other hand, the least apparent semidiameter of the obscuring and the obscurable body must be taken, namely of the Moon at apogee and of the shadow or penumbra with the Sun at perigee. For their sum gives the side EB, and this with the angle A gives the base BA, which is the distance from the node A within which the Moon, once placed there, necessarily suffers eclipse.

[Margin: How the necessary limits are found.]

Diagram. Set in the right column with the text running round it. A spherical figure with its apex at the right: an upper arc runs from D through E to A, a lower arc from C through B to A, a line joins E to B, and a line joins D to C.

- Left end of the upper arc: D
- On the upper arc: E
- Apex at the right: A
- On the lower arc: B

• Left end of the lower arc: C

So, once the Moon's greatest latitude in the syzygies has been taken from Book 4, chapter 12, the Moon's apparent semidiameter from Book 4, chapter 16, and the semidiameter of the shadow, or rather of the penumbra, from Book 5, chapter 4, number 14, the limits already mentioned can easily be defined according to the various hypotheses of the astronomers. They can, however, also be gathered from the small tables of semidiameters and from the motion of latitude, or its argument, already arranged in tables, by seeking in the body of these tables the Moon's visible latitude equal to the sum of the semidiameters of the Moon and of the shadow or penumbra, and in the margin the degrees of the argument of latitude under sign 0 or above sign 11, and using, if need be, the proportional part.

In these ways, then, the ecliptic limits were established by Ptolemy, Book 6, chapter 5; al-Battānī, chapter 43; Regiomontanus in the *Epitome of the Almagest*, Book 6, proposition 8; the Alphonsines in the tables, proposition 32; Copernicus, Book 4, chapter 30; Reinhold in the Prutenic Tables, precept 50, and on Peuerbach's *Theoricae* p. 198; Wurstisen in the same place, p. 347; Neander in the *Elements* p. 129; Mulerius in the *Tabulae Frisicae* pp. 77 and 428; Magini in the *Theoricae*, Book 2, chapter 26, and Canon 67 of the *Secunda Mobilia*; Tycho, *Progymnasmata* vol. 1, p. 126; Biancani, Book 9 of the *Sphaera*, chapter 5; Langius in the *Theoricae*, chapter 19; Kepler in the *Epitome of Copernican Astronomy* p. 863 and in the Rudolphine Tables p. 98. From these, and from the tables of these and of others, let the ecliptic limits be trigonometrically corrected and indicated in two ways: one by the Moon's distance from the node; the other, and better, by the Moon's true latitude itself, and that in true full Moons, where the words *In mean oppositions* [In Medijs ☍] will not be added.

Limits of an eclipse of the Moon: authors	Possible: distance from the node	Possible: true latitude of the Moon	Necessary: distance from the node	Necessary: true latitude of the Moon
Ptolemy, in mean oppositions	15° 38′ 0″			
in true oppositions	12° 12′ 0″	1° 8′ 43″	10° 50′ 0″	0° 55′ 38″
al-Battānī, in mean ones	14° 45′ 0″	1° 8′ 51″	10° 17′ 20″	0° 53′ 45″
Alfonso and Peuerbach	12° 31′ 17″	1° 5′ 1″	9° 52′ 0″	0° 51′ 16″
Copernicus	12° 39′ 30″	1° 5′ 41″	10° 26′ 55″	0° 54′ 21″
Reinhold, with the Sun's eccentricity greatest	13° 7′ 0″	1° 7′ 52″	10° 24′ 10″	0° 54′ 12″
Reinhold, with the Sun's eccentricity least	13° 1′ 0″[40]	1° 7′ 35″	10° 23′ 55″	0° 53′ 53″
Tycho, Mulerius	12° 36′ 0″	1° 5′ 0″	11° 12′ 0″	0° 58′ 4″
Magini, in the *Supplement to the Ephemerides*	12° 28′ 0″	1° 4′ 20″	11° 11′ 55″	0° 57′ 47″

[40]the degree figure is written over by hand in this copy; it reads 13 as it stands

Limits of an eclipse of the Moon: authors	Possible: distance from the node	Possible: true latitude of the Moon	Necessary: distance from the node	Necessary: true latitude of the Moon
Longomontanus	12° 24′ 0″	1° 4′ 0″	11° 12′ 0″	0° 58′ 4″
Kepler	12° 0′ 0″	1° 6′ 3″	10° 40′ 0″	0° 58′ 52″
Lansbergen	12° 3′ 0″	1° 4′ 8″	10° 11′ 18″	0° 53′ 2″
Boulliau	12° 25′ 0″	1° 4′ 5″	10° 58′ 40″	0° 56′ 51″
Wendelen	12° 8′ 13″	1° 3′ 0″	10° 11′ 20″	0° 53′ 3″
Ourselves, taking the penumbra into account	12° 50′ 0″	1° 6′ 0″	10° 0′ 0″	0° 52′ 6″

To these Kepler, in the Rudolphine Tables p. 98, adds limits of 11° 54′ with the Moon and Sun at perigee, but of 10° 46′ with the Moon and Sun at apogee. Therefore, in our opinion, taking the semidiameter of the penumbra into account, if the Moon in true full Moons is more than 13° from either of the nodes, an eclipse will not be possible; but if less than 10°, there will necessarily be an eclipse of the Moon. This shows how carelessly Argoli said in his tables, chapter 17: *If the Moon's nodes are not more than 15° distant from the Moon, the Moon will suffer an eclipse.*

PROBLEMA II.

Problem 2.

Magnitudinem Eclipſis Lunæ determinare.

To determine the magnitude of an eclipse of the Moon.

[Margin: How the magnitude of an eclipse is estimated.]

II. The magnitude of a lunar eclipse is the portion of the Moon that is obscured by the penumbra of the atmosphere or, in the opinion of the ancients, by the shadow of the Earth. It is usually expressed either in inches [vncias] or in digits [digitos], of which the Moon's visual diameter contains twelve; as in the figure added here, in which, of the Moon's diameter AF, roughly a third part DF is shown, that is, 4 inches or digits, eclipsed by the shadow or penumbra towards the south.

Diagram. A circle representing the Moon's disc, set into the left column, with a vertical diameter from A at the top to F at the bottom. The diameter carries a series of short cross-ticks. The lowest part of the disc is a solid dark segment with a convex upper edge, the part in shadow; the upper end of the shaded part meets the diameter just below D.

- A (top, outside the circle)
- G (left, outside the circle)
- K (right, outside the circle)
- C (on the right of the diameter, inside the circle)
- D (just below C, at the upper edge of the dark segment)
- F (bottom, outside the circle)

But when the whole Moon is eclipsed with some stay [mora] in darkness, then beyond the 12 digits as many digits are said to be eclipsed as there are between the circumference of the eclipsed disc and that of the eclipsing shadow or penumbra. For if the Moon's true latitude at mid-eclipse is greater than the sum of the visual semidiameters of the Moon and the shadow, there is no eclipse; if equal to it, the periphery of the Moon touches the periphery of the shadow; if less, some part of the Moon is obscured. If the latitude equals exactly the semidiameter of the shadow, exactly half, or 6 digits, are obscured. If the latitude is less than the semidiameter of the shadow, and equal to the remainder of the shadow's semidiameter when the Moon's semidiameter has been subtracted from it, the eclipse is total without stay, and of 12 digits; if less than this remainder, it is total with stay, and of more than 12 digits. For example, if the Moon enters the shadow so deeply that, if its diameter were of 15 parts of the kind of which it now has 12, it would still be wholly obscured, 15 digits are said to be eclipsed. Now to ordinary people either luminary appears a foot across, and so, like a foot, its diameter is divided into 12 inches, which the Greeks call δακτύλους [Greek: daktylous, "fingers", that is, digits], and some indeed call points. The eclipsed digits are determined in two ways and are set out in tables; these are given by Ptolemy, Book 6, chapter 7; Regiomontanus in the *Epitome*, Book 6, proposition 16; Copernicus, Book 4, chapters 31 and 32; Mulerius in the later part of the *Isagoge* to the *Tabulae Frisicae*, chapter 9; Magini in the *Theoricae*, Book 2, chapter 27; Kepler, precept 152 of the Rudolphine Tables.

[Margin: Rule 1, for the digits to be eclipsed.]

The first rule is this. Subtract the Moon's true latitude from the sum of the apparent semidiameters of the Moon and the shadow or penumbra. Multiply the remainder by 6 digits and divide the total so obtained by the Moon's semidiameter; or multiply the remainder by 12 and divide the total by the Moon's apparent diameter. Either way, there will result the digits, and the minutes or sixtieths, of the digits to be eclipsed. But if you wish to work more precisely, use, in place of the latitude, the arc between the centres at mid-eclipse, which I shall discuss in Problem 4 and in Scholia 1 and 2.

[Margin: Rule 2, for the portion of the diameter, and indeed for the area of the eclipsed disc.]

The second rule comes from Copernicus and runs as follows. In this second diagram let ABC be the circle of the shadow or penumbra, whose apparent semidiameter is AE; and let AFC be the Moon's disc, whose apparent semidiameter is AI; both are supposed given. And let the Moon's true latitude EI at the moment of greatest obscuration be given. For triangle AEI will be one of known sides, and so its angles will become known through the analysis of triangles; and when the straight lines EC and IC are drawn to the point of intersection C, triangle ECI will be not only similar but also equal to triangle EAI.

Diagram. Two intersecting circles set into the right column, the upper larger and the lower smaller, with a common vertical line through both centres from B at the top to F at the bottom. The upper circle is lettered in large capitals VMBRA VEL SOL [SHADOW OR SUN], split by the vertical line; the lower LVNA [MOON]. The circles cross at A (left) and C (right), joined by a horizontal chord through K. Straight lines run from E to A and C, and from I to A and C, forming a rhombus with the vertical line as its other diagonal.

- B (top of the upper circle, on the vertical)
- E (on the vertical, centre of the upper circle)
- G (on the vertical, above K, on the upper edge of the overlap)
- K (on the vertical, at the chord AC)
- D (on the vertical, below K, on the lower edge of the overlap)
- I (on the vertical, centre of the lower circle)
- F (bottom of the lower circle, on the vertical)
- A (left point of intersection)
- C (right point of intersection)

Therefore from angle AIC the arc AGC will be known, and from angle AEC the arc ADC, in units of which the whole periphery in each disc is 360 degrees. But since, from what was said in Book 1, chapter 4, the diameter of a circle is to the circumference as 100 to 314, and the semidiameter as 50 to 314, let it be made: as 50 to 314, so the Moon's given visual semidiameter AI to another quantity; and likewise the shadow's semidiameter AE to another. There will result, in the one case AGC, in the other ADC, in the parts in which the apparent semidiameters were known. In this way there will also result what is contained under EA, AD, and under IA, AG, which are the halves of the sectors AEC and AIC, the one of the one and the other of the other.

Moreover, in the isosceles triangles AEC and AIC, from the angle already found at E and at I, and from the semidiameters that form the equal legs, the common base AKC will be known by trigonometry. And if it is made: as the radius to the semidiameter AE or AI, so the second sine of the angle AIG or AED to another quantity, then KE on the one side and KI on the other will be known. Therefore, in the rectangle of AKE, when AK and KE are multiplied together, the parallelogram or area will be known, to which the double of triangle AKE is equal, that is, triangle AEC. Similarly, when AK and KI are multiplied together, the area of triangle AIC will be known. So [recte: ergo; printed ego], when each of these triangles is taken from its own sector, namely triangle AEC from sector AECDA and triangle AIC from sector AICGA, the eclipsed segment AGCDA will remain. If anyone is so curious as to want to know how large a part of the surface of the luminary is eclipsed. For Copernicus says, Book 4, chapter 32: *Many hold that the judgement should be made not by the diameters but by the surfaces, for it is not lines but surfaces that fail*; and before him Ptolemy, Book 6, chapter 7: *Most of those who observe eclipse indications measure the magnitudes of the observations not by the diameters of the circles but by their whole surfaces.* Finally, with the angles AIG and AED known

as above, if it is made: as the radius to the semidiameters of the obscuring and the obscured body, so the versed sine to another quantity, then KG and KD will be known, which taken together make up GD, the eclipsed portion of the diameter.

PROBLEMA III.

Problem 3.

De Duratione Eclipſis Lunæ eiuſq. partibus.

On the duration of an eclipse of the Moon and its parts.

III. The duration of an eclipse is the time from the beginning to the end of the eclipse. To know it, one must know beforehand the minutes of the zodiac that the Moon runs through from beginning to end, and the Moon's hourly motion from the Sun according to the Moon's equated anomaly: for those minutes, divided by the hourly motion, will give the time sought. Further, the astronomers, with Ptolemy, Book 6, chapter 7; Regiomontanus, Book 6 of the *Epitome*, propositions 17 and 18; Copernicus, Book 4, chapter 32; Reinhold on Peuerbach's *Theoricae* p. 199; Wurstisen in the same place, p. 353; Tycho, vol. 1, p. 130; Mulerius in the *Frisicae* p. 430; and Kepler in the Rudolphine Tables, precept 151, divide the minutes of the whole duration and the time corresponding to them: they divide them, I say, into two parts if the eclipse is not total with stay, but into four if it is total with stay; and these are the parts listed below.

[Margin: What are the minutes of incidence?]

The minutes of incidence [Incidentiæ Scrupula], or minutes of falling [minuta Casûs], in Ptolemy ἐξήκοστα τῆς ἐμπτώσεος [recte: ἐμπτώσεως] [Greek: exēkosta tēs emptōseōs, "sixtieths of the incidence"], are the minutes of the zodiac that the Moon, in overtaking the motion of the Sun, passes through from the beginning of the eclipse to mid-eclipse, if the eclipse is not total with stay, or from the beginning of the eclipse to the beginning of total obscuration, if it is total with stay.

[Margin: What are the minutes of repletion?]

The minutes of repletion [Repletionis ſcrupula], or minutes of evasion or of emersion [minuta Euaſionis, ſeu Emerſionis], in Ptolemy ἐξήκοστα τῆς ἀναπληρώσεως [Greek: exēkosta tēs anaplērōseōs, "sixtieths of the refilling"], are the minutes of the zodiac that the Moon, in overtaking the motion of the Sun, runs through from mid-eclipse to the end, if the eclipse is not total with stay; or from the beginning of its appearance out of the shadow, if it is total with stay.

[Margin: What are the minutes of half-stay?]

The minutes of half-stay [Moræ dimidiæ ſcrupula], in Ptolemy ἐξήκοστα τῆς ἡμίσεως μονῆς [Greek: exēkosta tēs hēmiseōs monēs, "sixtieths of the half stay"], are the minutes of the zodiac that the Moon, overtaking the Sun in motion,

runs through from the beginning of total obscuration to the middle or height of the eclipse; and equal to them are the minutes that it passes through from the middle to the beginning of its new appearance. The time corresponding to these is called the time of incidence, of repletion, and of half-stay.

For greater clarity, let the shadow BCESD be described about the centre A, with the ecliptic PR; and for a partial eclipse let the Moon's path be FGH, on which the centre of the Moon at the beginning of the eclipse is at F, and the contact with the shadow at C; at mid-eclipse it is at G, and at the end at H, with the contact with the shadow at B. Through these points let the straight lines ACF and ABH be drawn, though they are equivalent to arcs; and let AG be perpendicular to the Moon's orbit, which is called the arc between the centres. For the minutes of incidence will be the arc FG, and the minutes of repletion GH. But for a total eclipse with stay, let the Moon's path be KLQ, and the centre of the Moon at the beginning of the eclipse at K, with contact at I; at the beginning of total obscuration let it be at N, with internal contact at E; at mid-eclipse let it be at L; at the beginning of emersion at V, with interior contact at D; and finally at the end of the eclipse let it be at M [recte: Q], with external contact at O. And let the centres of the Moon K, N, L, V, Q be joined by straight lines to the centre of the shadow A, and let the arc between the centres be AL, perpendicular to the Moon's path. For the minutes of incidence will be the arc KN; those of half-stay NL for the earlier and LV for the later; and those of repletion VQ; which we shall presently teach how to find.

Diagram. A large solid dark disc, the shadow, stands in the lower part of the left column, with straight lines radiating from its centre A. Eight small discs of the Moon, each engraved with a human face and lettered at its centre, lie on two paths across it. Along the upper path, one at the top within the shadow's upper edge and two outside the shadow to left and right. Along the lower path, five in a row, overlapping one another and the shadow's lower half. A horizontal line through A carries P on the left and R on the right; a vertical line through A carries M at the top and S at the bottom.

- M (top, outside the shadow, above the upper central Moon)
- G (at the centre of the upper central Moon)
- H (at the centre of the upper left Moon, outside the shadow)
- F (at the centre of the upper right Moon, outside the shadow)
- B (on the shadow's edge, at the upper left Moon)
- C (on the shadow's edge, at the upper right Moon)
- A (centre of the shadow)
- P (left end of the horizontal line)
- R (right end of the horizontal line)
- Q (at the centre of the lower left Moon)
- O (on the shadow's edge, at the lower left Moon)
- D (on the shadow's edge, below O)
- V (at the centre of the second lower Moon)
- L (at the centre of the middle lower Moon)

- N (at the centre of the fourth lower Moon)
- K (at the centre of the lower right Moon)
- I (on the shadow's edge, at the lower right Moon)
- E (on the shadow's edge, below I)
- S (bottom, below the shadow)

PROBLEMA IV.

Problem 4.

Arcum inter Vmbræ terreſtris & Lunæ centra in ſummo ſeu medio Eclipſis inuenire.

To find the arc between the centres of the Earth's shadow and the Moon at the height or middle of the eclipse.

IV. In the diagram attached, let HAB be the ecliptic, in which A is the centre of the Earth's shadow KPN, and B the nearer node; and let BG be the Moon's path, on which the Moon's centre at the beginning of the eclipse is at C, at the end at G, and at mid-eclipse at I.

Diagram. A circle, the shadow, set in the right column, with centre A. The straight line HAB runs from the left edge through the centre and out to B far to the right. A second straight line, the Moon's path, runs from B down to the left across the lower part of the circle to G. Two small circles, the Moon, are centred on this path: one at C on the right near the shadow's edge, and one at G on the lower left. Lines run from A to C and from A to G, and from A down to L and to I on the path.

- P (upper part of the circle)
- A (centre, lettered just above the line HAB)
- H (left end of the line, outside the circle)
- B (right end of the line)
- N (on the right edge of the circle, at the line AC)
- C (in the small right circle)
- K (on the lower left edge of the circle, at the line AG)
- G (in the small left circle)
- L (on the path, below A)
- I (on the path, beside L)

Let the points of the lunar centres be joined to the centre of the shadow by the lines AC and AG, which are the sum of the semidiameters. Let AI be perpendicular to the Moon's orbit: this is called the arc between the centres [Arcus inter centra], and is the shortest distance of the lunar centre from the centre of the shadow. And finally let LA be perpendicular to the ecliptic, or the Moon's latitude given for the moment of full Moon, which occurs when the Moon is at L. For LI will be the arc by which BL, the distance of the Moon from the node, differs from AB, the distance of the centre of the shadow from the same node B. Therefore, as Kepler observes in the *Epitome of Astronomy* p.

864, and assumes in the Rudolphine Tables, chapter 31, precept 146, the arc LI will be equal to the arc of the reduction of the Moon to the ecliptic, which is known from the Moon's argument of latitude, either from its own small table based on the obliquity of the lunar orbit, which for most writers is 5° in eclipses, for Tycho 4° 58½′, and for Kepler 5° 18′; or from the solution of the triangle, discussed in Book 4, last chapter. With this laid down, there are three ways of finding the arc AI.

[Margin: First way of finding the arc between the centres: Kepler's.]

The first is Kepler's, in the *Epitome of Astronomy* p. 864. Subtract the arc LI of the reduction from the Moon's argument of latitude itself, or from its distance from the nearer node, if the Moon's latitude is northern ascending or southern descending; or add it, if the latitude is southern ascending or northern descending. Then IB will be known, a side of the triangle ABI, right-angled at I, in which the base AB is likewise supposed known for the moment of full Moon, namely the distance of the centre of the shadow from the same node B, or the angle B at which the Moon's orbit is inclined to the ecliptic. So the arc AI cannot remain hidden.

[Margin: Way 2: ours.]

The second way is ours, through the triangle ALI, right-angled at I, in which are given the base AL, which is the Moon's true latitude at opposition, and LI, the reduction of the Moon to the ecliptic; so the arc AI will easily be found.

[Margin: Shortcut for both ways.]

Briefly, in either way, let it be made: as the radius to the second sine of the given side, namely either IB or, in my way, LI, so the secant of the base AB or, in my way, AL, to the secant of the arc sought, AI. Or to the second logarithm of the given side add the residual of the second logarithm of the given base, and the result will be the second logarithm of the arc AI.

[Margin: Way 3: Kepler's and ours.]

The third way comes from Kepler in the Rudolphine Tables, chapter 31, precept 146, and his tables p. 98. Subtract the place of the nearer node from the place of the centre of the shadow, or the latter from the former if it comes first. With the degrees of the remainder enter the margin of the already mentioned table, under the minutes belonging to those degrees, and in the body of the table you will find, in place of the latitude, the arc between the centres. For Kepler holds that this differs insensibly from the Moon's latitude at the height of the eclipse, as I shall explain in Scholium 2. Or consult our table of the Moon's latitude for ecliptic conjunctions and oppositions; for there you have the arc between the centres.

PROBLEMA V.

Problem 5.

Inueſtigare ſcrupula Incidentiæ, Repletionis, Moræ dimidiæ, & Differentiæ inter momentum Plenilunij, & momentum ſummæ Eclipſis.

To investigate the minutes of incidence, of repletion and of half-stay, and those of the difference between the moment of full Moon and the moment of the height of the eclipse.

V. Small tables by practitioners do exist for this purpose. They are given by Ptolemy, Book 6, chapter 8; Alfonso, folio 116; Peuerbach, the penultimate table of eclipses; Reinhold in the Prutenic Tables p. 125; Magini in the *Secunda Mobilia* p. 687; and Lansbergen p. 40 and Renieri p. 349 of their tables. But they rest on the Moon's latitude at the moment of full Moon, used in place of the arc between the centres, and on the solution of a rectilinear triangle in place of a spherical one.

[Margin: On incidence in an eclipse of the Moon without stay.]

To solve the problem more exactly, then, repeat here the diagram of Problem 4, and in the triangle AIC, right-angled at I, in which are given the arc AI, found by Problem 4, and the base AC, consisting of the apparent semidiameter AN of the shadow and NC of the Moon, find the side CI, namely the minutes of incidence in an eclipse without stay. Equal to these are the minutes of repletion IG, because the triangle GAC, from the equality of the sums of the semidiameters AC and AG, is isosceles, and the perpendicular arc AI bisects the base GC, just as the chord of the arc AI bisects the chord of the arc GC, by 10 of the first book of Euclid.

[Margin: On incidence in an eclipse of the Moon with stay.]

But if the eclipse is with stay, repeat here the diagram of Problem 3, and in the triangle ALK, right-angled at L, from the arc AL, found by Problem 4, and the sum of the semidiameters AK, find the arc LK, namely the minutes of half-duration, to which the minutes LQ are equal. Then in the triangle ALN, right-angled at L, with the arc AL and with the base AN, which is the excess of the shadow's semidiameter over the Moon's semidiameter, find the minutes of half-stay LN, to which the minutes LV are equal; and when these are subtracted from LK, there will remain, in an eclipse with stay, the minutes of incidence alone, NK, which are equal to the repletion VQ.

Since, then, in all these triangles the base and one side are given, proceed as I said of the triangles of Problem 4. Or, in the manner of the old astronomers, treat them as rectilinear and, by 47 of the first book of Euclid, take the square number of the given side from the square of the given base; for a square will be left, whose square root will be the other side sought.

[Margin: Our quickest way.]

Or if you want to work more quickly, use the small tables, in the manner of the old astronomy, listed at the start of this Problem; but to the minutes of incidence found through them add the reduction of the Moon to the ecliptic, or subtract it, when it is to be added to or subtracted from the Moon. In a

total eclipse with stay, add or subtract that same reduction both to or from the minutes of half-duration and to or from the minutes of half-stay. The reduction itself is the difference between the opposition and mid-eclipse. Finally, multiply the already mentioned minutes by 3600″ of time, and divide the total by the Moon's hourly motion from the Sun, first reduced to seconds, and you will have the time corresponding to them.

PROBLEMA VI.

Problem 6.

De Horario Motu Lunæ à Sole.

On the hourly motion of the Moon from the Sun.

[Margin: On the hourly motion of the Moon from the Sun.]

VI. The Moon's hourly motion from the Sun becomes known by subtracting the Sun's true hourly motion from the Moon's true hourly motion in the zodiac. Both depend on the equation of the argument or anomaly, for the motion is neither perpetually equal nor always the same. For us, from what was said in Book 3, chapter 17, the Sun's mean hourly motion is 2′ 27″ 50‴ 50⁗, and the greatest equation of the solar motion, from Book 3, chapters 21 and 24, is 1° 59′. The Moon's mean hourly motion, from Book 4, chapter 23, is 32′ 56″ 27‴ 33⁗ 15ᵛ 40ᵛⁱ; and so the Moon's mean hourly motion from the Sun is 30′ 28″ 36‴ 43⁗ 15ᵛ 40ᵛⁱ. For others it is slightly different, from what was said in the same place; but there is no need of such subtlety, and it is enough to stop at seconds or thirds. There are, then, three ways in which the hourly motion of each heavenly body is obtained.

[Margin: Way 1 of finding the hourly motion.]

The first way is through the true motion of the Sun and Moon for the given day and for the day immediately before or after. For the difference of the true daily motion, whether it is collected directly from astronomical tables or from an accurate ephemeris, if divided by 24, will give the hourly motion sought. In place of division you can use the table that Reinhold made in the Prutenic Tables, p. 95, the use of which he teaches in precepts 19 and 31.

[Margin: Way 2 of finding the hourly motion.]

The second way, by which tables of the hourly motion are constructed, is this. Find the Sun's equation for the given time, and the equation belonging to a solar anomaly differing by one degree next to it, and take their difference. Of this take the proportional part according to the ratio of the mean motion 2′ 28″ to 60′. Subtract this proportional part from the Sun's mean hourly motion 2′ 28″ if the Sun's anomaly is less than 92° or 93°, at which the equation is greatest; but add it if the anomaly is greater than 93°, up to 183°; and you will have the Sun's true hourly motion. In this way you will construct a table of the solar hourly motion, such as Kepler has in the Rudolphine Tables p. 92. For the Moon, take the equation of the simple anomaly for the given time,

and the equation belonging to an anomaly next greater by one degree; and of their difference take the proportional part according to the ratio 41′ 49″ to 60′. Subtract this from the Moon's mean hourly motion 32′ 56″ if the anomaly is less than 95°; add it if greater, up to 180°; and thus you will construct a table of the Moon's hourly motion. When the Sun's hourly motion is subtracted from this, you will have the Moon's hourly motion from the Sun at syzygies. But if you use the difference of the equation composed from the first and second inequality, you will have the hourly motion outside the time of syzygies, the method by which tables of the Moon's hourly motion from the Sun are usually made for half a day before or after syzygies, so that it may serve for reducing mean syzygies to true or quasi-true ones.

[Margin: What gave the Tychonics the occasion of the Moon's Variation.]

Kepler notes in the Rudolphine Tables, chapter 31, precept 147, from Longomontanus's *Astronomia Danica* p. 173, that the occasion for detecting the lunar Variation was the acceleration observed at syzygies, and that the variation was cut off from the Moon's stay in the shadow. Further, the reason for the precept handed down by Regiomontanus is that the Sun's anomaly increases in one hour by 2′ 28″, and up to 93° of anomaly the equations grow, and from there they decrease; in the Moon's case, however, it is that one hour before or after mean syzygy the true anomaly differs from the mean by the hourly motion of the mean anomaly and by the equation of the centre, to which 41′ 49″ correspond.

[Margin: Way 3 of finding the hourly motion of the Moon and Sun.]

The third way is given by al-Battānī, chapters 31 and 43; Regiomontanus, Book 5 of the *Epitome*, proposition 21; Reinhold on Peuerbach p. 206; Magini, Book 2 of the *Theoricae*, chapter 25; and Barozzi, Book 4 of the *Cosmographia*, p. 341. For they say that the true hourly motion of the Sun is to the Sun's apparent diameter as 5 to 66, that is, in the subtredecuple sesquififth ratio [ratione ſubtredecupla ſeſquiquinta]. The Moon's hourly motion, moreover, is to the Moon's visual diameter as 48 to 47; or, on Copernicus's hypotheses, at apogee as roughly 29 to 30, but at perigee as roughly 37 to 35, or more accurately as 2255 to 2138.

[Margin: How to obtain the Moon's greatest and least hourly motion.]

Further, to have the least hourly motion of the Moon from the Sun, subtract the hourly motion of the Sun at perigee from the hourly motion of the Moon at apogee; but for the greatest, subtract the Sun at apogee from the Moon at perigee.

[Margin: Kepler's variation.]

Yet Kepler, in the *Epitome of Astronomy* p. 868, reports both his own and Tycho's opinion on the Moon's true hourly motion somewhat differently from the Rudolphine Tables, and differently from Tycho himself. For he says that the Moon's least hourly motion at apogee is for Tycho 29′ 46″, for himself 29′ 56″; the greatest at perigee, for Tycho 38′ 30″, for himself 38′ 43″. When the Sun's mean hourly motion is taken from these, there remains the hourly

motion of the Moon from the Sun: the least, for Tycho 27′ 18″, for himself 27′ 28″; but the greatest, for Tycho 36′ 2″, for himself 36′ 15″, because of the Variation, which is greater for him than for Tycho. Yet he concedes that it is better to use the hourly motion which holds at any given time. See also what the same Kepler teaches in our Book 4, chapter 19, Scholium 4. But Tycho, vol. 1, and following him Longomontanus, Mulerius and Magini, put the Moon's hourly motion at apogee as 27′ 43″, at perigee as 33′ 24″, at syzygies; but with the Sun placed at its mean distance, and its hourly motion as 2′ 28″. When this is added to the Moon's motion, the Moon's true hourly motion is obtained: in the former case 30′ 11″, in the latter 35′ 52″, as we have set down in the small table that follows.

[Margin: Authors of tables of the hourly motion of the Sun and Moon.]

If anyone wants tables of the hourly motion for mean and true syzygies, they are given, for Ptolemy, Copernicus and Tycho, by Mulerius in the *Tabulae Frisicae* pp. 128, 176, 306, 432; by Peuerbach in the Tables of Eclipses; Reinhold in the Canon, pp. 95 and 97; Tycho, vol. 1, p. 128; Longomontanus, Book 1 of the *Theorica*, chapter 9, p. 301; Magini in the *Secundum Mobile*, vol. 2, p. 673, and in the *Supplement to the Ephemerides* p. 290; Ke- pler in the *Epitome*, p. 868, and in the Rudolphine Tables, pp. 92 and 98; Lansbergen in the Tables, p. 36; Wendelen in the *Idea of the Atlantic Tables*, pp. 33 and 34; and Boulliau in the *Philolaic Tables*, p. 138. Among these, Peuerbach, Reinhold and Magini in his old Canon set out the true motion for a number of hours and days, the last adding the time for verifying the syzygies that corresponds to the hourly motion of the Moon from the Sun. Now let the true hourly motion of the luminaries, least at apogee and greatest at perigee, be taken from the authors just cited.

The true or apparent hourly motion of the luminaries; but of the Moon in conjunction and opposition.

PROBLEMA VII.

Problem 7.

De Maxima Duratione Lunaris Eclipſis & Maxima Mora in Totali Eclipſi.

On the greatest duration of an eclipse of the Moon and the greatest stay in a total eclipse.

[Margin: Method of finding the greatest duration and the stay of an eclipse of the Moon.]

VII. Once the hourly motion of the Moon from the Sun is known, it is easy to determine the longest duration of an eclipse of the Moon, and also the longest stay in the shadow or penumbra. For, as Kepler teaches in the *Epitome of Astronomy*, p. 869, the sum of the apparent diameters of the Moon and of the shadow or penumbra, divided by the true hourly motion of the Moon from the Sun, will give the hours and minutes of the greatest duration. Again, the difference of those same diameters, divided by the true hourly motion of the Moon from the Sun, will give the hours and minutes of the greatest stay in the shadow or penumbra. These occur when the Moon at mid-eclipse is at the node, for then the Moon's path differs imperceptibly from the arc of the ecliptic. And so, in the figure placed at no. 3, the eclipse begins at R and ends at P, and from the beginning of the total eclipse to its end the Moon traverses the diameter RAP and, besides that, as much space as the Moon's own diameter.

[Margin: The longest duration of an eclipse of the Moon, and the stay in darkness.]

It is enough for us at this point to gather into the following small table the view of Kepler on this matter, and from him that of Tycho, from p. 869 of Kepler's own *Epitome of Astronomy*, so that it may be clear that the duration is greatest when both luminaries are at apogee. For, as Kepler notes in the *Epitome of Astronomy*, p. 868, although the Earth's shadow is thicker at the place of the Moon at perigee, the Moon is faster there, and the hourly motion stands in a greater ratio than the traverse at perigee does to the traverse at apogee. Later we shall add a second small table, constructed by ourselves.

The greatest duration of an eclipse of the Moon, from Kepler's Epitome.

Luminaries: Sun	Moon	By Tycho's values	By Kepler's values
at apogee	at apogee	$4^h\ 20^m\ 4^s$	$4^h\ 18^m\ 18^s$
at apogee	at perigee	$3^h\ 39^m\ 22^s$	$3^h\ 38^m\ 46^s$
at perigee	at apogee	$4^h\ 19^m\ 40^s$	$4^h\ 18^m\ 6^s$
at perigee	at perigee	$3^h\ 38^m\ 40^s$	$3^h\ 37^m\ 26^s$

The longest stay of an eclipse of the Moon in the Earth's penumbra.

Luminaries: Sun	Moon	By Tycho's values	By Kepler's values
at apogee	at apogee	$2^h\ 8^m\ 36^s$	$2^h\ 7^m\ 58^s$
at apogee	at perigee	$1^h\ 50^m\ 38^s$	$1^h\ 50^m\ 46^s$
at perigee	at apogee	$2^h\ 7^m\ 20^s$	$2^h\ 6^m\ 38^s$
at perigee	at perigee	$1^h\ 49^m\ 24^s$	$1^h\ 48^m\ 48^s$

The greatest duration of an eclipse of the Moon, with the Sun and Moon at apogee, by our own computation and from the data of the authors named.

From the data of	Duration
Ptolemy	$4^h\ 6^m\ 42^s$
Copernicus	$4^h\ 8^m\ 8^s$
Tycho	$4^h\ 17^m\ 37^s$
Longomontanus	$4^h\ 15^m\ 0^s$
Kepler	$4^h\ 22^m\ 30^s$
Lansbergen	$3^h\ 57^m\ 40^s$
Boulliau	$4^h\ 7^m\ 45^s$
Wendelen	$4^h\ 13^m\ 0^s$
Ourselves	$3^h\ 57^m\ 6^s$

For physical reasons, however, a varying refraction of the Sun's rays can make the thickness of the penumbra vary, and with it the duration and the stay of an eclipse of the Moon.

SCHOLIA.

Scholia.

[Margin: The common error about the midpoint of an eclipse and the parts of its duration.]

I. It is commonly believed that the moment of full Moon and the moment of greatest obscuration are the same, and therefore that the Moon's latitude is the same at both moments, and that there is as much space from the beginning of the eclipse to the moment of full Moon as from the full Moon to the end of the eclipse. But if one is to proceed by strict astronomical right, these three things differ from one another, as is affirmed by Ptolemy, Book 6, chapter 17; Regiomontanus in the *Epitome*, Book 6, Prop. 15; Kepler in the Rudolphine Tables, chapter 31, Precept 145; Wendelen in the *Idea of the Atlantic Tables*, p. 38; and Boulliau, Book 4 of the *Astronomia Philolaica*, chapter 7, and in the Tables, p. 138. For the greatest obscuration occurs at the moment at which a perpendicular to the Moon's path can be drawn from the centre of the shadow or penumbra to the Moon's centre: this is the shortest line, by which the Moon's centre comes nearest to the centre of the shadow, unless the full Moon takes place at the nodes. But the moment of full Moon is commonly taken to be that at which a perpendicular can be drawn from the Moon's centre to the place on the ecliptic diametrically opposite the Sun, just as the moment of new Moon is when a perpendicular can be drawn from the Moon's centre to the Sun's centre on the ecliptic. Thus in the diagram of Problem 4 set out there, if two perpendiculars are drawn, one from the centre A to the Moon's centre at I, the other from the Moon's centre placed at L to the point A on the ecliptic, AI will certainly be shorter than AL, because in triangle ALI, right-angled at I, the right angle LIA subtends a greater side, AL, than the side AI, which is subtended by the acute angle ALI, by 19 of Book 1 of Euclid. Indeed, when the straight lines ANC and AKG are drawn, at the time when the Moon is there at the beginning and here at the end of the eclipse, no line shorter than AI can be drawn from A to GG [recte: GC] in triangle GAC. In this diagram, therefore, the moment of greatest obscuration, which occurs at I, precedes the moment of full Moon, which occurs at L, by the whole arc or side LI; namely, because the Moon has passed the node B.

Diagram. A geometric figure at the head of the left column. A large circle has its centre at A, with a straight line running from H on its left edge through A and out beyond the circle to B on the right. A second straight line runs from B down to the left, crossing the right edge of the large circle and its lower part. Two small circles, one at each end of this chord, lie on the edge of the large circle: the right-hand one with centre C, the lower-left one with centre G. Straight lines run from A to the chord through N towards C, through K towards G, and two short lines from A down to the chord at L and at I.

- P (upper part of the large circle, above A): label
- A (centre of the large circle): label

- H (left end of the horizontal line, on the circle): label
- B (far right, where the two straight lines meet): label
- N (on the line from A towards C, at the right edge of the large circle): label
- C (inside the right-hand small circle): label
- K (on the line from A towards G, at the lower-left edge of the large circle): label
- G (inside the lower-left small circle): label
- L, I (side by side on the chord below A, L to the left): labels

But if the Moon is approaching the node, the moment of greatest obscuration follows the moment of full Moon. Hence it comes about that, although the space IC, from the beginning of the eclipse to the height of the eclipse, is equal to the space IG, from the height of the eclipse to the end, because the perpendicular AI bisects the base GC of the isosceles triangle GAC, by 10 of Book 1 of Euclid, yet the space CL, from the beginning of the eclipse to a full Moon occurring outside the nodes, is longer than the space LG, from the full Moon to the end of the eclipse, when the Moon is receding from the nodes, that is, has a northern ascending or southern descending latitude; but conversely the former is shorter than the latter when the Moon is approaching the node.

[Margin: Whether the spaces between the beginning and end of an eclipse are equal?]

Finally, the Moon's latitude is less at the moment of greatest obscuration than at the moment of full Moon, and the arc between the centres, that is, the perpendicular determining the greatest obscuration, is greater than the latitude at the height of the eclipse but less than the latitude at full Moon. In the figure above, the arc between the centres is AI. But in the figure placed and explained already in chapter 4, problem 1, the arc between the centres is BM, the latitude belonging to the greatest obscuration is ME, and the latitude at the beginning of the eclipse is PI.

[Margin: What is the arc between the centres?]

[Margin: Whether the differences just mentioned should be passed over.]

II. Now Ptolemy, and Regiomontanus subscribing to him, say that it is indeed shameful for an astronomer not to know these differences and subtleties, but that they deliberately omitted them in the calculation of eclipses, because they are differences in some measure imperceptible to the appearance of the senses; and that if anyone seeks exact knowledge of this matter, the difficulty will distress him far more than the usefulness will delight him. But the more recent astronomers, Kepler, Wendelen and Boulliau, thought this difference not to be despised, since it can reach about 6^{m} of time. So in triangle ABL of the diagram above, right-angled at A, the latitude AL at the moment of full Moon is supposed given, together with the true distance of the centre of the shadow A from the node B; therefore the angle ALB, that is ALI, can be found. With this angle and with the latitude AL, in the small triangle ALI, right-angled at I, the side LI is found. Divided by the Moon's hourly motion from the Sun,

LI will give the time to be subtracted from the moment of full Moon if the Moon is receding from the nearer node, and to be added if it is approaching, so as to have the moment of greatest obscuration, which bisects the duration of the eclipse and the stay in the shadow. For that moment compute the Moon's place and reduce it to the ecliptic: for the difference between the place M in the orbit and the place E on the ecliptic will be BE, in the diagram of chapter 4, no. 2. With that difference and with the arc between the centres, BM, you will compute in triangle BME, right-angled at E, the Moon's true latitude belonging to the moment of greatest obscuration.

We do not need this latitude, however; it is enough to compute the arc between the centres, namely AI, in the former diagram, by means of the latitude AL and the arc LI, which is equal to the reduction of the Moon to the ecliptic; or with AB, the distance of the centre of the shadow from the node, and IB, the argument of latitude, which differs from the distance AB by the arc IL of the reduction of the Moon to the ecliptic, as Kepler notes in the *Epitome*, p. 863. Astronomers, moreover, use straight lines and chords of arcs in place of arcs, because in these, given their smallness, there is no danger of sensible error, as Ptolemy, Book 6, chapter 17, Copernicus, Book 4, chapter 32, and Kepler in the *Optics*, p. 418, point out; though we could also use arcs.

[Margin: Kepler's and Boulliau's tables for these things.]

For the arc between the centres and the latitude at the greatest obscuration, however, you can use Kepler's table, of which he speaks in the Rudolphine Tables, Precept 45, or our own table made for the purpose; and for the difference of the moment of full Moon from the moment of greatest obscuration, use Boulliau's small table, which he has on p. 138 of his Tables, or another like it in our own Tables, or the reduction of the Moon to the ecliptic converted into the time of the Moon from the Sun.

III. Nor is this the end of the subtleties. For Tycho, in a most learned letter to Rothmann, dated 1587 January 20, p. 72, relates that in 1584 on November 7, Old Style, he observed the beginning of an eclipse of the Moon, by the equatorial distance of stars from the meridian, at $11^h\ 12^m$ after noon at Uraniborg; the middle at $13^h\ 8^m$ and the end at $15^h\ 0^m$, so that the earlier part of the duration was longer than the later by 4^m of time. And he adds in parenthesis: *For these times are not always equal, as has been believed until now.*

[Margin: Whether the parts of the duration of an eclipse, computed from the moment of greatest obscuration, are equal.]

Yet Kepler, Wendelen and Boulliau passed over this inequality. Indeed Kepler says in the Rudolphine Tables, chapter 31, Precept 151: *There will remain the time of incidence or of emersion, without distinction: for they are equal, because we are working by the moment of greatest obscuration.* So, reckoning not from the moment of true full Moon but from the instant [punctiſtitio] of greatest obscuration, he counts the time of incidence equal to the time of repletion.

[Margin: Suspicion about Tycho's credit.]

Now as for Tycho's observation, Wendelen in the *Eclipses*, p. 48, charges it with being of slight credit. And why? Because the same Tycho, drawing it to his own tables in the catalogue, puts the middle at $13^h\ 12^m$; and because Wendelen, making the two times on either side of the middle equal, says that the middle was at $13^h\ 6^m$, since the duration was $3^h\ 48^m$.

But whatever may now be said of Tycho's credit, it must first be admitted that the moment of greatest obscuration cannot be observed exactly, because at the height of a partial eclipse the Moon lingers for some time; and in a total eclipse, such as that one of Tycho's was, the middle is not observed at all. In both, therefore, we are forced to infer the middle: in a partial eclipse from its beginning and end, by bisecting the time elapsed; but when the eclipse is total, the time of the stay is usually divided in two, and half of it shows the middle of the eclipse. We can, however, observe the time of incidence and of emersion, and it is not seldom found to be unequal. And in truth the times of these are not always equal, nor is the time from the beginning of total obscuration to the greatest obscuration equal to the time from there to the beginning of emersion. For neither the motion of the Earth's shadow, whose axis does not stay in the same place, nor the motion of the Moon is equal throughout the time of the eclipse (granted that the space of the ecliptic or of the Moon's orbit from the beginning to the height of the eclipse is equal to the space from the height to the end); rather, the motion becomes faster as the Moon tends towards perigee, and slower towards apogee. And although we use the hourly motion of the Moon from the Sun sought for the full Moon or for the point of greatest obscuration, and it seems to be the mean between the faster and the slower motion that belongs to the Moon from the beginning or at the end, it is nevertheless not always so. So, if every subtlety is to be taken into account, it is better to compute for the beginning and end of the eclipse, determined in the usual way, the most exact anomaly, and from it the hourly motion and the difference of motion, and by that difference to correct the moment of mid-eclipse and to separate exactly the time of incidence from the time of emersion. But because the difference is very small, and because, if it seems greater in observations, the excess is put down to the fallibility of observations, astronomers everywhere usually disregard it.

[Margin: On the Moon's stay in the sheer shadow.]

IV. From what was said in chapter 5, at the end of no. 10, the Moon's stay in the sheer shadow of the atmosphere could have been separated out, apart from the penumbra that makes the beginning and end of the eclipse on either side, and the axis of the cone TNV described there could have been brought to a measure. But because that measure varies with the inconstancy of refractions, and the moment at which the Moon begins to enter that inverted cone or to leave it is not easily observable, we have not wished to add this new labour to the calculation of eclipses or to draw up new small tables for that part of the eclipse.

V. Whatever was said in chapter 5 and in its Scholia 2 and 3 about the umbrago, about the arched clouds, and about the variation of the penumbra from various refractions should be recalled here, because these things can vary the duration and the beginning and end of the eclipse for physical and optical causes; as can any causes that vary the Moon's apparent diameter by accident.

[Margin: Whether the duration of an eclipse of the Moon is varied by a lunar air or by the Moon's refractions.]

Among these causes David Fabricius, as reported by Kepler in the *Ephemerides*, pp. 9 and 22, and Wendelen in the *Eclipses*, p. 5, posit a circumlunar air, on account of which the Moon's diameter is dilated up to 4′ or 5′, and the Moon appears larger, and is therefore touched by the shadow sooner and emerges from it later. But this does not please Kepler, there and in the *Optics*, p. 286; nor is that air so evident, or so dense or thick for this effect, as the increase of the atmospheric penumbra above the shadow computed in the old way is evident. It is to this increase, then, rather that the acceleration of the beginning and the greater duration of the eclipse are attributed. The refraction of the lunar rays, by contrast, on account of which the Moon looks larger near the horizon, does not change the beginning or end of the eclipse, though it may visibly raise the visible points of the lunar disc and make the uneclipsed digits larger; on this matter see what I reported from Longomontanus in Book 4, chapter 16, no. 8. Finally, remember the small equation to be applied in equinoctial eclipses, if indeed what

Kepler says in the Rudolphine Tables, Precept 171, is true: that the Moon goes under the Sun or the shadow later around the point of the vernal equinox, and earlier around that of the autumnal one. On this equation consult him, and ourselves in the precepts of the Tables.

[Margin: The optical enlargement of the Moon in sight has no laws.]

He also rightly points out, in the *Astronomia Optica*, p. 285, that in ecliptic full Moons the Moon appears larger next to the Earth's shadow, because bright things next to dark ones appear larger, and that thus the Moon's edges are not thinned but enlarged by an optical deception; yet the astronomical tables are not to be changed on that account, since this cause is inconstant and varies with the variety of eyes.

CAPVT VII.

Chapter 7.

De Typo Eclipſis Lunaris graphicè oculis ſubijciendo; eiuſq. plagis ac flexu tenebrarum, ſeu Inclinationibus.

On setting the delineation [Typus] of an eclipse of the Moon graphically before the eyes; and on its quarters and the bending of the darkness, that is, its inclinations.

[Margin: Authors who treat this technique.]

I. This technique too was handed down to us by Ptolemy, Book 6, chapter 13; al-Battānī, chapter 43; Peuerbach, proposition 17 of *On Eclipses*; Peter Apian in the *Astronomicum Caesareum*, statement 27; Reinhold in Peuerbach's *Theoricae*, p. 203, and in the Prutenic Tables, Precept 65; Magini in the *Secunda Mobilia*, Canon 74; Tycho, vol. 1, p. 131; Longomontanus in the *Astronomia Danica*, p. 309; and Origanus, vol. 1, p. 267. Most of them set out such delineations on their pages so that the north is in the upper part and the south in the lower; Regiomontanus, however, has the opposite in the diagram and notes to al-Battānī, chapter 43, as you see in the following diagram, in which the east is at I and the west at D, and the ecliptic is IFD, which the line AC cuts at right angles at F.

Diagram. A geometric figure in the left column. A large circle AICD has its centre at F; a vertical line runs from A at the top through F to C at the foot, and a nearly horizontal line from I on the left through F to D on the right. Inside it and concentric with it stands a second circle, on which G and S lie. A small circle stands on the vertical line above F, with L at its top, E at its middle and H at its foot. Two further small circles straddle the large circle: one upper left with centre M, one right with centre K. Straight lines run from M to L; from M through E to K; from H to K; from M through F to T on the large circle at lower right; and from K through F to Q on the large circle at lower left.

- Meridies (above A, top): "South"
- A (top of the large circle): label
- Septent. (below C, foot): "North"
- C (foot of the large circle): label
- I (left of the large circle): label
- D (right, on the large circle): label
- F (centre, below the crossing of the lines): label
- M (inside the upper-left small circle): label
- G (on the inner circle, below the upper-left small circle): label
- K (inside the right-hand small circle): label
- S (on the inner circle, left of the right-hand small circle): label
- L, E, H (on the vertical, in the small circle above F, top to foot): labels
- Q (lower left, outside the large circle): label
- T (lower right, outside the large circle): label

The apparent semidiameters of the Moon and of the shadow or penumbra must be known beforehand, as well as the Moon's true latitude at the beginning and end and at the middle of the eclipse, with the kind or quarter of the latitude. With these set down, from the point F, the centre of the shadow, at the distance FK, which should equal the sum of the semidiameters of the Moon and the shadow, describe the circle AICD; and from the same centre F, at the distance of the semidiameter FS of the shadow alone, describe the shadow's circuit LGS. Now let the Moon's latitude at full Moon be FE, southern, as in this delineation, and the Moon's centre at E; and on the line FA let FH be taken, equal to the

Moon's latitude belonging to the beginning of the eclipse. For if from the point H you draw to the outer circumference a straight line HK perpendicular to AF, you will have the point K, at which the Moon is at the beginning of the eclipse. From there, then, at the distance of the lunar semidiameter KS, describe the Moon's disc touching the shadow at S. Again on AF take the latitude FL belonging to the end of the eclipse, since in our delineation the latitude is increasing; and when ML is drawn perpendicular to AF, you will have at M the centre of the Moon touching the shadow at G, for the end of the eclipse. When the centres K, E, M are joined, you will mark out the Moon's path in the lunar orbit. A different procedure is needed if the Moon's latitude decreases, and a different one again if the latitude changes its kind in the course of the eclipse, as when, from K, having passed the node F, the Moon comes to Q by ascending, or from T to M by descending. For the proportion of those lines it is useful to have ready a line divided into 60 or more equal small parts representing minutes, from which lines in proportion can be carried over into the delineation of the eclipse. Recall also, from the diagram set out in chapter 4, no. 2, the delineation of an eclipse of exactly six digits, with the Moon receding from the ascending node; and, from chapter 6, no. 3, the delineation of a partial and of a total eclipse.

II. As for the quarters or regions towards which eclipses, that is, the portion of the eclipsed luminary, bend or incline, let us hear Ptolemy, Book 6 of the *Almagest*, chapter 11, who says: *It follows now that we should also consider the inclinations of the obscurations, in Greek* [Greek: ἐπισκοτήσεων προσνεύσεις (episkotēseōn prosneuseis, "inclinations of the obscurations")]*; the understanding of these depends on knowledge of the inclination that both the eclipses themselves have to the ecliptic and the ecliptic itself to the horizon, each of which, at the individual times of an eclipse, produces a very great and incomprehensible change in the transits, if anyone should wish with useless care to investigate the inclinations to come throughout the whole time of the eclipse, since this minute prediction is neither necessary nor useful.*

[Margin: Whether the quarters and inclinations of eclipses are useful to know.]

From this I see that both the theory and the practice of these inclinations have been neglected by almost all astronomers: only Regiomontanus, in Problem 50 of the *Primum Mobile* and in the *Epitome of the Almagest*, Book 6, Propositions 28, 29 and 30, and Kepler in the *Astronomia Optica*, from p. 407 on, have tried this ford. To astrologers, however, the diversity of these inclinations and quarters seems somewhat more useful, so that they may be able to predict which eclipses or phases of eclipses will do most harm or most good to which regions, as may be seen in Ptolemy in the *Quadripartitum*, Book 2, chapter 7, and his interpreters.

[Margin: What is the quarter or aspect of an eclipse?]

So Ptolemy, not to seem to have passed over this topic altogether, gave certain easier methods for the beginning and end of eclipses, and for the beginning

of total obscuration and of repletion. We too shall imitate him, after setting down two definitions first. Let the first be this: the quarter, or rather the aspect [respectus], of an eclipse is the point of the horizon towards which the part of the luminary eclipsed, or placed on the border of the eclipse, points straight; that is, the point on which falls the line or arc drawn from the centre of the obscured body through the centre of the obscuring one.

[Margin: What is the inclination of an eclipse?]

The inclination of an eclipse, or the bending of the darkness, is the angle between the ecliptic and the arc drawn through the centres of the obscuring and the obscured luminary. Thus, in the preceding figure, if the Moon at the beginning of the eclipse is at K, and we conceive the circle AICD to be the horizon, the line or arc KFQ drawn from the centre K through F, the centre of the shadow, will mark at Q the quarter on which the obscured part, or the part soon to be obscured, looks straight; and the inclination of the eclipse will be the angle KFD, equal to the angle QFI that the arc KFQ makes with the ecliptic IFD. But if at the end of the eclipse the Moon's centre is at M, when the line MFT is drawn, the quarter on which the eclipse looks will be T, and the inclination the angle MFI. Conversely, if the Moon were at T, the quarter would be M; and if at Q, the quarter would be K. Hence it comes about that at the beginning of an eclipse of the Moon or of total obscuration the eclipsed part usually inclines towards the eastern part of the horizon, and looks on the rising, now equinoctial, now summer, now winter, or on other quarters of the winds; while at the end of an eclipse of the Moon, or at the beginning of emersion, it inclines towards the western part of the horizon and towards the setting, equinoctial or summer or winter, or another region of the wind; and in the middle it usually inclines towards the north if the latitude is southern, and towards the south if northern. By contrast, in an eclipse of the Sun the eclipsed part of the Sun ordinarily inclines towards the setting at the beginning and towards the rising at the end, and in the middle, if the Moon's visible latitude is southern, towards the south, and if northern, towards the north. With these things explained, let there be.

PROBLEMA I.

Problem 1.

Inclinationem Eclipſis inueſtigare.

To investigate the inclination of an eclipse.

[Margin: Our method is better than Ptolemy's.]

III. Ptolemy (Book 6, chapter 11) and Regiomontanus (Book 6, Proposition 28) use straight lines for curved ones, and treat the Moon's path as parallel to the ecliptic, because the arcs are so small. But this parallelism is not necessary here, nor indeed are straight lines; and Regiomontanus himself warns us of this in the same place, saying: *But if you wish to rest on complete precision, do the work by the*

science of spherical triangles. In the preceding figure, then, let FH be given, equal to the Moon's latitude at the beginning of the eclipse, and FSK, the sum of the semidiameters of the obscuring and the obscurable body. For in the triangle FHK, right-angled at H, the angle HFK can be found, and its complement to a right angle will be the inclination KFD. Likewise at the end of the eclipse, FL, equal to the latitude, and FGM, the sum of the semidiameters, will in the right-angled triangle MLF reveal the angle MFL, which is the complement of the inclination MFI. But for the beginning of total obscuration, or of emersion, one must use for the sides, taken on the line AC, the Moon's latitude belonging to those phases, and for the base FK or FM the remainder of the shadow's semidiameter after the Moon's semidiameter has been subtracted from it. In an eclipse of the Sun, use the visible latitude. Ptolemy, however, used the arc between the centres at the middle of the eclipse, found by means of the ecliptic digits, and the right angle made by that arc both with the ecliptic and with the Moon's path. From that arc and the sum or remainder of the semidiameters he sought, in a right-angled rectilinear triangle, the angle opposite the arc through the centres, which, because of the sensible parallelism, is equal to sense to the angle of the inclination sought. And he composed the following small table, supposing the Moon to be at a mean distance from the Earth.

[Margin: The Ptolemaic small table of the inclinations of eclipses.]

The inclination of eclipses to the ecliptic.

Dig-its	Sun, at beginning and end of eclipse	Moon, at beginning and end of eclipse	Moon, at beginning of total obscuration and of emersion
0	90° 0′	90° 0′	0° 0′
1	66° 50′	72° 30′	
2	56° 59′	65° 10′	
3	49° 16′	59° 27′	
4	42° 36′	54° 27′	
5	36° 35′	50° 14′	
6	31° 1′	46° 15′	
7	25° 46′	42° 31′	
8	20° 44′	39° 2′	
9	15° 51′	35° 42′	
10	11° 6′	32° 29′	
11	6° 25′	29° 23′	
12	1° 42′	26° 23′	90° 0′
13		23° 28′	63° 27′
14		20° 36′	52° 24′
15		17° 48′	43° 26′
16		15° 1′	35° 41′
17		12° 18′	28° 38′
18		9° 36′	22° 1′
19		6° 55′	15° 43′
20		4° 15′	9° 36′
21		1° 36′	3° 35′

PROBLEMA II.

Problem 2.

Punctum Horizontis, quod flexus Eclipſium reſpicit, determinare.

To determine the point of the horizon towards which the bending of eclipses looks.

IV. Regiomontanus sets out this problem in Problem 50 of the *Primum Mobile* and in Book 6 of the *Epitome*, Proposition 30, by solving three triangles. Consult him, if you please, for exercise in these matters, which are not at all necessary. Or else, at any rate, take a globe and set it to the given elevation of the pole, turning it until the rising point of the ecliptic that belongs to the time of the phase of the eclipse stands on the eastern horizon. Then, according to the Moon's latitude given at the time of the eclipse and the inclination taken from the preceding table, draw an arc of a great circle through the centres of the obscuring and the obscured body; for that arc will mark on the horizon the point sought. But if the Moon has no latitude, the ortive amplitude of the ascending point of the ecliptic at the beginning of the eclipse and of the stay, or at the end, will indicate the point of the horizon sought. What pertains here specifically to an eclipse of the Sun will be stated below, in chapter 13, from Kepler's *Astronomia Optica*, p. 411, and the astronomical *Epitome*, from p. 887 on.

SCHOLION.

Scholion.

[Margin: Eclipse of the lunar spots.]

Someone might wish that, in the delineation of eclipses, the lunar spots were distinguished: those obscured first and those obscured last, or those across which the section of the Earth's shadow passes at a given time within the duration of the eclipse. For this our selenography, on which see Book 4, chapter 7, is not useless. But we reserve this for the Geographical Book, where the difference of longitudes is to be corrected by means of eclipses of the spots.

CAPVT VIII.

Chapter 8.

Quid & Quotuplex ſit Eclipſis Solis; & in quo differat ab Eclipſi Lunæ.

What an eclipse of the Sun is, and of how many kinds; and in what it differs from an eclipse of the Moon.

[Margin: The causal definition of an eclipse of the Sun, and its cause.]

I. An eclipse of the Sun, if you look for the definition drawn from its cause, following Aristotle in Book 2 of the *Posterior* [*Analytics*], chapter 1, *is the interposition of the Moon*, that is, between the Sun and our sight. *For it is evident that the Sun is hidden by the Moon coming between, and the Moon by the Earth's being set against it; and that they return the turn, the Moon by its interposition taking the same rays of the Sun away from the Earth, and the Earth from the Moon*, says Pliny the Elder, Book 2, chapter 10. It is evident, he says, but to the wiser. For although, according to Plutarch, Book 2 of *De placitis philosophorum*, chapters 24 and 29, a few held otherwise, and Anaximander said that the failing of the Sun comes about *when the breathing-hole in the rim of the solar wheel is blocked*; or at any rate, as Heraclitus says in the same author, *by the turning of the solar bowl, bright only on its hollow side, when it is then rolled over upwards*; or, if Xenophanes were listened to, who thought that there are, or appear to be, several Moons and Suns in different regions, *by a real extinction of the Sun, while another is meanwhile reborn*: nevertheless, as the same Plutarch reports in the same place, Plato, Aristotle and the mathematicians agree with Thales, *who first showed that the Sun is eclipsed when the Moon passes under it on the perpendicular, since the Moon is opaque by nature, just like the Earth.* Pericles convinced a frightened ship's captain of this by drawing his own cloak over the man's eyes, as we related in chapter 2, number 9, from Plutarch, who adds in the *Nicias* that it was somewhat better known to the Athenians that the Sun is darkened by the Moon coming between than that the Moon is darkened by the Earth's interposition. We have also already reported from Dio, in chapter 2, number 10, that by order of the Emperor Claudius the true cause of an eclipse of the Sun that threatened on his birthday was to be explained to the Roman people as well, lest some disturbance should arise from it.

[Margin: The essential definition of an eclipse of the Sun.]

II. Defined formally, as they say, or quidditatively, an eclipse of the Sun is nothing other than *the privation of solar light in the sublunary region, arising from the Moon's interposition between the Sun and that region.* For the Sun itself does not truly fail in itself, or lose its own light. It is rather that tract of aether, air and earth between which and the Sun the opaque body of the Moon intervenes, and hence also our sight, when we are in that tract. That is why Cleomedes, Book 2 of the *Cyclical Theory*, said: *It is surely not the Sun's condition but our sight's that is called a defect in the Sun.* For granted that the body of the Moon is of far smaller bulk than the body of the Sun, as we showed in Book 4, chapter 17, and is contained in the Sun not only 5848 times, as Tycho thinks, but 2123000 times, as we deduced there from our own principles, and indeed 13833632 times, as Wendelen's tenets require. Yet because of the Sun's immense distance it appears a foot across, and no larger than the Moon, indeed sometimes smaller.

[Margin: Pliny the Elder's slip.]

Yet Pliny the Elder erred in Book 2, chapter 11, in saying: *For the whole Sun could not, of course, be taken away from the lands by the Moon coming between, if the Earth were larger than the Moon.* For he thought that an eclipse of the Sun

occurs over the whole terrestrial hemisphere; if that were granted, Pliny the Elder's inference would be true. But it is not so. And Cleomedes, Book 2 of the *Cyclical Theory*, chapter 3, holds that *the Moon's own shadow cannot extend on the Earth beyond four thousand stadia.* Hence it comes about that at the same moment at which, for some, the whole Sun AB is covered by the Moon DE, as for a spectator at K, whom the outermost rays of the Sun, AK and BK, reach after touching the Moon at D and E, for others meanwhile the whole Sun appears, as for a spectator at F, whose visual rays FA and FB take in the whole Sun. For others again half of the Sun shines, as for a spectator at G, to whom the portion AC of the Sun appears while the portion CB is hidden from him; and for others it is otherwise.

[Margin: Why an eclipse of the Sun is not universal.]

For an eclipse of the Sun is not naturally universal over the whole diurnal terrestrial hemisphere, as an eclipse of the Moon is over the whole nocturnal hemisphere, because the Sun itself is not deprived of its own light, as the Moon is deprived of light that is another's, that is, received from the Sun, and because the Earth FGK is larger than the Moon DE.

Diagram. Set into the left column, beside the passage above. At the top, a large disc drawn as a rayed Sun with a human face. Two straight lines run from the left and right edges of the disc, crossing at the small Moon below, and a third runs down the centre from the foot of the disc. The small Moon, about two-thirds of the way down, has its lower half black. At the bottom a globe with land masses, its upper part drawn with coastlines, and a small standing human figure on top of it. Two further outer lines run from the sides of the Sun down to the sides of the globe.

- A (left of the Sun): the Sun's left edge
- B (right of the Sun): the Sun's right edge
- C (foot of the Sun, on the centre line): point on the Sun
- D (left of the small Moon): the Moon's left edge
- E (right of the small Moon): the Moon's right edge
- G (beside the standing figure on the globe): spectator on the Earth
- F (left of the globe): spectator on the Earth
- K (right of the globe): spectator on the Earth

[Margin: The cause and definition of an eclipse of the Sun are proved by 9 arguments.]

III. That an eclipse of the Sun comes from the Moon's intervention the astronomers show, with Ptolemy, Book 6. First, because it never occurs except at conjunctions of the luminaries, that is, only at apparent new Moons, which is of course the only time at which the Moon, shown in Book 4, chapter 14, to be lower than the Sun, can slip between the Sun and our sight.

[Margin: Second argument.]

Second, because it does not occur at all new Moons, but only at those at which the Moon's apparent latitude is less than the sum of the visual semidiameters of the Sun and the Moon.

[Margin: Third argument.]

Third, because it does not occur at the moment of the true new Moon unless that coincides with the visible one; when it does occur, it occurs at the visible conjunction, that is, when, along the longitude of the zodiac, the Moon is seen conjoined beneath the Sun by us who watch the luminaries from the surface of the Earth, even if, because of the parallaxes, it is not then always conjoined with the Sun with respect to a straight line drawn from the centre of the Earth to the luminaries.

[Margin: Fourth argument.]

Fourth, because an eclipse of the Sun is not total for all spectators in the hemisphere where it is otherwise day, but only for those from whose eyes a straight line can be drawn through the centres of both luminaries, provided that the Moon's apparent diameter is not less than the Sun's visual diameter. Nor is as much covered for all those for whom a part of the Sun is covered, but more for some and less for others, according to the difference in the position of the places, at which the Moon is seen so conjoined with the Sun that it cuts off for them a greater or lesser portion of the solar disc, as the lunar parallax in latitude requires.

[Margin: Fifth argument.]

Fifth, because an eclipse of the Sun never lasts longer than the time that the Moon's motion from the Sun requires for the Moon to be able to traverse, apparently, as much space as the Sun's disc or apparent diameter occupies; and, other things being equal, eclipses of the Sun are shorter when the Moon is faster and longer when it is slower.

[Margin: Sixth argument.]

Sixth, because an eclipse of the Sun begins at the Sun's western part, when the Moon, carried eastward by its apparent motion, which is faster than the Sun's, overtakes the Sun from that side; and for the same reason it ends at the Sun's eastern part.

[Margin: Seventh argument.]

Seventh, because ordinarily, when the Moon's apparent latitude is northern, the eclipsed part of the Sun, for those to whom it fails partially, is northern; but when the Moon's visible latitude is southern, the covered part of the Sun is southern.

[Margin: Eighth argument.]

Eighth, because the shape of a solar eclipse, when the whole Sun is not hidden, is such as the Moon's apparent circular figure requires when compared and conjoined with the Sun's circular figure, namely horned. So at the beginning and end of the eclipse, and also at the middle of a partial eclipse, the Sun appears horned like the Moon, or curved into horns, with the horns turned towards the west at the beginning and towards the east at the end of the eclipse, and towards the south if the Moon's visible latitude at the middle of the eclipse is southern, towards the north if northern; while the portion covered by the Moon appears as a segment of a black circle.

[Margin: Ninth argument.]

Ninth, because for those from whose eyes a straight line can be drawn through the centres of the luminaries, when the Sun's visible diameter is less than the Moon's apparent diameter, the whole Sun is eclipsed, with some stay in the eclipse and with dreadful darkness, and night is so turned into day that stars appear in the daytime. But when it is greater than the Moon's, a shining small circle of the Sun's body appears all round the Moon. And when, according to the anomaly of the luminaries and their distances already known from elsewhere, the apparent diameter of each is of the same size, the whole Sun is covered with no stay in the eclipse. Moreover, arguments 2, 3, 4, 5, 7 and 9 together show that among the causes of a solar eclipse are the parallaxes, or variations of view, in breadth and in length.

[Margin: The kinds of eclipse of the Sun.]

IV. Further, the kinds of eclipse of the Sun are as many as those of the Moon, indeed more.

[Margin: Total with a stay.]

For some are *total with duration*, in which the whole Sun is covered, so that for some stay the Moon remains beneath a Sun covered on all sides; and then more than twelve digits, or twelfths [vnciæ], of the Sun are said to be eclipsed, because if the Sun had more than 12 digits, it would still be obscured.

[Margin: Total without a stay.]

Some are *total without duration*.

[Margin: Partial, annular.]

Some are *partial and central*, or, so to speak, *annular*, in which a bright ring of the Sun, or crown, appears around the Moon. These three kinds occur when, and for those to whom, the Moon's apparent latitude is nil or almost nil, that is, when a straight line can be drawn from the eyes through the centres of the luminaries. But total eclipses with duration do not occur unless the Moon is nearer perigee and the Sun nearer apogee; and central ones do not occur unless the Moon is nearer its apogee and the Sun nearer perigee.

[Margin: Partial, horned.]

Others, finally, are *partial and horned*, in which the part of the Sun covered by the Moon appears crescent-shaped, that is, like a Moon curved into horns.

The diagrams of a partial non-annular eclipse, and of a total one with or without duration, are like the lunar diagrams set out in chapter 3, if in place of the shadow's circle the Moon is understood, and in place of the Moon there the Sun, but almost equal to the Moon in apparent size.

[Margin: How far the tip of the Moon's shadow extends in eclipses of the Sun.]

Meanwhile, it should be noted that in a central and annular eclipse the Moon's sheer shadow does not reach the Earth with its tip, as you see in the adjoining diagram, in which the sheer shadow HKI of the Moon HFI does not, with its tip K, reach the Earth P. And so of the Sun A only the portion enclosed by the arc CSD is hidden, while the small portion of it lying between BC and

DE is seen. You will understand this better from the following diagram, in which the eye at B sees the portion of the Sun MG and SK around

Diagram. Set into the right column, beside the passage above. At the top, a large circle, the Sun, with its centre at A; radii run from A out to points on the circumference at the left and right, and a vertical line runs down from A through the foot of the circle along the whole figure. From the two sides of the circle two long lines converge downward to a point at the foot of the figure. Partway down, a small circle, upper part blank and lower part solid black, with a horizontally hatched cone running down from its black part to a point. Below that, a second small circle, likewise part blank and part black. The long lines run on past it and meet at the bottom.

- A (centre of the large circle): the Sun's centre
- B (left, above the circle's side): point on the circumference
- E (right, above the circle's side): point on the circumference
- C (left, inside the circumference, lower than B): point on the circumference
- D (right, inside the circumference, lower than E): point on the circumference
- e (lower-case letter left of C, outside the circle): not cited in the text on this page
- S (just below the circle, on the vertical): foot of the arc CSD
- F (above the upper small circle, on the vertical): the upper Moon's top
- G (inside the upper small circle, on the vertical): not cited in the text on this page
- H (left of the upper small circle): the upper Moon's left
- I (right of the upper small circle): the upper Moon's right
- K (tip of the hatched cone): tip of the sheer shadow
- P (above the lower small circle, on the vertical): the Earth, as cited in the text
- L (inside the lower small circle, on the vertical): not cited in the text on this page
- N (left of the lower small circle): not cited in the text on this page
- M (right of the lower small circle): not cited in the text on this page
- R (below the point where the long lines meet): not cited in the text on this page the Moon, which lies between the rays ML and GEB on one side and KL and SDB on the other. And then in the tract of the Earth from which the rest of the Sun is hidden there is not sheer shadow but penumbra or umbrago, because, although it lacks many of the Sun's direct rays, it is still lit by some.

Diagram. Set into the left column, under its caption, *Figure 2*. At the top, the lower part of a large circle, the Sun, closed by a straight line across its top, with a second arc inside it leaving a crescent between the two. Dotted lines run from the two sides of the Sun down past the sides of a small Moon, part blank

and part black, with a short horizontally hatched cone below it; the dotted lines meet at the summit of a dome below, the Earth, closed by a straight base.

- S (top left): end of the Sun's top line
- K (top, right of S): point on the Sun's top line
- M (top, left of G): point on the Sun's top line
- G (top right): end of the Sun's top line
- D (left of the small Moon): the Moon's left
- E (right of the small Moon): the Moon's right
- L (tip of the hatched cone): tip of the shadow
- B (summit of the dome): point on the Earth's surface
- A (left end of the dome's base): the Earth
- C (right end of the dome's base): the Earth

But when an eclipse of the Sun is total, yet without any stay, the Moon's simple shadow then reaches the Earth exactly with its tip, as in Figure 3, in which the Sun is SFG, the Earth ABC and the Moon DE, and the outermost rays of the Sun, SDB and GEB, touch the Moon at D and E and meet at B, a point of the Earth's surface, and so bound the Moon's shadow DBE, ending at the point B.

Diagram. Set into the left column, under its caption, *Figure 3*. At the top, the lower part of a large circle, the Sun, closed by a straight line across its top. Two straight lines run from the ends of that line, touching the sides of a small Moon, part blank and part black with a hatched cone below it, and meeting at the summit of a dome, the Earth, closed by a straight base.

- S (top left): end of the Sun's top line
- G (top right): end of the Sun's top line
- F (below the Sun's arc, on the centre): the Sun's lowest point
- D (left of the small Moon): the Moon's left
- E (right of the small Moon): the Moon's right
- B (summit of the dome): the point where the rays meet
- A (left end of the dome's base): the Earth
- C (right end of the dome's base): the Earth

Finally, when an eclipse of the Sun is total and with duration, the Moon's shadow extends with its tip beyond the surface of the Earth, if the Sun's rays are imagined to penetrate the Earth. And just as the Moon in its eclipse transit cuts the Earth's conical shadow straight across, as if, to sense, with a flat disc, so that that conic section is, to sense, circular, so now the Earth cuts the Moon's shadow in such a way that on the surface of the Earth itself the shadowed tract is circular. So it is in Figure 4, in which the Moon DE is nearer the Earth ABCP, its shadow is DTE, and the part of the Earth obscured by it is BC.

Diagram. Set into the left column, under its caption, *Figure 4*. At the top, the lower part of a large circle, the Sun, closed by a straight line across its top. Two straight lines run from the ends of that line past the sides of a Moon, drawn larger than in the figure above, part blank and part black, and on to a point at

the base of a dome, the Earth. A hatched cone runs from the Moon's black part down through the dome to that point on its base.

- S (top left): end of the Sun's top line
- G (top right): end of the Sun's top line
- F (below the Sun's arc, on the centre): the Sun's lowest point
- D (left of the Moon): the Moon's left
- E (right of the Moon): the Moon's right
- B (left, where the cone enters the dome): the Earth
- C (right, where the cone enters the dome): the Earth
- A (left end of the dome's base): the Earth
- P (right end of the dome's base): the Earth
- T (below the base, at the cone's tip): the centre of the Earth, as cited in the text

Although in this diagram the tip of the lunar shadow is set as ending exactly at the centre of the Earth, T, that is not necessary in every total eclipse with duration. Indeed, when the Moon is at perigee, that tip is to be conceived far beyond the centre of the Earth, as we shall say in the next chapter. But this diagram was set down for the sake of an example.

V. From what has been said so far and what is yet to be said, it is easy to draw the comparison of lunar eclipses with solar ones and to discern the differences between them, which are very many; but we shall set them out more suitably in chapter 17.

SCHOLIA.

Scholia.

[Margin: Spurious eclipses of the Sun.]

I. This passage concerns an eclipse of the Sun taken astronomically, and its natural causes, of which there can be certain foreknowledge. Otherwise, that there are other eclipses from accidental causes, not falling under astronomical science, such as clouds, mists and the ashes of Vesuviuses, we have already related in chapter 1, Scholion 3; and in number 4 of the same chapter we showed that the extraordinary crimes of men are commonly counted among the moral causes of eclipses. These are nothing to us here.

II. The total and annular eclipses of the Sun that we have supposed here will be confirmed below, in chapters 19 and 20, by clear authorities and examples; although we have already argued for annular ones in Book 4, chapter 6, Scholion 1. Of the portents of evening and morning eclipses I shall speak in chapter 20, from number 7.

CAPVT IX.

Chapter 9.

De Vmbra & Penumbra Lunæ varijſq. Eclipſium Solarium Phaſibus inde ortis.

On the shadow and penumbra of the Moon, and the various phases of solar eclipses arising from them.

[Margin: What is the shadow of the Moon?]

I. Sheer shadow, which in this place is also simply so called, is the privation of all solar light, direct as much as refracted, in the sublunary region, because of the Moon's interposition. For the reflection of some rays from the Earth into air otherwise shadowed by the Moon, owing to the unevenness of valleys and mountains, does not fall under a definite measure, nor does it disturb the measures of eclipses.

[Margin: What is the penumbra or umbrago of the Moon?]

The Moon's penumbra, taken broadly, is rather an umbrago, that is, the privation not of all the Sun's direct light but only of some of it, because of the Moon's interposition, in the sublunary region. For those who see partial eclipses of the Sun are lit by some of the Sun's direct rays, but not by all, as those are who see the whole Sun. In this way the name penumbra is taken by Kepler in the *Epitome of Copernican Astronomy*, p. 875, and in the Rudolphine Tables, chapter 31, in these words: *The lunar penumbra is the space of the Earth's disc from which not the whole Sun but a part is covered by the Moon; the shadow, the space from which the whole Sun is covered.* For he restricts its subject to the Earth, because it is on the Earth that we observe eclipses.

[Margin: What is the penumbra of the Moon, taken strictly?]

The penumbra taken more strictly, as I said of a like case in chapter 5, is the privation of direct and unrefracted light, but with refracted light present, in the sublunary region, because of the interposition of the Lunatmosphere [Lunatmoſphęræ]: for so let us be allowed to call the sphere of the Moon clothed in an air or aether that is thicker and fit for refracting the Sun's rays, if indeed there is such a mantle around the Moon, on which see below.

II. It must be recalled, furthermore, what I said in the preceding chapter, number 4: namely, that the Moon's sheer shadow does not reach the Earth in annular eclipses; but that in total ones without duration it reaches the surface of the Earth exactly with its tip; and that in total ones with duration it extends beyond the surface of the Earth, the Sun's rays being prolonged by a fiction, and that by this fiction its tip ends now short of the centre of the Earth, now beyond it, now at the centre itself. First, therefore, we must discuss the Moon's shadow and its penumbra or umbrago, and their measures, disregarding refraction.

PROBLEMA I.

Problem 1.

