The eclipse of the Moon on June 14, which Gassendi observed at Aix with the Lord Joseph Gaultier de la Valette, as is found in his letters and in Wendelen, p. 87: the beginning at $11^h\ 15^m$ after noon, from a western altitude of Spica of 16° 58′, its southern declination being taken as 9° 8′ and its right ascension as 196° 20′, and the altitude of the pole observed there as 43° 33′. The total obscuration at $12^h\ 27^m$, with Arcturus at an altitude of 35° 34′ in the west, its declination taken as 21° 13′ and its right ascension as 209° 37′. The emersion at 14^h, as far as the clouds allowed, with the Crown at an altitude of 37° 15′, and its declination 28° 2′ and right ascension 229° 39′. ✢ At Verona, Wendelen says, it lasted with the penumbra until $3^h\ 50^m$. Therefore, he says, without the penumbra the end would have been at $3^h\ 20^m$. ✢ At Herk, so far as the gaps in the clouds allowed, Wendelen conjectured the beginning at $11^h\ 12^m$, the immersion at $12^h\ 17^m$, and the emersion a little before 14^h, because at 2^h after midnight some small part of it was already shining.

[Margin: Year 1620. ☾ Total.]

The eclipse of the Moon on December 9. It was predicted beforehand by the Fathers of our Society to the Prince of Caciani [?] in the Kingdom of Cochinchina, as Cristoforo Borri writes to Urban VIII in his *Relation* on that kingdom. That ruler's astrologers had ordered it to be watched for on the night following the 8th, and the Prince and his people waited in vain, with a great array of drums, to help the labouring Moon. It was therefore observed to begin on the following night, at 11^h after noon; and this won great esteem for our men, and that Prince, with many men of letters, at length embraced the Catholic faith. ✢ At Brussels Michael Florent van Langren, Royal Cosmographer, noted the emersion at $6^h\ 25½^m$, with the bright star of Aries at an altitude of 51° 15′, and the end at $7^h\ 24^m$, with the same star at an altitude of 57° 34′, as Wendelen reports in the *Eclipses*, p. 88. He adds ✢ that at Bethasii [?] he observed the beginning at about $3^h\ 52^m$, the immersion at $4^h\ 51^m$, with degree 329° 45′ of the equator culminating, the emersion at $6^h\ 29^m$, with 354° 30′ culminating, and the end at about $7^h\ 28^m$; and from this he gathers the middle at $5^h\ 40^m$.

[Margin: A note on the difference of meridians.] He too reports the observation in Cochinchina, which he gathers to be further east than Bethasii by $7^h\ 8^m$.

[Margin: Year 1621. Sun.]

The eclipse of the Sun on May 21, observed at Middelburg by Lansbergen at $8^h\ 16^m$ after midnight, of 11⅙ digits to the north; and at Dordrecht by Martinus Hortensius at $8^h\ 16^m$, of 10 digits 7′, through a telescope, as Lansbergen reports in the *Treasury of Observations*, p. 120. ✢ And at Aix by Gassendi and Gaultier, with the Sun's image passed through the concave lens of a most excellent telescope onto a board covered with very white paper, in a darkened room. On the board the diameter of a circle equal to the circle of the Sun was divided into 12 digits, each digit being subdivided into 15 parts, and the circumference was divided into 360°. Gaultier, in the next room, took altitudes of the Sun with a quadrant of a radius greater than 2 feet. A companion was present to give Gaultier a signal, at Gassendi's order, by a knock on the wall. In this way the beginning was observed at $4^h\ 54^m\ 28^s$ before noon, with the Sun at an altitude of 25° 30′, the Sun being taken to be in ♊ 0° 15′. The end was at $2^h\ 29^m$, with the Sun at an altitude of 51° 17′; the duration $2^h\ 25^m\ 14^s$; and 9 digits 23′. And because 77° 30′ of the circumference were failing on each side, the diameters of the luminaries seemed equal. The Moon was further north than the Sun. So Gassendi writes in his letters to a friend at Rome, who communicated this to the Lord Antonio Rocca of Reggio, and he to me. The Sun's anomaly, moreover, was 322° and the Moon's 90½°, and so for me the Sun's apparent diameter was 31′ and the Moon's 30½′, which comes very close to Gassendi's observation.

[Margin: Year 1621. ☾]

The eclipse of the Moon on November 28, observed at Aix by Gassendi, as I have it from his letters sent to Italy, and it is confirmed from Wendelen's *Eclipses*, p. 88. The sky was somewhat cloudy at the start, with Aldebaran at an altitude of 52° 10′ from the west. The beginning was estimated at $13^h\ 54^m$ from noon, the end at $15^h\ 52^m$, with the same star at an altitude of 32° 30′ and the right shoulder of Orion at 39° 30′ in the west. The middle was at $2^h\ 53^m$, at which, so far as he could, he estimated 3 digits 38′. But he adds here: *But do not trust it too much.* ✢ Kepler at Linz noted, somehow or other through clouds, the beginning at $14^h\ 33^m$, the end at $16^h\ 34^m$, and 4 digits. ✢ At Bethasii Wendelen noted the beginning of the umbrago at $13^h\ 59^m$, shown by the sundial; but the true beginning at $14^h\ 2^m$, the true end at $3^h\ 57^m$, and the spurious end at $4^h\ 3^m$ and beyond, and 3 digits 1′. [Margin: A note on the difference of meridians.] From this he works out a difference of meridians between Linz and Aix of 42^m of time, and between Bethasii and Linz of 37^m.

[Margin: Year 1623. ☾]

The eclipse of the Moon on April 14, observed at Digne by Gassendi, where he had observed the altitude of the pole as 44° 6′. He observed the beginning at $10^h\ 5^m$ [recte: $15^h\ 9^m$, per the book's errata] after noon, with the tail of Leo at an altitude of 20° 6′ in the west; nearly 11 digits, and the remainder of the

Moon, seen a little before, equal to the diameter of Jupiter. The end could not be noted because the Moon was setting. Indeed he adds that the observation of the beginning was difficult, because it began from the left and lower part, where the spots are blacker. ☩ At Linz Kepler noted, under a cloudy sky, the middle at 4^h 50^m after the following midnight, whereas from calculation he had fixed it at 5^h 15^m; and therefore he looked for an equation of 19^m to be subtracted from the time. ☩ At Leiden Hortensius observed the beginning at 9^h 22^m and the end at 12^h 23^m.

[Margin: Year 1624. ☾]

The eclipse of the Moon on April 3. Wendelen, as he has it on p. 91, observed the end already over at Bethasii at the very hour 8^h after noon. ☩ At Stuttgart Fridericus Ritelius [?] noted the emersion at 6^h 58^m and the repletion at 7^h 58^m, looking at the striking clock. But looking at the altitude of Arcturus, of 22° 45′ when 3 digits had already emerged, and the hour from this was 7^h 48^m, and of 24° 18′ when 6 digits were shining, that is, at 7^h 57^m, it follows that the emersion was at 7^h 27^m by celestial time and the end at 8^h 27^m. But Wendelen suspects a displacement in Ritelius's quadrant, because he had already fixed 14^m of time between Stuttgart and Bethasii.

[Margin: Year 1624. ☾ Total.]

The eclipse of the Moon on September 26. Kepler at Linz, with a skilled companion in another house, observed the duration as 3^h 38^m, the stay as 1^h 45^m and the middle at 8^h 55^m from noon: for the beginning was at 7^h 6^m, the immersion at 8^h 3^m, the emersion at 9^h 47^m and the end at 10^h 44^m. But because all the tables promised a longer duration and stay, he suspected that the Earth's shadow was oval, as also the atmosphere of vapours producing the penumbra; Wendelen, p. 92, judges this an escape born of despair. Lansbergen, however, says in precept 24 of his tables that, given the difficulty of observing the exact time of entry into and exit from the shadow, it is no wonder if Kepler noted a duration 8^m shorter and a stay 7^m longer than his tables require. ☩ At Bethasii Wendelen noted the first threats of the failing at 6^h 25^m, and already at 6^h 28^m the failing was noticeable; the immersion at about 7^h 23^m, but until 7^h 29^m a secondary light clinging to the immersed limb; [Margin: A note on the secondary light of the Moon in an eclipse.] the emersion at 9^h 7^m and the end at 10^h 4^m, although the [Greek: ἐπισκοτία (episkotia, "darkening")] of the umbrago lasted until 10^h 12^m. The duration therefore was almost 3^h 39^m, the stay 1^h 44^m, throughout which the Moon glowed red with a pure brightness, a light little cloud arising toward the middle. The middle therefore at 8^h 15^m. ☩ At Brussels van Langren noted 6 digits obscured at 6^h 48^m, with degree 285° 30′ of the equator culminating; the immersion at 7^h $18\frac{1}{3}^m$, with 293° 27′ culminating; the emersion at 9^h 2^m, with 319° 12′ culminating; the repletion at 9^h 59^m 40^s, with 333° 40′ culminating; and therefore the stay as 1^h 44^m and the middle at 8^h 10^m. From this is gathered a difference of longitude between

Brussels and Bethasii of 5^m of time, even if Wendelen puts Bethasii further east by 4^m 20^s, and Linz further east than Brussels by 44^m. [Margin: And for the difference of meridians.]

[Margin: Year 1625. ☾]

The eclipse of the Moon on March 24, observed at Paris by Gassendi, with a steel quadrant of one foot by Mydorge, but most accurately divided and very nimble in motion. The start was at 12^h 54^m, with Regulus at an altitude of 36° 20′ in the west. The end at 13^h 37^m, with the northern Scale at an altitude of 31° 30′ in the east. The size of the eclipse was seen scarcely to exceed 1 digit, and was certainly less than two. So from his letters, ✝ and from Wendelen, p. 93, who says that he expected at Bethasii an eclipse of 3 digits and a duration of two hours, but that it turned out far otherwise, for 2 digits and a duration of 1^h 17^m, the middle at 1^h 30^m after midnight. Wendelen adds these words: *These last two eclipses at length warned me of not a few things to be corrected in my Tables: the Moon's anomaly; its distance from the Earth (which until now I had set at only 57½ semidiameters). They also dictated to me a far different eccentricity, and showed altogether eight semidiameters of the Earth from apogee to perigee. Finally they also pointed out the Nodes of the Dragons; and it is incredible with what labours, with how often repeated Tables, in fitting them both to this last eclipse and to other eclipses, both backward and forward, I have scarcely at last attained my wish, so as to gladden you, Reader.* [Margin: The hazard for astronomy in small eclipses.] For there is a greater hazard in these small eclipses, which vanish with a modest error in the Tables, than in large ones, which leave a wider field to hypotheses; and this will also be clear from the next one. For me, moreover, the sum of the semidiameters of the shadow and the Moon was 53′ 55″ and the latitude of the ☾ 52′ 0″, and therefore the eclipse was of about one digit.

[Margin: Year 1626. ☾ Promised in vain, and imperceptible.]

The eclipse of the Moon on August 7, promised by the ephemerides as a half-digit eclipse with a duration of 44^m, whose middle should have been at Linz at 7^h 45^m. But Kepler, attending carefully there from sunset until 8^h 30^m, found nothing lacking in the Moon's roundness. Wendelen, p. 94, adduces this in support of his own Tables, which give no eclipse. My tables, however, give an imperceptible one: namely, the sum of the semidiameters of the shadow and the Moon as 62′ 5″, and the latitude as 62′.

[Margin: Year 1627. ☾]

The eclipse of the Moon on July 27, observed at Madrid by Fathers of our Society. Their observation had been sent to Ingolstadt, and Father Iacobus Viua [?] forwarded it to me. At 16^h[49] after noon the smoke began; at 16^h 12^m the true beginning; at 16^h 43^m the Moon reached the horizon, already failing by 9 digits; it set at 16^h 45^m. Shortly afterwards the Sun rose, and earlier because of the refractions, since it should have risen at 16^h 52^m, with the altitude of the pole at Madrid taken as 40° 26′. So the observation sheet has it.

[49] the page sets **Hor.16′.**, a minute mark with no minute figure beside it

[Margin: Year 1628. ☾ Total.]

The eclipse of the Moon on January 20. As we have it from his letters, communicated to me by D. Antonio Rocca, Gassendi observed at Aix the beginning at 7^h 49^m from noon, with Sirius at an altitude of 21° 9′ in the east; the immersion at 8^h 48^m, with the heart of Hydra at an altitude of 14° 10′ in the east; the emersion at 10^h 25^m, with the same star at 28° 33′; the end at 11^h 24^m, with Rigel at an altitude of 26° 37′ in the west. Wendelen too has these numbers, p. 95. [Margin: Colours of the Moon in eclipse.] With the help of the telescope, moreover, Gassendi distinguished the true eclipse from the smoke of the umbrago; and he distinguished a honey colour, then purple, and finally rust-red, and the same colours at the emersion in reverse order. ✢ At Paris Mydorge [printed Midorpius] observed the beginning at 7^h 35^m, with Procyon at an altitude of 28° 3′, and the immersion at 8^h 34^m, with the same star at 36° 20′. So Gassendi in the same letter, and Ismaël Boulliau in the *Astronomia Philolaica*, p. 467, who adds ✢ that at Oxford Bainbridge [John Bainbridge] observed the total immersion at 8^h 23^m and the emersion at 10^h 0^m. [Margin: Difference of meridians.] ✢ Pétau adds, in a letter to Wendelen, that at Paris the beginning was seen without the telescope at 7^h 27^m and with the telescope at 7^h 35^m; that the end of the stay or of the emergence [euasionis] could not be observed because clouds passed across; but that a little after the end, from Arcturus at an altitude of 9° 30′, namely at 11^h 7^m, it was certain that the duration had not exceeded 3^h 37^m. Wendelen, p. 94, relates that at Brussels, because of snow and fog, nothing certain was apparent to him except the end at 11^h 15^m, because at 11^h 3 digits were lacking and at 11^h 15^m nothing but the pallor of the penumbra could be made out. [Margin: Colours of the Moon.] As the clouds parted again and again, the Moon was seen to glow red like a burning coal, and all but to shine. ✢ He adds that at Bethasiis his brothers, Nicolaus above all and Io. Acanthius [?], observed the emersion at precisely 10^h 20^m on the sundial, and the end clearly at 11^h 19^m; ✢ and that at Prague Kepler, with learned men, had the beginning from the striking clock at 8^h 30^m, the immersion at 9^h 30^m, the emersion at 11^h 10^m, the end at 12^h 10^m, and the duration 3^h 40^m. But from the altitudes of stars Kepler found that 11^m were to be subtracted from the striking clock, and that the middle was therefore at 10^h 9^m. [Margin: † Note on the contraction of the shadow.] But since he had computed from the tables a stay of 1^h 50^m, and found by observing that it was 10^m less, he attributed the cause to a shortening of the shadow.

[Margin: Year 1628. ⊙ Annular.]

The eclipse of the Sun on December 26, observed at Barcelona by Father Io. Baptista Cyssatus [Johann Baptist Cysat] at 4^h 1^m after noon, of 8 digits 45′, with the Sun at an altitude of 4° 30′ and the altitude of the pole already observed there as 41° 30′. ✢ Kepler observed it in Austria with a bright and vaporous ring, as I find in my papers.

[Margin: Year 1629. ☉]

The eclipse of the Sun on December 14, in West America and the province of Macha, at a southern pole altitude of 20°. The beginning was observed at 1^h 45^m before noon and the end at 1^h 45^m after noon, as was written to me.

[Margin: Year 1630. ☉]

The eclipse of the Sun on June 10. Lansbergen, in the *Treasury of Observations*, p. 123, relates that it was observed at Dordrecht by Martinus Hortensius, under a dark roof, through an optical tube, at 7^h 15^m, and of 10 digits, a little more; ✢ and by himself at Middelburg at 7^h 10^m after noon, of 10 digits 42′, whereas the true conjunction there was at 5^h 57^m. ✢ Gassendi says in his letters that he observed at Paris the beginning at 6^h 16^m, the middle at 7^h 12^m, and then 11 digits 32′; and that the end could not be observed, since the Sun set while still in an eclipse of 2 digits. ✢ Father Andreas Arzet [?] of the Society of Jesus, together with Father Cysat at Ingolstadt, writes to me that he observed the beginning at 6^h 40^m, the middle at 7^h $54½^m$, and then 11 digits 57′, with the Sun visibly at an altitude of 5° 18′, and the diameters of the luminaries scarcely sensibly different. [Margin: Note on the diameters of the luminaries.] This agrees excellently with my hypothesis, which gives the Sun, at an anomaly of 351°, a diameter of 30′ 50″, and the Moon, at the anomaly of 101° it then had, a diameter of 30′ 58″. ✢ Boulliau, in the *Astronomia Philolaica*, p. 467, relates that at Oxford Bainbridge observed the beginning at 5^h 58^m and the end at 7^h 48^m from noon. ✢ We ourselves, at Foro-Nævii [?], 14 miles from Parma (where we were on account of the plague, which raged there and throughout Lombardy from the beginning of spring until the following autumn), having no instruments, noted the beginning on the sundial at about 6^h 45^m after noon.

[Margin: Year 1630. ☾]

The eclipse of the Moon on November 19, omitted by Magini and Argoli but set down by Origanus in his *Ephemerides*. Though I did not know this at the time, I was for some reason or other practising calculation, and found it, and confidently predicted it to the Most Serene Odoardo Farnese. It happened, though with a huge quantity of rain, yet so that it could be seen through gaps in the clouds, but its phases could by no means be noted. ✢ But Father Arzet observed it at Ingolstadt, of 9 digits 27′, with the beginning at 9^h 50^m and the end at 12^h 58^m, and the diameter of the shadow to the diameter of the Moon as 266 to 100. So I have it from his letters, very generously sent to me. My hypothesis, however, requires, at the Sun's anomaly of 143° and the Moon's of 53°, which they then had, the semidiameter of the shadow to that of the Moon as 271½ to 100. ✢ Hortensius noted at Leiden the beginning at 9^h 22^m and the end at 12^h 23^m; his duration is therefore 8^m less than Arzet's. ✢ Van Langren, at Brussels, noted the middle at 10^h 17^m, and 9 digits 30′ optical but 8 true, as Wendelen gathers from his observation, p. 97, where he reports Hortensius's observation.

[Margin: Year 1631. ☾]

The eclipse of the Moon on May 15, observed at Ingolstadt by Father Andreas Arzet, S.J., about which, in a letter sent to me, as follows: *When the Moon had risen above the vapours it was already wholly in the shadow of the Earth; but it began to recover its light when the bright star of Lyra stood at an altitude of 27° 30′ from the east, that is, at 9^h 15^m after noon; it emerged wholly when Lyra stood at an altitude of 36° 35′.* At Lyon on the Rhône it emerged a little before the eighth hour, as Father d'Auxon, mathematician of our Society, told Wendelen: so Wendelen, p. 97.

[Margin: Year 1631. ☾ Total.]

The eclipse of the Moon on November 8. At Lugdunum Batavorum, or Leiden, Martinus Hortensius observed the beginning at 9^h 30^m from noon, with the Moon at an altitude of 43° 9′. But with Aldebaran at an altitude of 36° 40′ from the east, that is, at 10^h 4^m, 6 digits were failing. The immersion was at 10^h 36^m, with Aldebaran at an altitude of 40° 48′; the emersion at 12^h 17^m, with the right shoulder of Orion at an altitude of 36° 30′; and with the same star now at 39° 42′, namely at 12^h 50^m, 6 digits returned. The end was at 13^h 23^m, with the Moon at an altitude of 51° 5′ in the west. So Hortensius has it in his dissertation on Mercury seen in the Sun, with Gassendi. [Margin: Note on the difference of meridians.] ✢ Gassendi, however, writes that all those things happened at Paris 12^m later, as I read in his letter. ✢ Wendelen, however, p. 98, says that at Paris the beginning was not apparent, and that the immersion was noted from the altitude of Jupiter at 10^h 17^m 30^s, but from the altitude of the Moon at 10^h 22^m 30^s. ✢ At Tübingen Schickard noted the immersion at 10^h 55^m or 52^m, and the emersion at 12^h 35^m. ✢ At Bethasiis Wendelen observed the beginning at 9^h 33^m, the emersion at 12^h 23^m by the sundial, and the end clearly at 13^h 28^m, but the penumbra lasted until 13^h 36^m. ✢ At Madrid van Langren noted the immersion at 10^h $4\frac{2}{3}^m$, with degree 14° 58′ of the equator culminating, though the observation was difficult because the phase was long doubtful; the emersion at 11^h 50^m; the end at 12^h 54^m 40^s.

[Margin: Year 1632. ☾]

The eclipse of the Moon on October 27, observed at Innsbruck by Father Andreas Arzet of the Society of Jesus. The beginning at 10^h 37^m from noon, with Aldebaran at an altitude of 38° 20′ from the east; the end at 12^h 59^m, with Aldebaran at an altitude of 56° 17′; 5 digits 22′, but with the smoke 6; to others, however, it appeared as 6 digits 6′. Smoke had preceded the beginning for a quarter of an hour. So he says in his letters to me. [Margin: Difference of meridians.] ✢ At Lyon on the Rhône Gassendi obtained the beginning at 10^h 3^m and the end at 12^h 30^m from the altitudes of stars, with the altitude of the pole taken as 45° 36′, as Wendelen writes, p. 99. ✢ At Leiden Martinus Hortensius noted the pallor of the umbrago a little after the tenth hour was heard to strike, but the true beginning at 10^h 20^m, with Jupiter at an altitude of

41° 36′ in the east, and the end at 12^h 44^m, with Aldebaran at an altitude of 50° 13′; and scarcely more than 4 digits 40′. So he says. ✢ At Liège Otgerus [?], a skilled mathematician, obtained the beginning at 10^h 18^m and the end at 12^h 40^m.

[Margin: Year 1633. ☉]

The eclipse of the Sun on April 8, observed at Regensburg by Father Andreas Arzet, S.J., of 6 digits 44′, at 5^h 3^m. He says that he then found the diameter of the Sun to the diameter of the Moon, in the bright circle, as 100 to 97, which comes close to my hypothesis: for the Sun's anomaly was 281° and the Moon's 277°, and the apparent semidiameter of the ☉ was 15′ 49″ and of the ☾ 14′ 54″, that is, about as 100 to 95. ✢ At Avignon, as Father Theophilus Raynaudus [Théophile Raynaud] wrote to me, the beginning was observed at 3^h 29^m, and at Paris at 3^h 18^m. ✢ We at Bologna noted 5 digits on the sundial at 5^h 15^m.

[Margin: Year 1634. ☾]

The eclipse of the Moon on March 14. At Aix, Nicolaus Fabricius Peireskius [Nicolas-Claude Fabri de Peiresc] observed the beginning at about 7^h 33^m, and the end at 10^h 49^m. ✢ Gassendi at Digne had the beginning at 7^h 41^m, 10 digits at 9^h 2^m, and the end at 11^h 2^m, as Wendelen writes, p. 110. ✢ At Madrid van Langren observed, at 8^h $13½^m$, 9 digits 33′ failing, and the greatest failing, of 10 digits 15′, from which Wendelen gathers the middle at 8^h 42^m; the end was at 10^h 19^m at most. Van Langren himself writes to me the selenographic places through which the section of the Earth's shadow was passing, with the degrees of the equator then culminating: consult, therefore, book 4, chapter 7, and the following small table.

Parts of the Moon through which the section of the Earth's shadow passed as it left them [Lunæ Partes per quas tranſibat ſectio Vmbræ Terræ illas deferentis]	Degrees of the equator then culminating [Aequatoris Gradus tunc culminantes]
Port of St Vincent, Mount Moretus [Portus S.Vincentij Mons Moreti]	118° 7′ 30″
Port of St Vincent, Mons Torri [Portus S.Vincentij Mons Torri]	123° 42′ 30″
Lake of Posidonius [Lacus Poſſidonij]	132° 50′ 30″
Mount Philip [Mons Philippi]	132° 54′ 0″
Middle of the Adriatic Port [Portûs Adriatici medium]	137° 23′ 0″
Mons Torri	144° 43′ 30″
Mount Puteanus and the Port of St Louis uncovered [Mons Puteani & Portus S.Ludouici detectus]	146° 2′ 20″
Mount Wendelen appeared [Mons Vendelini apparuit]	149° 22′ 0″
Mount van Langren appeared [Mons Langreni apparuit]	✢ ✢ ✢
End of the eclipse [Finis Eclipſis]	152° 29′ 0″

[Margin: Year 1635. ☾ Total.]

The eclipse of the Moon on March 3. Gassendi, in Peiresc's house at Marseille, observed the beginning of the stay at 7^h 45^m. ✢ But at Aix it was observed at 7^h 55^m. ✢ At Danzig, by Crüger [Peter Crüger], at 8^h 47^m. ✢ At Stettin, by Laurentius Eichstadius [Lorenz Eichstaedt], at 8^h 27^m, with Regulus at an

altitude of 41° 13′. ✢ At Königsberg in Prussia at 8^h 54^m, with Procyon at an altitude of 4° 1′. [Margin: Difference of meridians.] ✢ At Amsterdam, by Hortensius, at 7^h 51^m, with Regulus at an altitude of 52° 46′, and the middle at 8^h 40^m, as Boulliau has it, pp. 137 and 466 of the *Astronomia Philolaica*. ✢ But at Paris van Langren's father noted the emersion at 9^h 23^m or 24^m. ✢ At Brussels van Langren had the beginning at 6^h 49^m and the end at 10^h $39½^m$. ✢ At Leiden, with Golius [Jacob Golius] observing, it began to emerge at 9^h 39^m, with Regulus at an altitude of 41° 3′. ✢ At Herk Wendelen, from the sundial and culminations, obtained the beginning at 6^h 53^m, the immersion at 7^h 59^m, the emersion at 9^h 40^m, and the end at 10^h $45½^m$. But he adds ✢ that at Aix the beginning was observed at about 6^h 41^m, with Regulus at an altitude of 30° 25′; the immersion at 7^h $55½^m$, with the same star at 42° 10′; the emersion at 9^h $32½^m$, with the same star at 55° 50′; and the end at 10^h 38^m, with Arcturus at an altitude of 31° 50′. ✢ Boulliau himself, however, in book 3 of the *Astronomia Philolaica*, chapter 6, says that he observed the middle at Paris at 8^h 21^m, ✢ and that Gassendi observed it at Aix at 8^h 42^m 45^s.

[Margin: Year 1635. ☾ Total.]

The eclipse of the Moon on August 28, carefully observed at Paris by Boulliau, as he attests in book 3 of the *Astronomia Philolaica*, chapter 6. He obtained the middle at 2^h 52^m after the preceding midnight, and adds ✢ that the middle was observed by Hortensius at Amsterdam at 3^h 11^m. ✢ But Wendelen, p. 102, relates that Boulliau observed the immersion at 2^h 5^m, the emersion at 3^h 40^m, and six digits restored at 4^h 12^m, all from altitudes of Lyra. ✢ At Aix Peiresc had the beginning without the telescope at 1^h 21^m, from Aldebaran's altitude of 27° 5′, but with the telescope applied at 1^h 30^m or 31^m, from the altitude of Capella and the Moon; the immersion at 2^h 28^m; and the end, with the telescope, at 5^h 1^m. [Margin: Difference of meridians.] But Wendelen, from other phases, more truly draws the beginning back to 1^h 25^m, the immersion to 2^h 24^m, and the end to 4^h 56^m. ✢ At Digne Gassendi, though struggling with clouds, nevertheless observed various phases, from which Wendelen deduces the beginning at 1^h 29^m and the immersion at 2^h 28^m. At Leiden Golius noted the immersion at 2^h 25^m. ✢ At Herk Wendelen noted the beginning at 1^h 29^m, the immersion at 2^h 28^m, and the emersion at 4^h 1^m. He adds that at Rome the beginning was apparent, after a fashion, at 1^h 54^m, and the middle, gathered from the phases, at 3^h 39^m. ✢ And that at Cairo in Egypt the beginning was at 5^h $14½^m$ and the immersion at 6^h $16½^m$, Father Agathangelus [?], a Capuchin, and his companion Ioannes Molinus [?] observing through altitudes of the Moon. ✢ But that at Aleppo in Syria Father Cælestinus a S. Liduina [?], a Discalced Carmelite, and Father Michaël Angelus [?], a Capuchin and skilled mathematician, obtained from altitudes of the Moon the beginning at 5^h 28^m and the immersion at 6^h 27^m, as Wendelen deduces from those altitudes; but Boulliau, book 2, chapter 8, deduces from them 6^h 30^m. Gassendi too, in the

Life of Peiresc, after reporting the already mentioned observations at Cairo and Aleppo, says that those places are about 15 degrees closer to Marseille than most geographical maps show.

[Margin: Year 1636. ☾]

The eclipse of the Moon on February 20. On the testimony of Wendelen, p. 104, and of Boulliau, book 3, chapter 6, Pierre Gassendi observed its middle at Digne at $10^h\ 40^m$ after noon, gathered from the following phases. At $9^h\ 26^m$, a thin shading; at $9^h\ 42^m$, the limb could still, though with difficulty, be made out with the telescope; at $9^h\ 44½^m$, the limb was growing dark in the telescope, from which he gathered the beginning; already at $9^h\ 52^m$, half a digit at most seemed to be failing; at $11^h\ 26^m$, it returned to half a digit; at $11^h\ 33½^m$, it was almost the end; at $11^h\ 34½^m$, the end as judged from the beginning; at $11^h\ 36^m$, the limb restored in the telescope; up to $11^h\ 51^m$, a very thin shading remaining; digits 3 exactly. So Gassendi. Because of this care, Wendelen and with him Sirmanus [?] called it the Queen of Eclipses, and material for a proper commentary. ✢ At Brussels van Langren obtained the beginning at $9^h\ 38^m$. ✢ At Aix the end was apparent in the telescope at $11^h\ 33^m$. ✢ At Amsterdam Hortensius obtained the end at $11^h\ 32^m$. ✢ At Königsberg in Prussia Albert Linemann observed from 2½ to 3 digits, the beginning with Arcturus at an altitude of 26° in the east, the middle roughly with the same star at 30° 20′, and the end with Jupiter at an altitude of 48° 20′, as Boulliau relates from his letter to Hevelius, book 12 of the *Astronomia Philolaica*, p. 466. My tables give an eclipse of 2 digits 20′.

[Margin: Year 1637. ☾]

The eclipse of the Sun on December 31, in the morning, observed among the Hurons in New France by Father Castellanus [?] of the Society of Jesus, at its middle, at $6^h\ 15^m$ after midnight. From this Wendelen, p. 105, gathers from his own hypothesis the longitude of the Hurons from the Atlantic meridian as 303° 30′, adding: *whether this is true, time will tell.*

[Margin: Year 1638. ☾ Total.]

The eclipse of the Moon on the night between December 20 and 21, whose observations are reported by Boulliau, book 3 of the *Astronomia Philolaica*, chapter 6, and by Wendelen in the *Eclipses*, p. 105. ✢ At Digne Gassendi obtained the beginning at $0^h\ 36^m$ after midnight, half a digit at $0^h\ 38^m$, the immersion at $1^h\ 37^m$ or 38^m, the emersion at $3^h\ 13^m$, the end at $4^h\ 14^m$, and therefore the middle at $2^h\ 25^m\ 45^s$. ✢ At Paris Boulliau obtained the middle at $2^h\ 10^m\ 30^s$ and the immersion at $1^h\ 23^m$. ✢ At Amsterdam Hortensius had the immersion at $1^h\ 32½^m$, with Aldebaran at an altitude of 37° 6′ in the west. [Margin: Difference of meridians.] ✢ At Brussels van Langren obtained the beginning at $0^h\ 29^m\ 8^s$, with degree 96° 33′ of the equator culminating; the immersion at $1^h\ 26^m\ 49^s$, with degree 111° 1′ culminating; the emersion at $3^h\ 5^m$, with degree 135° 38′ culminating; clouds stole the end. The middle

was therefore at 2^h 16^m, and the stay 1^h 38^m 10^s. ✢ At Leiden Golius saw the immersion at 1^h 31^m, the emersion at 3^h 4^m 40^s, and 6 digits restored at 3^h 34^m 40^s, from altitudes of Aldebaran, of the bright star of the foot of ♊, and of Arcturus; from which Wendelen gathers a stay of 1^h 34^m and the middle at 2^h 18^m. ✢ At Herk Wendelen himself had the sheer beginning at 0^h 34^m, the immersion at 1^h 32^m, the emersion at 3^h 10^m, and the end at 4^h, although the penumbra lasted until 40^m; the duration therefore 3^h 34^m, the stay 1^h 38^m, the middle at 2^h 21^m. ✢ At Franeker Johannes Phocylides Holwarda obtained the beginning at 0^h $33½^m$, a failing of 6 digits at 1^h 5^m, the immersion at 1^h 37^m, the emersion at 3^h 12^m, and 6 digits recovered at 3^h 44^m; therefore the middle at 2^h 24^m 30^s.

[Margin: Year 1639. ☉]

The eclipse of the Sun on June 1, observed at Königsberg in Prussia by Albert Linemann in a darkened chamber through a single convex lens, with the altitudes of the Sun taken with an Electoral astrolabe. The beginning very nearly at 5^h 25^m 30^s; 6 digits obscured at 5^h 56^m 30^s, and then the Sun appeared with very blunt and thick horns. The greatest obscuration, of 11½ digits, was at 6^h 24^m 30^s, and then ☿ was splendidly seen, which vanished after 10½ digits of the decreasing failing. [Margin: Disagreement of the tables from observ-[50].] At the moment of greatest obscuration the bright periphery of the circle occupied 212 degrees out of 360. The end was accurately at 7^h 20^m 30^s after noon. Earlier, at 1^h after noon, a solar halo had been seen, of a diameter of 43 degrees. So Boulliau reports, p. 465 of his *Astronomia*. ✢ But in book 4, chapter 5, he says that he observed at Paris the beginning at 4^h 21^m, the middle at 5^h 27^m, the end at 6^h 25^m, and the duration 2^h 4^m, which by his own calculation should have been 2^h 15^m 48^s. He judges, moreover, that the motion of the Moon, as yet unknown to us, was the cause of this disagreement. He adds that the image of the Sun, taken with the telescope on paper, whose semidiameter was one third of a Paris royal foot, was one in which the Moon's semidiameter was slightly smaller than the Sun's, even though, he says, it cannot be judged smaller from lunar eclipses; and he thinks that the cause was both that a dark thing within a bright one appears less, and the refraction of the Sun's rays in the air around the Moon. But our hypothesis gives a smaller one.

[Margin: Year 1641. ☾]

The eclipse of the Moon on October 18. Wendelen, p. 106, says that he observed the beginning at Herk at 6^h 8^m from noon; for at 6^h 12^m half a digit had failed, and at 6^h 15^m one digit. Then at 7^h 29^m the arc through the centres of the Moon and the shadow was passing through the breast of Cassiopeia, which for him was an argument for the height of the eclipse. The end at 8^h 50^m; digits altogether 6 45′. ✢ At Brussels van Langren obtained the middle at 7^h 24^m, and then 6 digits 47′. ✢ At Leuven Erycius Puteanus [Erik van der

[50] the note's last word is cut off at the binding on the scan

Putte] found the beginning at 5^h 59^m and the end at 8^h 53^m, and the middle therefore at 7^h 26^m. So Wendelen relates of both. But Boulliau, book 12, p. 465, relates from a letter of Hevelius of Danzig to Gassendi ✢ that at Danzig Hevelius observed the beginning at 7^h 1^m 15^s and the middle at 8^h 26^m 15^s. ✢ At Rome Father Franciscus Niceronus [Jean-François Niceron], a Minim [Paulinus], obtained the beginning at 7^h 13^m, with Lyra at an altitude of 67° 38′, as he wrote to Father Cavalieri at Bologna. [Margin: Difference of meridians.] But if that observation and Hevelius's were true, Rome would lie further east than Danzig: with all geographical maps protesting, or going astray?

[Margin: Year 1642. ☾ Total.]

The eclipse of the Moon on April 14, than which no eclipse has so far had more observers or surviving observations. Some of these are reported by Boulliau, p. 465 of his *Astronomia*, and by Wendelen in his *Eclipses*, p. 107; but many more were sent by the observers themselves either to me or to Father Athanasius Kircher. I will report them in order.

[Margin: Italian observations.]

At Pisa Dom Vincenzo Renieri, an Olivetan and first professor of mathematics, observed at my request with his excellent telescope, though with a middling quadrant, and sent me the following phases reduced to apparent time, in which the particle *or.* indicates east and *occ.* west. He adds that a somewhat doubtful, secondary little light clung to the Moon's disc, already immersed in the shadow, in the part that faces south-west; but that the usual redness of the Moon did not appear, and that the Moon was altogether lost; from which he concludes that the Moon lacks a light of its own, even a secondary one. He did not note the end, because neighbouring buildings blocked the view of the Moon, but he gathered it from the other phases.

Phases [Phaſes.]	Stars [Stellæ.]	Altitude of the stars [Altitudo Stellarum]	Time from noon [Tempus à Meridie]
Beginning [Initium.]	Spica ♍	35° 6′ west	12^h 33^m 6^s
3 digits obscured [Dig.obſc.3.]	Arcturus	66° 52′ west	✢
6 digits obscured [Dig.obſc.6.]	Spica	32° 10′ west	13^h 18^m 42^s
11 digits obscured [Dig.ob.11.]	Head of Ophiuchus [Cap.Ophiuc.]	49° 7′ east	13^h 39^m 52^s
Total obscuration [Total.obſc.]	Head of Ophiuchus [Cap.Ophiuc.]	50° 24′ east	13^h 49^m 18^s
Emersion [Emerſio.]	Bright star of Aquila [Aquilæ luc.]	40° 12′ east	15^h 21^m 23^s
1 digit lit [Dig.luc.1.]	Aquila	41° 20′ east	15^h 30^m 40^s
3 digits lit [Dig.luc.3.]	Aquila	41° 50′ east	✢
6 digits lit [Dig.luc.6.]	Aquila	43° 54′ east	15^h 47^m 14^s
Therefore the whole duration [Duratio ergo tota]			4^h 6^m 0^s

Phases [Phaſes.]	Stars [Stellæ.]	Altitude of the stars [Altitudo Stellarum]	Time from noon [Tempus à Meridie]
Stay in darkness, from the 5th and 6th phases [Mora in tenebris ex 5.& 6.phaſi]			$1^h\ 32^m\ 5^s$
Middle, from the 5th and 6th phases [Medium ex 5.& 6.phaſi]			$14^h\ 35^m\ 20^s$
But from the 3rd and 9th phases [Sed ex 3.& 9.phaſi]			$14^h\ 32^m\ 58^s$
And from the 4th and 7th phases [Et ex 4.& 7.phaſi]			$14^h\ 35^m\ 16^s$

At Venice a noble patrician, who ordered his name to be suppressed, as I have it in his letter written to Fortunio Liceti, observed the beginning at $12^h\ 46^m\ 9^s$ and the end of the total failing at $15^h\ 38^m\ 41^s$. I believe, however, that he means the emersion, or that by a slip of the copyist's pen 15 hours were written for 16. He attests, moreover, that at Venice and at Vienna in Austria the Moon was seen throughout the eclipse, glowing red like a coal, and he puts the reason why it was not seen in some places down to vapours raised from those regions or carried into them by winds.

At Mantua Fathers Wilhelmus Weilhamer [?] and Francesco Maria Grimaldi, S.J., used a larger astrolabe, and Father Grimaldi deduced the times from the altitudes of Regulus, Spica and Arcturus: the beginning at $12^h\ 38^m\ 27^s$, the immersion at $13^h\ 45^m\ 7^s$, the emersion at $15^h\ 15^m$, the end at $16^h\ 25^m$.

At Trent Father Michael Staudacher, S.J., noted the immersion at $13^h\ 32^m$.

At Bologna we observed this eclipse both with the naked eye and with a very bright telescope, with several of our companions as witnesses and helpers. Its beginning Father Bonaventura Cavalieri, proposing an example of calculation in his *Trigonometria*, Problem 8, deduced at $12^h\ 46^m\ 50^s$; but he used Tycho's declination and right ascension of Spica, though my altitude of the pole. We judged that our own should be used; and we considered that the times should be counted with the pendulum treated in book 2, chapter 20, proposition 15, by companions highly practised beforehand. Not long after the total immersion, however, we so lost the Moon that we searched in vain for its place in the sky, although the sky, as it seemed, was clear and cloudless all around. So the first visible beginning of the true eclipse was with Spica ♍ at an altitude of $33^\circ\ 44'\ 15''$ in the west, that is, at $12^h\ 47^m\ 27^s$; the visible immersion at $13^h\ 54^m\ 30^s$, with the same star at $26^\circ\ 25'\ 20''$. The emersion was not observed through altitudes of stars, because, the Moon being now lost, I was wholly intent on its first reappearance, nor had my companion moved the quadrant in time; but the signal was given at once to those counting the times of the pendulum, and we relied on these. The visible end was at $16^h\ 38^m$, with the bright star of Aquila at an altitude of $50^\circ\ 0'\ 50''$ in the east.

But from the transit of Arcturus through the meridian, which from its right ascension and the Sun's was at $12^h\ 26^m\ 56^s$, up to the visible beginning of

the eclipse, there were counted with the greatest correctness $22^m\ 10^s$ of time; from there to the immersion $62^m\ 4^s$; from there to the emersion $106^m\ 12^s$; and from there to the visible end $62^m\ 8^s$. I trust this second observation far more, because it is not made up of the small deceptions that can arise from the use of instruments and from an analysis of triangles that presupposes many elements, but rests on the simplest counting of the times of a pendulum examined long and often beforehand and afterwards, in which the error of the individual vibrations involves only single seconds of an hour; and the time of Arcturus's transit through the midheaven [M.C.] is gathered from nothing but the right ascension of the Sun and of Arcturus. Following this observation, then, I obtain the beginning of the eclipse at $12^h\ 49^m\ 6^s$, the immersion at $13^h\ 51^m\ 10^s$, the emersion at $15^h\ 37^m\ 22^s$, the end at $16^h\ 39^m\ 30^s$, the half-duration $1^h\ 55^m\ 12^s$, and the half-stay $53^m\ 6^s$; and I noted it so in my notebooks.

Later, when the hypothesis of the Moon and Sun had been established on other grounds, from the most certain celestial marks, and the calculation had been carried out for apparent time, I obtained a half-duration of $1^h\ 56^m\ 3^s$, a time of incidence of $1^h\ 4^m\ 4^s$, and a half-stay of $51^m\ 59^s$. Nor was I greatly surprised at so small a disagreement of the hypothesis with observation; but at last I noticed that this very disagreement almost wholly vanishes when a correction is applied, not voluntary but necessary, about which I have said enough in chapter 15, number 14. In accordance with it, by subtracting one minute each from the beginning of the eclipse and of the emersion, and on the other hand adding one each to the immersion and the end, I obtain a corrected beginning very nearly in agreement with the calculation, as you see in the following small table. The full Moon, moreover, followed the middle of the eclipse by 3^s, according to the rule given in chapter 6, scholium 1.

Phases of the eclipse [Phaſes Eclipſeos]	Corrected time of the observation [Tēpus obſeruationis correctum]	Apparent time from the calculation of our tables [Tempus Apparens ex Calculo Noſtrar.Tab.]
Beginning [Initium]	$12^h\ 48^m\ 6^s$	$12^h\ 48^m\ 4^s$
Immersion [Immerſio]	$13^h\ 52^m\ 10^s$	$13^h\ 52^m\ 8^s$
Emersion [Emerſio]	$15^h\ 36^m\ 22^s$	$15^h\ 36^m\ 6^s$
End [Finis]	$16^h\ 40^m\ 30^s$	$16^h\ 40^m\ 0^s$
Half-duration [Semiduratio]	$1^h\ 56^m\ 24^s$	$1^h\ 56^m\ 3^s$
Half-stay [Semimora]	$0^h\ 52^m\ 6^s$	$0^h\ 51^m\ 59^s$
Incidence [Incidentia]	$1^h\ 4^m\ 18^s$	$1^h\ 4^m\ 4^s$
Duration [Duratio]	$3^h\ 52^m\ 24^s$	$3^h\ 52^m\ 6^s$
Stay [Mora]	$1^h\ 44^m\ 12^s$	$1^h\ 43^m\ 58^s$
Middle of the eclipse [Medium Eclipſ.]	$14^h\ 44^m\ 30^s$	$14^h\ 44^m\ 7^s$
or [vel]	$14^h\ 44^m\ 16^s$	

Phases of the eclipse [Phaſes Eclipſeos]	Corrected time of the observation [Tēpus obſeruationis correctum]	Apparent time from the calculation of our tables [Tempus Apparens ex Calculo Noſtrar.Tab.]
Full Moon [Plenilunium]	$14^h\ 45^m\ 9^s$	$14^h\ 45^m\ 0^s$

[Margin: French observations.]

At Paris Father Georges Fournier, Pierre Gassendi and Ismaël Boulliau observed this eclipse, and Father Fournier, with his usual kindness, gave me the observation in a letter written to me, although I later obtained it also in Boulliau's *Astronomia*, p. 212. Father Fournier affirms, moreover, that of the Moon, already immersed in the shadow, nothing at all, or no colour, let alone light, had appeared, and that the diameter of the shadow to that of the Moon was observed as 40 to 17, and that the altitude of the pole at Paris, often taken by him, was 48° 50′. [Margin: Altitude of the pole at Paris.] But that ratio of the diameters is suspect to me, and it certainly does not agree with the semidiameter of the Moon established by Gassendi, nor with the semidiameters posited for this eclipse by Boulliau, p. 212, who sets that of the corrected shadow at 44′ 21″ and that of the ☾ at 16′ 24″, whose ratio is as 17 to 41 8/11. The rest of the observation went as follows.

Phases of the eclipse [Phaſes Eclipſeos]	Western altitude of the stars [Altitudo Stellarum Occidua]	Apparent time [Tēpus Apparens]
1 Beginning of the penumbra [Penumbræ initiū]	Regulus 31° 30′	$12^h\ 6^m$
2 Beginning of the eclipse [Initium Eclipſ.]	Regulus 30° 53′	$12^h\ 9^m$
3 6 digits obscured [Digit.6. obſcur.]	Regulus 26° 52′	$12^h\ 34^m$
4 Total obscuration [Totalis obſcur.]	Regulus 20° 53′	$13^h\ 11^m$
5 Emersion [Emerſio]	Arcturus 50° 22′	$14^h\ 47^m$
6 6 digits recovered [Digit.6. recuper.]	Arcturus 45° 28′	$15^h\ 20^m$
7 End of the eclipse [Finis Eclipſeos]	☾ lower limb 12° 30′	$15^h\ 51^m$
Therefore the duration of the eclipse [Ergo Duratio Eclipſis]		$3^h\ 42^m$
Stay in the shadow [Mora in vmbra]		$1^h\ 36^m$
Middle from phases 2 and 7 [Medium ex 2. & 7. Phaſi]		$14^h\ 1^m$
But from phases 3 and 6 [Sed ex 3. & 6. phaſi]		$13^h\ 57^m$
And from phases 4 and 5 [Et ex 4. & 5. phaſi]		$13^h\ 59^m$

But Boulliau says that the beginning was perhaps *two minutes earlier*, and that the whole duration was *not true but nearly true,* $3^h\ 43^m$. For from his own calculation he had deduced a stay of $1^h\ 40^m\ 32^s$ and a duration of $3^h\ 47^m\ 34^s$. Wendelen, moreover, p. 108, relates that Gassendi had *clouds and later times*.

[Margin: Altitude of the pole at Avignon.] At Avignon Antonius Franciscus Payen [Antoine-François Payen], having observed the altitude of the pole at

43° 53′, says that the beginning of the eclipse was at 11^h 59^m, with Arcturus at an altitude of 66° 32′ in the east, with an azimuth of 6° 50′; but the total obscuration at 13^h 1^m, with Spica ♍ at an altitude of 33° 15′ in the west, with an azimuth of 21° 58′; that the colour of the Moon was then ash-grey; and that clouds buried the rest. But how slippery the observation of azimuths is, unless it is carried out in the way I hinted at in chapter 15, towards the end of no. 16, and shall set out more fully in the *Liber Organicus*, I shall explain in that same place; and Tycho has already, in the end, noted it, in volume 1 of the *Progymnasmata*, p. 604.

[Margin: Observations of Belgium and Holland.] At Leuven Gerardus Gutiscovius [Gerard van Gutschoven], physician and professor of mathematics, with his father-in-law Guilielmus Regius [?], most skilled in mathematics, observed the beginning of the failing at the very point of midnight, with the Moon just one degree past the meridian, and 3 digits obscured at 0^h 15^m after midnight. Puteanus, for his part, in the citadel noted that at the beginning of the failing the Moon's shadow had scarcely passed the meridian.

At Herk Wendelen, having prepared a telescope, a sundial, two water-clocks and a compound striking clock [Horiſonio cōpoſito], and having engaged several young men of sharp sight and of good wit, above all the brothers Io. and Philippus Vendelarius [?], observed the following phases.

Order of phases [Ordo Phaſium]	Observed phases of the Moon and culminations of stars [Phaſes Lunæ obſeruatæ & Culminationes Stellarum]
1	The Moon was grazing the meridian with its western limb [Luna ſtringebat Meridianum limbo occid.]
2	Nadir on the meridian, therefore midnight [Nadir in Meridiano ergo Media nox.]
3	Beginning of the failing clear [Initium Deliquij manifeſtum.]
4	A sextant of the periphery, a reddening digit [Sextans peripheriæ digitus rubens.]
5	4 digits, strongly reddening [Digiti 4. valde rubentes.]
6	7½ digits, with more than a faint semicircle [Digiti 7 ½. plus ſemicirculo languido.]
7	10 digits, now dark [Digiti 10. iam tenebroſi.]
8	10½ digits obscured; the Southern Scale culminating [Digiti 10 ½. obſcur. culmin. Lanx Auſtr.]
9	It was ceasing to cast a shadow, although a digit was still shining, in fact immersed [Deſinebat vmbram fundere, etſi lucebat adhuc digitus, reuerà immerſus.]
10	A weak limb of half a digit was still seen [Adhuc debilis limbus ſemidigiti videbatur.]
11	Now immersed, it had completely disappeared [Iam immerſa planè diſparuerat.]
12	The Crown was culminating, the Moon completely extinguished [Culminabat Corona, Lunâ planè extinctâ.]
13	The hand of Ophiuchus passed the meridian, 1° 15′ [Ophiuchi manus transijt Merid. Gr.1. 15′.]
14	It was emerging, and shedding light [Emergebat, fundebatq. lumen.]
15	At least 3 digits were shining [Digiti 3. ad minimùm lucebant.]
16	6 digits, quite precisely [Digiti 6. ſatis præciſè.]
17	9 digits; the Head of Hercules culminating [Digiti 9. Culmin. Caput Herculis.]
18	A very small amount was lacking [Deerat aliquid perexiguum.]
19	The end, clear by the votes of all [Finis manifeſtus omnium ſuffragijs.]
20	The Head of Ophiuchus was culminating [Culminabat Caput Ophiuchi.]

Order of phases [Ordo Phaſium]	Observed phases of the Moon and culminations of stars [Phaſes Lunæ obſeruatæ & Culminationes Stellarum]

[Margin: Moon wholly extinguished.]

Order of phases [Ordo Phaſium]	Striking clock [Horiſonij]	Celestial hour [Hora Cęleſtis]
1	$12^h\ 0^m$	$11^h\ 55^m$
2	$12^h\ 5^m$	$12^h\ 0^m$
3	$12^h\ 8^m$	$12^h\ 3^m$
4	$12^h\ 15^m$	$12^h\ 9^m$
5	$12^h\ 30^m$	$12^h\ 23^m$
6	$12^h\ 45^m$	$12^h\ 37^m$
7	$1^h\ 0^m$	$12^h\ 51^m$
8	$1^h\ 7^m$	$12^h\ 58^m$
9	$1^h\ 12^m$	$13^h\ 2^m$
10	$1^h\ 15^m$	$1^h\ 5^m$
11	$1^h\ 30^m$	$1^h\ 19^m$
12	$2^h\ 0^m$	$1^h\ 47^m$

16	$3^h\ 30^m$	$3^h\ 31^m$
17	$3^h\ 45^m$	$3^h\ 25^m$
18	$4^h\ 0^m$	$3^h\ 39^m$
19	$4^h\ 2^m$	$3^h\ 41^m$
20	$4^h\ 6^m$	$3^h\ 45^m$

Wendelen goes on and says: *The whole duration was $3^h\ 38^m$, as much as for Gassendi too, who at Paris had some clouds, and later times, through the fault either of his instrument or of his assistant. The earlier struggle* [Lucta] *lasted 1 hour for Gassendi, as also for van Langren; for me $1^h\ 16^m$, spurious; the later one only 59^m. As for those observations at Leuven and at Herk, they are certain and beyond doubt to me; and the middle was at $1^h\ 52^m$. For certainly at $2^h\ 10^m$ by the striking clock, that is, at $1^h\ 57^m$ celestial time, the eastern limb of the Moon, sought with difficulty and found with trouble, was already somewhat more evident than the rest of the Moon's body, which was completely extinguished. So in truth the middle had already passed. My Atlantic calculation for Herk gives the beginning at $0^h\ 3^m$, the immersion at $1^h\ 2^m$, the middle at $1^h\ 52^m$, the emersion at $2^h\ 42^m$, the end at $3^h\ 41^m$.*

At Leiden, as Father Athanasius Kircher writes, from altitudes of Regulus and Arcturus the beginning was noted at $12^h\ 0^m\ 12^s$, six digits obscured at $12^h\ 37^m\ 34^s$, the immersion at $13^h\ 14^m\ 36^s$, 6 digits recovered at $15^h\ 25^m\ 18^s$, the end at $16^h\ 2^m\ 30^s$; the emersion was not seen because of clouds. The Moon disappeared completely, although stars were visible nearby.

[Margin: German observations.] At Cologne Fathers Lubertus Middendorpius [?] and Henricus Sturnius [?] of the Society of Jesus observed the

beginning at $12^h\ 26^m\ 30^s$ and the total obscuration at $13^h\ 41^m\ 30^s$, from altitudes of Lyra. At Paderborn Father Henricus Modersohu [?], professor of mathematics, with Father Gerardus Lansintkius [?] S.J., noted the beginning with Spica at an altitude of 28° 18′, or $12^h\ 15^m$, perhaps of a spurious eclipse; the total immersion with Spica at an altitude of 23° 5′, or $13^h\ 41^m$; the emersion at $15^h\ 21^m$, with Spica at an altitude of 12°; and the end at $16^h\ 12^m$, with Arcturus at an altitude of 36° 58′, the altitude of the pole there being taken as 51° 50′.