Semiangulum & inde Angulum Coni Vmbræ Lunaris à radijs Solis irrefractis comprehenſæ in Nouilunijs dimetiri.

To measure, at new Moons, the semiangle, and hence the angle, of the cone of the Moon's shadow enclosed by the Sun's unrefracted rays.

III. We have already dealt with this problem in Book 4, chapter 17, Problem 4, by means of the diagram added here, in which the Sun is EMF, the Moon ABCD, and their centres K and H, on the straight line KG; and the Moon's shadow is the cone AGC, enclosed by the rays EG and FG, which touch the Sun at E and F and the Moon at A and C, and which therefore, by 18 of Book 3 of Euclid, make right angles at E and A with the semidiameters of the luminaries, EK and AH.

Diagram. Set into the right column. At the top, the lower part of a large circle, the Sun, its top closed by a shallow line through K and by lines running from K to E and F. Two long straight lines run from E and F, touching the sides of a small full circle, the Moon, and meeting at G at the foot. A vertical line runs from K through M and the centre H of the small circle down to G. A further slanted line runs from L, in the Sun, down to the centre H of the small circle.

- K (top, on the vertical): the Sun's centre
- E (left of the Sun): point of tangency on the Sun
- F (right of the Sun): point of tangency on the Sun
- L (in the Sun, on the slanted line): foot of the parallel HL
- M (below the Sun's arc, on the vertical): the Sun's lowest point
- I (top left of the small circle): point on the Moon
- B (top of the small circle, on the vertical): the Moon's upper point
- H (centre of the small circle): the Moon's centre
- A (left of the small circle): point of tangency on the Moon
- C (right of the small circle): point of tangency on the Moon
- D (bottom of the small circle, on the vertical): the Moon's lower point
- G (foot of the figure): tip of the cone

When HL is drawn, therefore, parallel to EAG, there arises, by 29 and 34 of Book 1 of Euclid, a right angle on each side at L, and a right angle AHI; EL is equal to AH, and the angle LHK is equal to the interior angle EGK; and the triangle LHK, right-angled at L, is, by 2 of Book 6 of Euclid, similar to the triangle EGK and has proportional sides. With these things set down, if the Moon's distance, known from Book 4, chapter 17, is subtracted from the Sun's distance, known from Book 3, chapter 7, or otherwise from tables showing these distances at each of the anomaly's degrees, the distance of the luminaries at new Moon will be known; this is KH, namely the base of the triangle LHK. And if the true semidiameter of the Moon, AH, that is, EL, is subtracted from the true semidiameter of the Sun, EK (on these see Book 4, chapter 17, Problem 1), the side LK will be known. So by trigonometry you will find the angle LHK, that is, AGH, which when doubled will give the angle

of the cone, AGC. It is useful, however, to repeat that angle here from the table of Book 4, chapter 17, Problem 4, leaving aside full Moons and quadratures, for the two extreme cases: with the Sun at apogee and the Moon at perigee, when this angle is at its smallest and the cone of the shadow at its most acute; and with the Sun at perigee and the Moon at apogee, when the angle is at its largest and the cone at its most obtuse, so that from these you may judge of the other, intermediate cases. See it, then, in the table of Problem 2, to be given shortly. Note, however, that if the semidiameters of the luminaries are taken in parts of which one semidiameter of the Earth is 100, as we ourselves did in Book 4, chapter 17, Problem 1, their distance too must first be multiplied by 100. Here and below I take the rays as unrefracted, because I do not suppose that there is air around the Moon sufficient for a sensible refraction.

PROBLEMA II.

Problem 2.

Lunaris Vmbræ Axem ſeu Longitudinem definire in Nouilunijs, poſitis radijs Solis irrefractis.

To determine the axis, or length, of the Moon's shadow at new Moon, assuming the Sun's rays to be unrefracted.

IV. In the preceding figure this is done in two ways. First, in the triangle AGH, right-angled at A, in which the angle AGH is given from Problem 1, along with the true semidiameter of the Moon, AH; for from these one finds the base HG, which is the axis of the cone of this shadow. Second, by the proportional triangles EGK and LHK, once these are known: KH, the interval of the luminaries at new Moon (which is had by subtracting the Moon's distance from the Sun's distance), and LK, the difference between the true semidiameter of the Sun, EK, and the true semidiameter of the Moon, AH, that is, EL. Take these semidiameters from Book 4, chapter 17, Problem 1. For let it be: as LK to EK, so KH to KG; for when KH is subtracted from KG, thus found, the axis of this shadow, HG, will be known. We have moreover dealt with this in Book 4, chapter 17, Problem 6. So let the following table serve for new Moons, when this axis is at its longest, namely with the Sun at apogee and the Moon at perigee, or at its shortest, with the Sun at perigee and the Moon at apogee.

[Margin: Axis and angle of the cone of the Moon's shadow.]

Axis of the Moon's shadow and semiangle of the cone, with the Sun's rays unrefracted.

From the data of the authors	Sun at apogee and Moon at perigee: axis of the shadow (Earth semidiameters)	Sun at apogee and Moon at perigee: semiangle of the cone	Sun at perigee and Moon at apogee: axis of the shadow (Earth semidiameters)	Sun at perigee and Moon at apogee: semiangle of the cone
Ptolemy	64 9/25	15′ 30″	59 6/52	16′ 50″

From the data of the authors	Sun at apogee and Moon at perigee: axis of the shadow (Earth semidiameters)	Sun at apogee and Moon at perigee: semiangle of the cone	Sun at perigee and Moon at apogee: axis of the shadow (Earth semidiameters)	Sun at perigee and Moon at apogee: semiangle of the cone
Copernicus	69 1/20	14′ 30″	58 0	17′ 6″
Tycho	66 1/2	15′ 0″	63 0	15′ 54″
Longomontanus	59 3/5	14′ 50″	57 4/5	16′ 4″
Kepler	61 0	14′ 49″	59 0	15′ 30″
Lansbergen	57 4/7	16′ 46″	57 0	18′ 8″
Boulliau	59 2/3	16′ 10″	57 0	16′ 49″
Wendelen	63 0	14′ 48″	61 0	15′ 18″
Ourselves	60 2/3	15′ 18″	52 35/60	16′ 39″

[Margin: Mean axis of the Moon's shadow according to Biancani.]

[Margin: Greatest axis of this shadow according to Boulliau.]

Among other authors, however, you may perhaps find the measures already mentioned somewhat different, but most of them neglect these measures. Thus Biancani, Book 9 of the *Sphere*, chapter 6, sets the Moon's shadow at mean distance at 60 Earth semidiameters in conjunction and 67 in opposition. But Boulliau, Book 4, chapter 3, with the Sun at apogee and the Moon at perigee, deduces the axis CE in the following figure as 58 55′ Earth semidiameters. For he draws the straight line ACE perpendicular to the semidiameters of the Sun, AB, and of the Moon, CD, just as if the Sun's ray BE touched the luminaries at B and D. He then draws FD parallel to AC, the interval of the luminaries, which for him is 1429 26′ Earth semidiameters. He sets BF, the difference of the true semidiameters, to BA, the Sun's semidiameter, as 0 16′ 45″ to 7 parts. And he makes it: as BF to BA, so FD, to which AC is equal, to AE, 1488 21′. Therefore, when AC, 1429 26′, is taken away, there remains for him CE, 58 55′. From his data, however, we have deduced that the true semidiameter of the Moon, CD or AF, is to the Sun's semidiameter, BA, as 28 to 700, and so BF is 672; and therefore we have deduced the axis CE as 59 2/3.

Diagram. Set into the right half of the right column, beside the passage above. A straight horizontal line at the top, with a shallow semicircular arc hanging below it for the Sun. Two straight lines run from the ends of the top line and converge downward to a point at the foot. A vertical line runs from the top line down the centre to that point, and a second vertical line, to the right of it, runs from the top line to the small circle. The small circle stands about two-thirds of the way down, its lower half black. Below it a short horizontal line crosses the cone, and the part of the cone beneath that line is hatched with horizontal strokes.

- A (top line, at the head of the centre line): end of the Sun's semidiameter on the line of centres
- F (top line, at the head of the second vertical): foot of the line parallel to AC
- B (top line, right end): where the Sun's ray leaves the Sun
- C (centre of the small circle): the Moon's centre
- D (right edge of the small circle): where the ray touches the Moon
- L (left of the short horizontal line): uncited in this passage
- N (at the centre line, on the short horizontal line): uncited in this passage
- M (right of the short horizontal line): uncited in this passage
- T (inside the hatched area, just right of the centre line): uncited in this passage
- E (foot, the point of the cone): the tip of the shadow

PROBLEMA III.

Problem 3.

Tabulam Axis & Semianguli Vmbræ Vniuerſalis vtilem Eclipſibus Solis condere: poſitis radijs Solis irrefractis.

To construct a table of the axis and semiangle of the universal shadow, useful for eclipses of the Sun, assuming the Sun's rays to be unrefracted.

V. This table is made by the method already given in Problems 1 and 2. But, as is usually done for the Earth's shadow, it is enough to find the Moon's shadow with the Sun at apogee, for each degree, or at least for every fifth degree, of the Moon's anomaly, and to add to it, in a separate column, the difference to be subtracted from the axis and added to the semiangle, according to each degree, or every fifth degree, of the Sun's distance from the solar apogee. In this way I thought the tables of eclipses should be enriched; they have neglected this part, though it is by no means to be neglected, as we shall soon see from its use. Let this now be a specimen of the table, for each whole sign of the anomaly; for you will have the full table, God granting, at the end of the work. Let the Moon's equated anomaly, then, be 3^{s}, and the Sun's likewise 3^{s}. Under the title *Axis* you will have 60 0′, and under the next title the difference 3 40′. Subtract this from the axis, and the axis of the Moon's shadow that remains is 56 20′. To the semiangle, 15′ 24″, add 41″, so that it is 16′ 5″.

Axis of the Moon's shadow with the Sun at apogee, and semiangle of the cone of the shadow in conjunction, with the difference up to the Sun at perigee.

Whole signs of the anomaly	Axis of the Moon's shadow (Earth semidiameters)	Difference to be subtracted from the axis (Earth semidiameters)	Semiangle of the cone of the Moon's shadow	Difference to be added to the semiangle	Whole signs of the anomaly
0^{s}	59 20′	0 0′	15′ 30″	0′ 0″	12^{s}

Whole signs of the anomaly	Axis of the Moon's shadow (Earth semidiameters)	Difference to be subtracted from the axis (Earth semidiameters)	Semiangle of the cone of the Moon's shadow	Difference to be added to the semiangle	Whole signs of the anomaly
1^{s}	59 30′	1 0′	15′ 28″	0′ 12″	11^{s}
2^{s}	59 43′	2 10′	15′ 26″	0′ 25″	10^{s}
3^{s}	60 0′	3 40′	15′ 24″	0′ 41″	9^{s}
4^{s}	60 17′	5 10′	15′ 22″	0′ 57″	8^{s}
5^{s}	60 30′	6 20′	15′ 20″	1′ 10″	7^{s}
6^{s}	60 40′	6 55′	15′ 18″	1′ 22″	6^{s}

PROBLEMA IV.

Problem 4.

Inueſtigare an ſpectatori Centralis Eclipſis Solis, ea ſit Annularis, an Totalis ſine mora, an Totalis cum mora, atq. adeò an apex Vmbræ Lunaris citra Terram, an ad Terram, an vltra ſuperficiem Terræ extendatur: poſitis radijs Solis irrefractis.

To investigate whether, for an observer of a central eclipse of the Sun, it is annular, or total without duration, or total with duration; and hence whether the apex of the Moon's shadow reaches short of the Earth, or to the Earth, or beyond the Earth's surface, assuming the Sun's rays to be unrefracted.

[Margin: First method of the Problem.]

VI. From the table of apparent semidiameters, of which you have a specimen for the Sun in Book 3, chapter 10, and for the Moon in Book 4, chapter 16, take the semidiameters of the luminaries, but as seen from the surface of the Earth. For if they are equal, the eclipse of the Sun will be total without duration for an observer placed on the straight line passing through the centres of the luminaries; and the apex of the Moon's shadow will end precisely at the Earth's surface. But if the Moon's semidiameter is smaller than the Sun's, the eclipse will be annular for the observer already mentioned, and the apex of the shadow will not reach the Earth. And if it is greater than the Sun's, the eclipse will be total with duration for the same observer, and the apex of the Moon's shadow will extend beyond the Earth's surface. Moreover, you will derive the semidiameters seen from the Earth's surface from the usual tables of semidiameters, if the distances from the Earth are set beside them, and if you look them up for distances reduced by one Earth semidiameter.

[Margin: Second method of the Problem.]

This Problem can also be solved by the following one, but more laboriously.

PROBLEMA V.

Problem 5.

Diſtantiam Apicis Vmbræ Lunaris à Terræ tum ſuperficie tum centro, citra aut vltra metiri.

To measure the distance of the apex of the Moon's shadow from both the surface and the centre of the Earth, whether short of it or beyond.

[Margin: Five cases of this Problem.]

VII. Find the Moon's distance from the centre of the Earth from its own tables, or by the Problems given in Book 4, chapter 14, and reduce it by subtracting one semidiameter of the Earth. Then find the axis of the Moon's shadow by Problem 2, and compare it with the Moon's distance, both whole and reduced. For if the axis is less than the reduced distance, the apex of the shadow will not reach the Earth's surface. If it is equal to the reduced distance, it will reach precisely to the Earth's surface. If it is greater than the reduced distance but less than the whole distance, it will penetrate the Earth, but short of the Earth's centre. If it is equal to the whole distance, the apex of the shadow will stop at the Earth's centre. And finally, if the axis is greater than the whole distance, it will stretch beyond the Earth's centre. The difference between the axis and the distance will show the distance of the shadow from the surface or the centre of the Earth, either short of it, toward the Moon, or beyond it. These things hold, however, for a place where there is no parallax of latitude; elsewhere some difference intervenes, but not so great that it is worth labouring over.

PROBLEMA VI.

Problem 6.

Inueſtigare Arcum ſuperficiei Terreſtris occupatum ab Vmbrâ Lunæ mera: Quando Eclipſis Solis eſt Totalis cum mora; poſitis radijs Solis irrefractis.

To investigate the arc of the Earth's surface occupied by the Moon's sheer shadow, when an eclipse of the Sun is total with duration, assuming the Sun's rays to be unrefracted.

VIII. Plutarch, Cleomedes, Kepler and Boulliau touch on this Problem. First, then, Plutarch, in the little work *On the Face in the Orb of the Moon*, or rather Empedocles in Plutarch, sang as follows of the Moon covering the Sun:

And it deprives of light as wide a space of the Earth As the orb of the grey-eyed Moon takes in.

But this conflicts with geometric rigour. For since the Moon is smaller than the Sun, and the Moon's shadow is therefore conical, and the Moon stands many Earth semidiameters away from the Earth, the circle in which this shadow cuts the Earth must be smaller than the base of this cone, whose diameter is very nearly equal to the Moon's diameter; and, for example, in Figure 4 of chapter 8, BC must be smaller than DE.

[Margin: Empedocles must be corrected, together with Kepler, his corrector.]

Nor did Kepler, reporting Empedocles' verses in the *Astronomia Optica*, p. 288, sufficiently qualify his opinion when he said: *Understand a somewhat smaller space.* For it is not somewhat but much smaller, since the Moon's true diameter is to the diameter of the Earth as 26 1/5 to 100, and the Earth's diameter takes up 8278 Bolognese miles, by what was said in Book 2, chapter 7. Now as 100 is to 26 1/5, so 8278 is to 2168 4/5, the number of miles that the diameter of the Moon's shadow would occupy if it were equal to the Moon's diameter. But when it is at its greatest, it does not occupy 400 miles, as we shall show below, in number 9. It is therefore at least five times smaller, and not merely somewhat smaller.

[Margin: Cleomedes' opinion on the Moon's shadow darkening the Earth.]

Cleomedes, for his part, in Book 2 of the *Cyclical Theory*, chapter 3, reasons in this way: *When therefore the Moon is joined to the Sun, and at the conjunction is in the middle of the zodiac, a conoid shadow must be sent down from it onto the Earth. This shadow itself is said to advance more than four thousand stadia; for every place in which the Sun is not then seen, with the Moon running beneath the Sun, is the Moon's shadow.* Cleomedes' basis is that, as he goes on to explain more fully in the same place, an eclipse of the Sun seen as total at the Hellespont was nevertheless observed at Alexandria (which he places on the same meridian, and 10000 stadia from the Hellespont) as partial, with 2 digits of the Sun, or a sixth part, standing clear; while at Rhodes, which lies midway between Alexandria and the Hellespont and is 5000 stadia from either, 1 digit was seen. From this he infers that the tract of Earth in which the Sun is not seen (understand: the whole Sun) is greater than 4000 stadia, or 500 Italian miles. But Cleomedes takes in not only the sheer shadow but also the umbrago, or penumbra; and, as Kepler holds in the *Optics*, p. 293, he relies on Eratosthenes, who assigns the Earth's circumference 250000 stadia.

[Margin: Kepler's teachings on the Moon's shadow.]

Kepler, in the *Astronomia Optica*, p. 287, shows that if nocturnal darkness falls by day because of an eclipse of the Sun, the Moon must be seen at a greater angle than the Sun, in such a way that the Sun's rays reflected from the Earth do not illuminate the air occupied by the Moon's shadow, and the material of twilight is thus extinguished. From this he infers that if the material of twilight were about 12 German miles high, as Tycho judged with the ancients, the Moon's shadow would have to occupy on the Earth's surface 300 German miles, of which the Earth's semidiameter holds 860; and that this would require a diameter of the Moon 20′ greater than the Sun's. Since these things are absurd, the material of twilight is therefore much lower than 12 German miles. Moreover, in the *Epitome of Astronomy*, p. 874, and in the Rudolphine Tables, precept 160, he says: *Take the minutes of latitude, or of the arc between the centres, from the semidiameter of the shadow, if there is one; and add that difference, and convert this sum into two arcs of a great circle of the Earth; for the difference of these will show the space of the Earth, extended in width, that the Moon's shadow envelops.*

[Margin: Boulliau's method.]

Finally, Boulliau, in Book 4 of his *Astronomy*, chapter 3, in the figure we have already set out towards the end of Problem 2, deduces the axis CE of the Moon's shadow, which, with the Sun at apogee and the Moon at perigee, he says extends beyond the Earth's centre N by 2 25′ Earth semidiameters. For when NM is drawn parallel to CD, the Moon's true semidiameter, two triangles arise, CED and NEM, with proportional sides, and to these the triangles AEB and FDB are also proportional. So let it be: as CE, the axis of the shadow, to NE, the excess of the shadow beyond the Earth's centre, so CD, the Moon's true semidiameter, to NM, in parts of which the Earth's semidiameter is known. Then let it be: as the Earth's semidiameter to the whole sine, so NM to the sine of the arc occupied by the Moon in the middle of the Earth's disc. In this way, from the data set out at the end of our Problem 2, he deduces that NM, at its greatest, is the 86th part of the semidiameter of the Earth's disc, and a sine of 39′, and that to these correspond 10 German miles; but that at the very edge of the limb the versed sine corresponding to NM is 1° 7′, or 16 3/4 German miles, and that this is the greatest semidiameter of the Moon's shadow, whose double is 33 1/2 German miles, that is, 134 Italian.

[Margin: First case of the Problem.]

IX. It seems to us that this procedure should be worked out differently, with the help of the following figure, in which the Moon is EK, the Earth LF, the centre of the Moon A, that of the Earth B, and the axis of the shadow in a total eclipse with duration is either AC, if it passes the Earth's centre, or AB, if it ends at the Earth's centre, or AI, if the apex of the shadow lies between the surface G and the centre B. These are already known from Problem 5. So if it ends at the Earth's centre, the apparent semidiameter of the Moon, seen from the Earth's centre, is the measure of the angle ABK. Let this now be imagined as GBF, which measures the arc GF, whose double is the arc of a great circle of the Earth occupied by the Moon's shadow.

[Margin: Second case.]

But if the apex of the shadow is beyond the Earth's centre, as at C, then when BF is drawn to the point F, where the extreme ray cuts the Earth's circumference, the triangle CBF arises. So in it, once BC is known, the excess of the axis of the shadow over the Moon's distance, by Problem 5, and the semiangle of the shadow, that is, ACK, by Problem 1, and BF, one semidiameter of the Earth, find the angle BFC. For the external angle GBF is equal to this angle and the angle BCF taken together, by proposition 32 of the first book of Euclid; and GBF measures the arc GF, namely half the arc occupied by the shadow on the Earth's surface.

[Margin: Third case.]

Lastly, if the apex of the shadow is short of the Earth's centre, as at I, and the Sun's ray is ELI, cutting the Earth at L, join L with B by the straight line

LB, and the point I with B; for this gives the triangle ILB, in which LB is known, one semidiameter of the Earth, in parts of which BI is known, the distance of the apex I from the Earth's centre, known by Problem 5; and the

angle BIL is known, which is the complement to two right angles of the semiangle of the shadow, that is, of the angle EIA, known by Problem 1. So find the angle LBI, that is, LBG, which measures the arc LG, half the arc occupied by the Moon's shadow on the Earth's surface. And by what was said in Book 2, chapter 7, it is easy to find the miles that correspond to these arcs. This Problem too holds for a place where there is no parallax of the Moon in latitude; elsewhere it undergoes some variation, but not so great as to be worth investigating.

Diagram. Set into the right half of the left column, beside the passage above. At the top, a circle for the Moon, its upper half white and its lower half black, cut by a horizontal diameter. From the ends of that diameter two lines converge downward to a point at the foot, enclosing a hatched cone. A vertical line runs down the axis of the cone. Lower down, a larger circle for the Earth, hatched round its rim, with its centre on the axis; the cone enters it at the top and leaves it at the bottom, the tip standing below the circle.

- E (left end of the Moon's diameter): edge of the Moon
- A (on the diameter, centre): the Moon's centre
- K (right end of the Moon's diameter): edge of the Moon
- L (top of the Earth's circle, left, inside the hatching): where the ray meets the Earth when the apex falls short of the centre
- G (top of the Earth's circle, centre): the surface point on the axis
- F (top of the Earth's circle, right): where the extreme ray cuts the Earth's circumference
- I (on the axis, inside the Earth): apex of the shadow in the third case
- B (on the axis, lower within the Earth): the Earth's centre
- C (below the Earth): apex of the shadow in the second case

[Margin: How great is the largest portion of the Earth occupied by the Moon's shadow.]

By this method we have found the greatest arc of the Earth that can be occupied on the Earth's surface by the Moon's sheer shadow, which occurs with the Sun at apogee and the Moon at perigee, to be 3° 31′ 30″, or 255 Italian miles of Bologna, or 317 ancient Roman miles. Here we take from Problem 1 the angle C as 15′ 18″; from Problem 2 the axis AC as 60 40′ Earth semidiameters; and from Book 4, chapter 14, the distance of the Moon at perigee, AB, as 53 45′ semidiameters. For from these BC comes out as 6 55′ Earth semidiameters, and the arc GF as 1° 45′ 45″, whose double is therefore 3° 31′ 30″. But when the apex of the shadow ends at the Earth's centre, which occurs at an anomaly of the Sun of 30° and of the Moon of 95°, the semidiameters of the luminaries are then equal, and are 15′ 20″. So the arc occupied by the shadow is 30′ 40″, or 36 55′ Bolognese miles and 49 12′ ancient Roman miles. Granted, Scheiner, in the *Rosa Ursina*, p. 612, says the Moon's shadow occupies at most only 350 Italian miles, and Origanus, in volume 1 of the *Ephemerides*, p. 266, thinks it occupies 64 German miles, that is, 256 Italian.

PROBLEMA VII.

Problem 7.

In Eclipſi Solis Annulari, Inquirere tum Latitudinem annuli lucidi de Sole viſibilis aut partis lunatæ eiuſdem, tum Tractum Terræ, intra quem integer hic annulus ſpectabilis eſt, poſitis radijs Solis irrefractis.

In an annular eclipse of the Sun, to find both the width of the bright ring visible of the Sun, or of its crescent part, and the tract of Earth within which this whole ring can be seen, assuming the Sun's rays to be unrefracted.

X. Consider the following diagram, in which the Sun is DRE, the Moon FG and the Earth NP; and the centres are A for the Sun, B for the Moon and C for the Earth, on the same straight line AC, on which the observer of the central eclipse is at S. When the Sun's rays touching the Moon are drawn, namely DFI and EGI, let the Moon's sheer shadow be FIG, whose apex stands at the interval IS from the Earth; and let the same rays, produced to the Earth, end at O and T. Then from the Earth's centre draw two rays touching the Moon and reaching the Sun, namely CFH and CGM, so that the angle HCM subtends and measures the apparent semidiameter of the Moon, FG; and two others touching the Sun, namely CD and CE, so that the angle DCE measures the visual semidiameter of the Sun, DAE. Finally, from Y draw the ray YFN, touching the Moon at about F and the Sun at Y; and ZGP, touching the Moon near G and the Sun at Z. For on the Earth's surface the arc OST will be the one within which, and not beyond, the bright ring of the Sun can be seen on either side, encircling the Moon. Outside it, however, if the observer is within NO, he will see the part of the Sun DH, but not the whole of ME; conversely, one who is within TP will see the part of the Sun ME, but not the whole of DH; while observers at the points O and T will see the Sun crescent-shaped, with its horns meeting at E or D; and an observer at S will see a ring of the Sun of equal width around the Moon. Further, the arc NSP will be the one occupied by the penumbra, or umbrago, of the Moon, lit by some direct rays of the Sun but not by all, that is, the arc within which some part of the Sun will be seen covered by the Moon; but outside it, as from N to Q and from P to V, the whole Sun will be seen.

[Margin: If the Sun and Moon were represented here as much farther from the Earth, as is proper, the lines DF and EG would fall beyond T and O, and would take in a larger arc than OT, indeed larger than the angle DCE subtends.]

Diagram. Occupying the full width of the right column. At the top a shallow arc, the Sun's upper limb, carrying D, H, A, M and E, with a large semicircle below it running from D to E through R. From the points on the arc, straight lines run down and cross one another. A small circle, its lower half black, stands below the crossing K, with a hatched cone beneath it ending at I.

Lower still a large arc, the Earth's surface, carries O, S and T near its top and N and P on its flanks; a straight line across the base runs from Q through C to V, with lines from C up to N and to P, and up through the Moon to the Sun's arc.

- D (left end of the upper arc): the Sun's limb
- H (on the upper arc, left): end of the ray CFH
- A (on the upper arc, centre): labelled as the Sun's centre on the axis
- M (on the upper arc, right): end of the ray CGM
- E (right end of the upper arc): the Sun's limb
- Z (left, on the Sun's lower semicircle): point of contact of ZGP
- Y (right, on the Sun's lower semicircle): point of contact of YFN
- R (foot of the Sun's lower semicircle): the Sun's limb on the axis
- K (crossing of the rays, above the Moon): uncited in this passage
- F (left of the small circle): edge of the Moon
- B (in the upper half of the small circle): the Moon's centre
- G (right of the small circle): edge of the Moon
- I (below the hatched cone, on the axis): apex of the sheer shadow
- O (on the Earth's arc, left of centre): end of the ray DFI
- S (on the Earth's arc, centre): the observer of the central eclipse
- T (on the Earth's arc, right of centre): end of the ray EGI
- N (left flank of the Earth's arc): end of the ray YFN
- P (right flank of the Earth's arc): end of the ray ZGP
- Q (left end of the base line): limit on the Earth
- C (centre of the base line): the Earth's centre
- V (right end of the base line): limit on the Earth

[Margin: First part of the Problem.]

With these things set down, the *first* part of the Problem is correctly solved, following Kepler in the Rudolphine Tables, precept 151, if you subtract the apparent semidiameter of the Moon from the apparent semidiameter of the Sun, that is, the angle BCG, or ACM, from the angle ACE. For this leaves the angle MCE, which measures the width ME of the solar ring as it appears to an eye at C or S; this is equal to the width DH, and double this will be the width of the crescent Sun as it appears to observers at O and T.

[Margin: Greatest width of the solar ring and of the solar crescent.]

It is at its greatest when the Sun is at perigee and the Moon at apogee, in which case the apparent semidiameter of the Sun is, by my reckoning, 16′ 34″ and that of the Moon 14′. So the greatest width of this ring is 2′ 34″, and that of the crescent Sun 5′ 8″.

The *second* part of the Problem, in which the arc OST is sought, is solved by means of the triangle ICT, in which there are taken as given the angle CIT, equal to the semiangle FIB of the Moon's shadow, known by Problem 1; the side CT, which is one semidiameter of the Earth; and the side CI, which is the distance of the apex of the Moon's shadow from the Earth's centre, known by subtracting the axis BI, known by Problem 2, from the Moon's distance BC. So with these three given, trigonometry will reveal the angle ICT, which

measures the arc ST, whose double is the arc OT, within which the bright ring of the Sun can be seen. This arc is at its greatest when the Sun is at perigee and the Moon at apogee, in which case the angle CIT is for us 16′ 39″, the axis BI 52 35′, and the Moon's distance BC 64 10′. So IC is 11 35′, in units of which CT is one; therefore the angle ICT, and the arc ST, is 2° 32′, and OT is 5° 4′, that is, 360 Bolognese miles or 480 ancient Roman miles. But Cleomedes, as Kepler reasons in the *Optics*, p. 292, relying on the hypotheses of Eratosthenes and Hipparchus, assigns to the arc OT 6°, and so 4000 stadia, or 500 miles. This Problem too holds for a place where the Moon has no parallax in latitude; outside this place it holds, but with some small difference, though not so large that further labour need be imposed on astronomers. As for the greatest arcs, however, which we have investigated both in this Problem and in the preceding one, it holds exactly, because they are not greatest except with respect to the already mentioned place on the Earth, and in other cases they are always smaller. See the notes in the margin at the diagram

PROBLEMA VIII.

Problem 8.

Inueſtigare Arcum Terræ occupatum à Penumbra vel Vmbragine Lunæ, ſeu intra quem non totus Sol videtur; ſi recta linea per centrum Luminarium ducta cadat in centrum Terræ.

To find the arc of the Earth occupied by the penumbra or umbrago of the Moon, that is, the arc within which the whole Sun is not seen; if a straight line drawn through the centre of the luminaries falls on the centre of the Earth.

XI. We seek the arc NSP, according to the preceding figure; but on this more conveniently below, chapter 12, Problem 5, and at the end of Problem 6.

XII. Gathering, then, into one synopsis the conclusions drawn from our hypotheses by Problems 6, 7 and 8, let the following be the theses.

Th. 1. The greatest Total Eclipse of the Sun with stay occurs with the Sun at apogee and the Moon at perigee, and with the centres of the Earth and of the luminaries placed on the same straight line.

Th. 2. The greatest arc of the Earth occupied by the Moon's shadow occurs when the greatest of the Total Eclipses of the Sun with stay occurs.

Th. 3. The greatest arc of the Earth occupied by the Moon's shadow is 3° 31′ 30″[41], or 255 Bolognese Italian miles, 317 ancient Roman miles.

Th. 4. In annular eclipses of the Sun, the greatest breadth of the bright ring, or the greatest crescent-shaped part of the Sun, occurs with the Sun at perigee, the Moon at apogee, and the centres of the Earth and of the luminaries lying on the same straight line.

[41]the page sets the last value as 30′, with a single mark; seconds are meant

Th. 5. The greatest and uniform breadth of the bright ring of the Sun that can be seen is 2′ 34″; that of the solar crescent, however, with its horns joined in one point, is 5′ 8″.

Th. 6. The greatest arc of the Earth within which the greatest bright ring of the Sun can be seen, and outside which the Sun is seen like the Moon but with its horns separated, or else round, is 5° 4′, or 360 Bolognese miles and 480 ancient Roman miles.

Th. 7. The penumbra or umbrago of the Moon is greatest when an annular eclipse of the perigee Sun is made by the apogee Moon, and the centres of the Earth and of the luminaries are on the same straight line.

SCHOLIA.

Scholia.

I. The Problems of the preceding chapter from 4 to 8, with their figures, are suited above all to a spectator who has the luminaries at the zenith with no parallax at all, and accordingly with the Moon having no latitude and the luminaries placed on a straight line in which the centre of the Earth lies. Outside this case the Moon's parallax in latitude disturbs those problems somewhat and varies them. As regards the measures of the arcs occupied by the shadow or penumbra, however, the difference does not come to so much that multiple diagrams and solutions of problems on its account would be worth the astronomers' concern; and, as regards these arcs, we can use those problems without inconvenience, just as if the centres of the luminaries were on a straight line drawn out from the centre of the Earth. For in an eclipse of the Sun there is always some spectator who is on the straight line drawn through the centres of the luminaries, by virtue of parallax in latitude. I am speaking, however, of cases in which the cone of the shadow cuts the Earth on both sides.

[Margin: The method of correcting the preceding Problems in cases of parallax.]

But if anyone wishes to be shown the method he ought to follow in other cases, I shall give at least one example in the following diagram, in which A is the centre of the Moon and B that of the Earth, and let the cone of the lunar shadow be ECK, whose axis AC is given by Problem 2, passing through the eye at I. Draw therefore through I, from B, the straight line BD, up to the zenith of the lunar heaven DAK, and let the Moon's distance AB be given, and let either semiangle of the cone at C be known by Problem 1. Then to the points G and F, at which the sides of the cone of the shadow cut the circumference, draw from the centre of the Earth, B, the straight lines BG and BF; and let the apparent distance of the Moon from the zenith be given, namely the angle DIA. For the remaining angles at I will then be given, namely CIR, vertically opposite to it, and BIA and CIM, its complement to two right angles.

First, then, in triangle BIA, in which the angle BIA is given, and the line BA, in parts of which BI is one, find the side AI. When this is subtracted from the

axis AC, there remains CI, in triangle CIR, in which the angles CIR, as I said, and RCI, the semiangle of the cone, are known. In this triangle, therefore, find the side IR. When this is subtracted from the Earth's semidiameter BI, the side of triangle BRF will be known, in parts of which BF, the Earth's semidiameter, is one; and the angle BRF is known, since it is the complement to two right angles of the sum of the known angles CIR and RCI. Find therefore the angle RBF, which measures the arc IF.

Second, in triangle CIM the angles CIM, as I said, and MCI, the semiangle of the cone, and the line CI are known. Find therefore the side IM, and join it to the Earth's semidiameter BI, so that the side BM becomes known, in the parts of which the side BG is the Earth's semidiameter, in triangle GBM, in which the angle GMB is likewise known, being the complement to two right angles of the sum of the angles CIM and MCI. Find therefore the angle GBM, which measures the arc GI; when this is joined to the arc IF, the arc of the Earth occupied by the Moon's shadow will be known. Likewise in other cases you must be diligent and resourceful, provided, however, that one side of the shadow, say AGC, does not fall outside the Earth.

Diagram. Let into the right half of the left column at its foot. A circle, the Earth, with its centre marked below the middle. At the upper right a small circle stands on an arc that runs from the upper left to the small circle and on past it. Two straight lines run from the point at the lower left, one touching the small circle's upper side and one its lower side, and cross the large circle. A line runs from the lower centre of the large circle up through the circle to the small circle and on to the arc; further lines run from the centre to points on the circle's upper edge.

- D (upper left, at the start of the arc): the zenith end of the lunar heaven DAK
- E (on the arc, upper side of the small circle): end of the cone's base, ECK
- A (centre of the small circle): the centre of the Moon
- K (right of the small circle, on the line beyond it): end of the cone's base, ECK
- M (on the cone's upper side, above the large circle): point of triangle CIM
- G (on the large circle's upper left): where a side of the cone cuts the circumference
- I (at the top of the large circle): the eye
- F (on the large circle, right of I): where a side of the cone cuts the circumference
- R (just below I): point of triangles CIR and BRF
- B (centre of the large circle): the centre of the Earth
- C (at the lower left, the apex of the cone): the apex of the shadow

Labels read: D, E, A, K, M, G, I, F, R, B, C. Labels not read: none known.

II. So far the discussion has been of the Sun's unrefracted rays. You will now ask what happens if they are refracted in air or in a denser ether around

the Moon. I reply that such air or ether is still unknown to me, and that with telescopes however excellent, which I have at last obtained, I have not been able to detect it around the Moon. And if there is such a thing, I do not think that its height or its refractions can be determined by anyone; rather, once it is admitted, it must only be asserted that the Moon's sheer shadow is shortened proportionally, as we said of the Earth's shadow in chapter 5; and that in this case the measures of the arcs of the Earth treated in Problems 4 to 8 nevertheless hold, but that the shadow placed there is the penumbra of the lunar atmosphere [Lunatmoſphæræ]; and that those arcs are not to be increased, except by a scarcely sensible little portion, because the height of the lunar atmosphere is very small, if I am not mistaken.

[Margin: Whether refractions vary the measure of eclipses.]

Because of the refractions of the Sun's rays that occur in the air around the Earth, the Sun is indeed visibly raised. But when this happens, and the sky is clear enough not to cut off the view of it, the Moon too is visible by the Sun's rays reflected from the Earth onto it and reflected again from the Moon to us; and these are likewise refracted on entering our atmosphere, by a refraction sensibly equal to the solar refraction. And so this refraction does not sensibly change the size of eclipses.

Longomontanus, however, teaches the contrary in *Theorica*, Book 1, chapter 9, p. 293, asserting that because of this refraction the Moon's diameter is not indeed diminished, but rather the Sun's apparent diameter is enlarged, so that in thicker air and under a more elevated pole a total eclipse of the Sun never occurs for that reason. To set this before the eyes, he uses the diagram added here, in which A is the Earth, B the Sun, and H and L the Moon. For just as at full Moons the Earth's shadow, which would be RPQ, becomes more contracted because of the refractions in our air, so that it comes out as RMQ, so because of the same refractions he thinks that the Moon's shadow, HV, is contracted. He adds, moreover,

Diagram. Let into the right half of the right column and running down it from the middle of the page to the foot. At the top a large circle, the Sun, with a horizontal diameter, inside a ring of hatched triangles. Two pairs of long lines descend from it and converge. About a third of the way down, a small circle, half shaded, stands between two curved arcs; below it a hatched cone narrows to a point. Further down a circle with its lower part shaded and hatched stands on the long lines, with a horizontal line through its centre. Below it a second small circle, half shaded, with a hatched cone beneath, and the long lines converge at the foot.

- E (far left of the top circle, outside the ring)
- C (left end of the diameter, inside the ring)
- B (centre of the top circle): the Sun
- D (right end of the diameter, inside the ring)
- F (far right of the top circle, outside the ring)
- H (in the upper small circle): the Moon

- G (on the second arc, left of the cone below H)
- K (on the second arc, right of that cone)
- V (the point of that cone, just above the third circle): the end of the Moon's shadow, HV
- R (left end of the line through the third circle)
- A (centre of the third circle): the Earth
- Q (right end of the line through the third circle)
- L (in the lower small circle): the Moon
- M (near the foot, on the axis): the end of the contracted shadow, RMQ
- P (at the foot, the point where the long lines meet): the end of the Earth's shadow, RPQ

Labels read: E, C, B, D, F, H, G, K, V, R, A, Q, L, M, P. Labels not read: none known.

that the Moon's shadow is thinned and lessened by the Sun's rays reflected from the Earth, so that the angle V, under which the Moon is seen, becomes narrower, and therefore some part of the Sun that would otherwise be hidden can be seen. But he errs on both counts. He does not attend to the refractions of the lunar rays, of which I have already spoken, and which compensate for whatever the refraction of the solar rays would increase; and the Moon's shadow can indeed be diluted by the Sun's reflected rays as regards degree of intensity, but cannot be lessened as regards extensive quantity. For even if, with the Moon otherwise covering the whole Sun, innumerable other lights were kindled between the Moon and us, even those of a second Sun wondrously shining through, we would not, by the force of these lights illuminating the Moon's shadow, see the ordinary Sun covered by the Moon. Read again here the other points I brought against Longomontanus in Book 4, chapter 16, number 8.

[Margin: Longomontanus's double optical delusion in eclipses of the Sun.]

III. It is customary for Lansbergen in his *Treasury of Observations*, Class 6 of the lunar observations, when the Sun's diameter from his own tables is greater or smaller than the observations of some eclipses of the Sun examined by him would require, to have recourse in the one case to an amplification, or optical dilation, of the Sun's rays, and in the other to a contraction. But how he contracts the rays he has not explained to us, and it seems a plainly arbitrary fiction. It would have been better to invent thick round clouds that amplified the Moon optically and covered more of the Sun than she could have done on her own. That amplification, moreover, although it holds when some part of the Sun is otherwise seen, because bright things placed next to dark ones appear larger, as we said of the Moon's bright ring in Book 4, chapter 6, yet when the whole Sun is covered it cannot be amplified. Kepler noted this in *Astronomia Optica*, p. 297, in these words: "Since these are bright, they are dilated, and they must cast the first ray to that place; but those which do not radiate, being impeded by the interposition of opaque bodies, as the Sun

by the interposition of the Moon, will not be able to be dilated either. This phenomenon is therefore not to be ascribed to vision."

[Margin: Lansbergen's double fiction in eclipses of the Sun.]

[Margin: Kepler's sounder teaching on this.]

He is speaking there of the cause for which, in a central conjunction of the luminaries, something of the Sun appears, as happens in an annular eclipse; and he assigns a threefold cause. The first is the visual diameter of the Moon, smaller because of its great distance from the Earth than the diameter of the Sun when nearer the Earth. The second, when the first does not hold, is a substance of air, or rather of denser ether around the Sun, set on fire by contact with the Sun, which seems to us to be the Sun's limb although it is not in fact. The third, when neither the first nor the second is present or acceptable, is air or denser ether around the Moon, in which the refracted rays of the Sun do not thin the Moon's diameter, as Tycho puts it, but amplify the Sun's diameter and make visible parts of the solar limb that would otherwise be hidden, just as the same rays refracted in our air bring it about that the Sun, otherwise hidden below the horizon, nevertheless appears to us. But on this third cause, hear what he says on p. 302: "I prefer, therefore, to attribute to the Moon an air, not of great depth, so that at times, but very rarely, it can advance as far as this effect. But I much prefer that the cause adduced in the next-to-last place should hold, and that this one should not be in use but stand in reserve."

[Margin: The threefold cause of an annular eclipse, from Kepler.]

Supposing, however, that the Moon does not of itself cover the whole Sun, he concedes, on p. 286, that especially in weaker sight the edges of the Sun around the Moon are amplified, the image of bright things placed next to dark ones predominating. But because of these accidents of vision, which are too various, he rightly denies that the astronomical tables are to be changed, or that one should rest on them in estimating eclipses: for it is the astronomer's part to bind by laws the things that occur of themselves, and to leave sight to the physicians for correction. This we also said of the amplification of the Moon, from the same chapter 6, at the end of Scholium 5. Granted, then, that the little table of Longomontanus adduced in Book 4, chapter 16, number 8, held for eclipses of the Moon, it does not hold for eclipses of the Sun. Rather, one must either have recourse to Kepler's causes, or better, the diameters of the luminaries must be corrected, if that can be done, so that they satisfy the observations without these evasions; or, if not even that can be done, human weakness must be forgiven.

IV. As for what is wanted at this place on the Moon's secondary light, by which the Moon is seen in eclipses of the Sun, enough has already been said of it in Book 4, chapter 6, from number 5. For we ascribed it to the Sun's rays reflected from the Earth to the Moon, and from there to us.

[Margin: The Moon's light in an eclipse of the Sun.]

As for the colours of eclipses of the Sun, apart from what was said in chapter 5, Scholium 3, note that the cause of their variety, in the part of the Sun not

covered by the Moon or in the surrounding air, is, as Kepler notes in the *Optics*, p. 303, both the preceding clearness of the air and diverse vapours. For if great clearness has preceded, as with a very serene sky and in summertime, when the Sun's rays, reflected more directly, illuminate the air more, then an eclipse suddenly bearing down seems more dreadful to those strongly steeped in the image of light, because it is more unusual; but if clouds or rain have preceded, then although the eclipse increases the darkness, it is nevertheless not seen as dreadful. And so it happened in the eclipse of the year 1590, July 31, in Swabia, on whose harvesters it cast a yellow colour everywhere, and in Styria a reddish one; whereas the eclipse of the year 1598, March 4, with a stormy and rainy sky and a low Sun, excited no complaint about colours. For what Cardano asserts in Book 4 of *De subtilitate*, p. 164, does not always happen: that at the time of a solar eclipse all things appear saffron, and headache comes to many whose heads are weak. Rather, just as at dawn the colours appear now saffron, now crimson, now blue-black, because of the diversity of vapours, so also in an eclipse of the Sun.

[Margin: The colours of the Sun or of the air in an eclipse of the Sun.]

CAPVT X.

Chapter 10.

De Parallaxibus Luminarium, earumq. effectibus, & vſibus in Eclipſibus Solis.

On the parallaxes of the luminaries, and on their effects and uses in eclipses of the Sun.

I. We must recall what we said on parallaxes in general in Book 1, chapter 35, on the parallaxes of the Sun in Book 3, chapter 8, and on the parallaxes of the Moon in Book 4, chapters 13 and 14, where we taught the methods of constructing a table of parallaxes in the circle of altitude, or in the vertical circle, and indeed a twofold table: one for a given true altitude, the other for the apparent altitude of a star above the horizon; and also the method of using either of these tables in both ways, or of transforming one into the other. With these things set down, we must explain the four principal kinds that arise from the parallax of altitude and always presuppose it as known: namely, parallax of longitude, of latitude, of right ascension, and of declination.

[Margin: On parallaxes of altitude.]

Yet only the parallax of altitude, longitude and latitude has usually been treated in eclipses, by these: Ptolemy, Book 5, chapter 19; al-Battānī, chapter 39; al-Farghānī, Differentia 27; Regiomontanus in the *Epitome of the Almagest*, Book 5, from Proposition 26 to 32; the Alphonsine astronomers, in Proposition 32 and the Canon on p. 112; Peuerbach in *De Eclipsibus*, from Proposition 8 to 12; Copernicus, Book 4, chapters 26 and 27; Reinhold in the Prutenic Tables, from Precept 54 to 64 and the Canon on p. 99, and on Peuerbach's *Theoricae*,

pp. 192 to 199; Wurstisen on the same *Theoricae*, from p. 320; Erasmus Oswald Schreckenfuchs on the *Passiones Planetarum*, and Nonius, annotation 7; Magini in the *Primum Mobile*, Book 12, Problems 12 and 13, and in the *Secunda Mobilia*, Canon 75, and their tables, p. 681 and from 691 to 703, and in the *Supplement to the Ephemerides*, from p. 279, or Canons 8 and 9 of the compendium of eclipses; Tycho, Volume 1, *Progymnasmata*, p. 132; Origanus, Volume 1, Part 2, chapter 10; Mulerius in the *Tabulae Frisicae*, pp. 434, 446 and 463; Longomontanus in *Astronomia Danica*, Book 2 of the *Spherica*, chapter 10, and Book 1 of the *Theorica*, chapter 8; Lansbergen in the Precepts of his Tables, 28 and 29, with the Canon on p. 51; Kepler in *Astronomia Optica*, chapter 9, in *Epitome of Copernican Astronomy*, p. 883, and in the Rudolphine Tables, chapter 28; Boulliau, Book 4, chapter 4, and Book 12, Precept 22, with the table on p. 173; Vincenzo Renieri in the *Tabulae Mediceae*, in their second edition, Part 2, chapter 3; and Langius [?] in the *Elementale*, from p. 406.

[Margin: Authors on the parallaxes of the luminaries.]

Among these, Magini in the *Primum Mobile*, Problem 14, also treats of the parallax of right ascension and of declination. From these authors, then, and from our own reflections we shall derive the whole doctrine of these parallaxes. For these, in the diagram added here, let there be the meridian HVP, etc., the horizon HAC, etc., and the quadrant of the circle of altitude VA, in which is the vertical point V. Let the pole of the world, or of the equator, be P, and from it let a small circle be described, which the pole of the ecliptic is imagined to trace by its motion. Let this pole now be at B, and from this pole let the ecliptic EGC, etc., be described. From the same pole of the ecliptic let arcs of the circle of latitude be drawn through the centre of the star as far as the ecliptic, or beyond it, as the northern or southern position of the star requires; so that if the star is at L, let the arc B

Diagram. Let into the right half of the right column near its foot. A semicircle stands on a straight base line. At the upper right a small circle touches the semicircle's outer edge. Several arcs cross the semicircle from upper right to lower left and from upper left to lower right; a line descends from the top of the semicircle to the middle of the base.

- V (top of the semicircle): the vertical point
- B (upper right, on the small circle): the pole of the ecliptic, at present
- P (centre of the small circle): the pole of the world, or of the equator
- E (upper left, on the semicircle): on the ecliptic EGC
- L (below V, right of the vertical line): the star, in the case set out
- D (below E, on an arc): the end of the arc from B through L
- F (below D, on the crossing lines)
- K (below F)
- M (below K, near the base)
- G (right of F, at the crossing of the arcs): on the ecliptic EGC
- H (left end of the base): on the meridian and the horizon
- A (middle of the base): the foot of the quadrant VA

• C (right end of the base): on the horizon and the ecliptic EGC

Labels read: V, B, P, E, L, D, F, G, K, M, H, A, C. A short upright stroke in the crossing of the lines between F and G may be a further letter, I, but it is merged with the lines and is not settled. The letters F, K, M stand close together below the crossing.

[Margin: Explanation of the figure for parallaxes.]

LD be drawn; but if it is at F, the arc BF; and if at K, the arc BK. These arcs, as is taught in the definitions and properties of these circles in the doctrine of the primum mobile, always make right angles on both sides with the ecliptic, which they cut or on which they fall, just as arcs of declination make right angles with the equator. With these things set down.

Definitiones Parallaxium, vel ad Parallaxes ſpectantium.

Definitions of parallaxes, or of things pertaining to parallaxes.

II. 1. The true place of a star, or of any phenomenon, is that point in the world on which a straight line drawn from the centre of the Earth and of the universe falls, according to the more common opinion, which holds these two centres to be the same. For what must be said according to the opinion of the Pythagoreans and Copernicans will be said in the Optical Book and in the Book of Systems.

[Margin: What is the true place?]

2. The apparent or seeming place of a star is that on which a straight line falls, drawn from the eye of a spectator positioned elsewhere than at the centre of the Earth and of the universe, or, as commonly happens, placed on the surface of the Earth.

[Margin: What is the apparent place?]

3. The true altitude of a star is the arc of the vertical circle, or circle of altitude, intercepted between the star's true place and the rational or astronomical horizon, as in the following diagram: if the star is at L, its true altitude will be the arc AL.

[Margin: What is the true altitude?]

4. The true distance of a star from the zenith is the arc of the vertical circle intercepted between the zenith, or vertical point, and the star's true place; or it is the complement of the true altitude to a quadrant. Thus if the star is at L, the true distance from the zenith V will be the arc VL, which with the true altitude AL makes up the whole quadrant ALV of the vertical circle.

[Margin: True distance from the zenith.]

Diagram. Let into the right half of the left column beside definition 4. A semicircle stands on a straight base line. At the upper right a small circle touches the semicircle's outer edge. Arcs cross the semicircle from the upper right to the lower left and from the upper left to the lower right; a line descends from the top of the semicircle to the base.

- V (top of the semicircle): the zenith
- B (upper right, on the small circle): the pole of the ecliptic
- P (centre of the small circle): the pole of the world
- E (upper left, on the semicircle): on the arc CE
- L (below V, on the vertical line): the star's true place
- D (below E): where the circle of latitude BD falls
- F (below D): the apparent place of the star at L
- K (below F): a further true place
- M (below K, near the base): the apparent place of the star at K
- G (right of F): on the arc MG
- H (left end of the base)
- A (middle of the base): the foot of the quadrant ALV
- C (right end of the base): the beginning of Aries and of the ecliptic

Labels read: V, B, P, E, L, D, F, K, M, G, H, A, C. Labels not read: I, which the text cites in the arcs KI and IG; a short upright stroke in the crossing of the lines between F and G may be this letter, but it is merged with the lines and is not settled.

5. The apparent or seeming altitude of a star is the arc of the vertical circle intercepted between the horizon and the star's apparent place. Thus if the star is at L, but appears at F, the apparent altitude will be the arc AF.

[Margin: What is the apparent altitude?]

6. The apparent distance of a star from the zenith is the arc of the vertical circle intercepted between the zenith and the star's apparent place; or it is the complement of the apparent altitude to a quadrant. Thus if the star is at L, but is seen at F, the apparent distance will be the arc VF.

[Margin: What is the apparent distance from the zenith?]

7. The true latitude of a star is the arc of the circle of latitude, that is, of the great circle drawn through the poles of the ecliptic, the ecliptic, and the centre of the star, intercepted between the ecliptic and the star's true place. Thus if the star's true place is at L, and the northern pole of the ecliptic is B, the true latitude of the star L will be the arc DL.

[Margin: What is the true latitude?]

8. The apparent latitude is the arc of the circle of latitude drawn through the star's apparent place, intercepted between the ecliptic and the star's apparent place. Thus if the star is at K, but appears at M, the true latitude will be the arc KI, but the apparent latitude GM.

[Margin: What is the apparent latitude?]

9. The true longitude of a star is the arc of the ecliptic counted from the beginning of Aries, following the succession of the signs, up to the point of the ecliptic on which falls the circle of latitude drawn through the centre of the star placed in its true place. Thus if the beginning of Aries and of the ecliptic is C, and CE is a western arc of the ecliptic, and the star's true place is at L, its true longitude will be the arc CD, because the circle of latitude BD, drawn through L, falls on the point D.

[Margin: What is the true longitude?]

10. The apparent or seeming longitude is the arc of the ecliptic counted from the beginning of Aries in the order of the signs, up to the point of the ecliptic on which the circle of apparent latitude falls. Thus if the star is at L, but appears at F, and EC is a western portion of the ecliptic, the apparent longitude will be the arc CF. But if you suppose the arc CE to represent a portion of the ecliptic that is eastern on one side and western on the other, and the star is in the eastern part, the true longitude of the star L would be the arc counted from the beginning C as far as E, and from E as far as D; whereas the apparent longitude would be the arc made up of CE, western, and EF, eastern.

[Margin: What is the apparent longitude?]

11. The true declination of a star is the arc of the circle of declination, that is, of the circle drawn through the poles of the equator, the equator, and the centre of the star, intercepted between the equator and the star's true place.

[Margin: What is the true declination?]

12. The apparent declination of a star is the arc of the circle of declination drawn through the star's apparent place, intercepted between the equator and the star's apparent place.

[Margin: What is the apparent declination?]

13. The true right ascension of a star is the arc of the equator counted from the beginning of Aries in the order of the signs, up to the point of the equator on which falls the circle of declination drawn through the star's true place.

[Margin: What is the true right ascension?]

14. The apparent or seeming right ascension is the arc of the equator counted from the beginning of Aries in the order of the signs, up to the point of the equator on which the circle of apparent declination falls.

[Margin: What is the apparent right ascension?]

There is no need to illustrate the last four definitions with examples or a special diagram; it is enough if the circles of declination are understood to be drawn through the pole of the world, P, and CE represents the equator.

15. The parallax of altitude is the difference between the true and the apparent altitude, and it coincides with the parallax of distance from the zenith. Thus if the star is at L, but appears at F, the arc LF is the parallax of altitude with respect to the horizon A, and of distance from the zenith with respect to the zenith V. The parallax of altitude is called by Ptolemy [Greek: παράλλαξις μηκοπλατῆς (parallaxis mēkoplatēs, "parallax in length and breadth")], because at times it is the same as that of latitude or of longitude, or causes both.

[Margin: What the parallaxes of altitude, latitude, longitude, right ascension and declination are.]

16. The parallax of latitude, for Ptolemy [Greek: παράλλαξις κατὰ πλάτος (parallaxis kata platos, "parallax in breadth")], is the difference between the true and the apparent latitude of a star; and it is called northern if it depresses the star towards the north, southern if towards the south.
17. The parallax of longitude, for Ptolemy [Greek: παράλλαξις κατὰ μῆκος (parallaxis kata mēkos, "parallax in length")], is the difference between the true and the apparent longitude; the parallax of right ascension, that between the true and the apparent right ascension; and finally the parallax of declination, the difference between the true and the apparent declination. Thus if the star is at L and appears at F, the parallax of latitude is the arc DL, and that of longitude the arc DF. But if the star is at K, but appears at M, the parallax of longitude will be the arc IG, while that of latitude will be the arc by which the apparent latitude MG exceeds the true latitude KI.
18. The angle of longitude is the one opposite the parallax of longitude, as in the figure given above the angle DLF.
19. The angle of latitude is the one opposite the parallax of latitude, or the one made by the ecliptic and the vertical, as in the figure given above the angle LFD.

[Margin: What the angle of longitude and of latitude is.]

20. The parallax of the Moon from the Sun is the difference by which the Moon's parallax exceeds the Sun's parallax, since, as we showed in Book 1, chapter 35, other things being equal, the parallax of a star nearer to the Earth, such as the Moon, is greater than that of a more remote one, such as the Sun.

[Margin: Parallax of the Moon from the Sun.]

The kinds already mentioned are, moreover, subdivided into other kinds, as genera are: thus the parallax of altitude, of longitude and of right ascension into an eastern and a western parallax, according as the star is in the eastern or the western quadrant of the vertical circle, or of the ecliptic, or of the equator; indeed, into a northern and a southern parallax, if the circle of altitude turns out to be either the meridian or the circle of latitude. The parallaxes of latitude and of declination, however, are subdivided into northern, southern, or mixed of both.

[Margin: The subdivision of parallaxes.]

That this may be understood, for the kinds of latitude and their various cases let there be a second diagram, in which all things are set out as in the preceding one, but for five cases let five arcs of latitude be drawn. The first is when the apparent as well as the true latitude remain of the same kind and of some quantity, but the true latitude is greater than the apparent, as if the star is at D and appears at F, and so the true northern latitude is the arc DM, but the apparent northern latitude is FN. The second is when the true latitude is

[Margin: Five cases of parallax in latitude.]

Diagram. Set across the right column near its foot. A semicircle stands on a straight base line, with a small circle at the upper right that crosses the semicircle's edge. Several arcs fan out from a point on the small circle, toward the left side of the semicircle. Straight lines descend from the top of the semicircle and cross the arcs, and meet the base.

- V (top of the semicircle)
- E [?] (upper left, on the semicircle; the letter could be read as F)
- D (right of E, below the top, on the straight line): the star in the first case
- M (left, below E): the end of the arc of true latitude, DM
- F (right of M): the star's apparent place in the first case
- N (below M): the end of the arc of apparent latitude, FN
- G (right of N)
- O (right of G)
- I (below N)
- K (below I)
- Q (right of K)
- B (upper right, on the small circle): the pole of the ecliptic
- P (in the small circle): the pole of the world
- H (left end of the base)
- A (on the base, below K)
- C (on the base, right of A)
- R (right end of the base)

Labels read: V, D, M, F, N, G, O, I, K, Q, B, P, H, A, C, R; with E [?]. Labels not read: none known.

of some quantity, but the apparent latitude is nil; for example, if the star is at F but appears at G, and the true latitude is northern, FN, while the apparent latitude, at G, is nil. The *third* case is when the parallax is mixed, from a true latitude on one side and an apparent latitude on the other; for example, if the star is at F and appears at I, and the parallax of latitude is composed of the true northern latitude FN, which it cancels, and the apparent southern latitude IO. The *fourth* case is when there is no true latitude, but the apparent latitude is of some quantity; for example, if the star is at G but appears at I, with the apparent southern latitude IO. The *fifth* case is when the apparent and true latitudes are of the same kind, but the apparent is greater than the true, because both are reckoned toward the other pole; for example, if the star is at I, with the true southern latitude IO, but appears at K, with the apparent southern latitude QK.

[Margin: What the nonagesimal degree is.]

21. The *nonagesimal* degree is the one 90° distant from the ascending degree: reckoned on the ecliptic if it is the nonagesimal of the ecliptic, or on the equator if it is the nonagesimal of the equator. In the following figure, for instance, if the arc NC of the ecliptic EC, standing above the horizon HCR, is 90°, the point or degree N is called, and is, the nonagesimal. Understand always the nonagesimal of the ecliptic, if nothing else is added.

[Margin: What the eastern and western quadrants are.]

22. The *eastern quadrant* of the ecliptic or equator is the one between the nonagesimal and the ascending degree; the western is the one that lies between the nonagesimal and the descending degree of the ecliptic or equator.

[Margin: What the horoscope or ascendant is.]

23. The *horoscope* or *ascendant* is the rising point of the ecliptic, that is, the one placed on the eastern horizon, as the point C in the following figure.

Theoremata Selecta de Parallaxibus prædictis cum Corollarijs ad Eclipſes Solis ſpectantibus.

Selected theorems on the parallaxes already mentioned, with corollaries bearing on eclipses of the Sun.

[Margin: Theorem 1.]

III. Theorem 1. A star at the nonagesimal degree of the ecliptic, in itself or in respect of its longitude, undergoes no parallax of longitude. This comes from Ptolemy, Book 5, Ch. 19, and from Copernicus, Book 4, Ch. 26, and it is common among the astronomers cited in Section 1. Regiomontanus demonstrates it as well, in Book 5 of the *Epitome*, prop. 28, and in *De Cometis*, Problem 5, as does Nonius on Peuerbach, p. 296. The reason is that the circle of latitude determining the star's longitude then passes at once through the nonagesimal of the ecliptic and through the vertex, and so also becomes a circle of altitude, cutting the ecliptic at right angles; and therefore it passes through both the true place and the apparent place. So it is in the adjoined figure, in which let the horizon be HCR, the meridian HVR, the vertex V, the ecliptic EC, and on it the nonagesimal N, distant from the ascendant C by the quadrantal arc NC.

Diagram. Let into the right half of the left column. A semicircle stands on a straight base; a heavy double-ruled line, slightly curved, runs from the upper left of the arc down to the base right of centre. Two small horned crescents, the Moon, lie along the upper part of the figure near that line. At the upper right a small circle stands on the arc.

- H (left end of the base, outside): horizon, per HCR, and meridian, per HVR
- A (on the base, just inside H): not cited on this page
- C (on the base, right of centre): the ascendant
- R (right end of the base): horizon and meridian, per HCR and HVR
- V (top of the arc): the vertex
- E (upper left, at the head of the heavy line): ecliptic, per EC
- R (beside a disc, upper left): the star's place in the text's "at R"
- N (beside a disc, below that R): the nonagesimal
- K (below that, beside the heavy line): a place of the star
- M (below K): not cited on this page

- B (at the top of the small circle): not cited on this page
- P (at the centre of the small circle): not cited on this page

Labels read: H, A, C, R (twice), V, E, N, K, M, B, P. Labels not read: none known.

So whether the star, the Moon for instance, is at R, at N, or at K, its place of longitude, both true and apparent, will still be the nonagesimal N itself; yet in that case there can be parallax in altitude and in latitude. This happens once a day; and the Moon at the nonagesimal, if it is horned, holds its horns upright, as I said in Book 4, Ch. 3, no. 3; see the figure there.

[Margin: Theorem 2.]

Theorem 2. For a star placed at the nonagesimal degree of the ecliptic, in itself or in respect of its longitude, the parallax of latitude is not merely equal to the parallax of altitude but the same. For, as I said, the circle of latitude and the circle of altitude then become one and the same. Thus in the figure just given, if the Moon is at R and appears at N or at K, the same arc RN or RK that is the parallax of altitude will also be the parallax of latitude.

[Margin: Theorem 3.]

Theorem 3. If the true conjunction of the luminaries occurs at the nonagesimal degree of the ecliptic, it will coincide with the visible or apparent conjunction; that is, the true and the apparent new Moon will be the same. This follows from Theorem 1, but the Moon is taken as reduced to the ecliptic.

[Margin: Theorem 4.]

Theorem 4. A star placed at the nonagesimal degree of the equator has no parallax of right ascension; but its parallax of declination is the same as its parallax of altitude, and if a true conjunction of the luminaries then occurs, it will occur at noon. The reason is that the same circle of altitude becomes a circle of declination, and indeed the meridian too.

[Margin: Theorem 5.]

Theorem 5. If the ecliptic passes through the spectator's vertex, as happens for many within the Torrid Zone, and the star is on the ecliptic itself, though away from the vertex, there is no parallax of latitude, while the parallax of altitude and that of longitude are the same and equal. For the ecliptic then becomes a circle of altitude, and on it lie the star's true and apparent places. You will easily understand this if, turning a globe or an armillary sphere, where the altitude of the pole does not exceed 23° 30′, you set some degree of the ecliptic under the zenith.

[Margin: Theorem 6.]

Theorem 6. For a star placed away from the nonagesimal of the ecliptic and in the eastern quadrant, the true longitude is less than the apparent, and the apparent conjunction of the luminaries precedes the true by an arc as great as the parallax of longitude, and by a time equal to the time produced by dividing the parallax of longitude by the Moon's hourly motion from the Sun, as then proper to the Moon: as in the first figure of Section II. If the arc EC of the ecliptic is eastern, and the place of the true longitude of the star L is D, while

that of its apparent longitude is F, the star will be seen at F, further east and further advanced in longitude than it really is, by an arc as great as the parallax DF; and if the true conjunction is going to occur at F, it will already be seen to have occurred, although the star is still short of it, at D.

[Margin: Theorem 7.]

Theorem 7. For a star placed away from the nonagesimal of the ecliptic in the western quadrant, the true longitude is greater than the apparent, and the apparent conjunction of the luminaries follows the true by an arc as great as the parallax of longitude, and by as much time as is produced by dividing this parallax by the Moon's hourly motion from the Sun. For the theorems already mentioned, see Reinhold on Peuerbach, p. 195.

[Margin: Theorem 8.]

Theorem 8. In regions on this side of the Tropic of Cancer the parallax of latitude diminishes a northern latitude; if it equals the true latitude, it cancels it; if it exceeds it, it carries it over into an apparent southern latitude as great as that excess. A southern latitude, however, it always increases. In the same way, in regions beyond the Tropic of Capricorn it either diminishes a southern latitude, or cancels it, or turns it into a northern one; but a northern latitude it always increases.

[Margin: Theorem 9.]

Theorem 9. Within the Torrid Zone the parallax of latitude can, for a spectator whether northern or southern, both increase and diminish either kind of latitude, according as the star on a vertical circle is depressed for them by the parallax of altitude toward the ecliptic or further away from the ecliptic. You will learn this more easily from the use of a globe or an armillary sphere than through long and multiple rules.

[Margin: Theorem 10.]

Theorem 10. If the culminating point of the ecliptic, that is, the one crossing mid-heaven, is further south than the inhabitant's vertical point, the parallax of latitude is southern, that is, it depresses the star toward the south; but if further north, it is northern, that is, it depresses the star toward the north. Ptolemy, Book 5, Ch. 19. I am not saying here that the apparent latitude is southern or northern, but the parallax itself; for the apparent latitude can remain northern and yet the parallax be southern, because it casts the star down toward the south, etc. But Ptolemy's statement must be limited to a star that is on the ecliptic; otherwise it would not be universally true.

[Margin: Theorem 11.]

Theorem 11. If the angle of the ecliptic and the horizon that faces north is greater than a right angle, and the parallax of latitude depresses the star to the south, the parallax of longitude is in the order of the signs [ad Succeſſionem Signorum]; but if the parallax of latitude depresses it to the north, it is against the order of the signs [in præceſſionem Signorum]. Conversely, if that angle is less than a right angle and the parallax of latitude is to the south, the parallax of longitude is against the order of the signs [in præcedentia Signorum]; but if the

parallax of latitude is to the north, it is in the order of the signs. Ptolemy, Book 5, Ch. 19; and recall here that it is one thing for the parallax to be to the south or north, and another for the apparent latitude itself to be northern or southern.

[Margin: Theorem 12.]

Theorem 12. If the star's distance from the meridian reckoned on the horizon, that is, the eastern azimuth, equals the rising amplitude of the rising degree of the ecliptic, or the western azimuth equals the setting amplitude, the star has no parallax in longitude; for it is then at the nonagesimal, and the azimuth of the nonagesimal equals the amplitude already mentioned. Nonius demonstrated this on Peuerbach, part 2, note 7, and Regiomontanus touched on it in the book *De Cometis*, Problem 5.

[Margin: Theorem 13.]

Theorem 13. All the parallaxes of latitude, in whatever degree of the ecliptic the star may be, are equal, provided that the same point of the ecliptic rises at the same altitude of the pole, and the star is equally distant from the eye. Kepler, in the *Astronomia Optica*, Ch. 9, no. 4, prop. 1, where he demonstrates this.

[Margin: Theorem 14.]

Theorem 14. All the parallaxes of latitude, in whatever degree of the ecliptic the star may be, at the same altitude of the pole and with the same point of the ecliptic rising, even if the star is unequally distant from the eye, provided it is equally distant from the centre of the Earth, are as nearly as possible equal. Kepler, above, prop. 2, where he also shows that the greatest inequality among them does not exceed 37″, and that this occurs only if the spectator's position lies midway between the one under the ecliptic and the one under the pole of the ecliptic, and when the parallax of altitude is at its greatest; otherwise that difference is much less than 37″.

[Margin: Theorem 15.]

Theorem 15. All the parallaxes of latitude are in fact equal, in whatever degree of the ecliptic the star may be, provided that it is seen on the ecliptic, that the star's distance from the centre of the Earth and the altitude of the pole are the same, and that the same point of the ecliptic is rising. Kepler, above, prop. 3.

[Margin: Theorem 16.]

Theorem 16. The parallax of altitude is rarely equal to the parallax of longitude or of latitude; usually it is greater than either, and never less. Mulerius, p. 434. To demonstrate these theorems here, along with others that bear on comets rather than on eclipses, would have been long and out of place, since they belong to the common doctrine of the primum mobile, or to our optical book, Section 1.

[Margin: Theorem 17.]

Theorem 17. The nonagesimal degree of the ecliptic is in the eastern quadrant when northern signs are ascending, but in the western when southern signs are ascending, for inhabitants of the north; the opposite happens for those of the south. This is evident to anyone who turns a sphere.

[Margin: Theorem 18.]

Theorem 18. The greatest parallax of longitude is, in the southern signs, below the horizon; at the equinoctial points, on the horizon; in the northern signs, above the horizon, to us in the north. Kepler, in the *Epitome of Copernican Astronomy*, p. 884.

PROBLEMATA.

Problems.

Parallaxium Lunæ & Solis, Eclipſibus Solis deſeruientia, aut ad has Parallaxes pertinentia.

Problems of the parallaxes of the Moon and the Sun, serving eclipses of the Sun or pertaining to these parallaxes.

[Margin: Three kinds of problems prerequisite for the parallaxes of the luminaries.]

IV. There are three kinds of these problems. The first consists of general problems that bear remotely on these parallaxes, such as finding the *right ascension* for a given point of the ecliptic, and the *angle of the ecliptic and the meridian* for a given point of the ecliptic, and, for a given time, seeking the *right ascension of mid-heaven* as well as the *culminating point of the ecliptic*, and other things of the kind. It is certainly not the business of this place to set these out; they are to be assumed here and sought from the doctrine of the primum mobile, to be set out in Book 10. The second kind consists of problems that are indeed general and to be set out under the primum mobile, but are required more nearly or most nearly for the parallaxes of the luminaries; and these we must touch on here, though as briefly as possible, with their fuller doctrine referred to Book 10. Such are those that deal with the *rising point of the ecliptic*, the *nonagesimal of the ecliptic*, the *altitude of the nonagesimal* or the *distance of that nonagesimal from the vertex*, and also the *altitude of the luminaries*; and finally the *angle of the ecliptic and the vertical*, which is called the *parallactic angle* [Angulus Parallacticus], whether that vertical is drawn through the true place of the luminaries, when they are on the ecliptic, or through the Moon, when it is off the ecliptic. The third kind includes the problems proper of the parallaxes of altitude, latitude and longitude, to be deduced directly. Let us now begin with the second kind.

PROBLEMA I.

Problem 1.

Dato Tempore apparente veri Nouilunij ante vel poſt meridiem, & Loco Luminarium in Zodiaco, Inuenire punctum Eclipticæ Aſcendens ſeu exoriens, atq. inde Nonageſimum Gradum, ſeu punctum Eclipticæ, ſitumq. Luminarium reſpectu Nonageſimi.

Given the apparent time of the true new Moon before or after noon, and the place of the luminaries in the zodiac, to find the ascending or rising point of the ecliptic, and from it the nonagesimal degree or point of the ecliptic, and the position of the luminaries with respect to the nonagesimal.

V. First, from tables or problems of the primum mobile look up the right ascension of the point of the ecliptic at which the luminaries are, and add the apparent time after noon, converted into degrees of the equator, to the right ascension, discarding 360° if the sum reaches or exceeds them. The remainder or the sum will be the right ascension of mid-heaven. Add 90° to it, and you will have the oblique ascension in an oblique sphere, or the right ascension in a right sphere, of the horoscope or ascending point of the ecliptic; this is to be used if it does not exceed 180°, or its complement to 360° if it exceeds them.

Second, if the place you are working for is in a right sphere, look up in the body of the table of right ascensions the right ascension of the rising point: opposite it on the left you will find the degree or point, and at the head of the table the sign of the ascending degree or point. But if you are working for an oblique sphere, look up the rising point or ascending degree in the same way, but in the tables of oblique ascensions suited to the given altitude of the pole, looking up in the body of the table the oblique ascension, or its complement, discussed here in instruction 1.

Third, subtract 90° from the ascending point of the ecliptic, and the nonagesimal degree of the ecliptic will remain known. If this point coincides with the true place of the luminaries on the ecliptic, they will be at the nonagesimal, which also holds in its own way of the Moon, if it has been reduced to the ecliptic. But if they are on this side of it, against the order of the signs, they will be in the western quadrant of the ecliptic; if beyond it, in the order of the signs, they will be in the eastern quadrant of the ecliptic. To these you will apply Theorems 1, 2, 3, 4, 6 and 7, discussed above.

Idem Aliter.

The same by another method.

VI. First, add together into one the given time, but the apparent time, from noon and the semidiurnal quantity, and convert the sum into degrees of the equator, discarding 24^h if it should exceed them. Then, with the given place of the Sun, look up under the appropriate altitude of the pole its oblique ascension; add this to the degrees of the equator already mentioned, discarding 360° if it should exceed them, and you will have the oblique ascension of the ascending

point. Second, therefore, in the body of the table of oblique ascensions look up, as above, the ascending point corresponding to the oblique ascension, and do the rest as above. Another way, by tables of houses (if you lack tables of oblique ascensions): find the Sun's place for the given time from noon; with it, in a table of houses under the appropriate altitude of the pole, in the column of the 10th house, look up the Sun's place, for opposite it in the left column stands the corresponding time from noon. Add to this the time from noon for which you calculated the Sun's place, and look up the combined time in the same table of houses: for opposite it, under the title *first house* or *ascendant*, you will find the point of the horoscope. Such tables are given by Magini in the Introduction to the Ephemerides, and by Argoli and Origanus in the same place.

PROBLEMA II.

Problem 2.

Altitudinem Nonageſimi ab Horizonte, atq. adeò eius diſtãtiam à Vertice inueſtigare.

To find the altitude of the nonagesimal above the horizon, and hence its distance from the vertex.

VII. In the adjoined figure let the horizon be HCR, the meridian HVR, on which are the vertex V, the pole of the world F, and the pole of the zodiac B, from which let there be described a portion of the ecliptic ENC, and on it the nonagesimal N, through which and the vertex V let there pass the circle BVNA, both vertical and of latitude.

[Margin: Finding the culminating point.]

First, then, from tables or problems of the primum mobile, with the Sun's place and the given time, look up the right ascension of mid-heaven, as I said in Problem 1, instruction 1; and with this, looked up in the body of the table of right ascensions, find the culminating point of the ecliptic, that is, the one then passing through the meridian, namely point E.

[Margin: Finding the angle of the ecliptic and the meridian.]

Second, from tables or problems of the primum mobile look up the angle HEC of the ecliptic and the meridian, corresponding to the culminating point of the ecliptic, and find the difference of longitude between the culminating point E and the point C, the ascending point of the ecliptic, known by Problem 1, by subtracting the longitude of the culminating point from the longitude of the ascendant. Call that difference, namely EC, the base of the spherical triangle HEC, right-angled at H, to which is adjacent the angle HEC of the ecliptic and the meridian.

Diagram. Set across the left column, interrupting the sentence above after "the point C,". A semicircle stands on a straight base. From the top, V, dotted and solid lines run down to the base. A curved line and a straight line run from

the upper left of the arc down to the right of the base; another arc runs from the left of the figure up to the right, to a small circle at the upper right.

- H (left end of the base): horizon and meridian, per HCR, HVR
- A (on the base, right of H): the foot of the circle BVNA
- [?] sign (on the base, right of A): a closed loop over two out-curving feet, not identified; not cited on this page
- T (on the base, right of that): not cited on this page
- C (on the base, right of centre): the ascending point
- R (right end of the base): horizon and meridian, per HCR, HVR
- V (top of the arc): the vertex
- E (upper left): the culminating point
- D (upper middle): a place of the star in Case 2
- N (below and to the left of D): the nonagesimal
- G (left, below N): a place of the star in Case 2
- O (between D and K, smaller than the other letters): not cited on this page
- L (below G): not cited on this page
- I (right of L): a place of the star in Case 3
- M (below I): not cited on this page
- K (right of I): not cited on this page
- B (upper right, on the arc): the pole of the zodiac
- F (in the small circle): the pole of the world

Labels read: H, A, S, T, C, R, V, E, D, N, G, O, L, I, M, K, B, F; one sign on the base, between A and S, not identified [?]. Labels not read: none known.

Third, by analysis of the triangle already mentioned, look up the other angle adjacent to the base, namely HCE. For it will be the angle of the east [Angulus Orientis], which measures the arc AN, because the angles at N and A are right angles, and NC, and hence CA, are quadrants. And AN is the altitude of the nonagesimal above the horizon, and the complement of this altitude to 90° will give the distance NV of that nonagesimal from the vertex.

Idem aliter per Tabulas.

The same by another method, using tables.

[Margin: Ptolemy's table of the angle of the east.]

VIII. First, in Ptolemy's *Almagest*, at the end of Book 2, you have tables of the angle of the east and of the west and of a luminary's distance from the vertex, entered with the equal hours by which the luminary is distant from the meridian. But they serve only seven climates, that is, from polar altitude 16° 2′ as far as altitude 48° 31′, and only the whole signs in which the luminaries are.