At Würzburg Father Henricus Marcellus S.J., with Father Rector and four other companions, obtained the beginning at $12^h\ 33^m$, the total immersion at $13^h\ 58^m$, the emersion at $15^h\ 18^m$, and the end at $16^h\ 32^m$. From this the Bishop of Würzburg discoursed publicly on a problem, and deduced 19 digits 53′.

At Ingolstadt Father Iacobus Viua [?] S.J. with others, using excellent telescopes, yet not agreeing exactly, especially at the beginning of the total obscuration, because of a certain little light that deceived some, and that lasted through the whole time of the eclipse near the Moon like a nebulous star: nevertheless he sent me the more probable moments as follows. The beginning of the legitimate eclipse at $12^h\ 46^m$, with Regulus at an altitude of 25° 15′; the immersion at $13^h\ 50^m$, with Regulus at an altitude of 13° 40′; the emersion at $15^h\ 28^m$, with Aquila at an altitude of 44° 40′; the end at $16^h\ 30^m$, with Aquila at an altitude of 44° 40′; of these altitudes of Aquila, the first was in the east, the second in the west.

At Eichstätt in Franconia Father Andreas Arzet [?] with Father Albert Curtz of the Society of Jesus observed the beginning at $12^h\ 44^m$, the immersion at $13^h\ 53^m$, and the emersion at $15^h\ 23\frac{1}{3}^m$; therefore the middle at $14^h\ 38^m$. From this they gathered the end at $16^h\ 32^m$, the duration $3^h\ 48^m$, and the stay $1^h\ 30^m$. He adds that for about a quarter-hour a certain imperfect obscuration, like smoke or fog, preceded the true beginning.

At Prague Fathers Theodorus Moretus and Vuolfangus, with Do- ctor Marcus, using a six-foot Tychonic quadrant granted by the Emperor, observed the beginning of a spurious darkness with Spica at an altitude of 29°; but the true beginning, as the telescope showed it, with Spica at an altitude of 28° 23′ in the west; the total obscuration at $14^h\ 10^m$, with Spica at an altitude of 22° 20′; and the emersion at $15^h\ 28^m$, with Spica at an altitude of 12° 15′. They say that no colours at all, no trace of its own light, could be seen in the Moon when it was totally immersed.

At Kłodzko Father Balthasar Conradus [?] of the Society of Jesus, using a quadrant of nearly six feet, observed the beginning at $14^h\ 26^m$, with Arcturus at an altitude of 52° 52′ 30″; but because of a little light that always clung to the Moon like a star, which Scheiner too noted at Neisse, this was doubtful, whereas the emersion was certain, at $15^h\ 48^m$, with the last star of the tail of Ursa Major at an altitude of 55° 7′ 38″.

At Stettin in Pomerania Lorenz Eichstaedt noted the beginning at $12^h\ 58^m$, with the tail of ♌ at an altitude of 39° 12′ in the west; the immersion at $13^h\ 56^m$,

with Spica at an altitude of 20° 18′ in the west; and the emersion at about 15^h 40^m, with Arcturus at an altitude of 42° 9′ in the west; from which he deduces the end at 16^h 38^m.

At Gedanum, or Danzig, Hevelius observed the beginning at 13^h 14^m, the immersion at 14^h 22^m, the emersion at 15^h 53^m, and the end at 16^h 56^m.

In Canada, at an altitude of the pole of 44° 20′, the eclipse was observed on day 13, at about 16^h 36^m, but not very accurately, as Father Bressani writes to Father Kircher.

Although the umbrago has misled some, I should still like to gather into one synopsis the intervals of this eclipse, both observed and deduced from the tables, so that at least from this the disagreement may be evident, both between the observations and the tables, and among the observations themselves, or among the tables themselves.

[Margin: Year 1642. ☾ Total.]
The eclipse of the Moon on October 7, observed in eight places.

At Rome Father Jean-François Niceron, a Minim [Paulinus], says that at the beginning of the eclipse the Moon's ray fell, on a catoptric dial [horologio catoptrico], on the line of the 15th astronomical hour from noon, and that a quarter of an hour later Rigel stood at an altitude of 37° 10′ in the east; from which the beginning is gathered at $15^{h}\ 1^{m}$. But the total obscuration, he says, was with Rigel at an altitude of 39° 25′ and Sirius at 27° 37′, or at $16^{h}\ 5^{m}\ 28^{s}$.

At Catacium, or Catanzaro, Don Francesco Zupi, very skilled in astronomy, as Father Giovanni Battista Zupi S.J. writes to me, noted the beginning of the total obscuration at $16^{h}\ 16^{m}\ 32^{s}$, with Regulus at an altitude of 24° 8′ in the east.

At Milan Don Curzolanus [?], at my request conveyed through Father Aloysius Confalonerius [?], observed the beginning at $14^{h}\ 44^{m}$ from noon, with Procyon at an altitude of 28° 10′ in the east, and the total obscuration at $15^{h}\ 47^{m}$, with Procyon at an altitude of 39°; clouds took the rest away.

At Březnice in Bohemia Father Theodorus Moretus says that the beginning was with the Moon at an altitude of 29° 51′ 20″ and its azimuth 57° 46′ in the west, that is, at $14^{h}\ 57^{m}$; and that clouds begrudged the rest.

At Lleida Antonius Garretus [?], at one time an amanuensis of Gassendi, observed the beginning at $14^{h}\ 9^{m}\ 30^{s}$, one and a half digits at $14^{h}\ 17^{m}$, two digits at $14^{h}\ 19^{m}\ 30^{s}$, 7 digits at $14^{h}\ 47^{m}$, 10½ digits at $15^{h}\ 3^{m}$, and eleven digits or more at $15^{h}\ 11^{m}$, which in truth was the total immersion, but a spurious light lasted until $15^{h}\ 17^{m}$; and the emersion at $16^{h}\ 50^{m}\ 30^{s}$, with the Moon still at an altitude of 11°. So Wendelen reports, p. 109.

On Majorca Don Vicenç Mut, most skilled in astronomy, as is clear from his own letter to me, observed the beginning of this eclipse at $14^{h}\ 21^{m}\ 8^{s}$ after noon, with Procyon at an altitude of 24° 54′ in the east; the total obscuration at $15^{h}\ 24^{m}\ 16^{s}$, with the same star at 36° 43′; the emersion at $17^{h}\ 2^{m}\ 20^{s}$, with Rigel at an altitude of 40° 10′ in the west; and the end at $17^{h}\ 59^{m}\ 8^{s}$, with Rigel at 35° 42′; at an altitude of the pole of 39° 35′.

At Madrid Don Andreas à Brinsuela [?], and Fathers of the Society of Jesus, observed this eclipse with Sirius at an altitude of 12° 36′, as the same Don Vicenç Mut writes.

At Bologna we observed this eclipse in both ways, namely through the altitudes of stars and through culminations, applying the times of that pendulum discussed in book 2, chapter 20, proposition 15; counting, that is, from the beginning of the legitimate eclipse as ascertained through the telescope, the times up to the transit of Aldebaran across the meridian, from there on to the total immersion, and from there to the emersion. Hills and the setting of the Moon below the horizon denied us the end, but from other phases and from the moment of time at which 6 digits had been recovered we obtained the end. We did, however, add to the immersion and to the end one minute each, which we subtracted from the beginning and the emersion, for the same reason discussed in the preceding eclipse and in chapter 15, no. 14. Here, then, are the corrected times: the true beginning at $14^{h}\ 55^{m}\ 50^{s}$; the total obscuration

at $15^h\ 57^m\ 10^s$; the emersion at $17^h\ 46^m\ 40^s$; the end at $18^h\ 44^m$. Therefore the whole duration was $3^h\ 48^m\ 50^s$, the interval of incidence $1^h\ 2^m$, the stay in the shadow $1^h\ 49^m\ 30^s$, and the middle at $16^h\ 49^m\ 35^s$. The calculation from our tables, however, gives the beginning at $14^h\ 56^m\ 15^s$, the emersion at $17^h\ 46^m\ 31^s$, the end at $18^h\ 42^m\ 45^s$, the duration $3^h\ 51^m$, the stay $1^h\ 49^m\ 32^s$, the incidence $1^h\ 0^m\ 44^s$, and the middle at $16^h\ 51^m\ 45^s$; and the moment of the true full Moon at $16^h\ 54^m$ in apparent time.

[Margin: Year 1643. ☾]

The eclipse of the Moon on September 27, which Wendelen observed at Antwerp with Gutiscovius and others. At $6^h\ 36^m$ the Moon, struggling out of the clouds, was seen failing by half of itself: the elevation of the western horn and the depression of the eastern showed that the middle had not yet passed, for they were not yet parallel to the Moon's path; the arc through the centres could not be marked out because of clouds. At $6^h\ 54½^m$ the arc through the centres was passing through the head of Andromeda, from which he gathered that the middle of the eclipse was at $6^h\ 52^m$. Already at $7^h\ 6^m$ 6 digits were failing, and the arc through the centres was passing through the extremity of the wing of Pegasus; from which it was confirmed that the middle of the eclipse was at $6^h\ 52^m$. But at $7^h\ 51^m$ 2 digits were still lacking. The shadow, frayed with unequal fringes, appeared piecemeal. The end at last was at $8^h\ 5^m\ 30^s$. ✢ At Paris Ismaël Boulliau observed the end of this eclipse at $7^h\ 59^m\ 36^s$. [Margin: Difference of meridians.] ✢ But at Succium [?] Gassendi, at $8^h\ 1^m\ 38^s$ (Succium, moreover, is 3 miles from Paris). ✢ And at Danzig Johannes Hevelius, at $8^h\ 59^m$, as Boulliau reports. ✢ But at Naples Father Giovanni Battista Zupi, as is gathered from corrected altitudes of the end of the tail of Ursa Major, observed the same end at $9^h\ 5^m\ 40^s$. ✢ At Venice the end was observed at $8^h\ 44^m$ by a nobleman who does not allow himself to be named. ✢ On Majorca Don Vicenç Mut, where he says the altitude of the pole certain to him is 39° 35′, observed the end with the bright star of Aquila at an altitude of 56° 36′ in the west; clouds prevented the rest: so he wrote to me. Further, from our former difference of meridians, the end should have been seen there at $8^h\ 1^m\ 10^s$. ✢ At Bologna we, using a very clear telescope, counted from the beginning of the eclipse very carefully corrected times of our pendulum, $61^m\ 45^s$, up to a western altitude of Aquila of 53° 29′, that is, up to $7^h\ 20^m$. Therefore the beginning was at $6^h\ 18^m\ 15^s$ after noon. At the end, moreover, the western altitude of Aquila was 47° 22′, from which the end was at $8^h\ 43^m\ 30^s$; from which the middle at $7^h\ 30^m\ 52^s$, and the duration $2^h\ 25^m\ 15^s$. But the pendulum times gave a duration of only $2^h\ 25^m\ 10^s$. The digits eclipsed at the greatest were, by the agreement of all, precisely 6, or 6¼. ✢ At Březnice in Bohemia Father Theodorus Moretus, at an altitude of the pole of 50° 15′, observed the end with the Moon at an altitude of 25° 32′, and the bright star of Aquila was at an altitude of 45° 16′; and he affirms to me in his letter that the greatest eclipse barely reached 6 digits. The end, therefore,

was at 8^h 34^m. ☩ At Pisa Don Vincenzo Renieri observed the end with Aquila at an altitude of 50° 40′.

[Margin: Year 1645. ☾]

The eclipse of the Moon on February 10. At Frankfurt on the Main an unnamed observer, as Father Kircher wrote to me, from the stroke of hour 6, at which the eclipse began, up to the end, counted 8305 oscillations of a pendulum, of which 2820 make one hour; therefore 3^h 3^m 13^s; and so the end was at 9^h 3^m 13^s, the middle at 7^h 31^m 36^s, and the amount 10 digits 15′. ☩ At Paris Boulliau noted the beginning of the penumbra at 5^h 28^m, the beginning of the eclipse at 5^h 32^m, and the end at 8^h 40^m, from altitudes of ☾ and of Regulus. ☩ But Gassendi, separately in the same place, noted the beginning at 5^h 33^m, with Procyon at an altitude of 22° 53′ in the east; the end at 8^h 40^m, with Regulus at an altitude of 34° 35′; and 9 digits 30′. So Boulliau writes, together with Gassendi, to Father Mersenne, a letter I have had in my hands. They add, moreover, that from the Rudolphine Tables the beginning there should have been at 5^h 31^m and the end at 8^h 59^m; but from the Philolaic Tables, by Boulliau's own admission, the beginning at 5^h 12^m and the end at 8^h 28^m. The duration of this eclipse from the Rudolphine Tables is 3^h 28^m; from the Prutenic, 3^h 13^m; from the Tychonic, 3^h 21^m; from Duret's Lansbergian, 3^h 25^m; from the Lansbergian of Montebrunus [?], 3^h 18^m; from the Philolaic, 3^h 16^m; whereas from observation it was 3^h 8^m, or at most 3^h 12^m, if we suppose that the true beginning preceded the visible one by two minutes, and that the true end followed by as many. Boulliau thinks that this variation comes from the libration of the Moon, an indication of which was the Caspian spot, then round and very far from the western limb. ☩ At Pisa Don Vincenzo Renieri observed the beginning of this failing with Procyon at an altitude of 29° 30′ in the east, and the end with Aldebaran at an altitude of 46° 10′ in the west, as he relates before the first page of the reprinted *Tabulae Mediceae*. On Majorca Don Vicenç Mut observed the end with Procyon at an altitude of 53° 45′ in the east. At the middle of the eclipse the illuminated part of the Moon nearly equalled the distance between the two western stars in the quadrilateral of the Pleiades. ☩ At Naples Father Giovanni Battista Zupi observed the end with Sirius at an altitude of 31° 20′, but the end of the penumbra with the same star at an altitude of 32° 6½′.

[Margin: Year 1645. ☉]

The eclipse of the Sun on August 21. Its beginning on Majorca, as Don Vicenç Mut, its observer, writes to me, was with the Sun at an altitude of 57° 38′ in the east; its end, with the Sun at an altitude of 62° 20′ in the west. ☩ At Rome Father Daniel Bartolus [Daniello Bartoli] S.J. affirms that the beginning was observed at 16^h 25^m of the Italian solar hour, or 52^m before noon. ☩ At Prague Father Theodorus Moretus noted the end by the altitude of the Sun seen on a gnomon, whose right shadow was to the height of the gnomon as 3119 to 3102; and he says that the digits were a little more than 6. ☩ Renieri at

Lucca in Tuscany observed the Sun at an altitude of 57° 30′ when 3⅔ digits were failing; it was at an altitude of 58° when 4 digits were, before noon; but after noon it was at an altitude of 55° 40′ when 1 digit 30′ was failing, and at an altitude of 54° 30′ when the Sun was freed. ✢ At Paris Gassendi observed the beginning at 5^h 32^m after midnight, and the end at 8^h 40^m. ✢ But in the same place Father Boudinus [?] S.J. observed the beginning at 5^h 28^m and the end at 8^h 37^m. ✢ At La Flèche, for his part, Father Ioannes Deoauer [?] S.J. observed the beginning at 5^h 20^m and the end at 8^h 35^m. ✢ Father Theodorus Moretus writes, moreover, that by a certain friend of his at Aldersbach, in the western region of the Danube, one league from Vilshofen and four from Passau, the beginning was observed at 11^h 0^m 9^s after midnight, the end at 1^h 20^m 18^s after noon, and the middle at 12^h 10^m 13^s, with 5 unmixed digits; but that if the largest arc, of saffron colour, is counted in, it was 5 digits 45′, and if the inner purple arc, 5 digits 20′. The observer suspects that these arcs come from the air around the Moon, but Father Moretus from the colour of the glass through which the observation was made. ✢ Father Moretus adds that the end at Prague, observed by him, was with the Sun past the meridian by 33° 40′, and holding that altitude which is given by the height of a suspended plumb line casting its shadow on a plane exactly tested to the level of the horizon, taken to its shadow as 3102 to 3119, the height of this plumb line being 90 Roman palms; from which the hour is gathered as very nearly 1^h 59^m. He adds that the Sun was eclipsed a little beyond half. ✢ We at Bologna observed the beginning at 44^m 50^s before noon, the end at 1^h 47^m 10^s after noon, and 4½ digits, counting the pendulum times up to the moment of noon, noted by a very fine meridian shadow, and from there further on up to the end of the eclipse, whose moment was certainly observed most exactly with telescopes, for about the beginning there was not such agreement among my companions.

[Margin: Year 1646. ☾]

The eclipse of the Moon which, as Wendelen writes to me, Gassendi observed at Paris on the morning of January 31, at 6^h 1^m after midnight. ✢ But in Canada, at an altitude of the pole of 44° 20′, Father Bressani observed it with great care and wrote the observation to Father Athanasius Kircher, from whom I received it. He says, then, that it was January 30 there; that the beginning of a very thin shading was at 10^h 25^m after noon; that the true beginning, seen with the telescope, was at 10^h 44^m; nearly 6 digits were already obscured at 11^h 12^m; and the total immersion was at 11^h 41^m; the rest was hindered by clouds. ✢ At Pisa, with Don Vincenzo Renieri observing, the observed altitude of the Moon's centre was 24° when it began to be obscured; afterwards clouds arose.

[Margin: Year 1646. ☾]

The eclipse of the Moon on July 27, observed at Smyrna in Ionia by Io. Faber [?] of Marseille, who noted its end at 8^h 30^m after noon; so Renieri relates, from a letter of Boulliau's, at the beginning of the reprinted *Tabulae Mediceae*.

[Margin: Year 1647. ☾]

The eclipse of the Moon on January 20, observed at Paris by Gassendi, as to the middle, at $9^h\ 12^m$ after noon, as Wendelen wrote in a letter sent to me on November 14 of the year 1647. ✢ At Danzig Johannes Hevelius observed the same eclipse, as he himself reports in his *Selenographia*, where he sets out this observation above the others as an example of observing lunar eclipses by telescope on the spots of the Moon. Its summary is written below.

Phases of the eclipse [Phaſes Eclipſis]	Altitudes [Altitudines]	Computed time [Tēpus ſupputatum]	Time of the clock corrected by altitudes [Tēpus Horologij correcti per altitudines]
Nothing of the penumbra [Pe umbræ nihil]	Procyon 33° 42′	$8^h\ 40^m\ 40^s$	
Trace of the penumbra [Penumb veſtigiū]	Jupiter 41° 9′	$9^h\ 7^m\ 27^s$	
Thicker penumbra [Penumb craſſior]	Jupiter 41° 46′	$9^h\ 12^m\ 12^s$	
Noticeable penumbra [Penūb. notabilis]	Jupiter 42° 24′	$9^h\ 17^m\ 40^s$	
Beginning [Initi m]	Jupiter 42° 40′	$9^h\ 19^m\ 12^s$	
Digits eclipsed [Digit. eclipſ. /.]			
0 digits 52′	Procyon 37° 22′	$9^h\ 24^m\ 36^s$	
1 digit 35′	Procyon 37° 44′	$9^h\ 29^m\ 17^s$	
2 digits 15′	Jupiter 44° 55′	$9^h\ 37^m\ 23^s$	
3 digits 0′	Procyon 38° 48′	$9^h\ 44^m\ 7^s$	
3 digits 22′			$9^h\ 47^m\ 23^s$
3 digits 45′	Procyon 39° 19′	$9^h\ 52^m\ 11^s$	
4 digits nearly [4 ferè]	Procyon 39° 40′	$9^h\ 58^m\ 7^s$	
4 digits 15′	Jupiter 48° 9′	$10^h\ 8^m\ 11^s$	
4 digits 22′	Regulus 32° 55′	$10^h\ 10^m\ 31^s$	
4 digits 32′	Jupiter 49° 4′	$10^h\ 17^m\ 0^s$	
4 digits 45′	Jupiter 49° 24′	$10^h\ 20^m\ 22^s$	
5: greatest eclipse [5 Sūma Eclip.]	Jupiter 50° 14′	$10^h\ 29^m\ 5^s$	
5 digits nearly [5 ferè]	Jupiter 50° 41′	$10^h\ 34^m\ 2^s$	
4 digits 30′			$10^h\ 45^m\ 0^s$
4 digits 18′			$10^h\ 49^m\ 30^s$
3 digits 44′			$10^h\ 57^m\ 0^s$

Phases of the eclipse [Phaſes Eclipſis]	Altitudes [Altitudines]	Computed time [Tēpus ſupputatum]	Time of the clock corrected by altitudes [Tēpus Horologij correcti per altitudines]
3 digits 18′	Jupiter 52° 58′	$11^h\ 2^m\ 59^s$	
2 digits 45′			$11^h\ 10^m\ 2^s$
2 digits 30′			$11^h\ 13^m\ 40^s$
2 digits 0′			$11^h\ 16^m\ 0^s$
1 digit 32′			$11^h\ 19^m\ 15^s$
1 digit 22′	Regulus 41° 22′	$11^h\ 20^m\ 53^s$	
1 digit 7′			$11^h\ 22^m\ 20^s$
0 digits 38′			$11^h\ 24^m\ 45^s$
End [Finis]	Regulus 42° 5′	$11^h\ 27^m\ 44^s$	
Dense penumbra [Penumbra denſa]	Regulus 42° 19′	$11^h\ 30^m\ 3^s$	
Thin penumbra [Penūbra diluta]			$11^h\ 33^m\ 16^s$
Very thin penumbra [Penūbra dilutiſſ.]			$11^h\ 35^m\ 48^s$
End of the penumbra [Penumbræ finis]			$11^h\ 38^m\ 40^s$

He adds other things worth noting: namely, that shortly before the beginning of the eclipse one of the four satellites of Jupiter stood off from the centre of Jupiter's disc to the right, by 2⅓ Jovial diameters.

Of the remaining three, however, to the left, that is, toward the east, the nearest stood off by 1 diameter of Jupiter, the next by 1 ⅔, and the farthest by 3 ⅓, as is clear from his drawing. Likewise, he says that the beginning of the eclipse started on the lower right side, toward degree 5 from the nadir point, and 38° from the line perpendicular to the nonagesimal, toward the east. At the greatest phase of the eclipse, of 5 digits, the section of the shadow passed through the Island of Lemnos [Inſulam Lemnam], Mount Sypilus [M. Sypilū], *Didymi*, Mount Moschus [M. Moſchum], etc. For that is how he names those parts of the Moon; but comparing them with our Selenography, I see that it passed through the outermost edge of *Parisiorum* and the middle of *Innocentij* and *Ferdinandi Francisci*. And after other remarks he concludes that the end was 45° from the nadir point toward the right, and about 38° from the line perpendicular to the nonagesimal. The rest can be seen in his own account; I omit it here because of the ambiguity of the names by which he designates the spots of the Moon. Perhaps, however, in the Appendix to this Book I shall interpret the names of the more notable parts and compare them with the names we set down in our Selenography, Book 4, Chapter 7.

✢ But Don Vicenç Mut wrote to me that he observed the beginning of the eclipse at Majorca with Procyon 39° 10′ high in the east, namely at $8^h\ 16^m$, and

the end with Capella 68° 28′ high in the west, namely at 10^{h} 31^{m}. [Margin: Note for the difference of meridians.]

✢ And Ismaël Boulliau at Smyrna, as is related from his letter sent to Io. Rhodius [?] and by him to Father Kircher, observed the beginning of the penumbra with Regulus 31° 5′ high in the east, the true obscuration with the same star 35° 10′ high, the end with it 58° 40′ high, and the end of the penumbra with the same star 59° 40′ high. He observed the altitude of the pole there as 38° 15′ from the Sun's meridian altitude, but as 38° 22′ from the stars of Orion, a difference he attributes to a fault of the instrument. I afterwards found part of this observation in Renieri's *Tabulae Mediceae*, page 1.

CAPVT XX.

Chapter 20.

Eclipſes Solis Totales & Annulares ex præcedenti Hiſtoria & Auctoritate Aſtronomorum Confirmatæ, deque Affinitate quam cum illis habent Eclipſes Solis Matutinæ ac Veſpertinæ.

Total and annular eclipses of the Sun confirmed from the preceding history and from the authority of astronomers; and on the affinity that morning and evening eclipses of the Sun have with them.

I. Who would ever have believed that Tycho, commonly called the Phoenix of astronomers, would be so ignorant or so contemptuous of ancient observations as to deny that the whole Sun can be covered by the Moon? Yet he did deny it, and he clung to his opinion so far as to think that not even Clavius, a very sharp-eyed witness against him, should be believed. For as Kepler reports in the *Astronomia Optica*, Chapter 8, page 285: *When he wrote to Clavius in the year 1600, he said he was surprised that Clavius had seen a total eclipse in Portugal in the year 1560, and nocturnal darkness in the daytime. For his own observations, he said, do not allow the Sun to be wholly covered by the Moon, however low she may be.* [Margin: Total eclipses of the ☉: who has denied them and why.] And so in Volume 1 of the *Progymnasmata*, page 134, Tycho, holding to his opinion, says: *Since it has been noticed in an ecliptic ☌ of the luminaries that the Moon does not keep the same visible diameter as she has at other times, but that her margins are thinned by the force of the Sun's light, some optical reason suggesting this, so that about a fifth part of the ☾ is in this way lost and does not present itself to sight, we therefore found it necessary to vary the Moon's apparent diameter somewhat in ecliptic ☌.* Accordingly he gives a table in the same place, with the Moon's semidiameter at full Moons 16′ at apogee and 18′ at perigee, but at new Moons the former 12′ 48″ and the latter 14′ 24″. Mulerius in the *Tabulae Frisicae*, page 426, and a few Tychonizers in Germany follow him in this opinion and table. Longomontanus too, following Tycho in part, teaches in the *Astronomia Danica*, Book 1 of the *Theorica*, Chapter 9, that in eclipses of the Sun the Moon's diameter is diminished because of refractions and other causes, so much that

from a pole altitude of 53° to one of 74° it decreases by 2′, 3′, 4′, 5′ and 6′. The cause or occasion of Tycho's error was this: eclipses of the Sun, whether viewed directly or by reflection on a board on which the Sun's ray is received through a hole, show the Moon smaller than at other times. But if you then look directly at the Sun, the Moon appears smaller compared with the Sun (as long as the Sun is not wholly covered) for this reason: bright things set beside dark, and white beside black, appear larger, because light and whiteness predominate in moving the sight and affecting the organ of sense, and in overwhelming, or at least blunting, the image of black and dark things; as Kepler shows from the structure of the eye and the account of vision in the *Optics*, Chapter 5, toward the end. If, on the other hand, you let the Sun's rays through a hole or small window onto a board, and from the distance of the boards and the semidiameter of the ray, or bright base, you seek the Sun's apparent semidiameter, then unless you subtract the semidiameter of the hole from the semidiameter of the base, you will find the Sun's semidiameter larger than it should be. And if you do the same at the time of an eclipse of the Sun, you will get a diameter of the Sun larger, and a diameter of the Moon smaller, than they should be, as Kepler has demonstrated in the *Optics*, Chapter 2, from Proposition 10 to 12, and Chapter 11, Problems 2, 7, 8 and 9. Now Tycho and the Tychonists, in measuring the Sun's diameter, and from it the proportion of the Moon's, and the Moon's diameter itself in ecliptic ☌, used a channel or tube of 32 feet, as Tycho has it in Volume 1 of the *Progymnasmata*, page 471, but divided into 1000 parts, of which the hole, or rather the small square window, was 10, as Kepler has it in the *Optics*, page 341. But he did not subtract the window's semidiameter from the bright base, nor add the same, as he should have done, to the portion of the Moon obscuring the Sun; and from this came his occasion for slipping and for diminishing the Moon's diameter and the obscured digits of the Sun in ecliptic ☌, as Kepler acutely recognized in the *Optics*, page 286.