[Margin: And Copernicus's table.]

Second, Copernicus gives a table of the same angle of the east, Book 2, Ch. 10, p. 42, which is entered, under polar altitudes of 39°, 42°, 45°, 48°, 51°, 54° and 57°, with the ascending point of the ecliptic known by Problem 1. But it

has only every sixth degree of the ascending signs, and it is constructed for an obliquity of the ecliptic of 23° 28′.

[Margin: The table of the angle of the east in Magini.]

Third, in the second volume of the *Primum Mobile* of Giovanni Antonio Magini and in his tables, which they call tables of directions, from p. 200, there is a better table of the angle of the ecliptic and the horizon, for each altitude of the pole from 30° to 54° and for each degree of the ascending signs, entered from the sides with the ascending degree known by Problem 1. But this table, like his preceding table of the angle of the ecliptic and the meridian, is constructed for the Tychonic obliquity of the ecliptic, 23° 31′ 30″.

[Margin: The table of the nonagesimal's distance from the vertex and from the meridian in Mulerius.]

Fourth, there is in Nicolaus Mulerius, in the *Tabulae Frisicae*, p. 448, a table containing both the distance of the nonagesimal from the vertex and its distance from the meridian reckoned on the ecliptic, entered with the degree of the ecliptic that is culminating or at mid-heaven, known by instruction 1 of Problem 2. He constructed this table for each culminating degree of the signs, and for polar altitudes of 42°, 45°, 48°, 51°, 52°, 53⅙° and 55° 55′, assuming the Tychonic obliquity of the ecliptic.

[Margin: The best table of the angle of the east, in Kepler,]

[Margin: and in Renieri.]

Fifth and last, Kepler, in the Rudolphine Tables, from page 26, has given us a table of the angle of the east, or, what is equivalent, of the altitude of the nonagesimal, and that for absolutely every altitude of the pole from 1° to 90° and for every third degree of the rising signs, expressing the minutes of the angle of the east in parts of a unit [per partes affis]. He teaches its use in the instructions, Ch. 14, or instruction 39. Don Vincenzo Renieri, in his *Tabulae Mediceae*, printed a second time, from p. 324, abridged this table to every third degree of polar altitude up to 30°, then to every degree but only up to 53°, then again to every third up to 62°, and to every second degree of the ascending signs; and the same table, but exactly as it stands in Kepler, Boulliau copied into his *Philolaic Tables*, p. 158. Kepler admits, in Ch. 12 of the Rudolphine Tables, that he constructed these tables of the primum mobile for the Tychonic obliquity of the ecliptic, 23° 31′ 30″, as if constant, although he says that from his own solar parallax, which does not exceed 1′, an obliquity of the ecliptic of 23° 30′ 30″ follows.

[Margin: The blemish of Renieri and Boulliau.]

But since this table does not give the altitude of the nonagesimal considered on the Moon's orbit, Renieri, in the instructions for eclipses, Ch. 3, instruction 3, and Boulliau, Book 12, instruction 22, say that the true place of the node ☊ is to be subtracted from the true place of the nonagesimal on the ecliptic; that with the remainder, as an argument of latitude, the latitude is to be sought as if it were the Moon's; and that this is to be added to the altitude of the nonagesimal if the latitude is northern, and subtracted if southern, so as to obtain the altitude

of the nonagesimal considered not on the ecliptic but reduced to the orbit of the Moon.

[Margin: Praise of Don Vicenç Mut.]

Don Vicenç Mut, a man most learned in astronomy, disapproves this method, as I gather from various letters he has sent me, on this subject too. First, because the same vertical cannot cut both the ecliptic and the Moon's orbit at right angles, except when the node is in the east. Next, because when the node is at the nonagesimal of the ecliptic, the node is then not a quadrant of the lunar orbit away from the rising. Finally, because at the same meridian altitude of the lunar orbit, the parallaxes of lunar latitude would be equal in any part of the orbit according to Kepler's doctrine as applied here, on which see our Theorem 13; and that, however, is false. So although it is better to use at least this method than no correction, still we do not attain complete precision by it, and in some places the error exceeds a whole 1′.

PROBLEMA III.

Problem 3.

Datis Nonageſimo Eclipticæ, eiuſq. Diſtantia à vertice, & ſideris ad idem tempus Longitudine ac Latitud. Inquirere ſideris in Ecliptica aut extra poſiti Altitudinem ab Horizonte Diſtantiamq à vertice, necnon Angulum in centro ſideris aut loco eius in Ecliptica factum à Verticali & Ecliptica aut circulo latitudinis.

Given the nonagesimal of the ecliptic, its distance from the vertex, and the longitude and latitude of a star at the same time, to find the altitude above the horizon and the distance from the vertex of a star placed on the ecliptic or off it, and also the angle at the centre of the star, or at its place on the ecliptic, made by the vertical and the ecliptic or circle of latitude.

[Margin: Four cases of this problem.]

IX. This problem has four cases, according as the star is either at the nonagesimal itself without latitude, or at the nonagesimal as to longitude but with latitude; or away from the nonagesimal without latitude; or away from the nonagesimal with latitude. The altitude AN of the nonagesimal and the distance NV are assumed as known by Problem 2.

[Margin: Case 1.]

First, then, in the figure given before no. 8: if the star is at the nonagesimal N, its altitude is already the same as the altitude of the nonagesimal.

[Margin: Case 2.]

Second, if in its place of longitude it is at the nonagesimal N, but has northern latitude ND or southern latitude NG, because the star is at D or G, add the northern latitude ND to the altitude AN of the nonagesimal, or subtract the

southern NG. In the first case AD will result; in the second AG will remain, the altitude of the star. In this case we do not need the angle of the vertical made at the centre of the star, because there is no parallax of longitude.

[Margin: Case 3.]

Third, if the star as to longitude is away from the nonagesimal, but on the ecliptic itself without latitude, as at I, let the vertical VIS be drawn through it, so as to form the triangle VNI, which is right-angled at N. In it are given NV, the distance of the nonagesimal from the vertex, by Problem 2, and the arc NI of the ecliptic, which is the difference between the nonagesimal known by Problem 1 and the place of the star's given longitude. Therefore by trigonometry the base IV, which is the star's distance from the vertex, will not remain hidden; its complement to 90°, IS, will be the star's true altitude. Nor will the angle HIV [recte: NIV], the one sought, remain hidden.

[Margin: A shortcut for the Problem.]

In brief, let it be: as the radius is to the second sine of arc NV, so is the second sine of arc NI to the second sine of the base IV. Then let it be: as the radius is to the tangent of arc NV, so is the second secant of arc NI to the tangent of the angle sought, NIV. Or join together the second logarithms of the arcs NV and NI, and their sum will be the second logarithm of the base IV. Then the mesologarithm of arc NV, added to the residual of the logarithm of arc NI, will make up the mesologarithm of the angle sought, NIV.

[Margin: Case 4.]

Fourth, if the star is away from the nonagesimal and has latitude, as when it is at K or at L, with its place in longitude at I, let there be drawn through it both the vertical, such as VKT or VLQ, and a third, VIS; and the circle of latitude, such as BKI or BIL.

Diagram. Set across the left column, interrupting the word that follows the sentence above. A semicircle stands on a straight base. From the top, V, solid and dotted lines run down to the base. A curve runs from the upper left of the arc down to the right of the base; another arc runs from the left of the figure up to the right, to a small circle at the upper right, and a line runs from B down toward the centre of the figure.

- H (left end of the base): the altitude HE, in Section X
- A (on the base, right of H): not cited on this page
- Q (on the base, right of A, a swash letter set close against the next): the foot of the vertical VLQ
- S (on the base, joined to that sort): the foot of the vertical VIS
- T (on the base, right of that): the foot of the vertical VKT
- C (on the base, right of centre): not cited with this figure
- R (right end of the base): not cited with this figure
- V (top of the arc): the vertex
- E (upper left): the culminating point, in Section X
- D (upper middle): not cited on this page

- O (below D, a small round letter): not cited in the fourth case; the foot of the perpendicular KO in the passage under Section X
- N (below and to the left of D): the nonagesimal
- G (left, below N): not cited on this page
- L and I (centre, side by side, L on the left, I on the right at the junction of the lines): a place of the star, and the place in longitude
- M (below them): the foot of the perpendicular LM
- K (right of centre): a place of the star
- B (upper right, on the arc): the end of the circles of latitude BKI, BIL
- F (in the small circle): not cited on this page

First, as in the third case, find the base VI in the triangle NVI, and also the angle NIV. Then, if the star is at K, consider the triangle IKV, in which the northern latitude IK is given, and the side IV has been found, as has the angle VIK, which is the complement to a right angle of the angle NIV already found (for the circle of latitude always makes right angles with the ecliptic). By trigonometry, therefore, you can find the third side or base KV, namely the star's distance from the vertex; and its complement to a quadrant, which is the altitude TK; and the angle IKV, whose complement to two right angles is the angle VKB. But if the star is at L, look at the triangle LIV, in which the southern latitude LI is given, and the side IV has been found, as has the angle LIV contained by them, which is made up of NIV, already found, and the right angle LIN. You can therefore find the base LV, namely the star's distance from the vertex, whose complement to a quadrant is the altitude QL. Then you will seek the angle VLI, that is, the angle sought, VLB.

[Margin: A shortcut for the Problem in Case 4.]

I am of course aware that at ecliptic new Moons, because of the Moon's slight latitude, astronomers treat the Moon just as if it were on the ecliptic. I do not, however, think that this latitude should be neglected. And if you shrink from the tedium of further trigonometry, you ought to subtract the northern latitude IK from the base IV already found, so as to have KV, or to add the southern latitude LI, so as to have LV; for in this way you will come closer to the truth.

Idem Problema Aliter iuxta Ptolemæum Regiomontanum & Copernicum, datis Longitudine, ac Latitudine ſideris, & puncto Eclipticæ Culminante.

The same Problem otherwise, according to Ptolemy, Regiomontanus and Copernicus, given the longitude and latitude of the star and the culminating point of the ecliptic.

[Margin: Case 1.]

X. Ptolemy (*Almagest*, Book 2, Ch. 12, and Book 5, Ch. 19), Regiomontanus (*Epitome*, Book 2, prop. 45, and Book 5, prop. 30) and Copernicus (Book 2, Ch. 12, and Book 4, Ch. 26), when these passages are taken together, complete both parts of the Problem as follows. Let everything be set out as in the preceding

figure for the second and this third Problem, and let the star, or the star's place, be given at I, together with the point of the ecliptic at E. For the arc EI will be given, and, from the Tables or Problems of the primum mobile, the angle IEV of the ecliptic and the meridian in the triangle IEV; and from the tables of declination and the polar altitude there will be given, for the culminating point E, both the altitude HE and the distance EV from the vertex. From these three data in the triangle EIV you will therefore find both the distance IV of the point I from the vertex and the angle EIV.

[Margin: Cases 2 and 3.]

Next, let the star be at K or at L. For once the arc IV and the angle EIV have been found in the first case, and that angle has been taken from the right angle EIK or joined to the right angle LIE, there will be evident the angle VIK in the one instance and LIV in the other. So, as we did above in the third and fourth cases, Copernicus seeks from the given latitudes IK or LI the distance KV and the angle VKI in the triangle IKV, or the distance LV and the angle VLI in the triangle LIV. Ptolemy and Regiomontanus, by contrast, draw from K to IV, already found, the perpendicular KO; and in the triangle IKO, right-angled at O, from the angle OIK, found as above, and the latitude IK, they seek IO and OK. Then, with IO taken from IV, the arc OV becomes known to them in the triangle VOK, right-angled at O; and so, with OK already found, they seek the distance KV and the angle OKV, which, joined to the angle IKO, makes the desired angle IKV, whose complement to two right angles is the angle VKB.

Similarly, when the star is at L, with the perpendicular LM drawn to SV, they seek the arcs LM and MI in the triangle LIM, right-angled at M, from the angle LIM, which equals the angle OIK, and the latitude LI. With IV and MI joined, the arcs MV and ML become known in the triangle LVM, right-angled at M; and so in that triangle they seek the distance LV, with which, in the triangle LIV, together with the latitude LI and the distance IV, they seek the angle VLI.

[Margin: Reason why Ptolemy multiplies so many operations.]

In the small triangles LMI and KOI, moreover, they use curved lines in place of straight ones, because of the imperceptible difference arising from the nearness and smallness of these arcs; and they turn the more willingly, when they can, to right-angled triangles, for they think that this ease offsets the labour of the many-fold operation. Regiomontanus, though, in Book 5, prop. 31, gives another method using spherical triangles alone.

[Margin: A saving of labour according to Ptolemy, Regiomontanus and Copernicus.]

Yet when all this has been done, Ptolemy (Book 5, Ch. 19), Regiomontanus (Book 5, prop. 30) and Copernicus (Book 4, Ch. 26) admit that it is neither expedient nor necessary, in hunting down the Moon's parallaxes, to use her latitude, and that we can safely use the altitude of the Moon's place on the ecliptic and the angle made there by the vertical and the ecliptic. For the greatest error that can arise from this in the parallax of altitude is 10′, as Ptolemy

and Regiomontanus say, or 7′, as Copernicus says, and that only when the Moon's latitude at perigee is 5° and the parallax is horizontal. In eclipses of the Sun, moreover, an error greater than a minute and a half, or 1′ 30″, cannot be committed in the parallaxes, because in them the latitude cannot be greater than 1° 30′.

Idem Aliter ex Magino aut D. Vincentio Muto per ſola triangula rectangula, Datis Longitud. & Latitud. Sideris vnà cum Pūcto Eclipticæ Oriente, & Angulo Orientis.

The same otherwise, from Magini or D. Vicenç Mut, by right-angled triangles alone, given the longitude and latitude of the star together with the rising point of the ecliptic and the angle of the rising point.

[Margin: Problem of D. Vicenç Mut.]

XI. In the letters of D. Vicenç Mut, of which I spoke at the end of number 8, a part of this Problem is supplied to me, and it certainly deserved to be made whole by me and inserted here. Let the horizon be HR, the meridian HVR, the ecliptic EC, and let there be three vertical quadrants VQ, VS, VT. Let the Moon be now at I, without latitude, now at K, with the southern latitude KI, now at O, with the northern latitude OI; through these three places let the circle of latitude BOIK pass, and from these three places let three arcs OC, IC, KC be drawn to the rising point C.

Diagram. Set across the right column, interrupting the sentence above after "VQ, VS,". A semicircle stands on a straight base. From the top, V, straight lines run down to the base. A curve runs from the upper left of the arc, at E, down to C on the base; another curve rises from the lower left through the centre of the figure to B and beyond the arc at the upper right; further lines converge on C.

- H (left end of the base): horizon and meridian, per HR, HVR
- Q (on the base, a swash sort, right of H): the foot of the vertical quadrant VQ
- S (on the base, right of Q): the foot of the vertical quadrant VS
- T (on the base, right of S): the foot of the vertical quadrant VT
- C (on the base, right of centre): the rising point
- R (right end of the base): horizon and meridian, per HR, HVR
- V (top of the arc): the vertex
- E (upper left of the arc): the ecliptic, per EC
- B (upper right, outside the arc): the circle of latitude BOIK
- O (right of centre, upper): a place of the Moon with northern latitude
- N (left of centre, upper): cited in the second case, angle NCQ
- I (centre): a place of the Moon without latitude
- L (right of I): not cited on this page
- K (left of I, lower): a place of the Moon with southern latitude

[Margin: Case 1.]

First, if the Moon is at I, then in the triangle ISC, right-angled at S, the angle of the rising point ICS is given, and from the Moon's place I compared with the rising point C the arc IC of the ecliptic is given. Therefore the Moon's altitude SI will not remain hidden, nor will the parallactic angle SIC; for it is so called because it is useful for deriving parallaxes in longitude and latitude.

[Margin: Case 2.]

Second, let the Moon be at K, which is the case set out by D. Vicenç. In that event, in the triangle KIC, IC is given as above, and the southern latitude KI; therefore KC will not remain hidden, nor the angle KCI, since the triangle is right-angled at I by virtue of the arc of latitude. Then in the triangle KQC, right-angled at Q, with the base KC now found, and the angle KCI, already found, subtracted from the given angle of the rising point ECQ, so that KCQ is known, you will seek the Moon's true altitude QK and the arc QC. Finally, in the triangle NQC, right-angled at Q, with the arc QC found, as I said, and the angle of the rising point NCQ given, you will seek the parallactic angle QNC.

[Margin: Case 3.]

Third, let the Moon be at O. For then in the triangle IOC, right-angled at I, with the arc IC given as above, and the northern latitude IO, you will seek the base OC and the angle ICO, which you will add to the angle of the rising point ECH, so that the angle TCO is known. Then in the triangle OTC, right-angled at T, with OC and TCO now known, you will seek both the Moon's true altitude TO and the arc TC. Lastly, in the triangle LTC, right-angled at T, with the arc TC now found and the angle of the rising point TCL given, you will seek the parallactic angle TLC.

[Margin: Otherwise, from Magini.]

Otherwise, from Magini's General Table of the primum mobile you will find the altitude of the Sun by entering it with the angle of the ecliptic and the horizon and with the Sun's distance from the rising point. And with the same data, in the table of the third analogy, which is found in the Tables of Directions of the same Magini, seek the angle, marking at the foot of the table the Sun's distance from its rising or setting and on the left side the angle of the rising point; for the angle found and subtracted from 90° will give the angle of the ecliptic and the vertical.

Idem Problema aliter Per Tabulas aut vſum Globi vel Sphæræ, quoad altitudinem Luminarium, Dato eorum loco in Eclip-tica ad datum tempus, & Data Poli Altitudine.

The same Problem otherwise, by tables or the use of a globe or sphere, as regards the altitude of the luminaries, given their place on the ecliptic at a given time and given the polar altitude.

XII. In the Prutenic Canons, p. 99, there are tables constructed by Erasmus Reinhold, which Magini, in the tables of the *Secunda Mobilia*, p. 691, Renieri,

in the first edition of the *Tabulae Mediceae*, p. 296, and Argoli, in his own tables, p. 165, copied out in mutilated form, but Lansbergen, on p. 51 of his tables, in full. These tables are entered with whole hours after or before noon, and under the beginning of the signs in which the luminaries stand, at certain polar altitudes. Their second column, opposite the given hour, shows the distance of the luminaries from the vertex, whose complement to 90° is their altitude above the horizon. But those tables are only for polar altitudes of 16°, 24°, 31°, 36°, 41°, 45°, 49°, 52°, 54°, 57°, 60°, 63°, 66° and 70°. So when the polar altitude differs from these, or the luminaries are not at the very beginning of the signs, or the hours are not whole, or all these differences come together, one has to hunt for the proportional part by repeated calculation, to the point of tedium.

[Margin: A blemish in the Prutenic Tables corrected.]

Moreover, these tables assume the star to be on the ecliptic itself, without any latitude, on account of the assurance which, as we saw at the end of the preceding number 10, Ptolemy, Regiomontanus and Copernicus urged; yet we should be safer if the northern latitude were subtracted from the distance found in these tables, or the southern added.

[Margin: Kepler's slip.]

Meanwhile one must be very much on guard against a slip of imagination or memory by Kepler, in the *Astronomia Optica*, p. 320, where he says that the already mentioned tables of Reinhold show the distance of the nonagesimal from the vertex, when what they show is the distance not of the nonagesimal itself but of the star. This is clear from Reinhold's precept 54 and Lansbergen's precept 29, and even from the table itself. For in it, for example, under the polar altitude 45°, with the Sun at the beginning of Aries, at 6 hours before noon, you will find a distance of 90° from the vertex, which is certainly the distance of the Sun, since the nonagesimal, which is the beginning of Cancer, is then on the meridian, and on it stands only 21° 30′ from the vertex.

[Margin: The use of a globe or sphere substituted for the tables.]

But without so much trouble over the proportional part, the wiser course for anyone who dreads trigonometrical calculation is to use a globe or armillary sphere, with the meridian raised to the given polar altitude, and with the sphere or globe turned as far as the time of the distance from noon requires, when converted into parts of the equator. For a pair of compasses from the horizon to the degree of the ecliptic where the luminary is, or the arc of a quadrant drawn through that place and divided into degrees, will show the luminary's altitude just as well as the already mentioned tables, indeed better.

PROBLEMA IV.

Problem 4.

Data Luminarium Altitudine ab Horizonte, aut Diſtantia à Vertice per Problema 3. Inquirere Parallaxim Altitudinis vtriuſq. & inde Parallaxim Lunæ à Sole.

Given the altitude of the luminaries above the horizon, or their distance from the vertex, by Problem 3, to find the parallax of altitude of each, and from that the parallax of the Moon from the Sun.

[Margin: Authors of parallactic tables.]

XIII. This Problem is completed by the methods already given in Book 3, Ch. 8, as regards the Sun, and in Book 4, Ch. 13, as regards the Moon; or by tables constructed for the purpose, though constructed for the true altitude of the luminaries, which are presented by Ptolemy, Book 5, Ch. 18; Copernicus, Book 4, Ch. 24; and Reinhold in the Prutenic Canons, p. 120, but for new Moons only, a table that Magini copied in the *Secunda Mobilia*, p. 681. Tycho also gives his own, in Vol. 1 of the *Progymnasmata*, pp. 80 and 120, and from there Longomontanus, Book 1 of the *Theorica*, Ch. 8, p. 279; Magini in the *Supplement to the Ephemerides*, pp. 59 and 293; Mulerius in the *Tabulae Frisicae*, p. 421; Argoli in his tables, p. 154; Renieri in the first edition of the *Tabulae Mediceae*, p. 185; and Lansbergen likewise gives his own, pp. 46 and 47. For horizontal parallaxes alone, one may consult Kepler in the Rudolphine Tables, p. 98, and at the head of the parallactic table, p. 320 of the *Astronomia Optica*; Renieri in the later Medicean Tables, p. 312, and outside the syzygies, p. 364; Boulliau in the *Philolaic Tables*, p. 138, and outside the syzygies, p. 139; and Wendelen in the *Eclipses*, p. 34.

[Margin: Parallax of the Moon from the Sun.]

Now if the Sun's parallax is subtracted from the Moon's parallax, what remains is the parallax of the Moon from the Sun.

PROBLEMA V.

Problem 5.

Datis Parallaxi Altitudinis Luminarium per Problema 4. & Angulo Verticalis & Eclipticæ, ſi careant latitudine per Problematis 1. partem 1. vel Angulo Verticalis & Circuli latitudinis, ſi latitudinem habeant, per Problematis 5. partem 2. Inquirere Parallaxim Latitudinis & Longitudinis.

Given the parallax of altitude of the luminaries by Problem 4, and the angle of the vertical and the ecliptic, if they lack latitude, by Problem 1, part 1, or the angle of the vertical and the circle of latitude, if they have latitude, by Problem 5, part 2, to find the parallax of latitude and of longitude.

[Margin: Authors of this Problem.]

XIV. This Problem is more difficult when the Moon has a true latitude than when she has no latitude; and therefore Ptolemy laboured over it in Book 5, Ch. 19; Regiomontanus in the *Epitome*, Book 5, props. 26 to 32; Copernicus, Book 4, Ch. 26; Tycho, Vol. 1, p. 132; Longomontanus, but very obscurely, in Book 2 of the *Spherics*, Ch. 10, and Book 1 of the *Theorica*, Ch. 8, p. 282; Magini in the *Primum Mobile*, Book 12, problems 12 and 13; and Mulerius in the *Tabulae Frisicae*, p. 439. But no one did so more expeditiously than Magini, although he too uses several figures, or superfluous lines, and yet does not cover all the cases. Ptolemy indeed, Copernicus and Mulerius in the places above, and Regiomontanus in prop. 32, judge that no perceptible error is committed if, even when the Moon has latitude, we treat her as having no latitude, and use the angle of the vertical and the ecliptic made at the Moon's place on the ecliptic in place of the angle of the vertical and the circle of latitude made at the Moon's own centre. They judge that there is no need for such precision, and that more labour than profit is gained from greater subtlety. Finally, Ptolemy and Copernicus use rectilinear triangles in place of spherical ones, thinking that because of their apparent smallness no perceptible error is made. We, however, to remove every scruple from inquisitive astronomers, shall first cover all the cases with a single figure, and shall use true angles and right-angled spherical triangles, because with the help of logarithms they are now no harder than rectilinear ones. Then we shall add a second figure, by which the same problem can be solved more exactly and more generally.

[Margin: Case 1 of the Problem.]

Let the horizon be HAR; the meridian HVR, on which are the zenith or vertex V and the pole of the world P, around which is the Arctic small circle, on whose circumference let B be, the pole of the ecliptic ESC; and let the vertical or circle of altitude be VIA, on which, *first*, let the Moon be at I, without any true latitude, but because of the parallax of altitude IL let her appear at L. For when the circle of latitude BL has been drawn from B through the Moon's apparent place on the vertical, Q will be her apparent place on the ecliptic, and so IQ will be the parallax of longitude and LQ that of latitude, which in this case will be the apparent latitude. And there will arise the triangle ILQ, right-angled at Q, in which are given the base IL, the parallax of altitude, and the angle LIQ of the ecliptic and the vertical. The parallaxes of longitude IQ and of latitude LQ will therefore not remain hidden. For let it be: as the radius or whole sine is to the sine of the angle LIQ, so is the sine of the base LI to the sine of the arc LQ. Or join the logarithm of the angle LIQ to the logarithm of the base LI, and the logarithm of the arc LQ, that is, of the parallax of latitude, will result. Again, let it be: as the radius is to the secant of the angle LIQ, so is the second tangent of the base LI to the second tangent of the arc IQ. Or add the residual of the second logarithm of the angle LIQ to the second mesologarithm of the base LI, and the second mesologarithm of the arc IQ will result, that is, of the parallax of longitude. In this and the following cases, however, one must use the parallax of altitude of the Moon from the Sun.

[Margin: Case 2 of the Problem.]

Second, let the Moon be at F, but appear at K. For when the quadrants of latitude have been drawn from B as far as the ecliptic, BFD through the Moon's centre and BKG through the place of the apparent altitude, D will be her true place on the ecliptic and G her apparent place; and so DG will be the parallax of longitude, the true latitude FD and the apparent latitude GK, though of the same side or kind. Therefore, with the arc KO drawn from K parallel to DG, and so perpendicular to FD, the parallax of latitude will be the arc OF.

Diagram. Set across the left column, interrupting the sentence above after the word `atque`. A semicircle stands on a straight base. From the top, V, straight lines run down to the base. From B, at the upper right, a sheaf of curved lines runs down to the left across the figure; a small circle at the upper right has P at its centre, with a line from P up to B. Longer curves run from the left side of the figure across to R at the right end of the base. The centre of the figure is a crowded cluster of small letters and sorts, not all of which are separated.

- H (left end of the base): the meridian, by the earlier statement HVR, and the horizon HAR
- A (on the base, right of H): the foot of the vertical VIA
- λ (on the base, right of A): the foot of the vertical Vλ
- ε (on the base, right of λ): the end of the quadrant Vε
- C (on the base, right of centre): the foot of the vertical VC
- R (right end of the base): the common point of the arcs RΦX and RθY
- V (top of the arc): the vertex
- E (upper left of the arc): the ecliptic, by the earlier statement ESC
- O (right of E): the foot of the arc KO
- F (right of O, below V): a place of the Moon
- B (upper right): the pole of the ecliptic
- P (centre of the small circle): the pole of the world
- D (left, below E): the Moon's true place in Case 2
- K (right of D): a place of the Moon
- G (below D): the Moon's apparent place in Case 2
- T (left, below G): cited in Case 5
- I (right of G): a place of the Moon
- L (below T): a place of the Moon
- Q (a swash letter right of L): cited in Cases 1, 4, 5
- S (below Q): cited in Case 4
- two sorts [?] stacked on the vertical line just left of X, the lower resembling δ (the text's true place of the Moon in Case 9); neither settled
- X (centre, upper right): the Moon's true place in Cases 8 and 9
- Z and ϒ (side by side below S, ϒ against the vertical line): cited in Cases 4 and 9
- Y (right of the central cluster): the Moon's apparent place in Cases 8 and 9
- N (lower left of the cluster): cited in Case 4

- M (right of N, lower): cited in Case 4
- Φ (right, upper): a place of the Moon in Case 8
- Ψ (below Φ): cited in Case 8
- θ (right of Ψ): the Moon's apparent place in Case 8

The arc OK, although strictly it is not a portion of a great circle, will nevertheless, because of the nearness, be such to the senses, and equal to the parallax of longitude DG. And there will arise the triangle KFO, right-angled at O, in which are given the base FK, which is the parallax of altitude, and the angle KFO of the vertical and the circle of true latitude. Let it be, therefore: as the radius is to the secant of the angle F, so is the second tangent of the base FK to the second tangent of the arc OF. Or add the residual of the second logarithm of the angle E [recte: F] to the second mesologarithm of the base FK, and the second mesologarithm of the arc OF will result, namely of the parallax of latitude. Again, let it be: as the radius is to the sine of the angle F, so is the sine of the base FK to the sine of the arc KO. Or add the logarithm of the angle F to the logarithm of the base FK, and the logarithm of the arc KO will result, which is equivalently the parallax of longitude.

[Margin: Case 3 of the Problem.]

Third, let the Moon be at K, but appear at I, a point of the ecliptic, so that the parallax cancels the whole true latitude. For with the single quadrant of latitude BKG drawn through the Moon's centre, the triangle GKI will be formed, right-angled at G, in which are given the base IK, which is the parallax of altitude, and the angle at K made by the vertical and the circle of latitude. Therefore, by exactly the same rules as in the second case, the arc GK will become known, which is the parallax of latitude, and GI, which is that of longitude.

[Margin: Case 4 of the Problem.]

Fourth, let the Moon be at L, but appear at M. For with two arcs of latitude drawn from the pole B across the ecliptic, one to the place of the apparent altitude M, which is to be BSM, the other through the Moon's centre as far as the point N, on which there falls from M the arc MN, parallel to the ecliptic or perpendicular to LN, Q will be the Moon's true place on the ecliptic and S her apparent place. And so the parallax of longitude, taken formally, will be the arc QS, while the true latitude, but toward the other pole, will be the arc LQ, and the apparent latitude MS. Therefore, with the arc LZ drawn from L, the Moon's centre, parallel to QS or perpendicular to SM, the parallax of latitude will be the arc MZ, and that of longitude, taken equivalently, the arc LZ. But because of the need to solve the problem, the triangle LMN is employed, right-angled at N, in which, because of the nearness and the already mentioned parallelism, the arc NL is perceptibly equal to MZ, the parallax of latitude, and NM to LZ and QS, the parallax of longitude. And in it are given the base LM, which is the parallax of altitude, and the angle NLM, made at the Moon's centre by the vertical and the circle of true latitude. Therefore, by altogether the same rules as in the second case, the arc LN will become known, which is equivalently the parallax of latitude, and NM, which is equivalently the parallax of longitude.

[Margin: Case 5 of the Problem.]

Fifth, let the Moon be at K, on this side of the ecliptic, but appear at L, beyond the ecliptic, so that the parallax changes her latitude from northern to southern, if the pole B is northern, or from southern to northern, if the pole B is southern. For draw two arcs of latitude from the pole B beyond the ecliptic: one to the place of the apparent altitude L, which is to be BL; the other, BGT, through the Moon's centre K as far as the point T, to which from L the arc LT can be drawn, parallel to the ecliptic or perpendicular to BGT. For the Moon's true place on the ecliptic will be the point G, and her apparent place Q; and so the formal parallax of longitude will be the arc GQ, and the true latitude toward one pole will be the arc KG, and the apparent latitude toward the other pole the arc QL. And so the parallax of latitude will be the arc KGT, because GT, on account of the nearness and the parallelism of the arc LT, is equal to LQ, just as TL is to GQ. There therefore arises the triangle KTL, right-angled at T, in which are given the base KL, which is the parallax of altitude, and the angle TKL, made at the Moon's centre by the vertical and the circle of true latitude. Therefore, by altogether the same rules as in the second case, the arc TL will become known to you, which is equivalently the parallax of longitude, and the arc KGT, which is equivalently the parallax of latitude. If you subtract from it the true latitude KG, there will remain GT, that is LQ, the Moon's apparent latitude.

[Margin: Case 6 of the Problem.]

The *sixth* case is when the vertical circle in which the Moon stands and the circle of latitude are the same; but then the star is at the nonagesimal, either with no latitude or with some, and then the parallax of altitude equals the parallax of latitude, as I said in Problem 3, Cases 1 and 2, and there is then no parallax of longitude.

[Margin: Case 7 of the Problem.]

The *seventh* case is when the vertical circle in which the Moon stands and the ecliptic are the same, a case that occurs only within the Torrid Zone; and then the parallax of altitude is the same as the parallax of longitude. Thus, if the quadrant Vε is at once the vertical and the ecliptic, and the Moon is at X, but appears at Y, the arc XY will be the parallax of altitude and of longitude, and there will be no parallax of latitude.

[Margin: Case 8 of the Problem.]

The *eighth* case is when the ecliptic is one of the verticals, but the Moon, because of her latitude toward your pole, is on another vertical; as if the ecliptic is Vε, but the Moon's vertical is VC, and the Moon is at Φ, but appears at θ. In this case, with the arcs of latitude drawn through the true and apparent altitudes as far as the ecliptic, namely RΦX and RθY (for the pole of the ecliptic will then be either on the horizon itself or not far from it), the Moon's true place on the ecliptic will be the point X and her apparent place Y, and so the parallax of longitude will be the arc XY, the true latitude ΦX and the apparent latitude θY. In the triangle RΦθ, therefore, seek the arc Rθ; for in it are given the angle

at Φ, made by the vertical and the circle of true latitude; RΦ, the complement of the true latitude to a quadrant; and Φθ, the parallax of altitude. For when θR is taken from 90°, there will remain θY, the apparent latitude. And with the arc ΦΨ drawn parallel to the ecliptic or perpendicular to RY, the arc Ψθ will be the parallax of latitude, which will be known when the true latitude XΦ, equal to YΨ, is subtracted from the whole Yθ. And so in the triangle ΦΨθ, right-angled at Ψ, are given the base Φθ, the parallax of altitude, and the side Ψθ, the parallax of latitude. The side ΦΨ will therefore not remain hidden, which differs imperceptibly from the parallax of longitude XY.

[Margin: Case 9 of the Problem.]

The *ninth* case is when the ecliptic is one of the verticals, such as Vε, but the Moon, because of her latitude toward the other pole, is on another vertical, such as Vλ. For let the Moon be at δ, but appear at ϒ; and with the circles of latitude produced as far as there, let the true latitude be δX and the apparent latitude ϒY, and let the Moon's true place on the ecliptic be X and her apparent place Y, and so the parallax of longitude XY. Draw, then, the arc ϒX, and in the triangle ϒδX seek both the arc ϒX and the angle ϒXδ, since in it are given the angle at δ, made by the vertical and the circle of true latitude; ϒδ, the parallax of altitude; and δX, the true latitude. Then in the triangle ϒYX, right-angled at Y, seek both ϒY, the apparent latitude, and XY, the parallax of longitude, since in it are given the base ϒX, already found, and the angle ϒXY, from the subtraction of ϒXδ, already found, from the right angle YXδ.

But for Cases 8 and 9 the Moon's altitude and the angle of the vertical and of latitude are found otherwise than by the method given above in Problem 3. For here, from the Moon's true place on the ecliptic, X, and the culminating point V, the difference between them, that is the arc VX, is obtained; and in the triangle VXΦ, right-angled at X, with the true latitude XΦ, both VΦ, the Moon's distance from the vertex, and the angle VΦX are obtained; or in the triangle VXδ, right-angled at X, with the true latitude Xδ, both Vδ, the Moon's distance from the vertex, and the angle VδX are obtained, whose complement to two right angles is the angle ϒδX. In this way I believe I have covered all the cases of these parallaxes when a star, as the Moon does at ecliptic or near-ecliptic new Moons, has a modest latitude.

Idem Problema exactiùs abſoluere Datis Latitudine vera Sideris, Parallaxi Altitudinis, & dato vel inuento Angulo Parallactico, ideſt facto ab Ecliptica & Verticali per centrum ſideris ducto.

To complete the same Problem more exactly, given the star's true latitude, the parallax of altitude, and the parallactic angle, whether given or found, that is, the angle made by the ecliptic and the vertical drawn through the star's centre.

XV. This Problem does not need arcs of circles that are not great circles, which, because of their nearness and parallelism, would be assumed to be

sensibly equal to arcs of great circles. It rests instead on arcs of great circles, whether remote from the ecliptic or near it, and it is therefore more exact, and indeed also more universal, and it holds for any star, however far from the ecliptic. So in the adjoined figure, placed at the beginning of the chapter at number 2, let everything be as set out there.

[Margin: Case 1.]

And *first*, let the star be at G, a point of the ecliptic EC, without any latitude, but let it appear at I, a point of the vertical VA.

Diagram. Set across the left column, interrupting the sentence above within the word `pun- / cto`. A semicircle stands on a straight base, with H at its left end, A and C below the base, and R at its right end. V stands at the top of the arc; a straight line runs from V down to the left, through D, to the base at A, and another short line runs from V to the right, to P. A small circle at the upper right has B near its centre, and a line runs from B down to P, at the circle's lower edge. From P a sheaf of curved lines runs down to the left across the figure, through the crowded cluster of letters. A longer curve runs from the upper left of the arc, through G, down to C on the base.

- Labels read: V (top of the arc); B (inside the small circle at upper right); P (lower edge of the small circle); D (on the line from V); M, N, G, O (the central cluster, N set small and close against G); I; Q (with a short flourish beneath it); K; H (left end of the base); A (below the base); C (below the base); R (right end of the base).
- Labels not separated: the letter at the upper left of the arc, which reads as E or F `[?]`, and the letter just below D, which reads as F or E `[?]`. The text calls for both an E and an F in this figure, but which stands where is not settled here.

For when the arc of latitude PI is drawn to the apparent place, the star's apparent place on the ecliptic will be the point O, and the parallax of longitude GO, and that of latitude, or rather the apparent latitude itself, IO, in the triangle GIO, right-angled at O. In this triangle GI, the parallax of altitude, is given, and the parallactic angle IGO, or at any rate let it be found by the method to be given at the end of the Problem. So IO, the parallax of latitude, and GO, that of longitude, will not remain hidden.

[Margin: Case 2.]

Second, let the star be at D, but appear at F. For when the arcs of latitude are drawn, PDM through the place of the true altitude and PFN through that of the apparent altitude, the true place on the ecliptic will be M and the apparent place N, and the true northern latitude DM, but the apparent latitude FN. So in the triangle MGD, right-angled at M, the latitude DM is given, and the parallactic angle MGD. Seek, then, the base GD and the side MG; next subtract the parallax of altitude DF from the base DG, and there will remain, known, the base FG in the small triangle NGF, right-angled at N, in which the parallactic angle NGF is given. Seek, then, the arc NF, which is the apparent latitude, and which, subtracted from the true latitude MD, will give the parallax of latitude.

Then find the arc NG, which, subtracted from the arc MG, will leave MN, the parallax of longitude.

[Margin: Case 3.]

Third, let the star be at F, but appear on the ecliptic itself at G. For in the triangle NGF, right-angled at N, the true latitude NF is given, the whole of which is cancelled by the parallax, and so the parallax of latitude is as great as the true latitude. The angle NGF is also given in the same triangle. Seek, then, the arc NG, namely the parallax of longitude.

[Margin: Case 4.]

Fourth, let the star be at I, but appear at K. For when the arcs of latitude are drawn, POI through the place of the true altitude I, and PQK through that of the apparent altitude, the true place on the ecliptic will be the point O, but the apparent place the point Q, and the true southern latitude OI, but the apparent latitude QK. Now in the triangle IGO, right-angled at O, the true latitude OI is given, and the parallactic angle IGO; therefore find the arcs GO and GI separately. Then in the triangle KGQ, right-angled at Q, by joining GI, the arc found, and IK, the parallax of altitude, the base GK will be given; with this and with the parallactic angle KGQ, search out the arc GQ, and KQ. For if from the arc GQ you subtract GO, found above, there will remain the parallax of longitude OQ; and KQ will be the apparent latitude, greater than the true latitude. So when the true latitude is subtracted from it, the parallax of latitude will be known.

[Margin: Case 5.]

Fifth, let the star be at F, but let it be thrown down by parallax across the ecliptic to I. For first, in the triangle NGF, right-angled at N, with NF, the northern latitude, given, and the parallactic angle at G, you will find the arcs NG and FG. Then, when FG is subtracted from the parallax of altitude FI, there will remain, known, the base GI of the triangle GIO, right-angled at O, with which and the angle G you will find GO and IO. So when the arcs of the ecliptic NG and GO are put together, the parallax of longitude NO will be known. The parallax of latitude, moreover, will consist of the true northern latitude NF, which it cancels, and of the apparent southern latitude IO.

[Margin: Method of finding the parallactic angle.]

This method is much quicker than the one indicated by Copernicus, Book 4, Ch. 26, or by Longomontanus, Book 1 of the *Theorica*, Ch. 8, as will be plain to anyone who compares it with them. For finding the parallactic angle is not difficult, since it is the angle opposite the true latitude, which is already given in a right-angled spherical triangle, in which there is also given, by Problem 3, the angle made at the star's centre by the vertical and by the circle of latitude. For example, in the triangle MDG, given the angle at D and the latitude MD, MGD is easily found; and so for the others.

Idem Problema per Tabulas Parallacticas aut illis æquiualentes abſoluere, Datis Longitudine Luminarium, & Tempore ante vel poſt meridiem, cum Altitudine Poli, vel Angulo Orientis, & Angulo Parallactico.

To complete the same Problem by parallactic tables or tables equivalent to them, given the longitude of the luminaries and the time before or after noon, with the polar altitude, or the angle of the rising point, and the parallactic angle.

[Margin: Method 1, by the Alphonsine, Prutenic and Lansbergian tables.]

XVI. The first method is by the tables of Alfonso, p. 112, which run from a polar altitude of 16° 39′ to 48° 40′; or rather by those of Reinhold in the Prutenic Tables, p. 99, and of Lansbergen in his tables, p. 51, from 16° to 70°. These are entered under the whole sign in which the luminary stands, under the appropriate polar altitude, and with the whole hours by which the luminaries are distant from noon, and one seeks the side of longitude [latus longitudinis], the side of latitude [latus latitudinis], and the luminary's distance from the vertex. With that distance one seeks, in the tables of parallaxes of altitude, the parallax of the Moon and of the Sun, and from these the parallax of the Moon from the Sun. But since in the right-angled triangle on which the tables already mentioned rest, the parallax of altitude is always assumed as 60′, therefore, if the parallax of altitude is not 60′, one must find the side of latitude and the side of longitude proportional to it, by making: as 60′ is to the corresponding parallax of altitude, so the side of latitude found in the table is to the parallax of latitude; and again, as 60′ is to the corresponding parallax of altitude, so the side of longitude found in the table is to the parallax of longitude. This would indeed be no great labour if the luminaries were precisely at the beginning of the signs, and the hours before or after noon were whole, without minutes, and the polar altitude set at the head of the tables were the very one being worked for. But since for the most part these things do not coincide, beyond the two operations already mentioned one must hunt again and again for the proportional part, for the difference between polar altitudes, between whole signs and between whole hours, as can be seen in the precepts that are given on this practice by the Alphonsines, prop. 32, from number 123; Reinhold, precept 54; Magini in the *Secunda Mobilia*, Canons 75 and 76; and Lansbergen, precept 29. This trouble becomes much greater when all this has to be repeated for the beginning and the end of a solar eclipse, so that Kepler, in the *Astronomia Optica*, p. 316, rightly said of Reinhold and his followers: *the ardour of the ingenious was crushed by the tedium of seeking the proportional part.*

[Margin: Method 2, by the tables of Peuerbach.]

The *second* method is by the tables of eclipses of Peuerbach, but these were computed only for Climates 6 and 7. In them, given the hours before or after noon, the whole signs in which the luminaries stand, and the whole signs of the lunar anomaly, one finds both the distance of the apparent conjunction

from the true conjunction and the parallax in latitude. But when these are not whole, a manifold search for proportional parts is needed.

The *third* and quickest method is by the parallactic table that Kepler constructed and presented in the *Astronomia Optica*, p. 320, based on Theorems 13, 14 and 15, brought forward above at number 3; from him Vincenzo Renieri copied it out at the end of the *Tabulae Mediceae* in their second edition, p. 332, and Boulliau in the *Philolaic Tables*, p. 173.

[Margin: Method 3, by the tables of Kepler, Renieri and Boulliau.]

In this table, under the luminary's distance from the centre of the Earth, or under the horizontal parallax of the Moon from the Sun, placed at the head of the table, which is supposed known from the anomaly and the tables of semidiameters, etc., and opposite the distance of the nonagesimal from the vertex, considered on the Moon's orbit, known by Problem 2, and indeed most easily by the precept and use of the table described there at number 8, precept 5, but corrected by the advice of Renieri in the same place: with these two elements, I say, the parallax of latitude is found in the fields of the table. Then by the altitude of the nonagesimal, under the greatest and horizontal parallax, the greatest parallax of longitude is sought; and when this has been sought again at the head of the table, opposite the apparent distance of the luminaries from the nonagesimal degree, the parallax of longitude is sought. Both are obtained accurately at the time of solar eclipses, because the Moon is almost on the ecliptic as far as appearance goes. The apparent distance of the Moon from the nonagesimal is obtained if the nonagesimal, by Problem 1, and the Moon's place on the ecliptic are known, for their difference will give their true distance. With this seek, rather roughly, the parallax of longitude, and add it to the true distance if the Moon is beyond the nonagesimal, subtract it if she is on this side of it, and the result will be the apparent distance from the nonagesimal. With this seek again, as above, a more exact parallax of longitude. This precept is to be observed at least when the Moon's apparent place is known from observation, as Kepler advises in the *Optics*, p. 320.

[Margin: Method 4, by logarithms.]

The *fourth* method is by logarithmic tables, either Kepler's in the Rudolphine Tables or ours in the Trigonometric Book, which will be the first of the second volume of the *Almagestum Novum*. So, following Kepler in the *Epitome of Copernican Astronomy*, p. 884, add into one sum the logarithm of the horizontal parallax of altitude and the antilogarithm, or second logarithm, of the angle of the rising point; and the sum will be the logarithm of the parallax of latitude. Then add into one sum three logarithms, namely those of the horizontal parallax of latitude, of the angle of the rising point, and of the star's distance on the ecliptic from the nonagesimal; and the result will be the logarithm of the parallax in longitude.

[Margin: Method 5, by the General Table of Magini.]

The *fifth* method is by Magini's General Table of the primum mobile, on whose right side the parallactic angle is sought, and at the head the parallax of

altitude of the Moon from the Sun, or of a star on the ecliptic or placed very near it; for in the field you will find the parallax of longitude. And in the same table, by seeking the parallax of altitude of the Moon from the Sun at the head, and the parallactic angle on the left side, the field gives the parallax of latitude of the Moon from the Sun. So Magini in the *Supplement to the Ephemerides*, p. 280, admitting that he used a rectilinear triangle, because its base never exceeds 66′.

SCHOLIA.

Scholia.

I. The definitions of parallax placed in the preceding chapter at number 2 were given according to the common view of those who hold that the centre of the world and of the Earth are the same; but in the view of some Pythagoreans and of the Copernicans these centres are different, and the centre of the world is the centre of the Sun itself. Whether, then, from parallaxes that suppose the same centre and yet display the phenomena quite accurately, any argument can be drawn against the Copernican system, I shall examine below in Book 9, where this system is treated. Meanwhile I am well aware that Kepler, in the *Optics*, p. 321, denies that from the appearances this Optical system rather than the Tychonic can be chosen.

[Margin: Comparison of the old astronomy with the recent in the hunt for these parallaxes.]

II. Although Ptolemy presents us, in Book 5, Ch. 19, with a lucid outline [hypotypoſim] of the parallaxes and of their variation, not so well understood by those who follow the Latin version, which is corrupt at this point, yet in use and practice he confidently judged that the subtlety he professed in theory could be neglected, because of the slight error that arises from this neglect, as I already said toward the end of number 10. Hence he knowingly admits that he neglected the parallax of the Sun, chose the analysis of rectilinear triangles in place of curvilinear ones, and took the angle of the vertical and the ecliptic in place of the angle of the vertical made on the Moon's orbit, neglecting the Moon's latitude. With him agrees Regiomontanus, as we have already said at the end of number 10, and Copernicus, Book 4, Ch. 26, who says that in the hunt for these parallaxes the Moon's latitude may safely be disregarded: "This computation, which is spent on the smallest matters, has more labour than profit." Moreover, in Ptolemy, in the same place, Hipparchus, seeing astronomers misuse the altitude of the Moon's place on the ecliptic and the angle made there by the vertical in place of the altitude of the Moon herself and the angle made at her, tried, though unsuccessfully, to remove this misuse. But neither did Reinhold, Lansbergen, Argoli and whoever else have used, in a table of the parallax of altitude, the altitude of the Moon's place on the ecliptic, just as if she had no latitude, remove it. Finally Kepler, who removed the tedium of solving triangles, or of repeatedly seeking the proportional part in the Prutenic

Tables, by his new and most highly praised parallactic table in the *Astronomia Optica*, p. 320, nevertheless slipped in two ways in the same place.

[Margin: Praise of Kepler, but a double blemish.]

First, he teaches there that one should use the distance of the nonagesimal from the vertex, with the nonagesimal itself considered on the ecliptic, whereas it is more correct to use its distance when considered on the Moon's orbit.

[Margin: Praise of Renieri, Boulliau and Vicenç Mut.]

This was corrected by Renieri and Boulliau, but more exactly by Vicenç Mut, as I said at number 8, precept 5. Second, he said that the distance of the nonagesimal from the vertex was to be looked up in Reinhold's table, p. 99, whereas that table contains the distance from the vertex not of the nonagesimal itself but of the luminary, as we showed at number 11. For he had not yet composed the Rudolphine Tables; but even when they were composed he did not recognise this error [Greek: ἀμάρτημα (hamartēma, "error")]. On the contrary, in Ch. 28, precept 132, he sent the reader back to his *Optics*, granted that he taught there and in the *Epitome of Copernican Astronomy* another method of seeking the parallaxes of longitude and latitude through his logarithms and antilogarithms, based on the angle of the ascending point and the Moon's distance from the nonagesimal.

[Margin: Disparity of the parallaxes because of the change of the solar apogee.]

III. One scruple remains, arising from the change of the apogee and of the eccentricity. As to the first, Reinhold, on Peuerbach's *Theoricae*, p. 194½, observes that points of the ecliptic equally distant from the solstitial points have the same variation of parallaxes, but in different quadrants of the ecliptic standing above the horizon. For example, because the beginning of [?] and of Pisces are equally distant from the solstitial points, in Climate 7 the true new Moon differs by 1¾ hours because of the parallax of longitude, if the true new Moon occurs 4 hours before noon with the Sun placed at the beginning of [?], or if it occurs 4 hours after noon with the Sun at the beginning of Pisces. This, he observes, is exactly true when the Sun's apogee stands near the solstitial points, and he indicates that it is not so exactly true when the apogee is farther from them. And so I did not list this property among the Theorems given at number 3.

[Margin: A small equation of the parallaxes because of the Moon's eccentricity.]

IV. As to the eccentricity, but of the Moon, the Alphonsines in their tables, p. 116, and in the precepts, prop. 32, marginal number 112, and Renieri in the later *Tabulae Mediceae*, pp. 286 and 313, but setting out the Alphonsine form of calculation, teach that the horizontal parallax given in the tables holds when the Moon, at the very moments of the syzygies, is at the apogee of the eccentric; but that outside those moments, even if only a few hours before or after conjunction and opposition, the Moon approaches the Earth because of the eccentricity and so increases the parallax, and that a correction is needed,

which is at most 51″. They therefore give a small table of these sexagesimal parts [horum ſcrupulorū], which, multiplied by the horizontal parallax, with the sum divided by 60, give the part to be added to the parallax, etc.

CAPVT XI.

Chapter 11.

De Terminis, Magnitudine, Duratione, Initio, Medio, Fine, alijſq. momentis Eclipſium Solarium.

On the limits, magnitude, duration, beginning, middle, end and other moments of solar eclipses.

THEOREMA I.

Theorem 1.

Cum PROBLEMATIBVS de Terminis Eclipſium Solis.

With Problems on the limits of solar eclipses.

[Margin: What the limits of a solar eclipse are, and how many.]

I. Some limits [Termini] of solar eclipses are possible, others necessary. They are the distances of the luminaries from the nodes of the lunar orbit with the ecliptic, within which a solar eclipse is possible somewhere, or even necessary, and outside which it is not possible, or is not necessary. Their determination depends on the apparent semidiameters of the Moon and the Sun, and on the Moon's visible, or apparent, latitude. For if the apparent latitude is equal to or greater than the sum of these semidiameters, there will be no eclipse; if it is less, there will be a solar eclipse somewhere. But the apparent latitude itself depends on the parallax of latitude, and this on the horizontal parallax of altitude, which is not the same among all astronomers, just as neither is the true latitude the same at the same distance from the nodes, nor the sum of the semidiameters the same; and from this a manifold variety of opinions on this subject arises. Besides, some fix these limits for mean new Moons, others for true new Moons; and again, some express them by the distance of the luminaries from the Moon's nodes, others by the motion of latitude counted from the northern limit, though from this the distance from the node is derived; others by the apparent latitude; and this last, some for the moment of the true synod, others for that of the apparent or visible synod. Finally, nearly all assign these limits for inhabitants on this side of the Torrid Zone, but not beyond the seventh Climate, with Ptolemy, that is, not beyond 48° 31′ of north polar altitude, and scarcely anyone determines them universally. We shall therefore divide these authors into various classes, and afterwards bring forward our own view, supplying what is lacking on this point in Copernicus, Tycho, Longomontanus, Boulliau and Wendelen, who have set down no limits.

[Margin: Opinion of Ptolemy and his followers.]

II. First, then, Ptolemy, Book 6, Ch. 5, and with him Regiomontanus, Book 6 of the *Epitome*, prop. 7; Reinhold on Peuerbach, p. 198, and in the Prutenic Tables, precept 61; Wurstisen on Peuerbach, p. 349; Neander in the *Elementa*, p. 130; Magini in Canon 84 of the *Secunda Mobilia*; Origanus in part 2 of Vol. 1 of the *Ephemerides*, Ch. 10; Mulerius in the *Tabulae Frisicae*, p. 77; and Argoli in his tables, Ch. 31, fix the possible limits: if at mean new Moons the Moon has not been distant from either node by more than 20° 41′ toward the north, or in round figures 20° 40′, and by no more than 11° 22′ toward the south, or, as Regiomontanus has it, 10° 55′. Understand this with respect to those who are on this side of the Torrid Zone and live in the North Temperate Zone, not beyond 49° of polar altitude. But with respect to those who live beyond the Torrid Zone, in the South Temperate Zone as far as 49°, if a solar eclipse is to be possible, the Moon must not be distant from either of the nodes by more than 20° 41′ toward the south, or 11° 22′ toward the north, as the parallax of latitude requires. For if she is distant beyond 11° 22′ toward the other pole, the parallax will increase the latitude, which at that distance is equal to the sum of the semidiameters; but if she is distant by more than 20° 41′ toward the pole of the place for which the calculation is undertaken, the latitude will be so great that, whatever parallax is computed as diminishing it, it will still never be less than the sum of the semidiameters of the Sun and the Moon. But if she is distant from the nearer node by less than 11° 22′ in the one case, and by less than 20° 41′ in the other, an eclipse will still not follow at once. For it can be that, either because of the semidiameters decreasing toward the apogee, or because of the parallax not diminishing the latitude sufficiently, or increasing it toward the other pole, there follows no eclipse, which could have occurred with another proportion [ſymmetria] of semidiameters and parallaxes.

[Margin: Argoli's threefold error in his way of speaking.]

Caution is therefore needed with Argoli, who does not speak with precision when he pronounces all too carelessly: *If, at the middle of the true conjunction of the luminaries, the equal motion of the Moon's latitude is not distant from the northern node ☊ by more than 20° 40′, or from the southern ☋ by 11° 22′, that synod will be ecliptic.* And giving an example he says that, since in it the Moon was not distant from the southern node by 11° 22′, *for that reason that conjunction had to be with an obscuration of the Sun.* For he errs in three ways. First, because he confuses the limits of the mean new Moon with the limits of the true new Moon. Next, because he confuses the limits of a possible eclipse with the limits of a necessary eclipse: for even if an eclipse necessarily occurs somewhere within the Torrid Zone if the Moon is not distant from the nodes by more than 15° 40′, let alone 11° 22′, still outside the Torrid Zone this is not true, and much less so if she is distant by less than 20° 41′ but by more than 15° 40′. Lastly, he confuses distance toward the north with distance from the northern node. For the Moon can be distant from the northern node and yet have a southern latitude, and so, even if she is distant from it by less than 20° 41′, a solar eclipse can be

impossible; and conversely she can be distant from the southern node and yet have a northern latitude, and so an eclipse can be possible, even if she is distant from it by more than 11° 22′. I do indeed believe that he understood it correctly, but his unconsidered way of speaking could harm beginners who have not been instructed from elsewhere. Ptolemy distinguished those distances from the nodes of the ecliptic most correctly by these formulas, [Greek: πρὸς αρκτους (pros arktous, "toward the north"); the mark over the alpha [?]] and [Greek: πρὸς μεσ[?]βρίαν (pros mes[?]brian, "toward the south")], that is, toward the north and toward the south; and Wurstisen most distinctly, saying that an eclipse is possible if it is less distant from the northern node than 11° 22′ before it or 20° 41′ after it, and from the southern node, before it, than 20° 41′, and after it, than 11° 22′. Mulerius, for his part, from Ptolemy's hypothesis added both the limits of an eclipse necessary somewhere, if at true new Moons the Moon's distance from the nodes is less than 15° 38′, and the limits of a possible eclipse for true new Moons, 17° 41′ toward the north and 8° 22′ toward the south.

[Margin: Opinion of al-Battānī and the Alphonsines.]

III. Yet some departed somewhat from Ptolemy: first al-Battānī, Ch. 43, because of a different opinion on the diameters of the luminaries, on account of which he fixes the possible limits at mean ☌ at 20° 12′ toward the north and 10° 40′ toward the south; second, the Alphonsines, prop. 32, who, in broad terms [Greek: ὁλοσχερῶς (holoscherōs, "in general, broadly")], defined these limits at 12° on each side.

[Margin: And of Langius, from Copernicus.]

Our own Langius, in the *Theorica* of his *Elementale*, decrees a solar eclipse impossible if the apparent latitude at the apparent synod of the luminaries exceeds 34′ 51″, possible if it is less than 34′ 51″, but necessary if it is less than 30′ 40″. In this he follows Copernicus, Book 4, Ch. 30, where, although he does not set down these limits, he nevertheless teaches that this criterion [Greek: κριτήριον (kritērion, "criterion")] is to be taken from the Moon's visible latitude at the moment of the visible conjunction. This requires the labour of investigating the parallax in longitude and latitude. So that such great labour may not be undertaken in vain, the others brought forward at number 2, with Ptolemy, seem to me to advise wisely that we should first form a conjecture about the risk of an eclipse for the time of the mean, or at most of the true, new Moon, from the Moon's bare distance from the nodes. So Renieri, in the precepts of eclipses, Ch. 1, number 4, considering the latitude, parallax and semidiameters of the Alphonsines, fixes these limits as in the following small table of the opinions already mentioned.

Limits of solar eclipses. Authors	Possible, North Temperate Zone to 49°: distance of ☾ from either node, toward the north	Possible, North Temperate Zone to 49°: distance of ☾ from either node, toward the south	Possible, South Temperate Zone to 49°: distance of ☾ from either node, toward the north	Possible, South Temperate Zone to 49°: distance of ☾ from either node, toward the south
Ptolemy, Reinhold, Neander, Wurstisen, Magini, Origanus, Mulerius, in mean ☌	20° 41′	11° 22′	11° 22′	20° 41′
Mulerius, in true ☌, from Ptolemy	17° 41′	8° 22′	8° 22′	17° 41′
Al-Battānī, in mean ☌	20° 12′	10° 40′	10° 40′	20° 12′
The Alphonsines, more or less	12° 0′	12° 0′	12° 0′	12° 0′
Regiomontanus, in mean ☌	20° 30′	10° 55′	10° 55′	20° 30′
Renieri, from the Alphonsines, in true ☌	17° 0′	✢	✢	17° 0′

Necessary limits in true ☌ are gathered from Ptolemy by Mulerius at 15° 38′. Necessary, I say, at least somewhere, that is, in the Torrid Zone. Langius, however, sets necessary limits in apparent ☌ if the apparent latitude is less than 30′ 40″, and possible limits if the apparent latitude is not greater than 34′ 51″.

[Margin: Kepler's method and opinion.]

IV. Kepler differs from these. In the *Epitome of Copernican Astronomy*, p. 880, and in the Rudolphine Tables, p. 98, he argues about these limits as follows. The semidiameter of the disc of the Earth and of the lunar shadow equal the sum arising from the parallax of the Moon from the Sun and the semidiameters of the luminaries; with those at apogee, this sum is 87′ 23″, and it is called the latitudinal arc [arcus latitudinarius]. But as the Moon's parallax 58′ 22″ is to the parallax of the Moon from the Sun 57′ 23″, so the latitudinal arc 87′ 23″ is to the latitudinal arc of the Moon's centre, 86′ 5″, to which there corresponds a distance from the Node of 15° 43′, as the limit of partial eclipses. With the Sun at perigee and the Moon at apogee, however, it is 15° 49′. The limit of total solar eclipses in this configuration is 10°, because the arc of the Earth's disc is 56′ 54″ and the latitudinal arc of the Moon is 56′. With the Moon at perigee and the Sun at apogee, on the other hand, the sum of the parallax of the Moon from the Sun and the semidiameters, which equals the sum of the semidiameter of the disc of the Earth and of the penumbra, is 92′ 37″, to which there corresponds a distance from the Node of 16° 57′ for the limit of partial eclipses; but with the Sun at perigee, 17° 3′. And since in this configuration the semidiameter of the Earth's disc is 62′ 12″, to which the latitudinal arc of the

Moon of 61′ 14″ corresponds, the limit of total eclipses is therefore a distance from the Nodes of 11° 7′; and it is not much different with the ☉ at perigee. In the Rudolphine Tables, p. 98, however, he sets these limits slightly differently, according to the Moon's motion first equated and nearly true, assuming an equal motion of the Nodes and a demonstrative semidiameter of the Sun and Moon, not one enlarged from physical causes. Here, then, is the following small table for his opinion.

Limits of possible ☉ eclipses according to Kepler (distance of the ☾ from the Node on either side)	☉ Apog., ☾ Apog.	☉ Apog., ☾ Perig.	☉ Perig., ☾ Apog.	☉ Perig., ☾ Perig.
In partial eclipses	15° 43′	16° 57′	15° 49′	17° 3′
In total eclipses	10° 0′	11° 7′	10° 0′	11° 7′
But from the Rudolphine Tables, at a nearly true ☌	15° 58′	16° 4′	17° 12′	17° 19′

V. For our part, in order to try these limits universally at true new Moons, we shall take from the astronomers' hypotheses the sum of the apparent semidiameters of the Moon and Sun, together with the horizontal parallax of the Moon from the Sun in the circle of altitude, when they are at perigee; for the parallax of latitude cannot be greater than this, but at most equal to it. Treating this aggregate as a latitude, sought in the body of the table of latitude for the time of new Moon, we shall look for the corresponding degree of the Moon's distance from the nearer Node, bearing in mind, however, Tycho's semidiameter of the Moon, contracted by him at new Moons, and Kepler's hypothesis, which at eclipse syzygies puts the angle at the Nodes at 5° 18′. And so we shall have the limits of a possible solar eclipse in the Temperate Zones, indeed even in the Frigid, if the Moon is in the semicircle of the ecliptic facing them, and with respect to those for whom the Moon's latitude tends toward their own pole. Next, with the aggregate of the semidiameters, treated as a latitude, we shall likewise seek in the body of the tables of latitude the distance from the nearer of the Nodes, or argument of latitude, which we shall set down as the limit of a possible eclipse in the same Zones when the Moon's latitude is toward the other pole. The necessary limits, at least for the Torrid Zone, we shall gather from the sum of the semidiameters of the Moon and Sun, but when they are at apogee, namely by seeking the Moon's distance from the nearer Node for this sum, looked for in the body of the table of latitude. Let this, then, be our small table.

TERMINI ECLIPSIVM SOLIS In Veris Nouilunijs ex Datis — Limits of Solar Eclipses at True New Moons, from the Data

From the authors	Possible in the North Temperate Zone and, if the Moon is in the northern signs, in the Frigid: toward the north	Possible in the North Temperate Zone and, if the Moon is in the northern signs, in the Frigid: toward the south	Possible in the South Temperate Zone and, if the Moon is in the southern signs, in the Frigid: toward the north	Possible in the South Temperate Zone and, if the Moon is in the southern signs, in the Frigid: toward the south	Necessary, at least in the Torrid Zone
Copernicus	18° 36′	6° 45′	6° 45′	18° 36′	5° 53′
Tycho	17° 21′	5° 22′	5° 22′	17° 21′	6° 3′
Longomontanus	18° 12′	6° 20′	6° 20′	18° 12′	5° 38′
Kepler	17° 19′	5° 46′	5° 46′	17° 19′	5° 25′
Lansbergen	18° 54′	6° 52′	6° 52′	18° 54′	6° 5′
Boulliau	18° 2′	6° 30′	6° 30′	18° 2′	6° 4′
Wendelen	18° 1′	6° 4′	6° 4′	18° 5′	5° 36′
Ourselves	18° 40′	6° 25′	6° 24′	18° 40′	5° 40′

All columns give the distance of the Moon from one or other of the Nodes within which they are possible or necessary.

[Margin: Our method, the quickest and the newest.]

But if you wish to know without labour whether any eclipse will occur, turn to Problem 4 of Chapter 12; for if there is to be no eclipse of the Earth, there will be none of the Sun either; but if there is some eclipse of the Earth, there will also somewhere be some eclipse of the Sun. And in the same place, Problem 4, no. 6, we shall set out these limits by another, more certain method, used by no one until now.

THEOREMA II.

Theorem 2.

Et PROBLEMA de Magnitudine Solaris Eclipſis.

And the Problem of the Magnitude of a Solar Eclipse.

[Margin: What the greatest solar eclipse is.]

VI. The magnitude of a solar eclipse is usually expressed in parts of an as, or unciae, or digits, of which the Sun's apparent diameter contains 12. But if a solar eclipse is total, and with stay, more than 12 digits are said to be eclipsed, because if the Sun had more than 12 they could still be covered by the Moon. So, when the excess of the Moon's apparent diameter over the Sun's has been multiplied by 12, and the sum divided by the Sun's apparent diameter, the result will be the digits, or fractions of digits, to be added to the twelve digits in a

total eclipse with stay. We have already shown that this is possible, in Book 4, Chapter 16, no. 15, and in this Book, Chapter 8, Scholium 3. For us, therefore, for whom the diameter of the Sun at apogee is 30′ 30″ and that of the Moon at perigee 33′ 30″, a solar eclipse cannot be greater than 13 digits 11′; and in the hypothesis of no celebrated astronomer is it greater than 13 digits 45′, or at the very most 14 digits. Magini, however, in his *Theoricae Planetarum*, Book 2, Chapter 31, states that beyond 12 digits hardly 17′ can be counted, and that the stay is therefore not sensible. This does not conform to Copernicus, whom he was otherwise following there. For in Copernicus the diameter of the Moon at perigee is 35′ 40″, and that of the Sun at apogee 31′ 24″; the excess is therefore 4′ 16″. Multiplied by 12 this makes 49′, and when these are divided by 31′ 24″ the result is 1 digit 34″ of excess over the Sun's diameter; and 4′ 16″ requires a time of about 8^{m}, which is certainly a sensible time. But Magini may then have followed another opinion about the diameters.

Further, you will find the digits of the Sun to be eclipsed, or to be covered by the Moon, by subtracting from the sum of the apparent semidiameters of the Sun and Moon the arc between the centres, or the distance of the centres of the Moon and Sun, multiplying the remainder by 6, and dividing the sum arising from this by the Sun's apparent semidiameter. How the arc between the centres is found from the apparent latitude at the moment of visible new Moon you will learn from solving a similar triangle, on which see Chapter 6, Problem 4. For what I said there about the true latitude and the true distance of the centre of the shadow from the Node applies here to the apparent latitude and distance. Or use the reduction of the Moon to the ecliptic, compiled for the moment of visible ☌, and the apparent latitude, so that in the same figure, by solving the triangle A L I, you may find the arc A I; or use precept 5 of Chapter 4 of Renieri, on which see below among the precepts of the tables. The ancient practitioners, however, used instead of the arc between the centres the Moon's apparent latitude at the moment of visible ☌, subtracted from the sum of the semidiameters, multiplying the remainder by 6 and dividing the sum by the Sun's apparent semidiameter. By this device was constructed the small table of digits given by Ptolemy, Book 6, Chapter 8, by Alfonso, fol. 117, and by Peuerbach in the penultimate table of Eclipses;

Reinhold, in the Prutenic Canons, p. 124; Magini, in the *Secunda Mobilia*, p. 683; Lansbergen, p. 38; and Renieri, p. 345 of the *Tabulae Mediceae*.

THEOREMA III.

Theorem 3.

Cum PROBLEMATIB. de Durationе & Partibus Eclipſis Solis.

With Problems on the Duration and Parts of a Solar Eclipse.

[Margin: Parts of the duration of a solar eclipse.]

VII. The duration of a solar eclipse is divided into two parts if it is not with stay, and into four if it is total with stay. In a partial eclipse, or a total one without

stay, the incidence, in Greek [Greek: ἐμπτώσις (emptōsis, "incidence")], is the interval from the beginning to the middle or maximum of the eclipse; the repletion, in Greek [Greek: ἀναπληρώσις (anaplērōsis, "filling up")], is the interval from the middle to the end. In a total eclipse with stay, however, the incidence is the interval from the beginning to total obscuration, and the repletion the interval from the beginning of emersion, or the point at which a small part of the Sun begins to appear again, up to the end, when the whole disc of the Sun appears to us full of light. The stay in total obscuration is divided into an earlier and a later part. Now the common run of astronomers think these parts equal. And they are indeed sensibly equal as regards the arcs of the zodiac and the diameters of the luminaries, as Ptolemy says in Book 6, Chapter 10, and Regiomontanus in Book 6 of the *Epitome*, prop. 26. But as regards time they are not always equal, whether incidence to repletion or earlier stay to later, as Ptolemy and Regiomontanus note in the places cited above, and Reinhold in Prutenic precept 63. These authors, however, except for Ptolemy, do not here distinguish the quadrants of the equator from the quadrants of the ecliptic, and they do not set out distinctly the causes of this variation; nor is Ptolemy's teaching complete, nor the translation clear enough.

[Margin: How great Ptolemy's diligence is here.]

Take both, therefore, from Ptolemy as elucidated by us. When the apparent synod of the luminaries occurs at the nonagesimal of both the ecliptic and the equator (which happens only when the cardinal points, that is, the equinoctial and solstitial points, are culminating on the meridian), then the time of incidence and the time of repletion, and the earlier and the later stay, are sensibly equal. For by as much as the parallaxes decrease in the eastern incidence, owing to the Moon's ascent toward the meridian, by so much do they increase in the western repletion, owing to its descent; and a compensation of the apparent slowness and speed results. For as the Moon gradually ascends the parallaxes of longitude decrease, on account of which the ☾ appears, in the eastern quadrant of the ecliptic, farther east than it really is, and so appears faster in its apparent motion in longitude. Therefore, as these decrease in this part, it appears in its ascent to the meridian to move more and more slowly, as regards apparent motion. Conversely, as the Moon descends toward the horizon the parallaxes of longitude increase; and on account of them it appears, in the western quadrant of the ecliptic, farther west than it actually is, and therefore slower in its apparent motion than in its true motion. But within this apparent slowness itself it is slower nearer the meridian, because of the smaller parallaxes, and faster farther from the meridian. Ptolemy therefore rightly concludes, on this account, that the times of a solar eclipse always come out greater because of the apparent motion, and that its times are slower in the motions nearer the meridian. But when the whole time of incidence passes in the eastern quadrant of the equator, whether the repletion is wholly completed in the same quadrant or part of it occurs in the eastern and part beyond the meridian in the western quadrant, the time of incidence is shorter than the time of repletion, because the Moon's

apparent motion is faster there and slower here, owing to the nearness of the meridian. Conversely, when the time of incidence passes either wholly or in part in the western quadrant, and the whole time of repletion in the western, the time of incidence is longer than the time of repletion. Nor is this contradicted by the fact that it may meanwhile be in the eastern quadrant of the ecliptic while, with respect to the meridian and the equator, it is in the western quadrant, or vice versa. For it is one thing for the apparent motion to be slower or faster than the apparent motion, and for the parallaxes of longitude and the time arising from them to have to be added to or subtracted from the true motion; it is another for the true motion to be slower or faster than the apparent motion. Kepler therefore rightly said [recte: dixit], in the *Epitome of Copernican Astronomy*, p. 886, that the visible hourly motion of the ☾ from the ☉ is almost always shorter than the true hourly motion, namely as regards the arc which it makes in one hour, and most of all near the nonagesimal, but that near the horizon they are almost equal.

[Margin: Why the method of calculating a solar eclipse is indicated here in advance.]

We cannot, however, determine in this place either the maximum duration or the times and conditions of the other phases belonging to solar eclipses unless we indicate here, by what is certainly a timely anticipation, the order and method of the calculation, which otherwise seem to belong to the second part of this volume. The examples are deferred to that part, but certain things that will have to be passed over there, so that the calculation is not disturbed, are not passed over here; especially since not all authors use the same completeness or the same clarity in this matter.

[Margin: Authors of the calculation of solar eclipses.]

Those to whom we nevertheless owe most in this are: Ptolemy, Book 6 of the *Almagest*, Chapter 10; al-Battānī, Chapter 44; the Alphonsines, prop. 32; Peuerbach, in the tables of Eclipses, from prop. 8 to 13; Regiomontanus, Book 6 of the *Epitome of the Almagest*, from prop. 19 to 26; Copernicus, Book 4, from Chapter 30; Erasmus Oswald Schreckenfuchs, on Peuerbach's *Theoricae*, from p. 341; Erasmus Reinhold, in the Prutenic Tables, from precept 54 to 65; Tycho, vol. 1, p. 136; Mulerius, in the *Tabulae Frisicae*, pp. 434, 443 and 463; Longomontanus, in the *Astronomia Danica*, Book 1 of the *Theorica*, Chapters 8 and 9, especially from p. 302; Magini, in the *Secunda Mobilia*, from Canon 75 to 91, and in the *Supplement to the Ephemerides*, from p. 279, or from Canon 9 of the Eclipses to 15; Lansbergen, from Precept 26 to 37; Kepler, in the *Epitome of Copernican Astronomy*, from p. 880, and in the Rudolphine Tables, from Chapter 29 to 32; Boulliau, in the *Astronomia Philolaica*, Book 4, Chapters 4 and 5, and Book 12, Chapters 22 and 24; Andrea Argoli, in his tables; Balthaſſar Capra [Baldassarre Capra], in the *Tyrocinium Astronomicum*; and Vincenzo Renieri, in the second part of the second edition of the *Tabulae Mediceae*, from Chapter 3 to 7.

[Margin: Comparison of these authors.]

Of these, Copernicus, Tycho and Longomontanus are too sparing; Kepler, Boulliau and Renieri are the most diligent; the rest stand in a middle position.

[Margin: Method of solar eclipses and first step.]

VIII. First, then, having found the true new Moon and, for that time, the true place of the luminaries, the equated anomalies, the true place of the Node ☊, and from these the argument of latitude, or the distance of the Sun from the Node ☊: if the ecliptic limits given in no. 5 give you reason to suspect a coming solar eclipse, convert the equal time of the new Moon into apparent time. And for that time, if the luminaries are not at the nonagesimal (for then the true and the apparent new Moon are the same), find by Problem 1 of Chapter 10 the rising point of the ecliptic and the nonagesimal point. When you have prepared, by Problems 2, 3 and 4 of the same chapter, what is necessary for Problem 5 of the same chapter, find by that Problem 5 the parallax of the Moon from the Sun in longitude; keep this, and call it the parallax of the new Moon, or the synodic parallax.

[Margin: Step 2, and the quickest way of collecting the Moon's apparent hourly motion and, by means of it, the apparent new Moon.]

Secondly, if the luminaries and their true synod are in the eastern quadrant of the ecliptic, add the synodic parallax of longitude to the Moon's true place found at the synod, and you will have the first apparent place of the Moon. Likewise add one hour to the time of the true new Moon, and for this aggregate time collect both the true place of the Moon and the parallax of longitude; add the latter to this second true place, and you will have the second apparent place of the Moon. Its difference from the first apparent place will be the Moon's apparent hourly motion; and when the Sun's hourly motion has been subtracted from this, there remains the apparent hourly motion of the Moon from the Sun. Multiply, therefore, by one hour, or rather by 60^{m}, the synodic parallax of longitude, and divide the sum by the Moon's apparent hourly motion; and you will have the apparent time, which, added in this eastern quadrant to the moment of the true new Moon, will give the exact moment of the apparent new Moon. You could, however, with the apparent hourly motion, in the tables of verification which Magini gives at p. 676 of the *Secunda Mobilia*, and we after him, look up the apparent hourly motion of the ☾ from the ☉ at the head and the synodic parallax of longitude at the side; for in the body you will find the time to be added to the true new Moon.

But if the true synod of the luminaries occurs in the western quadrant of the ecliptic, subtract the synodic parallax of longitude from the Moon's true place, and you will have the first apparent place of the Moon. Likewise subtract a whole hour from the moment of the true new Moon, and for the remaining time collect both the true place of the Moon and the parallax of longitude; subtract the latter from the second true place, and you will have the second apparent place. Its difference from the first apparent place of the Moon will be the Moon's apparent hourly motion; and when the Sun's hourly motion has been subtracted from this, there remains the apparent hourly motion of the

Moon from the Sun. Therefore, with this find, as above, the time corresponding to the synodic parallax of longitude, and subtract it from the moment of the true new Moon, and there will remain the exact moment of the apparent new Moon, or of the visible synod. So Regiomontanus, Book 6, prop. 21, and Magini, Canon 10 of the Compendium of computing eclipses. This way of deriving the Moon's apparent hourly motion has seemed to me far quicker than the one suggested by the same Regiomontanus in the second place above, by Reinhold, precept 55, by Magini in the *Secunda Mobilia*, Canon 77, by Lansbergen, precept 30, by Mulerius, p. 445 of the *Tabulae Frisicae*, by Renieri in the precepts on eclipses, Chapter 3, nos. 6 and 7, and by Kepler in the Rudolphine Tables, Chapter 32, precept 155.

[Margin: A still more exact moment.]

But if further meticulousness [Greek: περιεργίας (periergias, "over-elaborate care")] does not weary you, collect for the moment of apparent new Moon the true places of the luminaries, and from these their true distance from each other, and the parallax of the Moon in longitude. If this is equal to the distance of the luminaries in the zodiac, that was the most exact moment of apparent new Moon. But if they disagree, the difference must be converted into time, according to the proportion of the hourly motion of the Moon from the Sun already investigated above. You will add this time to, or subtract it from, the moment of apparent new Moon first found, according to the following small table, and the result will be the most exact moment of apparent new Moon.

If the true distance of the luminaries, compared with the parallax of longitude of the ☾ from the ☉, is	In the quadrant	Instruction (at the visible ☌)
GREATER	Eastern	Add the time
GREATER	Western	Subtract the time
LESS	Eastern	Subtract the time
LESS	Western	Add the time

For in a visible conjunction the distance of the true places of the Moon and Sun must be equal to the parallax of longitude, as Regiomontanus shows, Book 6, prop. 22, and as Reinhold takes from there in precept 58.

[Margin: Step 3, and the determination of the ecliptic new Moon.]

Thirdly, for the most exact moment of apparent new Moon, collect the Moon's true latitude and also the parallax of latitude, according to Problem 5 of Chapter 10. In the Temperate and Frigid Zones this parallax is always toward the opposite pole; in the Torrid Zone, however, it is in some places and at some times toward the visible pole, at other times toward the opposite one. If, therefore, the latitude is toward the same region toward which the parallax of latitude tends, add the parallax to the true latitude, and the result will be the apparent latitude, of the same region or denomination. But if the latitude is toward one pole of the ecliptic and the parallax of latitude toward the other, and they are equal to each other in quantity, the apparent latitude will be nil, and the centre of the Moon will be visibly on the ecliptic with respect

to the place on Earth for which you began the calculation. If the parallax is less than the true latitude, their difference will be the apparent latitude, of the same region or character as the latitude. But if the parallax is greater than the true latitude, the apparent latitude will be toward the opposite region, or of the contrary character. Compare, therefore, the apparent latitude with the sum of the visual semidiameters of the Moon and Sun, collected earlier or now, by means of the anomaly, from their own tables; for if the apparent latitude is less than that sum, there will be a solar eclipse at that place on Earth; if it is not less, there will not.

[Margin: Step 4, on the magnitude of a solar eclipse.]

Fourthly, as I said in no. 6, you will collect the ecliptic digits, using the arc between the centres rather than the apparent latitude.

[Margin: Step 5, for the minutes of incidence, etc.]

Fifthly, so that the whole duration of the eclipse and its parts may be ascertained: if the eclipse is without stay in darkness, then with the sum of the visual semidiameters of the Sun and Moon at the head of the tables, and with the apparent latitude corresponding to the apparent new Moon at the side of the tables, the minutes of incidence, or minutes of fall, are usually sought.

[Margin: Authors of tables of incidence, but imperfect ones.]

These tables are given by Ptolemy, Book 6, Chapter 8; Alfonso, fol. 116½; Peuerbach, penultimate table of Eclipses; the Prutenic Canons, p. 125; Magini in the *Secunda Mobilia*, p. 687; Lansbergen, p. 40; Argoli, p. 160; and Renieri, p. 349.

[Margin: Another way, by analysis of triangles.]

But in these tables the minutes of incidence and half-stay together, and then of half-stay alone, are not set out separately, even granting that these authors admit total solar eclipses with some stay. Therefore, to collect the minutes of each interval, solve in the old manner the rectilinear triangle treated by Ptolemy, Book 6, Chapter 11; al-Battānī, Chapter 44; Regiomontanus in the *Epitome of the Almagest*, prop. 24; and Mulerius in the *Tabulae Frisicae*, p. 443; and indicated by Tycho, p. 136. In the following diagram, then, let the ecliptic be EQ, on which is the centre of the Sun S and its semidiameter SG, from which the disc of the Sun is to be described; and let the sum of the semidiameters of the luminaries be S C on one side and S D on the other. At the beginning of the eclipse let the centre of the Moon be at C, at the middle at B, and at the end at D, so that the Moon's apparent path is CBD. To this path, from the centre S, let there be drawn the perpendicular S B, which is to be called the arc between the centres, or the apparent latitude of the Moon at the middle of the eclipse. The remaining lines belong to another problem, on which see below.

Diagram. A figure set into the right column, with the text narrowed to its left. Three equal circles stand on a line slanting from upper left to lower right. The middle circle is a disc black at the centre, with a pale flame-like band round its rim, carrying S at its centre and B within the black part. The upper and lower circles are each engraved with a human face and a hatched lower

rim. Straight lines pass through the three circles along the slant, a horizontal line runs through S, and a long straight line runs from near the left end of that horizontal line down to the lower right, outside the circles.

- N (top of the figure, above the upper circle): label only
- Q (left of the upper circle): label only; the prose names the ecliptic EQ
- V (left end of the horizontal line): label only
- G (on the long lower-left line, at the rim of the middle circle): the prose names the Sun's semidiameter SG
- S (centre of the middle circle): centre of the Sun
- I (on the limb of the middle circle, within the flame-like band, below S): label only
- B (within the black part of the middle circle): point on the Moon's path at the middle of the eclipse
- R (right of the middle circle): label only
- M (right of the lower circle): label only
- C (in the lower circle): centre of the Moon at the beginning of the eclipse
- H (in the lower circle, left of C): label only
- A (foot of the long lower-left line): label only
- E (foot of the lower circle): the prose names the ecliptic EQ
- D (in the upper circle, between the eyes of the face): centre of the Moon at the end of the eclipse
- F (in the upper circle, below the face's mouth, near the rim): label only

With these things laid down, because of the nearness and ease of calculation, and the security from sensible error, as the authors already mentioned suppose, they use, in place of the arcs of which the ecliptic, the Moon's path and the circle of latitude consist, their chords or semichords; and they use the Moon's path from beginning to end as if made through the same plane. In the triangle SBC, then, taken as rectilinear and right-angled at B, from the given side S B, which is the apparent latitude at the middle of the eclipse, and the base SC, which is the sum of the semidiameters, they investigate the side BC. This is the interval of incidence, and to it is equal the straight line BD, which contains the minutes of repletion, since the triangle DSC is isosceles and the perpendicular SB cuts its base CD in two at B, by 10 of Book 1 of Euclid. So, in solving the triangle already mentioned by 47 of Book 1 of Euclid, the square number of the side S B, subtracted from the square of the base SC, leaves the square of the side BC, whose square root gives the minutes of incidence.

[Margin: Inquiry into the apparent arc between the centres, and from it a more accurate incidence.]

But because of what is to be said in Scholium 1, you will work more accurately if you use the apparent arc between the centres, which is sought proportionally, as in a lunar eclipse, by the method already given in Chapter 6, Problem 4. For collect for the moment of apparent new Moon the apparent latitude and apparent longitude of the Moon, with the reduction of the Moon to the ecliptic, and make: as the radius to the second sine of the reduction, so the secant of

the apparent latitude to the secant of the arc SB. Or to the second logarithm of the reduction add the residual of the second logarithm of the apparent latitude, and the result will be the second logarithm of the arc SB, the apparent arc between the centres. When this arc has been obtained, let: as the radius to the second sine of the apparent arc between the centres, so the secant of the sum of the semidiameters to the secant of the incidence. Or to the 2nd logarithm of the apparent arc between the centres add the residual of the 2nd logarithm of the sum of the semidiameters, and the result will be the 2nd logarithm of the incidence. But if, in place of the sum of the semidiameters, you use the excess of the lunar semidiameter over the solar, and complete the rest as above, you will have the minutes of half-stay.

[Margin: The imperfection of this problem indicated.]

In this treatise, however, what error is committed by assuming the Moon's apparent path to be made, from the beginning to the middle or end, in the same plane and inclined at the same angle to the ecliptic, and by taking the apparent latitude at the moment of apparent new Moon for the arc between the centres, just as if that moment coincided with the moment of greatest obscuration and the middle of the eclipse, must be told below, more suitably, in the Scholia.

[Margin: Step 6, for the time of the duration of a solar eclipse and of its parts.]

Sixthly, so that the minutes of incidence and repletion, or if need be of each half-stay, may be converted into time, and finally the duration of the eclipse and its parts determined, the Moon's apparent hourly motion is needed, both before and after the middle of the eclipse. This is collected for the incidence one hour before the moment of apparent synod, and likewise one hour after for the repletion, by the method already given above in precept or step 2; then the minutes of incidence by

60 minutes of time, that is, by one hour, are multiplied, and the sum divided by the apparent hourly motion of incidence will give the time of incidence; the same sum divided by the hourly motion of repletion will give the time of repletion. But if the eclipse is total with stay, multiply the minutes of the half-stay by 60 and divide the sum by the hourly motion of incidence, for you will then have the time of the first half-stay; divide the same sum by the hourly motion of repletion, and you will have the time of the second half-stay. The aggregate of the times of incidence and repletion will be the duration of the eclipse, and the aggregate of both stays will be the time of the whole stay.

[Margin: Method of determining the greatest duration of a solar eclipse.]

IX. The greatest duration of a solar eclipse, moreover, occurs where and when these 2 elements come together: namely, the greatest sum of the semidiameters, and the least hourly motion of the Moon from the Sun, both true and apparent. Now the sum of the semidiameters is greatest when both luminaries are at perigee; but the Moon is then swiftest in true motion, and its true hourly motion is greatest. We must therefore try which of the four comparisons is better suited to this purpose, so that it may be clear which of them yields

the longer time. To that end we shall take the semidiameters and the hourly motion of the Moon from the Sun from our own hypothesis. Look at this in the following small table, so that you may take from it a similar specimen for the hypothesis of others.

From our hypothesis	☉ & ☾ at apogee	☉ & ☾ at perigee	☉ at apog., ☾ at perig.	☉ at perig., ☾ at apog.
Hourly motion of ☾ from ☉	26′ 57″	32′ 56″	24′ 12″	30′ 44″
Sum of the semidiameters	29′ 15″	33′ 20″	32′ 0″	30′ 34″
Time corresponding to the sum	$65^m\ 44^s$	$60^m\ 46^s$	$79^m\ 23^s$	$59^m\ 48^s$

It is clear, then, that the longest time for traversing a space as great as the sum of the semidiameters occurs with the Sun at apogee and the Moon at perigee, and that the time from the beginning to the middle of the eclipse, if it were accomplished by the Moon's true motion, is then $1^h\ 19^m$. To this, as Kepler teaches in the *Epitome of Copernican Astronomy*, p. 890, a quarter of an hour at most can be added on account of the apparent motion in central and greatest eclipses, so that the greatest half-duration from the beginning to the middle is $1^h\ 34^m$. Therefore, if the middle of this eclipse falls at noon and in the nonagesimal, where the time of incidence is equal to the time of repletion, the greatest duration of an eclipse by my hypotheses will be $3^h\ 8^m$, although for Kepler, in the same place, it does not exceed 2½ hours, because from the true hourly motion, taken separately, he had determined from his hypotheses a greatest duration of 2 hours. I, however, from his hypotheses, gather a greatest duration, considering the true hourly motion, of $2^h\ 23^m$; adding half an hour, then, as he himself teaches, it will come to $2^h\ 53^m$.

[Margin: Greatest duration of a solar eclipse.]

And indeed, in their calculations of solar eclipses, computers not rarely extend eclipses, even those that are not greatest, beyond 2½ hours: so Tycho, p. 136, who gives his own ☉ eclipse $2^h\ 52^m\ 56^s$; and Reinhold in the Prutenic Tables, precept 63, who gives about 2^h and 52^m; and Magini in canon 86 of the *Secunda Mobilia*, where he gathers the time of incidence as $1^h\ 21^m\ 17^s$ and of repletion as $1^h\ 16^m\ 8^s$, and hence of the duration as $2^h\ 37^m\ 25^s$. Now let there be a small table for the greatest duration of a solar eclipse.

Solaris Eclipſeos Duratio Maxima nempe ☉ Apogæo & ☾ Perigæa — Greatest duration of a solar eclipse, namely with the ☉ at apogee and the ☾ at perigee

From the data of	Duration
Ptolemy	$3^h\ 8^m$
Copernicus	$3^h\ 18^m$
Tycho	$2^h\ 56^m$
Longomontanus	$3^h\ 3^m$

From the data of	Duration
Kepler	$2^h\ 53^m$
Or as he himself would have it	$2^h\ 30^m$
Lansbergen	$3^h\ 18^m$
Boulliau	$3^h\ 12^m$
Wendelen	$3^h\ 0^m$
Ourselves	$3^h\ 8^m$

SCHOLIA.

Scholia.

I. What was said in chap. 6, Problem 4 and Scholium 1 against the ancient astronomers, about their confusing the middle of an eclipse with the moment of full Moon, and the arc between the centres, which determines the greatest eclipse, with the true latitude of the full Moon, holds here far more strongly for a solar eclipse. For the moment of the apparent new Moon is not the same as the moment of the middle or greatest eclipse; nor, to seek the minutes of incidence exactly, should one use that apparent latitude of the Moon which was found for the moment of the visible new Moon, but rather the arc between the centres of the Sun and Moon, drawn perpendicular to the Moon's path — at least when the eclipse is very large, or the Moon's apparent path is parallel to the ecliptic as far as the senses can tell. In this case, following Kepler's precept (*Epitome Astron.*, p. 890), look at the figure set out in the preceding chapter, no. 8, precept 5, in which let the Moon's path be CBD, parallel to the ecliptic EQ. For then, for a certain chosen interval of time before or after the apparent new Moon, the Moon's apparent latitude is to be gathered. Its antilogarithm, or second logarithm, subtracted from the antilogarithm of the sum of the visual semidiameters of the ☾ and ☉, leaves the antilogarithm of the difference, very nearly, between the places of longitude that the beginning and end of the eclipse require. To this difference the Moon's visible motion, gathered over that chosen interval of time, must be equal; or, if it is not, the interval must be corrected until they are equal. Therefore in the diagram already mentioned, and in triangle SHC, right-angled at H, having found for the beginning of the eclipse the apparent latitude CH, with this and the base SC, which is the sum of the semidiameters, you will find the minutes of arc SH, which are equal to the minutes of incidence CB. So too in triangle SDF, right-angled at F, having found for the end of the eclipse the Moon's apparent latitude DF, from this and from the sum of the semidiameters you will seek FS, that is, BD, the minutes of repletion.

[Margin: A more accurate inquiry into incidence, but in large eclipses.]

But surely, if the Moon's path is parallel to the ecliptic as far as the senses can tell, what is the point of so much [Greek: ὑπεριεργία (hyperiergia, "excess of labour")]? For then the arc between the centres SB and the arcs of latitude CH and DF are parallel as far as the senses can tell; it is enough, therefore, to use the

arc between the centres, and to work according to the rules of the preceding chapter, no. 8, precept 5. But if the eclipse is central for some place, the very sum of the visual semidiameters of the ☾ and ☉ is equal, as nearly as may be, to the minutes of incidence.

[Margin: In small solar eclipses it would be greater.]

II. I said "when eclipses are very large, or the Moon's visible path is nearly parallel to the ecliptic", because if they are small, or that path is very oblique, then, as Kepler points out in the *Astronomia Optica*, pp. 406 and 418, that is, chap. 11, Problems 30 and 32, and in the *Epitome of Copernican Astronomy*, p. 890, the angle of inclination of the Moon's visible path to the ecliptic is not 5°, as astronomers before Kepler have hitherto supposed, nor 5° 18½′, as Tycho did. It varies instead, so that at times it turns out twice, three times or even four times as great; as when the Moon is near the Node ☊ and the parts near the beginning of ♋ are rising, or near the Node ☋ and the parts near the end of ♐ and the beginning of ♑ are rising. The Moon's path is also sometimes inclined contrary to the true path, which happens when the Moon, near ☊, is rising toward the north and the signs near the beginning of ♑ are rising. From this it follows that the approach of the centres of the Sun and Moon must not rarely be considered in a circle drawn through the centre of the Sun and inclined toward the visible Node. In this, moreover, there is so great a variety that it cannot be embraced in a few rules, just as the duration of an eclipse in any given place cannot either, because of the great variations of the parallaxes which the Moon undergoes from beginning to end, as Ptolemy indicates in Book 6, in the last chapters, where he also declares that he does not pursue the highest precision in this matter.

[Margin: A flaw of the Prutenic Tables, of Magini and of Lansbergen.]

The reader therefore had to be warned not to rely on precepts 63, 64, 65 of the Prutenic Tables, and canons 86, 87, 88 of Magini's *Secunda Mobilia*, or precepts 35, 36, 37 of Lansbergen, and the like, where, assuming a constant angle of inclination of the Moon's path to the ecliptic of 5°, they teach universally how to find the minutes of incidence and the apparent latitude for the beginning and end of an eclipse, and from this to form the delineation of a solar eclipse. For that latitude is not apparent but nearly apparent, and the diagram of the eclipse built by those precepts is not true but nearly true. And since the Moon's visible path is twice, three times, four times as oblique to the ecliptic, the moment of greatest eclipse also differs more widely from the moment of the apparent new Moon, and the times of incidence and emersion vary more widely.

[Margin: Inclination of the Moon's visible path to the ecliptic of almost 20°.]

Outside eclipses, moreover, the same variation sometimes occurs, as Kepler confirms by the example of an observation of Bernhard Walther, with the Moon at its last quadrature and 37° from the Node ☊. Taking that observation as given, he shows that the Moon's visible path was inclined to the ecliptic at 19° 21′.

III. Besides what was said in Scholium 2, Kepler, in *Astron. Opt.*, chap. 11, Problem 32, does indeed grant that the space which the Moon covers in a solar eclipse in three hours at most may fairly be likened to a straight line, although it is an arc of a great circle; but nevertheless he rightly denies

[Margin: The Moon's visible path winding and compound.]

that the centre of the Moon proceeds through the same plane of a great circle from the beginning to the end of the eclipse. For this, he says, the parallaxes of longitude and latitude do not allow, since they vary unequally, and the faster the nearer they are to the nonagesimal; and therefore the Moon's path is winding and compounded of various curves. He concludes, however, that this tiny difference does not appear sensible except around the nonagesimal and the meridian.

CAPVT XII.

Chapter 12.

De Terræ Eclipſi ab Vmbra vel Penumbra Lunari obſcuratæ, ex Luna ipſa ſpectata.

On the eclipse of the Earth, darkened by the lunar shadow or penumbra, as viewed from the Moon itself.

I. Not every property of a solar eclipse viewed from the Earth has yet been sufficiently examined, when Kepler carries us, still unlearned, from the Earth to the Moon, so as to instruct us from there. In the *Epitome of Copernican Astronomy*, from p. 874, and in the Rudolphine Tables, chap. 32, precept 158, he introduces us to the true eclipse of the Earth itself, as viewed or viewable from the Moon.

[Margin: The intellect of Kepler and Boulliau praised.]

With him lighting the way, Ismaël Boulliau, a man of the keenest intellect, in Book 4 of the *Astronomia Philolaica*, chap. 4, considers that what is called an eclipse of the Sun is in reality an eclipse of the Earth itself, since the Earth is deprived of the Sun's light by the intervention of the Moon, just as an eclipse of the Moon is by the intervention of the Earth. Pliny the Elder, with his acumen, had touched on this in Book 2, chap. 10, in these words: *For it is plain that the Sun is hidden by the intervention of the Moon, and the Moon by the interposition of the Earth, and that they repay each other in turn, the Moon by its interposition taking the same rays of the Sun from the Earth, and the Earth from the Moon. As the Moon passes beneath, sudden darkness is drawn over; and again by the Earth's shadow the star is dulled.*

Boulliau had seen that the inquiry into the lunar parallax must be repeated so many times in calculating a solar eclipse, to the point of wearying anyone's astronomical patience, and that in the parallactic tables of the Prutenics, of Magini and of Lansbergen it is as unreliable as it is troublesome. He therefore considered that a solar eclipse could be calculated without parallaxes if in its

place one considered the eclipse of the Earth, darkened by the shadow or penumbra of the Moon, as viewable from the Moon. For just as we calculate a lunar eclipse without parallax, because the Moon is truly deprived of the Sun's light, wholly or in part, and the place of the Earth's shadow through which the Moon passes and the Moon's body are equally distant from the eye of the viewer, whereas someone who was then on the Moon would nevertheless judge the eclipse, which was really the Moon's, to be an eclipse of the Sun, brought about by the [Greek: ἐπιπροσθέσει (epiprosthesei, "interposition")] of the Earth, and would have to seek the parallax according to the proportion of the Earth's semidiameter: so we, while viewing from the Earth an eclipse of the Sun through the interposition of the Moon, must take account of the lunar parallax. But if we were on the Moon, we should see the Earth really deprived of the Sun's light by the intervention of the Moon, in the same place where the shadow or penumbra of the Moon is, without any parallax between the Earth and the place of the lunar shadow or penumbra. And just as in a lunar eclipse the Moon, with respect to two viewers of whom one is at the centre and the other on the surface of the Earth, undergoes parallax, but the place of the Earth's shadow through which the Moon's centre passes undergoes exactly the same parallax, so an eclipse of the Earth viewed by two people, of whom one is on the surface and the other at the centre of the lunar globe, has parallax, but the same as, and equal to, that which the place of the lunar shadow or penumbra through which the Earth's centre passes has. So, more or less, Boulliau, but not so explicitly.

[Margin: The author's judgement of this method.]

II. Indeed we admit that this inquiry and [Greek: ψηφοφορίαν (psēphophorian, "reckoning")] is ingenious, and useful, and easier than the customary method of computing solar eclipses, and deserving further cultivation, as I shall presently say, because of the fertility of new theorems and problems which it holds in its lap. Yet by this method alone we do not succeed in being able either to weigh solar eclipses already observed, or to predict future ones, with respect to viewers living on the Earth. That cannot be done without an inquiry into parallax, as is clear in itself and from the example of the solar eclipse of the year 1639 June 1, observed by Boulliau at Paris and brought to this new form of calculation in Book 4, chap. 5. For when he wants to reduce its phase to the meridian and horizon of Paris, and to determine the times of the phases, he investigates the parallax of altitude, of longitude and of latitude, and uses a calculation no less prolix and troublesome than others do, once a method of deducing parallaxes has been supposed; which method, however, he teaches in Book 12, precepts 22 and 24. So by this new method the astronomical Hercules is assigned to a new labour, though not unwillingly, yet is not wholly released from the old one.

[Margin: The method of the eclipse of the Earth advanced by the author.]

Meanwhile we must develop the method already mentioned, adding some demonstrations omitted by Kepler and Boulliau, and also by Renieri in his latest precepts for eclipses.

PROBLEMA I.

Problem 1.

Definire Semidiametrum Apparentem Diſci Terræ à Sole illuſtrati ex Luna viſam.

To determine the apparent semidiameter of the disc of the Earth illuminated by the Sun, as seen from the Moon.

III. Just as the luminaries viewed from the Earth, although they are spherical, look flat, because owing to their excessive distance the eye cannot distinguish the greater distance of points on a spherical surface from the lesser, but judges them to be equally distant and so all in the same plane, so the globe of the Earth viewed from the Moon would appear as a flat circle or disc, and viewed at new Moon it would appear, like a full Moon, illuminated by the Sun. Which of the three circles of the Earth that seem to bear on this matter is the disc we are speaking of must be determined from the adjoining diagram. On its perpendicular straight line AB, let A be the centre of the Moon in conjunction with the Sun, and C the centre of the Earth, from which let the terraqueous globe BFTE be described, whose diameter is DCE. From the extremities of this diameter, straight lines being drawn to the centre of the Moon, let an eye A be imagined to see the Earth under the angle DAE; for then the apparent semidiameter of the disc will be CE or CD, and its measure the angle CAE.

Diagram. Set into the right column, with the text running in a narrow measure on its left. A large circle stands above a small circle whose upper half is solid black; four long straight lines, in two close pairs, converge downward from the large circle to the small circle, with the vertical between them. A vertical line runs through the large circle from the top of the figure to the small circle. Three nearly parallel horizontal chords cross the large circle at about its middle, with several crossing lines between them near the right limb. Short lines stand above the upper chord inside the large circle. A long straight line, tangent at the right limb, descends from upper right to lower right.

- O (upper left of the large circle, at the end of a short horizontal line, beside the point where it meets the limb): O
- S (top of the large circle, to the left of B): S
- B (top of the vertical line): B
- P (inside the large circle, right of the vertical line, below B): P
- I (inside the large circle, left of the vertical line, below S): I
- N, V, M (standing on the upper chord, left to right): N, V, M
- H, D, F (left limb, top to bottom): H, D, F
- K, E, G (right limb, top to bottom): K, E, G

- C (centre, just above the lowest chord): C
- L (below C, under the lowest chord): L
- T (bottom of the large circle, on the vertical): T
- R (upper end of the tangent, upper right): R
- Q (lower end of the tangent, lower right): Q
- A (in the white lower half of the small circle): A

Now let the rays AF and AG be drawn from A, touching the Earth at F and G, where, by Euclid III.18, a right angle will be formed with the radius GC; and let the points of contact be joined by the straight line FG. For to the viewer at A, FG will be the diameter of the disc and LF its semidiameter, and its apparent measure the angle LAF. This angle is a very little greater than angle CAD, just as angle CAG is slightly greater than angle CAE, namely by about 15″, as will be clear to anyone who gathers these angles first in triangle CGA, right-angled at G, taking side CG as one semidiameter of the Earth and CA, the lunar distance, as base; then in triangle ACE, right-angled at C, taking as one side one semidiameter of the Earth, CE, and as the other side the lunar distance CA.

[Margin: 1. Method of determining the semidiameter of the Earth's disc.]

[Margin: 2. Renieri's method.]

In this second way, then, Renieri, in the new *Tabulae Mediceae*, Part 2, chap. 5, no. 1, takes the apparent semidiameter of the Earth's disc, when he instructs us to seek the Moon's horizontal parallax and to use it as its measure.

Thirdly, let QR be a ray of the ☉, touching the Earth at K, and by other rays let the arc EK beyond the quadrant TE be illuminated, to which let the arc DH be equal. When the straight line HK is drawn, then, it will be the diameter of a circle that is not a great circle, separating the segment HTK, illuminated by the Sun, from the unilluminated HBK; and therefore it will be the diameter of the terrestrial disc illuminated by the Sun, and its semidiameter MK, whose measure is angle MAK.

[Margin: 3. The method of Kepler and of Boulliau.]

In this 3rd way, then, Kepler, in the *Epitome of Copernican Astronomy*, p. 874, and in the Rudolphine Tables, chap. 31, precept 149, takes the semidiameter of the Earth's disc apparent to a lunar viewer at A, and so does Boulliau in Book 4, chap. 5. How much, however, the angle MAK is smaller than the angle of lunar parallax CAG, Kepler defines from his hypothesis, saying: *If from the Moon's horizontal parallax you take away one and a half times the Sun's horizontal parallax, there will remain the semidiameter of the Earth's disc.* This is very nearly true, however, in any hypothesis, as will be clear if you investigate the angle CAK (which is the same as MAK) in triangle CAK, in which AC, the distance of the Moon from the Earth, is given, and CK, one semidiameter of the Earth, and the angle they enclose. For that angle consists of the right angle ACE and the acute angle KCE, which measures the arc EK, illuminated beyond the quadrant by the unrefracted rays of the Sun, which it is sufficient to use here; and this arc becomes known through Problem 4 of chapter 11 of Book 3. It

will be clear if you then compare the angle thus gathered with the Moon's horizontal parallax. Yet the difference will be slight if in many problems we use CE itself for the semidiameter of the disc, because the angle CAE is nearly midway between the parallactic angle CAG and Kepler's angle CAK.

PROBLEMA II.

Problem 2.

Inueſtigare Semidiametrum Apparentem Vmbræ Lunaris, Porrectæ vltra Diſcum, aut centrum Terræ.

To investigate the apparent semidiameter of the lunar shadow, extended beyond the disc or the centre of the Earth.

IV. Here the Moon's shadow is supposed to extend beyond the centre of the Earth; how this is determined I have already shown in chap. 9, Problem 4. For if the apparent semidiameters of both luminaries are equal, the apex of the lunar shadow ends at the centre of the Earth, as in figure 4 of chapter 8. So for it to extend further, the Sun's apparent semidiameter must be less than that of the Moon. Then, therefore, says Kepler in the *Epitome of Copernican Astronomy*, p. 874, and in the Rudolphine Tables, chap. 31, precept 150: *if the Sun's apparent semidiameter be taken from the Moon's apparent semidiameter, there remains approximately the semidiameter of the lunar shadow as viewed from the centre of the Moon.*

To demonstrate this, since Kepler's *Hipparchus* has never, so far as I know, come to light, in the following figure let there be on the straight line AB the centres: A of the Sun, whose quadrant is SV; C of the Moon, whose hemisphere is DEF; and T of the Earth, whose hemisphere is GHK. Let TH be a semidiameter of the Earth, perpendicular to AB, and let H be joined to C by the straight line CH; for the angle TCH will measure the apparent semidiameter of the Earth's disc TH, viewed from the Moon. Next draw the straight line PB, tangent to the Sun at P and to the Moon at E, until it meets the straight line AB at B. For CBE will be the semicone of the lunar shadow, whose apex B is beyond the centre of the Earth T. And therefore, since the Moon is smaller than the Sun and much smaller than the Earth, PB will cut the Earth's semidiameter at M; let this point be joined to the Moon's centre C by the straight line CM. For the angle TCM will be the measure of the shadow's semidiameter TM, apparent to a viewer placed at C; and CME will be the angle subtending the Moon's apparent semidiameter, viewed from M, that is, very nearly from the centre of the Earth. Finally, from the centre of the Earth let the straight line TP be drawn, tangent to the Sun at a point that differs insensibly from the point P, because of the Sun's enormous distance. For the angle ATP will measure the Sun's apparent semidiameter, viewed from the centre of the Earth.

Diagram. Set into the left column, on the right of a narrow measure of text. A long vertical line runs from A at the top to B at the bottom. A short

horizontal line runs from A to V, and a second line from A down to P, just below V. A quadrant arc runs from S on the vertical up through P to V. A pair of close, nearly parallel lines descends from P to the lower left, one reaching T and one reaching B. Lower down, a small semicircle D-E-F stands against the vertical, and below it a larger semicircle G-H-K, with a horizontal line from T to H and several lines crossing between C, E, F, T, M and H.

- A (top left): A
- V (top right): V
- P (just below V): P
- S (on the vertical, at the foot of the quadrant arc): S
- D, C, F (on the vertical, against the small semicircle, top to bottom): D, C, F
- E (on the right of the small semicircle): E
- G, T, K (on the vertical, against the large semicircle, top to bottom): G, T, K
- M (just right of T, below the horizontal line): M
- H (right end of the horizontal line): H
- B (foot of the vertical): B

[Margin: Lemma 1.]

With these laid down, I say first that the two straight lines PT and PB are parallel as far as the senses can tell, as I have already shown in Book 3, chap. 5, from no. 6, granted that TB has no sensible ratio to the Sun's distance ATB. And it has none, because between TM, which is less than the Earth's semidiameter, and AT, the Sun's distance, which in my reckoning is 7500 semidiameters of the Earth, there is no ratio perceptible by us through any observations.

[Margin: Lemma 2.]

I say therefore secondly that the external angle ATP, that is, the Sun's apparent semidiameter, because of the sensible parallelism of the lines PT and PB, on which the straight line AB falls, is by Euclid I.29 equal, as far as the senses can tell, to the internal and opposite angle TBM; and so TBM is, without sensible difference, equal to the angle measuring the Sun's visual semidiameter.

[Margin: The solution of the problem and its proof.]

With these premised, since by Euclid I.32 the external angle CME, that is, the Moon's apparent semidiameter, is equal to the two internal and opposite angles CBM, that is, TBM, which is equal to the Sun's semidiameter, and BCM, that is, TCM, which measures the semidiameter of the lunar shadow TM, taken together: therefore, when the angle of the Sun's semidiameter CBM is taken from the angle CME of the Moon's semidiameter, there will remain TCM, the measure of the apparent semidiameter TM.

PROBLEMA III.

Problem 3.

Semidiametrum Penumbræ Lunaris apparentem ſpectatori in Luna collocato, & tranſeuntem per Terræ centrum Inquirere.

To find the semidiameter of the lunar penumbra apparent to a viewer placed on the Moon, and passing through the Earth's centre.

V. Kepler, in the *Epitome of Copernican Astronomy*, p. 875, and in the Rudolphine Tables, chap. 31, precept 150, says: *if you gather into one sum the apparent semidiameters of the Sun and Moon, and about half of the Sun's horizontal parallax, the semidiameter of the penumbra will be accumulated*; and he affirms that this was demonstrated in his *Hipparchus*. I demonstrate the same as follows.

In the diagram added at this place, let there be on the straight line ACB the centres: A of the Sun, which is DEF; C of the Moon; and B of the Earth, whose disc and diameter is HM. To this diameter let the extreme rays descend from the Sun, touching the Moon on opposite sides, namely DPL and FTG; and from very nearly the same points D and F to the points G and L let the Sun's rays DG and FL be drawn, so that from G and L the whole Sun begins to be seen, under the angles DGF and FLD. For the space GL will be that which the Moon's penumbra darkens, because within it there is no point that is illuminated by all the Sun's rays, but only by some; therefore GL will be the diameter of the penumbra, and GB its semidiameter.

Diagram. Set into the right column, with the text running in a narrow measure on its left. At the top, a shallow arc D–E–F hangs from a nearly straight line D–A–F, the arc bulging downward to E. A vertical line runs from A through E, C and S to B at the foot. Two heavy near-vertical lines run from D and from F down to the base line. Two pairs of slanting lines cross: from D toward the lower right and from F toward the lower left, crossing the vertical above a small circle centred at C; further lines from A slant down to G. Below, a large semicircle stands on the horizontal base H–G–B–L–M. A dashed line runs from N on the left limb of the semicircle to B.

- D (top left): D
- A (top centre): A
- F (top right): F
- E (below the arc, on the vertical): E
- T (above K, at the upper left of the small circle, where a ray touches the circle): T
- K (left of the small circle): K
- C (centre of the small circle): C
- P (right of the small circle): P
- T (small sort, on the upper left limb of the semicircle): T
- O (right of T, on the same limb): O
- S (top of the semicircle, on the vertical): S
- R (upper right limb of the semicircle): R
- N (left limb of the semicircle, at the head of the dashed line): N
- H, G, B, L, M (on the base, left to right): H, G, B, L, M

When the straight line GC is drawn from G to the Moon's centre C, then, the angle GCB will subtend and measure the semidiameter of the penumbra GB, apparent to the viewer at C. Now from the Sun's centre A let the straight line AG be drawn to G, so that the angle AGF subtends and measures the Sun's apparent semidiameter AF; and finally from A, the Sun's centre, let a ray be drawn tangent to the Earth at N, so that the angle NAB is the Sun's horizontal parallax. With these laid down, I say that the angle GCB, that is, the measure of the semidiameter of the lunar penumbra viewed from the Moon's centre, is equal to the angles AGF, which measures the Sun's apparent semidiameter, and TGC, which measures the Moon's apparent semidiameter (as the angle KBC also measures it, since the ray GIF touches the Moon at T), and the angle GAB, which is smaller than the Sun's horizontal parallax HAB [recte: NAB], all taken together. For by Euclid I.32 GCB is equal to the angle GAB and the angle AGC taken together; but these two are equal to the three already mentioned, since AGC consists of the angles AGF and TGC.

[Margin: Part 2 of the problem, concerning half of the Sun's parallax.]

Now the parallactic angle NAB is the angle under which an eye at A would see the arc NS of the Earth, which is almost a quadrant, since BNA is a right angle and NAB, the Sun's horizontal parallax, is not greater than 3′. The arc OS, as I shall say at the end of Problem 5, is about 35°; and OI is about as great as the angle IGO, that is AGF, of the Sun's apparent semidiameter, which is about 15′. The arc SI, therefore, never much exceeds 35° 15′, and will be about 36°. So if NS, of almost 90°, is seen under the angle NAB of the whole solar parallax, the arc IS, which is about 36°, will be seen under the angle GAB, about half of the horizontal solar parallax: and this Kepler asserts but does not demonstrate. You will therefore work more exactly if, to the sum of the semidiameters of the luminaries, you add not half but 4/9 of the Sun's horizontal parallax. Now, to have a specimen of the three preceding Problems from our hypothesis, look at the following small table.

Semidiametri Apparentes Oculo in ☾ fito. — Apparent semidiameters for an eye placed on the ☾.

Apparent semidiameter	Value
Of the Earth's disc: ☾ at apogee	53′ 20″
Of the Earth's disc: ☾ at perigee	63′ 45″
Of the lunar penumbra: ☾ & ☉ at apog.	29′ 27″
Of the lunar penumbra: ☾ & ☉ at perig.	33′ 30″
Of the lunar penumbra: ☾ at apog., ☉ at perig.	30′ 46″
Of the lunar penumbra: ☾ at perig., ☉ at apog.	32′ 11″
Of the sheer shadow of the ☾, greatest, with ☾ & ☉ at perigee	1′ 30″

PROBLEMA IV.

Problem 4.

Inquirere in vero Nouilunio Latitudinem veram Centri Penumbræ Lunaris, ſeu potiùs Arcum inter centrum eius, & centrum Diſci Terræ inuenire, Terminos Poſſibilis, aut Neceſſariæ Eclipſis Terræ ac Solis, & ſpeciem futuræ Eclipſis determinare.

To investigate, at the true new Moon, the true latitude of the centre of the lunar penumbra, or rather to find the arc between its centre and the centre of the Earth's disc; and to determine the limits of a possible or a necessary eclipse of the Earth and of the Sun, and the kind of the coming eclipse.

[Margin: Precept 1.]

VI. First, the true latitude is investigated here in the same way as the latitude of the Moon itself; for the axis and centre of the lunar penumbra recede from the ecliptic marked on the Earth's disc by just as much, and toward the same quarters of the world, as the Moon itself recedes in the sky. The arc between the centre of the lunar penumbra and the centre of the Earth's disc is likewise investigated in the same way as the arc between the centres of the Moon and of the Earth's shadow, on which see chapter 6, Problem 4. Next, the apparent semidiameter of the Earth's disc is to be sought by Problem 1, and that of the lunar penumbra by Problem 3. With these prepared, let there be a diagram in which the Earth's disc at true new Moon is AKI, with its centre C and semidiameters CI, CK, CL, and the terrestrial ecliptic is ACB, on which the nodes of the penumbra's path are at B or D.

Diagram. Set into the right column across its full measure, between the words prǽpa- and ratis. A large circle has its centre at C. A heavy straight line runs from A on its left limb through C and D, out past the right limb, to B. Lines run from C up to M and K at the top of the circle, and from C down through G and I. Four small stippled circles stand around it: the circle centred at L straddles the limb at the upper right; the circle centred at H lies inside the limb at the upper left of L; the circle centred at G lies inside the limb below the line; the circle centred at E lies below the limb and touches the circle G at I. Each small circle carries radii from its centre. Lines run from B to L and from B to E; lines run from D to H and from D to G.

- A (left limb of the large circle, on the line): A
- K (top of the large circle, outside the limb): K
- M (just inside the limb, below K): M
- L (centre of the upper right small circle): L
- H (centre of the upper left small circle): H
- C (centre of the large circle): C
- D (on the line, inside the right limb): D
- B (far right, the end of the line): B
- G (centre of the lower small circle inside the limb): G
- I (on the lower limb, where the two lower small circles meet): I

• E (centre of the lowest small circle): E

[Margin: Case 1, in which there is no eclipse.]

Second, let the centre of the penumbra be at E, the node of the penumbra's path EB with the terrestrial ecliptic at B, and the straight line CE from the disc's centre perpendicular to the penumbra's path; and let the penumbra's limb I, at the closest approach of the centre E to C, remain outside the limb of the disc, or merely touch it. For then there will be no eclipse of the Earth, and none of the Sun either. The test for this will be if the arc CE between the centres is not smaller than the sum of the apparent semidiameter CI of the disc and IE of the penumbra.

[Margin: Notable corollary on the limits of eclipses of the Earth and of the Sun.]

Now the greatest apparent semidiameter of the terrestrial disc can be known, which of course occurs when it is viewed from the Moon at perigee; and the greatest semidiameter of the lunar penumbra can also be known, which of course occurs with the Sun and Moon at perigee; and it can be known at the moment of true new Moon as well. The greatest of the arcs CE between the centres is therefore given. The angle of inclination of the penumbra's path to the ecliptic is supposed from the hypothesis of each of the more celebrated astronomers, since it is as great as the Moon's greatest latitude at ecliptic syzygies. In the triangle CBE, then, right-angled at E, given CE, the greatest arc, and the angle CBE, one can know EB, the distance of the centre of the lunar penumbra from the nearer node, and the distance of the Moon itself from the same node, at which or beyond which an eclipse of the Earth and of the Sun is not possible. If, however, the least arc is used, which occurs with the luminaries at apogee, the distance from the node for the limits necessary somewhere on Earth will become known; and the arc between these two distances will be for eclipses, but not necessary ones. I am glad, therefore, to bring these limits into one view in the following small table, according to the hypotheses of the more celebrated astronomers. The foundations of its synopsis are the parallaxes of the luminaries, on which see Book 3, chapter 8, and Book 4, chapter 13; their apparent semidiameters, on which see Book 3, chapter 10, and Book 4, chapter 16; the greatest inclination of the lunar path to the ecliptic, on which see Book 4, chapter 12; and finally Problems 1 and 3 of this chapter.

TABVLA PRO TERMINIS ECLIPSIVM TERRÆ & SOLIS. — Table for the limits of eclipses of the Earth and of the Sun.

From the data of the authors	Apparent semidiameter of the Earth's disc: greatest, ☾ at perig.	Same: least, ☾ at apog.	Apparent semidiameter of the lunar penumbra: greatest, ☾ & ☉ at perig.	Same: least, ☾ & ☉ at apog.	Arc between the centres at ecliptic ☌: greatest, ☾ & ☉ at perig.	Same: least, ☾ & ☉ at apog.	Inclination of the ☾'s path to the ecliptic, at ecliptic ☌	Limits of eclipses of the ☉ and of the Earth, and distance from the nearer node: possible	Same: necessary somewhere
Ptolemy	63′ 40″	53′ 24″	36′ 10″	32′ 50″	99′ 50″	86′ 14″	5° 0′ 0″	19° 25′	16° 42′

Ourselves	63′ 45″	53′ 20″	33′ 30″	29′ 27″	97′ 0″	82′ 47″	5° 0′ 0″	18° 49′	15° 58′

[Margin: Case 2, of a half-shadow.]

Third, if the arc between the centres, as CL in the diagram, where the centre of the penumbra is at L, is equal to the apparent semidiameter of the Earth's disc, only half of the penumbra, and half of the shadow if there is any shadow, will occupy the Earth. That eclipse will concern only the Frigid and Temperate Zones; the remaining half of the penumbra will fall outside the globe of the Earth, and there will scarcely anywhere be a central eclipse.

[Margin: Case 3, of the whole penumbra occupying the Earth without stay.]

Fourth, if the arc between the centres is smaller than the apparent semidiameter of the Earth's disc by as much as the apparent semidiameter of the penumbra, the whole penumbra will occupy the Earth, but without any stay of the whole penumbra. So it is in the diagram with the arc CG, the centre of the penumbra being placed at G; this arc differs from the semidiameter CI by GI, the semidiameter of the penumbra.

[Margin: Case 4, of the whole penumbra staying on the face of the Earth.]

Fifth, if the sum of the arc between the centres and the apparent semidiameter of the penumbra is smaller than the apparent semidiameter of the Earth's disc, the whole penumbra will occupy the Earth, with some stay of its whole self. So

it is in the diagram, the centre of the penumbra being placed at H, if the sum of the arc CH and the semidiameter HM is smaller than the semidiameter CK.

[Margin: Corollary for the discoveries of the new astronomy.]

In case 1, therefore, there will be no eclipse either of the Earth or of the Sun; in cases 2, 3 and 4 there will be some eclipse, and somewhere on Earth, both of the Earth and of the Sun. Astronomy may rejoice now for the first time that this can now be known without the tangles of the parallaxes. Here it is not worth the trouble of worrying over the sheer shadow, since it rarely occupies the Earth perceptibly, and then with a semidiameter of no more than 1′ 30″.

PROBLEMA V.

Problem 5.

Magnitudinem Eclipſis Terræ determinare & ſcrupula Diſci Terræ conuertere in arcum circuli magni Terræ.

To determine the magnitude of an eclipse of the Earth, and to convert minutes of the Earth's disc into an arc of a great circle of the Earth.

[Margin: Why there is no total eclipse of the Earth or universal eclipse of the Sun.]

VII. The Moon's horizontal parallax, by which we said the semidiameter of the Earth's disc viewed from the Moon is estimated, is always greater than the semidiameter of the lunar penumbra, that is, than the sum of the apparent semidiameters of the ☾ and ☉ and the semi-parallax of the ☉. For that reason there is no total eclipse of the Earth; and from this it also follows that there is no universal eclipse of the Sun over one entire terrestrial hemisphere. Speaking, then, of a partial eclipse of the Earth, it is as great as the diameter of the lunar penumbra, or the part of it occupying the Earth, compared with the diameter of the Earth's disc. Now to someone viewing from the ☾ the Earth illuminated by the Sun, the Earth would seem to the senses two feet across, since it is seen under nearly double the angle under which we see the luminaries, which we estimate at one foot. Since, then, the magnitude of an eclipse of the ☾ and of the ☉ is usually expressed in digits or inches, of which one foot has 12, it will not be unfitting to set out an eclipse of the Earth in inches or digits, but in such units as the apparent diameter of the Earth's disc has 24 of.

[Margin: Method 1 of determining the magnitude of an eclipse of the Earth.]

Let it be, then, as the apparent diameter of the Earth's disc is to 24, so the diameter of the penumbra, if the whole of it occupies the Earth, or the part of the diameter of the penumbra occupying the Earth, to the digits or inches of the Earth's disc obscured.

[Margin: Method 2 of the magnitude of an eclipse of the Earth.]

The same magnitude, however, is expressed another way by seeking the great arc of the Earth occupied by the penumbra, with the help of the figure

to be repeated here from number 3 of this chapter[42], in which we shall use the part of the Earth DBE as if it were DTE, for the solution of the problem will come to the same thing. Let the centre of the penumbra, then, be at B, at no distance from the place standing perpendicularly over the centre of the disc, and let the given semidiameter of the penumbra be VM, equal to IP, for example 32′, of which the disc's semidiameter HM, very nearly as great as DC, is 60′. Say, therefore: as HM or DC, 60′, is to the radius 100000, so 32′ is to IP, 53333, the sine of the arc SB. From the tables of sines, then, the arc SB is 32° 16′, and in this example the whole diameter of the penumbra occupies 64° 32′ of a great circle of the Earth. Next, let the centre of the penumbra be at V, its given semidiameter NV 32′, and the arc between the centres VM 10′. The whole NM is then 42′, of which, as above, HM, or nearly DC, is 60′. Say, therefore: as HM, 60′, is to the radius 100000, so NM, 42′, is to 70000, the sine OP of the arc OB, of 44° 26′. Then say again, or make it: as 60 is to 100000, so VM, 10′, is to IP, 16666, the sine of the arc SB, of 9° 36′. When these are taken from the arc OB, 44° 26′, there remains the arc OS, 34° 50′, occupied by the semidiameter of the penumbra; and this doubled will give the arc occupied by the whole penumbra, 69° 40′. Work in the same way, therefore, in other cases. As for how an arc of this kind is to be converted into miles, according to one's opinion of the size of the Earth, see Book 2, chapter 7.

[Margin: Kepler's rule is defective.]

Kepler's rule in the Rudolphine Tables, chapter 32, precept 159, comes to almost the same thing, as far as a portion of the disc beginning from the centre is concerned. But we have made it both easier and more universal, and have fortified it with a demonstrative diagram. For he does not teach how to find this arc except as reckoned from the centre of the disc, and he says that from its logistic logarithm the logarithm of the disc's semidiameter must be subtracted if this is less than 60, or[43] added if it is greater, so as to produce a logarithm which, sought among the logarithms of the semicircle or in the logarithms of the Heptacosias, will give the required arc in the column of arcs.

At the end of the following Problem I shall give in a small table the greatest and least arc of the Earth that the whole penumbra can occupy.

PROBLEMA VI.

Problem 6.

[42]no figure is printed at this place

[43]printed twice, vel at the line end and again at the head of the next line

Definire Durationem Eclipſis Terræ atque adeò Solis in Terra ſpectatam; Moramq eius, & Vmbræ ſi qua eſt, & Initium ac Finem Eclipſis huius.

To define the duration of the eclipse of the Earth, and so also of the Sun, as seen on the Earth; its stay, and that of the shadow if there is one; and the beginning and end of this eclipse.

VIII. In the following diagram let AB be the trace of the ecliptic on the Earth, and on it C the centre of the Earth's disc, which is AKF. Let the path of the lunar penumbra be BH, and the nearer node B. On this path let the centre of the penumbra first be at D, which is joined by the straight line CD, and let its limb touch the Earth at I. Next, if the whole penumbra is to occupy the Earth, let its centre be at G and the contact of the limbs at F, and let the centre G be joined to C by the straight line GC. Further, at the end of the shading, when the whole penumbra has now gone out, let its centre be at H and the contact of the limbs at L; and let H be joined to C by the straight line HC, for it will pass through the contact L, just as DC passes through I and CG through F, by Euclid III.12. Finally, from C let the arc CP be drawn, perpendicular to the path of the shadow, which at the moment of the middle of the eclipse of the Earth, that is, the moment next to the true new Moon, is known by Problem 4, number 6.

Diagram. Set into the right column across its full measure. A large circle has its centre at C. A heavy straight line runs from A on the left limb through C, out past the right limb, to B. A second straight line runs from B, slanting down to the left, through the small circle D and the small circle G and past P, to the centre H of a third small circle. Three small stippled circles stand on this line: D outside the right limb, touching the large circle from without at I; G inside the lower right limb, touching it from within at F; H outside the lower left limb, touching it from without at L. Straight lines run from C through I to D, from C through G to F, and from C through L to H, and a short line from C down to P. Each small circle carries radii from its centre.

- K (top, inside the large circle): K
- A (left limb, on the line): A
- C (centre of the large circle): C
- B (far right, the end of the line): B
- I (on the right limb, where the circle D touches): I
- D (centre of the right small circle): D
- G (centre of the small circle inside the limb): G
- F (lower right limb, below the circle G): F
- P (foot of the short line from C, on the slanting line): P
- L (lower left limb, above the circle H): L
- O (small sort, on the lower left limb, at the circle H): O
- H (centre of the lower left small circle): H

[Margin: Method 1, ours, of solving the problem.]

First, then, in the triangle CPD, right-angled at P, from the given CP, the arc between the centres, and the base CD, the sum of the semidiameters of the disc, CI, by Problem 1, and of the penumbra, ID, by Problem 3, find the arc PD, namely the minutes of the half-duration of the eclipse, to which PH, the minutes of the remaining half-duration, is equal.

[Margin: Minutes of the half-duration.]

Then in the triangle CPG, right-angled at P, from the given side CP, as above, and the base CG, which becomes known by subtracting the penumbra's semidiameter GF from the semidiameter CF of the Earth's disc, find PG, the minutes of the half-stay of the whole penumbra on the Earth; doubled, these will give the whole stay.

[Margin: Minutes of the half-stay of the whole.]

These minutes, converted into time according to the true hourly motion of the Moon from the Sun, will give the time of the whole stay and of the whole duration. The time of the half-duration subtracted from the middle of the eclipse, or from the ecliptic new Moon, will give the beginning, at which the Moon's penumbra starts to shade the face of the Earth; added, it will give the end, when the whole penumbra leaves the Earth.

[Margin: Minutes of the half-stay of the centre.]

But if you want the half-stay of the centre, resolve the triangle CPO, and let the base CO be the semidiameter of the disc, etc. Briefly: let it be, as the radius is to the second sine of the arc CP, so the secant of the base CD or CG to the secant of the minutes PD or PG. Or to the residual logarithm of the arc CP add the second logarithm of the base CD or CG, and the second logarithm of the arc PD or PG will result. But if the centre of the penumbra were to traverse the eclip- tic of the Earth, the sum of the semidiameters of the disc and penumbra would make up the minutes of the half-duration, while the difference of these semidiameters would give the minutes of half the stay. Further, if there is ever a sheer shadow of the Moon occupying the Earth, and someone wishes to know its duration and stay, and the beginning of the shading and the end, do everything as above, but using the semidiameter of the sheer shadow.

[Margin: Method 2, Kepler's.]

Second, Kepler proceeds differently in the Rudolphine Tables, chapter 32, precept 158. He says that the sum of the semidiameters of the disc and penumbra is to be found, and that from its antilogarithm the antilogarithm of the arc between the centres is to be subtracted, so that the antilogarithm of the minutes of the half-duration remains. But if from the antilogarithm of the disc's semidiameter the antilogarithm of the arc between the centres is taken away, he says, there remains the antilogarithm of the minutes of half the stay, for which the whole shadow stays on the face of the Earth; and these minutes are to be converted into time by the true hourly motion of the Moon from the Sun. But he confirms these things with no demonstration.

[Margin: Method 3, partly Renieri's, partly ours.]

Third, Renieri gives a special table for this in the second edition of the *Tabulae Mediceae*, p. 356, and its precept in Part 2, chapter 6, number 2. We could also use the usual table of incidence and half-stay, seeking on its side the minutes of the arc between the centres and at its head the minutes of the base CD, if that table were extended beyond 68 minutes. Let there now come forth from the foregoing Problems the greatest of the eclipses of the Earth, and the least of those in which the whole penumbra of the Moon falls on the face of the Earth, with the greatest and least duration and stay, according to the principles of our hypothesis.

Magnitudo Eclipſis Terræ. — Magnitude of an eclipse of the Earth.

Magnitude	☾ at apogee, ☉ at perig.	☾ at perigee, ☉ at apog.
Digits, of 24	13 3/5	12 2/3
Arc of a great circle of the Earth	71° 22′	57° 0′
Italian Bolognese miles	5136	1065
German miles	1065	900

Tempora Eclipſis Terræ. — Times of an eclipse of the Earth.

Time	Greatest, ☾ & ☉ at perigee	Least, ☾ & ☉ at apog.
Duration of the lunar penumbra on the Earth	$5^h\ 52^m$	$4^h\ 30^m$
Total stay of the penumbra on the Earth	$1^h\ 52^m$	$1^h\ 45^m$

PROBLEMA VII.

Problem 7.

Determinare locum in Terra, vbi eſt centrum Penumbræ Lunaris, atq. adeò vbi in Nonageſimo Eclipticæ gradu fit vera ſimul ac viſa Coniunctio, & Centralis Eclipſis Terræ Soliſq. & Horam qua ibi fiet.

To determine the place on the Earth where the centre of the lunar penumbra is, and so where the true and also apparent conjunction occurs at the nonagesimal degree of the ecliptic, and a central eclipse of the Earth and Sun; and the hour at which it will occur there.

IX. We shall teach how to determine this place on the Earth without a diagram, which can hardly be represented on a plane; the reader will be better helped by using and turning a terrestrial globe.

[Margin: Precept 1.]

First, find the altitude of the nonagesimal in the region where the Sun is centrally eclipsed in the nonagesimal itself, and so where the true and apparent synod coincide. So, according to Kepler in the Rudolphine Tables, precept 161, convert the arc between the centres of the disc and penumbra, or at least the

latitude of the Moon itself found at the moment of true new Moon, into an arc of the quadrant, following what was said at the end of Problem 5; for the complement of this arc to the quadrant is the altitude of the nonagesimal at the middle of the duration of the eclipse, which it was proposed to find. The nonagesimal will incline to the south if the ☾'s latitude is northern; to the north, if southern. Or, as Renieri teaches in Part 2 of the *Tabulae Mediceae*, chapter 5, number 2, look for the latitude belonging to the moment of true synod in the body of Kepler's parallactic table, placed in the *Optics*, p. 312, under the semidiameter of the Earth's apparent disc; for opposite the latitude, on the left side, you will find the altitude of the nonagesimal you want.

[Margin: Precept 2.]

Second, to the degree of the ecliptic in which the true synod takes place add 90°, and you will have the degree ascending in the region sought. For if you look for this degree on the side of the table showing the altitude of the nonagesimal, and go across from it until you find the altitude of the nonagesimal found by precept 1, it will show at the head of the table the altitude of the pole of the region in which the central eclipse occurs, etc. But if you do not find the altitude of the nonagesimal in it, the defect [Defectus] will be either central nowhere, or only in polar regions. In this case, subtract the sum of the semidiameters of the Sun and Moon from the true latitude of the Moon, which will then be greater, and with the remainder enter the parallactic canon, at whose head is the horizontal parallax of the luminaries representing the semidiameter of the terrestrial disc. Under this look for the remainder already mentioned, and opposite it you will have the altitude of the nonagesimal. With this, and with the ascending point of the ecliptic, as above, you will find the required elevation of the pole for a region outside the polar circles, in which the least eclipse of all will occur, and the Moon will only graze the Sun's margin. Therefore, if you subtract from the Moon's latitude something less than the sum of the semidiameters of the luminaries, and repeat the same operation as above with the remainder, you will find a region outside the polar circles at whose elevation some part of the Sun will be eclipsed. See Renieri above, chapter 5, number 3, and Kepler in the Rudolphine Tables, precept 162.

[Margin: Precept 3.]

Third, for the moment of true new Moon, find the right ascension of the degree of the ecliptic in which the luminaries are joined; and to that right ascension add the apparent hours at which the new Moon happens, converted into degrees of the equator, and you will make up the right ascension of mid-heaven for the meridian for which the astronomical tables are constructed. Next, under the altitude of the pole found by precept 2, find the oblique ascension of that ascending point spoken of at the beginning of precept 2, and from its oblique ascension subtract 90°; the result is the right ascension of mid-heaven of the region sought. Subtract this from the right ascension of mid-heaven of the tables, and there will emerge the difference between the meridian of the tables and the meridian of the region sought. Since, then, the longitude of

this region is known from this, and the altitude of the pole from what was said above, the place will also be known in which the central eclipse occurs, and with respect to which the true and also apparent synod of the luminaries occurs at the nonagesimal of the ecliptic. The difference of the meridians, converted into time, will give the time at which such an eclipse of the Earth and Sun will occur in that same place.

[Margin: Renieri's timely warning.]

But when the Moon's southern latitude is very great, or so great that, with the parallax of latitude toward the south added, the eclipse will occur only in a southern region, everything is to be done as above; but one must use not the place where the true and apparent conjunction occur together, but the opposite place, as Renieri rightly warns above, number 8, and Boulliau, Book 4, chapter 5, and the Rudolphine Tables, precepts 161, 162, 166, 167.

PROBLEMA VIII.

Problem 8.

Determinare an in loco Tabularum poſſibilis ſit Eclipſis Terræ, quæ alibi futura eſt centralis.

To determine whether an eclipse of the Earth that will be central elsewhere is possible at the place of the tables.

X. Look, by Problem 11, to be shown a little later, for the tract of regions within which the eclipse is completed. For if the place of the tables is within that tract, the eclipse can be seen there; if not, it cannot be seen. The place of the tables (which I want understood in other problems too) is the place for whose meridian the roots of the motions of the Sun and Moon are constructed, which anyone may choose to use.

PROBLEMA IX.

Problem 9.

Determinare locum, vbi Oriente Sole Penumbra Lunæ Diſcum Terræ incipit tangere, atque adeò Luna ſtringere limbum occiduum orientis Solis; qui proinde locus viſurus eſt Defectum ab initio ad finem. Et locum cui Occidente Sole, Penumbra Lunæ Terram deſerit; atq. adeò Luna ortiuum Solis marginem deſerit, finiturq. cum fine diei Labor, qui proinde locus vidit iam deliquium ab initio ad finem.

To determine the place where, at sunrise, the Moon's penumbra begins to touch the Earth's disc, and so where the Moon begins to graze the western limb of the rising

Sun; this place will therefore see the defect from beginning to end. And to determine the place for which, at sunset, the Moon's penumbra leaves the Earth, and so the Moon leaves the Sun's eastern margin, and the labour ends with the end of the day; this place has therefore already seen the eclipse from beginning to end.

[Margin: Precept 1.]

XI. First, take the minutes of the half-duration found by Problem 6, not yet converted into time, and subtract them from the true argument of the Moon's latitude; there will remain the true argument for the moment at which the eclipse first begins on the Earth. Or add them, and you will have the argument for the moment at which the eclipse ends. With the argument, moreover, work out the Moon's true latitude, and divide it by the sum of the three apparent semidiameters of the Sun, the Moon and the Earth's disc. For the remainder [Reſiduum], in the small column of the parallactic table spoken of above, the column standing under 60′, will show opposite it, on the left side, the altitude of the nonagesimal of the region for which the rising Sun begins to be eclipsed by the Moon, or, in the second case, for which the setting Sun ceases from the eclipse.

[Margin: Precept 2.]

Second, with the minutes of the half-duration found by Problem 6, but now converted into time, look up the Sun's mean motion, and subtract it from the Sun's place at true new Moon for the first phase; add it for the last. Next, look for the remainder or the sum on the side of the table showing the altitude of the nonagesimal, running across its cells to the right or left. For the cell in which you find the altitude of the nonagesimal found by precept 1 will show at the head of the table the altitude of the pole sought. If you do not find it, know that the region you seek is southern and that the Antarctic Pole is elevated in it, and that therefore the operation already mentioned is to be carried out with the place of the ecliptic opposite the one in which the true new Moon occurs.

[Margin: Precept 3.]

Third, with the altitude of the pole found for the first phase of the eclipse, under that altitude, and with the Sun's place at its moment, found as above by subtracting the ☉'s mean motion, look up the oblique ascension. Subtract 90° from it, so as to make the right ascension of mid-heaven for the meridian of that region. Next, from the time of true new Moon subtract the time produced from the half-duration of Problem 6, added to the moment of true new Moon, and turn the remainder into degrees of the equator. Add these to the right ascension of that degree of the Sun whose oblique ascension you have just found, and you will have the right ascension of the meridian of the tables at the moment of the first phase. By subtracting from this the right ascension of the former meridian, you will find the difference of longitude between the place of the tables and the place of the region sought, whose altitude of the pole you have already found. So the place of the first phase will be known.

[Margin: Precept 4.]

Fourth, for the last phase, with the Sun's place opposite to the one you found by precept 2 in order to obtain the altitude of the pole, and with the altitude of the pole found there for this phase, look up the oblique ascension and subtract 90° from it, so that the right ascension of mid-heaven remains for the meridian of the place sought. Next, add the time of the half-duration of Problem 6 to the apparent time of true new Moon, and add the sum, converted into degrees of the equator, to the right ascension of the Sun's place found for the moment of the last phase; for this will make the right ascension of mid-heaven for the meridian of the tables. By subtracting from this the right ascension of mid-heaven of the former meridian, the difference of longitude will be known, and consequently the longitude of the place sought, whose altitude of the pole is already known.

[Margin: Renieri's salutary warning.]

But if, in either of the phases, the altitude of the pole found is that not of the Arctic but of the Antarctic Pole, then add 180° to the right ascension of mid-heaven of the tables, and from the total subtract the right ascension of the former meridian, so that the difference of the meridians becomes known.

See, if you like, for this Problem the Rudolphine Tables, precepts 164, 166, 167, and Renieri above, chapter 6, numbers 3, 4 and 5, with examples there and in Boulliau, Book 4, chapter 5.

PROBLEMA X.

Problem 10.

Determinare locum Terræ, cui Sol Oriens aut Occidens centraliter deficit; ſiue Eclipſis ſit totalis, ſiue annularis.

To determine the place on the Earth for which the rising or setting Sun is centrally eclipsed, whether the eclipse is total or annular.

[Margin: Precept 1.]

XII. First, look up the minutes of the half-stay of the centre of the lunar penumbra and convert them into time, as stated in Problem 6, precept 1. Subtract this from the moment of true new Moon, and you will have the time of this first phase, that is, the time at which the central eclipse first appears on the Earth, in a place not yet known. Add that time again, and you will have the time of the second phase, at which the central eclipse will end.

[Margin: Precept 2.]

Second, take the minutes of the half-stay already mentioned, but not converted into time, and take them away from the true argument of latitude found for the time of true ☌, for the first central phase; add them for the second. With that argument look up the Moon's true latitude, and search for this latitude in the small columns of the parallactic table, under the minutes placed at the head that represent the semidiameter of the disc, so that on the left side you obtain the altitude of the nonagesimal for each phase.

[Margin: Precept 3.]

Third, take the Sun's mean motion corresponding to the interval of time between the true new Moon and the phases already mentioned. Subtract it for the first phase, and add it for the second, to the Sun's place found at true new Moon. With the remaining place or the total, looked up on the side of the table of the altitude of the nonagesimal, look in its cells for the altitude of the nonagesimal dealt with in precept 2, and at the head you will have the desired altitude of the pole.

[Margin: Precept 4.]

Fourth, with the altitude of the pole found, look up the oblique ascension of the Sun's place belonging to the first or second phase, and do all the rest as in precepts 3 and 4 of Problem 9, to obtain the difference of longitude from the meridian of the tables. When this is known, together with the altitude of the pole, the place on the Earth will be known in which the rising Sun first, or the setting Sun last, is centrally eclipsed. On these see Renieri above, chapter 6, numbers 6, 7, 8, 9; Kepler in the Rudolphine Tables, precepts 163, 166, 167; and Boulliau, Book 4, chapter 5.

PROBLEMA XI.

Problem 11.

Determinare Regiones in Terra, quibus toto tempore Durationis Eclipſis Penumbra Lunæ ſuperfertur.

To determine the regions on the Earth over which the Moon's penumbra is carried during the whole time of the eclipse's duration.

[Margin: Precept 1.]

XIII. First, having found by Problem 9 the places in which, at sunrise, the Moon's penumbra begins, or at sunset ceases, to touch the Earth: if you conceive an arc of a circle through them, passing through the place in which the central eclipse occurs at the nonagesimal, on which see Problem 7, you will have the tract of the Earth within which, during the whole time of the duration, the Moon's penumbra darkens the Earth with some part of itself.

[Margin: Precept 2.]

Second, having found by Problem 10 the places in which the rising Sun begins, or the setting Sun ceases, to be centrally eclipsed, that is, in which the centre of the lunar penumbra begins or ceases to be on the Earth: if an arc through these passes through the place of the central eclipse occurring at the nonagesimal, on which see Problem 7, you will have the tract of the Earth within which the phases of a total or central eclipse are observed. See Renieri above, chapter 6, number 11.

So far I have chosen to point out how many Problems concerning the eclipse, not only of the Earth but also of the Sun, we can settle without the circuitous

routes of parallaxes. The rest, with their examples, will be made clear in Part 2 of this volume.

[Margin: On the two phases omitted.]

But if anyone wishes to know two other phases, namely the place for which the rising Sun ceases to be eclipsed on its lower or eastern part, or the setting Sun begins to be eclipsed on its western and lower part, let him consult Kepler in the Rudolphine Tables, precepts 165, 166, 167.

CAPVT XIII.

Chapter 13.

De Formando Typo Eclipſis Terræ ac Solis & de Inclination-ibus Phaſium.

On forming the delineation of an eclipse of the Earth and Sun, and on the inclinations of the phases.

I. What I said in chapter 7 about the delineation of eclipses of the Moon will indeed help in understanding the present chapter, but it is not sufficient. So one should indeed consult Ptolemy, Book 6, chapter 13; al-Battānī, chapter 44; Peuerbach, toward the end of his precepts on eclipses; Regiomontanus, Problem 50 of the *Primum Mobile*, and in the *Epitome of the Almagest*, Book 6, propositions 28, 29 and 30; Reinhold in the Prutenic Tables, precept 65; Tycho, volume 1 of the *Progymnasmata*, p. 136; Kepler in the *Ephemerides*, pp. 41 and 44; Magini, Canon 90 of the *Secunda Mobilia*; Lansbergen, precept 37; and Renieri, Part 2, chapter 3, number 14. But they are to be corrected from Kepler's warnings in the *Astronomia Optica*, chapter 11, Problems 30, 31, 32, and in the *Epitome of Copernican Astronomy*, p. 890. Leaving aside the delineations that commonly circulate without art, the ones made with art are to be set out.

Diagram. In the left column, between the first and second sections, headed `Meridies.` (South) above and `Septentrio.` (North) below. A large circle has a vertical diameter from B at the top to D at the bottom, and a horizontal diameter from C on the left to A on the right, crossing at the centre E. A smaller concentric circle stands within it, and a further circle of the same size as two others is centred about H, above E. Two more circles of that size are centred on the circumference of the large circle: one upper right at Q, one on the left at G, the latter passing outside the large circle. A chord runs from G through H to Q, and P stands on the vertical above H. Lines run from Q through E to R at the lower left, and from G through E to S at the lower right. M stands on the vertical just below H, and K on the line from Q to E.

- Top, outside the figure: `Meridies.` (South)
- Bottom, outside the figure: `Septentrio.` (North)
- Top of the vertical: B
- Bottom of the vertical: D
- Left of the horizontal: C

- Right of the horizontal: A
- Centre: E
- On the vertical above the centre, downward: P, H, M
- Upper right: Q, with K on the line below it
- Left: G
- Lower right: S
- Lower left: R

II. The old way of forming this delineation is as follows. Given the apparent semidiameters of the luminaries, let their sum be AE. At that interval, from the centre E, let the circle ABCD be described, whose diameter AC is to represent the ecliptic, and BD the arc of latitude. And from E let the Sun's disc be described at the interval of the Sun's semidiameter EK. Next, let the apparent latitude of the Moon be given for the beginning of the eclipse; let EP be taken equal to it, and from P let a perpendicular to BD be drawn out as far as the circumference of the circle BD, to the point Q, where the centre of the ☾ is at the beginning of the eclipse. From this point, at the interval of the lunar semidiameter KQ, let the Moon's disc be described. Again, for the end of the eclipse let the apparent latitude of the Moon be given, and let EM be made equal to it. Then MG, drawn perpendicular to BD, will mark at G the place of the lunar centre at the end of the eclipse, from which a disc of the Moon equal to the former is to be described. With this done, let the Moon's centres G and Q be joined by the straight line GHQ, for this will be the Moon's apparent path. Where this path cuts at H the arc of latitude, or the arc through the centres of the luminaries at the middle of the eclipse, there, with that point as centre, let a disc of the Moon be described equal to the former ones. Finally, the straight lines QER and GES, drawn from the centres Q and G through the Sun's centre E, will mark at R and S the quarters of the horizon, but those opposite to the ones toward which the darkness tends: for at the beginning of a solar eclipse the darkness bends toward the western hemisphere, and at the end toward the eastern. These quarters and the bending of the darkness are themselves investigated in the way I indicated in chapter 7, Problems 1 and 2, where I also set out the small Ptolemaic table; but using the apparent latitude, and applying to the Sun what was said there about the Earth's shadow.

[Margin: Faults of the method already mentioned.]

III. But in fact the method already mentioned for forming the delineation of solar eclipses rests on a constant angle of 5°, at which the Moon's apparent path is supposed to be inclined to the ecliptic during the whole time of the eclipse. Indeed, in investigating the angle formed by the ecliptic and the sum of the semidiameters, or the semidiameter of the shadow there and of the Sun here, Ptolemy, Book 6, chapter 11, supposes straight lines in place of curved ones. He also supposes the Moon's latitude at the moment of true ☍ or apparent ☌ in place of the arc passing between the centres of the darkening and darkened bodies at the moment of the middle and greatest eclipse; and finally he supposes the Moon's path parallel to the ecliptic, because of the smallness and nearness

of the arc, and lying in the same plane; although he did sometimes correct the quantity of the arc between the centres from the ecliptic digits.

[Margin: Regiomontanus's warning.]

But as Regiomontanus warns, Book 6 of the *Epitome*, proposition 28, it would have been better to use spherical triangles, and the latitude of the Moon belonging to the beginning of the eclipse or of the stay.

[Margin: Kepler's notable warning.]

In an eclipse of the Sun, however, Kepler's warning and observation, in both the passages cited from the *Optica* and the *Epitome*, is of greater weight. For the form already mentioned can be tolerated when the Moon's visible path is parallel to the ecliptic, and in the greatest eclipses, as I said in Scholium 1 of chapter 11, where I also gave, from Kepler, a way of determining more accurately the minutes of incidence and repletion in large eclipses of the Sun. But when the eclipses are small, and the lunar visible path deviates noticeably from parallelism to the ecliptic, because of the great variation of the parallaxes in latitude, the Moon's visible path turns out winding and does not lie in one plane, and its angle with the ecliptic takes on an inclination greater than 5°, so that it sometimes reaches 19° or 20°, as I said in Scholium 2 of chapter 11. In this case, then, a delineation of the eclipse built to the old standard is not true. Moreover, the approach of the centres of the Moon and Sun is to be considered in a circle inclined from the centre of the Sun to the visible node; and in this matter, because of the difference of the parallaxes, the variation is so great that, even on Kepler's testimony, it cannot be comprehended by small rules. Lastly, the Moon's visible path is sometimes inclined contrary to the true path, as I said in the same Scholium. Read it again here, and repeat from it the following diagram for some delineation of an eclipse of the ☉, in which DC, the visible path of the ☾, is shown inclined contrary to the true path NR.

Diagram. In the right column, inset at the right with the text of the fourth section running down its left side. Three discs of equal size lie along an oblique line from upper left to lower right. The middle disc is the Sun, with centre S and a dark central disc marked B, rimmed by a stippled band. The upper and lower discs are the Moon, each drawn with a face, overlapping the Sun at upper left and lower right. A straight line runs obliquely along the lower left of the three discs, and another along their upper right. A line through S, the vertical, runs from V at the left to R at the right.

- Upper left, outside the upper disc: Q and N
- Inside the upper disc: D at the centre, F at its lower edge
- Right of the Sun's disc: R
- Left of the Sun's disc: V
- Below the Sun's disc, on the lower straight line: G; in the rayed band just above it: I
- Sun's centre: S, with B above it
- Inside the lower disc: C at the centre, H at its lower edge
- Right of the lower disc: M

• Below the lower disc: A and E

[Margin: On the quarters of eclipses of the Sun, from Kepler.]

IV. As regards the quarter of the world on which the defect stands at the Sun's margin, it is found as follows, from Kepler in the *Epitome of Copernican Astronomy*, p. 891, and the Rudolphine Tables, precept 177. Let the ecliptic be ESQ, the Moon's true path NR but its apparent path DC, and the Sun's centre at S. Let the Moon's centre be at B at the middle of the eclipse, at C at the beginning and at D at the end, and let the arc through the centres be BS. Let the vertical VR be drawn through the centre of the Sun, and the arcs through the centres of the luminaries: at the beginning the arc SC, at the middle the arc SB, at the end the arc SD. First, then, the angle RSE is to be investigated, which the vertical already mentioned makes with the ecliptic, and next the angles CSE, BSE and DSQ. The angle RSE becomes known if from the mesologarithm of the distance of the nonagesimal from the zenith you subtract the logarithm of the Sun's distance from the nonagesimal; for there will remain the mesologarithm of the angle sought. The other angles become known if you subtract the logistic logarithm of the distance of the centres, SC or SB or SD, from the logistic logarithm of the apparent latitude at these three moments, which is CH, BS or DF; for there remains the logarithm of the angle CSE or BSE or DSF. Thus, with CSE subtracted from the angle RSE, the angle RSC becomes known, from which the azimuth for the beginning of the eclipse can be gathered. Again, with RSE subtracted from the angle BSE, there remains the angle BSR, for the azimuth at the middle of the eclipse. And with the angles DSQ and RSE subtracted from two right angles, that is, from 180°, there remains the angle DSR, for the azimuth at the end of the eclipse. Or, from precept 177 of the Rudolphine Tables, use three points of the ecliptic that are supposed known from the calculation of eclipses: namely, the point in which the centre of the Sun is, the culminating point, and the nonagesimal degree. These, connected with the vertical point by means of arcs, make up two triangles, in which the angle at the nonagesimal is a common right angle. With their help the angle at the zenith is investigated, which measures the arc of the horizon that the Arabs call the azimuth. From the apparent time given for the moment of the eclipse, moreover, and from the Sun's place, the nonagesimal is supposed known, and its distance from the zenith, from the culminating point and from the Sun. The rest, concerning the quarters of the horizon toward which the darkened part of the Sun tends, you will complete more readily (says Kepler) by imagination or by inspecting a sphere.

SCHOLIA.

Scholia.

[Margin: Paradox 1, on the quarters in an eclipse of the Moon.]

I. Although an eclipse of the Moon ordinarily begins on the eastern part of the Moon and ends on the western, yet it sometimes happens that it begins on

the western and ends on the eastern. Pliny the Elder indicated this, Book 2, chapter 13, in these words:

[Margin: An obscure passage of Pliny the Elder explained.]

"And what is most wonderful in this marvel: although it is agreed that the Moon is dimmed by the shadow of the Earth, this happens to it now on the side of the setting, now on that of the rising." Kepler, in the *Astronomia Optica*, chapter 11, Problem 31, shows that this can happen when at true full Moon the Moon's true latitude is equal to the sum of the semidiameters of the Moon and the shadow, and the Moon's latitude is either southern decreasing or northern increasing. For then the arc between the centres turns out shorter than the latitude, and some eclipse of the Moon occurs, though hardly a hundredth part of the diameter is darkened. If the latitude is southern decreasing, the mark of the eclipse tends toward the west; if northern increasing, it will tend toward the east. He adds that such an eclipse was seen in the year 1603 November 18, at $6^h\ 21^m$, and that a similar one was seen by Tycho in the year 1594 October 19, in the morning, at $5^h\ 56^m$.