II. But against Tycho and Mulerius the whole of astronomy cries out, and has from its very cradle. For all other astronomers have so constructed their tables that the Sun's apparent diameter at new Moon is sometimes smaller than the lunar diameter, or not greater, and that the Sun can therefore be wholly covered by the Moon. [Margin: Total eclipses of the ☉ are confirmed by authority.] Their standard-bearer, Aristarchus, in his book *On the Distances and Magnitudes of the Three Bodies*, Proposition 8, says: *It is evident from observations that the whole Sun is eclipsed without stay.* After him, as Ptolemy reports in *Almagest* Book 5, Chapters 11 and 14, and Theon in his commentary on the same place, Hipparchus, in his book *On Magnitudes and Distances*, *assumes an eclipse, in the places around the Hellespont, that occurred precisely over the whole Sun, so that nothing of it appeared.* On this eclipse there is also Cleomedes, Book 2 of the *Cyclical Theory*, Chapter 4, saying: *The Sun, wholly eclipsed at the Hellespont, was observed at Alexandria with a fifth part of its diameter intact and the remainder eclipsed.* He asks in the same place how the Moon, though in fact smaller than the Sun, nevertheless sometimes covers it wholly. And Lucius

Taruntius Firmanus, in Plutarch's *Romulus*, assumed the same when he boldly declared to Varro that Romulus was conceived *when the whole Sun suffered a failing.* Ptolemy also assumes above the very thing Hipparchus does, namely that the whole Sun can be obscured by the Moon; and so does Pliny the Elder, Book 2, Chapter 11, in these words: *It cannot indeed be that the whole Sun is taken away from the lands by the intervening Moon, etc.*[51] Plutarch, in the little work *On the Face in the Orb of the Moon*, and al-Battānī, Chapter 30, hold this same thing as established, and so does Proclus in the *Hypotyposes*, q. 5, saying: *The whole Sun is at times seen to be covered from our view.* And Martianus Capella, in the book *De Nuptiis Philologiae* and of Mercury, says: *Often in the climate* [Greek: διὰ Μερόης (dia Meroēs, "through Meroe")] *the defect of the Sun shades the entire disc on every side.* Taking this truth as given, Vitellio [Witelo], as I said in Book 4, Chapter 6, no. 8, inquires into the reason why the Moon, in a total failing of the Sun, can nevertheless sometimes be seen by us. Lastly, Origanus too, in Volume 1 of the *Ephemerides*, Part 2, Chapter 10, and Magini in the *Supplement to the Ephemerides*, page 273, following Kepler's authority in the *Optics*, Chapter 8, departed from Tycho on this point; granted that Origanus, who professes to recognise total eclipses of the Sun, nevertheless in the Tychonic calculation of his *Ephemerides* presents them according to Tycho's mind. And the Braheans themselves, who, Tycho having died shortly before, attended in the year 1601 the observation of the solar eclipse of December 24 made at Prague by Kepler, acknowledged that the Moon's diameter is greater than Tycho states, as Kepler himself asserts in the *Optics*, page 359. And this is what is indicated in the Appendix of the *Progymnasmata*: namely, that by the eclipse of the Sun of the year 1601, shortly after Tycho's death (for he had died on October 24), his opinion on the diameter of the ☾ in ☌ was condemned.

III. [Margin: Examples of total eclipses of the Sun.] Kepler heaps up many examples of total eclipses of the Sun in the *Astronomia Optica*, Chapter 8; but he has neither brought forward all that exist in the writers, nor were all those he piles up necessarily total. Although these can be found from the preceding chapter, they must nevertheless be indicated briefly here, so that they may be ready to hand for anyone who wishes to pursue this controversy.

[Margin: 1. Eclipse of the ☉, total.] The first total eclipse of the Sun among those observed, then, was the one predicted by Thales, which was total at the Hellespont according to tradition; on it see what was said in Chapter 19, at the year 585 before Christ, May 28, and in Chapter 2, no. 8. The Sun's anomaly was then almost nil, the Sun being very near apogee, and the Moon's anomaly was 5^{s} 8°; and so for me the Sun's diameter was 30′ 50″ and the Moon's 33′ 10″.

[Margin: 2. Eclipse of the ☉, very nearly total.] The second, either total or very nearly total, was in the year 431 before Christ, August 3. For Thucydides, as I reported at that year, says that several stars were seen in the sky. The Sun's anomaly was then 32° and the Moon's about 90°, and for me the diameter

[51] the page prints *Non poſſe*, "it cannot be", a denial that seems to run against what the sentence is cited for; it is rendered as printed.

of the ☉ was 30′ 58″, but of the ☾ 30′ 23″. Now in an eclipse not quite total some, if not all, of the larger fixed stars or planets can be seen, as I shall say below, with Kepler's agreement. Still, it must have fallen as little as possible short of total; otherwise, if at its height the Sun had been visibly like the Moon, there was no reason for Thucydides to note that it afterwards became like a half Moon.

[Margin: 3. Eclipse of the ☉, total.] The third, in the year 310 before Christ, August 15, was plainly total, since Diodorus Siculus says: *the darkening was such that you would simply have called it night, with stars appearing everywhere.* And yet Tycho, who was not unaware of this eclipse, as is clear from Volume 1 of the *Progymnasmata*, page 745, does not present it as such. For us, however, the Sun's anomaly was then 2^{s} 14° and the Moon's 6^{s} 21°, and the Sun's diameter 31′ 22″, the Moon's 33′ 10″.

[Margin: 4. Eclipse of the ☉, total.] The fourth was in the year 49 before Christ, in which Gaius Julius Caesar crossed the Rubicon. For of the eclipse of the ☉ of that year Dio said [Greek: ὅτε ἥλιος σύμπαν ἐξέλιπε (hote hēlios sympan exelipe, "when the whole Sun was eclipsed")], *the whole Sun was eclipsed*; and because of it the nations despaired of the day, as Lucan sings, whose verses we have already brought forward at that year.

[Margin: 5. Eclipse of the ☉, total.] The fifth eclipse was before the death of Augustus, in the year of Christ 14 or the one before. For Cassius Dio says: *For the whole Sun too had been eclipsed.* This cannot be the one which Paulus, bishop of Fossombrone, affirms from calculation to have been total in the year of Christ 17; for that one was not quite total either, but very close to total, since the Sun's diameter was 32′ 8″ and the Moon's 31′ 20″; nor, according to the truer chronology, did Augustus die so late.

[Margin: 6. Eclipse of the ☉, total.] The sixth was the one Plutarch speaks of, referred in Chapter 19 to the year 97 or 98, although Kepler refers it to the year 113. For Plutarch says that stars shone out here and there in many places; and he gives another reason why the darkness was not altogether nocturnal but like twilight, and does not have recourse to a part of the Sun surviving and free from the eclipse. Moreover, in the years 97 and 98, on January 27, the day on which Nerva died shortly after the eclipse of the Sun, the Sun's anomaly was 216° and its diameter 32′ 26″, whereas the Moon's anomaly in the year 97 was 22°, with a diameter of 28′ 10″, but in the year 98 was 110°, with a diameter of 31′ 20″. So it was not total.

[Margin: 7. Eclipse of the ☉, nearly total.] The seventh was in the year of Christ 192, as Renieri judges, because Herodian in the life of the Emperor Commodus says that before his death stars were seen in the sky in the daytime; but it is enough that it was nearly total, unless something else is added.

[Margin: 8. Eclipse of the ☉, total.] [Margin: Lansbergen's tables erroneous.] [Margin: Kepler's error.] The eighth was in the year of Christ 237, April 12. For Julius Capitolinus says in the *Gordian* that it was so great *that it was not believed, and that nothing could be done without lights lit.* Lansbergen's

tables show this one as partial; but others, and ours, show it as total, for the Sun's anomaly was 10ˢ 16°, the Moon's 5ˢ 6°, and the Sun's diameter 31′ 4″, the Moon's 33′. I leave aside here the eclipse of the year 360, August 28, which Kepler shamefully and against his own tables makes total, as I said in Chapter 19 at that year; granted that, being a morning eclipse, it may have been like total ones: for see what I reported there from Ammianus Marcellinus.

[Margin: 9. Eclipse of the ☉, total.] [Margin: Lansbergen's tables erroneous.] The ninth was in the year of Christ 484, January 13. For Marinus says in the *Life of Proclus*: *The day was turned into night: for deep darkness came on, and stars were seen.* But Lansbergen's tables do not represent this one as total either; for me, however, the Sun's diameter was 32′ 50″, the Moon's 33′ 24″, the Sun's anomaly being 218° and the Moon's 169°.

[Margin: 10. Eclipse of the ☉, total.] The tenth was in the year of Christ 719, as Scheiner asserts in the *Rosa Ursina*, from the annals.

[Margin: 11. Eclipse of the ☉, total.] [Margin: Error of Petavius's, or the Parisian, tables.] The eleventh was in the year of Christ 840, May 5, since Aimoin, Book 5, Chapter 19, says it was very great, *so that stars were seen and the colour of things on Earth changed*, etc., and the author of the life of Louis the Pious says that *it differed in nothing from night, and all the fixed stars of the hemisphere were seen in their order, and the whole Sun was obscured by the Moon and then restored.* The Sun's anomaly was 10ˢ 25°, the Moon's 4ˢ 26°; and so for me the Sun's diameter was 31′ and the Moon's 32′ 38″. But Pétau, in his Parisian tables, computes this one at 9 digits 20′.

[Margin: 12. Eclipse of the ☉, total.] The twelfth was in the year of Christ 957, December 17, of which the author of the life of Lothair says: *There was an eclipse of the Sun, so that stars appeared from the first hour to the third.* The Sun's anomaly was then 185° and the Moon's 206°, and so for me the Sun's diameter was 33′ 8″ and the Moon's 33′ 6″, a difference that cannot be established; and so it must be counted exactly among total eclipses.

[Margin: 13. Eclipse of the ☉, total.] The thirteenth was, for Kepler, total, in the year of Christ 1113, August 2, because Dodechinus and Sigebert call it very great. The Sun's anomaly was 79° and the Moon's 163°, and so for me the Sun's diameter was 31′ 40″ and the Moon's 33′ 18″. It was therefore total somewhere.

[Margin: 14. Eclipse of the ☉, total.] The fourteenth was in the year of Christ 1187, September 4. For stars were seen as if at night, as Lycosthenes narrates. The Sun's anomaly was 2ˢ 18° and the Moon's 6ˢ 17°, and so for me the diameter of the ☉ was 31′ 38″ and of the ☾ 33′ 16″.

[Margin: 15. Eclipse of the ☉, total.] The fifteenth was in the year of Christ 1241, October 6, as Gemma Frisius affirms from tradition, and as all tables except Tycho's deliver. The Sun's anomaly was 3ˢ 20° and the Moon's 6ˢ 9°, and for me the Sun's diameter was 32′ 14″ and the Moon's 33′ 24″.

[Margin: 16. Eclipse of the ☉, total.] [Margin: Lansbergen's tables erroneous.] The sixteenth was in the year of Christ 1415, June 7, *so terrible that birds*

suddenly fell down, according to Polish history. And yet Lansbergen's tables make it partial. For us the Sun's diameter was 30′ 50″ and the Moon's 33′ 28″, with an anomaly of the ☉ of 11ˢ 21° and of the Moon of 5ˢ 26°.

[Margin: 17. Eclipse of the ☉, total.] The seventeenth was in the year of Christ 1485, March 16. For Lycosthenes says that there was *sheer darkness, and need of lit candles*, etc. The anomaly of the ☉ was 10ˢ and of the ☾ 5ˢ 16°, and for me the Sun's diameter was 31′ 20″ and the Moon's 33′ 18″.

[Margin: 18. Eclipse of the ☉, nearly total.] The eighteenth was that of the year 1506, January 14, in which Io. de Barres [João de Barros] says *that stars were seen on a clear day.* For it was as near as could be to total: the Sun's anomaly was 6ˢ 29° and the Moon's 7ˢ 12°, and the Sun's diameter 32′ 58″, the Moon's 32′ 34″.

[Margin: 19. Eclipse of the ☉, total.] The nineteenth, in the year 1530, March 29: for me the Sun's anomaly was 282° and the Moon's 150°, and the Sun's diameter 31′ 38″, the Moon's 32′ 58″.

[Margin: 20. Eclipse of the ☉, not quite total.] The twentieth, of the year 1544, January 14, was a morning eclipse; and so the birds that had been singing merrily at sunrise afterwards fell silent. Morning eclipses, though not quite total, nevertheless seem total if the eastern part of the Sun, free of the eclipse, is below the horizon or covered with thick vapours. For me it was not quite total, but close to total; for the Sun's diameter was 33′ and the Moon's 30′ 54″, with an anomaly of the ☉ of 208° and of the Moon of 102°.

[Margin: 21. Eclipse of the ☉, total.] The twenty-first was in the year 1560, August 21, seen at Coimbra by our Fathers Clavius and Emmanuel Vega, with Tycho opposing in vain; the Sun's anomaly was 34° and that of the ☾ 130°, and the Sun's diameter 31′, the Moon's 32′ 12″.

[Margin: 22. Eclipse of the ☉, total.] [Margin: Lansbergen's tables erroneous.] The twenty-second was in the year 1605, October 12; by the testimony of Wendelen the whole Sun was precisely covered, with dense darkness around Marseille. Granted that Lansbergen's canons make it partial. But for me the Sun's anomaly was 102° and the Moon's 134°, and the Sun's diameter 32′ 6″, the Moon's 32′ 22″.

One could add that total eclipse of the Sun which Zonaras, Volume 2, reports to have occurred when Scipio was fighting against Hannibal in Africa, if he had added other marks of the time.

De Annularibus Solis Eclipſibus.

On annular eclipses of the Sun.

IV. Annular eclipses of the Sun, in which, that is, a small circle or shining armlet of the Sun's disc appears around the Moon, like a golden ring of light, we have already asserted in Book 4, Chapter 6, Scholium 1, and we assert them again now. For all astronomers accept them, except Ptolemy and, nearly, Longomontanus, because in some position of the anomaly they grant that the

Moon's apparent diameter is smaller than the Sun's diameter; which Ptolemy denies, and Longomontanus too, of itself, granted that by the force of refractions he concedes in climates [Margin: Authors who deny annular eclipses of the Sun.]

nearer the pole of the World that the Sun's diameter can thus be enlarged, and the Moon's optically diminished, so that it appears smaller than the solar. But on Tycho's view all eclipses of the Sun would be annular in the places of the Earth where they appear central, or from which a straight line at the time of the eclipse passes through the centres of both luminaries, since at every ecliptic new Moon he makes the Moon's diameter smaller than the Sun's. These eclipses are accepted by Maurolico in Dialogue 3 of the *Cosmographia*, page 87; by Egnazio Danti in the *Astrolabium*, page 294; by Kepler in the *Astronomia Optica*, Chapter 8, no. 3; and by Bettini in *Apiarium* 8, Progymnasma 2, Proposition 10; if not of themselves, at least by benefit of refraction occurring in the air around the Moon. For otherwise, says Bettini, *the Moon's apparent diameter, in whatever position, always shows itself greater than the Sun's apparent diameter*; in which, however, he errs, but in company with Longomontanus and Ptolemy.

Let us now see the opinion of the more ancient astronomers. [Margin: The true opinion of Cleomedes.] Cleomedes, *Cyclical Theory*, Book 2, Chapter 4, says: *Some of the ancients held that in complete defects the centres of the luminaries are joined in a straight line, and that the orbit of the Sun appears all around on every side. This, however, is not among uncertain things. For all the projecting parts, being very bright and having no small projection, have been clearly seen by us, since the Sun is greater than the Moon.* So reads my codex, faithfully translated from the Greek. [Margin: Kepler must be corrected in reporting Cleomedes.] Granted that Kepler, in the *Astronomia Optica*, page 289, following some version or other, says that Cleomedes there speaks against Sosigenes' opinion, and says: *This has not been detected by observation, for that projecting limb would have been seen by us, being very bright.* The words of Cleomedes are these: [Greek: τοῦτο δὲ οὐ τῶν εὑρημένων ἐστίν. ἑωρᾶτο γὰρ ἂν ἡμῖν τὰ ἐξέχοντα λαμβρότατα γε ὄντα, καὶ μὴ βραχεῖαν ἐκφαίνοντα τὴν ἐξοχήν. (touto de ou tōn heurēmenōn estin. heōrato gar an hēmin ta exechonta lambrotata ge onta, kai mē bracheian ekphainonta tēn exochēn; "But this is not among the things found. For the projecting parts would have been seen by us, being very bright and showing no small projection.")] Nor would Cleomedes have argued rightly against the ancients by saying that he had never seen this; for the reply could be that he was not in the place of a central eclipse, or that no such eclipses occurred while he was observing. But neither was Sosigenes older than Cleomedes, so that he could be numbered among those ancients whom Cleomedes adduces. For Sosigenes flourished under the Dictator Gaius Julius Caesar and in the early days of Augustus, under whom he directed the correction of the calendar; whereas Cleomedes, author of the work [Greek: περὶ τῆς κυκλικῆς θεορίας (peri tēs kyklikēs theorias, "On the Cyclical Theory")], flourished a little earlier, as I have already said in Chapter 5, no. 16.

[Margin: The opinion of Sosigenes.] Moreover, Proclus Diadochus reports Sosigenes' opinion in question 5 of the *Astronomical Hypotyposes*. For having said, on Ptolemy's view, that the Sun's diameter never appears greater than the Moon's, he adds: *If this is true, what Sosigenes the Peripatetic relates in the work he entitled On Revolutions is not true: that the Sun, in eclipses occurring at perigee, is seen not wholly running forward, but at the extremes of its circumference escapes the Moon's circle and gives light by no means obstructed.* [Margin: Proclus an upholder of eclipses of the ☉ both total and annular.] Proclus himself certainly supports this opinion of Sosigenes when he says: *The whole Sun is at times seen to be covered from our view; at times, at the very moment when the two centres and the eye fall on the same line, the Moon is seen within the Sun's circuit.* [Margin: Plutarch's vote for annular eclipses.] Plutarch also favours it, in the little work on the spots in the face of the Moon, in these words: *Even if the Moon at times hides the whole Sun, that defect nevertheless lacks breadth and time; indeed, at times a brightness shines out around the orbit, not allowing the shadow to become deep and excessive.*

Eclipſes Solis Annulares.

Annular eclipses of the Sun.

V. It now remains to take up again from Chapter 19 the examples of annular eclipses of the Sun, certain or disputed.

[Margin: 1. Eclipse of the ☉ believed annular.] The first was, or seems to have been, the one believed to have been seen when Augustus entered the City; on it see what was said in Chapter 19, at the year 44 before Christ.

[Margin: 2. Eclipse, annular.] The second was in the year of Christ 95 or 96; on it see what was said in Chapter 19 at this year.

[Margin: 3. Eclipse, annular.] [Margin: Kepler's and Wendelen's tables in error.] The third was in the year of Christ 334, July 17; on it see what was said in Chapter 19 at this year. Kepler's and Wendelen's tables, however, show it as total, whereas ours leave it annular; for the Sun's anomaly was 46° and the Moon's 296°, and so for me the Sun's diameter was 31′ 8″ and the Moon's 30′ 16″.

[Margin: 4. Eclipse, annular.] The fourth was in the year of Christ 1567, April 9, which Clavius asserts he saw at Rome, saying in Chapter 4 of the *Sphere*: *at Rome the Sun was not wholly eclipsed, but there was left a certain thin shining circle all around.* And yet Kepler, in the *Astronomia Optica*, Chapter 8, who had condemned Tycho for not believing Clavius about the total eclipse of the Sun, calls into doubt in the same place, pages 297 and 302, Clavius's report or observation; evidently because, from the Keplerian hypothesis and tables, that eclipse cannot be computed as annular, and for him the Moon's diameter is then greater than the Sun's. [Margin: Tables of Kepler and of others erroneous.] In this the Alphonsine, Prutenic and Philolaic Tables also err, along with the Rudolphine and the Atlantic. And so Kepler, begging for escapes, says that that bright small circle appeared either because of the refraction of the Sun's rays

in the air that surrounds the Moon, or rather from the air or aether inflamed by contact with the nearby Sun; as if kindled air could have produced a bright ring, and not rather a broad space all around, suffused as with the light of dawn.

[Margin: 5. Eclipse, annular.] [Margin: Error of the astronomical tables.] The fifth was in the year 1598, February 25; on it see what was said in Chapter 19 at this year. But the Prutenic, Rudolphine, Philolaic and Atlantic Tables do not grant this one as such either; others, however, do, and mine above all, in which the Sun's diameter is 32′ 16″ and the Moon's 32′ 12″, with the Sun's anomaly 112° and the Moon's 130°.

[Margin: 6. Eclipse, annular.] The sixth was in the year 1601, December 24; on it see what was said in Chapter 19 at this year. The anomaly of the ☉ was 176° and the Moon's 7°, and for me the Sun's diameter was 33′ 8″, the Moon's 28′ 4″.

[Margin: 7. Eclipse, annular.] The seventh was in the year 1639, June 1, if what Boulliau says in his *Astronomia*, Book 4, Chapter 5, is true: that he observed the Moon's diameter at that time to be smaller than the Sun's diameter; for it must have been annular somewhere. Granted that, since his tables do not put the Moon's diameter smaller than the solar at that time, he too has recourse either to the optical enlargement of bright parts beside dark ones, or to the refraction of the Sun's rays produced by the thicker air around the Moon. But for me, without these detours, the Sun's diameter was then 30′ 56″, at an anomaly of 333°, and the Moon's diameter 29′ 54″, at an anomaly of 80°.

De Eclipſibus Matutinis ac Veſpertinis.

On morning and evening eclipses.

VI. [Margin: Morning and evening eclipses of the Sun similar to total ones.] Among morning eclipses of the Sun there are some in which the Sun rises astronomically covered in all that part of itself which otherwise stands above the horizon, so that the night seems to be prolonged. Therefore, even if they are not total at their height, they can nevertheless seem so somewhere. And since at dawn planets at times, and fixed stars that have not yet set heliacally, appear, they can appear much more easily when the Sun is then obscured. But because this does not seem unusual and new to common people, since stars were ordinarily seen earlier at the end of the night, the writers do not seem to be speaking of these eclipses when they narrate stars seen in the sky as something unusual and like a portent. The same must be judged of evening eclipses, in which the Sun, having suffered a failing a little before setting, sets in eclipse. For then night seems to fall more quickly, and stars which otherwise usually appear soon after sunset can be seen more easily, and that eclipse can seem total at its height, although in fact it is not, because the part of the Sun free of the eclipse has nevertheless sunk below the horizon.

VII. [Margin: Why morning eclipses of the Sun have been reported among portents.] But among morning eclipses of the ☉, those are commonly either less

known or more wonderful which begin a little before or a little after sunrise; so that the Sun rises shining either wholly or in some part of itself, but as the eclipse soon comes on or grows toward the east, the day seems to be extinguished and the night, which had been interrupted, to be called back. So much so that the ignorant crowd, not of birds only but of men, supposes that not the ordinary Sun, but some light like the Sun, has appeared unexpectedly in the night-time, and at times complains that it has been roused untimely to song or to work; while historians list phenomena of this kind, which are truly natural, among preternatural portents. And these too can seem to others total eclipses, although they are not. To this, not improbably, those words of Pliny the Elder, Book 2, Chapter 33, refer: *A light from the sky was seen by night when Gaius Caecilius and Gnaeus Papirius were consuls, and often at other times, so that a semblance of day shone by night.* Granted that Milich interprets this there of a meteorological chasm. To this also refers that passage of Julius Obsequens in the little book on prodigies: *The light shone so that, as if day had dawned, to work*

people rose; and again: *At Amiternum the Sun was seen by night, and its light was seen for some time*; and once more: *in Gaul, in the camp, a light shone at night*. Johann Georg Herwart von Hohenburg indeed refers these, not badly, to eclipses of this kind, in Chapters 86, 128 and 145 of his *Chronologia*, though he misuses them to establish dates, as I said in the chronological book, which will be the fifth of Volume 2 of our *Almagest*. Finally, to this class can be assigned that failing of the Sun which occurred in the Year of our Salvation 1544 January 14, since historians say that birds which had been cheerful at first light fell silent, etc. This eclipse was not indeed total, but it was very close to total ones, as I have already said at Eclipse 19. Such too was the one around the Year of Christ 957, on December 18 [15. Calendas Ianuarij], or in the 3rd year of Lothair, for me precisely total, of which the author of the life of Louis the Pious and Lothair says: *An eclipse of the Sun occurred, so that stars appeared from the first hour to the third hour.* Such was the one treated in Chapter 19 at the Year of Christ 360, from Ammianus Marcellinus, which began from the rising of dawn. And such without doubt was the one seen in the Year of Christ 1530 March 29 by Kepler's paternal uncle, who relates that, with the sky bitterly cold, *it had scarcely grown light when suddenly the light of day was extinguished and turned into night*. On this occasion Kepler in the *Optics*, page 295, prudently warns that morning eclipses of the Sun are gloomier, since the Moon's shadow from above the horizon strikes as if with a kind of blow and extinguishes the dawn. This one, however, was total for me.

VIII. It is pleasing now to imitate Kepler, who in the *Optics*, page 303, sets out certain notable corollaries on eclipses of the Sun; to these I will add some drawn from what has been said, thoroughly worth knowing for telling eclipses apart.

Theoremata de Solis Eclipſibus.

Theorems on eclipses of the Sun.

Theorem 1. *There are total eclipses of the Sun.*

This runs against Tycho and Mulerius, but it has been sufficiently shown above, nos. 1 and 2.

Theorem 2. *Whenever in an eclipse of the Sun the Moon's apparent diameter is greater than the Sun's, or not smaller, and the lunar shadow at the height of the eclipse falls wholly within the Earth's surface, that eclipse is total somewhere on Earth.*

This is clear from the definition of a total eclipse and from the causes that concur in it.

Theorem 3. *Whenever a total eclipse of the Sun occurs and the sky is clear, stars can be seen in the sky.*

So Kepler above, Corollaries 2 and 4. For if a sky filled with thick vapours glows around the Sun and is set on fire by the Sun, that meteorological light can hinder the appearance of the stars.

Theorem 4. *Whenever in an eclipse of the Sun, far from rising and from setting, stars appear as they do at night, that is evidence of a total rather than a non-total eclipse.*

Theorem 5. *The appearance of a few stars in eclipses of the Sun, especially evening or morning ones, is not sufficient evidence of a total eclipse, but it is evidence of one nevertheless very nearly total.*

So Kepler prudently above, Corollary 3; and it is clear from what was said above, nos. 6 and 7. See above Eclipses 2 and 17, among the nearly total ones. A concurrence of sunspots also contributes to the darkness of the air.

Theorem 6. *Morning and evening eclipses can seem total although they are not.*

This is clear from what was said in nos. 6 and 7, and from Corollary 5 of Kepler, who says that morning eclipses are more prone to darkness before their middle, namely in the descending node and semicircle, and evening eclipses after their middle, in the ascending node and semicircle; because, that is, they extinguish that part of the air lit by the Sun which, above our heads, brings us the most light.

Theorem 7. *Some eclipses that are not quite total can bring a greater darkness on the Earth than total ones.*

Kepler above, Corollary 7. It is clear in morning and evening non-total eclipses, if they are compared with those total ones in which the richer and thicker air is set on fire all round by the Sun.