[Margin: Paradox 2, on the quarters in an eclipse of the Sun.]

II. An eclipse of the Sun, too, ordinarily begins on the western part of the Sun and ends on the eastern; but, as Kepler shows in the *Astronomia Optica*, chapter 11, Problem 31, and in the *Epitome of Copernican Astronomy*, p. 895, it sometimes begins on the eastern and ends on the western; and indeed more evidently because of the parallaxes in latitude, which sometimes produce an inclination of the Moon's visible path of nearly 20°. For then, if at the moment of visible synod the visible latitude equals the sum of the semidiameters of the ☾ and ☉, the arc between the centres, or the distance of the centres, being smaller than the apparent latitude, will be able to produce an eclipse of one digit and more. For an eclipse of the Sun in such a case to be able to begin from the east, however, the Moon's true latitude must be either northern decreasing, with the eclipse occurring at the rising, or southern decreasing, with the eclipse at the setting. But if it must end from the west, the latitude required is either northern increasing, with the eclipse at the setting, or southern increasing, with the eclipse at the rising. But the parallax of latitude contributes chiefly to this. Now, the angles of the ecliptic and horizon begin to increase with ♈ rising, as far as ♎, and they increase most with ♋ rising, and the parallaxes of latitude decrease most. Therefore the Moon above the horizon is carried visibly toward the north more than it is by true motion toward the south, especially if by true motion it is ascending. So then a small southern eclipse of the Sun placed toward the west will be able to begin from the east, and a small northern eclipse to end from the west. Conversely, with ♑ rising, from ♎ to ♈, the angle of the horizon and ecliptic diminishes and the parallax of latitude increases, and the Moon is carried by visible motion toward the south. Therefore a small northern eclipse of the Sun placed in the eastern quadrant will be able to begin from the east, and a small southern one to end from the west. What Kepler has in the *Epitome* comes to almost the same thing: namely, near the eastern

horizon, in signs of right ascension, with the Moon slipping down to the node ☋, the Sun is seen to undergo eclipse either at its vertex or toward the left, and soon to be refilled from the same quarter; or near the western horizon, in signs of right descension, with the Moon fleeing from the node ☊ toward the north, the Sun is seen to undergo eclipse at its lowest margin, or a little above the left, and the eclipse is seen to end from the same quarter, higher up. Because also, with the Sun placed near the nonagesimal, with ♊ or ♋ rising and the parallax of latitude therefore very rapidly diminished, but with ♐ or ♑ rising and the parallax of latitude very rapidly increased, if the Moon in the former case ascends toward the north near ☊, and in the latter descends toward the south near ☋, the true and apparent variation accumulate, and the angle of the visible path becomes very great, and an eclipse of quite noticeable size can begin and end from the same quarter.

[Margin: Kepler's diligence.]

All of this we owe to Kepler's diligence and subtlety.

[Margin: Examples of such eclipses.]

III. To confirm this doctrine, Kepler relates that similar eclipses, varying from the usual quarters, occurred in the year 1588 February 16, the hour of the beginning at Uraniborg being $1^h\ 32^m$ after noon; and in 1595 October 3, a little after noon at Tübingen, with Mästlin observing and asserting in thesis 53 that the edge of the Sun that failed at the beginning inclined not to the west but to the east, by 9°, and that 2½ digits were eclipsed; and that the diagrams of the same eclipse observed at Strasbourg, found in Tycho, display the eclipse at the left. And he relates that in the year 1598 a great eclipse of the ☉ in ♓ near ☊ began at Graz in Styria from the right, precisely as if in the nonagesimal, and ended from the left, but near the vertex of the Sun. Thus in the year 1599 July 22, in the morning, the rising Sun was seen by Tycho to fail at its vertex, from which he deduces that in some southern climate the defect stood on the west from beginning to end. Again, in the year 1593 May 20, at Zerbst [Serueſtæ], the Sun failed to 2 digits, at the left, toward the beginning and the end. Lastly, in the year 1614, an eclipse of the ☉ in ♎ near ☋ began at Munich about noon from the right, and ended on the lower part of the Sun.

CAPVT XIV.

Chapter 14.

De Interuallis, Numero, ac Reuolutione Eclipſium Lunæ Solis ac Terræ.

On the intervals, number and revolution of eclipses of the Moon, Sun and Earth.

I. We have now come to the contemplation, as pleasant as it is noble, of divine Providence in dispensing eclipses. For it was fitting that there should be neither no eclipses, lest we be deprived of those opportunities we listed in chapters 1 and 2, nor too frequent ones, lest either so frequent a withdrawal

of the life-giving lights should do too much harm to the natures of sublunary things, or some, stupefied by excessive terror, and others, on the contrary, with their wonder growing stale, should turn out too contemptuous of heaven and of celestial spectacles. I have decided, then, to propose in separate theorems first the intervals of eclipses, then their number, and finally their restitution, that is, their revolution to the same day of the year or part of the zodiac, after first giving a single diagram and two small tables, which greatly help in discerning these things more easily.

Diagram. In the right column, inset at the right with the text running down its left side. Two circles of nearly equal size cross at A on the left and B on the right, the ecliptic ARBP and the Moon's orbit AMBS. R stands on the top of one circle and M just inside it below; S stands on the bottom of the other and P just inside it above. Short strokes cross the band between the circles on either side of A and of B, marking the limits.

- Top, outside: R
- Top, inside: M
- Bottom, inside: P
- Bottom, outside: S
- Right, at the crossing: B, followed by the sign ☊
- Left, at the crossing: A, preceded by the sign ☋
- Upper right, on the band, from the top: L, F
- Lower right, outside the band, from the top: C, G
- Upper left, on the band, from the top: K, E
- Lower left, outside the band, from the top: D, H

Let the ecliptic, then, be ARBP, and the circle of the Moon's orbit AMBS, whose southern semicircle is AMB and northern BSA, the southern node A and the northern B. Let the limits of a possible eclipse near B be F and C for lunar eclipses, but L and G for solar; and near the node A let them be D and E for lunar, H and K for solar. And let us take from chapter 7, number 1, the greatest arc BF and those like it as 15° 38′ in mean ☍, but 13° in true ☍, and the least as 10°. From chapter 11, numbers 3 and 5, and chapter 12, number 6, let us take the arc BL and those like it, the greatest as 20° 41′ in mean ☌, but 19° in true, and the least as 5° 25′, looking to the authors who hold the extreme opinions; for what holds of these will hold much more of the intermediate ones. Let us also take the likewise extreme opinion on lunar months from Book 4, chapter 19, and the motion of latitude from Book 4, chapter 23, taking into account, however, the equation, which at its greatest can befall this motion after one month or more. And so let the first table be the table of the arcs comparable in the foregoing figure, so that, looking at the motion in latitude of the ☾ in the second table, you may distinguish the intervals of months suited to eclipses from those not suited, according as the motion in latitude puts the Moon within or beyond the limits of eclipse.

I. TABVLA. Arcus Comparabiles cum motu Latitudinis ☾ pro Eclipſibus.

Table 1. Arcs comparable with the motion in latitude of the ☾, for eclipses.

Arcs	Greatest in ☍: in mean	Greatest in ☍: in true	Least: in true
For an eclipse of the ☾			
BF. BC. AD. AE	15° 38′	13° 0′	10° 0′
FC. DE	31° 16′	26° 0′	20° 0′
BSD. AMF	170° 0′	170° 0′	164° 22′
BSE. AMC	195° 38′	193° 0′	190° 0′
DMC. FSE	211° 16′	206° 0′	200° 0′
CSD. EMF	160° 0′	160° 0′	149° 36′
FSD. CSE. DMF. EMC	185° 38′	183° 0′	174° 22′
For an eclipse of the ☉

[Margin: Table of some lunar months and of the motion in latitude in them.]
II. TABVLA.
Table 2.

Number of lunar months	[Kind]	Time	Motion in latitude
1	Mean	$29^{d}\ 12^{h}\ 44^{m}$	30° 40′
1	Greatest	$30^{d}\ 3^{h}\ 14^{m}$	32° nearly
1	Least	$28^{d}\ 22^{h}\ 14^{m}$	28° nearly
5	Mean	$147^{d}\ 15^{h}\ 40^{m}$	153° 21′
5	Greatest	$150^{d}\ 16^{h}\ 10^{m}$	159° 5′
5	Least	$144^{d}\ 15^{h}\ 10^{m}$	147° 37′
6	Mean	$177^{d}\ 4^{h}\ 24^{m}$	184° 1′
6	Greatest	$180^{d}\ 19^{h}\ 24^{m}$	189° 51′
6	Least	$173^{d}\ 13^{h}\ 24^{m}$	178° 21′
7	Mean	$206^{d}\ 17^{h}\ 8^{m}$	214° 42′
7	Least	$202^{d}\ 12^{h}\ 38^{m}$	208° 47′
7	Greatest	$210^{d}\ 22^{h}\ 38^{m}$	220° 37′

THEOREMA I.

Theorem 1.

Non poſſunt eſſe ſingulis menſibus Eclipſes Solis aut Lunæ.

There cannot be eclipses of the Sun or Moon in every month.

II. For Pliny the Elder is right, Book 2, chapter 13: "But the eclipses of both are neither fixed nor monthly, because of the obliquity of the Zodiac and the

Moon's many-wandering windings, as has been said, the motion of the stars not always agreeing in the minutes of the degrees." That is, as Milichius [Jacob Milich] explains there, because of the obliquity of the ecliptic to the Moon's orbit, and of the orbit to the ecliptic, and because of the Moon's latitude, which prevents diametrical oppositions of the luminaries, or conjunctions, from always or for the most part occurring within the degrees and minutes required for eclipses. For let the earlier eclipse of the ☾ have occurred within arc FC, or of the ☉ within LG, and double, triple or quadruple the motion in latitude given in Table 2. You will always find the Moon, when the second, third and fourth lunar month is complete, beyond C and G but short of D and H, toward S; that is, in arc CSD, in which no eclipse of the ☾ occurs, or in GSH, in which none of the ☉ occurs. And the same happens if an eclipse of the ☾ occurs within DE, and of the ☉ within HK: for whether after the 2nd, after the 3rd or after the 4th month, the Moon will be within arc EMF, in which none of the ☾ occurs, or within KML, in which no eclipse of the ☉ occurs.

THEOREMA II.

Theorem 2.

Poſſunt Sol & Luna in Sex Menſibus Lunaribus bis Eclipſim pati.

The Sun and Moon can undergo eclipse twice within six lunar months.

III. So say Ptolemy, Book 6, chapter 6; Regiomontanus, Book 6 of the *Epitome*, proposition 9; Milich on Book 2 of Pliny the Elder, chapter 13; Magini, Book 2 of the *Theoricae*, chapter 26; and Mulerius [Nicolaus Mulerius] in the *Tabulae Frisicae*, p. 78. It is plain to anyone who compares the arcs of the first table with the motion in latitude of the second table, that is, with the motion that belongs to the months, whether mean, greatest or least, as the need may be. Ptolemy and Regiomontanus, however, use mean months, whose motion in latitude is 184° 1′. Therefore, if the earlier eclipse occurs within FBC for the ☾, or within LBG for the Sun, the Moon can certainly be, after six months, within DAE, the limits of an eclipse of the ☾, or HAK, the limits of an eclipse of the ☉. We have very many examples of eclipses in every sixth month below, in chapter 21. If, however, the earlier eclipse occurs very close to F, the Moon can be, after 6 lesser months, short of D, within arc DSC; or if it occurs very close to C, it can be beyond E after 6 greater months, and in this way a second eclipse does not occur.

Diagram. Set into the right column, with the text of the third section running in a short measure to its left. Two circles of equal size cross at two points, B on the right and A on the left. Near the top the upper arc of one lies outside the other, with R on the outer arc and M on the inner; near the foot the order is reversed, with P on the inner arc and S on the outer. Short cross-strokes mark off the limits on either side of each crossing.

- Top, outer arc: R
- Top, inner arc: M
- Upper right, nearer the rim: L; just below it: F
- Right crossing: B, with the sign ☊ outside it
- Lower right, on the outside: C; below it: G
- Bottom, outer arc: S
- Bottom, inner arc: P
- Lower left, on the outside: D; below it: H
- Left crossing: A, with the sign ☋ outside it
- Upper left, inside the rim: K; just below it: E

Labels read: R, M, L, F, B, C, G, S, P, D, H, A, K, E, ☊, ☋. Labels not read: none.

[Margin: The error of Martianus Capella.]

From this you may refute the error of Martianus Capella in Book 8 of *De Nuptiis Philologiae*, in the chapter on the eclipse of the Moon, where he says: "An eclipse cannot recur within the sixth month."

THEOREMA III.

Theorem 3.

Poſſunt Sol & Luna in quinque Menſibus bis Eclipſim pati, ſed rarò & paruam, nec niſi verſus eumdem Polum.

The Sun and Moon can undergo eclipse twice within five months, but rarely, and a small one, and only toward the same pole.

[Margin: The sagacity of Hipparchus.]

IV. So say Ptolemy, Book 6, chapter 26; Regiomontanus, Book 6 of the *Epitome*, propositions 10 and 12; Magini and Mulerius in the places above; and in part Pliny the Elder, Book 2, chapter 13, with Milich on that place. For [Pliny the Elder] says: "Within two hundred years it was discovered by the sagacity of Hipparchus that an eclipse of the Moon also sometimes occurs in the fifth month after the previous one, but one of the Sun in the seventh." For the motion in latitude of five greatest months is 159° 5′, while the least arc CSD, or EMF, is 149° 36′. Therefore, if the earlier eclipse occurs not far from C, between B and C, the Moon can be, in the fifth month, beyond D, within DA, and a second eclipse can occur, although nearer to D itself than to A; and so neither eclipse is large. And because in five months the Moon cannot pass from C, through S, beyond A, nor from E, through M, beyond B, both eclipses are therefore toward the same pole. It is easier, however, as far as the arcs themselves are concerned, for two eclipses of the Sun to occur after five greater months, because arc GSH, which the motion in latitude has to surmount, is smaller than arc CSD, just as KML is smaller than arc EMF. Regiomontanus adds that if the earlier eclipse of the ☉ was near sunset, the other will fall 6^h before sunset; or if the earlier was at 3^h after noon, the other

will fall at 3^h before noon; and if the earlier was in 15° ♎, the other will be in 15° ♓, or thereabouts. Now we have more frequent examples of solar eclipses of the fifth month than of lunar ones. For, as will be clear from chapter 21, from the year 1490 to 1700 we have only two pairs of lunar ones: namely between 1658 June 14 and November 9, and again between 1668 November 18 and 1669 April 15. Of solar ones, however, there are more, as you see in the following list.

If, then, an eclipse of the Moon recurs twice within one century in the fifth month, there is no need to wait two hundred years, as Pliny the Elder thought, with Hipparchus.

Solis Eclipſes interuallo Menſium Quinque.

Eclipses of the Sun at an interval of five months.

Years of Christ	Month	Day	Years	Month	Day
1601	December	24	1624	April	17
1602	May	21	1624	September	26
1602	June	11	1627	August	11
1602	November	13	1628	January	6
1605	October	12	1639	January	4
1606	March	8	1639	June	1
1609	July	30	1652	October	2
1609	December	26	1653	February	27
1613	May	19	1660	November	2
1613	October	13	1661	March	29
1616	September	10	1676	June	25
1617	February	5	1677	May	31
1620	January	4	1690	September	3
1620	May	31	1691	February	27

THEOREMA IV.

Theorem 4.

Non poteſt in menſibus 7. licet minoribus fieri bis Eclipſis Lunæ poteſt autem Solis, ſed verſus eumdem Polum.

An eclipse of the Moon cannot occur twice within 7 months, even lesser ones; but one of the Sun can, though toward the same pole.

V. So say Ptolemy, Book 6, chapter 6; Regiomontanus, Book 6 of the *Epitome*, propositions 11 and 13; and in part Pliny the Elder, whose words I reported in Theorem 3. For let the Sun be slow and moving in the upper semicircle of the eccentric, but the Moon fast and in the lower part of the epicycle, and so let the 7 months be lesser, and the least motion in latitude 208° 47′; and let the arc FSE, or DMC, in mean ☍ be at its greatest 211° 16′. Yet in true ☍, which are what is under discussion when the subject is months that are not mean but lesser, it is only 203° according to Ptolemy, though according to

others 206° at most. And so the Moon, having undergone eclipse at the limit F, is found after seven lesser months beyond E, by way of S. Conversely, however, if an eclipse of the Sun occurs at L, then, because arc LSK in true ☌ is nearly 218° and greater than the 208° 47′ of latitude, there can occur within seven lesser months one eclipse around L and the other around K, or one around H and the other around G, and so both toward the same pole. Yet this rarely happens, and once or twice within one and the same century. Such was the interval between the eclipse of the Sun of 1623 October 23 and that of 1624 May 18.

THEOREMA V.

Theorem 5.

Non poteſt Solis Eclipſis in vno menſe bis fieri verſus eumdem Polum; poteſt verſus alterum; non tamen vtraq. valde magna.

An eclipse of the Sun cannot occur twice within one month toward the same pole; it can toward the other pole, yet not both of them very large.

[Margin: Corrupt manuscripts have eamdem.]

VI. So say, as to the first two parts, Ptolemy, Book 6, chapter 6; Regiomontanus, Book 6 of the *Epitome*, proposition 14; and before them Hipparchus in Pliny the Elder, Book 2, chapter 13, where, with Milich, one must read thus: "Within two hundred years it was discovered by the sagacity of Hipparchus that an eclipse of the Moon also sometimes occurs in the fifth month after the previous one, but one of the Sun in the seventh; that the same Sun is hidden twice within thirty days above the lands, but that this is seen by different peoples." For if it can occur within one month, this is surely when the earlier occurs near L and the other near G, with the parallaxes of latitude helping; or the earlier near H and the later near K. Therefore, if one occurs toward the north pole in semicircle BSA, the other will occur with a noticeable true southern latitude, which will be increased by parallax, and thus there will be no eclipse with respect to those in the north. For the same reason, if the earlier occurs in the southern semicircle AMB, the later will be no eclipse visible to those in the south, since parallax increases the northern latitude. Moreover, that two eclipses of the ☉ can occur within one month, at least a lesser one, is clear, because the mean motion in latitude of one mean month is 30° 40′, and therefore the least, of a least month, is less than 30°, while arc LG, or HK, in true ☌ can be nearly 38°. And so, from one new Moon to the next, the luminaries can be within the ecliptic limits. Yet both eclipses cannot be very large: for if LB as well as GB is 19°, then even if the least motion in latitude of one least month is taken as only 26°, in one of the eclipses the Moon will still be farther from node B than from the limit L or G. But if LB is taken as 19° and BG as 5° 25′, it is clear that there will be no second eclipse.

[Margin: A rather obscure passage of Pliny the Elder explained.]

On this occasion Milich emends those words of Pliny the Elder, Book 2, chapter 13, "For that both heavenly bodies should be looked for within twelve days also happened in our own age, when the Emperors Vespasian were consuls, the father for the third time and the son for the second," by substituting "fifteen". But it is not extraordinary for two eclipses to occur within 15 days, one of the ☉, the other of the ☾. Pliny the Elder, however, is reporting something extraordinary and rare; therefore he is speaking of 12 whole days elapsing in a lesser month. On these, see the history of eclipses below, chapters 19 and 21.

THEOREMA VI.

Theorem 6.

Poſſunt in vno Menſe tres Eclipſes fieri, vna Lunæ & duæ Solis; Quo caſu Lunæ Eclipſis eſt neceſſaria & plerumq. Totalis; & Solis Eclipſes vna ad vnum, altera ad alterum Polum ſpectat, neq. vtraq. valde magna eſt.

Three eclipses can occur in one month, one of the Moon and two of the Sun. In this case the eclipse of the Moon is necessary and usually total; and of the Sun's eclipses, one looks toward one pole and the other toward the other pole, and they are not both very large.

VII. A large part of the theorem has already been proved in Theorem 5, namely the part on the two eclipses of the ☉, but what I said about the lunar one follows from it. For if two eclipses of the Sun happen, the Moon, in coming from the one to the other, must cross the node and travel from L, through B, to G, or [vel vel] from H, through A, to K. In addition, at the full Moon between them it must be distant from the new Moons on either side by at least $14^{d}\ 11^{h}\ 7^{m}$, which is the least semilunation; and so it must be distant from the node in motion in latitude by far fewer degrees than 10. And therefore an eclipse of the Moon is necessary, and usually total because of the nearness of the node, from which in this case it is usually less than 5° distant, and it has a latitude smaller than 26′, and so smaller than the difference of the semidiameters of the shadow and the Moon.

THEOREMA VII.

Theorem 7.

Quando Plenilunium fit in Nodo aut quamproximè, ideòq. Totalis Eclipſis Lunæ; rarò ac fortè nunquam vtrumque Nouilunium circumſtans caret Eclipſi Solis, ſed neutrius Eclipſis valde magna eſſe poteſt.

When full Moon occurs at the node or as close to it as can be, and therefore a total eclipse of the Moon, rarely and perhaps never are both new Moons on either side without an eclipse of the Sun; but the eclipse of neither can be very large.

VIII. So says Kepler, as to the first part, in the *Epitome of Copernican Astronomy*, p. 881. This can easily be proved from my figure and small tables set out in number 1. For if, for example, an ecliptic full Moon occurs at node B ☊, then the new Moon is no more than $15^{d}\ 1^{h}\ 37^{m}$ distant from it, this being of course the greatest semilunation. But in that time the motion in latitude will not exceed 19° or 20°; and if it comes to that much in one half-month, it will not come to that much in the other. Therefore in one or the other of the new Moons the Moon will be within arc BL or BG, of 19°, and so there will be some eclipse of the ☉ somewhere, yet very small, whether both or one, because of the great distance from the node.

THEOREMA VIII.

Theorem 8.

Omnis Partialis Lunæ Eclipſis vicinum habet Nouilunium Eclipticum; & omne Nouilunium Eclipticum paruæ Eclipſis, vicinum habet Plenilunium Eclipticum.

Every partial eclipse of the Moon has an ecliptic new Moon nearby; and every ecliptic new Moon with a small eclipse has an ecliptic full Moon nearby.

IX. The first part is Kepler's, above; the second is mine. For if an eclipse of the ☾ is partial, the Moon's latitude is greater than the difference of the semidiameters of the shadow and the Moon, and so greater than 30′, and therefore the distance from the nearer node is greater than 5°. Let the Moon, then, be partially eclipsed at F, and arc FB be at least 5°. For after $15^{d}\ 1^{h}\ 37^{m}$, which is the greatest semilunation, the motion in latitude will not be greater than 19° or 20°. So when 5° is subtracted, arc BG will be left, not greater than 14° or 15°, and thus within the ecliptic limits. And very often it will be smaller, because neither will the motion in latitude be so great, since usually the month is not the greatest, nor will arc FB be only 5°. Therefore, if a partial eclipse of the Moon occurs near F, with southern latitude decreasing, the following new Moon will be ecliptic, at least for those in the north, in arc AH; but if with southern latitude increasing, as at E, the preceding new Moon was ecliptic, at least for those in the north, in arc BG. By a similar argument the second part of the theorem will be clear. For let a partial and small eclipse of the ☉ occur in

arc BL, at L. The Moon at L, then, will be distant from node B, in true ☌, by at most 19°, as far as H will be distant from node A. Now let the semilunation be the least, $14^{d}\ 11^{h}\ 7^{m}$, and the motion in latitude the least, 13°, or indeed nearly 14°. For when these are subtracted from 19°, arc FB will be left, at least 5° or 6°, to which arc DA is equal.

THEOREMA IX.

Theorem 9.

Quando Nouilunium fit in Nodo aut proximè, ideòq. Eclipſis Solis alicubi centralis reſpectu centri Diſci Terræ, Plenilunia circumſtantia tranſeunt ſine Eclipſi; & viciſſim ſi Plenilunia Nodum circumſtantia tranſeunt ſine Eclipſi, Nouilunium intercedēs eſt cum Eclipſi Solis centrali in Nodo, aut quam-proximè.

When a new Moon occurs at the node or very near it, and therefore an eclipse of the Sun that is somewhere central with respect to the centre of the Earth's disc, the full Moons on either side pass without eclipse; and conversely, if the full Moons on either side of the node pass without eclipse, the new Moon between them comes with a central eclipse of the Sun at the node, or as close to it as can be.

X. Both parts are Kepler's, above. And the reason is that the least motion in latitude of the least half-month, running between ☌ and ☍, is about 14°, and so greater than the arc contained within the limits of a possible eclipse, which in true ☍ does not exceed 13°.

THEOREMA X.

Theorem 10.

Poſſunt interſtitio ſemeſtri fieri duæ Eclipſes Solis Centrales aut quaſi Centrales. quo caſu toto anno nullæ ſunt Lunæ Eclipſes.

Two eclipses of the Sun, central or nearly central, can occur at an interval of six months. In this case there are no eclipses of the Moon in the whole year.

XI. So says Kepler, above. The second part of the theorem is indeed clear from Theorem 9. The first is shown as follows: if an eclipse of the ☉ occurs at one node, say ☊, the six months that follow can be slightly greater than six lesser months and slightly less than six mean months, and so the motion in latitude can be 180° or very near it; and when semicircle BSA is completed, a new Moon can occur at the other node ☋, or very near it, since the motion in latitude of 6 mean months is 184° 1′, and of least months 178° 21′. Further,

within this century, from the year 1600 to 1700, the years already mentioned, with only two eclipses of the Sun and no lunar ones at all, are 1604, 1611, 1615, 1622, 1633, 1640, 1644, 1651, 1655, 1662, 1666, 1680, 1691, 1698, as will be clear from chapter 21.

THEOREMA XI.

Theorem 11.

Si in vno anni ſemiſſe contingat Eclipſis Lunæ Centralis aut quaſi, ſeu proxima Nodo, non poterit oppoſitus anni ſemiſſis carere ſua Lunari Eclipſi.

If in one half of the year there occurs an eclipse of the Moon that is central or nearly so, that is, very close to the node, the opposite half of the year cannot be without its lunar eclipse.

XII. This too is Kepler's, above. For if, for example, an eclipse of the ☾ occurs at node ☊, then after six mean months the Moon will be no farther than 4° 1′ from node ☋; after six least months, no farther than 1° 39′; and after six greatest months, no farther than 9° 51′, as is clear in the second small table of number 1. Therefore it will always be within the limits of a necessary eclipse.

DE NVMERO ECLIPSIVM.

On the number of eclipses.

THEOREMA XII.

Theorem 12.

Nullus Annus vacat ab omni Eclipſi, nullus pauciores quàm Duas, aut plures quàm Octo Eclipſes habet.

No year is free of every eclipse; none has fewer than two or more than eight eclipses.

[Margin: The number of eclipses.]

XIII. For in the course of one lunar year, let alone a solar one, the Moon celebrates the syzygies ☌ and ☍ at least twice near the nodes. Now if on the first day of the year an ecliptic new Moon occurs, say in L, and the ecliptic full Moon following it around B, and the succeeding ecliptic new Moon at G; and if after five greater months further eclipses occur, of the ☉ in H, of the ☾ at A, and again of the ☉ in K; then the remaining months that succeed will not be lesser, but mean or greater. So toward the end of the year, when 5 greater months and 7 mean have been completed, the motion in latitude will be 362° 8′. Therefore the Moon, by way of SM, will return to L and will be 17° 52′ from node B; and so a seventh eclipse of the year, but the fifth of the ☉, can occur, and after about 15 days an eighth at B, but the third of the ☾. But by

then the lunar year will be complete, and indeed, before the following new Moon, the solar year as well. So if an eclipse of the ☉ returns at G, it will not belong to the preceding year. The same follows if 7 mean months come first and 5 greater follow; and nearly the same if six months are least and the other six middling, for they amount to a motion in latitude of 362° 22′. Nor indeed can all of them be either least, or mean, or greatest.

THEOREMA XIII.

Theorem 13.

Poteſt vnus Annus habere duas tantùm Solis abſque vlla Lunæ, vel duas Lunæ Eclipſes cum vnica Solis.

One year can have only two eclipses of the Sun without any of the Moon, or two eclipses of the Moon with only one of the Sun.

XIV. This is clear from Theorems 7, 8 and 9 taken together and carefully weighed.

THEOREMA XIV.

Theorem 14.

Anniuerſarius Eclipſium numerus, plurium ſæculorum Eclipſibus numerandis conuenientior, eſt potiùs medius inter Ternarium & Quaternarium, quàm Quaternarius, & quàm Quinarius.

The annual number of eclipses better suited to counting the eclipses of many centuries is a mean between three and four, rather than four, and rather than five.

[Margin: What is the annual number of eclipses?]

[Margin: 1. The opinion of Longomontanus.]

XV. Longomontanus stands for the number four, in the *Astronomia Danica*, Book 1 of the *Theorica*, toward the end of chapter 9. There he supposes that at the mean distance of the luminaries the greatest ecliptic limits are 12° for the ☾ and 6⅙° for the ☉, but with the aid of parallax 17½°. These he doubles around one of the nodes and quadruples around both, so that for the Moon they come to 48 and for the Sun to 70. He also supposes that the Moon, after 12 mean lunations, before the end of the solar year, completes 132° 35′; and, adding the annual precession of the nodes of 19° 20′, he collects the Moon's whole annual excess over the Sun as 151° 55′, after whole revolutions. Then he makes: as 12 semirevolutions of the Moon are to the excess, so 48 to 1⅔, the number of lunar eclipses; and as 12 semirevolutions are to the excess, so 70 to 2 5/12, the number of eclipses. So when the two are combined the number of eclipses comes to 4, if mean motion is considered. For if true motion is considered, he admits that

there can be more or fewer, yet in such a way that over a period of about eight or nine years, in which the Moon's apogee completes its circuit beneath the zodiac, that number of four eclipses comes round again, and in every 8 or 9 years 32 eclipses occur, which he confirms from the *Ephemerides* of Origanus,

[Margin: 2. The opinion of Kepler.]

Kepler, on the other hand, fights for the number five, in the *Epitome of Copernican Astronomy*, p. 882. For he says that in nearly all half-years eclipses of the Sun occur, more often two in succession, very rarely and almost never none; and that in all lunar years there occur either two or three eclipses of the Sun, and one or two of the Moon, and so 5 in all to which a sixth eclipse is sometimes added around the beginning or end of the solar year. And indeed, since the extremes of the possible number are 2 and 7, the mean between these is 4½, that is, in whole numbers, either 4 or 5.

[Margin: 3. Tycho's opinion and its kindly interpretation.]

[Margin: Ignorance of eclipse doctrine in some interpreters of the sacred oracles.]

But Tycho's statement in volume 1, p. 328, that *six eclipsations occur every year in the Sun and Moon, by reason of different horizons*, holds at most under the Ptolemaic hypothesis and the limits of possible eclipses taken by the hundred [centenos], as Longomontanus kindly interprets him above. Nor does this stand in the way of Tycho's chief purpose, which is to refute those who interpreted the natural eclipses that occur every year as the signs of the impending end of the world given by the Prophets and by CHRIST. To refute them it is enough that about six, or nearly six, eclipses can occur every year by the necessity of the course of the luminaries; Longomontanus also refutes them in the same place. In actual fact, moreover, there are some years made up of six eclipses, such as the year 1620; on these see Kepler in his ephemeris for that year, at the beginning, and our chapter 21 below.

[Margin: How many eclipses from the beginning of the world.]

But since from the year of Christ 1600 to 1700, as will be clear from chapter 21, there are 350 eclipses in all, if 100 gives 350, then one year gives 3½ rather than 4 or 5; and in the 57 centuries elapsed from the beginning of the world, up to the year of Christ 1650, about 20,000 eclipses have occurred. See the rest in Scholium 3.

THEOREMA XV.

Theorem 15.

In eadem Terræ Regione Plures fiunt Eclipſes Lunæ quàm Solis; In toto autem Orbe reſpectu diuerſarum Regionum Plures Solis quàm Lunæ. Vniuerſim autem plures ſunt Partiales Solis quàm Lunæ qualibet; Totales verò Solis pauciores quàm Lunæ qualibet ſeu omniuariæ; Totales verò Solis plures quàm Totales Lunæ; denique Totalium Solis, & omnimodarum Lunæ idem penè numerus.

In the same region of the Earth more eclipses occur of the Moon than of the Sun; but in the whole world, taking account of different regions, more of the Sun than of the Moon. In general, moreover, partial eclipses of the Sun are more numerous than eclipses of the Moon of any one kind; total eclipses of the Sun, however, are fewer than eclipses of the Moon of any one kind or of all kinds; but total eclipses of the Sun are more numerous than total eclipses of the Moon; and finally the number of total eclipses of the Sun and of eclipses of the Moon of every kind is almost the same.

XVI. Mulerius holds this as to the first two parts, in the *Tabulae Frisicae*, p. 78; as to the others, Kepler in the *Epitome of Copernican Astronomy*, p. 881. It can be confirmed from the preceding theorems, from the motion in latitude of the ☾ compared with the arcs spoken of in number 1, and from the ephemerides and the history of eclipses. See, then, if you please, chapters 19 and 21 below.

THEOREMA XVI.

Theorem 16.

Diuina Prouidentia in Oeconomia Eclipſium Admiranda imprimis & Amanda eſt Mortalibus.

Divine providence in the management of eclipses is above all to be admired and loved by mortals.

[Margin: Arguments of divine providence in the dispensing of eclipses.]

XVII. For since through eclipses he has so provided for us that they should harm us as little as possible, GOD is to be loved by us and honoured in the highest degree with a grateful heart. He is to be admired, moreover, because he has so distributed the eclipses of the Sun, which do more harm to the nature of sublunary things, that they should be of shorter duration than lunar ones; that they should not be universal to a whole hemisphere at the same time; that they should not be large in the month in which the greatest and central or nearly central eclipses of the Moon occur; or that, when eclipses of the Sun are central, there should be no lunar ones in that month; and finally that two of the Sun should not occur in the same month toward the same quarter of the world. In this way compensation would be made by the smallness, or the fewness, or the dissociation of solar eclipses. These and similar things may be contemplated in the preceding theorems.

DE APOCATASTASI ECLIPSIVM.

On the restitution of eclipses.

[Margin: On the revolutions of eclipses.]

XVIII. Let us begin with Pliny the Elder, who in Book 2, chapter 13, states it thus: *It is certain that eclipses return to their own circuits in two hundred and twenty-two months.* I believe indeed that he has this from the opinion of Hipparchus, for a little later he adds: *Within two hundred years it was discovered by the sagacity of Hipparchus that an eclipse of the Moon, too, sometimes occurs in the fifth month from the previous one, but one of the Sun in the seventh.*

[Margin: Opinion on the revolution of the node and of eclipses: the opinion of Pliny the Elder; of Ptolemy; of Copernicus; of Milich; of Magini; of Martianus Capella.]

He is speaking of the revolution to the same place of the zodiac, but with respect to the same node, not with respect to the luminaries. For when 222 lunar months are complete, the node ☊, moving against the order of the signs, has completed the zodiac; or in 18 Egyptian solar years $223^{d}\ 6^{h}\ 12^{m}$, as Magini, with Copernicus, judges in Book 2 of the *Theoricae*, chapters 26 and 30; or in 18 Egyptian years $228^{d}\ 3^{h}\ 50^{m}$, as Kepler holds in the *Epitome*, p. 788; or in 18 years and 9 months, as Milich gathers from the Ptolemaic motion of the nodes, on Pliny the Elder, Book 2, chapter 13. But Martianus Capella, in *De nuptiis Philologiae*, Book 8, in the chapter on the parts of the latitude of the zodiac, where he treats of the Moon, says: *Yet it could not return to the same point, that is, just as it was placed, in the same month, in the same part, to the Sun in this way, at the same portion of latitude, except in the 235th month, that is, in the 19th year.* For in 19 solar years there are 235 lunar months, and this is the Metonic period. But this revolution of eclipses is not one of the node to the same degree of the zodiac; it is one of ecliptic new and full Moons to the same day of the year or the next to it, and to the same degree of the zodiac or the next to it. On the truth of this revolution, see the examples of lunar eclipses set out by us for nine Metonic cycles in Book 4, chapter 19, number 5.

[Margin: Kepler's opinion on these matters.]

But Kepler, in the *Epitome of Copernican Astronomy*, p. 895, affirms that because of the many principles that concur in eclipses, especially of the Sun, no exact order of revolution is known to us. Speaking, however, of the lunar ones, which are simpler, he says that there is a notable period of 223 months, or 18 lunar years, so that one simple lunar year remains to make up the nineteen-year cycle; for in this period eclipses mostly return not much different, though each time preceding by 10° of the zodiac. He adds that sometimes two eclipses of the Sun recur, on completion of the cycle of 19 years, at the same place of the zodiac, as happened in the years 1579 and 1598, for each was very large, and each fell on February 25, old style, at 16° ♓; but that this was a singular concurrence of causes, and that a similar eclipse was expected in vain in the following cycle, in the year 1617.

[Margin: The opinion of Cicero and of Macrobius.]

But if a perfect restitution of eclipses had to occur at the same moment of the year, in the same minute of the zodiac, with the same magnitude and duration, and at the same distance from the same node toward the same quarter of the world, the motions and periods of the Moon and the Sun would have to be commensurable, and the Greatest Year would have to be completed, to say nothing of that Great Year of which Cicero speaks in Book 6 of the *Republic*, in Macrobius on Book 2 of the *Dream of Scipio*, chapter 11, saying: *For just as the Sun once seemed to men to fail and be extinguished when the soul of Romulus entered these very precincts, so whenever the Sun shall again have failed in the same part and at the same time, then, with all the signs and stars called back to the same starting point, consider the year completed.* This year, on the opinion of some natural philosophers or other, Macrobius there defines as 15,000 years.

SCHOLIA.

Scholia.

[Margin: 1. The error of certain people about the end of the world, drawn from natural eclipses.]

I. Because of ignorance of the science of eclipses, a double error above all has gained ground among some interpreters of the sacred oracles, or others, in this and the preceding century. The first was that of those who twisted natural failures of the luminaries to those extraordinary and preternatural ones by which CHRIST the Lord, or other prophets, foretold the end of the world. Their error is refuted by Tycho, volume 1 of the *Progymnasmata*, p. 328, and by Longomontanus, Book 1 of the *Theorica*, p. 314, on the ground that every year from the beginning of the world there have occurred, if not 6, at least 4 eclipses, when the years in which there were more are reckoned with the years in which there were fewer. Let preachers beware, then, lest, by stirring the people to terror and tears with empty arguments, they themselves provoke laughter at their own expense among the experts.

[Margin: 2. The error about there being more eclipses now than formerly.]

II. The second error was that of those who saw future eclipses noted even below the horizon in the *Ephemerides* of Origanus, or of Kepler, or of similar practitioners, and therefore more of them than the older writers of ephemerides used to note, since these noted only those that were visible above the horizon of their tables; and who suspected that the number of eclipses is greater in these centuries of ours than formerly. Origanus refutes them at length in the preface to volume 2 of his *Ephemerides*, showing that an equal number of eclipses existed formerly, from the beginning, in ancient centuries, as the number in recent centuries; and that the number of these could not have grown greater now through any variation, whether of the Sun's apogee, of the eccentricity, of the obliquity of the ecliptic, or of the lunar latitude.

[Margin: The number of eclipses and of revolutions from the beginning of the world.]

III. Since from the beginning of the world up to the year of CHRIST 1650 there are, according to our chronological book, not more than 5703 years and not fewer than 5694, it is clear, at any rate from the syzygies that Mulerius set in order in the *Tabulae Frisicae*, that there were not more than 70,538 lunations and not fewer than 70,426. Again, eclipses of the ☉ and ☾ together, from what was said in the preceding chapter, number 15, were not more than 28,515, by multiplying 5703 by 5, and not fewer than 22,776, by multiplying 5694 by 4. And ecliptic revolutions of 19 years were not more than 317 and not fewer than 316; but of 18 years, not more than 300 and not fewer than 299. And so anyone can try out his own number according to the opinion he has chosen on the age of the world. But from what was said above, at the end of number 15, the more probable number is 20,000 eclipses.

[Margin: The inequality of ecliptic intervals.]

IV. Proclus, in the *Commentary* on Book 1 of Euclid's *Elements*, proposition 8, uses proposition 7 of the same book to show that three eclipses cannot occur at equal intervals from one another. Father Mario Bettini, in volume 1 of the *Aerarium Philosophiae Mathematicae*, p. 250, testifies that an explanation of this was sent to him by Scipione Chiaramonti. But that demonstration supposes an anomalous motion of the luminaries and an irregular motion in latitude; otherwise, if those motions were equal, and completed equal arcs in the ecliptic or the Moon's orbit in equal times, the intervals in months between several eclipses, to say nothing of three, could be equal.

[Margin: The Sun and the world created in a great eclipse, in the opinion of Kepler.]

V. Kepler, throughout the Rudolphine Tables, but especially at the ends of the epochs, and in chapter 18, p. 52, and chapter 29, p. 97, judges that the world was created in the year 3993 before CHRIST, on July 24. And in the same chapter 29, precept 138, from his own table containing the cycle of the meetings of the ☉ and of the nodes of the Moon ☊ and ☋, he gathers that on that day there was a great eclipse of the Sun, the luminaries being joined at the node ☊, at noon of the 24th, at the solstitial point itself, that is, at the beginning of ♋, but by the true motions at 28° ♊, with a southern latitude of the ☾ of about 11′; and that a total eclipse of the Sun was seen in Ethiopia, midway between those living under the Tropic of Cancer and those living under the equator. From this, as Kepler hints in the margin, some astrologer might infer that the Ethiopians had the cause of their blackness from this first eclipse. He adds, moreover, in accordance with our Theorem 9, that neither full Moon, whether that of June, if there had been one, or that of August, was ecliptic; and that on the preceding January 29, if the stars had existed then, there would have been a great eclipse of the Sun at ☋, and perhaps a small one of the Moon on February 12.

[Margin: But an improbable one.]

But I cannot be persuaded that the world or the Sun was made by God in an eclipse, or that the first phenomenon of the Sun was its failure. On the contrary, in this the beginning of the innocent world was the opposite of the end of a world defiled by the filth of sins: the former began from the light and gladness of the divine countenance, represented by the Sun as by a symbol; the latter is to end in the foulest eclipses of the luminaries, foreshadowing the dreadful judgement and wrath of God.

CAPVT XV.

Chapter 15.

De Modo Obſeruandi Eclipſes Luminarium & de Cauſis Diſſidij Obſeruationes inter ac Tabulas Aſtronomicas.

On the method of observing eclipses of the luminaries, and on the causes of the disagreement between observations and astronomical tables.

[Margin: Authors on this subject.]

I. Few indeed have handed this down, and very little; and not even all of them together have handed down everything that this practice requires. But in a matter of such moment, in which above all the crucial test of astronomy and the trial of astronomical reliability consist, I will not allow my own diligence to be found wanting. What it has achieved will be judged if this chapter is compared with what has been indicated on this subject by Gemma Frisius, *De Radio Astronomico*, chapter 18; Reinhold, on Peuerbach's *Theoricae*, p. 198; Maurolico, Dialogue 3 of the *Cosmographia*, p. 87; Daniel Santbech, *De Observatione* [Greek: τῶν φαινομένων (tōn phainomenōn, "of the phenomena")], Proposition 13; Barozzi, Book 4 of the *Cosmographia*, p. 325; Longomontanus, Book 1 of the *Theorica*, chapter 9; Kepler, in the *Astronomia Optica*, chapter 11, from p. 349; Tycho, in the letter to Rothmann of 1587 January 20, old style; Biancani, in the *Sphaera*, Book 10, chapter 19, and on the mathematical passages of Aristotle, at Problem 10 of Section 15; Bettini, *Apiarium* 6, Progymnasma 2, chapter 6; and Wendelen, in the preface to the eclipses of his own age. First, however, the things to be observed in eclipses of the luminaries must be listed; then this method of observing them must be taught in order and point by point, free of all deception, so far as is permitted to man.

[Margin: Things to be observed in eclipses.]

II. The things to be observed, then, are these. First, the quantity or magnitude of the eclipse: whether it is total, or partial, or none, especially where it is established that the astronomical tables disagree on this, some promising a partial eclipse, others a total one, others none or an imperceptible one; and if it is partial, how many digits or inches or points it is at the height of the failure. Second, the ratio of the semidiameters of the obscuring and of the obscured body. Third, the apparent semidiameters of the obscuring and of the obscured body. Fourth, the arc or distance between the centres of the obscuring and of

the obscured body. Fifth, the shining or the dark arc of the circumference of the obscured luminary at the middle or height of the eclipse. Sixth, the Moon's path and the position of the horns, so that it may be established when they are parallel to the Moon's path; and thus, in a partial eclipse, the moment of the height of the eclipse. Seventh, the inclinations and quarters toward which the failure tends. Eighth, the interval of time from beginning to end, both of the spurious eclipse arising from smoke or umbrago, and especially of the true and legitimate eclipse. Ninth, the stay in darkness, and the incidence and repletion of a total eclipse. Tenth, the moment of time at which the eclipse begins and ends; and if it is total, at which the obscuration becomes total and at which the luminary begins to emerge from the obscuring body. Eleventh, the moments of time of other principal phases, namely when 3 digits, or 6, etc., appear obscured or already recovered; and when the Moon changes colour, or in some total eclipse loses those colours along with all its secondary light, and recovers them again. Twelfth, the spots of the Moon, or islands, or mountains, or small areas through which the section of the shadow or penumbra passes; and the moments of time at which that section either grazes or leaves parts of the Moon. Thirteenth, the colours of the eclipsed luminary, or of the surrounding air, and the state of the air around the times of the eclipse. Fourteenth, the stars that appear in an eclipse of the Sun, and whether they are planets or not. Fifteenth, the position of the luminaries in the principal phases of the failure, for example the transit through the meridian, the azimuths and verticals in which they stand, the distance of the centres or edges from the more notable fixed stars, the line drawn through the centres of the luminaries or through the horns, and through two fixed stars; and finally the altitude of the luminaries. As for the method of observing the diameters of the luminaries, I have taught it sufficiently in Book 3, chapter 10, and Book 4, chapter 16.

PROBLEMA I.

Problem 1.

De Magnitudine Eclipſis Obſeruanda, & Arcu circumferentiæ obſcurato.

On observing the magnitude of an eclipse, and the arc of the circumference obscured.

[Margin: 1. Method of observing the magnitude.]

III. The first method is estimation by eye. One first conceives beforehand, by the power of the imagination, the apparent size of the luminary as if it were a foot long, with its diameter divided into twelve digits or inches; then one inspects the luminary with a direct gaze, but with the eye protected against the injury of the Sun's glare by coloured glasses, or by the interposition of translucent paper or of a rather fine veil. If you use a telescope, those are better here that show the whole disc of the luminary at once; of this kind are small ones, or large ones indeed, but with a second, or even three, convex lenses

set near the eye at a certain interval (which experiment will determine), and a fourth and principal convex lens far from the eye, turned toward the object.

[Margin: The deceptiveness of this method.]

But except for the case of exactly six digits obscured, in which the deception is usually smaller, as Kepler points out in the *Optics*, p. 349, this direct estimation by the eyes is very deceptive. Thus in the eclipse of the ☾ of 1603 May 24, Lansbergen gave 7½ digits, Wendelen 8; and on November 18 Lansbergen 3 digits, Kepler less than 3, others more than 3; and in the eclipse of the ☾ of 1612 May 14, Longomontanus and Wendelen gave 6½ digits, but Scheiner 8; again, in the eclipse of the ☾ of 1621 November 28, Kepler gave 4 digits

Gassendi 3⅔, Wendelen 3; and in the eclipse of the ☾ of 1643 September 27, Wendelen gave more than 6 digits, Father Theodorus Moretus fewer, or hardly 6. We estimated exactly 6. And you will see the same throughout in the history of eclipses, chapter 19. Judgement is also slippery when an eclipse is on the border of total without stay, or with a very small stay, or nearly total but not wholly, because of that doubtful boundary of the penumbra or of the edge; or when the eclipse is so small that it escapes duller eyes and is barely evident to sharper ones. We have an example of the first case below in chapter 19, in the eclipse of the ☾ of 1616 August 26, when some asserted it was partial and others total; and in the eclipse of the year 1580. Of the second case, in the eclipse of the ☾ of the year 1625, and perhaps in the eclipse of the ☾ of the year 1626 and of 1619 June 26.

[Margin: 2. Method.]

[Margin: Its deceptiveness.]

The second method, formerly used by Cornelius Gemma and Tycho, is by the astronomical radius, with which, outside an eclipse, one takes the distance between the edges of the Sun or Moon, that is, the apparent diameter, and at the height of an eclipse the greatest distance of the periphery of the obscuring body from the periphery of the obscured one. But Kepler in the *Optics*, p. 350, rightly rejects this method as crude, and Tycho finally repudiated it because of the imperfection of this instrument, on which see what was said in Book 3, chapter 10, number 3.

[Margin: 3. Method.]

IV. The third method, either used or praised by Gemma Frisius, Reinhold, Santbech, Mästlin, Barozzi, Maurolico, Biancani and Bettini, and not displeasing to Kepler in the *Astronomia Optica*, chapter 11, Problem 7, is by the image or ray of the luminaries, let in through a slit, or a hole, or a small window, into a dark room and received on a wall, a tablet, or white paper. But it must be done in such a way that the plane both of the hole and of the tablet or paper receiving the bright base of the radiant cone is illuminated perpendicularly by the central ray of the luminaries, and that their planes are parallel to each other, so that the image is circular, not oval; and the tablet receiving the image must be kept at a fixed and constant distance from the hole during the whole time of the eclipse.

Therefore, if the eclipse is solar you can, on the preceding day, or if lunar, on the same night, with the tablet fixed to the instrument, namely a small beam at one end of which is the plate with the hole, observe the diameter of the circle of the bright base. Half of this will give the semidiameter for describing a circle from a suitable centre, that is, from the point on which the ray passing through the centre of the hole falls perpendicularly. Although the periphery of this circle is usually subdivided into 360°, or at least its semiperiphery into 180°, and its diameter not only into 12 equal parts but into more small particles, it is better, nevertheless, to describe on another tablet, separate from the instrument, a circle equal to it, and to divide its semicircumference into 180° and its diameter into as many and as small equal particles as possible; for this division is done more conveniently and more exactly than on a tablet already fixed to the beam. With this done, once the eclipse has begun, the small beam must be moved so that the bright image follows the motion of the Sun or Moon from the opposite side and the bright circle coincides with the circle described.

Then, whether at the height of the eclipse or at any other moment you please, take with the compasses the greatest interval, such as GB, which lies between point G of the periphery GCHD of the obscuring body and point B of the periphery BCEDB of the obscured luminary. For when the compasses are transferred to the diameter of the equal circle, already divided into particles, the portion then free of the eclipse will be known, and its complement to the whole diameter, namely GE, will be the eclipsed portion. Let it be made, then: as the particles of the whole diameter BE are to 12 digits, so is that complement GE to the required amount, namely to the digits then obscured.

Diagram. Set into the foot of the left column, with the text wrapped to its left. Two concentric circles form a narrow ring at the top, the outer marked B and the inner N, with centre A on a vertical line that runs from B down to H; the outer circle continues as a white arc through the disc, crossing the vertical at E. A large solid dark disc, the obscuring body, rises from below into the lower part of the circles, its top at G and its foot at H; a white vertical line continues through it. Two arcs cross the upper circles above the disc. The vertical line carries, from the top, B, N, A, P, G, I, E, F, H.

- B (top of outer circle)
- N (top of inner circle)
- A (centre of the upper circles, on the vertical)
- P (on the vertical, on the lower of the two arcs, MPR)
- G (on the vertical, top of the dark disc)
- K (left end of the arc, outside the circle)
- M (on the arc, left)
- R (on the arc, right)
- L (right end of the arc, outside the circle)
- C (left, where the circle meets the dark disc)
- D (right, where the circle meets the dark disc)
- I, E, F (on the white vertical within the dark disc, in that order downward)

• H (foot of the dark disc)

Others, however, usually keep ready several circles, larger and smaller, on the same tablet or on different tablets, so that at the time of the eclipse they may choose the one with which the bright base of the radiant cone let in through the hole agrees most closely, as Kepler reports that Mästlin did, in the *Optics*, p. 352; or, as Kepler teaches in the *Optics*, chapter II, Problem I, they use various small crescents.

[Margin: The deceptions of this method.]

This method, besides the deception to be exposed under the fifth method, has this inconvenience: if the distance of the passive tablet from the hole is small, the diameter of the circle can be divided into only a few particles, and small ones too, and from their excess or defect a greater error results in measuring the magnitude of the failure. But if the distance is increased, as when the hole is in the roof of a lofty church, the way Kepler relates above that Mästlin used it, the image becomes fainter and weaker, the borders of light and shadow are harder to discern, and the motion of the bright image is more fleeting, so that the points of the compasses can hardly be applied at the right moment to the desired extremes; and while one hesitates and the hand trembles, the opportunity slips away. For that reason it is advantageous to have two people, each of whom with a very sharp needle quickly pricks the tablet at one of the points B and G, to which the compasses may then be fitted in a calm operation; and, moving the instrument before the failure perceptibly grows or shrinks, to test whether the section of the shadowing body passes through the marked points.

[Margin: The absent or shining arc of the circumference.]

The absent or obscured arc of the circumference, such as arc CED in the diagram, will become known either by opening the compasses to the interval of the chord CD, or by two observers pricking the circumference BCD at C and D with two needles, then taking the interval CD with the help of the compasses and applying it to the degrees of an equal circle or semicircle already divided. But if you want to work more exactly, let the semidiameter of the hole be known to you; subtract it from the semidiameter AB, so that AN remains; with this interval describe circle NMR; add the same to the portion EG, so that EP results; and with the interval FP describe the circle or arc MPR. For points M and R will bound the arc MNR shining on one side and the arc MIR obscured on the other. The reason for this correction will be indicated presently, in numbers 6 and 9.

[Margin: 4. Kepler's method.]

V. The fourth method is Kepler's, in the *Astronomia Optica*, p. 350, who says: *To rely on somewhat firmer supports, I was accustomed to estimate the absent arc of the Moon's circumference.* Let the figure set out in chapter 6, number 5, be repeated here, in which the absent or obscured arc of the Moon, AGC, is known; for when that is given, and the ratio of the diameters of the Moon and the shadow, the quantity of the defect is given.

Diagram. Set into the right column, with the text wrapped to its left. Two overlapping circles on one vertical line: the upper and larger is inscribed VMBRA VEL SOL (SHADOW OR SUN), with centre E; the lower and smaller is inscribed LVNA (MOON), with centre I. They cross at A on the left and C on the right. Straight lines join A and C to E and to I, and a horizontal chord joins A to C, crossing the vertical at K.

- B (top of the upper circle)
- VMBRA VEL SOL (legend across the upper circle)
- E (on the vertical, apex of the lines from A and C)
- G (on the vertical, top of the lower circle)
- K (on the vertical, on the chord AC)
- A (left intersection)
- C (right intersection)
- D (on the vertical, foot of the upper circle)
- I (on the vertical, centre of the lower circle)
- LVNA (legend across the lower circle)
- F (foot of the lower circle)

For let AGC be 60°, and AG 30°, namely the angle AIK; and therefore, by Euclid I.32, AKI is 90°, and AI, the secant, is 200,000 parts of which AK is 100,000. And let the ratio of the lunar semidiameter AI to the semidiameter of the shadow AE be as 1 to 3; for AE will be 600,000, the secant of the angle EAK, 80° 24′. The tangents of the same angles will be IK, 173,205, and EK, 591,236. These, subtracted from IG, of 200,000 parts, and from ED, of 600,000, leave GK, 26,795, and KD, 8,764, so that the whole deficient part DG is 35,559 of the parts of which AI, the apparent semidiameter of the Moon, is 200,000. Now let that semidiameter be 16′; for if one makes: as 200,000 to 16′, so 35,559 to another, GD, the obscured part, will be 2′ 51″. After handing this down in nearly these terms, Kepler adds: *Here, although sight and the estimate of sight can go somewhat astray, yet only a tiny little portion of that error must be reckoned to fall upon the Moon's diameter. I wish astronomers would take pains that some more certain methods of this observation be established. For on this one thing depends what is commonly made most of in astronomy, the measurement of the altitude and of the body of the Sun: for if the greatest parallax of the Sun is 3′, and one errs by a third part of a digit in estimating the lunar defect, it is all over with 600 semidiameters of the Earth. But if the greatest solar parallax is 2′, we shall err by 1700 semidiameters of the Earth, by the omission of one minute in the lunar defect, as can be seen on the front of our parallactic [?]* [in fronte noſtræ parallacticæ].

[Margin: Kepler corrected.]

In these words Kepler does not explain how he estimated the absent arc: whether by looking directly at the Moon, or in the bright image, with the points C and D marked as we taught above. Next, how can the error that spills over from this into the obscured part of the diameter be small, if an error of even one minute produces an error of 1700 terrestrial semidiameters in the Sun's distance? It is false, moreover, that the measurement of the Sun's distance and

magnitude depends on *this one thing*; for there are other methods, and indeed more certain than this one, on which see Book 3, chapter 7.

[Margin: 5. Kepler's method.]

VI. The fifth method, proposed by Kepler in the *Astronomia Optica*, chapter 11, Problems 8 and 9, supposes the bright image of the Sun received through a hole on a tablet set perpendicularly opposite the radiation, as we said in the third method; but in such a way that the semidiameter of the hole is known in parts of which the semidiameter of the bright base of the radiant cone is known. Therefore subtract the particles of the semidiameter of the hole or small window from the semidiameter of the bright base, AE, so that AI remains; and add the same particles to the remainder IG, so that the obscured part IP results; and complete the rest as above in method 3, or in the figure of the *fourth* method. For from this will come a more correct quantity of the eclipse and a more correct ratio of the semidiameters. The reasons for the addition and subtraction just mentioned are shown by Kepler in the *Astronomia Optica*, chapter 2, propositions 10, 11 and 12, and by us in the Optical Book [in libro Optico]. To these Kepler adds, in Problem 10 of chapter 11, a way of marking the points of the sections C and D in the earlier figure by means of a transverse rule [Regulæ tranſuerſalis]; but at p. 357 he shows it to be so deceptive that in the year 1600, on July 10, when 3 digits were failing in the bright image, the rule cut off only 1⅔ digits. For that reason, in Problem 13, he at last settles on various small paper crescents made beforehand from portions of different circles, so that when they are applied to the segment of the shadowing body, the one that best fits it may be chosen.

[Margin: 6. Method.]

VII. The sixth method is carried out with the help either of a whole telescope or of a single lens, whether convex or concave, by receiving the image of the Sun or Moon on a tablet or on very white paper. It is made very white if it is covered not with one but with several sheets of the cleanest paper, joined with a paste not of the ordinary kind but made from starch. Here too this tablet must be parallel to the plane of the glasses and directed straight, that is perpendicularly, onto the axis of the radiant cone. And before the eclipse the distance must be tested at which the image grows large, yet in such a way that the circumference of the bright base can still be clearly distinguished from the surrounding dark. At that distance the diameter of the bright base must be taken, either with compasses or by two points marked on the circumference with very sharp needles, so that a circle equal to it can be described on another tablet, its periphery divided into 360° and its diameter into 100 or 200 or more particles; and the rest is to be done as we said in the third method.

[Margin: Use of the telescope and choice of the glasses.]

As regards the glasses of the telescope, if you use it whole, the telescope must be such that, either by its shortness, or by the breadth of its lenses, or with the help of other lenses, it takes in the whole luminary and something more; otherwise it will be unfit to show you that obscured part which it does

not take in. For that reason some use a single convex glass, as we shall say in chapter 19 that Albert Linemann [Albertum Linnemanum] did at the eclipse of the Sun of the year 1639; others use a concave glass only, which we shall say in the same place that Gassendi used at the eclipse of the Sun of the year 1621. This is certainly better, because, other things being equal, it paints a cleaner image on the paper and a very fine periphery of the bright circle, with a very evident distinction between it and the surrounding dark field.

[Margin: 7. Method.]

VIII. The seventh method, better suited to an eclipse of the Sun, is by the image of the obscured luminary received in a mirror, either of water, in a basin full of water placed beneath, or of glass, and by estimating the deficient portion with the eyes.

[Margin: 8. Method, Langren's and ours.]

The *eighth* method, in a lunar eclipse, is to observe with an excellent and very bright telescope the parts of the Moon through which the section of the shadow passes, as Michael Florent van Langren pointed out to us by his example at the eclipse of 1634 March 14, of which I shall speak in chapter 19. For since the longitude and latitude of the lunar particles, and their distance from the edges, are already established from the selenography, on which see Book 4, chapter 7, it will also be easily established what fraction is deficient at that moment. But it will be useful to note at least three distinct particles or points through which that section passes, and to dictate them to an amanuensis or keep them in memory, so that the periphery of the shadow passing through them can be described.

PROBLEMA II.

Problem 2.

Proportionem Semidiametrorum Obſcurantis & Obſcurati, & data vnius Semidiametro, alterius Semidiametrum obſeruatione inquirere.

To find by observation the ratio of the semidiameters of the obscuring and of the obscured body, and, given the semidiameter of one, the semidiameter of the other.

IX. In the first figure, set in number 4, let three points C, G, D be marked at the height of a partial eclipse, or at any other more notable moment of a total eclipse, for example when 6 digits are obscured, or when the section of the periphery of the shadowing body passes through the centre A of the shadowed body; let them be marked, I say, at the same moment by two or three observers with very sharp needles; or, if the section were passing through the centre A, the points K, A, L. And let the interval between the extremes CD or KL be taken with compasses, as also their intervals from the third, intermediate point, namely the intervals CG and DG, or KA and LA. Then on another tablet or paper, having drawn a straight line equal to the interval CD or KL,

and having taken from its ends a point outside it in which the intervals of the points C and D from the point G, or the intervals of the points K and L from the point A, meet, describe, by the Scholium to proposition 5 of Book 4 of Euclid, a circle whose circumference passes through the three points C, G, D or K, A, L. For that circle will be equal to the image of the shadowing circle, that is, of the shadow in an eclipse of the Moon, or of the Moon in an eclipse of the Sun. Therefore measure its semidiameter GF in the particles into which the semidiameter AB has already been divided and which are known beforehand, and you will have the required ratio of the semidiameters. If, then, the apparent semidiameter of one is known in minutes and seconds, whether from observation or from astronomical tables, the semidiameter of the other will not remain hidden. For example, if AB is found to be 100 parts and GF 300, and it is established from elsewhere that the semidiameter of the Moon, AB, is 15′, it will follow: as 100 to 15′, so 300 to 45′, the semidiameter of the shadow. But if you use a bare hole rather than a whole telescope or a single glass, you must subtract the semidiameter of the hole from the semidiameter AB of the shining body, so that AN remains; and conversely add the semidiameter of the hole to the visible eclipsing portion GE, so that, for example, EP results. For AN will be the correct semidiameter of the shadowed body, and FP that of the shadowing body, as Kepler teaches in the *Optics*, chapter 11, Problem 9. Otherwise the semidiameter of the obscured body would be gathered as larger, and that of the obscuring body as smaller, than is correct, and the digits as fewer than in the sky, as he likewise teaches in chapter 2, propositions 10, 11, 12, and chapter 11, Problem 7. If, however, only the semidiameter of the luminary is sought, it is enough to subtract the semidiameter of the hole from the semidiameter of the bright base, as he teaches in the same chapter 11, Problem 2. Again, if you wish to continue the circumference CGD itself by proposition 5 of Book 4 of Euclid, it will suffice to note any three points on it quickly, etc.

PROBLEMA III.

Problem 3.

Diſtantiam Centrorum in ſummo Eclipſis, ſeu arcum inter centra Obſcurantis & Obſcurati obſeruatione deprehendere.

To determine by observation the distance of the centres at the height of an eclipse, that is, the arc between the centres of the obscuring and of the obscured body.

X. Find, by method 5 or 6 of Problem 1, the just and corrected quantity of the defect, namely IP in the figure of number 4, and by Problem 2 the apparent semidiameter of the shadowing body and of the shadowed body in minutes and seconds; and reduce the eclipsed part to the proportion of either of them. Subtract it from the sum of the semidiameters, and AF will remain known, namely the distance of the centre A of the shadowed luminary from the centre F of the shadowing shadow or Moon. For example, let the semidiameter AI

be 100 particles, but 15′ in minutes, and FP 300, but 45′ in minutes, and let the eclipsed portion PI be 30 particles. For if one makes: as 100 to 15′, so 30 to another, PI will be found to be 4½′. These, therefore, being subtracted from the sum of the semidiameters, which is now 60, AF, the distance of the centres, will remain, 55½′. So, nearly, Kepler in the *Optics*, p. 433, where he calls the uncorrected diameter of the luminary fringed [fimbriatam], but the diameter corrected by subtracting the diameter of the hole he calls enucleated [enucleatam].

PROBLEMA IV.

Problem 4.

Inclinationes Eclipſium obſeruare.

To observe the inclinations of eclipses.

XI. I assume here that the tablet on which the image of the deficient luminary is received is fixed immovably and at right angles to a small beam, and is parallel to the plane of the hole or of the glasses through which the ray is transmitted; and that a circle has already been described equal to the bright base of the radiant cone, as I said in method 3 of Problem 1, namely, in the following figure, the circle BCD, with its diameter marked there as EB, in such a way that it is inclined to neither side; and that, in whatever direction the small beam has been moved following the motion of the luminaries, EB remains in the plane of the vertical circle. With these things laid down, if the horns of the bright segment, say CD, are parallel to the horizon, and the straight line CD, drawn through them with the help of a stretched thread or a rule, cuts the diameter BE at right angles, the vertical circle will coincide with the arc drawn through the centres. Otherwise the arc through the centres will be inclined to the vertical circle. In that case, therefore, with the thread or rule passing through the centre A, draw a straight line parallel to the straight line drawn through the horns: for example, if one horn is B and the other M, let KL be taken parallel to the straight line BM, drawn through these in imagination. For the arc GK will be the arc measuring the angle GAK, the inclination sought; and this arc will be known with the help of compasses applied to the circumference of an equal circle already divided into degrees, as was said in Problem 1. At that time, moreover, the altitude of the luminary must be taken, without which these inclinations are of no use or little, as Kepler warns in the *Optics*, chapter 11, Problems 14 and 15; to which he adds, in Problems 16 and 17, a way of marking the inclinations on the floor.

Diagram. A geometric figure set into the left column, beside the text of number XI. A circle with centre A. A vertical diameter runs from B at the top down through A, and on through P and E to F at the foot. A horizontal line runs from G at the left through A to the right edge at M and H. A straight line runs obliquely from upper left, where R and K stand together, through A to

lower right, past D and L, ending outside the circle at Q. A second oblique line runs from C at lower left through A to T at upper right. A dotted line joins B to M at the upper right, and beside it a solid arc curves from B down to M inside the circle. A dotted line crosses the lower part of the circle from C to D. An arc bulging upward passes from C to D across the vertical above P; beyond C and D it continues outside the circle, down on each side to a straight base line through F. The circle's own lower edge crosses the vertical between P and E.

- B (top of the circle): point on the circle, the highest point
- R (upper left, outside or on the circle): end of the rule RAQ
- K (upper left, beside R): end of the line KL
- T (upper right, on the circle): end of the transverse CAT
- G (left, on the circle): end of the horizontal line
- M (right, on the circle): second horn in the example
- H (right, directly below M): on the circle
- A (centre): centre of the circle
- C (lower left, on the circle): horn of the bright segment
- D (lower right, on the circle): horn of the bright segment
- L (lower right, beside D): end of the line KL
- P (on the vertical, below A): between the upward arc and the lower edge of the circle
- E (on the vertical, below the circle)
- F (below the base line, at the foot of the vertical)
- Q (lower right, outside the circle): end of the rule RAQ

[Margin: Other methods for the Problem.]

But the image of the Moon on paper is not very clear, and the operations just mentioned cannot be carried out evidently enough in the darkness of the night, while the glare of a lighted lamp or candle is a hindrance to some. Kepler therefore, in the *Optics*, chapter 11, Problems 18 and 19, suggests two or three other methods. The *first* is by mere estimation with the eye, looking to see whether the horns of the eclipse are turned exactly upward on their backs or downward face-down; for then they lie parallel to the horizon, and there is no inclination from the vertical. It is the contrary if each horn stands perpendicularly upright; for then the arc through the centres will be parallel to the horizon and inclined to the vertical by 90°. The *second* is with the help of a circle, suspended or fixed on a tripod, which is held up to the Moon in such a way that it receives the ray or bright image of the Moon perpendicularly. Let its periphery BCD be divided into 360°, the division beginning from B, the highest point; and let there be a rule RAQ, longer than the diameter of the circle and turning about its centre A, with another transverse rule orthogonal to it, such as CAT. Then, with the eye transferred, let the rule be moved until it stands evenly under the horns B, M, as you see in the figure; for the transverse CAT will at once indicate the arc of inclination BT. The *third* is to observe the moment at which the horns of the eclipsed Moon are in the same straight line

with some fixed star or planet, or are turned perpendicularly toward it. For from the situation of the sphere, from the time and the place of that star, and taking account of the lunar parallaxes, you will find the inclination by means of trigonometry. In all these methods, moreover, Kepler at p. 367 supposes, as something known of itself or nearly known of itself, that the straight line joining the horns of the eclipse, that is, the points at which the circles of the Moon and of the shadow intersect, is orthogonal to the line drawn through the centre of each. Our *fourth*, for lunar eclipses, is to observe with a telescope two or more small spots of the Moon whose centres are in the same perpendicular line, and two or more through which the section of the terrestrial shadow passes; for from these, together with the time and the altitude of the Moon, the inclinations of a lunar eclipse will easily be clear. Note, however, as has been warned repeatedly in advance, that the telescope must be such that you can take in the whole disc of the Moon in a single look, and can determine more surely, by estimation with the eye, the vertical line of those of the already mentioned spots that are most distant from one another.

PROBLEMA V.

Problem 5.

Plagas Eclipſium obſeruare.

To observe the quarters of eclipses.

XII. How the quarters toward which eclipses tend are gathered from inclinations observed by Problem 4, and from azimuths and altitudes, was said sufficiently in chapter 7, number 2. When, however, in the image received through a hole or glasses on paper or a tablet, of which Problem 1, method 3 speaks, the horns are in a straight line parallel to the horizon, the azimuth alone, taken at that time, indicates the quarters.

PROBLEMA VI.

Problem 6.

Interualla temporum ad Eclipſes ſpectantia dimetiri.

To measure the intervals of time that pertain to eclipses.

XIII. These intervals are not only those that lie between the beginning and the end, or between the beginning and the total obscuration, and from there to the emersion, and from there to the end, or between, for example, six digits obscured and six digits recovered again; but also those counted from the transit of some fixed star through the meridian, or from its altitude or azimuth when taken, up to the beginning of the eclipse, or conversely from the beginning or end of the eclipse up to the transit of the star, etc. These intervals can be measured most exactly by the vibrations of that pendulum about which enough

was said in Book 2, chapter 20. If on that day you have tested sand-clepsydras or striking clocks against that pendulum, you can also use their times. Striking clocks, however, are also tested against a sciatheric solar clock, astronomical and horizontal [Horologium ſciatericum Solare Aſtronomicum & Horizontale]; either by stopping them so that the 12th hour after midnight does not strike until the shadow of the gnomon coincides exactly with the meridian line; or, what is better, against the transits through mid-heaven of two fixed stars of known right ascension, namely if the times of the striking clock are equal to the difference of right ascension converted into times of the equator. The other methods, by counted pulses of the artery, or by a certain stretch of a journey completed, or by the recitation of some verses, which Wendelen hints at in the preface to his *Eclipses*, seem to most people not so certain.

PROBLEMA VII.

Problem 7.

Principium ac Finem legitimæ Eclipſis, aut Totalis obſcurationis exactè diſcernere.

To discern exactly the beginning and end of a legitimate eclipse, or of total obscuration.

XIV. I speak of the legitimate eclipse, not of the smoke or umbrago, on which see chapter 5, especially number 2. The end is indeed more easily observed than the beginning, because the observer is already certain of the eclipse as practically finished, and does not wait in vain for the end of the phenomenon; but before it begins he has no certainty other than from an ephemeris or a calculation, which can go astray and keep the observer long in suspense, to the point of weariness; and unless he is patient and circumspect, the opportunity of the true beginning can escape him. It is certain, further, that the visible beginning of the eclipse etc. comes as soon as the disc of the Moon or Sun, viewed whether with the naked eye or with telescopes, and whether by direct looking or in the image received through a bare hole or glass on paper or a tablet, of which Problem 1, method 3 speaks, has begun to lose its perfect roundness, and its limb to be grazed or tasted by a small black lentil-shaped spot, as if by the overlay [recte: paring, per the book's errata] of a blackish little fingernail. Just so, it is established that the visible end of the eclipse is when the apparent disc of the luminaries has first returned to its perfect roundness, and has been so filled with primary light that no blemish in it, or trace of the former shadowing, appears. But one must beware of small arched clouds, which may perhaps imitate the disc of the shadowing circle, and also of solar spots, which might perhaps rise or set in the part of the limb first or last deficient.

[Margin: The difference between the true and the visible beginning, etc.]

I said above "of the visible beginning and end" because that blackish lentil-shaped spot, which first touches or last leaves the limb of the luminaries, and is the indicator of the beginning and end of the failing, is not an indivisible

point but some divisible part. However keen an eye or however excellent a telescope you use, it cannot become visible unless it has reached a certain quantity, as much as, and no smaller than, the least visual angle requires. Below that quantity it may be present when the eclipse has already begun, or remain when the eclipse is not yet completed, and yet not be seen by us. Hence it comes about that the true beginning of the eclipse, which occurs immediately upon the mutual contact of the Moon and the penumbra, or of the line drawn from the Earth and touching the western edge of the Sun and the eastern edge of the Moon, is earlier than the visible beginning, while the true end is later than the visible end. For the same reason, that lentil-shaped spot or small crescent of the lunar disc which is last immersed in the penumbra, or which first emerges from it, is not the indicator of the true immersion or emersion, since it is not visible to us except under a certain quantity; and the true immersion is later, but the emersion earlier, than the visible one. Indeed, it usually happens that although the spot just mentioned, whether bright or dark, could be seen by the eye or telescope, perfect and most attentive, it is nevertheless not seen, and about two or three minutes of time slip by between the true instant [verum punctiſtitium], at which the beginnings and ends of the phases just mentioned occur, and the instant visible to us or seen by us. For when I compared that smallest lentil-shaped spot with the small spots or small areas nearer the eastern limb of the Moon and marked on the Moon with a telescope, of which I have already spoken in Book 4, chapter 7, it appeared no smaller than those spots whose breadth is 20″; indeed, it usually appeared equal to those whose breadth is 25″ or 30″, of which seconds there are 1920, or at least 1900, in the diameter of the Moon, taken in that selenography as 32′. Now the mean hourly motion of the Moon from the Sun is 30′, or 1800″. Therefore, as 1800″ to one hour or 60^{m}, so 20″ to $0\frac{2}{3}^{m}$. And if one makes: as 1800″ to 60^{m}, so 30″ to another, the result will be one minute of time.

[Margin: Correction of the observed beginning and end of eclipses.]

We shall therefore come closer to the true moment of these phases if we subtract at least one minute of time from the visible beginning of the eclipse and of the emersion, and add one minute each to the end and to the immersion. But if that spot is somewhat larger, nearly two minutes will have to be taken from the time from noon in the former cases, and added in the latter.

PROBLEMA VIII.

Problem 8.

Tempus à meridie aut ante meridiem, quo Eclipſium Phaſes contingunt, obſeruare.

To observe the time from noon or before noon at which the phases of eclipses occur.

XV. This problem is common to the observing of the times of other phenomena, and so is to be treated in Book 10 among the problems of the primum mobile. Here, however, some of the chief methods must be indicated.

[Margin: 1. Method.]

The *first* method is by sundials, solar by day and lunar by night. It is indeed very useful at the time when an eclipse of the Sun and its phase occurs on the meridian or very close to it; for then the altitudes of the Sun that are taken differ insensibly from the meridian altitude, and so can, with a slight error of their own, produce a great error in the time. Therefore it is better then to use the inclination of the solar ray, or of the shadow, to the meridian line.

[Margin: 2. Method.]

The *second* is by the azimuths of the Sun, or of the Moon, or of the fixed stars. For from the complement of the azimuth to a semicircle, as the angle opposite one of the sides, and from the complement of the declination of the stars to a quadrant, as one side, and from the distance of the zenith from the pole of the equator, as the other side, one obtains, by the analysis of a spherical triangle, the angle contained by those sides. This angle measures the equatorial distance of the star from the meridian; added to the right ascension of a western star, or subtracted if the star is in the eastern quadrant, it leaves the right ascension of mid-heaven, that is, the point of the equator then culminating. From this at last, and from the right ascension of the Sun at that moment, the time from noon is found. But how slippery the practice of azimuths is, although Kepler trusts it too much in the *Astronomia Optica*, p. 375, Tycho had already warned in his *Mechanica Astronomica* and in the first volume of the *Progymnasmata*. We, so as to err here as little as possible, are accustomed to wait for the centre of the star until it passes through the plane of a vertical circle already determined and passing through the limits of whole degrees; to mark that plane with our thread triangle, that is, one consisting of threads, of which more below; and from the azimuth taken to count the times of the pendulum up to the desired phase of the phenomenon.

[Margin: 3. Method.]

The *third* method is by the equatorial distance from the meridian of a fixed star by night, or of the Sun by day, taken with equatorial armillaries [Armillis Æquatorijs]. Tycho considered this method most certain, in the *Epistolae Astronomicae*, p. 72; but the complicated construction and use of the armillaries do not satisfy as well as we should wish, as we shall teach in the *Liber Organicus*.

[Margin: 4. Method.]