Theorem 8. *There are annular eclipses, not only incidentally, from air or aether set on fire around the Sun, or from a refraction of the solar rays occurring in our air or in the air around the Moon, but of themselves, because of the excess of the Sun's apparent diameter over the lunar.*

This runs against Ptolemy, Bettini and, nearly, Longomontanus; but it is firmly enough established by what was said in nos. 3 and 4.

Theorem 9. *Whenever in an eclipse of the Sun the Sun's apparent diameter is greater than the lunar diameter, and around the middle of the eclipse the line drawn through the centres of the luminaries falls within the Earth, that eclipse is annular somewhere on Earth.*

This is clear from the definition of an annular eclipse and from the causes that concur in it.

Theorem 10. *Because of an eclipse of the Sun the Sun can seem to have risen at night, or to have risen twice on the same day.*

This is clear from certain morning eclipses, about which enough was said in no. 7.

CAPVT XXI.

Chapter 21.

Catalogus Eclipſium ex Ephemeridibus ab Anno CHRISTI 1485. vſq. ad Annum 1700.

A catalogue of eclipses from ephemerides, from the Year of Christ 1485 to the Year 1700.

I. It greatly helps, in comparing tables with the observations (19) set out above, and for the exeligmi and restitutions of eclipses, to have ready to hand, without the labour of calculation, the eclipses of many years computed continuously by the authors of ephemerides, even if not from tables perfect in every respect. So I should like here too to collect them in summary for candidates in astronomy, noting only the time, the duration and the digits. The authors are those listed below. [Margin: Authors of the ephemerides.] An unnamed author of an old ephemeris, from the year 1484 to 1506 inclusive; Iacobus Ptlaumen [Jacob Pflaum] [?] and Johannes Stöffler [Io. Stœflerinus], for the meridian of Ulm, from the year 1507 to 1534; Luca Gaurico [Lucas Gauricus], for a latitude of 45°, from the year 1534 to 1551; Peter Apian [Petrus Appianus], for the meridian of Leisnig [Leyſingæ], from the year 1538 to 1578; Stöffler [Io. Stœflerus], for the meridian of Tübingen, from the year 1543 to 1554; Pietro Pitati [Petrus Pitatus], for the Venetian meridian, from the year 1544 to 1556; Georg Joachim Rheticus [Georgius Ioachimus Rheticus], in the ephemeris of the year 1551; Nicolò Simi [Nicolaus Simus], for the meridian of Bologna, from the year 1552 to 1568; Michael Mästlin, for the meridian of Tübingen, from the year 1577 to 1590; Stadius [Io. Stadius], for the meridian of Antwerp, from the year 1554 to 1574; Giovanni Antonio Magini [Io. Antonius Maginus], for the Venetian meridian, from the year 1581 to 1630; David Origanus, for the meridian of Frankfurt on the Oder, from the year 1595 to 1654; Andrea Argoli [Andreas Argolus], for the meridian of Rome, from the year 1630 to 1700; Francesco Montebruni [Franciscus Montebrunus], for the meridian of Bologna, from the year 1641 to 1660. Among these, Stadius, Mästlin and Magini followed the Prutenic Tables;

Origanus the Prutenic and Tychonic; Argoli the Tychonic; Montebruni, like Duret too, the Lansbergian; the rest, for the most part, the Alphonsine.

II. So that the places for which, and the tables from which, the following eclipses were computed may be ready to hand, consult the following canon, in which the years are taken inclusively at both ends.

Ephemeridum Interualla, & Loca.

The intervals and places of the ephemerides.

Years	Place and tables
From 1485 to 1506	Place and author unknown
From 1507 to 1553	Ulm in Swabia [Vlma Sueu.], from the Alphonsine
From 1554 to 1576	Antwerp, from the Prutenic
From 1577 to 1585	Tübingen, from the Prutenic
From 1586 to 1594	Venice, from the Prutenic
From 1595 to 1600	Frankfurt on the Oder, from the Prutenic
From 1601 to 1640	Frankfurt on the Oder, from the Tychonic
From 1641 to 1660	Bologna, from the Lansbergian
From 1661 to 1700	Rome, from the Tychonic

For although Origanus computed up to the year 1654 in the Prutenic manner as well, and Argoli from the year 1630 to 1700 in the Tychonic, I nevertheless judged it enough, for trial and comparison, to give Prutenic eclipses of 24 years, Tychonic of 80 years, and Lansbergian of 20 years. The time noted, moreover, is apparent time, and from the year 1582 the days are Gregorian.

ECLIPSES EX EPHEMERIDIBVS Ab Anno Chriſti 1485. Ad Annum Chriſti 1700.

Eclipses from the ephemerides, from the Year of Christ 1485 to the Year of Christ 1700.

Year	Eclipse	Month	Day	From noon	Duration	Digits
1485	☉	March	16	$4^h\ 35^m$	$2^h\ 1^m$	Total

1627	☉	August	11	In Tenduc and in		10 0′
1628	☉	January	6	Corte Reali		5 40′
1628	☾	January	20	$10^h\ 11^m$	$3^h\ 40^m$	18 T. 13′
1628	☉	July	1	Around the Cape of Good Hope		11 44′
1628	☾	July	16	$11^h\ 26^m$	$3^h\ 56^m$	12 T. 57′
1628	☉	December	25	In France, England, etc.		
1629	☾	January	9	$1^h\ 36^m$	$2^h\ 13^m$	4 27′
1629	☉	June	21	In the Gangetic Gulf		11 25′
1629	☉	December	14	In Peru		10 14′
1630	☾	May	25	$17^h\ 56^m$	$2^h\ 40^m$	6 0′
1630	☉	June	10	$7^h\ 47^m$	$1^h\ 38^m$	9 8′
1630	☾	November	19	$11^h\ 24^m$	$3^h\ 25^m$	9 27′
1630	☉	December	3	Toward New Guinea		10 10′
1631	☉	April	30	Around the Antarctic		
1631	☾	May	15	$8^h\ 15^m$	$3^h\ 40^m$	21 T. 32′
1631	☉	October	24	Toward the Antarctic		
1631	☾	November	8	$12^h\ 0^m$	$4^h\ 17^m$	19 T. 49′
1632	☉	April	19	Toward the Cape of Good Hope		9 2′
1632	☾	May	4	$1^h\ 24^m$	$2^h\ 37^m$	6 35′
1632	☉	October	13	In Mexico		8 37′
1632	☾	October	27	$12^h\ 23^m$	$2^h\ 46^m$	5 31′
1633	☉	April	8	$5^h\ 14^m$	$1^h\ 36^m$	4 30′
1633	☉	October	3	Toward the Maldives		12 T. 4′
1634	☾	March	14	$9^h\ 35^m$	$3^h\ 43^m$	11 18′
1634	☉	March	28	In Japan		10 19′
1634	☾	September	7	$5^h\ 0^m$	$3^h\ 11^m$	12 T. 10′
1634	☉	September	22	Toward the Cape of Good Hope		9 54′
1635	☉	February	17	Toward the Antarctic		

Year	Eclipse	Month	Day	From noon	Duration	Digits
1635	☾	March	3	9^h 26^m	4^h 13^m	17 T. 41′
1635	☉	March	18	In northern Mexico		0 16′
1635	☉	August	12	In Iceland		5 0′
1635	☾	August	27	16^h 4^m	3^h 36^m	16 T. 59′
1636	☉	February	6	In Peru and New Guinea		
1636	☾	February	20	11^h 34^m	3^h 21^m	3 23′
1636	☉	August	1	In Tartary, etc.		11 20′
1636	☾	August	16	4^h 34^m	1^h 24^m	1 25′
1637	☉	January	26	Cambodia, Malacca, etc.		
1637	☉	July	21	In Yucatán, etc.		
1637	☾	December	31	0^h 44^m	3^h 8^m	10 45′
1638	☉	January	14	In Persia and India		9 45′
1638	☾	June	25	20^h 17^m	3^h 4^m	17 T. 7′
1638	☉	July	11	In the Strait of Magellan		9 5′
1638	☉	December	5	In southern Magellanica		2 10′
1638	☾	December	20	15^h 16^m	3^h 43^m	18 T. 8′
1639	☉	January	4	In Tartary		0 30′
1639	☉	June	1	5^h 59^m	1^h 54^m	10 40′
1639	☾	June	15	2^h 41^m	3^h 40^m	11 9′
1639	☉	November	24	In Magellanica		11 0′
1639	☾	December	9	11^h 57^m	2^h 19^m	3 46′
1640	☉	May	20	In New Spain		10 30′
1640	☉	November	13	In Peru		10 36′
1641	☾	April	25	1^h 2^m	3^h 3^m	9 49′
1641	☉	May	9	10^h 16^m	Peru	10 16′
1641	☾	October	18	8^h 19^m	2^h 47^m	6 31′
1641	☉	November	2	18^h 46^m		
1642	☉	March	30	In Estotilant		4 0′
1642	☾	April	14	14^h 31^m	3^h 47^m	18 T. 36′
1642	☉	September	25	In southern Magellanica		
1642	☾	October	7	16^h 45^m	3^h 46^m	20 T. 30′
1643	☉	March	19	13^h 53^m		
1643	☾	April	3	21^h 10^m	2^h 8^m [?]	3 9′
1643	☉	September	12	17^h 0^m		
1643	☾	September	27	7^h 38^m	2^h 35^m	6 0′
1644	☉	March	8	6^h 20^m		
1644	☉	August	31	18^h 10^m		
1645	☾	February	10	7^h 45^m	3^h 18^m	8 52′
1645	☉	February	26	In Insul. Romerij [?]		10 46′
1645	☾	August	7	2^h 4^m	3^h 46^m	13 T. 47′
1645	☉	August	21	0^h 35^m	2^h 30^m	4 40′
1646	☉	January	16	In the Strait of Anián		
1646	☾	January	30	18^h 11^m	3^h 42^m	18 T. 43′
1646	☉	July	12	6^h 57^m		

Year	Eclipse	Month	Day	From noon	Duration	Digits
1646	☾	July	27	$6^h\ 2^m$	$3^h\ 41^m$	13 T. 48′

In this year the leap day is omitted in the Gregorian calendar.
LIBRI QVINTI FINIS.
End of Book Five.

LIBER SEXTVS DE STELLIS FIXIS.

Book Six. On the Fixed Stars.

CAPVT I.

Chapter 1.

De Nomine & Excellentia Siderum Inerrantium.

On the Name and Excellence of the Non-Wandering Stars.

[Margin: Difference between a star and an astrum.]

I. A star [stella], in Greek ἀστὴρ [Greek: astēr, "star"] and in Hebrew *Cocaû*, differs from a sidus, which in Greek is called ἄστρον [Greek: astron, "star, group of stars"] and in Hebrew *Nghas* or *Nghais*, if these names are used in their stricter sense. For, as Achilles Tatius points out in his *Isagoge* to Aratus's *Phaenomena*, ch. 14, and also Suidas in his lexicon, Galen on Book 1 of the *Epidemics*, and St Basil on Isaiah ch. 13, an ἀστὴρ or star is a single, separate, shining celestial body, whether it is a planet or not: such are Mercury, Saturn, or the bright star of Lyra. But ἄστρον δὲ τὸ ἐκ πολλῶν ἀστέρων σύστημα [Greek: "an astron is the system of many stars"], that is, *an astrum is a system composed of several stars*, and those non-wandering ones. Some think that the Latin name *sidus* suits this, as if it derived from the Greek σὺν εἴδειν [Greek: syn eidein, "to see together"], that is, from the fact that several stars are seen together in it; whereas this name is rather Latin, from *sedendo* or *subsidendo*, sitting or settling down, in setting. But the Hebrew word *Nghas* certainly suits it, from the verb *Nghus*, which means to be gathered together.

In a looser sense, however, you will find that not only the poets but also Plato among the Greeks and Cicero among the Latins call single stars, even wandering ones, *astra* and *sidera*. Conversely, Callimachus called the asterism of Coma Berenices ἄστερα [Greek: astera, "star"]. But you will more rarely find the celestial images [imagines], configured into one astrum, called a star by a singular name; to this bears that saying of Tatius above: *For every star is an astrum, yet not every astrum is a star.*

[Margin: Difference between the Astra of the Zodiac and the celestial Houses.]

The celestial images, however, especially those in the Zodiac or more closely connected with it, are called ἠστερισμένα ζώδια [Greek: ēsterismena zōdia, "starred animals"] by Hipparchus of Bithynia, that is, star-bearing or starred animals. They differ from those twelve segments of the Zodiac that the Greeks call δωδεκατεμόρια [recte: δωδεκατημόρια] [Greek: dōdekatēmoria, "twelfth-parts"] and the Latins the celestial Houses. For these segments are equal to one another, take in an equal space of the sky, and are in themselves invisible; but the figures of the celestial images, after which those houses are named, occupy unequal spaces of the sky and are visible in themselves. Sometimes they belong with one part of themselves to one house, or to one segment of the Zodiac, and

with another part to another. Some are larger than the dodecatemory named after them, some smaller. Finally, some belong to two domiciles: thus the image of Scorpio marks out the house of Libra with its Claws or arms, and the dodecatemory of Scorpio with the rest of its body.

[Margin: What are the celestial Signs?]

But because both these asterisms and the dodecatemories are called by the Greeks σήμα or σῆματα [Greek: sēma, sēmata, "sign, signs"], that is, Signs, you will find that some writers have confused the Astra of the Zodiac with the dodecatemories, and have attributed to the one certain things that suit only the other, as our Pétau learnedly shows in the dissertations of his *Uranologion*, Book 2, ch. 3 and following.

[Margin: Why are they called Fixed or non-wandering stars?]

II. Now those seven stars that with varied and anomalous motion repeatedly change their distance from one another and from the ecliptic are called wandering and erratic, or wanderers [errones], by the Latins, and πλανῆται [Greek: planētai, "wanderers"] by the Greeks. The rest, with which the sky above these glows on every side, are called *Fixed* or *Non-wandering* [Inerrantes], because they move with a regular motion, always keeping the same distance from one another and from the ecliptic, just as if they had been fastened into the sky like golden nails or light-spewing fire-gems [pyropi luciuomi], as Empedocles and Anaximenes held. As Plutarch says in Book 2 of *De placitis philosophorum*, ch. 13 and 14, they said that *the non-wandering stars are fixed or tied to crystal like nails*.

Hence the eighth sphere, filled with non-wandering stars, was called by the Greeks ἀπλάνη [Greek: aplanē], that is, non-wandering, or free from wandering; for πλάνη [Greek: planē] means wandering [error]. This is perhaps why the multitude of these stars, like a drawn-up battle-line of a camp, advancing in order at fixed intervals from one another, is more than once called in Holy Scripture *the host of heaven* [militia cæli]. Hence that line in the song of Deborah and Barak, who ascribe their victory to God: *From heaven the battle was fought against them: the stars, remaining in their order and course, fought against Sisera* (Judges ch. 5); and Ecclesiasticus 47: *A vessel of the camps on high*, etc., as below at the end of no. 3.

[Margin: Praises of the Fixed Stars.]

III. For a different reason, however, the fixed stars belong to the host of heaven. For they serve as soldiers for God, either when with their rays they hurl on the earth influences harmful to some, harmless and wholesome to others, yet always harmlessly, and fight with secret lightnings while they flash with open gleams; or when, like sentries armed with adamantine splendours, they seem to keep the night watches by the fixed turns of their evening risings. To this belong those words of the sacred canticle, Baruch 3, v. 34: *And the stars gave light in their watches and rejoiced; they were called, and they said: Here we are; and with gladness they shone for him who made them*; and the passage of Ecclesiasticus 47, of which below.

And yet it is God, God I say, who not only with a hundred starry eyes like Argus, but as wholly mind and wholly eye, either keeps watch over the good or keeps watch against the wicked: with one eye indeed, the one Jeremiah saw (ch. 1) and that we read of in the hieroglyphics as darting out of a rod and as it were blossoming from it, yet dispensing a manifold providence on account of its innumerable effects. Those innumerable stars are accordingly the symbol of this. You might call them the shining footprints of divine providence as it goes round all things, or the eyes of the upper World and, as it were, of God: metaphorically indeed, but more magnificently than if you called them the flowerets of the celestial field, or the gems of Olympus, or the torches of the ethereal ceiling, or the lamps of our life, or the funeral torches of the setting Sun, or the shining chorus of the Moon or Diana, or by other such ἄλογαις [Greek: alogais, "irrational"] analogies, by which, with a comparison by far the lowest, you would cast the stars down rather than raise them up.

I for my part would certainly prefer to draw their praise from the sacred word, and to call them the fiery and glowing tongues of heaven, which, by the perpetual wonder of their lights and the never-interrupted harmony of their most constant motions, tell the glory of their Maker while they call mortals to the praise of God; or which instruct the minds of those who contemplate more deeply in the more hidden mysteries of divine Providence toward us. So much so that for this reason they have become the symbol of sacred learning and of the learned, by the testimony of an angel, or rather of God, in Daniel ch. 12, where it is said: *But those who have been learned will shine like the splendour of the firmament, and those who instruct many to justice, like stars for perpetual eternities.* Or they are the signs of that heavenly glory to which they invite us, and as it were a kind of specimen of that inner and eternal tabernacle in which, without a veil, the Maker of the Stars will make his face shine upon the Elect. Or, finally, with a certain sacred dread of their splendour they terrify the wicked, who lie in wait amid the darkness of night and the hiding places of crime, as witnesses who will stand with the Saints against them at the Last Judgement; according to that passage of Ecclesiasticus 47, which gathers up much in their praise: *A vessel of the camps on high, shining gloriously in the firmament of Heaven. The beauty of heaven is the glory of the stars; the Lord illuminating the world on high. At the holy words they will stand for judgement, and will not fail in their watches.*

[Margin: Why the Astra contain irregular figures.]

IV. Yet to the foolish the stars could seem scattered and dispersed through the tracts of the sky by chance rather than by design, since they are not arranged at equal intervals from one another and are not enclosed in a regular figure such as we aim for in flower-beds, a square, say, a rhombus, a hexagon, a circle, an ellipse, but sprinkled ὁλοσχερῶς [Greek: holoscherōs, "wholesale, at large"] and with incredible variety, of irregular and dissimilar figures

distributed here sparsely, there thickly and in heaps. But this very thing is evidence of a providence that is indeed higher, yet more solid. First, that position and form were required by the variety of natural affections, which

had to flow down from the sky into the sublunary region in fixed alternations. Accordingly, figures that are irregular to our mere and bare geometry are regular to Theophysics, that is, to the divine science with which He governs Nature, and are commensurate with a heavenly plan and purpose. Next, had all the astra obtained a mathematically regular form, they would not be told apart by so evident a distinction, nor would their varied positions have marked out for us the different changes of the seasons. For suppose that the astra we now call the Wagons or Bears had only the form of a square or a rhombus: then, with the pole or tail turned over, they could by no means divide morning time from evening. In addition, it was in this way that the efforts of mortals were to be sharpened: only after long contemplation of the sky, devising by their own industry the images and figures of the astra and designating them with names fitted to their understanding, would they, as it were, win the sky for themselves and for all posterity. Finally, that variety, as the experience of the centuries has established, is of the greatest service not only to medicine and agriculture but above all to navigation and astronomy. Ship-masters recognise more clearly from the diversity of the astra that they are in different regions; and astronomers, observing the places of the planets or the moments of time from the altitude or the intervals of the stars, tell star from star by the surest marks, and the likeness of figures does not lead them into error.

V. Who, moreover, were the first to reduce the images of the astra to definite forms of animate or inanimate things — the Egyptians, the Chaldeans or the Greeks? And did they merely smear those images with the honey of fables, so that the young would commit them to memory more gladly, or did they intend, under the covering of those forms as under hieroglyphics, to indicate allegories and various tropologies, or a more secret power of influence upon these lower things? This is not the place to discuss it. I give only this notice about the order of my books. Because the places of the five minor planets cannot be properly observed without the places of the fixed stars, I have decided to place this book before the book on those five Wanderers.

[Margin: Authors who treat the fixed stars before the five planets.]

So too did Ptolemy, in Book 7 of the *Magna Constructio*; Geber [Jābir ibn Aflaḥ], Book 6 of his *Astronomy*; Regiomontanus in the *Epitome of Astronomy*; Copernicus, Book 2 of *De revolutionibus*, from ch. 14; Fracastoro, *Homocentrica*, section 2, from ch. 9; Johannes de Sacrobosco, ch. 1 of the *Sphere*, and Clavius there, from p. 148; Apian, proposition 4 of the *Astronomicum Caesareum*; Tycho, vol. 1 of the *Progymnasmata*, ch. 2 and 3; Longomontanus in the *Astronomia Danica*, Book 2 of the *Sphaerica*, ch. 4 and 5, and Book 1 of the *Theorica*, ch. 2, in the commentary on the fixed stars, and ch. 4, in the catalogue; Kepler, Book 3 of the *Epitome*, *of Astronomy*, and Book 4, part 1; Boulliau, Book 5 of the *Astronomia Philolaica*.

[Margin: Authors who treat the five planets before the fixed stars.]

Granted, some, following the order of the spheres, have delivered their treatment of the fixed stars, or of the motion of the eighth sphere, after the

doctrine of the five minor planets: namely, al-Battānī, ch. 51; al-Farghānī, from *differentia* 18; Peuerbach in the *Theoricae*; Io. Stadius [Johannes Stadius] in the *Canones Bergenses*, in the commentary on the fixed stars; and Biancani in the *Sphaera*, Books 17 and 18. The others who have dealt with the motion of the fixed stars without the minor planets, or have compiled various catalogues, calendars or canons of them, will be listed below in their proper places.

CAPVT II.

Chapter 2.

De Substantia & Qualitatibus Fixarum præsertim de Figura, Lumine ac Scintillatione.

On the Substance and Qualities of the Fixed Stars, Especially on Their Shape, Light and Twinkling.

I. Some things that these share with other stars I touched on in Book 3, ch. 1 and 2. More will have to be said in Book 9, on the System of the World: namely, whether the celestial bodies consist of sublunary matter, of a different matter, or of none; whether the stars are animate, or are moved and directed only by Intelligences that assist them, standing in one place or going around with them, or are moved by their own form though inanimate; again, whether they have been or will be receptacles of souls, when they were created by God, and the like.

[Margin: Opinions of the ancients on the nature of the stars.]

Speaking now of what seems to belong particularly to the fixed stars: if we believe Plutarch, *De placitis philosophorum*, Book 2, ch. 13, Thales held that the stars are ignited earth; Empedocles, ethereal fires fastened to crystal; Anaxagoras, stones snatched from the Earth by the ether, scorched by the vehemence of its revolution and turned into stars; Diogenes, exhalations of the world through holes, as in pumice; Plato, that they are for the greater part of themselves fiery, with an admixture of the other elements; Orpheus, Heraclides and the Pythagoreans, that each star is a world with its own elements; Xenophanes, coals kindled from inflamed clouds.

[Margin: And of the more recent.]

Among the more recent, Iordanus Brunus [Giordano Bruno], in his book *De Infinito & innumerabilibus*, holds that the stars are infinite worlds and as many Suns; and Io. Caramuel [Juan Caramuel y Lobkowitz], Suffragan of Mainz, that the fixed stars are an image of the Sun, replicated by the force of a refraction taking place in the Aplanes. Antonín Maria Šírek reports this in his *Radius Sidereomysticus*, p. 177, and refutes it, on the ground that the Sun, because of the enormous distance of the fixed stars, is a mere bright point relative to them, and insufficient to propagate its image in the eighth sphere. In the same place, however, he thinks it not improbable that the stars are parts of the Empyrean heaven, shining and flaming on all sides, which shine for us through holes

in a lower heaven, or through its more diaphanous parts. Mastri the Scotist, however, in disputation 2 *De caelo*, q. 2, art. 3, thinks this contradicts holy Genesis, which relates that the stars were made on the fourth day as something distinct from the Heaven and were placed in the firmament. But I am weary of these and similar opinions, since they are highly uncertain and have a very tiny spark of probability.

[Margin: Whether stars differ in species.]

Nor can we define with certainty what the Apostle says in 1 Corinthians ch. 15, *Star differs from star in brightness*. Is it to be understood of a merely accidental difference, in the intensity and brightness of their light, since we see in one and the same magnet the power of attracting iron on one face here and of repelling it on another there? Or, as most would have it, of a specific, substantial difference under the same genus? (For Aristotle, *De caelo* Book 2, t. 41, said that they are of the same genus, not of the same species.) This is what the different influences and the majesty and wisdom of the Maker seem to require: that He did not create so many and such vast bodies to no purpose all within one and the same lowest species, but several of them different in species as in power. We might perhaps discern that difference of species more clearly from other accidents, if we could look at them from closer by. As it is, because of the likeness of their light and shape and the uniformity of their motion, we judge them just as if we saw from a very long distance a forest full of various trees, or a ship carrying different living creatures, and, the rays and images being confused, reckoned all of them to be of one kind.

[Margin: Whether there is gravity, levity, penetrability in the fixed stars.]

II. As to qualities: just as you would falsely or rashly attribute gravity or levity to the non-wandering stars, so you would attribute to them still less probably penetrability, which the natural philosophers deny to every body, while the theologians grant it only to the bodies of the blessed, or by force of a miracle — even granted that Petrus Io. Prouenzalis [?] conceded it to the stars in *Quodlibet* 3, q. 7. Nor is there any danger, such as someone might perhaps suspect in the case of the planets, that they strike one another or are worn away by the ether in their very rapid motion, since they are seen to move at an always constant interval, together with the whole eighth sphere. On the fluidity and solidity of the celestial bodies, as on their sound, I shall have to speak in Book 9, on the System of the World.

[Margin: Density, rarity, opacity, diaphaneity.]

Now some density or rarity certainly belongs to the stars, since this is nothing other than a large or small number of parts of substance in the same bulk. There is also some opacity and diaphaneity, since they arrest and bound our sight in such a way that they nonetheless emit light and other influences not from their surface alone but from within themselves.

[Margin: Colour.]

From this comes some colour, at least an intentional one, especially in the nebulous stars or in those reddening like a live coal; many are of this kind, especially Cor Scorpii, Oculus Tauri, Arcturus and Capella.

[Margin: Heat.]

But whether these stars are hot in act, as some say with Telesius [Bernardino Telesio], *De natura rerum*, Book 4, ch. 16, and Cardano, *De subtilitate*, Book 4, or only in power, as the Peripatetics judge from *De caelo* 2, t. 42, is very difficult to establish. What I touched on regarding their fiery nature in Book 3, ch. 1, is however relevant here.

Granted, several sayings of the Church and the Fathers can be understood of a calorific and inflaming force, with no necessity of a heat that is, as they say, formal.

[Margin: The shape of the stars.]

III. The shape of the fixed stars, taken one by one, seems round to those looking from afar. According to Plutarch, *De placitis philosophorum*, Book 2, ch. 14, the Stoics affirmed that they are globular; Cleanthes, that they taper like a turning-post; Anaximenes, that they are like nails fixed in crystal; others, that they are as it were bright foils and plates of pictures, of no great depth. Scheiner, however, in *Apelles post tabulam*, and Antonín Maria Šírek, p. 198 of his *Radius Sidereomysticus*, hold that they are of different shapes, bounded by several faces and angles, with larger telescopes supporting this; yet because of their enormous distance they appear round, with better right than the flames of candles and lamps seen from afar. Granted, the Peripatetics assign them a spherical form on account of the perfection, on one side, of the spherical figure and, on the other, of the celestial bodies, as can be seen in the Coimbra commentators on *De caelo* 2, ch. 5, q. 1; in Rubeus [Antonio Rubio] in the same place, tr. 3, q. 1; and in other interpreters of Aristotle. But if you call them spherical at least physically, though mathematically many-angled and many-sided, like icosahedra or hecatehedra, you will walk a middle path and will not expose yourself to the refutations of the larger telescopes, to which, as Kepler says in the *Epitome of Copernican Astronomy*, p. 497, they appear not round but like bright points darting out rays.

DE LVMINE FIXARVM.

On the Light of the Fixed Stars.

[Margin: Whether the fixed stars have light from themselves or from the Sun.]

IV. Who is so blind as to deny light to so many lights of the sky? But is it received from the Sun, or implanted by nature and God? And is it greater than the light of the planets, or less?

[Margin: The opinion of Metrodorus; of al-Battānī and Witelo.]

All the fixed stars are illuminated by the Sun and receive their light from it, said Metrodorus, as Plutarch reports in *De placitis philosophorum*, Book 2, ch. 17. Al-Battānī, ch. 30, and Witelo, Book 4, prop. 77, thought the same, not only

of the Moon and all the planets but also of the non-wandering stars. Witelo therefore thinks that these change the configuration of their illuminated part from time to time with the motion of the Sun, because of the intersection of the bases of the visual pyramid and the pyramid of illumination, and he says: *And this indeed is more evident in the Moon because of its nearness to our sight; but in all the other stars, which receive their light and the actuality of their light from the Sun or from other stars, the same figures must arise from the three preceding theorems, and according to this the aspects and modes of the celestial influences are diversified. This does not appear visibly, however, in stars other than the Moon, because of their great remoteness from sight, by reason of which error befalls the sight, as is evident by 16 of this book. And so all the other stars besides the Moon are seen as always round, because of their remoteness from the eyes, for which reason a fire remote from the eyes is also seen as round. The same stars, however, when they are at their fullest, are seen sometimes larger, sometimes smaller, which we believe, from the premises, must be ascribed to the smallness of their illumination or to its abundance.*

[Margin: The opinion of Reinhold, Biancani and Scheiner.]

Reinhold subscribes to this in the *Theoricae*, p. 163. Biancani held the same in the *Sphaera*, Book 17, ch. 12, as did Scheiner in the *Disquisitiones Mathematicae*, no. 35, asserting: *If we admit that light flows to the Wanderers from the Sun, there is no reason why we should deny the same to the fixed stars*; and the Coimbra commentators on *De caelo* 2, ch. 7, q. 4.

[Margin: The view of Macrobius.]

Macrobius taught the opposite view, in Book 1 on the *Dream of Scipio*, ch. 19. Placing all the stars except the Moon above the Sun, he says: *A more perceptive observation, however, discovered the better order; and, besides the investigation of sight, this reasoning too commends it: the Moon, which lacks light of its own and borrows from the Sun, must necessarily lie below the source of its light. For this reasoning is what makes the Moon have no light of its own while all the other stars shine with their own, namely that those, being placed above the Sun, are in the very purest ether, in which whatever exists is natural light and its own.*

[Margin: Kepler's earlier opinion.]

Kepler had defended this view in thesis 25 and in the *Optics*, p. 261. There he had rejected those who said that the light of the stars comes from the Sun but passes through diaphanous bodies and is darted out by refraction: for if this were so, that light would pass only along a line diametrical from the Sun, as happens in the tails of comets, and they would not send their very bright rays to us, and would be seen only at a great distance from the Sun, contrary to experience and to Ptolemy's rules on the emersions of the stars from under the Sun's rays. With these arguments, I say, he had taught that all the planets, and especially Venus, have a light of their own and do not shine only with a light communicated by the Sun; I shall report his arguments about Venus in Book 7, ch. 5, no. 1. And he had confirmed this, because among sublunary things too many animate and inanimate things have some small light implanted in them,

and also because brilliance and twinkling argue a light of one's own, while nebulosity and sluggishness argue another's.

Afterwards, however, he read these words in Galileo's *Sidereus Nuncius*, p. 16: *The difference between the appearances of the planets and of the fixed stars also seems worth noting. For the planets present their globes exactly round and circular and, like so many little Moons flooded with light on all sides, appear orbicular; but the fixed stars are by no means seen bounded by a circular periphery, but rather as flashes of a sort, darting rays all around and twinkling a great deal. In the end they appear, with the spyglass [Perspicillum], endowed with a shape just like that which they have when viewed with natural sight, but so much larger that a little star of the fifth or sixth magnitude seems to equal the greatest Dog.* When he had read this, I say, he changed his opinion as regards the planets and speaks as follows in the *Dissertatio cum Nuncio Sidereo*, p. 9: *Another most delightful observation of yours is that of the rayed shape of the fixed stars, differing from the circular shapes of the planets. What else, Galileo, shall we gather from this, than that the fixed stars emit their light from within, while the opaque planets are painted from outside: that is, to use Bruno's words, that the former are Suns, the latter Moons or Earths?*

[Margin: The opinion of Giordano Bruno.]

For Giordano Bruno, in his book *De Infinito & innumerabilibus*, reckoned that the fixed stars are infinite in number, and as many Suns shining of themselves.

[Margin: And of Galileo.]

Galileo himself too, in Dialogue 3 on the World or Cosmic System, says in the person of Salviati: *See further how neatly that most headlong 24-hour motion is removed from the universe, and how the fixed stars, which are so many Suns conforming to our Sun, enjoy perpetual rest.*

[Margin: And of Descartes.]

Add to these Descartes, who in the *Principles* of the new philosophy, part 3, nos. 9, 10, 20 and 23, teaches that all the planets have their light from the Sun, because they are near it, and shine with a duller light; but that the fixed stars shine of themselves and are not smaller than the Sun, because they dart out a lively light, and that between them and Saturn, let alone the Sun, there is a very great interval, and around each one of them a very vast space. Our own Aguilonius [François d'Aguilon] too, in Book 5 of the *Optics*, prop. 81, and before these Cardano, *De subtilitate*, ch. 3, p. 138, affirmed that the fixed stars shine with their own light; indeed Cardano said that all do, even the Moon as regards its secondary light.

[Margin: And the opinion of Antonín Maria Šírek of Rheita.]

Finally Antonín Maria Šírek, p. 177 of his *Radius Sidereomysticus*, says that the Sun is so far from the fixed stars that it is like a point relative to them, and therefore insufficient to illuminate them, or to generate them by the refraction of its image.

The opinion of these men seems far more probable to me too, both because of the reasons brought by Galileo, Kepler and Descartes, and because it better suits the majesty of the divine Craftsman that He should have kindled not

one single star shining of itself, but several, like the Sun, and that they should acknowledge no other source of their light than GOD, the Father of all lights, according to that verse of Baruch 3: *The stars gave light in their watches; they were called, and they said, Here we are; and they shone with gladness for Him who made them.*

I do not know whether from forgetfulness of himself or for some other reason Kepler, as if doubting what he had already affirmed, says in the *Epitome of Copernican Astronomy*, p. 824, that the distance of the fixed stars is so great that the Sun appears to them at most 6‴, adding from this: *It is therefore doubtful to Galileo and to me whether from so great a distance they can receive from the Sun so much light that they reflect it to us; nor therefore do I affirm anything, but they can have it, just as certain animals and gems receive a constant light by a chemical force.*

[Margin: The bold opinion of Leucippus.]

There is no need, moreover, for us to refute Leucippus, who dared to assert that the very light of the Sun was kindled in it by the fixed stars, as Diogenes Laertius testifies in Book 9. But the discussion of the light of the planets will come up again in Book 7, ch. 5.

[Margin: The light of the fixed stars is compared with the light of the planets.]

V. The next question is whether the light of the fixed stars is greater and stronger than the light of the Sun, let alone of the other planets. Scheiner denies it in the *Disquisitiones Mathematicae*, no. 35, stating that the light of the fixed stars is, to us, much weaker than the brilliance of the Wanderers: otherwise these would tremble more than those, because they would be more easily overcome by vapours. He states too that those are mistaken who think that the light of the Dog is livelier than the light of the planets,

for it is whiter, and therefore more effective at moving the sight, but not on that account stronger. He then concludes: *The splendours of all the fixed stars are certainly as if most thinned with water; those of the planets, by contrast, are full of vigour. Who has ever read by the Dog, while one can by Venus?* Comparing the fixed stars with the Sun alone, Kepler says in the *Dissertatio cum Nuncio Sidereo*, p. 9, that *the body of this our Sun is by an inestimable measure brighter than all the fixed stars*, even taken together. For the single Sun, shining through a tiny hole into a closed room, lets you read clearly by that light; whereas all the fixed stars of the whole hemisphere pour so dim a light into the most open places that by its force you cannot see where you are putting your foot. Nor, he says, can this difference be put down to their excessive distance, *because the more distant they are, the greater in diameter than the Sun they are, even singly*. So he says; yet he had related in the *Optics*, p. 263, that in 1601 December he saw the distinct lights of Jupiter and of Spica through the same window on the same white wall. By contrast, Simon Marius in his *Mundus Iovialis* affirms that the fixed stars shine for us more strongly than the planets.

To me, as I said in Book 3, ch. 2, it seems not improbable that, if the fixed stars were as near to us as the Sun, while the Sun either, keeping the distance

it has, were divided into particles no larger in appearance than 2′ or 3′, or were removed as far from the Earth as the fixed stars are in the Copernican or Keplerian hypothesis, very many of the fixed stars would shine as much as the Sun, and conversely the Sun would then shine no more than the fixed stars do now. What moves me is, first, their very ruddy and very lively brilliance, striking our eyes in spite of so great an interval; and second, that the tiny rim of the Sun left immune from eclipse, though greater in length than any fixed star in apparent size, nevertheless does not overcome the darkness, and in spite of it fixed stars have sometimes been seen in the sky in an eclipse of the Sun that was not quite total, as I showed with Kepler in Book 5, ch. 19 and 20. A power united, moreover, is far stronger than the same power dispersed. And granted that they had a true diameter greater than the diameter of the Sun, the excessive distance of the fixed stars nevertheless makes their apparent diameter far too small, and prevents you from reading by the light of the Dog or of Lyra, as you can by the light of nearer Venus, with the light of twilight usually helping. The cause, however, for which the fixed stars, though more resplendent, seem to tremble more than the planets, is neither common to all of them nor drawn from their lesser light in respect of intensity, but is sought elsewhere.

DE SCINTILLATIONE STELLARVM.

On the Twinkling of the Stars.

VI. The twinkling of the stars, which belongs to all the fixed stars but is disputed by some in the case of the planets, has its cause either in the eye itself, or in the medium through which the rays pass, or in the object itself, or in all of these, or in two of them. The opinions of the authors who have written on this matter are therefore reduced to six classes.

[Margin: Opinion 1, attributing the twinkling of the stars to the eye.]

First, then, Aristotle, *De caelo* 2, t. 48 or t. 158, and there many Peripatetics, especially Philaltæus [?] and Amicus [Bartolomeo Amico], tr. 5, q. 7, d. 3, and with them Cardano, *De subtilitate*, attribute it to our sight, trembling and quivering towards distant things. For the Philosopher says, speaking against the rotation of the Sun asserted by some: *Of the stars the Sun alone seems to do this when rising and setting; and it does so not of itself but because of the extending of our sight: for sight stretched out far wavers because of its weakness. This perhaps is the reason why the fixed stars seem to twinkle and the planets not to twinkle. For the planets are near, so that the sight can reach them by its vigour; but towards the fixed stars it trembles because of the distance; and its trembling makes the star seem to move, since it makes no difference whether the sight moves or the thing looked at.*

[Margin: Argument for distance and place among the fixed stars, from twinkling.]

This opinion about the distinction between wandering and non-wandering stars has so prevailed that Copernicus, in Book 1, ch. 10, said: *That there is still a very great distance from Saturn, the highest of the wanderers, to the sphere of the fixed stars is shown by their twinkling lights, the sign by which they are chiefly*

distinguished from the planets. Indeed, Tycho too, vol. 1 of the *Progymnasmata*, ch. 6, p. 401, confirms from its continuous and great twinkling that the new star which appeared in Cassiopeia in the year 1572 was in the sphere of the fixed stars, saying: *Its outstanding twinkling, moreover, flashing beyond the other lights of the sky, showed most openly of all that it had chosen its place within the supreme and most vast region of the fixed stars, and had surmounted the revolutions of all the planets, let alone the lowest, elementary World.* And on p. 401: *It will have to be admitted, rightly and without any evasion, that this New star, since by a continuous twinkling, persisting as long as it could be seen, it not only imitated the fixed stars but also, especially at the start, surpassed them in this vibration of light, was not within those limits of the sky in which the revolutions of the seven planets are contained, but stood among the remotest non-wandering stars.* By a similar sign Kepler, in his book on the new star seen in the foot of Serpentarius in the year 1604, ch. 17, counts it among the fixed stars, but arguing *ad hominem* against the Aristotelians.

[Margin: Opinion 2, attributing twinkling to the medium and to restless vapours.]

Second, however, most writers on optics ascribe this to the medium through which the rays and images of the stars pass: especially Witelo, Book 10, prop. 55; Scheiner in the *Disquisitiones Mathematicae*, nos. 34 and 35; Io. Baptista Benedictus [Giovanni Battista Benedetti] in his disputation against Aristotle, ch. 21; and with them Biancani in the *Sphaera*, Book 17, ch. 12, and Bettini in *Apiarium* 8, Prog. and prop. 4. For the images of the stars formed on the convex surface of our atmosphere, they say, are spread apart and pulled asunder when the corpuscles of air and fire are moved up and down by force of levity and gravity, and around in a circle with the motion of the sky, because their continuous passage is interrupted, the rays of the more remote stars being unable to overcome and penetrate the density and opacity of the vapours. So all the fixed stars twinkle, and always; but the planets, whose rays, stronger because of their nearness, penetrate the vapours, do not twinkle except when thicker and watery vapours run between.

They confirm this, first, because the twinkling of the stars is greater near the horizon, where the vapours are more numerous and thicker, and greater in humid or windy weather, because of the greater thickness or agitation of those vapours. Second, they confirm it from the likeness of the image of the stars on the surface of running water, which seems to twinkle because of that rippling and tremulous quivering, as Witelo says; or of pebbles on the bottom of a brook, in which the fleeing water labours to tremble over the rough places, for their image too trembles from this, says Biancani; or of the bright image of the Sun, received on a small board, through the smoke of a chimney or dust raised upwards; or reflected from the gilded balls of towers when they are wet with dew, or with vapours and small clouds running between: for in the former case the image appears to tremble, in the latter those balls seem to leap this way and that, or up and down, says Scheiner. His conclusion in the end,

at no. 35, is this: *The twinkling of the stars is the one and only interruption of the images that have fallen into the eye, made by the restless running-between of vapours variously affected.* He explains this, however, in two ways: either by alternating refraction, by which denser but diaphanous vapours, refracting the rays of the stars, make the images more brilliant; or by the alternating obstruction which they interpose by their opacity to the transmission of the rays, especially from smaller stars or those radiating from a greater distance. From this, he thinks, the reason is given why all stars twinkle, but more so the fixed stars, the more northerly, those nearer the horizon, and in more humid weather; why they flicker with an irregular and disordered motion; and why Canis Major, viewed through a convex glass, seems to be almost wholly extinguished or stifled, and suddenly kindled whole. Finally he adds: *And the planets indeed all twinkle: with an agitation, though a gentle one, Saturn most, Jupiter little; with flashing, Jupiter much, Saturn virtually not at all; Mars most and violently, especially at apogee; Venus at apogee and perigee, less at mean distance; Mercury always; the Moon more rarely, as also the Sun, so far as it can be noted by the senses without a telescope.*

[Margin: Opinion 3, embracing more or less the two preceding.]

Third, the Coimbra commentators, on *De caelo* 2, ch. 8, q. 1, art. 1, ascribe this effect both to the weakness of the visual power towards distant things, because the images of the more remote stars at length give out and scarcely move the sense, and to vapours scattering the images. And they admit, with Simplicius, that some planets twinkle, especially Mercury. Yet the fixed stars move our sight far more strongly than many sublunary objects, even though those are nearer.

[Margin: Opinion 4, attributing twinkling to the stars themselves.]

Fourth, Giordano Bruno, in *De maximo & immenso*, Book 4, ch. 8, refers twinkling to the stars themselves, which, as Plato held, move about their own centre, so that their image seems to hop. Yet he says that Mars twinkles moderately because it shines with another's light; and that the Sun, if

it stood far off, would appear to twinkle because of its rotation. François d'Aguilon too, in *Optics*, Book 5, prop. 81, attributes twinkling to a very swift whirling [raptui], greater in some stars than in others, by which the stars, moved in their own cavities, turn towards us, in a reciprocal disparity, parts now brighter and now darker. In the same place, however, he rejects those who say that it comes from the speed of the diurnal motion, which very rapidly shifts the broken rays. For if this were the cause, the planets too would twinkle, and the fixed stars nearest the Pole of the World would not sparkle, because that motion is slow there. Raffaele Aversa approves Aguilon's opinion, *De caelo*, question 34, sect. 3, but he adds another probable cause, namely a mixture of opacity with diaphaneity in the very body of the stars, because of which the light is propagated irregularly to us from the innermost parts of the stars through the outermost, so that they appear to glow red.

[Margin: Opinion 5, attributing twinkling both to the stars themselves and to vapours.]

Fifth, twinkling is ascribed both to the stars themselves and to intervening vapours by Tycho, Vol. 1 of the *Progymnasmata*, ch. 6, from p. 402; by Kepler in *Astronomia Optica*, ch. 6, no. 12, in the book *De Stella Nova*, ch. 18, and in the *Epitome of Copernican Astronomy*, p. 825; and by Bartolomeo Mastri, Disp. 2 of *De caelo*, q. 5, from no. 163. Tycho grants that the planets do sometimes twinkle, but rarely and incidentally: Mercury and Venus most of all, Mars hardly at all, and Saturn least. Yet if Witelo's reasoning held, Saturn, being more remote, would have weaker rays and would twinkle more. Tycho adds that Sirius strikes our eyes with a stronger light than Mars, and so overcomes the vapours, and yet twinkles the most of all the other fixed stars. He further adds that the twinkling of both fixed stars and planets is assisted by the perpetual but varying agitation of the interposed air; but that the essential cause why the fixed stars twinkle, with a perpetual and continuous vibration of their light that is yet greater or smaller, is probably their revolution about their own centre, faster or slower, which the planets lack, and because of which the images of the fixed stars appear to spread apart.

Mastri, though he grants with Simon Marius that Mercury twinkles more than Saturn, and therefore rejects the view of Aristotle and Witelo, nevertheless recognizes the cause of twinkling as being incidentally from vapours and essentially from revolution about the star's own centre, subscribing to Aguilon and Aversa.

Finally, Kepler says in the *Epitome* that this happens either from a trembling due to intervening vapours, or from an internal alteration, as if from a paroxysm, or from the revolution of stars that display different angles, or colours or spots, one after another on their external surface. In the *Optics*, however, p. 262, he affirms that Sirius sparkles longer and more sharply than Arcturus, the Heart of the Scorpion more quickly than the Eye of the Bull, and that Venus, even in the clearest sky and the coldest air, twinkles and undulates most excitedly with a real twinkling, that is, either from a perpetual internal alteration of the body, as if in a paroxysm, or from revolution, with one part displayed after another. Lastly, in the book *De Stella Nova*, ch. 18, examining Scaliger, although he appears either to approve all Scaliger's reasons or to draw them to his own opinion, he nevertheless declares that he remains in the opinion given in the *Optics*: namely, that it arises from a motion either of the light in the body of the star or of the body of the star itself as it revolves. That is, it arises either from a reciprocal production of light through the diaphanous body of the star, from the centre sparkling like a heart, or from a turning such as there would be in a diamond, which, rolled about its own centre, would flash as it displayed different faces and angles.

He adds that all the fixed stars probably move about their own centre, and indeed all the planets as well, however remote, so that they may share with their whole surface in the life-giving rays of the Sun. The Moon is the exception, yet it is wholly illuminated by the Sun, part after part, through its own monthly turning about the Earth. He teaches moreover that twinkling belongs to Venus

and Mercury, obscurely to Mars, and not at all to Jupiter and Saturn; and that incidentally these planets and the fixed stars sparkle more when winds blow, or in moist air, or near the horizon, because of vapours or fumes disturbing and obstructing the continuous propagation of the rays. But distance alone, in itself, contributes nothing to twinkling, since the nearer planets twinkle; nor does the motion of the diurnal carrying-round, for otherwise Saturn and Jupiter would twinkle, and indeed more than Venus and Mercury, because they move faster in the diurnal motion.

[Margin: Opinion 6, coalescing from nearly all the others.]

Sixth and last, Scaliger, in Exercise 63, touches on and heaps together nearly all the causes already mentioned, but chiefly the motion of the air, the motion of the light in the star, and the motion of the star in itself, adding the size and brightness of the luminous body. For this reason, he says, larger and brighter stars twinkle more, other things being equal; and Kepler testifies that this happened in the new star when it appeared larger.

[Margin: The author's opinion.]

7. Although almost nothing is left for me to add to the opinions and modes already mentioned, and although the fifth and sixth seem more probable than the others, I add this: not only the vapours and exhalations of our atmosphere assist twinkling, but also the tiny particles of dust and fibres that fly about perpetually through the air, because of the continual fluctuation of the air. For when the air is moved in one part by winds in some region, it necessarily moves in to take its place in one part after another. In the Church of San Petronio in Bologna, when I was receiving the image of the Sun on a board, transmitted through an opening more than 170 feet from the board (on which see Book 3, ch. 14, no. 3), I observed that the image flitted about with a very rapid motion but with an immense and most manifest tremor, because of the restless fluctuation of those atoms, evidently boiling up in wonderful vortices in the Sun's ray. Fathers Francesco Maria Grimaldi, Zenus and others observed the same with me.

I say moreover that a complete rotation of the stars does not seem necessary; a libration or oscillation of them is enough. Further, if it seemed to Tycho that twinkling can be attributed to the rotation of the stars, then it is not an evident sign for placing a star among the fixed stars; for that rotation could coexist with a new star, even one placed in the region of the planets or in the sublunary region. Finally, if anyone were to admit the alternating nutation of discrete motion, of which I shall speak in ch. 18, no. 16, he would have a not improbable cause of twinkling.

SCHOLIA.

Scholia.

[Margin: On the density of the fixed stars.]

1. In Dialogue 1 of the *Cosmic System*, Galileo thinks that the fixed stars are nothing other than a denser part of their orb or heaven, which Suárez, in *De Opere sex dierum*, and many others also thought. His inference from this, that the density of the fixed stars exceeds almost infinitely the density of all the rest of the heaven, is indeed like Kepler's assertion about the Sun containing more matter than the whole aethereal air contains, of which we spoke in Book 3, ch. 2, no. 4. But I am not satisfied with Galileo's reason, which is, he says, that the heaven is supremely transparent and the stars supremely opaque. For it is uncertain whether the stars are supremely opaque, since not a few grant that they are partly diaphanous, as was said above in reporting the 4th and 5th opinions. And an increase of opacity does not necessarily bring with it an increase of density, since smoke or clouds or writing ink are more opaque than crystal, and yet not denser.

[Margin: On fixed stars viewed through glasses.]

2. Scheiner teaches in the *Disquisitiones Mathematicae*, no. 35, that if the images of the stars are received through a convex glass, the eye sees both a successive variety of colours and certain gaps and black openings between the bright parts. These effects, he says, come from the glasses, as Simon Marius said, when they too rotate and change position with the rotation of the glass; otherwise they come from the humours of the eye, or from droplets illuminated in the eye.

[Margin: On the colours of the stars.]

3. As to the colours of the fixed stars and planets, Kepler in *Astronomia Optica*, ch. 6, p. 261, says that if a black surface is strongly illuminated, it gives the colour of Mars; if a clear red one, of Jupiter; if a leaden or white one, of Saturn; if a yellow one, of Venus; if a blue one, of Mercury. In the Dog and Arcturus the colours of the rainbow are seen, in Lyra none, in the Heart of the Scorpion and the Eye of the Bull red. But these do not appear so evidently to every eye or at every time.

CAPVT III.

Chapter 3.

De Aſtrorum quæ ſunt in Zodiaco Forma, Numero Stellarum illa componentium, cum ſummula Fabellarum, & varia eruditione.

On the Form of the Constellations in the Zodiac and the Number of Stars Composing Them, with a Short Summary of the Fables and Various Learning.

[Margin: Authors from whom this chapter and the two following are drawn.]

1. The forms or images of the constellations are handed down, or expounded, or both, by Aratus in the *Phaenomena*, and there by Hyginus, Cicero, Germanicus Bassus and Rufus Festus

Avienus. After these come Vitruvius, Book 9, ch. 6 and 7; Marcus Manilius, Book 1 of the *Astronomica* [Aſtronomicōn], ch. 4; Julius Firmicus, Book 8,

from ch. 5 to 32, who adds the apotelesmata and the meanings of what they portend; Ptolemy, *Quadripartitum*, Book 1, ch. 9; Martianus Capella, *De Nuptiis Philologiae*, Book 8; St Isidore, *Origins*, Book 3, at the end; Bede, at the end of Vol. 1, in the opuscule *De Stellis & Signis*; Johannes Stöffler on the *Sphere* of Proclus, from p. 80, together with Proclus; the Arab Azophi [al-Ṣūfī] in his *Catalogue of Stars*; Peter Apian in the *Astronomicum Caesareum*, enunciation 4; Alessandro Piccolomini, after his *Sphere*, in the book *De Stellis Fixis*; Francesco Giuntini in the compendium *De Stellarum Fixarum observationibus*; David Origanus, Vol. 1 of the *Ephemerides*, part 3, ch. 2; Johannes Stadius in his commentary *De Stellis Fixis*; Johann Bayer Rhenanus in his *Uranometria*, made illustrious by its most beautiful engravings of the constellations; Christoph Grienberger in the catalogue of fixed stars with their diagrams; and the Persian Tables of al-Ṣūfī or Ebennensophi, in Boulliau, Book 5, ch. 3, and at the end of the *Philolaic Tables*.

✢ To these add, for the fables or histories, the *Mythologies* of Palaephatus, Fulgentius and Natalis Comes [Natale Conti], the *Dictionarium Poeticum* of Carolus Stephanus [Charles Estienne], and the interpreters of Ovid's *Fasti*. ✢ For the images, add the star globes made according to the mind of Tycho, or of the more distinguished navigators, published by Petrus Theodori [Pieter Dirkszoon Keyser], Jodocus Hondius, Willem Blaeu [Gulielmo Ianſonio], Jacob Floris van Langren, Jakob Bartsch [Iacobo Barſthio] and Frederick de Houtman [Friderico Houthmanno], to whom we owe very many southern stars observed on the island of Sumatra. The others, who compiled bare catalogues of the longitudes, latitudes, declinations, right ascensions, mediations of the heaven, and risings and settings of the fixed stars, do not belong here, but will be reviewed below in their own places. ✢ The astrological properties are reported by Ptolemy, Firmicus, Giuntini and Origanus in the places already named; but they are for the most part empty and utterly deceptive.