The *fourth* method is by the altitude of the Sun by day, or of some fixed star by night, or, if clouds prevent this, by the altitude of the Moon. These apparent altitudes must be reduced to true ones, by adding the parallax and subtracting the refraction, if they have any that is sensible. It is well, however, to avoid the altitude of a star when it is nearer the horizon or the meridian: there, lest it be exposed to refractions that may be extraordinary; here, lest a difference from the meridian altitude that is insensible or small over much time produce a

great error in the time. The instruments with which the altitude of a star, or its distance from the zenith, is taken must be divided most exactly, and show single minutes of degrees, or even aliquot parts of minutes; the pinnules must be fixed exquisitely in their position; the plane of the instrument must first be set most perfectly to the perpendicular of the horizon; and the whole instrument must turn at the slightest touch, so that as soon as one of the observers has given the signal for taking the altitude, its plane can be directed at the centre of the star, and it or the alidade [dioptra] raised; and yet, if it has been tilted from the perpendicular position by that motion, it can at once be restored to the perpendicular position. All of this cannot be managed with Tychonic quadrants, as I shall teach in the *Liber Organicus*, where I shall also teach a more certain way of setting up these instruments quickly and fitting them at once in the required position. How the culminating point of the equator is obtained from the altitude of a star and its declination and right ascension, and from that and the right ascension of the Sun the time from noon, belongs to the problems of the primum mobile. Here someone might well wonder with what unconcern, not to say carelessness, Kepler, otherwise an outstanding weigher of minutiae [apicum trutinator], used in this business quadrants or astrolabes of paper, of the size of a three-quarter foot or a span, as is established from his *Optics*, pp. 367 and 368. But there he admits that he took the altitudes [Greek: ὁλοσχερῶς (holoscherōs, "roughly, in the gross")]; otherwise it is established that Tycho, at p. 72 of the *Epistolae Astronomicae*, condemned the observation of an eclipse made both by Heinrich Brucaeus [Henrico Brucæo] with a small brass quadrant, and by Paul Wittich [Vuitichio] with the large Landgrave's quadrant, but not duly set up.

[Margin: 5. Method.]

The *fifth* method is by the culminations of the stars, that is, their transits through mid-heaven or through the meridian, if you have previously obtained a most exact meridian line, and the plane of some instrument has been set on it, inclined to neither side with respect to the horizon but standing on it most exquisitely to the perpendicular, or at right angles. For since the right ascension of the star, as also of the Sun, is supposed to be known beforehand, the difference of the right ascensions, converted into times, gives the time from noon without any analysis of triangles. Therefore, if the beginning or another phase of the eclipse happens to take place at that moment, the matter is finished and you have got what you wanted; otherwise the interval of time between such a transit and the phase preceding or about to follow must be counted by the methods indicated under Problem 6, but above all with the help of the pendulum and its oscillations. This is not, however, the place to teach the way of obtaining a most exact meridian line; I presuppose it, partly from what was said in Book 1, chapter 10, partly from what will be said in Book 10. The greater difficulty lies in finding and using a plane that exactly represents the plane of the meridian and is in no way inclined from it. For the use of an ordinary plumb-line with a cord parallel to the very plane of a quadrant or astronomical

square, or to the plane of an astrolabe, does not attain so great a fineness and evi- dence as we require here. Not undeservedly does Wendelen, in his preface to the *Eclipses*, all but laugh at Kepler for saying: *We used large quadrants to note the arrivals of the stars at the meridian.* As if the size of quadrants were enough for this business! We therefore, after trying and rejecting many methods over a long time, have settled on this one alone, which we shall briefly describe in the following figure.

[Margin: Our method of marking out the vertical plane.]

XVI. First let a plumb-line AB be made, whose thread is twisted as little as possible, so that it does not wobble, turned about too much by its own rotation. Let the thread be passed through a fine sewing needle, and let the needle be passed through a metal cone CBD, exquisitely turned on a lathe, whose circular base CD is pierced at its very centre as far as the apex of the cone B. The point of the needle is to reach this apex and indeed to project beyond it; for in this way the parts of the cone will balance all round about the needle, as about the axis of the cone, and the tip of the needle B will lie on the same perpendicular straight line as A when the plumb-line hung from A has come to rest.

Diagram. Woodcut set in the left column, interrupting the sentence just rendered. At left a plumb-line hangs from A, with the cone at its foot: base CD above, apex B below. At upper right a plate with a pivot and two screw-clasps stands at the head of the window; from the loop beneath it a solid line runs obliquely down to the left to E, and a second solid line runs straight down through N to F, so that the threads form the triangle of the text. Along the bottom lies the horizontal rule, with its slotted plate at E on the left and its plate at F, and running on to the right past G to the eye-point O, where an eye is drawn. A dotted line runs from the star S at upper left, crossing the oblique thread, down to the eye at O. A chequered graduated arc is struck from F, from its upper end near the left of N round to its lower end at V; solid lines join N to the upper end of the arc and F to V.

- A (upper left): head of the plumb-line
- S (upper left, with a star sign): the star
- C, D (left, either side of the base of the cone): the base of the cone
- B (left, foot of the cone): apex of the cone and tip of the needle
- L (top right, head of the plate): screw-clasp
- K (top right, on the plate): the pin about which the plate turns
- M (top right, foot of the plate): screw-clasp
- I (right of centre, at the apex of the triangle): the loop
- N (right of centre, above F): notch of the needle-piece
- P, R, E (lower left, set close together as PR and E on the rule): end of the rule, slit and plate
- F (lower right of centre): the point on the meridian line
- G (lower right, on the rule): on the meridian line
- O (lower right, before the eye): place of the eye
- Q (top of the arc): upper end of the arc

• V (foot of the arc): lower end of the arc

Next let there be a very high window or door-leaf in the observatory, say of six, eight, ten or more cubits, and beneath its top a flat marble table, exquisitely levelled so as to be parallel to the plane of the horizon. On this table let there be a most exact meridian line GE, long tested. At the top of the window let a plate be fixed above the meridian line, movable about a small pin K and having a small loop I, from which the plumb-line AB is to be hung, of such a length that its point B almost touches the table already mentioned. Let an assistant be on hand to move the plate ML about K until the plumb-line, at rest from all oscillation and rotation (and to this rest it helps for the place to be closed off all round and protected from every breath of air, even the slightest), stands with its tip on the meridian line itself, say at F. When this has been done, let your assistant or companion clamp the plate to the small beam of the window with the screw-clasps L and M, so that it can no longer be moved from that position. You, for your part, mark the point F on the meridian line, over which the tip of the plumb-line came to rest, and there bore through the stone at right angles with a very small hole. Into this hole insert a piece of sewing needle FN, having its notch N, and solder it to the stone with molten lead. Then let a metal rule OP be made, with projecting plates pierced at F and E by the smallest possible hole, and let the small plate E have an open slit RE running up to the hole E, so that the thread can be put in through it directly. Afterwards fit the plate onto the small cylinder or needle FN. Take a fine thread, as little fibrous as possible, passed through the notch N and tied with a knot, and hang it from the loop I, so that, led through the loop and stretched downward, and passed through the slit R and the hole E, it reaches the small cylinder FN, to which, or to another hole set in the same straight line, it is to be tied. For the thread, stretched in this way, will form the triangle EIF, right-angled at F, whose plane, contained within the threads as its sides, will exactly coincide with the plane of a vertical circle, without any sensible inclination to the horizon; indeed, when the thread EF coincides with the meridian line RG, it will mark out for you the plane of the meridian circle.

So, when you are going to observe a star's transit through the meridian, unless the star is the Sun or the Moon, place two lamps near the threads, with their glare blocked by some obstacle so that it does not strike your eyes. With your head resting on or set into some support, and your eye still at O, where you see the thread EI covered by the thread FI, the visual ray leaving the centre of your eye (let me be allowed for now to speak with the old opticians) will run through the plane of the meridian, or of any vertical you like, at which you choose to await the star's arrival. Therefore, as soon as you see the star optically cut in two by that plane, or by the threads, now acting as one single thread, know that the centre of the star is crossing the meridian, or any other vertical, and give a signal to your companion, who must either take the star's altitude or count the times of another pendulum. But it is advisable to have warned him beforehand that the star is about to reach that position, so that he

may check the position of the quadrant and be ready for a sudden and precise capture of the altitude. In this way we have been accustomed to wait for the stars at a fixed degree of the circle VQ etc., described from the centre F, and to take azimuths much more accurately than, as far as we know, has been done so far by earlier astronomers. Nor can there be any doubt that the stretched thread EF marks out a perfectly straight line more evidently than the edge of any ruler.

[Margin: A reliable way of taking azimuths.]

While these pages were about to go to press, Father Iacobus Viua [?], S.J., wrote to me from Rome that Johannes Hevelius has published his *Selenographia*, cut and engraved with his own hands in a most graphic manner, in which he teaches a way of observing lunar eclipses by the Moon's spots and by the passage of the section of the shadow across them, in almost the same manner that I indicated above and had already told that same Father about. He adds that this same author directs that the vertical point of the Moon's upper limb be observed at every notable phase of the eclipse. This is done by noting two or more small spots that at that moment lie on the same perpendicular line, since that line, produced upward, will lead to the point already mentioned. He also wants the centre of the lunar disc as it appears to us to be observed, which he says varies every month, and indeed every day, because of the motion of the Moon's libration. This motion, which I have so far thought could be attributed to the variation of latitude, I shall not unwillingly accept, once I have obtained and read through this author's whole work, if observations persuade me of it; for I do not aim at [Greek: φιλοδοξίαν (philodoxian, "love of reputation")], but at [Greek: φιλαλήθιαν (philalēthian, "love of truth")].

[Margin: An addition from Johannes Hevelius.]

[Margin: On the motion of the Moon's libration.]

SCHOLIA.

Scholia.

I. To observe the quarters of eclipses, and to determine from the position of the horns their parallelism to the Moon's path, it helps, besides the doctrine of the primum mobile, to inspect an armillary sphere, or zodiacal armillaries duly set so as to correspond to the position of the celestial sphere. It is also useful to take the distances of the Moon's edges from fixed stars on either side, which Kepler attests in his *Optics*, p. 370, was done by Tycho; and to draw an arc through the centres of the Moon and the shadow and through some fixed star, with imagination and the eye as guide, or with a thread stretched between both hands; and to mark out the verticals with the azimuths in which the luminaries stand, which you will do very well with our thread triangle; and, if greater [Greek: ἀκρίβεια (akribeia, "precision")] is desired, to take at the same moment the altitude of each horn, or their distance from two fixed stars.

II. The great and frequent disagreement between observations and astronomical tables, at which you will marvel again and again in the history of eclipse observations to be given in chapter 19, and of which we have already given a sample in Book 4, chapter 21, no. 9, sometimes arises from the observation itself, because not everything discussed in the preceding chapter was exactly kept: as if smoke and umbrago were taken for the true eclipse, or the moments of the phases were not corrected, or some small cloud deceived the observer, or the instruments were not exactly made or placed, or were not used with care, and at the very instants of the phases, etc. Sometimes, however, even though the observation has been diligent and accurate in every respect, the error lies in the calculation by which observations are examined through trigonometry, either through the fault of tables swarming with mistakes, or through a slip of the pen, or through a disturbed and less attentive imagination. This happens also in the calculation by which eclipses, especially solar ones, are predicted, at times even to practised men, and Homerically

[Margin: Cause of the disagreement between observations and astronomical tables.]

nodding. Sometimes, finally, it arises from the very hypothesis on which the astronomical tables rest, when it is false and in places in conflict with itself; of this conflict we have already given examples in Book 3, chapter 11, no. 8, and in this very book, chapter 4, no. 14. And indeed so many elements sometimes come together for a single practical conclusion, or for completing one problem (such as the position of the meridian line, the altitude of the pole, the declination and right ascension of the stars, the obliquity of the ecliptic or of the Moon's path, the semidiameters of the luminaries and of the shadow, the latitude, the arc through the centres, the intricacies of parallaxes, and things like them), that one would have to be an Argus, not to say an angel, for no sensible error to creep in from all of these together. It is therefore very hard to judge to which side the cause of the disagreement should be referred, especially when the calculation is transferred from one meridian to another. And there is hardly any observer who does not commend his own diligence in observing. When, however, the calculation promises an eclipse that is either very large, or total, or with a sensible stay, and yet by the agreement of the observations there was none, or a slight one, or not a total one, or one without a sensible stay, the presumption stands against the tables. I hope, however, that from what we have said, and shall say in chapter 19, posterity will be roused to observe eclipses most accurately, and that astronomy will thereby be advanced to a wonderful degree.

[Margin: Why the image of the Sun in its eclipse is crescent-shaped, but the Moon's is not in a lunar eclipse.]

III. Aristotle asks (section 15, problem 10) why, in an eclipse of the Sun, rays passed through a sieve, or broad leaves, or crossed fingers onto the pavement appear as little crescents. He answers that this arises because the Sun's rays are forced into two cones, one having its base on the Sun, the other on the

pavement, and each its vertex in the hole; that this base would be circular if the interposed Moon did not intercept part of the rays, according to the shape of the segment occupying the Sun; that for this reason what is lacking from the circle of the bright base appears crescent-shaped on the ground, as does the remainder of the bright base; but that in the bright image of the Moon, whether failing or not yet full, this does not appear, because the brightnesses of its extremities are not manifest, or do not evidently move the sense. See, if you like, our own Biancani in his exposition of that passage, marginal number 350.

CAPVT XVI.

Chapter 16.

In quo Comparatio ſeu Antitheſis Eclipſium Lunæ, Solis, ac Terræ.

In which a comparison or antithesis of eclipses of the Moon, of the Sun, and of the Earth.

I. I am pleased to gather, by way of epilogue, the more notable marks and properties by which eclipses of the Moon and of the Sun or Earth differ from one another. We shall do this more briefly under one and the same heading, setting apart eclipses of the Moon on the left and of the Sun or Earth on the right, and yet we shall point out far more than do Peuerbach in the *Theoricae*, and Reinhold there, p. 204, and Wurstisen, p. 340; Magini, *Theoricae Planetarum*, Book 2, chapter 31; Barozzi, *Cosmographia*, p. 328; Biancani, *Sphaera*, Book 10, chapter 19.

[Margin: Essence. Cause. When visible. Occasion of the eclipse. Universality. Quarter toward which they incline. Greatest duration. Frequency. Affinity. Intervals.]

☾ Eclipse of the Moon.	☉ Eclipse of the Sun and of the Earth.
1 It is a deprivation of the Sun's primary light in the Moon, and so a true defect of the Moon.	1 It is a deprivation of the Sun's light not in ☉ but in the sublunary region; and so a true defect, not of ☉, but of the Earth and of the sublunary region.
2 It is caused by the shadow or penumbra of the Earth interposed between the Sun and the Moon.	2 It is caused by the shadow or penumbra of the Moon interposed between the Sun and the Earth.
3 It can be seen only at night, or at the extremes of the night.	3 It can be seen only by day, or on the boundary of day and night.
4 It occurs only at a true ☍, at full Moon.	4 It occurs only at an apparent ☌, at new Moon.
5 It is universal to the entire and whole nocturnal hemisphere of the Earth, and of equal magnitude and duration for all who watch it, except for a very few to whom an eclipse appears total that is not total for most.	5 It is not universal to the whole diurnal hemisphere: to some it appears greater and longer, to some smaller and shorter, or not at all; to some, on the contrary, total, or central and annular, and to others corniculate.
6 It ordinarily begins at the eastern edge of the Moon and ends at the western.	6 It ordinarily begins at the western edge of the Sun and ends at the eastern.

☾ Eclipse of the Moon.	☉ Eclipse of the Sun and of the Earth.
7 In the greatest partial obscuration, the obscured part inclines to the north if the Moon's true latitude is southern; but to the south if the latitude is northern.	7 In the greatest obscuration, the obscured part inclines to the south, if the apparent latitude is southern, for those in the north; to the north, if it is northern.
8 It has its greatest duration, of about 4 hours, with ☾ and ☉ at apogee.	8 It has its greatest duration with ☉ at apogee and ☾ at perigee: about 3 hours in the same region; about 5 in different ones.
9 It occurs more often than a solar eclipse in the same region of the Earth.	9 It occurs more often than a lunar eclipse in different regions of the Earth.
10 When it occurs at the node or very near it, the new Moon on either side has had or will have a small eclipse of the Sun.	10 When it occurs at the node or very near it, the full Moons on either side are entirely free of any eclipse.
11 When it occurs far from the node, it has a neighbouring ecliptic new Moon.	11 When it occurs far from the node, it has a neighbouring ecliptic full Moon.
12 It can occur twice in a year: in the sixth month after the former; rarely, and small, in the fifth; never in the seventh.	12 It can occur twice in a year: in the sixth month after the former; rarely, and small, and toward the same pole, in the fifth and seventh.
13 It cannot occur twice in the same month, that is, at two successive full Moons.	13 It can occur twice in the same month, but not toward the same pole.
14 In the same solar year it cannot occur more than three times.	14 In the same solar year it cannot occur more than five times.

CAPVT XVII.

Chapter 17.

De Vſu Crucis Noſtræ Geographicæ, pro non fruſtra admonendis futuræ Eclipſis obſeruatoribus, & aut pro tranſlatione calculi Ecliptici non fruſtra ſuſcepta ad alia atq. alia Terræ loca.

On the use of our Geographical Cross, so that the observers of a future eclipse may not be alerted in vain, and or [?] for a transfer of the eclipse calculation, not undertaken in vain, to one place on Earth after another.

I. Nineteen years ago I was thinking about transferring the calculation of eclipses to other places on Earth, so that a single labour might serve all for whom it could be done. I saw that what was needed for this above all was to distinguish day from night at one horizon after another, lest we should labour in vain, in a lunar eclipse for regions in which it will be day, or in a solar eclipse for those in which it will be night, for the whole time of the eclipse. And finally I saw that it was very tiresome to look up the altitudes of the pole one by one, and the semidiurnal arcs according to them, and that these could not be represented at once, at a single glance, on geographical globes. So I set my mind to devising a way by which, for any given moment of a given day, there might easily be represented on some geographical map all the places of the Earth, at least within the Torrid and Temperate Zones, in which the Sun would then be rising on this side and setting on that, and in which it would

be noon on one side and midnight on the other. From this one might see at a single glance where at that same moment it was day and where night; and what hour it was at any place whatever, reckoned from noon or before noon, from midnight or before midnight, from sunset or sunrise, or before sunset and sunrise; and finally in what proportion northern places had a greater or a smaller semidiurnal or diurnal arc than southern ones. This at length, with God, Best and Greatest, favouring our efforts, we found could be done in less time than it takes to say so, with the help of an instrument to which we gave the name of GEOGRAPHICAL CROSS; for it consists of two fine rulers, of which one represents the meridian and the other the equator, bisected at right angles by the meridian. The equator of this cross carries at its ends two arms imitating the shape of a large, Latin sigma, whose position and suitable inclination toward the meridian resolve all the problems already mentioned. But since, as early as the year 1643, with friends wresting it from us, we published at Bologna a little work in which the construction and use of this instrument are explained, together with a geographical map adapted to it, and since the same is to be inserted in our *Geographical Book*, which will be the fourth of volume 2 of the *New Almagest*, we refer the reader there.

[Margin: Application of the Geographical Cross to eclipses.]

II. Now therefore, if you duly place the Geographical Cross on our geographical map for the time of the beginning, middle and end of a lunar eclipse, you will at once be able to view on it, at a single glance, all the regions of the three principal zones in which it will be night, and in which, on the contrary, day; and so which places are suited to observing the whole eclipse, or its beginning, or middle, or end. For eclipses of the Sun, however, one must find the beginning and end of the eclipse of the Earth, that is, the moment at which the Moon's shadow or penumbra begins or ceases to be on the face of the Earth, according to Problems 9, 10 and 11 of chapter 12, and at those moments apply the Geographical Cross to the map, so that with its arms it embraces the tracts of land in which it will be day for the whole time of the eclipse, and for which, as far as this part is concerned, the labour of calculation will not be in vain.

CAPVT XVIII.

Chapter 18.

De Miraculo Eclipſis Solis in Morte CHRISTI Domini, & de Eclipſibus Præternaturalibus Extremam Mundi Diemne an Noctem? portendentibus.

On the miracle of the eclipse of the Sun at the death of Christ the Lord, and on preternatural eclipses portending the last day of the world, or its night?

I. The properties of natural eclipses of the Moon and Sun explained so far, and their antithesis briefly set out in chapter 16, remind us that before the history of all other eclipses we should recall the sacred horrors of that eclipse, and the

wondrous darkness from which the immortal divinity of Christ, dying on the cross, flashed out like lightning through the clouds of the world. That darkness, ending with its shadows the shadows of the old Law, offered itself as a most brilliant dawn to the Gospel. And to the great Dionysius, accustomed long ago to judge most justly in the darkness of the Areopagus, it brought, by its own, so to speak, sacrosanct darkness, such a splendour of almost prophetic light that, most justly and most wisely alike, he burst out from the miracle into that oracle: *Either the God of Nature is suffering, or the machine of the world will be dissolved.* For this reason we take up in this same chapter two kinds of eclipses divinely ordained above the order of nature: one, which was a witness of the divinity and innocence of God in Christ, most unjustly judged by men; the other, of those which will go before the machine of the world, now on the very point of dissolution, and before God in the same Christ, who will most justly judge the world.

[Margin: History of the eclipse of the Sun at the death of Christ, from the Gospel.]

II. First, then, concerning the former, we read thus in the sacrosanct Gospel: in Matthew, chapter 27: *From the sixth hour darkness fell over the whole earth until the ninth hour.* Then in Mark 15: *And when the sixth hour had come, darkness fell through the whole earth until the ninth hour.* But St Luke, chapter 23, is more expressive still: *It was about the sixth hour, and darkness fell over the whole earth until the ninth hour, and the Sun was darkened, and the veil of the temple was torn in the middle.*

[Margin: Oracles concerning this eclipse.]

This same eclipse had been foretold long before by Jeremiah 15, in these words: *Her Sun set while it was still day*; or, as St Jerome reads on Matthew 27: *The Sun went down while it was still midday.* And by Amos, chapter 8, in these words: *The Sun will set at noon, and I will make the earth grow dark on a day of light.* For St Jerome refers both prophecies to this event in the passage just cited; and indeed also that of Joel, chapter 2: *The Sun will be turned into darkness and the Moon into blood, before the great and horrible day of the Lord comes. And it shall be: Everyone who calls on the name of the Lord will be saved; for on Mount Zion and in Jerusalem there will be salvation.*

[Margin: St Jerome's interpretation.]

Since St Peter (Acts 2) and St Paul (Romans 2) cited these words to confirm this time of Christ's first manifestation, St Jerome therefore says in his commentary on Joel 2: *The Sun too was turned into darkness, when it did not dare to look on its Lord hanging; and the Moon into blood. This we may either believe happened according to the history, and these things were passed over in silence by the Evangelists (for not everything that Jesus did is reported in writing, etc.); or certainly, just as the Sun was turned into darkness, not because it was itself changed into darkness, but because it brought darkness over the world, so too ☾ was not turned into blood, but condemned the Jews, covered with the horror of blasphemies and of denial against Christ, by the eternal blood of their own testimony, when they said: His blood be upon*

us and upon our children. All these things he describes as going to happen before the great and horrible day of the Lord. The great and horrible day of the Lord, moreover, must be believed to be either that of the resurrection, or certainly, many ages later, the day of judgement, which is truly great and horrible. But since there follows: And it shall be that everyone who calls on the name of the Lord will be saved, and the Apostle Paul refers this to the time of the Lord's passion, it is rather to be understood of the day of the resurrection. And further down in the same place: *This passage is most difficult, and admits a threefold explanation: so that, under tropology, we may refer everything that has been said to those times to which the Apostles Peter and Paul referred it, that is, when he suffered and rose again.* Salmeron [Alfonso Salmerón] subscribes to this opinion, vol. 10, tractate 42, which is entitled *On the Darkness from the Sixth Hour.*

[Margin: Oracles of the Sibyls.]

To these is added the Sibylline oracle from Book 1 of the *Sibylline Oracles*:

But when, with hands spread out, having measured all things, he has borne a crown of thorns, and a reed, driven by hand, has pierced his side, for his sake, for three hours, a dark and monstrous night will fall at midday.

And that of another Sibyl, in Salmeron, above: *And the veil of the temple will be torn, and at midday there will be night for three hours.*

[Margin: Phlegon's testimony on this eclipse.]

Moreover, this enormous failing was also entered in his annals by Phlegon Trallianus [Phlegon of Tralles], Hadrian's freedman, on whom Suidas says more, and an outstanding reckoner of the Olympiads, as Origen relates, tractate 35 on Matthew, saying: *And Phlegon indeed wrote in his Chronicles that this happened in the principate of Tiberius Caesar, but he did not indicate that it happened at full Moon.* And in *Against Celsus*, Book 2, where he says: *Of the Sun darkened in the time of Tiberius Caesar, in whose reign Jesus is believed to have been fixed to the cross, and of the great earthquakes that then occurred, Phlegon wrote in the thirteenth, or as I judge the fourteenth, book On Times.* Eusebius Cæsariensis [Eusebius of Caesarea] also, in his *Chronicle* for the year of Christ 33, seems to recite the testimony not only of Phlegon but also of other pagans on these matters, when he speaks thus: *Jesus Christ, the Son of God, etc., according to the prophecies that had been uttered about him, came to his passion in the 18th year of Tiberius; at which time we find also in other commentaries of the pagans these things written word for word: An eclipse of the Sun took place, and darkness over the whole earth; Bithynia was shaken by an earthquake, and in the city of Nicaea very many houses collapsed. — All of which* (says Eusebius) *agree with what happened in the Saviour's passion.* Then he cites Phlegon as a distinct witness, saying: *Phlegon too, who is an outstanding reckoner of the Olympiads, wrote about these things, saying thus in his fourteenth book: — In the fourth year of the 202nd Olympiad a great eclipse of the Sun took place, one excelling all that had happened before it: the day at the sixth hour was turned into dark night, so that the stars of the sky were seen; and an earthquake in Bithynia overthrew many houses of the city of Nicaea.*

This testimony of Phlegon is then adduced on this matter above all by Cedrenus [Georgios Kedrenos] in the *Annals*, p. 155; Scaliger, Book 6, *De emendatione temporum*, p. 561; Baronio at the year of Christ 34, p. 176; Salmeron, vol. 10, tractate 42; Salianus in the *Annals* at the year of the world 4086, of Christ 33, no. 54; Cornelius à lapide [Cornelius a Lapide] on Matthew 27, verse 45.

[Margin: Testimony of St Lucian the Martyr.]

But long before, for the testimonies of the Gentiles already mentioned, the pagans themselves are cited, both by St Lucian in the acts of his martyrdom, in Eusebius, *Ecclesiastical History*, Book 9, chapter 9, who says: *I bring forward the Sun itself as a witness of these things for us, which, when it saw these things being done on earth by the impious,*

hid its light at midday in the sky. Search your annals, and you will find that in the time of Pilate the Sun was put to flight and the day broken off by darkness. And by Tertullian in the *Apologeticum*, where he has this to say about Jesus:

[Margin: And that of Tertullian.]

Yet, once nailed up, he showed many marks proper to that death of his; for he gave up his spirit of his own accord, with a word, forestalling the executioner's office. At that same moment the day was overcast, while the Sun was marking the middle of its circuit. Those who did not know that this too had been foretold concerning CHRIST certainly took it for a failing; and yet you have that disaster of the world recorded in your archives.

That stars were seen at that time is affirmed not by Phlegon alone, but also by Paulus Orosius, Book 7, chapter 4, whose words are these:

[Margin: Testimony of Paulus Orosius.]

On that same day too, at the 6th hour of the day, the Sun was wholly darkened, and a black night was suddenly drawn over the lands, and the impious ages feared eternal night. It is so plain that neither the Moon nor clouds stood in the way of the Sun's light that the Moon, on that day in its fourteenth day, is reported to have been very far from the sight of the Sun, with the whole region of the heavens lying between them, and that the stars then shone over the whole sky during the hours of daylight, or rather in that dreadful night. This is attested not only by the faith of the holy Gospels, but also by a fair number of books of the Greeks.

St Augustine too speaks as follows:

[Margin: And of St Augustine, Letter 80, to Hesychius.]

That failure of the Sun when Christ was crucified was not such as the other failures of the ☉, but truly marvellous and prodigious. But through the jealousy of the pagan Romans, lest heaven be thought to have mourned the death of Christ as of a divine man, they had this written down in their annals, yet forbade it to be made public.

Sedulius also chimes in, in Book 4 of the *Paschal Work*, as follows:

[Margin: Verses of Sedulius on the same eclipse.]

Meanwhile dreadful darkness suddenly came on and held the whole pole, and with mournful funeral rites wove the blackening day; the Sun, hiding his flashing rays in a cloud, veiled in a foul mantle, lay concealed, and filled the sad world with lamentation.

Because Delia, full, had her brother opposite her, when she was beneath the earth and he above at the height of heaven, the impious ages feared perpetual night.

III. But among so many ancient assertors of this eclipse none, the Evangelists excepted, is older or more trustworthy than the most clear-sighted eyewitness himself, St Dionysius the Areopagite. Having taught that the order and motion of the heavens can be changed by the power of God alone, of which kind was the Sun's retreat through 10 lines, he says:

[Margin: Testimonies of St Dionysius the Areopagite on this eclipse. Letter 7, to Polycarp.]

This rightly and deservedly terrified the Babylonians, and without a battle subjected them to Hezekiah, as though he were equal and like to God and surpassed men. I do not speak of the great works performed in Egypt, or of certain other signs and portents of God that happened elsewhere, but of those common and heavenly, which are celebrated both throughout the universe and on the lips of all. But Apollophanes flatly denies that these things are true. The priests among the Persians especially relate this by report, and the Magi moreover perform rites in memory of the threefold Sun; but let him indeed be allowed, through ignorance or inexperience, not to believe these things. Ask him, however, what he thinks about the failure of the Sun that occurred when the Saviour was driven onto the cross. For we were together, both of us, and were standing at Heliopolis, and we saw the Moon unexpectedly falling upon the Sun, for it was not the time of conjunction; and again the same Moon, from the ninth hour until evening, setting itself against the middle line of the Sun, contrary to the order of nature. Recall something else to his memory as well. For he knows too that the incidence itself was seen by us to begin from the rising of the Sun, to reach the Sun's edge, and then to vanish; and again that the incidence and the withdrawal did not occur from the same part of the Sun, but from the part that was, so to speak, diametrically opposite. These are the marvels of that time, which CHRIST, author of all things, alone can bring about, who does great and marvellous things without number. Refute these things, Apollophanes, if it is lawful for you and if you can, even against me, who was then, as you know, with you, and was present, and saw, and examined everything with the greatest wonder. Then indeed Apollophanes began even to prophesy, I do not know from what source, and, as if comparing with me what was happening, said this: These, Dionysius, are changes of things divine. Let this much be said by us, as far as the nature of a letter required. But you can both supply what is lacking and perfectly offer and consecrate to GOD a man who is endowed with great wisdom, and who perhaps will not be unwilling to learn calmly the most wise truth of our religion.

Again, writing to Apollophanes himself, who had by then surrendered to the truth, he writes as follows in Letter 11:

[Margin: A second testimony of St Dionysius.]

But as soon as the heavenly light of the Father's glory, by its own will, disposed its splendour to shine into the darkness of your mind, it straightway poured into the inmost chambers of my heart that I should set before your eyes a most pious recollection and memorial of what was done. Namely: at Heliopolis, you nearly my contemporary and I passing a span of about twenty-five years, we had settled and were staying

together, when, on a certain sixth day of the week and also at nearly the sixth hour, the Sun was suddenly covered with horrible darkness, with the Moon passing across it, because, being not God but a creature of God, it could not shine at the setting of that true light. For I was then asking you, who seemed to me truly very wise, what you yourself thought of it; and you with wonderful prudence added something that stuck so deep in the inmost parts of my mind that no forgetfulness can erase it, no image of death ever wear it away. For we ourselves were covered in darkness, the gloom occupying the Sun's disc on every side and evenly; and after the cleansing and restoration had been made, the Moon, turned to the Sun's diameter, fled away. And then too we took up the canon of Philip Arrhidaeus; and when we had found, what was also very well known, that the Sun could by no means have suffered an eclipse at that time, and that nonetheless the Moon had covered the Sun's radiance from the east with dark, blackening veils, though she usually comes under the Sun from the western side. Then, having wandered as far as the western bounds of the Sun, as we ourselves thought, she hid the light-making treasures with the darkness she herself had begotten, though the Moon lacked that time too, and the time of the synod was known not to be near. Then I said to you (for I was not yet aware of the mystery of so great a thing): O storehouse of immense prudence, what, I say, O mirror of learning, Apollophanes, do you ascribe to these secrets? To this you, by I know not what divine inspiration and not by human sense, added: These, good Dionysius, are surely changes of things divine. At last, having found by experience that the day of the week and the year, carefully noted, agreed and accorded with the announcement that holy Paul poured into our attentive ears, the signs consenting, I submitted my hands to the truth and was released from the bonds of falsehood. This truth I extol marvellously and share with you, the truth that is the way and the life and the true light, which enlightens every man coming into this world; and to it you at last, as a truly prudent man, have come.

O splendid gloom, O eclipse to be kissed, which joined these two wisest lights of Greece, Dionysius and Apollophanes, made subject to CHRIST, the eternal light!

Although some suspect these Letters of St Dionysius to be spurious, they are nevertheless accepted as genuine by St Thomas Aquinas, part 3, question 44, article 2; by Baronio, Cornelius à Lapide and Salmerón, with most of those in the places listed earlier; and by Neander, Maurolycus, Clavius, Barozzi and Biancani, who are to be brought forward below. This can be confirmed both from Michael Syngelus [Michael Syncellus] in the *Encomium of St Dionysius* and from Suidas in two places, where they add that, having heard Apollophanes, he cried out:

[Margin: What the exclamation of St Dionysius was.]

[Greek: ἄγνωστος πάσχει θεὸς δι' ὃν τὸ πᾶν ἐζόφωται καὶ σεσάλευται (agnōstos paschei theos di' hon to pan ezophōtai kai sesaleutai)], that is, *The unknown God is suffering in the flesh, and therefore the universe is shaken and darkened by this darkness*; or at any rate [Greek: Ἢ τὸ θεῖον πάσχει, ἢ τῷ πάσχοντι συμπάσχει (ē to theion paschei, ē tōi paschonti sympaschei)], namely *Either the Divinity is suffering, or it suffers with one who suffers*. Granted that, by a certain

tradition, that saying now goes around: *Either the God of nature is suffering, or the machine of the world is being dissolved*, as Sacrobosco reports at the end of the *Sphere*; Barozzi at the end of the *Cosmographia*; Biancani, Book 10, chapter 19; Salmerón above; Fonseca and Cornelius à Lapide. But the earlier words are reported by Neander in the *Elements of the Doctrine of the Sphere*, p. 130, and by Maurolycus in dialogue 3 of the *Cosmographia*, p. 86, from the *Onomasticon* of Suidas.

IV. That is now enough, and more than enough, of witnesses for the truth of the eclipse already mentioned. I now pass on to discussing its efficient cause, intending to speak later about the final cause; on the efficient cause I find eight opinions.

[Margin: 1. Opinion: on the withdrawal of the Sun's rays.]

The first is that of those who attribute it to the Sun itself, withdrawing its rays and as it were reabsorbing them inward. St Cyprian favours them in the sermon *On the Good of Patience*, saying: *Since the Sun, lest it be forced to look on the crime of the Jews, withdraws both its rays and its eyes.* St Chrysostom also favours them, as is contained in the *Catena*, in the sermon on the Lord's Passion: *The creature could not bear the injury done to the Creator; hence the Sun drew back its rays, so as not to see the crimes of the impious.* With these St Jerome agrees, on Matthew chapter 27, saying: *It seems to me that the brightest light of the world, that is, the greater luminary, drew back its rays, so that it should neither see the Lord hanging, nor the blaspheming impious enjoy its light.* Although Saints Cyprian and Chrysostom seem to have said these things metaphorically and in the manner of preachers, or almost poetically, as Virgil had sung, in Book 1 of the *Georgics*, about the Sun darkened after the slaying of Gaius Julius Caesar:

He too, with Caesar dead, took pity on Rome,
when he covered his shining head with dusky rust, and the impious ages feared eternal night.

St Jerome, however, seems to have adduced it as the more probable cause. For he had said: *Those who wrote against the Gospels suspect that the disciples of Christ, through inexperience, interpreted a failing of the Sun, which usually happens at fixed and appointed times, with reference to the Lord's resurrection; though a failure of the Sun never usually occurs except at the rising of the Moon. And no one doubts that at the time of Passover the Moon was at its fullest. And lest perhaps the shadow of the earth, or the disc of the Moon set opposite the Sun, should seem to have made a brief and rust-coloured darkness, a span of three hours is stated, so that every occasion for cavil might be removed.* And, after a few words in between, he adds: *And it seems to me that the brightest light of the world, etc.*, as already reported. To the same opinion Salmerón adds Cajetan and Paulus Orosius; but Orosius only denies that that eclipse was produced by the Moon or by interposed clouds, as is plain from what was said in no. 2.

[Margin: 2. Opinion, of Euthymius.]

The second opinion seems to be that of Euthymius, on Matthew chapter 27: that the cause is God, angered and denying his concurrence to the Sun's rays.

For he says: *This happened after they had had their fill of insolence and jeering, so that, with their fury now subsiding, something could be done by the miracle. For it was more wonderful for the one hanging on the cross to do these things than to come down from the cross. But if they did not suppose that he was doing these things, but that they came about with God working them, they surely ought to have been afraid, and to have understood that God had been moved to anger on this man's account. For they could not say that it was an eclipse of the Sun according to nature, since such an eclipse both occurs in one moment of time, and in one part of the earth, and not on the fourteenth day of the Moon; whereas this darkness both lasted up to three hours, and was over the whole earth, and fell on the fourteenth day of the Moon, when it is impossible according to nature for an eclipse of the Sun to occur.*

[Margin: 3. Opinion, of Origen.]

The third opinion was that of Origen, tractate 35 on Matthew. There he recounts at length the slanders of some against the Gospel, on the ground that it narrates an eclipse of the Sun at an unsuitable time, namely that of the full Moon; and who do not accept the answer of the faithful, who say that this happened not naturally but by a divine prodigy, on the ground that no one among the Greeks or barbarians records it in their chronicles, nor does Phlegon, who mentions it, say that it occurred at full Moon. So, in order to cut away the handle for slandering the Gospels, he says: *We say therefore that Matthew and Mark did not say that a failure of the Sun occurred then, nor did Luke, according to most copies, which have it thus: And darkness came over the whole earth, and the Sun was darkened; but in certain copies it does not stand as: Darkness came and the Sun was darkened; but thus: Darkness came over all the earth, the Sun failing.* He attributes this change of phrase either to one of the faithful who thought that that darkness could not have come about otherwise than through a failure of the Sun, or to one of the unbelievers, so that an occasion for slandering the Evangelists might arise from it. Finally he concludes that that darkness came over the whole earth, but that of Judea only, in which alone the rocks and the veil were split, and that it came from clouds. For he says: *We answer first of all that the Evangelists did not name the Sun at all in that place, but only that darkness came over all the earth. For if darkness came over all the earth with the Sun not named, it follows without doubt that one should understand certain very dark clouds, and perhaps not one but many, and larger ones, to have gathered over the land of Judea and Jerusalem to cover the Sun's rays.*

[Margin: The opinion of Origen rejected.]

But Origen is not consistent with himself, since he admitted that that particle is found in most copies of St Luke: *and the Sun was darkened*; and we are in any case obliged to follow it in the Vulgate version by the precept of the Holy Council of Trent and of Clement VIII. Next, the authority of Phlegon stands in the way, which was not unknown to Origen: he, like Paulus Orosius too, says that stars were then seen in the sky, and those thick clouds would surely have blocked them. Finally, the Evangelists did not say over the whole of that land, or over the whole land of Judah, but absolutely over the whole earth: [Greek:

εἰς ὅλην γῆν (eis holēn gēn, "over the whole earth")], or [Greek: εἰς πᾶσαν τὴν γῆν (eis pasan tēn gēn, "over all the earth")]. It agrees less with the letter, therefore, to confine that darkness, with Origen, Euthymius and Maldonato [Juan Maldonado], to Judea alone, than, with Chrysostom, Theophylact and others, whom Salmerón and Cornelius à Lapide follow, to extend it to the whole earth; and that better befits the power of God in this miracle, as we shall say below.

[Margin: 4. Opinion, of Kepler.]

The fourth opinion is Kepler's, in the *Epitome of Copernican Astronomy*, p. 896. There he deals with spurious eclipses, some of which are produced by globes of ash belched out by Vesuviuses, of which kind, he says, was the one that Cassius Dio reports seen under Domitian, when Vesuvius had spewed ash as far as Palestine. Because an earthquake usually accompanies or precedes these, and the eclipse at our Saviour's death came with an earthquake, he inclines to the view that it arose from ash spewed upward, and he compares it with the eclipse of Dio. For he says: *Compare also that darkness which veiled the Sun at the time of the Passion of our Lord; for it came with an earthquake, although Dionysius the Areopagite, in Suidas, ascribes this darkness to the motion of the Moon.* And he had held the same in the *Astronomia Optica*, taking no account of the authority of Dionysius.

[Margin: It is refuted.]

But this is to detract from the miracle; there would then have been neither darkness over the whole earth, nor stars seen in the sky, against the authority of Phlegon and Orosius.

[Margin: Kepler's bold cast of mind, here and on the Star of the Magi.]

But I am not surprised that Kepler delighted in detracting from this miracle concerning the luminaries at the death of CHRIST, since he had already detracted from the miracle performed at his Nativity concerning the new star that appeared to the Magi. For he says that it was lit by God, but at the conjunction of Saturn, Jupiter and Mars in the fiery triplicity, which took place in Julian Year 39; that the Magi, from the Chaldaean rules on great conjunctions and their effects, expected that conjunction to rouse some new star naturally; and that God, accommodating himself to them, lit it divinely at that time, and perhaps also placed it in the very location to which the eyes of the Magi were most of all being directed on account of the threefold gathering of the planets. So he says in the book *De Stella Nova* in Serpentarius, near the end of chapter 26, or from p. 134, subjecting to the natural faculty of the stars what the Fathers commonly recognize as a wholly sacred phenomenon and a spectacle born of pure miracle, to the point that they show from it that the Nativity of CHRIST did not depend on the stars or on the rules of the Chaldaeans.

But Julian Year 39 was too far from Julian Year 44 or 45, in which most assert that CHRIST was born. So, in order to be able to assert that he was born only a year or two after the great conjunction of the three superior planets, with only a two-year interval between the appearance of the new star and

the Magi's arrival in Judea, he undertook to defend the Theorems of the Pole Laurentius Suslyga [Wawrzyniec Suślyga], in which that author contends that our commonly used Christian Epoch falls short by four or five years, and that our Saviour was in truth born four years before it is commonly thought. To this end, therefore, Kepler wrote a little work which he calls the *Silva Chronologica* [Chronological Forest], as he openly testifies in its dedicatory letter and at the very beginning of the little work. And so that neither the Gospel of St Luke nor the authority of Phlegon on the year of the beginning of the preaching, or of the Passion, should stand in the way, he says at the end of the *Silva* already mentioned that the Saviour began preaching and came to Baptism at 32 years of age or a little more; and in the Rudolphine Tables, chapter 27, precept 62, he has this: *Phlegon of Tralles, as Eusebius reports, noted in the fourth year of Olympiad 202 a very great eclipse of the Sun at the 6th hour of the day. Eusebius understands this of the eclipse that occurred while the Saviour was hanging on the cross at the feast of Passover.* This year, from his own rules, he gathers to be Year 32 of the common Christian Epoch. Then, however, he adds: *But because the Passion of CHRIST certainly falls in the preceding 31, we understand from this that a corruption befell Phlegon's text, and that the numeral [Greek: γ (gamma, 3)] was changed to [Greek: δ (delta, 4)].* For what does this man, so very eager for innovation, not dare, lest the offspring of his most hot-headed intellect should fail to live?

But I long ago laid the axe to that chronological *Forest*, tangled as it is with the most tortuous knots and thickets of thorns, in my *Chronological Book*, which with God's favour will come out and will be the fifth of the second volume of the *New Almagest*. Tycho, by contrast, was far wiser in recognizing the Star of the Magi as wholly supernatural, volume 1 of the *Progymnasmata*, p. 325, condemning Cardano of impiety for having counted it among the comets.

[Margin: 5. Opinion, of Cornelius à Lapide.]

The fifth opinion is that of Father Cornelius à Lapide on Matthew chapter 27, verse 45. He holds that this eclipse was caused partly by the Moon, supernaturally interposed before the Sun, and partly by the Sun, which at God's action withdrew its rays from the Christ-killing earth. For he thinks that the Moon, being always smaller than the Sun, could not have covered the whole Sun, and that in any eclipse of the Sun much light is diffused from it over the earth; and therefore that, in the part where the Sun stood out, this eclipse was completed by another miracle, through the withdrawal of rays. But he does not

[Margin: Who is excused.]

remember, good father that he is, the dreadful eclipses in which stars were seen in the sky. He is nevertheless to be pardoned, not being a professor of astronomy, for what astronomers otherwise not to be disdained held with Tycho, namely that no total eclipses of the Sun can occur naturally; on these see what was said in Book 4, chapter 16, no. 15, and in this Book, chapter 20.

[Margin: 6. Opinion, of Scheiner.]

The sixth opinion is that of Scheiner in the *Rosa Ursina*, p. 612. Since the Moon's shadow occupies only 350 Italian miles, he thinks the eclipse was

produced partly by the interposition of the Moon and partly by an extraordinary mass of spots on the Sun.

[Margin: 7. Opinion, of the Jews.]

The seventh opinion was that of the Jews themselves, if credence were to be given to the apocryphal Gospel of Nicodemus, which Salmerón adduces in volume 10, tractate 42. For it recounts that the Centurion came to the Governor reporting all the signs that had occurred, and that, when the Jews had been summoned, he said: *Have you seen the signs that occurred in the Sun, and all the others that occurred while Jesus was dying?* And that the Jews replied: *An eclipse of the Sun occurred according to the old custom.* By the old custom they meant either the natural manner of a solar eclipse or, as Salmerón interprets it, the force of magical and demonic art, with which, as was their habit, they had out of envy more than once besmirched Christ.

[Margin: 8. Our own view, and that of very many.]

The eighth and true view is that this eclipse was produced by an interposition of the Moon between the Earth and the Sun that was natural indeed as regards substance (to speak in theological fashion) but supernatural as regards mode, or as to accidents. So hold Petrus Comestor; Vincent of Lérins, Book 8, chapter 45; Syngelus in the *Encomium of St Dionysius*; St Thomas Aquinas, part 3, question 44, article 2; Salmerón, volume 10, tractate 42; Baronio at the year of Christ 34; Salianus in the *Annals* at the year of the world 4086; Fonseca, *On the Life of Christ*, p. 594; Gretserus [Jacob Gretser], *On the Holy Cross*, Book 1, chapter 31; Barradius [Sebastião Barradas] on the Gospels, Book 7, chapter 20; and Iansenius [Cornelius Jansen] in the *Concordia*, chapter 143. Among the mathematicians: Johannes de Sacrobosco at the end of the *Sphere*, and Clavius in that place; Michael Neander in the *Elements of the Doctrine of the Sphere*, p. 130; Maurolycus in dialogue 3 of the *Cosmographia*, p. 86; Barozzi in the *Cosmographia*, p. 348; Biancani, Book 10 of the *Sphere*, chapter 19; and, as regards the principal cause, Cornelius à Lapide on Matthew chapter 27, verse 45, and Scheiner in the *Rosa Ursina*, p. 612. That it was miraculous, though not produced by the Moon or by clouds, we have already seen asserted by St Jerome, Orosius and Euthymius. St Augustine may stand for them, in Letter 80 to Hesychius, in Book 3 of the *City of God*, chapter 15, and in the book of *Questions on the New Testament*, question 105; in these places he teaches that this failure of the Sun was marvellous and prodigious because it happened at full Moon. And to Salmerón he seems to have held the same view, namely that it was produced by the interposition of the Moon.

[Margin: Enumeration of the miracles within the miracle of this eclipse.]

V. With the miracle and the cause of this eclipse established, the miracles contained in it as parts are now to be enumerated. Euthymius, Syngelus and Fonseca, in the places already listed, think there were three: namely that it was at full Moon, that it was universal, and that it came with duration of three hours, or that it began from the eastern part of the Sun and ended in the same part. Barozzi, however, counts five: namely the three already mentioned, and in

addition that the whole Sun was covered by the Moon, and that the Moon had a greater latitude than the ecliptic limits require. Biancani likewise counts five, but differently: namely the time of full Moon; 2. its totality and universality over the whole earth; 3. the beginning from the eastern part of the Sun and the end from the western; 4. the Moon's progress to conjunction with the Sun against the order of its own motion, that is, with a motion towards the west; 5. an unusual approach of the Moon to the earth, so that it could cover the whole Sun for so long for the whole earth. But St Thomas sets down five differently: 1. the time of full Moon; 2. that within an interval of three hours the Moon was joined to the Sun and then opposed to it; 3. that the eastern part of the Sun began to be hidden; 4. that the western part of the Sun began to emerge from the eclipse, although otherwise the same part that begins to be uncovered is the one that had begun to be covered; 5. from St Chrysostom, that it lasted for 3 hours. Cornelius à Lapide, however, lists seven: that is, 1. the time of full Moon; 2. a duration of three hours; 3. the beginning from the eastern part of the Sun; 4. the reversal of the Moon towards the east to opposition with the Sun, for so he interprets St Dionysius, in a manner contrary to Biancani; 5. the total obscuration of the Sun, even though the Moon was smaller than the Sun; 6. stars seen in the sky by day, and an earthquake, though these have been seen at other times; 7. the shadowing of the whole earth.

We, however, contemplate 10 things in this eclipse that are altogether marvellous and above the order of the natural course of the luminaries. For some of them, however, I assume for the present, from my *Chronological Book*, that CHRIST suffered in Year 33 of our common Christian Epoch, on April 3, as is also the view of Tonstatus [?], Roger Bacon, Io. de Muris [Johannes de Muris], Buntingus [Heinrich Bünting], Paul of Burgos, Johannes Stadius, Origanus, Scaliger, Io. Lucidus [Giovanni Lucido], Pererius [Benet Perera], Zarlinus [Gioseffo Zarlino], and the old Calendar of the Dominican Fathers.

[Margin: 1. Miracle.]

The first miracle was an eclipse of the Sun produced by the Moon at the time of full Moon. For it is certain that the paschal lamb was eaten by Christ in the evening of the fourteenth day of the Moon, and that he suffered on the fifteenth day of the Moon, that is, in the opposition of the Moon, at least the mean opposition, with the Sun; but it is also certain that an eclipse of the Sun cannot occur naturally by the Moon's interposition except at new Moon.

[Margin: 2. Miracle.]

The second was the beginning of the eclipse from the eastern part of the Sun, as St Dionysius testifies, although naturally, in an eclipse of the Sun, the Moon usually comes under it from the western part.

[Margin: 3. Miracle.]

The third was the beginning of the emersion in the part of the Sun different from and opposite to the one that had first been darkened, that is, in the western part, as St Dionysius likewise testifies; whereas naturally the same part that is

first to fail in the Sun is also the first to begin to be refilled and to emerge from the eclipse.

[Margin: 4. Miracle.]

The fourth was the Sun's stay in darkness for three equinoctial hours, whereas naturally the Sun in a total eclipse does not stay beyond 8^m or 10^m of time, from what was said in chapter 11, Theorem 2. I think this was done through a slowness in the Moon's hourly motion, which otherwise usually overtakes the Sun.

[Margin: 5. Miracle.]

The fifth was the total obscuration of the Sun by the Moon, occurring at a time when the Moon's apparent diameter was smaller than the Sun's diameter. For from my tables, in that Year 33, at noon on April 3, the anomaly of the ☉ was $10^s\ 1^\circ\ 13'\ 32''$, and therefore its apparent semidiameter $15'\ 34''$; while the Moon's equated anomaly was $1^s\ 6^\circ\ 17'\ 21''$, and therefore its visual semidiameter $14'\ 14''$. So if this miracle lay only in the motion of the luminaries, the Moon was made nearer the earth than it naturally should be, or the Sun was made more remote from the earth, upward, so that it could be wholly covered by the Moon.

[Margin: 6. Miracle.]

The sixth was the extent of the Moon's shadow, which occupied the whole hemisphere above the horizon of Palestine, since the Evangelists say that darkness came over the whole earth, or over all the earth. For St Matthew 27 has [Greek: εἰς ὅλην τὴν γῆν (eis holēn tēn gēn, "over the whole earth")], and St Mark [Greek: εἰς πᾶσαν τὴν γῆν (eis pasan tēn gēn, "over all the earth")]; and the testimony of Phlegon supports this, concerning this eclipse observed far from Palestine, to say nothing of Dionysius, its observer at Heliopolis. And there is the reason: if the miracle of the Sun's retreat through 10 lines in the time of Hezekiah extended as far as the Babylonians and beyond, how much more this one, especially since the Saviour's Passion was to be preached to the whole world? How this miracle was done, however, we cannot define with certainty; and the views of Cornelius à Lapide on the withdrawal of the Sun's rays, or of Scheiner on an extraordinary gloom owing to the gathering of several spots of the Sun around its edges, are not improbable. Otherwise the sheer shadow of the Moon, even at its greatest, that is, with the ☉ at apogee and the Moon at perigee, occupies on the surface of the earth only 255 Italian miles equal to the recent Bolognese ones, or 317 ancient Italian miles, or, as Scheiner holds, 350, as we said in chapter 9, no. 9; nor would it occupy the whole hemisphere even if the Moon descended all the way to the Earth, because it is smaller than the Sun and than the Earth.

[Margin: 7. Miracle.]

The seventh was a motion of the Moon contrary to its proper natural motion, by which it apparently tends towards the east. For St Dionysius saw it carried from the east towards the meridian, come under the Sun, and fall upon it from the eastern part of the Sun; granted that afterwards, going back through

the same semicircle, it returned to opposition with the Sun according to the succession of the signs.

[Margin: 8. Miracle.]

The eighth was the wonderful speed of the Moon in completing a semicircle of the zodiac twice within the briefest time, almost in a moment. For St Dionysius says that that eclipse was sudden and abrupt, that it occupied the whole Sun not gradually but *suddenly*, and that after the Sun was restored the Moon *fled away* to diametral opposition with the Sun; whereas otherwise it does not complete this semicircle except in about 14½ days, and the circle in 29½.

[Margin: 9. Miracle.]

The ninth was such an adjustment of the Moon's motion that the order of the celestial motions was not disturbed outside this time, but the Moon returned that evening to the place in the zodiac where it had to be, just as if no change had been made. St Thomas Aquinas noted this in the First Part, question 44, article 2. It is also gathered from the calculation of eclipses which, by astronomical tables, we find to have been observed by the Chaldeans in the years 700 before the birth of Christ, exactly at the time they recorded: for through this miracle the series of motions was not interrupted except for a short time, and that very lapse [intermorium] was corrected by a compensation made by God.

[Margin: 10. Miracle.]

The tenth was the changing of the lunar eclipse into a solar one outside the solar ecliptic limits. For on that day, 33 April 3, the true full Moon occurred at Jerusalem at 7^{h} 10^{m} after noon, with the Sun placed at 11° 25′ of Aries and the Moon at 11° 25′ of ♎; the anomaly of the Sun was 302°, and that of the Moon 38° 18′. The Moon was distant from the nearer node, namely the southern one, by 7° 10′, with a southern latitude of 37′. The corrected semidiameter of the Earth's penumbra was 41′ 36″, and that of the Moon 14′ 42″. The eclipse of the Moon was therefore of 7 digits 52′, by which the northern part of the Moon was obscured.

[Margin: Note the eclipse of the Moon on the evening on which Christ was buried.]

But at that distance from the node and with a southern latitude, an eclipse of the Sun was impossible for northerners on this side of the Tropic, because of the parallax, which increases the latitude and depresses the Moon towards the south; and this even if it had then been a new Moon. There was therefore an eclipse of the Moon on that day towards evening. Salianus teaches this, from unnamed mathematicians, at the year of the world 4086, no. 53, and before him Scaliger, book 6 of *De emendatione temporum*, page 561, saying: *That dreadful darkness of the Sun was therefore out of the ordinary, at the very full Moon itself; at which the astronomical reckoning* [Epilogismus] *shows that something of the Moon also failed around sunset.* This agrees very well with St Jerome too, who understands of an eclipse of the Moon on the day of the Lord's Passion that prophecy of Joel,

chapter 2: *The Sun shall be turned into darkness, and the Moon into blood*, as I have already reported in no. 2. Granted that the Evangelists did not report it, since it happened naturally and was to be slighted in comparison with the supernatural eclipse of the Sun. The blood-red or crimson colour of the failing Moon can already be recognised from what was said in chapter 5, in the scholia.

[Margin: Final cause of the eclipse that occurred at the Passion of Christ.]

VI. It is not my business, however, to digress into the mysteries or tropologies which the holy Fathers or the interpreters of the Gospels have derived from the eclipse of the Sun just mentioned. See, as standing for them all, Salmerón, vol. 10, tractate 42, who deduces eight mysteries from it, and Cornelius à Lapide on Matthew 27, verse 45; from these you will gather the end God intended in this eclipse.

[Margin: On the eclipses at the end of the age.]

VII. There remain the last eclipses of the luminaries, reserved for the last time of the world. On these, those Sibylline verses stand in St Augustine, *City of God* 18, chapter 23:

The Sun's radiance is snatched away, and the chorus of the stars perishes; The heavens will be dissolved, the Moon's splendour will pass away.

Most interpreters, moreover, also understand of these that passage of Isaiah, chapter 13: *For the stars of heaven and their splendour shall not spread forth their light*; and of Ezekiel 32: *And when you are extinguished I will cover the heavens, and I will make their stars grow black; I will cover the Sun with a cloud, and the Moon shall not give her light. I will make all the luminaries of heaven mourn over you, and I will set darkness upon your land.* And of Joel 2: *The Sun shall be turned into darkness and the Moon into blood, before the great and terrible day of the Lord comes.* And of chapter 3: *Peoples, peoples in the valley of slaughter: for the day of the Lord is near in the valley of slaughter; the Sun and Moon are darkened, and the stars have withdrawn their splendour.* But without doubt, whatever Alcazarius [Luis de Alcázar] may say on chapter 6, verse 12, drawing Christ's prophecy to the destruction not of the world but of the city of Jerusalem, it is of these that the passage of Matthew 24 is to be understood: *Immediately after the tribulation of those days the Sun shall be darkened, and the Moon shall not give her light, and the stars shall fall from heaven, and the powers of the heavens shall be moved.* Or as it is said in Mark 13: *But in those days, after that tribulation, the Sun shall be darkened, and the Moon shall not give her splendour, and the stars of heaven shall be falling, and the powers that are in the heavens shall be moved.* And in Luke 21: *And there shall be signs in the Sun and Moon and stars.*

[Margin: "Their light", that is, their accustomed light.]

These are not to be understood only comparatively, with respect to the splendour of Christ, beside which the stars would be seen as dark, as Saints Hilary, Chrysostom and Jerome, and Theophylact, at times held; nor only in a mystical or symbolic sense, of men otherwise illustrious in faith and grace like the stars, but who will fall from faith and grace because of the persecution of Antichrist, as St Augustine held in Letter 80 to Hesychius. They are to be

understood in the literal sense as well, as is learnedly taught above all by José de Acosta, book 4 of *De novissimis temporibus*, chapter 7, and by Cornelius à Lapide on Matthew 24, verse 29, and on that passage of Apocalypse 6, verse 12: *The Sun became black as sackcloth, and the whole Moon became as blood.*

By what means those eclipses will come about is not established, although Cornelius collects much on this matter. Yet it seems certain that they will be supernatural as to their mode; and among the astronomers Tycho, vol. 1, p. 328, and Longomontanus in *Astronomia Danica*, p. 314, teach the same, inveighing severely against those who interpret the prophecies of Christ of the eclipses that happen every year according to the laws of nature and of the celestial motions. On the falling of the stars, let the interpreters consulted there, and Tycho in the place above, be seen; for these matters are nothing to us now, lest everything be put into everything.

CAPVT XIX.

Chapter 19.

Eclipſium Solis ac ☾ ab Anno DCCLXXII. ante CHRISTVM ad Annum vſque CHRISTI MDCXLVII. obſeruatarū Hiſtoria: Indicatis ſubinde Quantitate & Duratione earum ex Tabulis Aſtronomicis; Quæ ſanè ingēs eſt pro ASTRONOMIA, GEOGRAPHIA, & CHRONOLOGIA THESAVRVS.

A history of the eclipses of the Sun and ☾ observed from the year 772 before Christ up to the year of Christ 1647, with their magnitude and duration indicated from time to time from astronomical tables; which is truly an immense treasury for astronomy, geography and chronology.

No one, as far as I know, has so far collected all the observations of eclipses that survive in the writers. Nor indeed do all those who treat of them, taken together, possess all observations of this kind, especially those which, observed in recent years by more recent astronomers, among whom are many professors of mathematics from our Society, have been communicated by letter to me or to Father Athanasius Kircher (to whose kindness and generosity I owe a very great deal).

[Margin: Authors from whom the history of eclipses comes.]

Yet either very many, or at least some, are reported by Ptolemy in books 4, 5 and 6 of the *Magna Constructio*; his own by al-Battānī in chapter 30; by Regiomontanus in the *Epitome of the Almagest*, books 4, 5, 6, and in his own and Peuerbach's observations, to which are added the observations of Bernhard Walther, published anew and revised by Willebrord Snel; his own and some of Ptolemy's by Nicolaus Copernicus in book 4; his own by Tycho in book 1 of the *Progymnasmata*, p. 113, or in the letters; a few of the ancients' and his own by Longomontanus in *Astronomia Danica*, book 1 of the *Theorica*, chapter 2, in the

Commentary on the Moon; some of the older ones and his own by Kepler in *Astronomia Optica*, chapters 7, 8 and 11; Ptolemy's by Nicolaus Mulerius in the *Tabulae Frisicae*, p. 79, and Tycho's lunar ones at p. 296; several, ancient and more recent, by Philips van Lansbergen in the *Treasury of Lunar Observations*, classes 1 and 6, and in the *Uranometria*, book 2, from p. 53 to 115. Very many are reported by Dionysius Petavius [Denis Pétau] of the Society of Jesus, book 8 of *De doctrina temporum*, chapter 13, and by Dom Vincentius Reinerius [Vincenzo Renieri], the Olivetan, pp. 1 and 52 of the *Tabulae Mediceae* in the second edition; some, ancient and recent, by Ismaël Boulliau in *Astronomia Philolaica*, book 3, from chapter 3 to 8, and book 4, chapters 5 and 7, and p. 465. The eclipses of his own age are reported by Govaert Wendelen in his *Eclipses*, or in the *Idea of the Atlantic Tables*, from the year 1573 to the year 1643.

[Margin: Historians who report eclipses.]

Besides these, not a few are given by Joseph Justus Scaliger in the books of *De emendatione temporum*; Johann Georg Herwart von Hohenburg in his *Chronology Established by Eclipses*; Salianus in the *Annals*; Bünting in his *Chronology*; Lycosthenes in the *Chronicle of Prodigies*; Theophanes and Idatius; and others to be named below.

As for the calculation, we have decided largely to omit here the places of the luminaries, over which Longomontanus, Lansbergen and Boulliau took pains in some cases, reserving a fuller calculation according to the various tables for volume 3 of our *Almagest*. We have therefore chosen only to indicate, where we judged it more useful, the magnitude and duration of the eclipse and the anomaly of the luminaries; for it is rather from these that the reliability of the tables is to be examined. Matters that concern the difference of meridians will be treated at length in the Geographical Book, which is the fourth of volume 2 of the *New Almagest*, and those that concern chronology in the Chronological Book, which is the fifth of the same volume.

[Margin: Year 772. ⊙ Total, by calculation.]

The eclipse of the Sun at the conception of Romulus, if not observed, at least asserted by backward calculation by Lucius Taruntius Firmanus, a very celebrated mathematician, whom Marcus Varro urged to this calculation: Dionysius of Halicarnassus, book 2, where he says that at the conception of Romulus *the whole Sun was obscured, and the sky covered in darkness as at night.* I am not reluctant to copy here the whole passage from Plutarch's *Life of Romulus*: *In the age of Varro the Roman philosopher, a man very well versed in histories, there was a certain Taruntius, his friend, a philosopher and mathematician by profession, who had also touched on astronomy through a study of contemplation, and seemed to excel in it. To him Varro proposed that he should gather the birthday and hour of Romulus from the things that had happened to him, in the way the resolution of geometrical questions is found from ends to beginnings. For it belongs to the same science, given the time of some man's birth, to foretell his life, and conversely, his life being set out, to investigate the time at which he was born. Taruntius complied, and having looked into the deeds of Romulus, what had happened to him, how long he had lived, by what*

death he had died, and other things of this kind, and having compared them all with one another, he boldly and fearlessly declared that Romulus was conceived in year 1 of the second Olympiad, on day 23 of the month which the Egyptians call Choeac, at the third hour, when the Sun suffered a total failing; that he was born on day 21 of the month Thoth, around sunrise; and that Rome was founded by him on the 9th day of the month Pharmuti, between the 2nd and 3rd hour.

[Margin: Herwart's opinion, and a chronological knot.]

✢ Nevertheless Georgius Heruartus [Johann Georg Herwart von Hohenburg], chapters 107 and 108 of his *Chronology*, conjectures this eclipse into the year 765 before Christ, on February 10, at $3^{h}\ 29^{m}\ 26^{s}$ before noon at Rome, and says that it was of 10¾ digits. Nor is the disagreement of 7 years to be wondered at, since Censorinus, *De Die Natali*, chapter 8, says of the time from the first Olympiad to his own age: *Concerning the third period, however, there was some dissension among the authors, of only six or seven years. But whatever darkness there was here, Varro dispelled, etc.* But this is not the eclipse Taruntius speaks of, since it did not fall on the 23rd of the month Choeac, that is, June 23 of year 1 of Olympiad 2, the year in which, according to Varro's opinion, we shall show in our Chronological Book that Romulus was conceived. Taruntius, however, did not say that that failing was seen in Italy or in Europe. ✢ For me, therefore, it was a total failing at about 21^{h} after noon at Rome (if Rome had existed then); it fell on the civil day June 24, and was seen beyond the Tropic of Cancer. Now since from Choeac 23 to Thoth 21 there are 291 days, in which are contained 9 lunar years [recte: months] and 25 days besides, the bearing of Romulus lasted ten months; and for that reason, perhaps, Romulus chose a lunar year of ten months. Ovid hints at this in *Fasti* book 1, in this couplet:

As much as suffices for an infant to come forth from its mother's womb, So much time he established to be in his year.

[Margin: Herwart's acute chronological observation.]

From this, Herwart thinks, it came about that through misuse of a twelve-month year in place of a ten-month one, great errors crept into the Consular Fasti, up to the year 404 from the founding of the City, from which the year of 12 months first came into use at Rome. But we treat this elsewhere.

[Margin: Year 754. ☉]

The eclipse of the Sun in year 1 from the founding of the City, in Plutarch's *Romulus*, who says: *It is agreed that the City was founded on the eleventh before the Kalends of May* [April 21]*, and the Romans call this day the birthday of their fatherland and keep it as a feast.* And shortly after: *But it is recorded that the rising of Rome fell on the thirtieth day of the month, and that there was then a conjunction of the Moon and Sun and a failing of the latter, which the poet Antimachus of Teos also observed, and which happened in the third year of the sixth Olympiad.* He speaks of the 30th day in the Greek manner, for he had said beforehand: *In our own time the Roman Kalends differ altogether from the beginnings of the Greek months.* And yet it is strange that Taruntius omitted this eclipse, since he knew that the City was founded in the yoke of the Moon with the Sun. For Cicero says,

On Divination book 2: *Lucius Taruntius Firmanus, our close friend, learned above all in Chaldean reckonings, also traced back the birthday of our city from the Palilia, on which he accepted that it was founded by Romulus; and he said that Rome was born when the Moon was in the Yoke; and he did not hesitate to sing its fates.* With Manilius, Libra can also be understood by the name Yoke, in which sign he says the City's horoscope stood; granted that Solinus writes that Rome was founded with the Sun placed in Taurus and the Moon in Libra. Now Scaliger, *De emendatione temporum* book 5, p. 388, denies that this new Moon was ecliptic, because of the eclipse of the Sun which happened exactly 38 years later, in the following month, the interval of eclipses being preserved. ✢ Pétau, book 8, chapter 13, computes for this year, on July 6, an eclipse of 3 digits at 6^h 51^m after noon at Rome, and in the following year another, but one which could not be seen in Asia by Antimachus; granted that Mulerius accepts it in the Appendix to the *Tabulae Frisicae*. ✢ Herwart, however, in chapter 109, throws this one back to the year 744 before Christ and to December 9, at 3^h before noon, of 7⅕ digits. ✢ But in the year 754, on July 5 according to the Julian year, but April 21 of the old year, there was an eclipse of ☉ of nearly 4 digits, at $4½^h$ after noon at Rome.

[Margin: Year 753. ☉]

✢ In the year 753, however, there was an eclipse on May 26 at 6^h 27^m after noon, but unobservable by Europeans because of the ☾'s southern latitude, greater than 46′. See what we said of the City's birthday in the Chronological Book.

[Margin: Year 721. ☾ Total.]

The total eclipse of the Moon observed by the Chaldeans at Babylon, an hour or more after moonrise at the start of the eclipse, in year 1 of Mardocempadus, but 27 of Nabonassar, on day 29 of the month Thoth; from Ptolemy, *Almagest* book 4, chapter 6, who says that the beginning was there 4^h 30^m before midnight and the middle 2^h 30^m, but at Alexandria 3^h 20^m before midnight. It was March 19 in the Julian manner, feria 2, in the 3rd year of the lunar cycle and the 17th of the solar, as Scaliger has it, *De emendatione temporum* book 5, p. 394. Lansbergen in the *Treasury of Observations* computes 17 digits 52′ and a duration of 3^h 50^m; Pétau, book 8, chapter 13, a duration of 4^h 6^m and 18 digits 30′; but Boulliau, book 3, chapter 7, 19 digits 10′. On this one, see what was said in book 4, chapter 20, no. 9.

[Margin: Year 720. ☾]

The eclipse of the Moon in year 2 of Mardocempadus, or 28 of Nabonassar, observed at Babylon on the night between the 18th and 19th of the month Thoth, at midnight itself, of 3 digits in the southern part of the Moon; from Ptolemy, book 4, chapter 6. Lansbergen in the *Treasury*, p. 55, corrupts his text, putting 3′ [ſcrupula 3] in place of 3 digits, so as to twist the observation to his tables and to 1¼ digits, whereas Ptolemy expressly says [Greek: ἀπὸ νότου δακτύλους τρεῖς αὐτοῦ τοῦ μεσονυκτίου (apo notou daktylous treis autou tou

mesonyktiou, "from the south, three digits, at midnight itself")]. It was the night between March 8 and 9, the following day being feria 6, as Scaliger has it, book 4, p. 323. Pétau, book 8, chapter 13, gathers 3 digits 20′.

[Margin: The unreliable good faith of Lansbergen.]

[Margin: Year 720. ☾]

A second eclipse of the Moon in the same year, observed at Babylon on the night between the 15th and 16th of Phamenoth. It began to fail after its rising, and failed on the northern side by 6 digits at most; from Ptolemy, book 4, chapter 6, who computes a duration of almost 3^h. But Lansbergen in the place above has 2^h 30^m and 5 digits; Pétau 2^h 42^m and 5 digits 20′; but Boulliau 6 digits 17′.

[Margin: Year 715. ☉]

The eclipse of the Sun at the death of Romulus, in year 2 of Olympiad 16, on the 8th of Choeac and the Nones of Quintilis in the old year; from Dionysius of Halicarnassus, book 2, Plutarch in *Romulus*, Seneca book 19 to Lucilius, St Augustine, *City of God* book 3, chapter 15, but above all Cicero in the *Dream of Scipio*, where this stands: *For just as the Sun once appeared to men to fail and be extinguished, when the soul of Romulus entered these very precincts, so when at some time the Sun shall have failed again in the same part and at the same time, then, all the constellations and stars being called back to the same starting point, consider the year completed.* Florus too says, of the departure of Romulus at the Marsh of the Goat: *But a storm arose, and the failing of the Sun gave the appearance of a consecration.* To this Ovid alludes in *Fasti* 2:

There is a place the ancients called the Marsh of the Goat; Perhaps you were giving laws there, Romulus. The Sun flees, and the clouds coming up take away the sky.

But Ovid refers this death to the Quirinalia in the month of February, while Lampridius in *Commodus* and Plutarch refer it to the Nones of Quintilis; since in our manner it was May 26, feria 7, on which, as Scaliger has it, book 5, p. 395, and Pétau, book 8, chapter 13, there fell an eclipse of 3 digits 45′, which lasted $1¾^h$.

[Margin: Year 709. ☉]

The eclipse of the Sun on July 18 indicated by Homer in the *Odyssey*, in Herwart's *Chronology*.

[Margin: Year 621. ☾]

The eclipse of the Moon in year 5 of Nabopolassar, but 27 of

Nabonassar, observed at Babylon on the night between the 27th and 28th of Athyr. It began to fail towards the end of the 11th hour of the night, and around the 6th hour after midnight at most a quarter of the Moon's diameter failed; from Ptolemy, book 5, chapter 14. It was April 22, feria 7. Lansbergen computes 2 digits 16′, but Pétau in the place above 3 digits 45′.

[Margin: Year 607. ☉]

The eclipse of the Sun on July 30, seen at Sardis at 1^h 43^m before noon, of 5 digits 40′, in Pétau, book 8, chapter 13.

[Margin: Year 603. ☉]

The eclipse of the Sun on May 28, of 7 digits 20′, in Pétau, book 8, chapter 13.

[Margin: Year 597. ☉]

The eclipse of the Sun on July 9, of 9 digits 22′, in Pétau, book 8, chapter 13.

[Margin: Year 585. ☉ Total, the eclipse of Thales.]

The eclipse of the Sun that Thales first predicted to the Ionians. It occurred in year 6 of the war between Cyaxares the Mede and Alyattes the Lydian, as Herodotus relates, book 1; Eudemus in Clement of Alexandria, *Stromata* book 1; and Pliny the Elder, book 2, chapter 12, who adds that it was year 4 of Olympiad 48 and year 170 of the City. I reported their words in chapter 2, no. 8. That it was total on the Hellespont, but of 10 digits at Alexandria, is attested by Cleomedes, book 2 of the *Cyclical Theory*, chapter 3, and by Theon in his Commentary on the *Almagest*, book 6, chapter 11, who says of Hipparchus: *He takes an eclipse in the places around the Hellespont, which occurred exactly in the whole Sun, so that nothing of it appeared in the surrounding places.* ✢ Calvisius wrongly thinks this was the eclipse of the year 607, departing from Pliny the Elder by a full 18 years. But Scaliger with Bünting, and Salianus at the year of the world 3469, recognise it in year 4 of Olympiad 48, but in year 168 from the founding of the City; for Pliny the Elder, they say, confused this one with the eclipse of the year 581 before Christ, March 16, of 2½ digits at Sardis.

[Margin: Year 581. ☉]

✢ Lansbergen computes it in year 3 of Olympiad 48, year 163 of Nabonassar, on day 13 of Tybi, that is, May 28, of 12 digits 20′ on the Hellespont, but of 10 digits 12′ at Alexandria. These years, however, are reconciled, because in the same year 585 year 4 of Olympiad 48 began, if not from this ♂, at least shortly after. ✢ Further, for me that eclipse, in that year 585, May 28, comes out around the Hellespont, in the place where it appeared central, as of 12 digits 56′, and at Sardis around the 6th hour after noon, and so in the very heat of the battle which this eclipse broke off, as was said in chapter 2, no. 8. ✢ Pétau attributes to it from his Parisian tables 11 digits 20′; and yet in book 10, chapter 1, he prefers for himself the eclipse of the year 597, of 9 digits 22′, July 9, which occurred in the earliest morning. This suits neither the time of a longer battle nor the magnitude of the eclipse seen in Pontus and Asia Minor, as D. Io. Antonius Rocca [Giovanni Antonio Rocca], a man of high judgement in mathematics, also observed against Pétau in a letter sent to me. Nor are Bünting's 11 digits 30′ from the Prutenic Tables sufficient. ✢ Kepler too accepts this one in the *Optics*, p. 290, and has it occurring in that summer from the middle of which year 4 of Olympiad 48 began. Since the Sun was almost at apogee itself, and the Moon very near perigee, distant from it by only 12°, Lansbergen judges that Hipparchus used this eclipse to demonstrate the distances and sizes of the Sun, Moon and Earth. But Kepler in the *Optics*, p. 292, thinks that it was observed by Timocharis or by Hipparchus, and so is different from the eclipse of Thales, though agreeing with it in magnitude.

[Margin: Year 523. ☾]

The eclipse of the Moon in year 7 of Cambyses, king of the Persians, or 225 of Nabonassar, observed at Babylon on the night between the 17th and 18th of Phamenoth, 1^h before midnight, at which 6 digits failed from the north; from Ptolemy, book 5, chapter 14. It was July 16, feria 4, according to Scaliger, book 4, p. 402. Mercator places it in year 2 of Olympiad 64. But Scaliger puts year 8 of Cambyses in place of 7; and Pétau, book 8, chapter 13, has 7 digits 25′; but Lansbergen, p. 59 of the *Treasury*, 6 digits 2′; and Boulliau in the place above 5 digits 15′.

[Margin: Year 502. ☾]

The eclipse of the Moon in year 20 of Darius son of Hystaspes, who succeeded Cambyses, or 246 of Nabonassar, observed at Babylon on the night between the 28th and 29th of the month Epiphi, 6^h 20^m of equal time after sunset and 24^m before midnight. Three digits failed from the south, or a quarter of the Moon's diameter: Ptolemy, book 4, chapter 9. It was November 19, the following day, the 20th, being feria 2. Lansbergen, p. 62 of the *Treasury*, computes 2 digits 25′, but Pétau 4, and Boulliau 3 digits 3′.

[Margin: Year 491. ☾]

The eclipse of the Moon in year 31 of Darius I son of Hystaspes, or 257 of Nabonassar, at Babylon, on the night following day 3 of the month Tybi, [Greek: ὥρας ς μέσης (hōras 6 mesēs, "at the middle of the 6th hour")], that is, in the middle of the sixth hour of the night. Two digits failed: Ptolemy, book 4, chapter 9. Or, as Trapezuntius [George of Trebizond] renders it, *half an hour before midnight*; for Ptolemy adds: *For the middle time preceded midnight by half an hour at Babylon, but at Alexandria by one hour and a third part of one equal hour.* There Trapezuntius or the printer omitted the one hour, content with a third part of an hour. Mulerius in the *Tabulae Frisicae*, p. 80, better restores 10^h 40^m after noon at Alexandria. Lansbergen, p. 61 of the *Treasury*, put it very badly: *one hour before midnight at Babylon*, and computes 1 digit 33′. ✢ But Pétau has a duration of 1^h 48^m and 2 digits 20′, and Boulliau 2 digits 40′. It was April 25, feria 4.

[Margin: Lansbergen's false report.]

[Margin: Year 480. ☉ Approximately.]

The eclipse of the Sun seen when Xerxes was setting out from Sardis for Abydos. It is much disputed, so we must be the more diligent in clearing up its date. Herodotus relates it thus in book 7: *Xerxes set out from Sardis, where he had wintered, towards Abydos at the beginning of spring. As he moved off, the Sun, leaving its seat in the sky, ceased to appear, although there were no clouds and the air was perfectly clear; and night took the place of day. Noticing this, he was seized by anxiety to ask the Magi what that portent foretold. They answered that the god was signifying to the Greeks the falling away of their cities, because he said that the Sun was the guardian of the Greeks and the Moon of themselves. On hearing this Xerxes went on his way exceedingly glad.* Then, speaking of the preparations of the Greeks against Xerxes, he adds: *The remaining allies too were spirited to action, for the time of the Olympiad had fallen on these affairs.* And not long after:

When the King, having taken Thermopylae, was going further, Arcadian deserters, asked what the Greeks were doing, answered that they were celebrating the Olympia and watching the gymnastic contest. Then in book 8: *From the crossing of the Hellespont, from which the barbarians began their march, they spent one month in crossing into Europe, three others until they reached Attica, while Calliades held the supreme magistracy at Athens, and they took the deserted city.* ✢ Agreeing on this time is Dionysius of Halicarnassus, book 9, near the beginning, saying: *Caeso Fabius, for the second time, was designated consul by the Senate, he who had prosecuted Cassius on a charge of tyranny; by the plebs Spurius Furius, in Olympiad 75, with Calliades chief at Athens, at which time Xerxes made his expedition into Greece.* ✢ And with him Diodorus Siculus, book 11, where he writes in these words: *Calliades therefore being in charge of the Athenians, the consuls created among the Romans were Spurius Cassius and Proclus Virginius, the thirtieth* [trigeſimus]*, in the seventy-fifth Olympiad, in which Asylus of Syracuse won the stadium race; at this time, therefore, King Xerxes took up arms against the Greeks.* ✢ Besides these, Pindar is said to have been born in Olympiad 65 and to have been 40 years old at the crossing of Xerxes, as Scaliger agrees, book 5, p. 407. Therefore the first expedition of Xerxes into Greece fell at the end of year 4 of Olympiad 74, and was completed with Olympiad 75 begun shortly before. On this time agree Scaliger in the place above, Bünting, and Kepler in the *Optics*, p. 291. ✢ Nor does Eratosthenes dissent in the *Canon of Times*, or another old anonymous chronologer in Clement of Alexandria, who count from the first Olympiad to the crossing of Xerxes 297 years, which make 74 whole Olympiads with one year, namely the first of Olympiad 75. For they had regard to the very arrival of Xerxes, and counted those years not as whole but with the last one only begun; granted that Scaliger, understanding them as whole, says that they erred. ✢ But Polybius, book 3, says that the treaty made between the Romans and the Carthaginians under the first consuls preceded Xerxes' departure into Greece by twenty-eight years, that is, by a full 7 Olympiads; and the first consuls were created at Rome in the year 244 from the founding of the City. Adding 28 years, therefore, Xerxes' departure falls in the year of the City 272 completed and 273 begun, the year 481 before Christ according to Varro, but according to Dionysius's computation 480. ✢ Thucydides, however, book 1, says that Xerxes came to Greece in the tenth year after the battle of Marathon; so too Gellius, book 17, chapter 21: *In the two hundred and sixtieth year after the founding of Rome, or not much later, it is recorded that the Persians were conquered by the Athenians, in that celebrated battle of Marathon under the leadership of Miltiades.* And Sulpicius Severus in his *Chronicle* records the same battle in the year 260 from the founding of the City. The City was founded in the year 753 before Christ according to Varro, or 752 according to Dionysius of Halicarnassus; so the battle of Marathon was either in the year 492 or 491 before Christ, and in year 1 of Olympiad 72, or in year 4 of Olympiad 71. Therefore Xerxes' arrival would have been in year 4 of Olympiad 74.

But when the eclipses around these years are examined, no eclipse of the Sun is found in the year 480 before Christ visible in Europe and western Asia.

[Margin: Year 481. ⊙]

But neither is that one to the point which Scaliger affirms in the year 481, on April 19, feria 4, and Bünting too; for either there was none at all, if we believe Pétau, book 8, chapter 13, and book 10, chapter 24, or it was of scarcely 3 digits, as Kepler says in the *Optics*, p. 291, and was therefore unfit to turn day into night.

[Margin: Year 478. ⊙]

As for the one that occurred two years later, that is, in year 3 of Olympiad 75, on the testimony of Herodotus, book 9, and that terrified Cleombrotus, it does not concern this time; it fell on October 2 and was of scarcely 7 digits. Finally, with the sky otherwise clear, a little ball of cloud beneath the Sun could not have made night out of day. And so, concerning this darkness reported by Herodotus, we still remain in a great darkness of uncertainty.

[Margin: Year 463. ⊙]

The eclipse of the Sun in year 1 of Olympiad 79, at Athens, on April 30, in Eusebius, in the *Chronicle*, at the year of Abraham 1556, which Pétau computes as of nearly 11 digits and of a duration of $2^h\ 8^m$. ✢ In its place Scaliger offers another, which occurred in the following year on October 13; but it is rejected by Pétau, because at Athens it fell at $21^h\ 21^m$ after midnight, and was thus nocturnal and invisible there.

[Margin: and Year 462. ⊙ Not observed.]

✢ But the one Eusebius reports under the consuls L. Ebusius and P. Servilius, Renieri wrongly assigns to the year 298 from the founding of the City; or else there is a transposition of figures, for it should have said the year 289 from the founding of the City.

[Margin: Year 431. ⊙ Nearly total.]

The eclipse of the Sun in the first year of the Peloponnesian War, while Pericles was setting sail for the Peloponnese, which terrified his ship's captain but not Pericles, as we said in chapter 2, number 9. Plutarch in the *Pericles* says that *night was drawn over the sky*. ✢ But Thucydides, who was flourishing at that time, says in book 2: *That same summer, on the first day of the month, at the new Moon, the only time at which it is evident that the Sun can fail, the Sun was so obscured after noon that some stars were seen in the sky; and shortly afterwards, when it had taken the form of a halved Moon, it returned to its former shape.* Moreover, the beginning of the Peloponnesian War was in the first year of Olympiad 87, according to Eusebius and Suidas; but the whole first year of the war took up, with the greater part of itself, the second year, as Diodorus Siculus relates, and as Scaliger teaches, book 5, p. 410, of *De emendatione temporum*, Pétau, book 8, chapter 13, Salianus at the year of the world 3623, and Kepler in the *Optics*, p. 291. They also assign this eclipse to August 3, feria 4; but Pétau reckons only 10 digits 25′ and a duration of $1^h\ 54^m$. Kepler asserts that it was total.

[Margin: Year 424. ⊙]

The eclipse of the Sun in year 8 of the Peloponnesian War, observed and reported by Thucydides, book 4, where he says that some part of the Sun failed. ✢ Mästlin, in Kepler's *Optics*, p. 291, computed 7 digits from the Prutenic Tables. ✢ Pétau, however, book 8, chapter 13, places it on March 22 [recte: March 21, per the book's errata] at 8^h 17^m after midnight at Athens, and of 9 digits with a duration of 2^h 34^m. ✢ And Salianus refers it to the year of the world 3630, year 1 of Olympiad 89.

[Margin: Year 413. ☾ Total.]

The eclipse of the Moon in year 19 of the Peloponnesian War, and in year 3 of Olympiad 93, reported by Polybius, book 9, Diodorus Siculus, book 13, Thucydides, book 7, and Plutarch in the *Nicias*. Plutarch says that Nicias, deterred by superstition on this account, was afraid to withdraw, and so offered himself and his army to the Syracusans to be slaughtered, as I related in chapter 2, number 13. It fell on August 27, as Scaliger says, book 1, p. 56, and Pétau, who adds that it was of 13 digits, at Syracuse at 10^h 11^m after noon, and that it lasted 3^h 28^m,

[Margin: A chronological knot.]

but with duration in total darkness of 41^m. ✢ But Apian, in the *Astronomicum Caesareum*, refers this eclipse to the year 414, September 8, when three digits were obscured after sunset; see him.

[Margin: Year 406. ☾ Total.]

The eclipse of the Moon in year 3 of Olympiad 93, in which the old temple of Minerva at Athens burned down, reported by Xenophon, book 2 of *On the Affairs of the Greeks*. ✢ Pétau assigns it to the year of the Julian Period 4308, April 15; he computes 15 digits, a duration of 3^h 45^m, a stay in the shadow of 1^h 14^m, and the middle at 8^h 49^m after noon at Athens.

[Margin: Year 404. ☉]

The eclipse of the Sun in the first year of Olympiad 94 and the last of the Peloponnesian War, in which Dionysius, tyrant of Syracuse, was defeated by the Carthaginians. On this eclipse, Xenophon, book 2 of the *Hellenica*. It fell on September 3, feria 6, in the sixth month after the Peloponnesian War was finished, as Scaliger has it, book 5 of *De emendatione temporum*, p. 411. ✢ Pétau, however, says that it was at 9^h 12^m after midnight, and that 8 digits 40′ failed at Athens.

[Margin: Year 394. ☉]

The eclipse of the Sun in Xenophon, book 4, who says that while Conon was defeating the Persians in a naval battle, the Sun appeared sickle-shaped like the Moon. Salianus refers it to year 2 of Olympiad 96. ✢ Pétau assigns it to the year of the Julian Period 4320 and to August 14, with 11 digits, and at Cnidus in Cyprus at 10^h 35^m after midnight.

[Margin: Year 383. ☾]

The eclipse of the Moon, in the archonship of Phanostratus at Athens, in the month of Posideon, in year 366 of Nabonassar, observed at Babylon on the

night between the 26th and 27th of Thoth, at 5^h 30^m temporal after midnight, from Ptolemy, book 4, chapter 11, who says that a small part of the Moon failed from the summer rising, when half an hour of the night remained, and that it set still in eclipse. ✢ It fell in the morning at the onset of December 23, feria 3, as Scaliger has it, and Mulerius in the *Tabulae Frisicae*, p. 81. Pétau computes 3 digits, Boulliau 2 digits 20′.

[Margin: Year 382. ☾]

The eclipse of the Moon, with Phanostratus still archon at Athens, in the month of Scirrophorion, but according to the Egyptians in year 366 of Nabonassar, on the night between the 24th and 25th of Phamenoth, at a temporal hour of at most 5½ before midnight at Babylon; and it failed from the summer rising. So Ptolemy, from Hipparchus, book 4, chapter 11, where he does not give the digits. ✢ But Pétau computes them, at June 18, as 7 digits 30′, whereas Boulliau has 6 digits 40′.

[Margin: Year 381. ☾ Total.]

The eclipse of the Moon, with Evander archon at Athens, in the first month of Posideon, but according to the Egyptians in year 367 of Nabonassar, on the night between the 16th and 17th of Thoth. It failed, says Hipparchus in Ptolemy, book 4, chapter 11, beginning from the summer rising when 4 hours of the night had elapsed, and it failed totally. And yet shortly afterwards he says that it was 2½ hours before midnight, and so read the codices, both the Basel one and two manuscripts of the Royal Library, as Boulliau affirms, p. 144. But Ptolemy contradicts himself: for after 4 temporal hours of the night, two hours remained until midnight, and therefore not two and a half. ✢ Boulliau therefore restores the letter γ, which signifies 3 hours elapsed, in place of the letter δ, which signifies 4, and holds that Ptolemy was speaking loosely, not strictly. ✢ This eclipse fell on December 12, and was of 17 digits according to Pétau, with a duration of 3 hours and a stay of 1^h 24^m. But Boulliau, book 3, chapter 7, has 19 digits 42′.

[Margin: Year 364 or 365. ☉]

The eclipse of the Sun in Olympiad 104, in the year in which Pelopidas fought against Alexander of Pherae, from Diodorus Siculus, book 15, and Plutarch in the *Pelopidas*, where he describes the omen of this eclipse clearly. I do not repeat that here, because this is the very eclipse of the Sun after which Pelopidas was slain, of which I spoke in chapter 2, number 10, when I was treating of eclipses that portend some omen.

[Margin: Year 343. ☉]

The eclipse of the Sun of which Herwart, chapters 80 and 81 of his *Chronology*, thinks Livy was speaking when he said that on July 1 [Calendis Iulij], in year 109 from the founding of the City, after the temple of Juno Moneta had been dedicated, *night seemed to come on in the daytime*; there he adds many things that bear on chronological knots.

[Margin: Year 331. ☾ Total.]

The eclipse of the Moon in year 2 of Olympiad 112, and 11 before the victory that Alexander the Great won over Darius at Arbela, from Diodorus Siculus, book 17, Q. Curtius, book 4, Arrian, book 3, Plutarch in the *Alexander*, and Pliny the Elder, book 2, chapter 70, where he adds: *At the famous victory of Alexander the Great at Arbela the Moon is recorded to have failed at the second hour of the night, and the same Moon while rising in Sicily.* ✢ It fell on feria 2, on the night between September 20 and 21, as Scaliger has it, book 5 of *De emendatione temporum*, p. 420. There he says that Plutarch is mistaken in saying that it was [Greek: τῇ εἰκάδι Βοηδρομιῶνος (tē eikadi Boēdromiōnos, on the twentieth of Boedromion)], namely on the 20th of Boedromion, and he contends that it was on the 20th day of [Greek: Μεταγειτνιῶνος (Metageitniōnos, of Metageitnion)]; and that Arrian is therefore still more mistaken, who has it in the month Panepsion, that is, in our November, with Aristophanes archon at Athens.

[Margin: Error of Arrian, Plutarch, Cicero.]

He also charges Plutarch with contradicting himself, since Plutarch admits that the battle was fought not indeed at Arbela but at the nearby place Gaugamela, [Greek: ἐνδεκάτη ἀπὸ τῆς ἐκλείψεως νυκτὶ (endekatē apo tēs ekleipseōs nykti, on the eleventh night after the eclipse)], on the eleventh night after the eclipse, and yet says shortly afterwards that it was [Greek: πέμπτη Βοηδρομιῶνος φθίνοντος (pemptē Boēdromiōnos phthinontos, on the fifth of waning Boedromion)], the 25th day of Boedromion; for how, from day 20 to 11, are there 5 days? Moreover, he convicts of the same error Cicero, *De Divinatione* 1, and the author of the little book on the rising and setting of the stars falsely attributed to Ptolemy. For Cicero says: *If the Moon should have failed shortly before sunrise in the sign of Leo, Darius and the Persians would be defeated by force of arms in battle by Alexander and the Macedonians, and Darius would die.* And the other author notes at August 10 [IV. EID. Augusti]: *An eclipse of the Moon usually falls on this day*; for both wrongly thought that this eclipse occurred with the Sun placed in Leo, whereas it was at 24° of Virgo, nor before sunrise, but at the second hour of the night, as the calculation shows and as Pliny the Elder rightly affirms; nor are eclipses tied to the day on which they once occurred. ✢ Pétau, book 8 of *De doctrina temporum*, chapter 13, computes 14 digits 17′, and says that the ☾ began to be obscured at $8^h\ 20^m$ after noon, was wholly obscured at $9^h\ 38^m$, emerged at $10^h\ 40^m$, and wholly escaped at $11^h\ 58^m$. Pliny the Elder's passage must therefore be understood of the beginning of the eclipse. ✢ But Eusebius places this victory and eclipse in the year of the world 4871, which for him is 328 before Christ.

[Margin: A chronological knot.]

✢ Apian, however, in the *Astronomicum Caesareum*, Enunciatum 29, contends that this eclipse was in the year 326 before Christ, on July 11, at $11^h\ 51^m$ after noon at Gaugamela, of 7 digits 15′; read him here on the chronology.

[Margin: Year 310. ☉ Total.]

The eclipse of the Sun in the consulship of C. Junius and Q. Aemilius, when Agathocles, king of Sicily, was taking his fleet across to Africa against Carthage;

he used this eclipse most skilfully to steady his soldiers, as I said in chapter 2, number 11. It was in year 3 of Olympiad 117, from Justin, book 22, and Diodorus Siculus, book 20, who adds: *On the following day so great an obscuration of the Sun took place that you would have called it plainly night, with stars appearing everywhere.* ✝ Salianus, following a series of consuls different from that of Diodorus Siculus, assigns this eclipse to the consulship of M. Rutilius and Q. Fabius Maximus, though he agrees on year 3 of Olympiad 117. He says, I believe from Bünting, that it fell on August 15, at Syracuse at $8^h\ 15^m$ after midnight, and of more than 11 digits; for the Prutenic calculation does not reach a total eclipse, as it ought to; nor does that of Pétau, who has 11 digits 10′ and puts the beginning at $6^h\ 57^m$ and the end at $9^h\ 5^m$. My tables give the diameter of the Sun as 31′ 22″ and of the Moon as 33′ 10″, the corrected anomaly of the Sun as 74°, and that of the Moon as 201°.

[Margin: Year 256. ☾]

The eclipse of the Moon in year 4 of Olympiad 130, before the death of Carneades, from Diogenes Laertius in his life.

[Margin: Year 220. ☉]

[Margin: Year 217. ☉]

Two eclipses of the Sun, commonly confused by writers because the years are close together, and placed in the year from the founding of the City either 533 or 536. Of these Livy, book 22, and Julius Obsequens say, under the consuls Gn. Servilius and C. Flaminius, *that the orb of the Sun was seen to diminish, and to be struggling with the Moon.* Silius Italicus adds that there was dense and immense darkness in Calabria, and that the light of day was taken away. ✝ Georgius Heruartus, in his *Chronology*, chapter 82, draws it back to the year 209, saying that it was in Sardinia at $2^h\ 13^m$ after noon and of 9 digits 50′ 27″. ✝ But Pétau says that this very eclipse began on February 11 at Cagliari in Sardinia after noon, at $2^h\ 3^m$ after midnight, ended at $4^h\ 20^m$, and was of 8 digits.

[Margin: Year 219. ☾ Total.]

The eclipse of the Moon in the year from the founding of the City 535, in the consulship of C. Livius Salinator and Aemilius Paulus, seen in Mysnia, of which Polybius, book 4. It fell on the night between March 19 and 20, of 12 digits 40′; it began there 18^m after midnight, was total at $1^h\ 45^m$, emersion at $2^h\ 25^m$, end at $3^h\ 52^m$, as our Pétau has it. ✝ But Herwart, chapter 83, refers it to the year 211 before Christ, and to the night between October 12 and 13.

[Margin: Year 203. ☉]

The eclipse of the Sun in the consulship of Gn. Cornelius Caepio and C. Servilius Geminus, seen at Frutinum [recte: Frusino, per the book's errata] in Latium, of which Livy, book 30, speaks rather obscurely. Others refer it to the preceding year, when the consuls were Cethegus and Tuditanus; ✝ Salianus to this year, with Bünting, and Pétau; for him it fell on May 6 around noon, of 5 digits and 40′.

[Margin: Year 202. ☉]

The eclipse of the Sun in the consulship of Tiberius Claudius Nero and M. Servilius Geminus, seen at Cumae in Campania, from Livy, book 30, or book 10 of decade 13 [recte: 3], in the year from the founding of the City 552. It fell on October 19, of 1 digit, and at $10^h\ 24^m$ after midnight, from Pétau.

[Margin: Year 201. ☾]

The eclipse of the Moon in year 54 of the Calippic Period and 547 of Nabonassar, observed at Alexandria and reported by Hipparchus in Ptolemy, book 4, chapter 11, where he relates that on the night between the 16th and 17th of Mesori the Moon began to be obscured half an hour before its rising, that it was replenished in the middle of the third hour, and that the middle time was at the beginning of equal hour 2 before midnight. It fell on September 22, feria 6, of 10 digits 17′ according to Pétau, but of 9 digits 8′ according to Boulliau, from the south, although he admits that it was observed as of 7 digits.

[Margin: Year 200. ☾ Total.]

The eclipse of the Moon in year 55 of the second Calippic revolution and 548 of Nabonassar, observed at Alexandria on the night between the 9th and 10th of the month Mechir; it failed totally, and began at $11^h\ 20^m$ after noon. So Ptolemy, from Hipparchus, book 4, chapter 11. ✢ This one, by a slip of the pen I believe, Renieri in his Catalogue refers to the year of Nabonassar 550, and to the day from the 8th into the 9th. Boulliau gives it, from his own calculation, 16 digits 14′. ✢ And it fell in March on the night between the 19th and 20th, feria 3, as Mulerius has it in the *Tabulae Frisicae*, p. 82.

[Margin: Year 200. ☾ Total.]

Another eclipse of the Moon, likewise in year 55 of the second period of Callippus and 548 of Nabonassar, observed at Alexandria on the night between the 5th and 6th of Mesori; the Moon began to be obscured at $6^h\ 40^m$ of the night and failed totally, as Ptolemy relates from Hipparchus, book 4, chapter 11, adding from his own calculation that the middle time was $14^h\ 15^m$ after noon. ✢ For Mulerius, in the place above, it fell on September 12, feria 4; for Pétau it was of nearly 18 digits and a duration of $3^h\ 16^m$, but for Boulliau of 19 digits 45′.

[Margin: Year 190. ☉]

The eclipse of the Sun in the year from the founding of the City 564, in the consulship of L. Cornelius Scipio Asiaticus and C. Laelius Nepos, on Quintilis 11 [V. Idus Quintiles] of the old year, of which Livy speaks, book 7 of decade 4: *With the sky clear the light was darkened by day, when the Moon had passed beneath the orb of the Sun.*

[Margin: Renieri's slip.]

✢ It fell not on August 9, as Renieri has it, p. 54, but on the day before the Ides, that is, March 14 of the Julian year, as Scaliger has it, book 5 of *De emendatione temporum*, p. 387, and Pétau, book 8, chapter 13, who adds 11 digits 36′, the beginning at $5^h\ 31^m$ after midnight, and the end at $7^h\ 20^m$. ✢ But Herwart, chapter 84, abusing the years, refers it to October, with the Sun at 22° ♎, at $1^h\ 16^m$ before noon, of 8 digits 4′.

[Margin: Year 188. ☉]

The eclipse of the Sun in the year from the founding of the City 565, in the consulship of C. Livius Salinator and M. Valerius Messala. The Sun failed at Rome between the third and fourth hour of the day: from Livy, book 8 of decade 3. ✢ For Pétau, book 8, chapter 13, it fell on July 17, of 11 digits 12′; it began at 5^h 5^m and ended at 7^h 7^m after midnight. ✢ Herwart, chapter 85, while confessing that it occurred in the year from the founding of the City 565, nevertheless says that it was in the year 180 before Christ, departing from the truth by a whole 8 years for the sake of his chronological mysteries, and says that it was at 2^h 12^m before noon, of 7 digits 48′.

[Margin: Year 174. ☾]

The eclipse of the Moon in year 7 of Philometor and 574 of Nabonassar, observed at Alexandria on the night between the 27th and 28th of Phamenoth at 14^h 20^m after noon, of nearly 7 digits, from the north, as Ptolemy reports, book 6, chapter 5, where he adds that it began to fail at 8^h and was replenished at 10^h. ✢ It fell on May 1 [Calendis Maij], feria 7, as Mulerius has it in the *Tabulae Frisicae*, p. 82; for Pétau of 7 digits 20′, but for Boulliau of 7 digits 13′.

[Margin: Year 168. ☾ Total.]

The eclipse of the Moon that Sulpicius Gallus was the first among the Romans to predict, as I related in chapter 1, number 6, in the year from the founding of the City 586, in the consulship of L. Aemilius Paulus and C. Licinius Crassus, *on the day before King Perseus was defeated by Paulus*, as Pliny the Elder says, book 2, chapter 12, and Plutarch in the *Aemilius Paulus*. It failed in Macedonia from the 2nd to the 4th hour on the night preceding September 4, as Livy has it, book 4 of decade 5; but the Pompilian year was dislocated by faulty intercalation, as Scaliger notes with several examples, book 2 of *De emendatione temporum*, pp. 186 and 584; ✢ he adds that it was on June 21 of the Julian year, feria 3, with feria 4 following. But he wrongly gives the Varronian year of the City as 584, although he admits that it was year 4546 of the Julian Period, namely 168 before Christ, in which year the Varronian year of the City 586 began and 585 ended. ✢ Pétau, book 8, chapter 13, computes nearly 16 digits, and says that the eclipse began in Macedonia after noon on June 21 at 5^h 59^m, total obscuration at 7^h 42^m, emersion at 8^h 22^m, end at 10^h 5^m. ✢ Herwart, chapter 86, following the *Fasti Capitolini*, places it in the year of the City 585, but in his usual way in the year 160 before Christ.

[Margin: Apian's slip.]

✢ But Apian, in the *Astronomicum Caesareum*, Enunciatum 30, clinging to the day, but September 2, and forgetting the dislocated year, contends that this eclipse was in the year 172 before Christ at 12^h 41^m.

[Margin: Year 159. ☉]

Herwart, chapter 127 of his *Chronology*, thinks that that phenomenon was an eclipse of the Sun of which Julius Obsequens says: *At Capua the Sun was seen at night; at night an appearance of the Sun shone forth at Pisaurum*; because in

fact on January 1 the Sun, failing by 11 digits at its setting, was seen by the aid of refraction.

[Margin: Year 141. ☾]

The eclipse of the Moon in year 37 of the third period of Callippus and 607 of Nabonassar, observed on the island of Rhodes on the night between the 2nd and 3rd of Tybi; it began at the start of the fifth hour of the night, and at most three digits failed, from the south. Ptolemy, book 6, chapter 5. ✢ It fell on January 27, feria 3, according to Mulerius; but Lansbergen gathers 2 digits 56′, while Pétau has 3 digits 50′ and a duration of 2^{h} 8^{m}.

[Margin: Year 127. ☉]

Herwart, chapter 128, posits an eclipse of the Sun on account of those words of Julius Obsequens, *The Sun seen at night*: because at the beginning of February a morning eclipse of the Sun of 9 digits 57′ was taken for a night of the Sun already risen.

[Margin: Year 113. ☉ False.]

The eclipse of the Sun indicated by Pliny the Elder, book 2, chapter 33, where he says: *A light from the sky was seen by night in the consulship of C. Caecilius and Cn. Papirius and often at other times, so that an appearance of day shone by night.* But, as Milich rightly explains there, what is meant is a chasm [Chaſma] and a meteorological burning, and not an eclipse of the Sun. ✢ Granted that Herwart, chapter 86 of his *Chronology*, drags Pliny the Elder to an eclipse so as to drag those consuls into the year 105 before Christ,

[Margin: Year 105. ☉ From calculation.]

in which year he finds an eclipse of the Sun at 12° of Aquarius, at 4^{h} after noon at Rome, of 11 digits 2′; and from this, by a remarkable chronological paralogism, he concludes that the common era, which assigns those consuls to the year 113, is in error by 8 years.

[Margin: Year 104. ☉]

The eclipse of the Sun in Varronian year 650 from the founding of the City, but according to the *Fasti Capitolini* 649, in the consulship of C. Marius, for the second time, and C. Flavius Fimbria. Of it Julius Obsequens writes as follows in his little book on prodigies: *The Moon appeared by day with a star, from the 3rd hour until the 7th. The regions among the Thurini were laid waste by fugitives and deserters. The Cimbri, having crossed the Alps, joined themselves to the Teutons through ravaged Spain. At the third hour of the day an eclipse of the Sun darkened the light. In Picenum three Suns were seen.* ✢ Herwart, however, obtained this eclipse by astronomical calculation in the year 104 before the common era of Christ, with the Sun at 22° of Cancer, at 4^{h} 4^{m} before noon at Rome, which was the 3rd temporal hour, of 11 digits 20′. Since he sees that the common fasti are confirmed by this eclipse, it is remarkable by how many tunnels and circuits he tries to undermine it through the following chapters. ✢ But Kepler too, from a corrupt codex, in *Astronomia Optica*, p. 293, and from him Renieri, p. 55, place it in the consulship of C. Marius and C. Flaccus, who were consuls in the year 100 before Christ.

[Margin: Year 102. ⊙ Doubtful, or occurred in the year 94.]

The eclipse of the Sun in the consulship of C. Marius and Q. Lutatius, and so according to the common fasti in the year 102 before Christ, foisted by Herwart, chapter 86 of his *Chronology*, on Julius Obsequens on account of those words: *In Gaul in the camp a light shone by night*, although this can be understood of a nocturnal chasm. But Herwart does this, in his usual way, so as to contend that our era runs over by eight years. For his argument, reduced to dialectical form, stands thus: Under the consuls already mentioned there was an eclipse of the Sun; but this was not in the year 102, to which the common fasti assign them, but in the year 94, at 2° of Cancer, of 8 digits 58′, at 4^h 20^m after noon, around the Fossae Marianae; therefore those consuls are to be recorded at the year 94, not 102.

[Margin: Year 49, perhaps. ⊙ Total.]

The eclipse of the Sun in the year from the founding of the City 704, in the consulship of L. Aemilius Paulus and Claudius Marcellus: the Sun failed wholly, namely at the time when C. Julius Caesar crossed the Rubicon. For Dio Cassius says in book 41: [Greek: ὅ, τε ἥλιος σύμπαν ἐξέλιπε (ho te hēlios sympan exelipe, and the Sun failed wholly)]. And it seems to be indicated by Lucan, who writes thus of that year in which Pompey fled:

When the Titan himself bore his head in mid Olympus, He hid his burning chariot in black darkness, And wrapped the day in shadows, and compelled the nations To despair of day: such a night as Thyestean Mycenae Drew on when the Sun fled through the east.

It is doubted, however, whether this is that eclipse of the Sun which Herwart, chapter 130, and Pétau, book 8, chapter 13, find in the year 51 before Christ, at 14° 21′ ♓, at Rome at 2^h 12^m after noon on March 7, since they say that it was of only 9 digits 2′ or 10 digits 34′. For that reason Herwart dares to say that this is the very one which in the year 38 before Christ preceded the civil war of Octavius Augustus and M. Antony, and that the prodigies of those civil wars were confused by writers, because in that year 38 there was a total eclipse, as we shall soon say. But it is certain for us that Caesar crossed the Rubicon in the year 49 before Christ, namely the year preceding his second consulship.

[Margin: Year 44 or 43. ⊙]

An eclipse of the Sun after the murder of C. Julius Caesar seems to be indicated both by Aurelius Victor, who says: *When the body of the murdered C. Julius Caesar had been placed before the rostra, the Sun is said to have hidden its orb*; and by Dio Cassius in these words: *The light of the Sun too was seen to diminish and be extinguished, and at times to shine out in three circles.* But Appian says nothing else to the point about the same year, except that many grim prodigies occurred around the Sun. Virgil sang of it more splendidly in book 4 of the *Georgics*, in verses already cited in chapter 1, number 4, where you also have the verses of Petronius Arbiter and the passage of Pliny the Elder. I now add, from Josephus the Jew, book 14 of the *Antiquities*, chapter 21, the words of M. Antony from a letter written to the high priest Hyrcanus: *We take*

vengeance on those who have committed injustices against men and wickedness against the gods. Indeed, on account of those crimes of theirs, we believe that the Sun too, abhorring them, turned its face away from them, as one that had itself looked on the crime committed against Caesar not willingly but with horror and disgust.

[Margin: Annular?]

Yet Georgius Heruartus, in chapter 145 of his *Chronology*, judges that this eclipse was the same as that appearance [Epiphaſi] of the Sun which occurred when C. Octavius Augustus was entering the City after Caesar's murder, in the consulship of Hirtius and Pansa; namely an annular eclipse, as we usually call it, with a bright small circle of the Sun left around the Moon. And he tries to drag here those words of Suetonius in the *Augustus*, chapter 95: *After Caesar's murder, when Augustus had returned from Apollonia and was entering the City, suddenly, in a clear and pure sky, a circle in the likeness of a rainbow surrounded the orb of the Sun.* And also those words of Julius Obsequens in his little book on prodigies: *When C. Octavius was entering Rome at the third hour of the day, with a huge crowd pouring round him, the Sun, enclosed in a moderate orb of a pure and clear sky, surrounded him with a circle of an outermost line, such as a bow usually stretches in the clouds*; and soon after: *Three Suns shone, and around the lowest Sun a crown like a spike of grain flashed out in a ring, and afterwards, the Sun being reduced to one circle, the light was feeble for many months.* This is confirmed by Orosius, book 6, chapter 20. But Seneca, book 1 of the *Natural Questions*, chapter 2, openly refers this to a meteoric appearance [Phaſma], saying: *It is recorded that on the day when the deified Augustus entered the City on returning from Apollonia, a circle of varied colour was seen around the Sun, such as there usually is in a rainbow; this the Greeks call* [Greek: ἅλως (halōs, halo)]*, and which we usually call a crown.* At other times, however, these crowns come from an eclipse. Thus Philostratus in the *Life of Apollonius*: *In the sky such a prodigy appeared: a certain crown like a rainbow surrounded the orb of the Sun, and obscured the rays and light of the Sun.* And after he has added that the prefect of Greece feared that all things would be turned to night, he adds that Apollonius said to him: *Take heart: from this night a light will rise, that is, the slaughter of the tyrant*, namely of Domitian. Soon after, recounting the killing of Domitian carried out by his chamberlain Stephanus, he says that this very thing was foreshadowed by the form of that prodigy, namely by that crown which obscured the Sun, since a crown in Greek is [Greek: στέφανος (stephanos, crown)]. The words of Pliny the Elder, book 2, chapter 28, also favour this: *Stars too are seen with the Sun, generally for whole days, and around the orb of the Sun crowns like spikes of grain and circles of many colours, as when Augustus Caesar, in his first youth, was entering the City after his father's death to take up his great name.* For if stars were seen, then the Sun seems to have been obscured in a great part of itself; and those words of Julius Obsequens (*the Sun enclosed in a moderate orb*) seem to indicate an annular eclipse.

But since it is certain for us, from the series of consuls and of Julian years, that C. Julius Caesar was killed in the year 44 before the era of Christ, on March 15, and that Hirtius and Pansa were consuls in the year 43, in which Augustus

also entered the City, then if that display [Emphaſis] of a bright crown and rainbow accompanied an eclipse, it cannot be the same as the eclipse of which Aurelius Victor spoke above, who affirms that it was seen when Caesar's body had been placed before the rostra. The new Moons of the year 44 after March 15 must therefore be examined. Since Herwart found no eclipse at them, he assigns this Caesarian eclipse, which he thinks was the same as the annular one of Octavian, to the year 38 before Christ,

[Margin: Year 38. ☉ From calculation, not from observation.]

in which on January 14 the Sun, at 22° 8′ of Aquarius, at Rome 3^h 6^m before noon, failed by 11 digits according to the Prutenic Tables, as Herwart has it; but I believe there is an error in the text, for how on January 14 could the Sun have been at 22° of Aquarius? Perhaps the day should be read as 24 and the degree as 2. He adds, however, from two different calculations, 11 digits 13′ or 11 digits 59′. From this he infers that Hirtius and Pansa were consuls in that year 38, and that there is an error of 5 years in the published fasti. But we have already refuted the violence of this chronologism in our Chronological Book.

[Margin: Year 4. ☾]

The eclipse of the Moon: in Julian year 42, on the night between March 12 and 13, which by the calculation of Pétau, book 8 of *De doctrina temporum*, chapter 13, and in the *Rationarium temporum*, book 4, chapter 22, was of 6 digits, and at Jerusalem began at 1^h 17^m after midnight and ended at 4^h 13^m. ✝ But by the calculation of Kepler in the Rudolphine Tables, p. 103, it was of 5 digits 34′, and began in Judaea at 3^h 20^m and ended at 5^h 15^m after midnight. They judge, moreover, that this is the eclipse which Josephus the historian, book 17 of the *Jewish Antiquities*, chapter 8, and book 2 of the *Jewish War*, chapter 21, relates was seen before the death of Herod the child-killer. That Herod, it is certain from the Gospel, was still alive when Christ the Lord was born. Kepler therefore contends, in his *Silva Chronologica*, that Christ was born in Julian year 41 or 40, and thus that to our common era, which places his birth in the year 45, at least 4 and perhaps 5 years are lacking, so that the year 1606, in which Kepler was writing that *Silva*, was in truth the year of Christ 1610 or 1611. But I have treated this matter at length throughout the whole of book 3 of my *Chronology*. Meanwhile I point out that there were other eclipses of the Moon before the Saviour's birth, which could have preceded Herod's death, if the history of Josephus, Dio, Tacitus and others did not, on other grounds, compel us to choose this eclipse.

[Margin: Year 1. ☾ ☾ Twin eclipse.]

For as Scaliger notes in *De emendatione temporum*, pp. 16 and 463, and as Salianus with many others notes at the year of the world 4053, number 23, an eclipse of the ☾ occurred in Julian year 45, on the night following January 8; from which Salianus concludes, and Scaliger does not deny it, that the Saviour was born in Julian year 44. But in that same year too, on December 29, there was an eclipse of the ☾ visible in Judaea, and it was total with stay.

SEQVVNTVR ECLIPSES POST NATVM CHRISTVM

Annis Epochæ vulgaris Christianorum consignatæ.

The eclipses after the birth of Christ now follow, marked by the years of the common era of the Christians.

[Margin: Years of Christ.]

[Margin: Year 5. ☉]

The eclipse of the Sun under the consuls L. Valerius Messala and Cn. Cornelius Cinna, concerning which Dio, book 55, says: *Some part of the Sun failed.* ✢ Pétau, book 8, chapter 13, places it on March 28, of 4 digits 45′, and has it begin at Rome at 3^h 21^m after noon and end at 5^h 2^m. ✢ But Herwart, chapter 131 of his *Chronology*, places its middle at 4^h 51^m, in ♓ 29° 57′, and gives it 5 digits 10′.

[Margin: Year 14. ☉ Total, or Year 17.]

The eclipse of the Sun shortly before the death of Augustus, of which Dio Cassius says: *For the Sun too had failed entirely.* And the Chronicle of St Jerome agrees, saying: *An eclipse of the Sun occurred, and Augustus dies at the age of 76.* Nicephorus, book 1, chapter 17, adds that a severe famine also followed. ✢ But because astronomical calculation shows no eclipse of the Sun in this year, Herwart, chapter 147 of his *Chronology*, supposes it to have been the one that Paulus, bishop of Fossombrone, reports as follows: *In the year of the Lord and Saviour 17 by the customary reckoning, the whole Sun was seen to be obscured at Rome and in very many places in Italy on February 15, at about the noon hour, by 12 points, in 16° of Aquarius, with the Sun holding the royal house; therefore, according to the opinions of the Chaldeans, it portended the death of the supreme King.* And because Herwart thinks that Augustus died in the year of Christ 19 of the common era, he therefore says that this eclipse occurred in the third year before Augustus's death.

[Margin: Year 14. ☾ Total.]

The eclipse of the Moon under the two Sextuses as consuls, Pompeius and Apuleius, in the year of the City 767 and Julian year 57, after the death of Augustus, who died on the 19th of the month of August. By the portent of this eclipse Drusus quelled the mutiny of the Pannonian legions, as we said in chapter 2, from Tacitus, *Annals* book 1, with whom Dio, book 56, agrees. ✢ On the authority of Scaliger, book 5, p. 465, this failing fell on September 27, feria 5. ✢ For Pétau, however, book 8, chapter 13, it was of 19 digits 30′, and began in Pannonia at 3^h 19^m after midnight; it was total at 4^h 22^m; the Moon began to emerge at 6^h 7^m and was wholly refilled at 7^h 7^m, the Sun having already risen. ✢ But because this eclipse condemns Herwart's chronology, and because Tacitus mentions clouds, on whose rising the mass of the soldiers believed that the Moon had again been hidden in darkness, the good Herwart affirms, in chapter 257 of his *Chronology*, that it was not a true eclipse but came

from clouds, and that from the death of Tiberius[44] to September 27 there was not enough time for the son of Blaesus to travel from Pannonia to Rome, and for Drusus to travel from there to Pannonia with the praetorian cohorts. But Herwart labours in vain. For unless it had been certain to the soldiers that the Moon, the sky around it having been clear beforehand, had undergone a true eclipse, Drusus would not have exposed himself to greater danger, as though he wished to frighten them with an empty portent and to turn into a prodigy what clouds very often do; yet once they had been terrified, it was easy for them to think the eclipse had been repeated. Nor would Tacitus have added the words: *The soldier, ignorant of its cause*; since even boys know that the Moon is often hidden by clouds. Nor would Dio Cassius have said outright: *Dismayed by the Moon's failing, they were calmed.* Herwart does admit that in this year 14 of the common era, on September 27, there was an eclipse of the Moon; but he denies that it fell in the consulship of Sextus Pompeius and Sextus Apuleius. ☩ And Renieri errs in his *Catalogue of Eclipses* when he says this one took place at the beginning of the night.

[Margin: Year 33. ☉ ☩]

The eclipse of the Sun at the death of Christ, which we discussed sufficiently in chapter 18.

[Margin: Year 45. ☉]

The eclipse of the Sun under the consuls M. Vinicius II and M. Statilius Corvinus, in the year of the founding of the City 798, of which Dio, book 60, says of the Emperor Claudius: *Since an eclipse of the Sun was going to occur on his birthday, he feared that some disturbance might arise from it, as certain other prodigies too had occurred; he therefore published not only that this failing would occur, and its time and magnitude, but also the causes by which it must necessarily come about.* Now Claudius died in the year of the City 800, on October 13 [3. Idus Octobris], and had been born on August 1 [Kalendis Augusti], as Suetonius attests, chapter 2. ☩ For that day, at this year 45, Pétau, *De doctrina temporum* book 8, chapter 13, computes an eclipse of 3 digits, with its beginning at $7^{h}\ 43^{m}$ and its end at $9^{h}\ 1^{m}$ after midnight. ☩ Scaliger, *De emendatione temporum* book 5, p. 466, says it was feria 1.

[Margin: Year 59. ☉]

The eclipse of the Sun under the consuls M. Vipsanius Apronianus and L. Fonteius, in Tacitus, *Annals* book 14, who counts it among the prodigies occasioned by Nero's killing of his mother Agrippina. Pliny the Elder, book 2, chapter 70, says this of it: *The eclipse of the Sun that took place under the consuls Vipsanius and Fonteius, who held office a few years ago, on April 30* [pridie calendas Maias]*, Campania noticed between the seventh and eighth hours of the day; the general Corbulo, in Armenia, between the tenth and eleventh hours of the day.* This passage serves to correct Martianus Capella, book 6, who gives April 21 [11. Calendas Maij], and hour 7 in Campania and hour 11 in Armenia.

[44] the page prints `Tiberij`; the death named earlier in this entry is that of Augustus.

[Margin: Year 69. ☾]

An eclipse of the Moon indicated by Dio, book 65, on October 18, which it hardly matters to examine.

[Margin: Year 72. ☉ and ☾.]

An eclipse of the Sun and, after twelve full days, a horizontal eclipse of the Moon are indicated by Pliny the Elder, book 2, chapter 13, in these words: *By what reason, since at the Sun's rising that dulling shadow ought to be below the Earth, it has once already happened that the Moon failed at its setting, with both bodies visible above the Earth; for that both bodies should be looked for within twelve days happened also in our own age, under the Emperors Vespasian.* We discussed this passage sufficiently, as regards the force of refraction, in chapter 5, number 16. But whether these are the eclipses, the solar one on the 8th and the lunar one on the 22nd of February, which the astronomical tables gather, the former shortly after sunrise and the latter shortly after sunset, I shall examine elsewhere.

[Margin: Year 95. ☉ Annular.]

The annular eclipse of the Sun recorded by Philostratus in the *Life of Apollonius*, as foretelling the murder of Domitian. For he says: *In the sky a prodigy of this kind appeared. A kind of crown resembling a rainbow surrounded the orb of the Sun, and obscured the Sun's rays and light.* Hence, when the Prefect of Greece feared [Greek: μὴ ἐς νύκτα μεταστῆ πάντα (mē es nykta metastē panta, "lest everything turn to night")], that all things might be turned into night, Apollonius replied: *Take heart: from this night light will arise*, signifying the slaughter of Domitian soon to be carried out by Stephanus his chamberlain; whose name, says Philostratus, the figure of that prodigy signified. Yet Ptolemy's series of the Emperors places this killing in the year 96, on September 18.

[Margin: Year 97 or 98. ☉ Perhaps total.]

The eclipse of the Sun on January 27, shortly after noon, the day on which the Emperor Nerva died, in the year of Christ 97 or 98; on this eclipse, Aurelius Victor and Eutropius. And perhaps it is the one that Plutarch, in his little work on the spots in the face of the Moon, designates as total in the words with which he reminds his interlocutors of that synod of the Sun with the Moon which had recently occurred, *in which, as it began right around noon, stars shone out in many places throughout the sky, and the temper of the air was such as it is in the uncertain light of twilight.* Then, in giving the reasons why *the darkness is not so deep in eclipses, nor the air taken over by them just as it is at night*, he does not resort to a part of the Sun exempt from the eclipse but to other things; he therefore shows that it was total, as Kepler rightly argues in the *Astronomia Optica*, p. 293.

[Margin: Year 113. ☉ Total.]

✝ Yet Kepler, in the Rudolphine Tables, precept 150, or p. 104, says that having examined many eclipses around the year of Christ 100, none presents itself as more likely, or as agreeing better with Plutarch's words, than the one that took place in the year 113 on June 1; but he does not add there the place where it was total.

[Margin: Year 125. ☾]

The eclipse of the Moon observed at Alexandria in Egypt by Ptolemy, in year 8 [recte: 9, per the book's errata] of Hadrian and year 872 of Nabonassar, the 17th of the month of Pachon having passed and the 18th following, 3^h 36^m before midnight, when a sixth part of the Moon's diameter failed from the south: Ptolemy, book 4, chapter 9. ✢ For Pétau this was on April 5, of 2 digits 18′, beginning at 7^h 31^m and ending at 9^h 20^m after noon. ✢ Boulliau gives year 8 of Hadrian and 2 digits 12′. Lansbergen, p. 64 of the *Treasury*, gives year 9 of Hadrian; 1 digit 48′. ✢ Renieri, p. 55, gives year 8 of Hadrian and the month Payni, and adds: *Lansbergen, from a corrupt text, states that it failed at hour 8 51′.* ✢ But in truth Lansbergen does not corrupt the text: for he admits that it has hour 8 24′ [Horam 8. 24′], but says that it should have been 8^h 51^m, given both his own calculation and the completed circles of latitude, as Ptolemy says, from the eclipse of year 31 of Darius son of Hystaspes to this one.

[Margin: Lansbergen vindicated from Renieri's accusation.]

The Greek codex of Basel has [Greek: τῷ ῆ ἔτει Ἀδριανοῦ (tō ē etei Hadrianou, "in the 8th year of Hadrian")], that is, in year 8 of Hadrian, as Herwart too points out, chapter 259 of his *Chronology*, although the Latin and the Arabic have year 9.

[Margin: Year 133. ☾ Total.]

[Margin: Renieri's error,]

The eclipse of the Moon observed with the greatest exactness by Ptolemy at Alexandria, in year 17 of Hadrian and year 880 of Nabonassar, the 20th of the month of Payni having passed, at 11^h 15^m after noon at the middle, and it failed entirely: Ptolemy, book 4, chapter 6. ✢ Renieri wrongly gives the 17th of Payni. Lansbergen computes 12 digits 26′, Pétau nearly 16 digits, Boulliau 13 digits. ✢ According to Mulerius in the *Tabulae Frisicae*, p. 80, it was on the night after May 6, feria 3. Copernicus uses this eclipse, book 4, chapter 5.

[Margin: Year 134. ☾]

The eclipse of the Moon observed at Alexandria by Ptolemy in year 19 of Hadrian and year 882 of Nabonassar, the 2nd of Chocac or Choeac having passed, at the 11th hour from noon; 10 digits failed toward the north: Ptolemy, book 4, chapter 6. ✢ For Mulerius, in the place above, it was on October 20, feria 3. Lansbergen inferred 10 digits 31′, Pétau 10 digits 20′, Boulliau 11 digits 6′, while setting the observed value at 9. Copernicus uses this eclipse, book 4, chapter 5.

[Margin: Year 136. ☾]

The eclipse of the Moon observed at Alexandria by Ptolemy, in year 20 of Hadrian and year 883 of Nabonassar, the 19th of Pharmuthi having passed, at the 16th hour after noon; and half of the Moon was darkened from the north: Ptolemy, book 4, chapter 6. ✢ It was on the 5th of March, with the 6th following. Lansbergen computes, p. 67 of the *Treasury*, 5 digits 47′, but Pétau 5 digits 24′, Boulliau 6 digits 27′. ✢ Further, in Copernicus, who uses this eclipse in book 4, chapter 5, the year of Christ is 135 [CXXXV], March 6 [Martij VI.]

having passed; but 136 [CXXXVI] should be read, because the years of Hadrian are to be reckoned from August 11 of the year 115, on which he entered on his rule. Year 20 therefore began on the same day in the year 135, in which on July 20 the year 883 of Nabonassar had already begun; and so the 19th of Pharmuthi falls in the leap year 136 of Christ and on March 5, and the 20th on March 6. ✝ Mulerius therefore rightly, on p. 80 of the *Tabulae Frisicae*, gave the day as March 6, feria 2, but with 4^h from midnight of the 20th of Pharmuthi, and 16^h after noon of the 19th of Pharmuthi, that is, March 5; ✝ and Pétau gives March 6, but with the hours counted from the preceding midnight.

[Margin: Year 192. ☉ Total.]

The eclipse of the Sun indicated by Herodian in the life of the Emperor Commodus, when he says that before Commodus's death stars were seen in the sky by day; Renieri, p. 56, takes it as total. Commodus was killed, moreover, on December 31 by conspirators.

[Margin: Year 237. ☉ Total.]

The eclipse of the Sun in the year in which Gordian the younger began to rule, of which Julius Capitolinus speaks in these words: *So great was the eclipse of the Sun that it was believed to be night, and nothing could be done without lamps lit.* ✝ Kepler, in the *Astronomia Optica*, p. 293, affirms that it was necessarily total, although he admits that on April 12 the Prutenic calculation shows less than 11 digits. ✝ Lansbergen, in the *Treasury*, p. 124, infers it at Rome at 5^h 2^m after noon and of 11 digits 27′, and adds that it was seen as total, because a particle of the Sun exempt from the eclipse was near the horizon.

[Margin: Lansbergen's bold error against Censorinus.]

But he errs badly when he says that in this year the consuls were Ulpius and Crinitus, and that Censorinus erred, who puts them in Julian year 283, that is, the year of Christ 238, because Lansbergen thinks this eclipse an index of that consulship. But where does Lansbergen get this fancy, since Censorinus says nothing of this eclipse? Or is it because Capitolinus said: *This was a sign that Gordian would not rule for long, that so great an eclipse of the Sun, that it was believed to be night, etc.*, that this was an index of that most famous year in which Censorinus fixed the roots of chronology, so splendid and so clear to himself that all good chronologers draw many axioms of chronology from them? ✝ Herwart, surely more prudently, chapter 256, places this eclipse in this year 237, but under the consuls P. Titius Perpetuus and L. Ovinius Rusticus Cornelianus, at 4^h 56^m after noon at Rome, and of 10 digits 46′. ✝ Pétau, book 8, chapter 13, and Scaliger, p. 492, agree with Censorinus, although Pétau infers 10 digits from his Parisian tables. My tables give then a semidiameter of the Sun of 15′ 32″ and of the Moon of 16′ 30″; for the anomaly of the ☉ was 316° and that of the ☾ 156°.

[Margin: Year 238. ☉]

The eclipse of the Sun in Julian year 238, under the consuls Ulpius Crinitus and Proculus Pontianus, beginning on the morning of April 2, by Pétau's calculation, at Rome at 6^h 29^m after midnight, of 8 digits 15′. Although this

could be taken for the one Capitolinus spoke of above, and could have seemed larger because it was in the morning near the vapours of the horizon, the one of the previous year is nevertheless more probable, as Pétau and Kepler hold. ✢ But Mulerius, in the *Tabulae Frisicae*, p. 236, says that it was this one of the year 238, and adds an Alphonsine calculation, because he does not find it from the Prutenic Tables.

[Margin: Year 291. ☉]

The eclipse of the Sun in year 7 of Diocletian, under the consuls Tiberianus and Dio, the year in which the Caesars Maximinus Armentarius and Constantius Chlorus were created, was seen at Carthage, as Idatius reports in the *Fasti*: namely, by Pétau's calculation, on May 15, of 11 digits 20′; it began there at 2^h 2^m after noon and ended at 4^h 32^m.

[Margin: Year 301. ☾]

The eclipse of the Moon mentioned in the acts of St Felix, martyr and African bishop, and of his companions, in Baronius, but at the year of the Lord 302. For in those acts it is said: *And he was led to the place of his passion, when the Moon itself too was turned to blood, on August 30* [die tertio Kal. Sept.]. Scaliger, in the Prolegomena to *De emendatione temporum*, p. 18, understands these words of a failing of the Moon that the astronomical tables show in the year 301 on September 3 [tertio Nonas Septēbris], and on the fifth day after St Felix was led with his companions into Campania to the place of his passion, because they had refused to hand over the divine books, that is, sacred scripture. Hence Scaliger convicts Baronius of the anachronism [Greek: ἀναχρονισμοὶ (anachronismoi, "anachronisms")], by which he assigns this martyrdom to the year 302.

[Margin: Year 316. ☉]

The eclipse of the Sun seen at Constantinople on July 6, from the Constantinopolitan *Fasti*; for Pétau it was of 4 digits, and began there at 4^h 11^m and ended at 5^h 42^m after midnight.

[Margin: Year 317. ☉]

The eclipse of the Sun in the year in which Crispus Constantinus, son of the Emperor Constantine, and Licinianus, son of Licinius, were named Caesars; on it, Aurelius Victor. ✢ For Pétau this was on December 20, of 7 digits 20′; it began at Paris at 11^h 52^m and ended at 14^h 28^m after midnight.

[Margin: Error in Renieri.]

✢ But Vincenzo Renieri must be corrected, who places it in the year 291, p. 57 of the *Tabulae Mediceae*.

[Margin: Year 334. ☉ Annular.]

The eclipse of the Sun under the consuls Optatus and Paulinus, of which Julius Firmicus, book 1, chapter 2, says: *The Sun at the time of midday, hindered by the rays of the Moon as if by certain obstacles, denied to mortals the brilliant light of its splendour*; and he adds that it was seen at Byzantium. ✢ For Pétau, book 8, chapter 13, it was on July 17 and of 10 digits 24′; it began at Rome at 10^h 19^m

and ended at $13^h\ 14^m$ after midnight. But Lansbergen, in the *Treasury*, p. 126, infers from his tables that it was annular, the whole orb of the Moon being seen within the orb of the Sun. For this is what those words of Firmicus, *the rays of the Moon* etc., signify; for the Moon appeared to radiate all around. My tables represent it as annular: for the anomaly of the ☉ was 46° and that of the Moon 296°, and therefore the apparent diameter of the Sun 31′ 8″ and that of the Moon 29′ 16″.

[Margin: Year 346. ☉]

The eclipse of the Sun that St Jerome assigns to the year of Eusebius 2364, but Theophanes in the *Miscella* to year 10 of Constantius; Kedrenos also speaks of it. ✢ For Pétau this was on June 6, of 7 digits 36′; it began at Constantinople at $4^h\ 44^m$ and ended at $6^h\ 18^m$ after midnight. Since therefore it was in the morning, and the Sun rose in eclipse, it is no wonder if Theophanes says that stars were seen in the sky. ✢ Kedrenos says that it was on the 6th of the month Daesius, that is, June 6; but Scaliger, p. 510, denies that this synod was ecliptic, for a reason to be given shortly.

[Margin: Year 347. ☉]

The eclipse of the Sun in year 11 of Constantius, as St Jerome notes in Eusebius's *Chronicle*. ✢ By Scaliger's calculation, book 5 of *De emendatione temporum*, p. 510, it was on October 20, feria 3. ✢ But for Pétau it was of nearly 7 digits; it began at $3^h\ 25^m$ after noon at Rome and ended at $5^h\ 15^m$, and the Sun set at $5^h\ 20^m$. But since between this ecliptic new Moon and the new Moon of June 6 of the year 346 there are only 16 lunations, and Scaliger does not consider this interval ecliptic, he therefore accuses Kedrenos of ignorance for assigning an eclipse of the Sun to year 10 of Constantius on June 6 [Greek: Λαισίου ς (Laisiou 6, "on the 6th of Laisios"; the Latin above gives the month as Desius)]. For although eclipses can return at the fifth and also at the sixth month, they cannot do so again straight away at the fifth month, and thus at 16 months, as we taught in chapter 14; Kedrenos therefore shows himself ignorant of the ecliptic intervals.

[Margin: Error of Marianus Scotus.]

✢ You may rightly also blame or correct Marianus Scotus, who moves this eclipse to December 15 [18. Kalend. Ianuarij], on which day there was certainly no new Moon, except in the year 350, in which he affirms there was no eclipse of the Sun.

[Margin: Year 348. ☉]

The eclipse of the Sun seen at Byzantium at hour 3 of the Lord's day: from Theophanes in the *Miscella*. For Pétau this was on October 9, of

8 digits; it began at $6^h\ 28^m$ and ended at $8^h\ 31^m$ after midnight.

[Margin: Year 360. ☉]

The eclipse of the Sun under the consuls Constantius X and Julian III, recorded by Ammianus Marcellinus, book 20, in these words: *Throughout the eastern regions the sky was seen dark with gloom, and from the first rising of dawn until noon stars glittered continuously. To these terrors was added the fact that, when*

the heavenly light was covered and light had been taken wholly from the world's sight, the frightened minds of men reckoned that the Sun had failed for a long while, first thinned to the shape of a horned Moon, then grown to the appearance of a month-and-a-half [ſeſquimeſtrem] *one, and afterwards restored whole.* ✢ This eclipse was on August 28, and was seen in Mesopotamia by the Tigris, on the same author's authority, and by the Prutenic calculation it was annular in some place. ✢ For Pétau it was of 11 digits; but because it began there at 4^h 29^m after midnight and ended at 6^h 33^m, stars were therefore seen in the sky; and in the eastern and more easterly regions it began in some places after the Sun had already risen, and lasted almost until noon. Ammianus, therefore, confusing the places of the observations on the strength of differing reports, exaggerated it as though it had lasted in Mesopotamia from dawn to noon.

[Margin: Kepler's error, and his contradiction of himself.]

✢ But Kepler contends in vain, in the *Optics*, p. 294, that it was total, while admitting that the Moon was at apogee but concealing that the Sun was then nearly at perigee. For the anomaly of the Sun was 157° and that of the Moon 358°, and therefore the diameter of the Sun by the Rudolphine Tables is 31′ and that of the Moon 30′; but by my reckoning that of the Sun is 33′ 2″ and that of the Moon 28′ 2″. He therefore contradicts himself.

[Margin: Year 364. ☾]

The eclipse of the Moon of which Theon speaks in his Commentary on Ptolemy, book 6, in the year of Nabonassar 1112, on the 6th of Phamenoth, or November 25, feria 5, as Scaliger has it, book 5, p. 496.

[Margin: Year 365. ☉]

The eclipse of the Sun in the year of Nabonassar 1112, on the 22nd of the month of Payni, whose beginning Theon, father of Hypatia, observed at Alexandria in Egypt at 2^h 50^m after noon, its middle at 3^h 45^m, and its end at about hour 4½, as Theon reports in his Commentary on book 6 of Ptolemy's *Syntaxis*. It was on March 10.

[Margin: Year 393. ☉]

The eclipse of the Sun under the consuls Theodosius III and Abundantius, at hour 3 of the day, of which Marcellinus and Prosper speak in the *Chronicle*, seen at Byzantium and at Rome. ✢ Pétau, therefore, fitting the calculation to both places, says that on November 20 it was at Rome of 9 digits 31′, from 8^h 31^m to 10^h 50^m after midnight, but at Byzantium of 10 digits 44′, from 11^h 16^m to 13^h 30^m. If the intervals of eclipses are therefore to be preserved, there could not have been in this same year in Europe an eclipse of the Sun at hour 4 of the day near Pentecost, as Baronius has it; and in this year Pentecost was on June 5, and the preceding new Moon on May 27.

[Margin: Year 402. ☉]

The eclipse of the Sun on November 11 [3. Idus Nouembris], under the consuls Honorius V and Arcadius V, in Idatius in the *Fasti*. ✢ For Pétau it was of 10 digits 30′, from 7^h 36^m after midnight to 9^h 42^m.

[Margin: Year 410. ☉]

The eclipse of the Sun in which stars were seen in the sky, in the year in which Alaric took Rome, from Nicephorus, book 13, chapter 36.

[Margin: Year 418. ☉]

The eclipse of the Sun on the 14th before the Kalends of August [XIV. Kalend.Auguſt.], or July 16[45], under the consuls Honorius XII and Theodosius VIII, which is asserted by Liechtembergius [?], at the time of St Martin; by Iornandus [Jordanes] in the *Chronicle*, and Marcellinus at Indiction 1; by Idatius in the *Fasti*; and by the *Chronicon Alexandrinum*. ✢ For Pétau it was of 11 digits 30′, from $11^h\ 32^m$ at Rome to $13^h\ 20^m$ after midnight, although Kepler, in the *Optics*, p. 294, considers it to have been total, because he is wholly taken up there with asserting total failings of the Sun.

[Margin: Year 421. ☉]

The eclipse of the Sun of which Prosper speaks in the short *Chronicle* edited by P. Pithou, saying: *Jerome dies at Bethlehem in the 98th year of his age; and in the following year, in this year, an eclipse of the Sun took place; Pharamond reigns.* It is established from the consular *Chronicle* of Prosper that St Jerome died under the consuls Theodosius IX and Constantius III, that is, as Marcellinus has it, in Indiction 3, or the year of Christ 420. The eclipse was therefore in the year 421, namely, as Scaliger says, book 6 of *De emendatione temporum*, p. 611, on May 17, feria 3; and thus the beginning of Pharamond belongs to the year 421 and not to 419, as Sigebert wrongly has it.

[Margin: Year 450. ☉]

The eclipse of the Sun of which St Gregory of Tours speaks, book 2, chapter 3, on the coming of the Huns: *Then the Sun too appeared foul, so that scarcely even a third part of it shone. For I believe that for such great crimes and the shedding of innocent blood* etc. It was in year 1 of the Emperor Marianus, under the consuls Valentinian VII and Avienus, Indiction 3, as Gregory notes, and according to Scaliger on April 27, feria 5; and in the following year, namely the year 451, Attila burst into the Gauls.

[Margin: Year 451. ☾]

The eclipse of the Moon at its rising, on September 26 [6. Kal. Octobr.], of which Idatius speaks in the *Fasti*, p. 28, seen at Compostela, where he lived, from hour 15 55′ to 19 25′, of 10 digits, as Pétau's calculation shows.

[Margin: Year 458. ☉]

The eclipse of the Sun on May 28 [V. Kalend. Iunias], in Idatius in the *Fasti*, of 11 digits, at Compostela at $9^h\ 9^m$ after midnight, as Pétau computes.

[Margin: Year 462. ☾]

The eclipse of the Moon on March 2 [VI. Nonas Martij], feria 6, as Idatius says in the *Fasti*, p. 40, seen at Rome, ✢ although Pétau directs the calculation to Compostela, and says that there it began on March 1 at $22^h\ 33^m$ after midnight and ended at $1^h\ 41^m$ of the following day, and finally that it was of 9 digits.

[45]the page prints 16; the 14th before the Kalends of August is July 19 by inclusive count

[Margin: Year 464. ☉]

The eclipse of the Sun on July 20 [13.Kal.Auguſti], seen at Constantinople, of which Idatius speaks in the *Fasti*, adding, p. 42, that it was seen at Rome from hour 3 to hour 6. ✢ Pétau, by his calculation, states 8 digits, and that it began at Byzantium at 7^h 28^m after midnight and ended at 9^h 55^m.

[Margin: Year 465. ☉ ☉ by calculation.]

The eclipse of the Sun computed, on the occasion of the preceding one, by Francesco Montebruni, who consulted me about it for I know not what purpose, and found from Lansbergen's tables on July 9, 21^m before noon, at Athens, together with another ecliptic new Moon on January 12, at 17^h 53^m after noon, at Constantinople.

[Margin: Year 484. ☉ Total.]

The eclipse of the Sun on January 13, *by which day was turned into night, for deep darkness came on and stars were seen*, as is found in Renieri's *Catalogue*, from the life of Proclus written by Marinus and from the Greek text, which is kept in the library of the Grand Duke of Tuscany. The corrected anomaly of the ☉ was 218° and that of the ☾ 169°, and therefore, for me, the diameter of the Sun was 32′ 50″ and that of the Moon 33′ 24″.

[Margin: Year 486. ☉]

The eclipse of the Sun on May 18, from the life of Proclus, of which above, in Renieri.

[Margin: Year 574. ☉]

The eclipse of the Sun in the year before the death of Justinian, which Paul the Deacon, book 2, chapter 31, says was so great that not even a fourth part of the Sun remained shining, but that it appeared foul and discoloured, as if a sack. But because he says that it was on October 1 [Kal. Octobris], ✢ and Scaliger, book 6, p. 617, finds it by calculation on September 1 [Kal. Septembris] rather than in October, Scaliger therefore corrects Paul the Deacon.

[Margin: Year 581. ☾]

The eclipse of the Moon on April 4. The Moon failed in year 6 of Childebert the Younger, as St Gregory of Tours writes, book 6, chapter 25. ✢ For Pétau it was of 7 digits; it began at 23^h 53^m after midnight and ended on the following day at 3^h 13^m.

[Margin: Year 582. ☾ Total.]

The eclipse of the Moon in year 7 of Childebert the Younger, on March 24, from St Gregory of Tours, book 5, chapter 21. ✢ By Pétau's calculation it was of 22 digits 7′; it began at Paris at 1^h 47^m after midnight; total immersion at 2^h 57^m; emersion at 4^h 55^m; end at 6^h 5^m.

[Margin: Year 582. ☾ Total.]

Another eclipse of the Moon, on September 17, in the same St Gregory of Tours, book 5, chapter 21. ✢ For Pétau it was of 21 digits; beginning at Paris at 22^h 45^m; total immersion at 23^h 55^m; emersion after midnight of the following day at 1^h 27^m; end at 2^h 37^m.

[Margin: Year 590. ☉]

The eclipse of the Sun of which St Gregory of Tours speaks, book 5, chapter 21, in year 15 of Childebert, where he says that at Tours in the month of October the Sun failed so that it scarcely had, for shining, as much as the horns of a fifth-day Moon have. ✢ By Pétau's calculation it was on October 4, of about 7 digits; it began at Paris at $9^h\ 7^m$ and ended at $11^h\ 3^m$ after midnight. ✢ Scaliger, book 5, p. 620, confuses this one with the eclipse of the year 597, of which we shall speak shortly.

[Margin: Year 592. ☉]

The eclipse of the Sun in year 9 of Maurice and year 32 of Guntherhamnus, in the spring, as the Constantinopolitan *Annals*, Theophanes and Fredegar in the appendix to Gregory of Tours have it, and the year there is 32. ✢ For Pétau it was on March 19, from $8^h\ 54^m$ to $11^h\ 23^m$, at Constantinople, and of 10 digits. ✢ Granted that Kepler, in the *Optics*, p. 294, places it among the total eclipses on a surely weak conjecture, namely because he thinks that eclipses of the Sun are rarely found in writers of those centuries, since they noted only total ones; but from the year 360 to 418 he had read of no eclipses of the Sun being noted.

[Margin: Year 597. ☉]

The eclipse of the Sun on November 15, of which Scaliger, book 6, p. 620, holds that Fredegar spoke when he said: *The Sun suffered an eclipse in the middle of the eighth month, and its light diminished so that it scarcely had, for shining, as much as the horns of a fifth-day Moon retain.* But the eighth month is October, so Fredegar or St Gregory speak of the eclipse of the year 590. ✢ Sigebert wrongly places this one in the year 596.

[Margin: Year 603. ☉]

The eclipse of the Sun in year 8 of Theodoric and Theodebert, kings of the Franks, of which Fredegar speaks in the appendix to St Gregory of Tours. By Pétau's reckoning it occurred on August 12, at Paris at 3^h after noon, of 11 digits 20′.

[Margin: Year 605. ☉]

The eclipse of the Sun on May 5, after which came a plague of 3 months, in which a good Angel together with a bad one was seen going round the cities and marking the houses, as Regino has it in his *Chronicle*, book 1, and Gregorius Tholosas [Pierre Grégoire of Toulouse], book 2 of *De Republica*, p. 128.

[Margin: Year 664. ☉]

The eclipse of the Sun on May 1 [Calendis Maij], granted that Bede, by mistake, in book 3 of the *History of the English*, chapter 27, puts the 3rd of the month; it was seen at London at about the third hour. ✢ Pétau says that it was of 10 digits 20′, that it began there at $3^h\ 7^m$ after noon and ended at $5^h\ 14^m$. Yet Kepler, in the *Optics*, p. 294, judges it to have been total, on the strength of that slight conjecture of which we spoke at the year 592.

[Margin: Year 682. ☉]

The eclipse of the Sun on May 3 [V. Nonas Maij], which an eclipse of the Moon had preceded, in Lycosthenes, in the *Chronicon prodigiorum*, an author, however, tainted by excessive spite against the authority of the Roman Pontiff.

[Margin: Year 719. ☉]

The eclipse of the Sun, total in Spain, from certain annals that Scheiner adduces in the *Rosa Ursina*.

[Margin: Year 760. ☉]

The eclipse of the Sun in year 20 of Constantine Copronymus, on August 15, at Constantinople, from Theophanes. For Pétau it occurred at 5^h after noon, of 10 digits.

[Margin: Year 787. ☉]

The eclipse of the Sun in year 7 of Constantine, son of Irene, on September 16, at hour 5 of the day, of which Kedrenos speaks under that year 7, and Theophanes. The Prutenic Tables give 11½ digits. ✝ Pétau gives 9 digits 47′, and the hour as 8^h 47^m after noon at Constantinople. But Kepler, in the *Optics*, p. 294, would have us believe that it was total.

[Margin: Year 806. ☾ Total.]

The eclipse of the Moon on September 2 [4. Nonas Septembris], in Aimoin, book 4, chapter 95, and Regino, book 2 of the *Chronicle*. ✝ For Pétau it was of 16½ digits; it began at Paris at 19^h 57^m after midnight, the total obscuration was at 21^h 11^m, the emersion at 22^h 47^m, and the end at 0^h 1^m of the following day.

[Margin: Year 807. ☉]

The eclipse of the Sun on February 11 [3. Idus Februarij], of which speaks an anonymous writer on the life of Charlemagne, published by Pierre Pithou, who is believed to be a monk of Angoulême. For Pétau it occurred there at 9^h after midnight, of 9 digits 42′.

[Margin: Year 807. ☾ Total.]

The eclipse of the Moon on February 26 [4. Kalend. Martij], of which Aimoin speaks, book 4, chapter 95, and Regino, at Paris near midnight; of 12 digits 20′ for Pétau.

[Margin: Year 807. ☾ Total.]

The other eclipse of the Moon in the same writers, which began on August 21 at 20^h 26^m after midnight; the complete immersion was at 22^h 8^m, the emersion at 22^h 32^m, the end on the following day at 0^h 14^m; 12 digits 12′ for Pétau.

[Margin: Year 808. ☉]

The eclipse of the Sun in year 8 of Charlemagne, on May 14, in Theophanes and Lycosthenes.

[Margin: Year 809. ☉ ☾]

An eclipse of the Sun and then of the Moon in December, in Regino, book 2.

[Margin: Year 810. ☉]

The eclipse of the Sun on November 30 [pridie Kal. Decembris], of which Regino speaks, book 2; at 11^h 48^m after noon at Königsberg in Prussia [Regiomontis Prussiae], as Pétau computes, and of 11 digits 10′. But the one that the same Regino says occurred on June 9 [V. Idus Iunij] is false; for there was no new Moon on that day, nor an ecliptic one in that month, as Pétau points out.

[Margin: Year 811. ☉]

The eclipse of the Sun in year 44 of the life of Charlemagne, on May 15 [Idib. Maij], in the *Annals of the Franks*.

[Margin: Year 812. ☉]

The eclipse of the Sun of which the anonymous writer on the life of Charlemagne speaks, and Regino, seen at Constantinople on the day before the Ides, not of June, as the corrupt codex has it, but of May, as Pétau would have it. At 14^h 13^m after midnight, of 9 digits.

[Margin: Year 813. ☉]

The eclipse of the Sun in year 2 of Michael Curopalates, of which Theophanes speaks at the year of the world 6305, and the *Miscella*, book 24, seen in Cappadocia on May 4 at sunrise; of 10 digits 35′ for Pétau. This year was the last of the Emperor Michael and the first of Leo the Armenian, at which the history of Theophanes ends.

[Margin: Year 840. ☉ Total.]

The eclipse of the Sun from the *Annals of the Franks*, in the year 840, on May 5, before the death of Louis the Pious, king of the Franks, of which Aimoin speaks, book 5, chapter 19, the anonymous writer published by Pithou, mentioned above, and the author of the life of Louis the Pious, who add that it was on the Vigil of the Ascension, and *very great, so that stars were even seen because of the darkness of the Sun, and the colour of things on earth changed*. Indeed, as the author of the life of Louis says: *So that it seemed to differ in nothing from true night; for the sparse order of the stars was so discerned that no star suffered the dulling of the Sun's light. Rather the Moon, which had presented herself opposite it, gradually making for the east, first restored to it a horned light from the western side, after her own manner when she is seen one or two days old; and so by increments the whole wheel of the Sun recovered all its beauty.* From this it appears that this author was skilled in astronomy and in distinguishing the stars; this is also confirmed by the conversation he adds, held with Louis the Pious, about the comet [stella Crinita] of the preceding year, as Kepler points out in the *Optics*, p. 295. ✢ It was therefore total, with the Moon set nearly at perigee; and therefore not of only 9 digits 20′, as Pétau computes for 11^h after midnight.

[Margin: Year 842. ☾]

The eclipse of the Moon on March 30 [3. Kal. Aprilis], feria 5 of Holy Week [Maioris Hebdomadae], at hour 10 of the night, of which the already mentioned *Annals of the Franks* speak. ✢ Pétau computes 14 digits 30′, and at

Paris the beginning at 0^h 48^m, totality at 2^h 2^m, the emersion at 3^h 14^m, and the end at 4^h 28^m from midnight.

[Margin: Year 878. ☾ ☉ Total.]

The eclipse of the Sun on October 29, at hour 9 of the day, which an eclipse of the Moon had preceded on the 14th, in year 29 of Louis the Stammerer, from the *Annals of the Franks*, in Kepler's *Optics*, p. 295. The author of the life of Louis says that *after hour 9 the Sun was so obscured for half an hour that stars appeared in the sky, and all thought that night was upon them*. Kepler, with Gemma Frisius, supposes that it was total, since it came from a Moon near perigee. Moreover, Louis died in the following year, on April 10 [4. Idus Aprilis]. For me it was total with no perceptible difference; for the anomaly of the Sun was 136° and that of the ☾ 220°, and the diameter of the ☉ 32′ 42″, but that of the ☾ 32′ 40″.

[Margin: Year 883. ☾]

The eclipse of the Moon in year 1631 of Nabonassar, 1206 from the death of Alexander the Great, and 1194 of the Terik era (that is, the era of Dhil-karnain), on the 23rd of the month Kenir, observed at Arachta in Syria at 8 equal hours or a little more after noon; al-Battānī, *De scientia stellarum*, chapter 30, where he says that it failed toward the north by more than 10 digits. Lansbergen concludes 11 digits 35′, Bünting and Pétau 11 digits.

[Margin: Year 888. ☾]

A great eclipse of the Moon on October 16, in Regino, in the *Chronicle*, book 2.

[Margin: Year 891. ☉]

The eclipse of the Sun in the year of Dhil-karnain 1202, 1214 from the death of Alexander the Great, on the 8th of Ab, that is August, feria 1, observed at Arachta by al-Battānī; there two and more parts of three of the Sun failed, and the apparent conjunction preceded the true by about an eighth part of an hour. So al-Battānī, chapter 30. See Scaliger, book 5, p. 428; Regiomontanus, book 5 of the *Epitome of the Almagest*, proposition 21; Lansbergen, who computes 9 digits 22′; and Pétau, who computes 9 digits 20′.

[Margin: Year 894. ☉ Or rather Year 901.]

The eclipse of the Sun observed by al-Battānī at Antioch in Syria on the 23rd of the month Huni the second, that is January, in the year of Dhil-karnain 1205, 1217 from the death of Alexander, at about 3^h 40^m before noon, and a half and a little more of the Sun was obscured. So al-Battānī, chapter 30. There, however, Lansbergen reads the year 1224 from the death of Alexander, that is, of Christ 901, on January 23; al-Battānī adds that it was observed at Arachta at about hour 3½ before noon, and that less than two thirds of the Sun was obscured there.

[Margin: Year 901. ☾]

The eclipse of the Moon observed by al-Battānī at Antioch in the year 1224 from the death of Alexander the Great, by night between the 2nd and 3rd of the month Ab, or August, at 15^h 20^m, but at Arachta at 15^h 35^m after noon. So

al-Battānī, chapter 30, affirming that the Moon was eclipsed almost wholly. Regiomontanus adds, in book 5 of the *Epitome of the Almagest*, proposition 21, that according to the Ptolemaic tables 10 digits ought to have been obscured, and the eclipse ought to have preceded by 50^{m}. Lansbergen, p. 69 of the *Treasury*, computes 12 digits 51′, but holds that al-Battānī did not see it wholly obscured, because it was not deeply plunged in the shadow. Pétau too concludes 12 digits 30′. ✝ Scaliger, p. 420, says that it was feria 1 going into the following feria 2. From my tables come fewer than 12 digits, as al-Battānī's observation requires.