2. I have decided, therefore, to put the constellations of the zodiac first, which Manilius, Book 1, ch. 4, has gathered very elegantly in these verses:

> *Aries, the leader, shining in his gilded fleece, looks back in wonder at Taurus rising opposite, who with lowered face and brow calls to the Gemini. Cancer follows them, Leo Cancer, Virgo Leo. Then Libra, when day is equal to the time of night, draws on Scorpio, shining with his burning star, at whose tail he that is mixed with a horse aims his bent bow, now about to let fly a winged arrow. Then comes Capricorn, bent in his narrow constellation; after him Aquarius pours out his tilted urn into the accustomed waters, which Pisces eagerly enter; and these, closing the last of the signs, Aries touches.*

No less elegantly Plutarch, *De placitis philosophorum*, Book 1, ch. 7, has enclosed the zodiac in these verses, beginning from Cancer:

> *Cancer is in it, after this Leo, Virgo, then the Claws, Scorpio, the Archer, Capricorn; the pourer of water after these, the two bright constellations the Fishes; next Aries; Taurus follows, and the twin brothers.*

But Ausonius does it more briefly in the *Eclogarium*:

> *Here Aries, Taurus, Gemini, Cancer, Leo, Virgo, and Libra, Scorpio, the Archer, Capricorn, and he who holds the urn, and Pisces.*

The same Manilius, following the view of the Pythagoreans, on which see Ficino, *Platonic Theology*, Book 4, assigns to the twelve constellations or signs of the zodiac their own deities, singing in Book 2, ch. 11:

> *Pallas protects the wool-bearer; Cytherea protects Taurus; Phoebus the handsome Gemini, the Cyllenian Cancer; Jupiter himself, with the mother of the gods, rules Leo; Virgo is corn-bearing Ceres', and Libra, once fashioned, Vulcan's; warlike Scorpio clings to Mars; Diana cherishes the hunter, a man, yet of equine part; and Vesta fosters the narrow constellation of Capricorn; but Aquarius, opposite Jupiter, is Juno's star, and Neptune acknowledges his own Pisces in the sea.*

Ptolemy reports, *Quadripartitum*, Book 1, ch. 9, which planets' nature they share. The same Manilius, Book 2, ch. 13, teaches over which members these, or the twelve signs, preside: Aries over the head, Taurus the neck, Gemini the arms and shoulders, Cancer the chest, Leo the flanks and shoulder-blades, Virgo the loins, Libra the buttocks, Scorpio the groin, Sagittarius the thighs, Capricorn the knees, Aquarius the shins, Pisces the feet. As for the astrological fictions, on which see Ptolemy, Firmicus, Manilius, Giuntini and Origanus above, I am more ashamed than reluctant to report them.

ASTRA ZODIACI.

The Constellations of the Zodiac.

[Margin: The order of the constellations of the zodiac.]

[Margin: 1. Aries.]

3. Aries, the first of the constellations, is called [Greek: Κριος (krios, "ram")] Chrysomallus, Vervex [the Wether], Jupiter Ammon and Arietinum caput [Ram's Head]; in Arabic, Hammel, or with the article Elhammel. According to Ptolemy it consists of 13 stars, with 4 unformed; but according to Bayer of 19, among which three are of the third magnitude, two in the western horn and one in the eastern, called in Hebrew Sartai, Mesarthim. The star in the eastern horn, above the crown of Aries, however, seems to be of the second rather than the third magnitude, or midway between them. This star Tycho calls the principal and bright star above the head of Aries, and he preferred to begin from it the distances of the others in longitude, as from a more certain starting point, as is evident from Vol. 1 of the *Progymnasmata*, pp. 194 and 226. Copernicus, granted, in Book 2, ch. 14, reckoned the longitudes of the fixed stars not from the vernal section, which he thought irregularly movable, but from the first star, the one in the head of Aries, that is, from the westernmost in the horn.

The position of the first star of Aries in Ptolemy is not so certain, however, since he puts 170° from it to Spica and 115° 50′ to Regulus, whereas Tycho found

170° 39′ to Spica and 116° 40′ to Regulus. Now the bright star in the northern horn of Aries, or above its head, in the year 1600 stood 32° 6′ from the point of the vernal equinox, as Kepler gathers from Tycho in the Rudolphine Tables; but the first star, in the southern and western horn, stood, by the same source, 27° 37′. So Kepler rightly warns in the same place that anyone wishing to compare Tycho's longitudes of the fixed stars with Copernicus's must compare them with the southern and western star, from which Copernicus began.

[Margin: When the first star of Aries was at the beginning of the zodiac.]

Now if the first star of Aries was, in the year of Christ 1600, 27° 37′ east of the vernal section, this star would have been in the vernal section, or in the equinoctial colure (for it has a northern latitude of 7° 8′), in the year 349 before Christ by Tycho's reckoning, but by mine in 388. Govaert Wendelen, however, in Petavius [apud Petauium], Book 2 of the dissertations of the *Uranologion*, ch. 4, judges that in the year 1263 before Christ the first star of Aries preceded the vernal section by 15°; on this see Pétau's verdict in the same place.

[Margin: The fable of Aries.]

The reason for placing Aries in the heaven is sung to have been this. Ino, daughter of Cadmus and second wife of Athamas the Theban in place of the deceased Nephele, pursued with a stepmother's hatred Phryxus and Helle, the children of Athamas and Nephele. When she had given the farmers roasted seed so that it would not sprout, a great dearth of grain followed. A messenger sent for this reason to the Delphic oracle, bribed by Ino, reported that Phryxus and Helle must be sacrificed. As they stood at the altar with veiled heads, on the very point of being slaughtered, Nephele appeared over them, wrapped them in a cloud and snatched them away, and set them on a ram with a golden fleece so that they might escape. Helle fell from it into the Pontus and gave that sea the name of Hellespont. Phryxus, unharmed, reached Aeetes, king of Pontus, and after sacrificing that ram to Jupiter the Preserver, fastened the golden hide to the temple. For this reason Jupiter raised that ram to heaven. No wonder if it shines with few stars, since it left its golden fleece on earth; so Rufus Festus playfully jests, singing of it:

> *But though you may follow it in vain with your eyes through the aether,*
> *for it always lacks fires of its own, etc.*

Ovid writes elegantly of this fable in *Fasti* 3, but Hyginus tells it differently, where he treats of Jupiter Ammon; consult him.

[Margin: 2. Taurus.]

4. Taurus, the second constellation of the zodiac, is called [Greek: ταῦρος (tauros, "bull")], Bos [the Ox], Io, Isis, and in Arabic Ataur. Because of its bent knees Aratus calls it [Greek: πεπτηκῶτα (peptēkōta, "crouching")]. According to Ptolemy it consists of 33 stars with 11 unformed, that is, 44; but according to Bayer of 48, and according to Kepler, with the semi-Tychonic stars, of 52. Among these there is a single star of the first magnitude, in the southern eye of Taurus, called by the Greeks [Greek: λαμπαδίας (lampadias, "torch-like")], by Ptolemy [Greek: ὑπόκιρρος

(hypokirrhos, "somewhat tawny")], by the Arabs Aldebaran, that is, the ruling star, and also Atin Elthaur, that is, the eye of Taurus; by the Egyptians [Greek: πιώριων (piōriōn)], that is, the station or dominion of Horus, which the Sun, of course, exercises when in conjunction with this star; and by the Romans Palilicium, because it once rose at Rome on April 21 [XI.Kal.Maij], the day on which the Palilia, that is, the festival of Pales, the holiday of the shepherds and the birthday of the City, were celebrated, according to Varro, Book 5; Ovid, *Fasti* 4; and Pliny the Elder, Book 18, ch. 26. After this one the notable star is the one in the northern horn, of the second magnitude.

[Margin: The fable of Taurus.]

Taurus, moreover, is feigned to have been raised to heaven by Jupiter because, sailing to Sidon in a ship marked with the form of a bull, he carried off Europa, daughter of Agenor, as she played near the temple of Aesculapius, and took her away to Crete. From this comes the fable of Jupiter turned into a bull, on which see Ovid, *Fasti* 5, and, somewhat differently, Hyginus in the *Poetic Astronomy*. For some say that this constellation is Io, or Isis, turned into a cow by Juno and raised to heaven by Jupiter; and for this reason, or because its hinder parts are lacking, Ovid sang:

Whether it is a cow or a bull is not easy to discern: the front part shows, the hinder parts lie hidden. But whether it is a bull, or a female in this sign, against Juno's will it has this as love's reward.

[Margin: The Hyades and their little fable.]

The Hyades, of which Palilicium is one, are seven stars on the head of Taurus, two at the outgrowth of the horns and 5 on the face. They are called Hyades and Succulae, from [Greek: ἀπὸ τοῦ ὕειν (apo tou hyein, "from raining")], which means to rain, because at their cosmical rising they bring on rains and moisture; or because they imitate the gaping mouth of a pig, for in Greek pigs are [Greek: ὗες (hyes, "pigs")], and hence Suculae; or, as Bassus prefers, from the Greek letter [Greek: υ (hy, upsilon)], which they imitate; or because, born of Atlas and Hya, daughter of Oceanus, and weeping for their brother Hyas, killed by a lion in the hunt, they were raised to heaven for the sake of piety and solace and placed partly on the face of Taurus, partly at the beginnings of the horns. As Hyginus and Cicero, *De Natura Deorum* 2, report, the sisters of Hyas were Ambrosia, Eudora, Phesile, Coronis, Polixo, Phileto or Phaeo, and Thyene. Of them Ovid writes, *Fasti*, Book 5:

The face of Taurus gleams, radiant with seven flames, which the Greek sailor calls Hyades from the rain.

And in Book 6:

The next day calls forth the Hyades, the horns of the bull's brow, and the earth grows wet with much water.

Job too mentions them, ch. 9, v. 9, saying: *Who makes Arcturus and Orion, and the Hyades, and the inner parts of the South.* In Hebrew the Hyades are here called Kimah; and because among certain Hebraists that name means a

constellation made up of seven stars, as Pineda [Juan de Pineda] teaches on this passage, some refer it to the wagons of the Bears, others to the Pleiades. But the Vulgate better has Hyades. For when Job had said of God: *Who commands the Sun and it does not rise, and seals up the stars as under a seal; who alone stretches out the heavens and walks upon the waves of the sea*, describing his power in stirring up and calming storms and tempests, he adds: *Who makes Arcturus and Orion and the Hyades*, namely three constellations that are very stormy and the most tempestuous of all, rainy, gloomy and unclear. So Pliny the Elder, Book 2, ch. 39, calls the name of the Suculae rainy, and Book 18, ch. 26, stormy. For the tropological meaning of that passage, see Saints Gregory and Thomas Aquinas on that place in Job. Stöffler has more on these stars, and learnedly, on Proclus, p. 96.

[Margin: Whether the Pleiades are 7, and their little fable.]

The Pleiades too, on the back of Taurus, called Septistellium and the Huckster's Garment [Veſtis inſtitoris], are seven stars. They are called Vergiliae from the end of spring, when they once rose; in Arabic not Athoraie or Atarage but Altorieh or Benat Elnaásch, that is, the daughters of the assembly. The Egyptians call them [Greek: ἑξάστρον (hexastron)], that is, the constellation of six stars; the Hebrews call them Succoth Benoth, that is, the daughters of the tabernacle. In German they are Bruthean, in English Butrio, that is, a hen brooding her chicks, popularly the hen's brood [maſſa gallinæ]; to the Italians la Gallinella; to the Greeks [Greek: πλειάδες ἀπὸ τοῦ πλεῖν (pleiades apo tou plein, "Pleiades, from sailing")], because at their rising they show the time for sailing; or from their mother Plione, who bore them to Atlas. There are seven in Aratus and Hipparchus, but six in Attalus and Geminus, because one of them is rather nebulous and is hard to distinguish from the others. Hence Ovid's line, *Fasti* 3:

Which are usually called seven, yet are six.

For it is said in the fables that they were placed in the heaven because they had been the nurses of Jupiter or of Bacchus, and that their names were: Maia, the mother of Mercury, the brightest in the quadrilateral and of third rank; Sterope, Taygeta and Celeno, who form the quadrilateral; then Electra, Merope and Alcinoe. Among these, it is said, Electra after the burning of Troy refused to lead the dances with the others any longer, and therefore hides and scarcely appears. Others in Hyginus say that the one that hides is Merope, because she married a mortal man, Sisyphus, whereas the rest married immortal gods: Electra, Maia and Taygete married Jupiter, Sterope Mars, Alcinoe and Celeno Neptune.

But Michael Florent van Langren observed their exact figure and sent it to me; in it are added two stars unnamed by others, which he himself calls Atlas and Pleione. I do not know whether they are the ones that Wendelen says are observed as new because they appear at one time and hide at another. Viewed by telescope, however, more than 40 appeared to Galileo, as is told in the *Sidereus Nuncius*, and more than 50 to Father Zupi of our Society with a

Fontana telescope, and about as many appeared to us too. Pétau gives more, and learnedly, on the rising and setting of the Vergiliae in the *Uranologion*, Book 2 of the dissertations, ch. 9 and 10. For although these stars are small and occupy a small space, namely a single degree in longitude and 37½′ in latitude, they nevertheless have been and are indicators of great things. And rightly Aratus sings, in Cicero's translation:

[Margin: Notable points on the rising and setting of the Vergiliae.]

> *…placed in a small part, you will see the Vergiliae with a faint light. These faint ones shine, gliding with a small light; yet the name of the sign is great and is called famous, because they make bright the beginnings of summer, and afterwards, spreading their rising in the winter season, they warn mortals to entrust seeds to the lands.*

But Festus Avienus distinguishes the morning rising and setting more expressly, thus:

> *For if the Vergiliae lift themselves from the deep, it is the days for plying curved sickles on the yellow fallows; if they hide their flames in the sea, it is the time to break the earth with the pressed plough.*

Understand here, with Pétau, the morning rising, though the heliacal one, and the cosmical setting, because of those verses of Hesiod, Book 2 of the *Works* [Greek: ἔργων (ergōn, "of the Works")]:

> *When the Pleiades, born of Atlas, are rising, begin the harvest; but the ploughing when they are setting. These indeed for forty nights and days are hidden; but again, as the year turns round, they appear, as soon as the iron is sharpened.*

For in Hesiod's age, between the heliacal setting of the first or westernmost of the Pleiades and the heliacal rising of the same star or of the bright star of the Pleiades, that is, from about the beginning of Aries to 11° of Taurus, 40 days intervened; and at that same time the bright star of the Pleiades rose heliacally on May 11, but the last of the Pleiades on May 16, which was harvest time in Greece. Virgil's passage in *Georgics* 1, however,

> *Let the Eoan Atlantides hide from you, and the Cnossian star of the burning Crown depart, before you entrust the due seeds to the furrows, etc.,*

must be understood of the morning cosmical setting, not the heliacal, as Servius ignorantly thought, as if the Vergiliae were in Scorpio, where the Sun is in November, when it is time for sowing. Virgil, *Georgics* 4, on bees, also marks two times for gathering honey, one after the morning rising of the Pleiades, at the end of spring, the other after the morning setting, at the start of autumn:

> *Twice they gather the heavy produce: two times of harvest: as soon as Taygete the Pleiad shows the earth her comely face and with her foot has spurned the scorned streams of Ocean, or when the same, fleeing the constellation, etc.*

But Pétau, in that ch. 8 and 9, supplies far more, and corrects many writers who are false or obscure on the rising and setting of the Vergiliae. See also Stöffler on Proclus, p. 95.

[Margin: What are the Pleiades in Sacred Scripture?]

It remains to explain that saying of God to Job, ch. 38, v. 31: *Will you be able to join the sparkling stars, the Pleiades, or will you be able to scatter the circuit of Arcturus?* In Hebrew Arcturus is here called Chesil, of which we shall speak in ch. 4, no. 5. The Pleiades are here called Chimà or Kimà, which among Hebraists means Septistellium, that is, the knot and binding of seven stars; granted that Pineda here thinks that the Pleiades are stormy, and suspects that the Greek Chimà, which means winter or storm, is derived from this original name Chimà. But Pagninus [Sante Pagnini] translates: *Will you be able to bind the delicate fruits of the Vergiliae, or will you make the late fruits of Orion open?* The Tigurine version has it thus: *Will you hold back the delights of the Pleiades, or open the contractions of Orion?* In the same place, however, Vatablus [François Vatable] and the Royal Bible [Regia] translate *the delights of the Pleiades*; for in Hebrew it is Ghadanoth, from Ghadan, which means to delight. It is as if God were saying that no one can prevent, at the end of spring, about the rising of the Pleiades, the flowers and the first yield of fruit and grain from coming to birth; or can bring it about that in the autumn season, about the rising of Orion, the earth and the plants open for bearing fruit. The Septuagint, however, translates thus: *Have you understood the bond of the Pleiad?* On this passage Olympiodorus interprets most aptly as follows: *That chain, so to speak, and that fitting together of the stars which the Pleiades make up: is it the work of your wisdom and understanding? Or do you hold the reason why those same stars cohere so aptly with one another?* For, as St Gregory adds in the same place: *They were founded so near to one another and yet so divided, that they are both together and yet can in no way be joined.* That is why Seneca aptly said in the *Medea*, chorus of Act 1, *the dense flocks of the Pleiades*, and Manilius calls them *Sidus glomerabile*, a star-group massed like a ball. For this reason the Complutensians, Caietanus [Cajetan] and others, in Pineda on this passage, read: *Will you gather, or bind, the chains or the applications of the Pleiades?* as though deriving *Ghadanoth*, by transposition, from *Ghanad*, which means "I surround" or "I bind". But what would they have said if they had known that in so narrow a space, which is scarcely 85′, more than 40 stars have been divinely gathered, as the telescope has revealed?

[Margin: 3. Gemini.]

5. GEMINI, the third constellation of the Zodiac, Δίδυμοι [Greek: Didymoi, "the Twins"], or the Tyndaridae, or the Ledaean youths, or the Spartan offspring, or the Dioscuri, namely Castor and Pollux, as Hyginus has it; or Apollo in the preceding head and Hercules in the following one, as Varro thinks; or Triptolemus and Iasion, as others in Hyginus have it; or Amphion and Zethus, or the Samothracian gods, as others in Bayer have it. The preceding head of Gemini, namely Castor or Apollo, is called in

Arabic *Ras Algeuze* or rather *Ràs Elgiautze*, and, by a corrupted Greek name, *Apullùn*; in Chaldean *Anhelar*. The following head, namely Pollux or Hercules, is in Chaldean *Abrachaleus* or, by a corrupted name, *Garacles*, but better *Elhenaat* or *Ketpholtsumman*, that is, the shoulders. Both stars, of the second magnitude, are called by the Arabs by the common name *Elhakaach*. There is likewise a star of the second magnitude at the top of Pollux's left foot, which Proclus and most others call πρόπους [Greek: propous, "forefoot"], although Bassus and Hyginus call it πρόπος [Greek: propos], because it is nearest to Cancer and to the summer turning. This constellation consists of 25 stars according to Ptolemy, counting 7 unformed, but of 30 according to Kepler and 33 according to Bayer.

[Margin: The tale of the Twins.]

The little tale of the Twins, from Ovid, *Fasti* 5, and others, is this. Jupiter, taking the form of a swan, lay with Leda, the daughter of Cebalus and wife of Tyndareus. She laid an egg, from which were born Castor, Pollux and Helen. Castor and Pollux were bound to each other by such goodwill and concord that they never contended over rule and did nothing without common counsel. Indeed, as Homer, Hyginus and Lactantius say, when Castor was killed in the war of the Lacedaemonians against the Athenians, or when Lynceus and Idas were attacking Sparta, Pollux obtained from Jupiter that he might grant half of his life to his brother, so that they lived on alternate days; according to that passage of Virgil, *Aeneid* 6:

If Pollux ransomed his brother by alternate death, And goes and returns along the road so many times.

Therefore, as a monument of this devotion and brotherly friendship, Jupiter raised them into the heavens, where they shine in a mutual embrace, and indeed on alternate days, as Homer imagines and Hyginus relates. Hyginus adds that Neptune gave them horses and the power to calm storms and prevent shipwrecks.

[Margin: The flames of the Twins, salutary to sailors.]

For, on the testimony of Porphyrio, when they show themselves to sailors they offer hope of safety; for those twin flames that kindle about the yards during storms were taken to be Castor and Pollux. For as Pliny the Elder says, book 2, ch. 37, *they are grievous when they have come singly, and sink ships, and if they fall into the lowest part of the keel they burn them up; but twin ones are salutary and heralds of a prosperous voyage, at whose coming, they say, that dread and threatening one, called Helen, is put to flight; and for that reason they assign this divinity to Pollux and Castor and invoke them as gods at sea. The heads of men too shine round about in the evening hours, with great portent. All this for an uncertain reason, and hidden in the majesty of nature.* So sailors thought a single flame was Helen, the occasion of the burning of Troy, and unlucky for sailors, and a twin flame salutary. And Seneca, in the *Natural Questions*: *In a great storm they appear like stars settling on the sail; those in danger then believe that they are helped by the*

divinity of Pollux and Castor. Horace too mentions them, praying for a fortunate voyage for Virgil, book 1, Ode 3:

So may the goddess who rules Cyprus, So may the brothers of Helen, shining stars, And the Father of the winds guide you, etc.

and Propertius in that verse:

To behold and to seek the longed-for Tyndaridae.

[Margin: Fire of St Elmo.]

The Greeks call this meteor πολυδεύχεα [Greek: polydeuchea]; the Spaniards *El fuego de Sant'Elmo*. I have read in the narrative of Antonius Pigafetta [Antonio Pigafetta], in Ramusius [Giovanni Battista Ramusio], that it appeared more than once, with a fortunate light, in the storms of the Magellanic voyage. On the cause of this meteorological impression natural philosophers say much in their *Meteorics*: for Xenophanes, in Plutarch, *De placitis*, book 2, ch. 18, thought they were little clouds kindled above the ships by the motion of the storm, whereas Metrodorus thought they were flashings of the eyes of those hallucinating from fear.

[Margin: 4. Cancer.]

6. CANCER, the fourth constellation of the Zodiac, Κάρκινος [Greek: Karkinos, "crab"]; or ὀκτάπους [Greek: oktapous, "eight-footed"], that is, *Octipes*; or ὀπισθοβάμων [Greek: opisthobamōn], that is, walking backward; likewise *Nepa*, *Astacus*, *Cammarus*; in Arabic *Elsartan*, not *Asartan*. It consists of 13 stars according to Ptolemy, counting 4 unformed, of 17 according to Kepler and 35 according to Bayer. Two of these are of the third magnitude: one on the arm, or claw, or acetabulum, called in Arabic *Azubene*; the other on the last southern foot. In addition, in the quadrilateral there are two following stars of the fourth magnitude, which the Greeks call ὄνους [Greek: onous, "asses"] or ὀνίσκους [Greek: oniskous, "little asses"], *Asini* or *Aselli*, as Proclus has it; but Manilius calls them *Iugulae*; in Arabic *Elnatret*. Finally there is a famous star, likewise of the fourth magnitude, on the breast of Cancer, called *Nebulosa*, *Praesepe* and *Praesepium*; in Greek τὸ νεφελοειδὲς [Greek: to nepheloeides, "the cloudy one"], and φάτνη [Greek: phatnē, "manger"], and συστροφὴ [Greek: systrophē, "gathering"]; and in Arabic *Meeleph* or *Melleff*; in Chaldean *Pesebre*. This nebulous star, examined with Galileo's telescope, contains 36 little stars; and astrologers say that it portends ruin to the eyes if it is in the Ascendant with the Luminaries, or in any circle of position.

[Margin: The little tale of Cancer.]

Cancer is feigned to have been set in the heavens through the prayers of Juno, because it had been killed by Hercules, whose foot it had seized with its bite while he was fighting against the Hydra on the bank of the Lernaean swamp. The Aselli with their manger are said to have ascended to the heavens because, as Hyginus reports from Eratosthenes, Liber, Vulcan and the Satyrs, riding on asses, more easily defeated the Giants, who were terrified by the

uncouth braying of the asses; or because they carried Liber across a swamp in such a way that he did not touch the water.

[Margin: The gate of Cancer and of Capricorn.]

As to why the Platonists imagined two gates of the Sun in the heavens, one of Cancer, through which descending souls were poured into bodies, and the other of Capricorn, through which those souls that were passing into gods returned to those above, see Macrobius on the *Dream of Scipio*, book 1, ch. 12; Stœflerus [Johannes Stöffler] on Proclus, p. 89; and the most learned Iacobus Mazzonus [Jacopo Mazzoni] in the *Defence of Dante*, book 3, ch. 42.

[Margin: 5. Leo.]

7. LEO, the fifth constellation of the Zodiac, Λέων [Greek: Leōn, "lion"], the Herculean Lion, Cleonaean, Nemean, set in the heavens through the prayers of Juno, who was always hostile to Hercules, by whom it had been killed. In Arabic or Chaldean it is called not *Alezet* or *Alatid*, but *Ellessed*. It consists of 27 stars, besides 8 unformed, in Ptolemy; but of 40 in Kepler and 43 in Bayer. Among these, two are notable and of the first magnitude. The first is in the breast, called *Cor Leonis* or *Regulus*; in Greek βασιλίσκος [Greek: basiliskos, "little king"], or βασιλικὸς ἀστὴρ [Greek: basilikos astēr, "royal star"], *Stella Basilica*, that is, the regal star; in Arabic *Kalbellessed* or *Fetzanis*; among the Moroccan and the other Nubian astrologers *Kalbelasid*, which means Heart of the Lion to them as well; and it is the Prince of the celestials, as Theon says. The other is at the extremity of the Tail, in Arabic *Deneb-ellessed*, or among the Nubian astrologers *Nebolassid*, that is, Tail of the Lion, or in al-Ṣūfī *Alazet*. I do not discuss here the image of Leo which some people impress in gold for cordial medicines and for curing diseases of the kidneys, when the Sun in the heart of Leo culminates in the heavens, following Marsilius Ficinus [Marsilio Ficino], *De vita caelitus comparanda*, book 3, and Stöffler on Proclus, p. 90½.

[Margin: 6. Virgo.]

8. VIRGO, the sixth constellation of the Zodiac; πάρθενος [Greek: parthenos, "virgin"], Astraea, Erigone, Atargatys, but in Avienus Isis; in some writers Ceres, the Spike-bearing Virgin, Pax; in Arabic *Elaadari*, in others *Adrenedefa*. It has 26 stars in Ptolemy, with 6 unformed, 39 in Kepler, 42 in Bayer. Among these two are most famous, one of the first magnitude in the left hand of the Virgin, called *Arista* or *Spica*, in Greek στάχυς [Greek: stachys, "ear of grain"]; and in the Persian Tables of Chrisococca [Georgios Chrysokokkes] called μικρὸς κοντάρατος [Greek: mikros kontaratos]; in Arabic *Azimech*, or in Hermes *Alhaiseth*, as Bayer has it. But according to Kircher it is called among the Arabs *Sombalet Elaadari*, that is, *Spica Virginis*, or *Eltsamach*; and among the Nubian astrologers *Elaazelet*, and corruptly *Alaazel* or *Alzimon*, that is, *fusus* of the Virgin [*fusus*: spindle]. The other is the preceding star in the right wing, called *Praevindemiatrix*, *Vindemiator*, in Vitruvius,

book 9, ch. 6, *Provindemia*; in Greek προτρυγητὴρ [Greek: protrygētēr, "fore-harvester"], or in Proclus προτρυγητὴς [Greek: protrygētēs]; in Arabic *Alaraph*, *Almuredin Alcalft*.

[Margin: The tale of the Virgin.]