[Margin: Year 926. ☾]

The eclipse of the Moon on April 1 [Calendis Aprilis], with a certain particle of light left, as though she were two days old; and so, with dawn now beginning, she changed wholly to a blood colour. Flodoard, in the *Chronicle*; on which see Kepler, p. 274 of the *Optics*.

[Margin: Year 944. ☉]

A terrible eclipse of the Sun on feria 6, at hour 3 of the day, on the day when Addaram [?], king of the Saracens, was defeated by Rhadamiro [Ramiro], king of Galicia. Sigebert, in the *Chronicle*.

[Margin: Year 95[?]. ☉ Total.]

The eclipse of the Sun on December 18 [XV. Kal. Ianuarij], in year 3 of Lothair, so great *that stars appeared from the first hour up to the third hour*, from the life of Lothair, and from Kepler in the *Astronomia Optica*, p. 295. For me the anomaly of the Sun at that time was 185° and that of the Moon 206°, and therefore the diameter of both Sun and Moon was 33′ 8″, and the eclipse was precisely total.

[Margin: Year 969. ☉]

The eclipse of the Sun on December 22, at hour 3 of the day, shortly after the death of Nicephorus Phocas, from Kedrenos and Curopalates.

[Margin: Year 1009.]

And another in year 7 of the Emperor Henry, of Christ 1009, in which Jerusalem was captured by the Saracens.

[Margin: Year 103[?]. ☉ ☉]

And another in the year 1032, on the 3rd before the Kalends

[Margin: Year 1039.]

[Margin: Year 1093. ☉ ☉]

of July [Iulij], at hour 6, in Lycosthenes, in the *Chronicle*. And another in the year 1039, on May 14 [prid. Idus Maij], in Vbo Emmius [Ubbo Emmius]. And lastly another in the year 1093, almost total, on October 1 [Calendis Octobris], at hour 3, in Meyer and Dodechinus, in the appendix to Marianus Scotus.

[Margin: Year 1113. ☉ Total.]

The eclipse of the Sun on August 2 [4. Nonas Augusti], at hour 7 of the day, on feria 6, very great, in Dodechinus, Sigebert, and Kepler in the *Astronomia Optica*, p. 295, who says that it was total; and rightly, for the anomaly of the

Sun at that time was 79° and that of the Moon 163°, and the diameter of the Sun 31′ 40″ and that of the Moon 33′ 18″.

[Margin: Year 1147. ☉]

The eclipse of the Sun at the end of October, in Sigebert, in the *Chronicle*.

[Margin: Year 1149. ☾]

[Margin: Year 1155. ☾ ☾]

Three eclipses of the Moon in Ubbo Emmius: one in the year 1149, on March 22 [XI. Kal. April.], the day before Palm Sunday, at about hour 9 of the night; the second in the year 1155, on May 22 [XI. Kal. Iun.]; and the third in the same year, on the Sunday before Christmas.

[Margin: Year 1177.]

[Margin: Year 1179. ☉ ☉ ☾]

Eclipses of the Sun in the year 1177, on September 13 [Idib. Sept.], at hour 6, in Lycosthenes; and in the year 1179, in September, in Emmius, with an eclipse of the Moon on August 18 [15. Kal. Septembr.], at hour 8½ of the night, in Lycosthenes.

[Margin: Year 1181. ☉]

The eclipse of the Sun on July 15 [Idib. Iulij], in Sigebert. Alexander III and the Emperor Louis the Fat [Ludouicus Crassus Imper.] died.

[Margin: Year 1187. ☉ Total.]

[Margin: A false note of Lycosthenes.]

The eclipse of the Sun on September 4, so great that stars are related to have been seen by day as if at night; Baldwin was captured by Saladin, and our people lost Jerusalem. Lycosthenes in the *Chronicle*, and Kepler in the *Astronomia Optica*, p. 295, who says that it was made total by the Moon's being at perigee. In that year the golden number was 10 and the Epact 19; therefore the ☌ could not have been on August 29 [4. Kal. Sept.], as Lycosthenes has it, but on September 4 [4. Sept.].

[Margin: Year 1191. ☉]

The eclipse of the Sun that Alberic affirms to have been total; but Kepler, in the *Astronomia Optica*, p. 298, denies it, because the Moon was at apogee.

[Margin: Year 1197.]

[Margin: Year 1239.]

[Margin: Year 1241. ☉ ☉ ☉ Total.]

[Margin: Year 1307. ☉ ☾ ☾]

Four eclipses of the Sun and two of the Moon. The first in the year 1197, on September 4 [prid. Nonas Septembr.], so great that stars appeared, of which Gregorius Tholosas speaks, book 21 of *De Republica*, chapter 27. The second in the year 1239, on June 3 [3. Non. Iunij], of which Gassendi speaks in the life of Claudius Fabricius Peireskius [Nicolas-Claude Fabri de Peiresc]. The third in the morning, on October 6, in the year 1241, and total, as Gemma Frisius has it, of which Kepler speaks in the *Optics*, p. 295. The fourth in the year 1307, on February 11 [3. Idus Febr.], which was followed by an eclipse of the Moon on February 26 [4. Cal. Mart.] and again on August 21 [12. Cal. Septembr.],

and our people were routed by the Saracens from Rhodes. Lycosthenes in the *Chronicle*.

[Margin: Year 1346.]

[Margin: Year 1347. ☾ ☾ ☾]

Three eclipses of the Moon from notes to Ptolemy in a Greek manuscript of the Most Serene Grand Duke of Tuscany, in Vincenzo Renieri. The first in year 1665 of Alexander the Great, on the 13th of Athyr going into the 14th, at $2^h\ 24^m$ after midnight at Thessalonica. The second in year 1666 of Alexander, on the 2nd of Athyr going into the 3rd, at $3^h\ 5^m$ after midnight at Thessalonica. The third in the same year, on the 30th of Pharmuthi, on the following night, at $1^h\ 47^m$ after midnight in the same place.

[Margin: Year 1387. ☉]

A great eclipse of the Sun on December 9, in Bonfinius [Antonio Bonfini], book 9 of Decade 2 of the *Hungarian History*.

[Margin: Year 1415. ☉ Total.]

The eclipse of the Sun on June 7, feria 6 after the feast of Corpus Christi, dreadful in the middle of Bohemia, so that birds, terrified by the sudden darkness, fell down. Of it speak, from the Polish historian, Lvovický and Lycosthenes; Reinhold in the *Theoricae* of Peuerbach, saying that it was seen at Constance at hour 6 of the morning, that is, as Lansbergen computes in the *Treasury*, p. 129, at $6^h\ 5^m$ after midnight; Gassendi, relating that it was observed at Aix at 7^h after midnight; and Kepler in the *Astronomia Optica*, p. 295, saying that it was total because of the Moon at perigee, which he confirms by calculation in the Rudolphine Tables, precept 169, adding $6^h\ 43^m$ after midnight at Prague. See also Origanus in the preface to volume 2, who confirms it from Mathias Mechovius [Maciej Miechowita], the Polish historian. My tables give the diameter of the Sun at that time as 30′ 50″ and that of the Moon as 33′ 28″, with the anomaly of the Sun at 351° and that of the Moon at 176°.

[Margin: Year 1419.]

[Margin: Year 1424.]

[Margin: Year 1448.]

[Margin: Year 1449. ☉ ☉ ☉ ☉]

Four eclipses of the Sun. The first in the year 1419, in ♈ 15°, in Origanus, preface to volume 3. The second in the year 1424, of which we spoke in the scholia to chapter 2. The third in the year 1448, on August 29, in Garcaeus, p. 288, and in Origanus, cited above. The fourth in the year 1449, on August 29 [4. Kal. Septemb.], at hour 6 of the day, in Lycosthenes, who adds that the Venetians were defeated at that time.

[Margin: Year 1457. ☾ Total.]

The eclipse of the Moon on September 3, at Melk in Austria, which is 11 German leagues west of Vienna, observed by Regiomontanus and his teacher Peuerbach. The beginning of total obscuration was when the last-but-one of the Pleiades stood 22° high in the east, from which they derive $10^h\ 24^m$ after

noon. The beginning of the emersion was when the same star stood 36° high, from which $11^h\ 49^m$. Snel, in the *Observations*, and, following him, Renieri, p. 59. Lansbergen, p. 71 of the *Treasury*, adds that it was of 14 digits 27′.

[Margin: Year 1460. ☾ ☾]

[Margin: Total.]

Two eclipses of the Moon observed by Peuerbach and Regiomontanus, as is found in their observations and in Snel, p. 14. The first was observed on July 3, at Vienna in Austria, of 4 digits 12′, at $8^h\ 13^m$, from the apparent eastern altitude of the Moon at the end, 15° 18′, whereas the Alphonsine Tables gave $9^h\ 10^m$ and 2 digits 56′. The second was observed in the same place on December 27. The beginning was at $11^h\ 42^m$ after noon, as they judged from the eastern altitude of Arcturus, 7°; the beginning of the stay at $12^h\ 47^m$, from the altitude of the same star, 17°; the end of the stay at $13^h\ 55^m$, from the altitude of the same star, 28°. But they assumed for Arcturus a declination of 22° and a right ascension of 297° 53′, which are to be corrected either from the Tychonic observations or from our own observations of the fixed stars, of which we shall speak in the next book. They add that at the beginning of the eclipse the Moon was seen on a great circle passing through the head of the leading Twin and the brighter star of Canis Minor, but at the end on one circle passing through the head of the following ♊ and Canis Minor. To this record Tycho attached this note: *If these things were exact, the places of the stars could be verified from here*, as Kepler reports in the *Astronomia Optica*, p. 371.

[Margin: Year 1461. ☾ ☾]

[Margin: Total.]

Two eclipses of the Moon observed by Regiomontanus, as is found in his observations and in Renieri, p. 59. The first was observed at Vienna in Austria on June 22: at the beginning of the stay Aquila stood 26° high, and at the end of the whole eclipse 47° 30′, in the east, from which he derived the middle at $13^h\ 21^m$ after noon. The second on December 17, at Vienna, of more than 8 digits; at the end Capella stood 38° 30′ high and Aldebaran 29°, from which he derived $0^h\ 54^m$ after sunset; whereas from the Alphonsine Tables, says Regiomontanus, it ought to have ended at $1^h\ 56^m$ after sunset. So indeed my codex; but Renieri adds that the Moon rose at Rome obscured by 10 digits.

[Margin: Year 1462. ☾]

The eclipse of the Moon observed at Viterbo by Regiomontanus on June 11, of 7 digits to the north, at $14^h\ 48^m$ after noon, at the middle. Lansbergen, p. 72 of the *Treasury*, concludes 7 digits 9′, and the beginning there at $14^h\ 45^m$.

[Margin: Year 1462. ☉]

The eclipse of the Sun on November 21, about noon, observed at Viterbo by Regiomontanus; it failed on the south by 2 digits. At the beginning the Sun stood 26° 30′ high in the east, and at the end 24° 36′ in the west. Regiomontanus in his observations. But Lansbergen, in the *Treasury*, p. 130, concludes 2 digits 48′, and at Viterbo the hour $0^h\ 15^m$ after noon.

[Margin: Year 1464. ☾ Total.]

[Margin: Renieri's slip.]

The eclipse of the Moon on April 21, observed at Padua by Regiomontanus on his way to Rome, from his observations, although Renieri, p. 59, puts it as observed at Rome. At the beginning Cor Scorpii stood 12° 45′ high in the east, from which, assuming the altitude of the pole at Padua as 45° 44′, and the rest from the table of Alfonso, he derived $11^h\ 15^m$; and total obscuration at $12^h\ 33^m$, the middle at $12^h\ 59^m$, the end of the stay at $13^h\ 25^m$, the end at $14^h\ 43^m$, and 13 digits 27′.

[Margin: Year 1469. ☉]

The eclipse of the Sun, on which see the evidence above, chapter 2, in the scholium.

[Margin: Year 1471. ☾]

The eclipse of the Moon observed by Regiomontanus on June 2, at Nuremberg. The Moon began to be eclipsed with Cor Scorpii standing 14° 15′ high in the west; and when 4 digits had been obscured, the muzzle of Pegasus [muscida Pegasi] stood 22° 30′ high in the east.

[Margin: Year 1473. ☉]

The eclipse of the Sun on April 27, observed at Nuremberg by Regiomontanus, when at the end the Sun stood 25° high from the west; from the same man's observations.

[Margin: Year 1478. ☉]

The eclipse of the Sun on July 29, observed at Nuremberg by Bernhard Walther. At the beginning the Sun's altitude in the west was 54° 30′, and at the end 41° 30′, *from the observations of Walther*. Lycosthenes is therefore to be corrected, who puts this one in the year 1479.

[Margin: Year 1485. ☉ Total.]

[Margin: Kepler's petty slander against Walther.]

The eclipse of the Sun on March 16, observed by Walther at Nuremberg, of nearly 11 digits from the south. The beginning at $3^h\ 26^m$ after noon, the middle at $4^h\ 27^m$, the end at $5^h\ 28^m$. The Alphonsine calculation gives 12 digits; Lansbergen, p. 131 of the *Treasury*, computes 10 digits 50′. Yet Kepler, in the *Astronomia Optica*, p. 295, rightly, and with my tables agreeing, contends that it was total, because the Moon was at perigee, and on account of these words of Lycosthenes: *There was sheer darkness, so that there was need of lighted candles; in the cities the hens, and out of doors animals of various kinds, betook themselves to their usual night-time places of rest*. And he adds that Walther was deceived by a fallacy of sight; as though indeed it had to be total everywhere, or at Nuremberg, because it was total elsewhere. The fallacy here is rather one of memory, on the part of Kepler, who forgot the parallaxes.

[Margin: Year 1487. ☾ Total.]

The eclipse of the Moon on February 8, observed by Walther at Nuremberg, total; the beginning at about 2^h after midnight, the end at $5^h\ 20^m$.

[Margin: Year 1491. ☉]

The eclipse of the Sun on May 8, observed at Nuremberg by Bernhard Walther. At the beginning of the eclipse ♊ 19° was in mid-heaven, and at the end ♋ 26°, in Walther's observations, fol. 38.

[Margin: Year 1493. ☾]

The eclipse of the Moon on October 22, predicted and then seen by Cristoforo Colombo, by the portent of which he terrified the barbarians and obtained provisions from them, according to what we said in chapter 2, number 14; recall it.

[Margin: Year 1494. ☉]

The eclipse of the Sun on October 10, observed by Walther, fol. 39, at Nuremberg. The beginning between hours 1 and 2 after noon, the end, precisely, at $4^h\ 24^m$.

[Margin: Year 1497. ☾]

[Margin: A fallacy of observations.]

The eclipse of the Moon on January 18, of which Johannes Werner speaks in the commentary on Ptolemy's *Geography*, book 1, chapter 4, where he says that the beginning was observed at Rome at $5^h\ 24^m$ but at Nuremberg at $4^h\ 52^m$ after noon. If that had been so, the difference of longitude between Rome and Nuremberg would be 32^m of time, or 8°, which neither any geographical maps nor other observations bear out; they give scarcely 5½°. It was therefore easy to err by 12^m in time, especially with each observer contributing his share of the error.

[Margin: Year 1497. ☉]

The eclipse of the Sun on July 29, whose end Walther observed at Nuremberg at $3^h\ 24^m$ after noon, fol. 39.

[Margin: Year 1500. ☾]

The eclipse of the Moon on November 5 going into the 6th, observed at Rome by Copernicus, as he himself relates in book 4 of *De revolutionibus*, chapter 14. He says that the middle was at 14^h after noon, and that 10 digits failed from the north. But Lansbergen, p. 73 of the *Treasury*, derives from his own tables 10 digits 35′.

[Margin: Year 1504. ☾]

The eclipse of the Moon on February 29, observed through an astrolabe by Johannes Stöffler at Ulm in Swabia, who says that its beginning was at about $11^h\ 49^m$ after noon. ✢ But Bernhard Walther at Nuremberg, with the equatorial armillaries, observed the end at $3^h\ 7^m$ after midnight; clouds hindered the rest.

[Margin: Year 1506. ☉ Nearly total.]

The eclipse of the Sun on January 13, feria 4, from hour 1 to hour 2½ after noon, so great that *stars were seen in broad daylight*, says João de Barros, and, following him, our people in the account of the observations of the comets of the year 1618. And yet for me the Sun did not fail wholly, for the diameter of the Sun was 32′ 58″ and that of the Moon 32′ 34″; it came close, however, to total eclipses.

[Margin: Year 1509. ☾]

The eclipse of the Sun[46] on June 2, observed at Kraków by Copernicus, book 4, chapter 13, of about 8 digits from the south, at 11^h 46^m after noon. But Lansbergen, p. 74 of the *Treasury*, concludes 7 digits 31′.

[Margin: Year 1511. ☾ Total.]

The total eclipse of the Moon on October 6, observed at Frombork in Prussia by Copernicus, from his book 4, chapter 5. The beginning at 10^h 52^m, the end at 14^h 20^m after noon, from which he derives the middle at 12^h 35^m. Lansbergen, p. 75 of the *Treasury*, concludes 12 digits 15′ and a duration of 3^h 22^m.

[Margin: Year 1516. ☉]

The eclipse of the Sun at the beginning of ♌, in Origanus, volume 3 of the *Ephemerides*, in the preface.

[Margin: Year 1518. ☉]

The eclipse of the Sun in June, in ♊ 26°, from which astrologers conjectured the death of the Emperor Ferdinand; from Henri de Sponde, in the *Epitome of the Annals*.

[Margin: Year 1520. ☉]

The eclipse of the Sun in [?] 10°[47], in Origanus, in the preface to volume 3 of the *Ephemerides*.

[Margin: Year 1522. ☾ Total.]

The eclipse of the Moon on September 5, observed at Frombork by Copernicus, book 4, chapter 5. The beginning at 11^h 36^m, and it failed wholly. Lansbergen concludes 12 digits 54′.

[Margin: Year 1523. ☾ Total.]

The eclipse of the Moon on August 25, observed at Frombork by Copernicus, book 4, chapter 5. The beginning at 14^h 48^m, and it failed wholly. Lansbergen, p. 77 of the *Treasury*, gives 14 digits 19′. ✝ Cardano says that at Milan it was at 15^h 15^m after noon, of 13 digits 50′. A huge plague followed.

[Margin: Year 1530. ☉ Total.]

A great eclipse of the Sun, and total for me, very early in the morning of March 29, shortly after sunrise, seen by Kepler's paternal uncle, as is said in the *Astronomia Optica*, p. 295, who reported that when day had scarcely dawned it was suddenly extinguished and turned into night.

[Margin: Year 1539.]

[Margin: Year 1540.]

[Margin: Year 1541. ☉ ☉ ☉ and ☾]

Three eclipses of the Sun. The first on April 18, at 4^h 19^m after noon, at Milan, of nearly 9 digits, from Cardano. The second in the year 1540, in ♈ 27°.

[46] the page heads this entry `Solis Eclipsis`, while the sign beside it in the margin, without rays, is of the kind this page uses for the Moon.

[47] the sign is a small pictorial sort, a many-legged creature with curled ends, unlike the Cancer sign printed in the Year 1491 entry

The third in the year 1541, in ♍ 7°, in Origanus, volume 3 of the *Ephemerides*, in the preface. And one of the Moon at the beginning of ♈, in the same place.

[Margin: Year 1544. ☉]

The eclipse of the Sun on January 14, observed at Leuven by Gemma Frisius through the hole of a window, of 10 digits, at $8^h\ 53^m$, as he himself has it in chapter 18 of the *Radius Astronomicus*, and Daniel Santbech, *De observatione*, proposition 13. ✢ But Functius, in Kepler's *Optics*, p. 296, says that the day began to grow dark, as if into evening twilight, and that the birds that had been merry at first light fell silent; and he estimated an eclipse of 11 digits, the figure Lansbergen gives. Yet Kepler maintains that it was total somewhere, as Reinhold had predicted it from calculation. For me it was partial, nor does the history prove otherwise, for morning eclipses appear larger because of the night that precedes and, as it were, continues.

[Margin: Year 1545. ☉]

The eclipse of the Sun on June 9 [5. Idus Iunii], at 4^h after noon, of 4⅔ digits, observed at Leuven by Gemma Frisius, chapter 15 of the *Radius Astronomicus*, and, from there, Daniel Santbech, *De observatione*, proposition 13.

[Margin: Year 1551. ☉]

The eclipse of the Sun in ♍ 17°, in Johannes Garcaeus, *De genituris*, p. 288.

[Margin: Year 1555. ☾]

The eclipse of the Moon on June 4, at 3^h after midnight, at Wittenberg, in Reinhold, in the *Theoricae* of Peuerbach.

[Margin: Year 1560. ☉ Total.]

[Margin: Tycho's error.]

The eclipse of the Sun on August 21, observed at Coimbra by our Clavius, total about noon and with stay, as he himself reports in chapter 4 of the *Sphere* of Sacrobosco, where he says: *The Sun lay hidden, covered for no short time; the darkness was in a way greater than that of night, for one could not see where to put one's foot, and stars appeared very brightly in the sky; birds too, marvellous to tell, fell from the air to the ground in horror at so foul a darkness.* Father Emmanuel Vega was present, who says that it lasted for nearly three hours, with women howling and crying aloud that the last day of the world had come; that the stars had never been seen so clearly, that men under their roofs scarcely recognized one another, and that lamps were needed; so Scheiner reports from his mouth in the *Rosa Ursina*, book 3, chapter 7. ✢ Egnazio Danti observed the same eclipse at Rome at $1^h\ 30^m$ after noon, as he has it in the *Astrolabe* [Astrolobio]. ✢ Tilemann Stella and Paul Fabricius observed it at Vienna in Austria, of 5 digits, and the end at $2^h\ 55^m$ after noon, as Gerard Mercator relates in the *Chronicle*. ✢ Giuntini, as he reports in the preface to his *Tables*, observed its beginning at Venice at $11^h\ 50^m$ after midnight. ✢ Lansbergen, p. 110 of the *Treasury*, says that it was observed at Brussels, of 6 digits 31′, and that the end there was at $1^h\ 48^m$ after noon, as Stadius says in his ephemeris for this year; but from calculation Lansbergen concludes 12 digits 4′, yet says that a longer stay was seen, because

the Sun contracted itself, so that an eclipse of 12 digits 38′ was seen; this is a subterfuge devised to prop up his hypothesis. But since Tycho, admitting no total eclipses of the Sun, did not believe this, he wrote in wonder to Clavius in the year 1600, as Kepler relates in the *Astronomia Optica*, p. 285. But the falsity of the Tychonic hypothesis on this point is refuted by so many total eclipses of the Sun, of which above and below, chapter 20. My tables then give the diameter of the Sun as 31′ 0″ and that of the Moon as 32′ 12″, with the anomaly of the Sun at 34° and that of the Moon at 130°.

[Margin: Year 1560. ☾]

The eclipse of the Moon on March 11, observed at Leuven by Cornelius Gemma, as he relates in his *Cosmocritice*, book 2. The beginning at $15^h\ 40^m$, the end at $17^h\ 26^m$ after noon. Lansbergen, in the *Treasury*, p. 78, gives 2 digits 58′.

[Margin: Year 1567. ☉ Annular.]

[Margin: Kepler's violence against observations.]

The eclipse of the Sun on April 9, observed by our Clavius at Rome, who affirms in chapter 4 on the *Sphere* of Sacrobosco: *At Rome the Sun did not fail wholly, but a certain thin shining circle was left all around.* ✢ This one, as Kepler reports in the *Astronomia Optica*, p. 297, Tycho says in a letter to Clavius that he observed as a youth at Rostock on the shore of the Baltic Sea, at almost exactly noon, of not quite 7 digits; and in the *Progymnasmata* he has 12^h after midnight, 6 digits 20′; and on another sheet 11^h, 9 digits. ✢ Mästlin, however, observed at Tübingen nearly 10 digits from the south. ✢ Gerard Mercator, at Duisburg in Cleves, the beginning at $10^h\ 25^m$ and the end at 1^h. ✢ Cornelius Gemma, at Leuven, the beginning at $10^h\ 12^m$, the greatest phase [vigorem] at $11^h\ 40^m$, the end shortly after $12½^h$, nearly 9 digits; the light very pale, the time as if evening, but no stars. Lansbergen shows from his tables that Clavius's observation was true. ✢ Nevertheless Kepler, in the *Optics*, from p. 297 to 302, calls it in doubt, because at such an anomaly his tables do not admit it. He therefore judges that that bright small circle was either a denser part of the aether set alight by contact with the Sun, or the Sun's rim optically enlarged by its own rays refracted in the air around the Moon. But our hypothesis needs no such subterfuges, and, with the credit of other observations unimpaired, upholds also this annular eclipse seen by Clavius; for it gives the diameter of the Sun as 31′ 28″ and of the Moon 30′ 54″, at an anomaly of the Sun of 69° and of the Moon of 100°.

[Margin: Year 1569. ☾ Total.]

The eclipse of the Moon on March 3, observed at Leuven by Cornelius Gemma, from book 2 of the *Cosmocritice*: after midnight, with dreadful colours, blood-red, crimson, green, livid, etc. I have seen Kepler on it, p. 274 of the *Astronomia Optica*.

[Margin: Year 1572. ☾]

The eclipse of the Moon on June 25, observed by Mästlin, of 6 digits, although Gemma, in book 2 of the *Cosmocritice*, affirms that about 8 digits were seen by him. See Kepler in the *Optics*, p. 349.

[Margin: Year 1573. ☾ Total.]

The eclipse of the Moon on December 8 at 8^h 3^m after noon, total, observed by Tycho at Uraniborg, from volume 1 of the *Progymnasmata*, p. 114, and by Longomontanus in the *Astronomia Danica*, book 1 of the *Theorica*, chapter 2. Wendelen, p. 43, computes it at 7^h 50^m at Uraniborg, and says that the sooty darkness of the penumbra drew out a spurious end.

[Margin: Year 1576. ☾]

The eclipse of the Moon on October 7, observed by Tycho at Uraniborg at 11^h 32^m after noon; the rest did not show. ✢ Egnazio Danti, in the *Astrolabe*, says that it was observed by him at Rome at 11^h 15^m, although it is established from elsewhere that Rome is more easterly than Uraniborg.

[Margin: Year 1577. ☾ ☾ Total.]

The 2 total eclipses of the Moon observed at Uraniborg by Tycho, from volume 1 of the *Progymnasmata*, p. 114. The first was on April 2 at 8^h 50^m, unless the penumbra deceived him; for Wendelen says in the *Eclipses* that it ought to have been at 9^h 15^m. ✢ But Egnazio Danti says that at Rome it was at 8^h 40^m, from his own observation, in the *Astrolabe*. The second was on September 26 at 13^h 3^m after noon; Wendelen's calculation, p. 44, requires the hour 13^h 17^m, from which he infers that Tycho's observation or calculation is spurious. ✢ [Margin: A note on the difference of meridians.] He adds that it was observed at Madrid by Lupo Velasco [Juan López de Velasco], at its end, at 2^h 16^m after midnight; at Toledo by Io. Alcantara [?] at 2^h 12^m; at Valladolid [Valle-Oletana] by Doctor Sobrino at 2^h 8^m; and at Seville by Roderico Zamorano [Rodrigo Zamorano] at 2^h 4^m. In Mexico, moreover, at S. Ioannem de Luâ [San Juan de Ulúa ?], the same end was observed at 7^h 50^m after noon, and at Angelopolis in Mexico at 7^h 36^m. From this Andreas Garcia Cespedius [Andrés García de Céspedes], because Mexico is 1° more westerly than Angelopolis, pronounced Mexico to be 100° more westerly than Toledo. These observations were undertaken both to correct the map of Spain and to settle the dispute between the Castilians and the Portuguese over the meridian dividing the western lands and the Moluccas from the eastern ones.

[Margin: Year 1578. ☾]

The eclipse of the Moon of 2½ digits, observed by Tycho at Uraniborg, as above, on September 15 at 13^h 17^m after noon. ✢ Wendelen adds, p. 45, that its end was observed at Toledo by Lupo Velasco at 13^h 20^m, and by others at Angelopolis at 6^h 46^m.

[Margin: Year 1579. ☉]

The eclipse of the Sun on February 25, observed by Tycho at Uraniborg at 5^h 50^m after noon, of 5 digits 50′, whose exeligmus [exeligmum] the eclipse of the year 1633 will reproduce, as Wendelen says, p. 46.

[Margin: Year 1580. ☾ Total.]

The eclipse of the Moon on January 31, total, observed at Uraniborg by Tycho, from volume 1 of the *Progymnasmata*, p. 114, at 10^h 9^m after noon, or at 10^h 10^m as Longomontanus has it. ✢ And Mästlin says in the *Isagoge* that it was observed by him as total, *but that it lay wholly hidden in the shadow for a very short time.* ✢ And as is said in the *Astronomia Optica*, Kepler at Vittemberga [Vittembergæ] at 10^h, *while still a boy, with his father pointing it out, saw it whole and red on every side*; and my hypothesis favours these things. [Margin: Disagreement of the calculation from observation.] Wendelen's calculation, p. 46 of the *Eclipses*, gives it as total with duration of about 4^m, but computes the middle at Uraniborg at 10^h 30^m. He therefore thinks that the penumbra deceived Tycho; [Margin: Wendelen's birth.] and he adds that he himself was born in this year, on June 6. But Lansbergen's calculation, p. 79 of the *Treasury of Observations*, gathers 11 digits 51′; and so he adds: *The Moon failed very nearly wholly, so that the remaining particle of light could hardly be distinguished from the darkened part.* On this night, moreover, Henry, King of Portugal, died, according to Henri de Sponde in the *Epitome Annalium*.

[Margin: Year 1581. ☾ ☾ Total.]

The 2 eclipses of the Moon observed at Uraniborg by Tycho. The first, on January 19, total, at 9^h 59^m after noon, or, as Longomontanus has it, at 10^h. Wendelen, by his own calculation, p. 47, gathers 10^h 6^m. The second, on June 15, total, at 16^h 57^m after noon; but Longomontanus has 17^h. Wendelen's calculation, p. 47, shows 16^h 45^m at Uraniborg. [Margin: A blemish in Tycho's observation.] He adds that beyond the beginning the remaining phases did not show to Tycho, since elsewhere, in the letters [in Epiſtolis], he writes: *This eclipse was observed at least so far that the Moon had entered half of the shadow before it set*; and therefore the rest were added from conjecture or calculation.

[Margin: Year 1584. ☉]

The eclipse of the Sun on April 30, in the old style of the year, observed by Tycho, as above, at Uraniborg at 5^h 39^m after midnight, of 3 digits 0′. Wendelen, p. 49, by his own calculation gives 5^h 36^m.

[Margin: Year 1584. ☾ Total.]

The total eclipse of the Moon on November 7, old style, observed at Uraniborg by Tycho at 13^h 12^m after noon; but in the *Epistolae Astronomicae*, p. 72, he has 13^h 8^m, and Longomontanus 13^h 9^m. ✢ But since Tycho says in the letters that the beginning was at 11^h 12^m and the end at 15^h 0^m, and the duration accordingly is 3^h 48^m, it seems to Wendelen, p. 48, that the middle ought to have been put at 13^h 6^m; and so he adds: *From this he makes it plain that he is no longer reciting his observations faithfully, but presenting the calculation of his*

tables. But it is rather Wendelen himself who (not in bad faith, indeed, but from forgetfulness, I would believe) omits Tycho's words in the letter of January 20 of the year 87, in which he says, on p. 72: *I found that the very first beginning was at 11^h 12^m from noon of November 7; the middle at 13^h 8^m; the very last end at 15^h 0^m. (For these times are not always equal, as has been believed up to now.)* On this matter, however, see what we have said in chapter 6, in the Scholia. [Margin: Wendelen's excessive censure of Tycho.] Wendelen nevertheless goes on and says: *Which is surely unworthy of that man, and an excessive unconcern about censure; and so we rightly understand that all credit in him, in other matters too, is weak.* But go more sparingly with such words toward a man who has deserved so well of Astronomy. For if later, rereading his calculations, he judged, with everything weighed, that two or three minutes should be added, did he on that account deserve so harsh and so sweeping a censure? Let Wendelen remember that saying of Horace:

We know it, and this indulgence we both seek and grant in turn.

Yet I would rather that Tycho had indicated the reasons for the correction, so that it might be clear that he had not departed from the observation when better considered. Tycho, moreover, adds in the same letter: *As for Wittich's noting the middle of this failing at Kassel at 13^h 3^m, as you wrote to me, it lacks exact precision. For your meridian is at least a fifth part of an hour more westerly than ours, as I also said above.* ✢ Further, Wittich, as Rothmann writes to Tycho, p. 88, using the Landgrave of Hesse's pair of clocks, corrected by the azimuths of the right shoulder of Orion, found at Kassel the beginning at 11^h 20^m, the immersion at 12^h 20^m, the emersion at 13^h 45^m, the repletion at 14^h 45^m; from which he concluded the middle at 13^h 3^m. But Rothmann admits that he had not attained the required precision. ✢ Tycho further adds this: *Heinrich Brucaeus, the distinguished mathematician at Rostock, a singular friend of ours, observed the same eclipse there and found its middle at 1^h 4^m after midnight [post M. N.], a time slightly earlier than ours, when rather it ought to have been almost the same, since the difference of the meridians is imperceptible. But he, by means of a quadrant, of brass indeed, but very small, granted to him by me some time ago, from altitudes of stars taken only in degrees, was examining the times in a broader manner; and this, especially in stars moving toward the meridian, is exposed to evident error.* [Margin: Wendelen's correction of Tycho, itself needing correction.] But Wendelen, passing over this remark of Tycho's, and relying rather on Brucaeus's observation, goes on to criticise Tycho's, and finally concludes from his own calculation that the duration of this eclipse was 3^h 36^m, not the 3^h 48^m of Tycho or the 3^h 25^m of Wittich. But of course Wendelen omits the equation of natural days: he is pleased to have omitted it when observations favour his calculation, but when they differ markedly, he carps at the observations of others.

[Margin: Year 1587. ☾]

The eclipse of the Moon on September 6, old style, observed at Uraniborg by Tycho, of 9 digits 45′, at 9^h 16^m. But Longomontanus has 9^h 30^m, certainly

a great error or disagreement. Wendelen, p. 49, by his own calculation shows 9^h 16^m, in remarkable agreement here.

[Margin: Year 1588. ☉]

The eclipse of the Sun on February 16. Tycho at Uraniborg observed the beginning at 1^h 32^m and the end at 2^h 51^m. At the start the failing is drawn, in Tycho's papers [Schedis], as inclining to the right by 36°, and at the end by 12° or 15°, again to the right, that is, the West, as Kepler reports in the *Astronomia Optica*, p. 414, where he weighs these inclinations in a rather lengthy calculation.

[Margin: Year 1588. ☾ Total.]

The total eclipse of the Moon observed at Uraniborg by Tycho on March 2, old style, at 15^h 2^m. And in the letters he says: *The clearness of the sky was moderate, and it was found that the middle exceeded the Prutenic calculation by half an hour*; which calculation, however, would give 14^h 18^m, says Wendelen on p. 50, adding from Kepler these words noted in Tycho's papers at the hour 2^h 58^m: *Now the Moon appeared brighter toward the East: therefore it has passed the middle.* Granted that from other phases he set the hour, in the *Progymnasmata*, p. 114, at 3^h 2^m after midnight; this was on account of the deceptiveness of the penumbra, says Wendelen; ✢ who adds that the beginning was observed by him at Herk about the middle of hour 1 after midnight, the immersion after the middle of hour 2, the emersion immediately after the third, and the end a little after hour 4, his father, the prefect of the Watch, regulating the clock. ✢ At Lisbon, however, Doctor Sobrino observed the beginning at 11^h 56^m. [Margin: A note on the difference of meridians.] But Wendelen adds: *Unless perhaps he meant to write 11^h 36^m; for then the agreement with the beginning at Herk would be stupendous.* ✢ Finally a Florentine nobleman, at the Cape of Currents [promontorium Currentium] beyond the Cape of Good Hope, noted the beginning at 4^h 15^m.

[Margin: Year 1588. ☾]

The eclipse of the Moon on the 26th coming into the 27th of August Julian, but the 6th into the 7th Gregorian, observed at Lisbon by the most learned Sobrino, began at 1^h 49^m after midnight. ✢ Its beginning was observed at Portus Vetus [Puerto Viejo] in Peru, under the Equator, at 8^h 54^m after noon, and was so reported in writing to the King, as Wendelen says, p. 51, [Margin: A note on the difference of meridians.] who gathers from this a difference of longitude of 4^h 55^m, or 73° 45′.

[Margin: Year 1589. ☾]

The eclipse of the Moon on August 25 Gregorian: Wendelen's father and others noted the end of the eclipse at about a quarter before the eighth hour; Wendelen's calculation, p. 51, requires 7^h 47^m from noon.

[Margin: Year 1590. ☾]

The eclipse of the Moon on July 17, in the morning. Mästlin at Tübingen saw the Moon failing by several digits from the South, and still almost two degrees

high above the horizon, although the centre of the Sun was already emerging above the horizon; and as the Moon's centre went down below the horizon, he saw the Sun raised by about 2°. Kepler attributes this to extraordinary refraction, in the *Astronomia Optica*, p. 137; but Wendelen, in the *Eclipses*, p. 51, says that a single degree is to be ascribed to the refraction of both luminaries, the rest to the parallaxes, since the Moon was far to the North. Mästlin adds that the Moon set before the greatest obscuration. Wendelen's calculation grants the beginning at Tübingen at $3^h\ 38^m$ after midnight, and the middle at $4^h\ 28^m$, 13^m after sunrise.

[Margin: Year 1590. ☉]

The eclipse of the Sun on July 31, new style, observed at Uraniborg by Tycho, of 5 digits, at $7^h\ 54^m$ after midnight. But on this I find, in Magini's *Tables of Directions*, p. 81, what was written in a letter of Tycho's to Magini from Uraniborg, of the year 590[48], December 1 [Cal. Decembr.], in these words: *The last eclipse of the Sun occurred here, as to its very first beginning, when $6^h\ 51^m$ had elapsed from midnight; the very last end came at exactly the ninth hour. And no more than four digits of the Sun were covered, that is, a third part of it, although the canons promised, in our climate, eight, and an interposition of the Moon twice as great.* He is speaking of the Prutenic canons. [Margin: Tycho's account is suspect.] But why in the *Progymnasmata*, p. 114, does he assign 5 digits to this eclipse? Was it to draw the observation toward his own tables? ✢ Mästlin observed it at Tübingen at $7^h\ 36^m$, as Kepler relates in the *Optics*, pp. 406 and 4[?]1; and on p. 396 he says that the diameter of the ☉ was observed to be to that of the ☾ as 24 to 23. Lansbergen, in the *Treasury of Observations*, p. 133, gathers 9 digits at Tübingen; and in the *Uranometria*, p. 111, he says, wrongly, that the middle was observed by Mästlin at $7^h\ 44^m$.

[Margin: Year 1590. ☾ In Gregorian reckoning 1591.]

The eclipse of the Moon on December 30, old style, but in Gregorian reckoning in the year 1591, on January 9, observed at Uraniborg by Tycho at $6^h\ 55^m$, or, as Longomontanus has it, at 7^h. But Tycho admits that he could not have all the phases. Wendelen, p. 52, computes $6^h\ 50^m$, omitting, as usual, the equation of natural days.

[Margin: Year 1591. ☉]

The eclipse of the Sun on July 10, old year, observed at Uraniborg by Tycho, of 2½ digits, at $3^h\ 33^m$ after noon.

[Margin: Year 1592. ☾]

The eclipse of the Moon on June 14, old style, observed at Uraniborg by Tycho, of 8 digits, at $10^h\ 16^m$ from noon, as Tycho has it in volume 1 of the *Progymnasmata*, p. 114, or at $10^h\ 20^m$, as Longomontanus has it in book 2 of the *Theorica*, chapter 2. But let us hear Kepler on it, in the *Astronomia Optica*, p. 350: *Tycho Brahe*, he says, *in the year 1592, on June 14, at the start observed by the radius the diameter of the Moon, still whole, as 32′. Then about the middle of*

[48]that is, 1590

the eclipse he found 14′ remaining, so that 18′ of these had failed. But this quantity departs much from his own calculation, which claims 26¼′ of the Moon's body for the shadow. And so I attribute this to the difficulty of observing. For even if someone should call into doubt the Tychonic calculation, or the diameter of the Moon, he will still never bring it about that this eclipse with this quantity squares with the others to one standard. Hence Wendelen, in his *Eclipses*, p. 54, concludes that there is nothing sound in this observation except the beginning of the failing, and the middle, which from this is reckoned to have occurred later.

[Margin: Year 1592. ☾]

The eclipse of the Moon on December 8, old style, or the 18th Gregorian, observed at Uraniborg by Tycho at $7^h\ 41^m$, to which is added *it did not show*. ✢ But Lansbergen, p. 83 of the *Treasury of Observations*, says that it was observed by him at Goes, of almost 5 digits, with the end at 8^h and the middle at $6^h\ 51^m$; but from calculation he gathers 4 digits 46′. Wendelen's calculation gives the middle at Goes at $6^h\ 49^m$.

[Margin: Year 1593. ☉]

The eclipse of the Sun on May 20 at Zerbst [Seruestæ], where the Sun was observed to fail, to the extent of two digits, from the lower part, the failing inclining at the start a little to the left, and at the end more. The hour was about $2^h\ 40^m$: Kepler in the *Optics*, p. 414.

[Margin: Year 1594. ☾]

The eclipse of the Moon on October 19, old style, observed at Uraniborg by Tycho, at the hour after noon $19^h\ 26^m$, with the addition *it did not show*. But Longomontanus has $19^h\ 16^m$. ✢ In the *Optics*, moreover, p. 413, Kepler adds, from Tycho's papers, that in the morning at $5^h\ 56^m$ it began to be darkened at Uraniborg at the top of the limb or a little to the right. ✢ Lansbergen, p. 84 of the *Treasury of Observations*, relates that the beginning was observed by him at Goes at $5^h\ 12^m$ from midnight, and 9½ digits; but from his own calculation 9 digits 21′, and in the middle $6^h\ 48^m$. Wendelen, p. 55, says: *My calculation grants the beginning on Hven at $5^h\ 56^m$ and the middle at $7^h\ 28^m$, which is A STUPENDOUS AGREEMENT, and by itself alone commends all my hypotheses.* All of them? Indeed, if in all of them there were such agreement. But why here is Tycho's observation not condemned, and no recourse had to the penumbra, while elsewhere it is otherwise? Is it not from an already presumed esteem for the Atlantic Tables?

[Margin: Year 1595. ☾ Total.]

The eclipse of the Moon on April 13, old style, observed at Uraniborg by Tycho at $16^h\ 36^m$, total. ✢ Lansbergen, p. 85 of the *Treasury of Observations*, says that the beginning was observed by him at Goes at $13^h\ 40^m$, and in his calculation sets 19 digits 40′. ✢ Kepler, in the *Astronomia Optica*, p. 367, says that the beginning was observed by him at Graz in Styria [Greek: ὁλοσχερῶς (holoscherōs, "roughly", "in general terms")] *with a paper astrolabe of three-quarters of a foot, suspended*; but he admits that the observation is not altogether

most certain, and that on Hven the beginning should in Tycho's reckoning have been at $14^h\ 51^m$. ✢ Wendelen, p. 55, relates that the beginning was observed at Herk when hour 2 from midnight had scarcely been heard, the immersion at the very stroke of 3, the emersion at about the hour $4^h\ 38^m$; and he contends that at Goes the middle ought to have been at $3^h\ 40^m$.

[Margin: Year 1595. ☉]

The eclipse of the Sun on September 23, old style, observed at Uraniborg by Tycho, of 3 digits 50′, at $1^h\ 8^m$ after noon. ✢ But Mästlin, in the disputation on eclipses published in the year 96, thesis 53, says: *At the beginning, a little after noon, the failing edge of the Sun inclined from the vertical not to the West but to the East by 9 degrees, and it failed by 2 digits and a half, and nothing beyond that, as careful observation at Tübingen attests.* ✢ Kepler adds in the *Optics*, p. 416, that at Strasbourg the beginning was observed before hour 12, and the end at exactly the first hour, and that all the diagrams show the shadow always inclining from the vertex to the left. ✢ For himself, he says, at Graz the Sun began to be darkened at the vertex when the Sun was 51⅙° distant from the vertex, by a small wooden quadrant; and when three digits had failed in the image on the tablet, the Sun stood 55° from the vertex; and a little later it began to incline from the vertex by 15°; and the apparent diameter of the Moon was less than that of the Sun. At Uraniborg, moreover, the end was observed at $2^h\ 5^m$, and the digits darkened there were 4.

[Margin: Year 1595. ☾ Total.]

The eclipse of the Moon on October 7, old style, observed at Uraniborg by Tycho, total, at $20^h\ 29^m$ from noon, which Longomontanus also has, and not $20^h\ 36^m$, as Wendelen, p. 57, reports; but from his own calculation he required $20^h\ 44^m$. The middle, moreover, was set by Tycho from the observation of the beginning and from conjecture or calculation.

[Margin: Year 1596. ☾]

The eclipse of the Moon on April 2, old style, observed at Uraniborg by Tycho at $9^h\ 29^m$; the rest did not show. Longomontanus has $9^h\ 25^m$. [Margin: A huge disagreement of Tycho's observation from calculation.] Here Pétau, in book 8 of *De doctrina temporum*, chapter 13, is at a loss, seeing that Tycho's observation differs greatly from the calculations of all the tables: the reason being, as Wendelen says on p. 58, that Tycho saw only the beginning, and the middle did not show. From his own Atlantic Tables he says that the middle at Uraniborg ought to have been at $8^h\ 45^m$, especially since at Tournai [Tornaci] ✢ the beginning was observed at 7^h and the end at $9^h\ 15^m$. If these things are true, Tycho's note of the observation differs from the truth by a full 44^m.

[Margin: Year 1598. ☾ Almost total.]

The eclipse of the Moon on February 9, old style, in Tycho's catalogue, p. 114, of 11½ digits, at $18^h\ 7^m$ after noon, in any case either from calculation or from Tycho's pupils, for Tycho had already left Denmark; or at $18^h\ 5^m$, as Kepler has it in the *Optics*, p. 368, adding *(the observation of the beginning aided*

by calculation, for the end was under the Earth). ✢ Kepler had, moreover, reported his own observation at Graz in Styria with a wooden quadrant of a span, and with clouds in the way; yet from it he conjectures the beginning at just before hour 5. ✢ At Leuven it began a little after hour 4 in the morning, or rather at $4^h\ 10^m$, as Wendelen says, p. 59. ✢ Lansbergen at Goes noted the beginning at $15^h\ 40^m$ and 11⅖ digits. ✢ At Aachen Io. Rotarius [?], on Lansbergen's testimony, observed the beginning at $4^h\ 30^m$, but gathered the middle at $5^h\ 30^m$ from midnight. In these observations Wendelen suspects deceit or carelessness, and trusts Kepler's rather, because it conspires with his own calculation, which gives the beginning at Graz at $4^h\ 54^m$. Origanus by his calculation makes it total, although all those above observed it as not wholly total; ✢ and Kepler says that it was observed at Wandsbek [Vandesburgi] as not quite total. My tables show it not total, but very nearly total.

[Margin: Year 1598. ⊙ Annular.]

The eclipse of the Sun on February 25, old style, of 9 digits 20′, at $0^h\ 44^m$ before noon, in Tycho's catalogue, p. 114. But Tycho himself, at Wandsbek [VVandesburgi], observed the beginning by the armillary spheres at $9^h\ 12^m$ after midnight, as Kepler says in the *Optics*, p. 383, adding, ✢ that on Hven a pupil of Tycho's observed the beginning at $10^h\ 3^m$, the end at $12^h\ 32^m$, and 9 digits 40′. ✢ At Graz, indeed, Kepler himself, lacking suitable instruments and under a cloudy sky, still somehow obtained the end at $12^h\ 55^m$, and conjectured the beginning from calculation at $10^h\ 19^m$. ✢ Lansbergen, from Kepler, in the *Treasury of Observations*, p. 114, relates that at Torgau in Meissen [in Miſnia] the eclipse was observed by Doctor Iessenio [Jan Jessenius] as almost central, with the Moon placed within the Sun and the entire margin of the Sun standing out like a bright circle. But Kepler, in the *Optics*, p. 299, in *De Stella Nova*, chapter 23, and in the *Epitome of Copernican Astronomy*, p. 895, contends that it was the brightness of the air, inflamed by contact with the Sun, because his hypothesis gives nothing else; further, he hunts out the times of this eclipse by a rather lengthy calculation in the Rudolphine Tables, p. 111, and its inclinations in the *Optics*, p. 419. ✢ Origanus, as he testifies in the ephemeris of this year, observed at Frankfurt on the Oder 9 digits at $11^h\ 28^m$ and again at $11^h\ 46^m$, and the beginning at $10^h\ 20^m$ and the end at $12^h\ 32^m$ from midnight; and he says that the Prutenic calculation errs, which shows it almost total. But I return to Lansbergen, who adds: *There was then such great darkness that it seemed to be a dusky night; yet the exact size of the failing could not be taken by us because of the cloudy sky*; that is, at Goes; and from calculation he gives 11 digits 15′. But Wendelen, p. 60, ascribes to him the saying *The Sun failed wholly*, which I find nowhere said by him. Finally Magini, in the *Tables of Directions*, p. 90, sets out the calculation of this eclipse under an elevation of the pole of 42° and a longitude of 36° 45′, as you see in this small table, and in hours after midnight of February 25.

[Margin: Disagreement of the tables.]

From the Tables of the Authors	Beginning	Middle	End	Duration	Digits
Alfonso	$10^h\ 46^m$	$11^h\ 44^m$	$12^h\ 42^m$	$2^h\ 56^m$	8 20′
Copernicus	$8^h\ 32^m$	$9^h\ 50^m$	$10^h\ 50^m$	$2^h\ 18^m$	11 26′
Tycho	$9^h\ 58^m$	$11^h\ 7^m$	$12^h\ 16^m$	$2^h\ 18^m$	10 6′

My Tables acknowledge this eclipse as annular, since they show the diameter of the Sun as 32′ 16″ and that of the Moon as 32′ 12″, at an anomaly of the Sun of 112° and of the Moon of 130°.

[Margin: Year 1599. ☾ Total.]

The eclipse of the Moon on January 30, old style, total, at $17^h\ 50^m$, as noted in Tycho's observations, p. 114 of volume 1 of the *Progymnasmata*. But Longomontanus has $17^h\ 56^m$, to whom Wendelen, p. 62, ascribes the observation, and he rejoices in a stupendous agreement with his own calculation, which shows $17^h\ 56^m$ on Hven. ✢ Kepler, p. 249 of the *Optics*, conjectured the beginning from the striking clocks [ex Horiſonijs] at $3^h\ 45^m$ from midnight, at Graz.

[Margin: Year 1599. ☉]

The eclipse of the Sun on July 12, old style, the 22nd Gregorian, at $4^h\ 8^m$ after midnight, of 3 digits, reported by Tycho, p. 114 of volume 1 of the *Progymnasmata*, and referred to Uraniborg, though from an observation at Prague; for Kepler says in the *Astronomia Optica*, p. 414, that at Prague a slight failing was observed by Tycho at the rising of the Sun, almost at the very vertex of the Sun's body.

[Margin: Year 1599. ☾]

The eclipse of the Moon on August 6, seen by the Dutch at Tidore and Ternate about hour 8 of the night, as Levinus Hulsius relates in chapter 30 of the Dutch voyages [nauigat. Holland.].

[Margin: Year 1600. ☾]

The eclipse of the Moon on January 30 in the morning, observed at Calidianum [?] in Provence, a town six minutes farther east than Aix, by Govaert Wendelen. The Moon began to fail at $5^h\ 45^m$ after midnight, and 2 digits failed toward the North; and it set, still in eclipse, as hour 7 was striking, the failing having lasted more than an hour; and after a quarter-hour the Sun rose, at the hour there of $7^h\ 10^m$, which corrected the striking clock, says Wendelen in the *Eclipses*, p. 65. For him the Atlantic calculation, assuming equal natural days and the Moon's oscillatory prosthaphaereses, as I explained in book 4, chapter 27, no. 17, gives the beginning at Calidianum at $5^h\ 46^m$, but the Tychonic at $5^h\ 49^m$.

[Margin: Year 1600. ☉]

The eclipse of the Sun on June 30 Julian, but July 10 Gregorian. In volume 1 of Tycho's *Progymnasmata*, p. 114, it is set at 5 digits 0′ and at $1^h\ 44^m$ after noon at Uraniborg. ✢ But Kepler in the *Optics*, from p. 422 to p. 430, setting out at length his own observation and those of others together with the calculation, says that Tycho's people at the castle of Benatek [Benátky], which lies 5 German

miles from Prague toward the north-east [verſus Euroaquilonem], observed the middle at 1^h $46½^m$ from noon, and about 5 digits; that Mästlin at Tübingen observed nothing other than that the Sun failed notably beyond the middle; and that he himself at Graz observed the beginning at 12^h $37½^m$ from midnight, the middle at 13^h $47½^m$, the end at 14^h $57½^m$, and 7½ digits. And he says that he later disputed about the beginning with Tycho, who feared that this observation would destroy his own, having obtained the beginning at 12^h 46^m. But in vain, because, as Kepler says on p. 427, he was farther south than Tycho by 3° and almost as many minutes, and saw the Sun more covered; and therefore he saw the beginning earlier and the end later, although he was farther east than Tycho. Magini, in the *Directions*, p. 91, gathers for the castle of Benátky, from the Tychonic tables, 4 digits 50′, and the beginning there at 0^h 47^m and the end at 2^h 47^m.

[Margin: Year 1601. ☾]

The eclipse of the Moon on December 9, on which Kepler says, in the *Optics*, p. 349: *A good part of the Moon's body indeed remained, but how much could not be discerned by anyone with confidence. Ambrosius Rhodius, at one time Tycho's calculator, estimated the failing at 10 digits at Wittenberg.* But on p. 371 he says that he himself observed the beginning by the Tychonic clock at 5^h 35^m, but from the culminations of the stars at 5^h 22^m; and the middle by the automaton at 7^h 7^m, but from the stars at 6^h 53^m. [Margin: A note on the difference of meridians.] ✢ Now Lansbergen, from p. 88 of the *Treasury of Observations*, observed at Goes the beginning at 4^h 35^m, the middle at 6^h 12^m, the end at 7^h 49^m, and 10 digits 37′ from the South. ✢ Adrianus Metius [Adriaan Metius], in the book *De usu Globi*, writes that he observed at Franeker in Frisia the beginning at 4^h 42^m, the middle at 6^h 30^m, the end at 8^h 18^m. ✢ Wendelen, in the *Eclipses*, p. 66, says that at Valensole [Valentiolæ] the Cluniacs observed the beginning a quarter of an hour after sunset, or at 4^h 38^m after noon, and the duration of exactly 3^h; but at Digne he and his people observed the beginning at 4^h 40^m, the end at about 7^h 45^m, and the middle at 6^h 11^m or 12^m. Magini, in the *Directions*, p. 92, by calculation gathers the digits: by the Alphonsine 11 digits 2′, by the Copernican 11 digits 17′, by the Tychonic 10 digits 55′.

[Margin: Year 1601. ☉ Annular.]

The eclipse of the Sun on December 24, observed at Goes by Lansbergen at 1^h 51^m after noon, in such a way that the whole Moon was within the Sun, and the northern margin of the Moon coincided with the northern margin of the Sun, while the southern margin stood 6¾′ from the Sun's margin. And he adds, but from the tables, that the diameter of the Moon at apogee was 29′ 15″, and that of the Sun, almost at perigee, 35′ 18″, from p. 103 of the *Treasury of Observations*. ✢ Kepler, in the *Astronomia Optica*, pp. 359 and 430, says that he observed it at Prague at about 2^h 53^m from noon, of 8 digits and more, and that the diameter of the Moon by the radius on the tablet was to the diameter of the

Sun as 30½ to 31. [Margin: A note on the diameters of the luminaries.] And in the Appendix to Tycho's *Progymnasmata* he says that this eclipse, seen by Tycho's people shortly after Tycho's death, did not agree with the diameters of the luminaries established by Tycho, even if it did not differ in other respects; and that this disagreement is removed if the Sun's diameter is assumed as 31 and the Moon's as 30½. This he says from his own hypothesis, as Lansbergen also does. But these hypotheses do not satisfy certain other eclipses, as was said in book 4, chapter 16.

☩ Longomontanus, in book 1 of the *Theorica*, chapter 9, reports that he observed this eclipse 18 miles beyond Trondheim [Nidrosiam], under an elevation of the pole of 64° 40′, at hour 1 after noon, on the horizon, with the Sun, because of the lunar parallaxes and the marked refraction, very conspicuous as to its upper limb. And when he had come to Bergen in Norway, he was shown by M. Andrea Fossio [Anders Foss], a distinguished theologian, botanist, historian and mathematician, a delineation of this failing, such as he had drawn from the report of fishermen; in it the Sun so surrounded the Moon on every side that the bright circle of the Sun stood out by about a digit and a half. [Margin: Note 2 on the diameters of the luminaries.] From this he strives to confirm that the visible diameter of the Moon in an ecliptic new Moon is diminished, and that of the Sun enlarged, especially where the vapours are thick. But although the image of bright things appears larger next to black ones, owing to its predominance in our eye, and although horizontal refraction optically enlarges the diameters of the stars, as we showed in book 4, chapter 15, and will teach more fully in the book on optics when we solve the objections, nevertheless this second enlargement is common to both luminaries and to the edges of the Moon lit by the Sun, and the first is no greater than what appears in a new Moon with its ring standing out, which is scarcely one or two minutes. So the whole of the excess already mentioned, of a digit and a half on this side and a digit and a half on that, that is, of 3 digits, by which the Sun's diameter was seen to exceed the Moon's, cannot be attributed to that optical enlargement, but at most two or three minutes of it. The rest must therefore be attributed to the ordinary excess of the Sun's apparent diameter over the Moon's. Now the Sun's anomaly was then 176° and the Moon's 7°, at which, for us, the Sun's diameter is ordinarily 33′ 8″ and the Moon's 28′ 4″. Let it be, therefore: as 28′ to 12 digits, so 33′ to 14⅐. For two of the three digits of excess will be owed to the Sun's ordinary excess, and the remaining one digit to the optical enlargement, that is, three minutes. And so we aligned our hypothesis for reconciling the diameters of the luminaries, in book 4, chapter 16, with this eclipse too, but with others along with it.

Moreover Scheiner reports in the *Rosa Ursina* that at Villeregia [?] in Spain some stars were seen in this eclipse. Finally Magini, in the *Tables of Directions*, p. 92, derives for Prague, from the Alphonsine calculation, 7 digits 36′; from the Copernican 9 digits 19′; from the Tychonic 9 digits 33′, with the beginning at $1^h\ 7^m$ and the end at $3^h\ 38^m$ after noon.

[Margin: Year 1602. ☾]

The eclipse of the Moon on June 4, in the evening, observed at Prague by Kepler, as he has it in the *Astronomia Optica*, p. 369: he observed the end with the help of a Tychonic clock showing minutes and seconds, regulated by the Sun's altitude. He observed it at $9^h\ 3^m$, and yet he admits that the Tychonic calculation requires $9^h\ 19^m$, taking the equation of time, the diameters and the difference of meridians from Tycho. *These*, he says, *can be changed without harm to the hypothesis that represents the very moments of the oppositions.* Wendelen's calculation, p. 69, gives, without the equation of time, the end at Prague at $9^h\ 5^m$.

[Margin: Year 1602. ☾]

The eclipse of the Moon on the morning of November 29, seen, contrary to the expectation the ephemerides had raised, by Wendelen, from the *Eclipses*, p. 70, who says that it began at Aix at $7^h\ 10^m$ after midnight. Origanus, however, by the Tychonic calculation, gives $7^h\ 30^m$ there, but with the equation assumed that Wendelen neglects.

[Margin: Year 1603. ☾]

The eclipse of the Moon on May 24, observed at Prague by Kepler, as is found in his *Optics*, at $12^h\ 32^m$ after noon. But because he adds that at $12^h\ 44^m$ *the horns were in a straight line with Jupiter, and the more westerly part was now being raised, which indicated the middle*, Lansbergen, on p. 90 of the *Treasury of Observations*, therefore gathers that the middle at Prague was at $12^h\ 40^m$ and not at $12^h\ 32^m$, which Kepler, he says, gathers from a faulty end and beginning. ✢ Lansbergen himself, however, says that he observed the middle at Goes at $11^h\ 56^m$, and 7½ digits from the South. But Wendelen, in the *Eclipses*, p. 72, because Kepler had said that at $12^h\ 25^m$ *the Moon stood on its back with its horns equally lowered*, and afterwards at $12^h\ 44^m$ *the horns with Jupiter*, etc., gathers from the places of Jupiter and the Moon and from the parallaxes that the horns were not parallel to the Moon's path at that time, but about half an hour before, and that the middle of the eclipse fell at $12^h\ 18^m$ at Prague. [Margin: Disagreement of observations.] ✢ He himself, moreover, at Valensole, observed the beginning at $10^h\ 14^m$, the middle at $11^h\ 38^m$, the end at $13^h\ 2^m$, the duration $2^h\ 48^m$, and 8 digits. Further, he says that Lansbergen could not have had the middle at Goes except at $11^h\ 33^m$, and that he was deceived by the penumbra or by his striking clocks, or else is deceiving us in order to foist his own tables on us. Finally he adds that by the Tychonic calculation the middle comes out at $12^h\ 40^m$ at Prague, but by his own at $11^h\ 38^m$ at Valensole and $12^h\ 18^m$ at Prague.

[Margin: Year 1603. ☾]

The eclipse of the Moon on November 18, observed by Wendelen, from p. 73: at Digne the beginning at about $5^h\ 52^m$, the end exactly at $7^h\ 4^m$, 3 digits. From this he sets the middle at $6^h\ 47^m$, as also from the Atlantic calculation. ✢ At Prague Kepler, as is found in his *Optics*, p. 417, observed the same eclipse.

He says that it began when it inclined 65° from the vertex to the left, and that it ended with the shadow not reaching quite to the vertex but still inclining to the left toward the east, since the Moon was descending southward and the failing was southern, in the eastern quadrant. Again he says that it began ten minutes after the right shoulder of Aquarius had culminated, with the Sun in ♏, 25° 55′, from which he infers the hour $6^h\ 21^m$; and that it ended three minutes after the head of Andromeda had culminated, and therefore at $8^h\ 17^m$, and that it lasted $1^h\ 56^m$, although the Tychonic calculation gives $2^h\ 10^m$. He adds that at the middle it seemed to him to be darkened by less than a quarter, and to others by more than a quarter, and that of the circumference less than ⅓ and more than ¼ was missing. He concludes: *The middle was at $7^h\ 19^m$, the very minute that Tycho's calculation shows on the meridian of Hven for the true conjunction in longitude, which differs somewhat from the middle of the eclipse.* [Margin: A note for geography.] From these, considering the end of the eclipse, Wendelen derives a difference of meridians between Digne and Prague of 35^m; but from the eclipse of the year 1601, of 41^m. He therefore chooses the mean, 38^m, the same number he had derived from the spring eclipse of this year.

[Margin: Year 1605. ☾]

The eclipse of the Moon on April 3, observed at Tübingen by Mästlin, who published a little book on it, and says in Thesis 152: *In the lunar eclipse on the evening of Palm Sunday in the year 1605, there was seen in the body of the Moon, toward the north, a certain blackish spot, darker than all the rest of the body, which presented the shape of red-hot iron. You would have said they were clouds extended over a wide region, heavy with rain and stormy showers, of the kind one not rarely happens to see from the ridges of high mountains, in the lower places of the valleys.* ✢ Lansbergen observed the same eclipse at Goes, from p. 92 of the *Treasury of Observations*, at $8^h\ 35^m$. He says that it lasted $3^h\ 18^m$ and that 11½ digits failed from the North, but from calculation 11 digits 25′. ✢ But Wendelen, in the *Eclipses*, p. 75, says that when he observed at Forcalquier, which is about midway between Digne and Aix, the beginning was at $6^h\ 37^m$ or 38^m and the greatest failing at $8^h\ 12^m$, of no fewer than 11 digits 40′, and that the horns were then parallel to the Moon's path, an argument for the middle of the eclipse, and that the remainder was not visible. And he adds that Lansbergen prolonged the end of the failing, and hence the middle, because of a spurious end due to the penumbra.

[Margin: Year 1605. ☾]

The eclipse of the Moon on September 26, whose middle Lansbergen observed at Goes at $16^h\ 30^m$ from noon, of 8 digits 30′, but from calculation he puts it at 8 digits 22′, p. 93 of the *Treasury of Observations*. ✢ Wendelen, p. 75, says that at Forcalquier he, with his pupil Scipio Arnaudus [?], observed the beginning at $2^h\ 42^m$ from noon [?], by night, fairly accurately on a sundial; that the digits did not much exceed 8; that it ended at $5^h\ 40^m$, the middle being at $4^h\ 11^m$. [Margin: A note on the difference of meridians.] He adds that Lansbergen,

while foisting on us a more prolonged calculation, cannot have seen the end at Goes, and is writing a refutation of himself. [Margin: Wendelen's untimely censure of Lansbergen.] But Lansbergen did not gather the middle from the end, but from the moment of the middle itself, compared with the observations. For the eclipse was partial, and from the earlier half-duration he gathered the later one, and only from this the end.

[Margin: Year 1605. Sun. Total.]

The eclipse of the Sun on October 12, Gregorian style, observed at Middelburg by Io. Rotarius [?] at $1^h\ 15^m$ after noon, of more than 10 digits and less than 11, from the South, as Lansbergen reports, p. 118 of the *Treasury of Observations*. ✢ But at Naples it was observed to be exactly total, or with a very brief stay, although the air all around appeared fiery, as Kepler reports in *De Stella Nova*, chapter 23, and in the *Epitome of Copernican Astronomy*, book 6, p. 893, adding that it was total, but that at Antwerp the whole Sun was not covered. ✢ So too Wendelen, from p. 77 of the *Eclipses*, saw the Sun at Forcalquier enter eclipse immediately after noon and leave it at $2^h\ 40^m$, the whole Sun being obscured except for a very thin thread of light toward the north, which he attributes not to the Sun but to the atmosphere shining through, either through our air or through the lunar air. ✢ He adds that at Marseille and on the nearby sea a total eclipse and dense darkness were observed. For me this eclipse was total, with the Sun's diameter 32′ 6″ and the Moon's 32′ 22″.

[Margin: Year 1607. Sun.]

The eclipse of the Sun, on the indication of which see the Scholia to chapter 2.

[Margin: Year 1608. Sun.]

The eclipse of the Sun on August 10, observed at Goes by Lansbergen at $4^h\ 8^m$ after noon, of 2 digits 30′, from the South, as he himself reports in the *Treasury of Observations*, p. 120. ✢ But Longomontanus, in the *Astronomia Danica*, book 2, chapter 9, says that it was observed at Wittenberg by Melchior I[?]östelius, of almost 2 digits; but that by him and by five other men of very sharp sight no trace of the eclipse could be noted at Copenhagen, although there ought to have been some; he puts the cause down to the thicker air of that place.

[Margin: Year 1609. ☾]

The eclipse of the Moon on January 19, observed at Goes by Lansbergen, as he reports on p. 94 of the *Treasury of Observations*: the beginning at $13^h\ 12^m$, the middle at $14^h\ 40^m$ after noon, 9 digits 30′ from the North, but from calculation 9 digits 36′. ✢ Adriaan Metius, in *De usu Globi*, says that he observed the middle at Franeker at $14^h\ 42^m$. ✢ Wendelen, from p. 77, observed at Forcalquier with Arnaudus the beginning at $1^h\ 10^m$ after midnight and the end at $4^h\ 16^m$.

[Margin: Year 1609. ☾ Total.]

The eclipse of the Moon on July 16, observed at Copenhagen by Longomontanus, who, reducing it to Uraniborg, says that it was at $12^h\ 10^m$.

☩ At Forcalquier, for Wendelen, from p. 78, it began to fail at 9^h 53^m and was immersed before the eleventh hour; soon clouds, thunder and lightning followed.

[Margin: Year 1610. ☾ ☾]

Two eclipses of the Moon. The first on July 6, observed at Forcalquier by Wendelen in the morning, 5^m before the third hour, and it set still failing. The second on December 30, about which Galileo writes in the letter prefixed to Kepler's *Dioptrice*; ☩ and Wendelen, p. 79, saying that at Forcalquier he observed the beginning a little before 2^h 40^m after midnight and the end at 4^h 50^m.

[Margin: Year 1612. ☾]

The eclipse of the Moon on the evening of May 14, which, as Wendelen says, Io. Remus [Johannes Remus Quietanus], physician and mathematician, observed at Rome but did not publish. ☩ At Liège Wendelen, as he relates in the *Eclipses*, p. 79, observed the beginning at about 8^h 37^m, the end exactly at 11^h 15^m, the duration 2^h 36^m, and 6 digits 30′. ☩ At Munich Father Christoph Scheiner noted the beginning half a quarter of an hour, as it were, before the ninth evening hour. He says that it ended at the twelfth hour itself, and that it exceeded the calculation in duration and magnitude, for it was of 8 digits. But Wendelen thinks that Scheiner counted the penumbra with the shadow. ☩ Longomontanus, in the *Astronomia Danica*, book 1 of the *Theorica*, chapter 9, writes that he and his people observed at Copenhagen the beginning with Regulus at an altitude of 35° 52′ in the west, from which he derived 9^h 14^m; but he says that it more probably happened a little earlier. The middle, with Spica at an altitude of 23° 57′ in the west, or at 10⅗ hours, and 6½ digits; although from his own calculation he gathers the beginning, in apparent time, at 9^h $13\frac{2}{3}^m$, the middle at 10^h $38\frac{2}{3}^m$, and 6 digits 35′.

[Margin: Year 1612. Sun.]

The eclipse of the Sun on May 29, observed by Father Christoph Scheiner at Munich, of 8 digits: the beginning at 10^h, the end at 12^h 45^m after midnight, as he relates in the *Apelles post tabulam*, p. 49. ☩ Longomontanus, in the *Astronomia Danica*, book 1 of the *Theorica*, chapter 9, says that he observed it at Copenhagen with seven others, and that the beginning was at 10^h $14\frac{2}{3}^m$, with the Sun at an altitude a little beyond 51°, and the end a little later than the calculation allows, which requires 12^h $23\frac{3}{4}^m$, because of the uncertainty arising from the Sun's almost meridian altitude; and 8 digits, although the Copernican calculation gives 9½.

[Margin: Year 1612. ☾]

The eclipse of the Moon on November 8, whose beginning was observed at Nagasaki at 9^h 30^m after noon by the most illustrious martyr Father Carlo Spinola of the Society of Jesus; ☩ but at Macau, on the borders of China, by Father Giulio Aleni, S.J., at 8^h 30^m, with the end at 11^h 45^m, from the Moon's altitude and azimuths. He adds that at Macau the altitude of the pole was

observed to be 22° 13′ to the north, and that Beijing is more easterly than Macau by 5°. Father Aleni wrote all these observations to Giovanni Antonio Magini, whose pupil he had once been at Bologna, and this letter, found among Magini's papers, was communicated to me by Magini's successor in the principal chair of mathematics and my very good friend, Father Bonaventura Cavalieri. This agrees with the observation of Father Vremannus [?] at Macau, sent to Belgium, which Wendelen reports, p. 80, where the beginning is given at $8^h\ 30^m$ and the end at $11^h\ 45^m$. ✢ Scheiner, at Ingolstadt, at about $4^h\ 53^m$, saw *the whole globe of the Moon, but tinged with a bloody and black colour; and its upper parts were still wrapped in darkness, so that the Moon shone through very grudgingly. As the fifth hour was striking, these wrappings began to slip away, but this struggle of light and darkness lasted for almost three quarters of an hour, until a little after the middle of the sixth evening hour the Moon smiled out serene; these remnants of the failing lasted almost* 40^m. From this he gathers the end at 5^h, as also from his tables.

[Margin: Year 1613. ☾ Total.]

The eclipse of the Moon on October 28, observed by Longomontanus at Copenhagen and reduced to Uraniborg, at $3^h\ 57^m$. ✢ David Fabricius, at Emden in Frisia, as Wendelen relates, p. 80, and Kepler in the *Ephemerides*, p. 21, thought that with the telescope he observed the end earlier than calculation or the naked eye would show, but he devised an extraneous cause, on which see Kepler in that place.

[Margin: Year 1614. ☾]

The eclipse of the Moon on the morning of April 24, whose beginning was seen at Leuven and at Mechelen by the night watchmen as the third hour after midnight was striking. So Wendelen, p. 81, whose calculation gives $3^h\ 1^m$.

[Margin: Year 1614. Sun.]

The eclipse of the Sun on October 3, in Frisia near Emden. Fabricius, and Kepler at Linz, and others at Venice and at Munich, namely Simon Marius and Scheiner, observed that the eclipse came earlier and was greater than Tycho's hypothesis allows, as Kepler relates in the *Ephemerides*, p. 11, and Wendelen, p. 81. For Tycho, in ecliptic new Moons, makes the Moon's diameter too small. ✢ Kepler adds, in the *Epitome of Copernican Astronomy*, p. 895, that at Munich the failing began about noon on the right and ended below.

[Margin: Year 1616. ☾]

The eclipse of the Moon on March 3. The end of the eclipse was observed at Goa at $7^h\ 53^m$ after noon, as Father Athanasius Kircher reports in his *Magnes*, which at Frankfurt on the Oder, from Origanus's calculation, should have been at $3^h\ 51^m$ after noon; but Wendelen's calculation, p. 82, requires $3^h\ 58^m$. From this he conjectures that Goa is further east than Frankfurt by $4^h\ 11^m$.

The eclipse of the Moon on August 26. At Rome our Grienberger observed the beginning at $1^h\ 43^m\ 30^s$ after the following midnight and the end at $4^h\ 56^m$

24ˢ; therefore the duration was almost 3^h 13^m and the middle at 3^h 20^m. ✢ At Rome likewise others, separately, using a telescope, noted the immersion at 3^h $6½^m$ and the emersion at 3^h $33¾^m$; therefore the middle at 3^h 20^m, in admirable agreement, as Kepler relates in the *Ephemerides*, pp. 11 and 12. ✢ But Wendelen, p. 83, says that at Liège he observed the beginning at 1^h 23^m, the immersion at 2^h 42^m, the emersion at 3^h 13^m, the end at 4^h 31^m, the duration 3^h 8^m, but with the deception of the umbrago 3^h 13^m. ✢ At Tübingen Mästlin, from Kepler above, observed the start at 1^h 33^m, by the altitude of 9° of the right shoulder of Orion, and the end at 4^h 43^m, by the altitude of Sirius of 11° 20′; therefore the middle at 3^h 8^m. ✢ At Linz Kepler, from the Moon's western azimuth of 31° 20′, observed the beginning at 1^h 48^m and the end at 5^h 16^m. But because of the faults and deceptions of sight, which he admits, he shortens the duration and puts the middle at 3^h 30^m. From this he gathers 5½° between Tübingen and Linz, agreeing very nearly with the distance by road, and 2½° between Linz and Rome, or 10^m of time. [Margin: A note on the difference of meridians.] In the Rudolphine Tables, however, p. 103, he says: *Of the observers, some assert that it was total, others partial.* But Wendelen thinks that the penumbra was on both sides the reason why the duration seemed to Kepler to be 3^h 32^m, when in reality it was 3^h 8^m; and he puts the middle at Linz at 3^h 34^m. ✢ At Ingolstadt, as Father Iacobus Viva writes to me, the total immersion was observed at 15^h 15^m after noon and the emersion at 15^h 45^m. In that case Rome would turn out to be further west than Ingolstadt, which is altogether false.

The eclipse of the Moon on August 16. Kepler, in a circle of nobles, observed the middle of the eclipse at Linz at 8^h 10^m after noon, as Wendelen gathers from his discussion, p. 85, who says ✢ that at Herk he observed the emersion at 8^h 15^m and the repletion at 9^h 17^m.

[Margin: Year 1619. ☾]

The eclipse of the Moon on June 26. At Herk, when midnight had passed, the Moon's limb was seen to be dulled very faintly, yet the quantity of 3 digits that the ephemerides promised nowhere appeared. Hence Wendelen, who reports this on p. 85, suspected either that the Moon's latitude in the syzygies is wider, as Kepler holds, or that the distance from the node was greater than the tables allow, or that the Earth's shadow was thinned by refractions. But this also confirms our hypothesis on the semidiameters, whose sum was 52′ 53″, while the Moon's latitude was 51′ 10″, and therefore the failing was not of a whole digit.

[Margin: Year 1619. ☾]

The eclipse of the Moon on December 20, observed at Mechelen by Wendelen, from his p. 86. The Moon began to fail at 1^h 27^m after the following midnight, when Canis Major had not yet passed the meridian by one degree. The end was at most at 4^h 28^m, the middle at 2^h $57½^m$, and almost 11 digits. ✢

At Herk, Wendelen's brothers and apprentices noted the beginning at $1^h\ 30^m$, when Canis Major had passed the meridian by a degree and a half and the hour $1^h\ 30^m$ was just striking. It ended at $4^h\ 30^m$, and they too judged the digits to be 11. ✢ At Ingolstadt, as Father Iacobus Viva writes to me, the smoke began at 2^h after midnight; the shadow was already noticeable at $2^h\ 15^m$; the Moon was leaving the shadow and the eclipse ending at $5^h\ 15^m$, with the Moon at an altitude of 32° 40′. [Margin: A note on the difference of meridians.] ✢ He adds that at Lisbon the altitude of the pole was taken as 39° 38′, and that the eclipse began with Sirius at an altitude of 35° 20′, that 11 digits were noted, and that it emerged completely with Sirius at an altitude of 18° 40′, namely at $15^h\ 48^m$; and that this was written from there to Ingolstadt.