She is said to have been the daughter of Jupiter and Themis, if we believe Hesiod; or of Astraeus and Aurora, if Aratus; or, as others in Hyginus have it, Erigone, daughter of Icarius. As the golden age was ending in the iron, she turned away from the earth because of the injustice and avarice of men and flew off into the heavens, according to that line of Virgil's *Georgics*:

Astraea, last of the heavenly ones, left the earth.

But Albumasar [Abū Maʿshar] the Arab, in the *Introductorium in Astronomiam*, book 6, ch. 2, says that she is the Virgin Mother of God.

[Margin: 7. Libra.]

9. LIBRA, or *Iugum* in Cicero, in Greek στάθμος [Greek: stathmos, "balance"] or στατὴρ [Greek: statēr, "balance"]; in Hebrew *Mizan*; in Arabic *Azubene*. According to Ptolemy it consists of 8 stars, with the unformed ones around it 9; but according to Bayer of 15, and according to Kepler of 18. Among these are two notable stars of second rank, called *Lances*, the Pans, or the Claws of Scorpius, and by Ptolemy *Forfices*, the Pincers. The first is the southern Pan, χηλὴ νότιος [Greek: chēlē notios, "southern claw"], in Arabic *Zubeneschemalì*; the second is the northern Pan, χηλὴ βόρειος [Greek: chēlē boreios, "northern claw"], in Arabic *Zubenelgenubi*, as Bayer has it. But Kircher says that the southern is better called *Vazneganubi* and the northern *Vazneschemali*; this one, however, is in reality on the beam, though nearer the northern Pan. There is no separate tale by which Libra was carried up into the heavens apart from Scorpius, because among the Egyptians and Chaldeans Scorpius with its Claws was a single constellation, and so there were eleven Signs, speaking of visible asterisms and signs. Hence Ovid on Scorpius:

He stretches his limbs over the space of two signs.

[Margin: To whom are Libra and Scorpius one Sign?]

And Aratus calls it μέγα θήριον [Greek: mega thērion], a great animal; and Hyginus said: *This Scorpius, because of the size of its limbs, is divided into two signs, the figure of one of which our people have called Libra.* Rightly, therefore, Martianus Capella, *De Nuptiis Philologiae*, book 8, chapter on the Fixed Signs: *The Zodiac completes twelve equal portions of Signs, but it has eleven signs: for Scorpius occupies its own space with its body just as it occupies that of Libra with its Claws.* This explains that verse of Virgil, *Georgics* 1:

Where there is room between Erigone and the following Claws.

[Margin: Of Julius Caesar and Augustus [?].]

There he wishes for Augustus a place between the Virgin and the Claws of Scorpius, as one who would fill that place and would stand in the place of a twelfth asterism; and there Servius rightly notes that Virgil followed the opinion of the Chaldeans, who make up eleven starry signs. Moreover Pliny

the Elder and Suetonius, in *Caesar*, penultimate chapter, say that in that space between the Virgin and the Claws, after the murder of Gaius Julius Caesar, a hairy star appeared for 7 days while Augustus was consecrating games to him; it was believed to be the soul of Caesar received into heaven. Perhaps, then, Virgil had this in view, that Augustus should occupy a place in the heavens kindred and neighbouring to Gaius Julius. Finally, this Sign is most famous, both because it was in the horoscope of the City of Rome when it was founded, according to the calculation of Lucius Taruntius Firmanus, as Cicero testifies, *De divinatione* 2, Plutarch in *Romulus*, and Solinus, ch. 2; and because it was formerly nearest the autumnal section, in which both the Equinox occurs and a kind of equilibrium, as it were, between day and night, as Virgil sings, *Georgics* 1:

When Libra has made the hours of day and sleep equal, And now divides the globe midway between light and shadows.

[Margin: 8. Scorpius.]

10. SCORPIUS, or Scorpio, the eighth constellation; in Quintus Cicero *Nepa*; Σκόρπιος [Greek: Skorpios, "scorpion"]; in Arabic *Hacerab*, *Alatrab* or *Alacrab*, as Bayer has it, but as Kircher says it is called *Aakrab* or, with the article, *Elaakrab*. In Ptolemy's Catalogue it has 21 stars with three unformed, in Bayer 29, in Kepler 10 Tychonic and 18 semi-Tychonic. The ruddiest of these, and of first rank, on the breast of Scorpius, is called *Cor Scorpii*; in Greek ἀντάρης [Greek: antarēs], Antares; in Hesychius ἀντάρτης [Greek: antartēs], Tyrant; among the Arabs *Kalbelaakràb*, that is, Heart of Scorpius; in Sophocles *Vespertilio*, the Bat. Ptolemy wrongly places it among the stars of the second magnitude. The star on the brow of Scorpius that is the most northerly of three is very famous in the observations of the ancients. The one that precedes on the sting of the tail is called *Lesath*, or *Moshlek*, or *Alascha*; but by the Arabs, as Kircher affirms, it is called *Lessaa Elaakràb*, that is, the bite of Scorpius, or *Denneb Elaakràb*, the Tail of Scorpius.

[Margin: The little tale of Scorpius.]

Since Orion sets when Scorpius rises, the mythographers feigned that Scorpius brought death upon Orion while he was boasting that there was no animal so fierce that he could not overcome it, and that it was therefore raised into the heavens, to be a portent for restraining the display and boasting of men. So, roughly, Hyginus.

[Margin: 9. Sagittarius.]

11. SAGITTARIUS, the ninth constellation of the Zodiac, Centaur, Chiron, Philerides, Thessalian arrows, etc. In Greek τοξευτὴρ [Greek: toxeutēr, "archer"], οἱ ῥύτωρ τόξου [Greek: rhytōr toxou, "drawer of the bow"]; in Arabic *Elkusu* or *Elkausu*, or, as Kircher says, it is called *Kàus* and, with the article, *Elkaus*, that is, the bow. It has 31 stars in Ptolemy, 32 in Bayer, and in Kepler 16 Tychonic and 18 semi-Tychonic. Among these are two

of the second magnitude, one on the left hock of the right forefoot, the other on the leg of the same foot.

[Margin: The tale of Sagittarius.]

Some in Hyginus say that this is Crotus, added to the heavens by the prayers of the Muses, because he was the son of Euphene, their nurse, very swift in hunting on horseback and very keen in poetry; and that both these qualities are signified by the half-horse body and the arrows. But Macrobius, *Saturnalia*, book 1, ch. 21, says: *Sagittarius, which is the lowest and last of all the domiciles of the Zodiac, therefore degenerates from man into beast through its hinder limbs, as if thrust down by its last parts from the higher regions to the lower; yet it shoots an arrow, which indicates that even then the life of all things depends on the ray of the Sun, even as it comes from the lowest part.* He calls it lowest because it is the last of the six descending Signs, with respect to northern inhabitants.

[Margin: 10. Capricornus.]

12. CAPRICORNUS, Αἰγόκερως [Greek: Aigokerōs, "goat-horned"], *Caper*, *Aegipan*, *Hircus aequoris* (He-goat of the sea), *Pelagi procella* (Storm of the deep), *Imbrifer* (Rain-bringer); in Nonnus ἀθαλπὴς [Greek: athalpēs, "unwarmed"]; in Arabic *Elgedi* or *Alcantarus*. The star in the Tail of Capricornus is called *Denneb Elgedi*, that is, tail of Capricornus. It consists of 29 stars according to Ptolemy and Kepler; of 29 according to Bayer.

[Margin: Its tale.]

Hyginus narrates that, in fear of the giant Typhon, many of the Gods who had gathered in Egypt fled clothed in various forms, and that Pan turned himself into a Capricorn, but half fish, so as to be safe on land and sea; because of this invention he was received into heaven by Jupiter. At that time Apollo turned himself into a crane, Mercury into an ibis, Venus and Cupid into fishes, Diana into a cat. Macrobius, *Saturnalia*, book 1, ch. 21, says that this sign imitates the climbing of goats, when it brings the Sun back from the lowest parts to the upper, since from Capricorn the Sun begins to ascend towards the north.

[Margin: Capricorn, the natal Sign of Augustus.]

Capricorn is said to have been the natal star or sign of Augustus; for Suetonius says of him: *Augustus soon had such confidence in his fate that he published his horoscope and struck a silver coin with the mark of the star of Capricorn, under which he was born.* The same author, in ch. 5, testifies that he was born in the consulship of Marcus Tullius Cicero and Antonius, on September 23 [IX. Kal. Octobris]. Understand this of the old year, dislocated by the faulty intercalations of the priests; otherwise Capricorn could not have been the horoscope in the month of September of the Julian year, shortly before sunrise. On this controversy, however, see Bayer in the *Uranometria* at this constellation, and the dispute on this matter between Thesaurus [?] and Monodus [?]. Certainly Manilius, who was living then, *Astronomica*, book 2, ch. 14, sings:

He loves Erigone; Capricorn in turn turns his gaze Upon her; for what greater thing will he marvel at Than that he shone, auspicious, on the birth of Augustus?

And on this same matter there survive these verses of Germanicus:

Here, Augustus, with your natal star, your divinity, Amid astounded nations and a trembling fatherland, It bore into the heavens, and brought among your mother's stars.

[Margin: 11. Aquarius.]

13. AQUARIUS, the eleventh visible Sign, Ὑδρόχοος [Greek: Hydrochoos, "water-pourer"], Ganymede, the pourer of water; in Apian *Hydridurus*; in Horace Tyrant of the water; in others Deucalion, Aristaeus or Cecrops; in Arabic *Edeleu*. In Ptolemy it consists of 42 stars with 3 unformed, but in Bayer of 41, and in Kepler of 45. Among these one is of the first brilliance, shining in the outpouring of the water, and commonly and corruptly called *Fomahant*, although the Arabs say *Phomaut* or *Phomelhaut*, that is, mouth of the fish, as Kircher says. The star on the left shin is called *Scheat Edeleu*.

[Margin: The tale of Aquarius.]

Very well known indeed is the tale and the disgrace of Jupiter, who is feigned to have carried off to heaven, by means of the Eagle, Ganymede, son of Troilus and Callirrhoe, while he was hunting on Mount Ida, and to have made him cupbearer of the Gods. Note, from Vitruvius, book 9, ch. 6, that the outpouring of Aquarius is called ἑρμηδόνην [Greek: hermēdonēn], that is, the gift of Mercury, or his delight.

[Margin: 12. Pisces.]

14. PISCES, the twelfth constellation of the Zodiac, οἴχθυες [Greek: oichthyes, "the fishes"], one southern, the other northern; *Proles Dercia*, *Dea Syria*, Διώνη [Greek: Diōnē]; Venus and Cupid; in Arabic *Haut* or, with the article, *Elhaut*, *Sameh* or *Elhautine*; the northern, however, is called *Haut Elschemali*, and the southern *Haut Elgenubi*. In Ptolemy it has 34 stars with 4 unformed, in Bayer 37, in Kepler 59.

[Margin: The tale of Pisces.]

of which the most famous, though of third rank, is the one on the knot of the Line, which line Aratus calls σύνδεσμον [Greek: syndesmon, "bond"], or knot. Venus and Cupid turned themselves into these fishes when, fleeing Typhon, they were carried to Syria; and for that reason the Syrians once abstained from eating fish, so as not to seem to devour Gods. See the little tale in Hyginus and in Ovid, *Fasti* 2.

SCHOLIA.

Scholia.

[Margin: On the distinction of the twofold Zodiac.]

1. I have said on more than one occasion as it arose, especially in Book 1, ch. 14, and Book 3, ch. 14, in the Scholia, that there are at least two Zodiacs. One of them is Rational, that is, thinkable only by reason or imagination, but of itself invisible and ἀνάστρον [Greek: anastron, "starless"]. It is the band of the highest heaven divided into 12 equal segments, which the Ecliptic bisects, and it is wide on either side of the Ecliptic by at most 10

degrees, which is the greatest latitude of the Planets, according to what was said in Scholium 1 of Chapter 14 of Book 1. Its segments are called celestial Domiciles, and by the Greeks δωδεκατημόρια [Greek: dōdekatē-moria, "twelfth-parts"], and each occupies 30 degrees in longitude. The other is the visible and starry Zodiac, filled with the images of twelve constellations, from which the twelve segments of the rational zodiac took their name, when the beginnings of the visible Signs, or of these constellations, coincided with the beginnings of the dodecatemories, or occupied their spaces with the greatest part of themselves. But since the ancient astrologers, in order to comply with the common people and to indicate the seasons of the Year and the changes of the weather to citizens, farmers, sailors and physicians by signs visible in the heavens, used the asterisms of the Zodiac rather than the dodecatemories, great misuse and great confusion arose among writers as a result. This was because of the progress of the Fixed Stars in longitude and their recession from the segments of the rational Zodiac, which is so great that the first star of Aries was found by us in the year of Christ 1644 in rational ♈ at 28° 12′ 52″, and according to our motion of the Fixed Stars it was at the beginning of rational ♈, or on the Colure drawn through the vernal section, in the year 388 before Christ. On that confusion of the Zodiac and the Signs, review what I said in Book 3, ch. 14, in the Scholia.

It remains, then, for me to set down here, from our table of longitudes and latitudes of the Fixed Stars, how much of the heavens these twelve constellations occupy in length and in breadth, so that they may be more easily distinguished from the Segments of the rational Zodiac. I shall add the Year before the Epoch of Christ in which the beginning of these asterisms, that is, their first star, according to Tycho's opinion and mine on the motion of the Fixed Stars, was at the beginning of its own Dodecatemory, the one named after it, that is, on the great circle drawn through the poles of the Ecliptic and through the beginning of each Sign of the invisible Zodiac; and also where it was at the beginning of the World according to Kepler or ourselves. I hope that this will be very pleasant and equally very useful to my Readers. I suppose that the World was founded in the Year 4063 before CHRIST, even if Kepler favours the Year 3993, according to what was said in Book 3, ch. 25, no. 5 and 6. Note, moreover, that in the following table longitude is counted from the westernmost to the easternmost star of each constellation.

[Margin: The places here are taken from our hypotheses.]

Constellations of the Zodiac, in order	Extent of longitude	Greatest latitude, north	Greatest latitude, south	Year before (A) or after (P) Christ in which the first star of the constellation was at the beginning of its dodecatemory: Tycho	The same: ourselves	Place in the rational Zodiac of the first star of the constellation in the first Year of the World	The same in the first Year of Christ
Aries	20° 13′	12° 25′	4° 1′	349 A	388 A	♒ 8° 57′	♈ 5° 23′
Taurus	33° 38′	5° 45′	14° 30′	507 P	480 P	♒ 26° 55′	♈ 23° 21′
Gemini	26° 6′	10° 58′	10° 9′	191 A	225 A	♈ 6° 42′	♊ 3° 8′
Cancer	16° 40′	10° 23′	7° 5′	82 A	120 A	♉ 5° 14′	♋ 1° 40′
Leo	39° 9′	17° 40′	7° 39′	916 P	904 P	♉ 21° 1′	♋ 17° 20′
Virgo	46° 46′	16° 15′	9° 16′	348 P	324 P	♉ 29° 4′	♋ 25° 30′
Libra	18° 37′	8° 35′	10° 57′	986 P	976 P	♌ 20° 2′	♎ 16° 28′
Scorpius	8° 17′	1° 54′	8° 27′	325 A	344 A	♍ 8° 16′	♏ 4° 42′
Sagittarius	27° 22′	3° 6′	3° 50′	200 A	236 A	♎ 6° 50′	♐ 3° 16′
Capricornus	23° 19′	7° 16′	6° 58′	314 A	352 A	♏ 8° 28′	♑ 4° 54′
Aquarius	38° 32′	15° 23′	16° 31′	1162 P	1154 P	♏ 17° 32′	♑ 13° 58′
Pisces	41° 9′	23° 3′	9° 4′	680 P	649 P	♐ 6° 50′	♒ 20° 48′

2. From the preceding table I infer that, if the first star, that is, the westernmost of each of the twelve images of the Zodiac, is the one which now, in recent figures according to the catalogue of the Rudolphine Tables, is the first of them, the ancient astronomers who flourished before Christ did not look to that star in beginning all the Signs of the Rational Zodiac; since some of those stars were at the beginning of their dodecatemory after Christ. According to Kepler, moreover, the first star of Aries in the first Year of the World was in ♒ at 8° 23′ 25″, and in the first Year of the Christian Epoch in ♈ at 4° 57′.

[Margin: Foreign names of the Signs of the Zodiac, from Kircher.]

3. Now, Reader, receive the Arabic, Chaldean, Hebrew and Egyptian names of the Zodiac and of the Signs, which Father Athanasius Kircher, at my request, recently sent me. The Zodiac, then, was once called among the Egyptians ταμετούρο ἐντενὶφθα [Greek: tametouro enteniphtha], that is, the realm of the 12 Gods; among the Arabs *Pholck Albarugi*, that is, the Sphere of the 12 citadels; among the Chaldeans *Hadronitho Demalusche*, the Orb of the Signs, or the circuit of the 12 mansions; among the Hebrews *Galgal hammataloth*, the sphere of the Signs.

Signs of the Zodiac	Arabic	Chaldean	Hebrew	Egyptian, with its meaning
1 Aries	Hammel	*Emro*	Telch	ταμετούρο Αμνοὺ [recte: Αμοὺν, per the book's errata], of the Kings of Ammon
2 Taurus	Tur	*Tauro*	Schor	ὥριας, Station of Horus
3 Gemini	Gieuz	*Tammch*	Theomim	Κλύσος, Enclosure of Horus
4 Cancer	Sartàn	*Sartono*	Sartan	Κλαρία, beast or station of Typhon
5 Leo	Essed	*Ario*	Arieh	πιμεντεκέων, cubit of the Nile
6 Virgo	Sombalet	*Btultho*	Betulàh	ἄσφολια, station of love, which the Gods showed at the increase of the Nile
7 Libra	Mizan	*Masathe*	Miznaim	λαμβαδία, station of propitiation
8 Scorpius	Aakrab	*Acrobo*	Akrab	Ισιας, station of Isis
9 Sagittarius	Elkaus	*Kertho*	Kescheth	πιμάηρε, station of delight
10 Capricornus	Elgedi	*Gadio*	Gedi	ὀπέυτυς, arm of sacrifice
11 Aquarius	Edali	*Daulo*	Delli, that is, a bucket	ὑπευθέριαν, beneficent arm
12 Pisces	Elhaut	*Dagiotho*	Dagim	πικοτώριων, fish of Horus

For the mystical reasons, see the *Oedipus Aegyptiacus* of the same Athanasius, in the treatise on Hieroglyphic Astrology.

CAPVT IV.

Chapter 4.

De Astris Borealibus extra Zodiacum.

On the Northern Constellations outside the Zodiac.

[Margin: 1. Ursa Minor.]

1. URSA Minor, or the Lesser Wagon [Plaustrum minus], or *Cynosura* and *Phoenice*, so named because the Phoenicians and Sidonians especially used it in navigating. In Greek it is ἄρκτος μικρᾶ [Greek: arktos mikra, "little bear"], that is, the Small Bear, and ἅμαξα [Greek: hamaxa, "wagon"], namely the Wagon (understand: the Lesser), and κυνόσουρα [Greek: kynosoura, "dog's tail"]; and in Arabic *Alrukabah*, which means Wagon. It consists of 7 stars, with an eighth unformed, in Ptolemy, but of 8 in Bayer and 20 in Kepler. Among these two are of the second magnitude. One is the upper of the preceding stars in the quadrilateral, or on the right shoulder of Ursa Minor, and is called by the Arabs *Dhub Elezguar*. The other is at the extremity of the tail, called by the Ishmaelites *Ruccabah*, the name being taken from the whole asterism; commonly *la Tramontana*, the Star of the Sea, and the Pole Star, since in these centuries it is the nearest of all to the pole of the world. It was not so formerly, however, about the times of Christ, as I shall say in the appendix on the Pole Star and its declinations, to be added shortly. The two remaining little stars, which are in

the tail of Ursa Minor, are called *Vigiles* and *Circitores*, the Watchmen and the Patrollers, and by Hyginus χορέυται [Greek: choreutai, "dancers"]. Of this constellation's ἀνάστρωσει [Greek: anastrōsei; glossed by the author as "relation among the stars"], that is, its relation among the stars, and its difference from Ursa Major, I shall speak shortly, after Ursa Major.

[Margin: 2. Ursa Major.]

2. URSA Major, the Greater Wagon, Arctos Maior, *Helice*, *Callisto* or *Megisto*, and by patronymic *Parrhasis*, *Maenalis*, *Erymanthis*, *Nonacrine*. In Greek it is ἄρκτος, μεγίστη [Greek: arktos, megistē, "bear, greatest"], or ἑλίκη [Greek: helikē, "the turning one"], and ἅμαξα μείζων [Greek: hamaxa meizōn, "greater wagon"] or μέγα [Greek: mega, "great"], that is, the Greater Wagon; and in Homer ἑλικῶπις [Greek: elikōpis]. In Arabic it is *Dubbeh*, that is, Bear, and *Alrukabah*, that is, Wagon (understand: the Greater). Hence, by a corrupted word, *Dubbhelacbar*, although it ought rather to have been called *Dubbherukabah*, as though Bear-Wagon [Ursiplaustrum]. It consists of seven more notable stars, which are called *Septem Triones*, as though *teriones*, from treading [terendo] a path around the pole, going and returning around it in a restless revolution that is always visible to us. In all, however, there are 27 in Ptolemy, with 8 unformed, but 32 in Bayer and 56 in Kepler. I am surprised that these two placed the four brighter stars of the quadrilateral among the stars of the second magnitude, since it is evident that the one at the root of the tail is scarcely of third rank, as Ptolemy has it. Now, among the seven already mentioned, certain Arabs call the one on the shoulder, as the chief of them, *Dubbeh*; the first of the tail *Alhaiath*, that is, life-giving; the middle one *Mizar*; and the last *Alalicth*, that is, nocturnal, or *Benenath* or *Benenaim*.

[Margin: Arabic proverb.]

And near the middle star of the tail it has a little star barely visible, called in Arabic *Alcor*, from which comes the Arabic proverb, reported by Apian, about a man who sees tiny things and does not see, or pretends not to see, greater ones: *You saw Alcor but not the full Moon.* The Christian Arabs, however, as Father Athanasius Kircher informed me by letter, call this Greater Wagon *Naasch Laazar*, that is, the bier of Lazarus, made up of the four stars of the quadrilateral; but the three brighter stars of the tail, or wagon-pole, they call *Benath Naasch*, that is, the daughters of the Bier: the first of the tail is Mary Magdalene, the middle of the tail Martha, and the last the maidservant, for them *Ellamath*.

[Margin: Tale of both Bears.]

Further, Aratus, Avienus and Germanicus hold that Cynosura and Helice were Jupiter's nurses in Crete, when Ops was bringing him up in secret from Saturn, most voracious devourer of his sons, while the Corybantes prevented the wailing of Jupiter from reaching Saturn's ears by the clashing of bronze; and that Jupiter therefore carried each of his two nurses up into the heavens, which Agatosthenes also followed in his *Asiatic poems*. But Hesiod, the comic writer

Amphis, Ovid in the *Metamorphoses* and Hyginus in the *Poetic Astronomy* tell the tale that Ursa Major, or Callisto, was the daughter of Lycaon and a follower of Diana, who consented to debauchery with Jupiter on Mount Nonacris in Arcadia; that she was therefore turned into a Bear, either by Diana or by Juno; that when hunters pursued her she fled into a temple which it was forbidden to enter, and for that reason was to be killed, had not Jupiter, taking pity on her, carried her up into the heavens; and that she does not set because Tethys, the nurse of Juno, refuses to receive her, lest Tethys be defiled by her. Ovid referred to this in *Metamorphoses* 2, fable 6, singing:

Forbid the seven oxen the blue gulf, And drive off the stars received into heaven as the price of debauchery, Lest the concubine be dipped in the pure water.

Neat, too, is that line of Virgil, *Georgics* 1:

The Bears that fear to be dipped in the water of Ocean.

and this from Ovid, *Fasti* 3:

That there are two Bears, of which this one is called Cynosura By the Sidonians, and the Greek keel marks out Helice. Beasts great and lesser, of which the one steers Greek ships, The other Sidonian, and both themselves dry.

[Margin: Why Ursa Minor served the Sidonian and Ursa Major the Greek ship-masters.]

For to those sailing in the Mediterranean, to the Greeks in the Archipelago and in the Pontic or Euxine sea, Ursa Major did not set; but from the more southerly Sidonians, Phoenicians and Carthaginians some part of Ursa Major was hidden, either in itself and by reason of its position in the sphere, or incidentally through the vapours of the horizon; whereas Ursa Minor, turning around the pole in a tighter circuit, set for them in neither way. Therefore the Greeks directed the course of their navigation by the Greater Bear, and the Sidonians and Phoenicians by the Lesser, measuring from their revolution the time of night and the quarter of the journey completed. Germanicus, following Aratus, sang this elegantly in the following verses:

Here the nurses of Jupiter, Helice and Cynosura, shine; Helice gives the Greeks their courses by greater stars; Cynosura guides the Phoenicians. But bright all over And with liquid splendour shines Helice; no other sooner, When the Sun has hidden his gleaming face in the ocean, Sparkles as a star in the sky than the Cretan one with its seven flames. Yet Cynosura is surer for those who furrow the sea, For in a short circuit she turns her whole self about the Hinge, And, once observed, has never misled a Sidonian ship.

With this Manilius agrees, book 1 of the *Astronomica*, ch. 3:

And the greater Helice traces out the greater Bear [arcton]: Seven stars turning mark her with their light, Under whose guidance the Greek keels set sail through the waves. Small Cynosura wheels in a narrow circle, Lesser both in space and in light, but in the Tyrian's judgement she surpasses The greater: for the Phoenicians she is the surer authority As they seek on the sea a world not in view. Nor are they set with their fronts level: each turns her tail Toward the other's muzzle, and follows her follower.

Appendix De Stella Polari

Eiusq. accessu ad Polum, & erroribus Auctorum aliquorum circa illam.

Appendix on the Pole Star, its approach to the Pole, and the errors of certain authors concerning it.

[Margin: Whether the star that is now the Pole Star was also the Pole Star formerly.]

3. As we are turning this Wagon about, it seemed opportune to weigh briefly certain things said rightly or wrongly about the Pole Star: first, whether the star now called the Pole Star was formerly too, as it is now, the nearest to the North Pole among all the stars of Cynosura, and so has always deserved the name of Pole Star; next, whether it moves perceptibly, approaching the pole of the world. There are, as I said, two notable stars in the constellation of Cynosura, of the second magnitude. One is on the shoulder, the upper of the preceding stars of the quadrilateral, which the ancients used as the head of the Bear; and in the age of Eudoxus and of Hipparchus too it was the most northerly of all this asterism and the nearest to the north pole, and so it was this star that then deserved the name and office of Pole Star. The other, which sparkles at the end of the tail, was then the most southerly of all this constellation. Now, however, conversely, owing to the motion in longitude and the variation of declination, the bright star of the shoulder has become the most southerly, and the last of the tail the most northerly. That this is so will become evident first by authority, then by astronomical calculation.

Hipparchus, then, called the last star in the tail of Ursa Minor the most southerly in his time, as Marinus of Tyre attests in Ptolemy, *Geography* book 1, ch. 7. Marinus's words are: *It is related by Hipparchus that the* νοτιώτατος [Greek: notiōtatos, "most southerly"]*, that is, the most southerly star of Ursa Minor and the last of its tail, is 12° and two-fifths distant from the Pole.* So all the Greek codices have it, manuscript and printed alike, says Pétau, *Uranologion* book 3, ch. 3: for they have νοτιώτατος. So it is a wonder that so many of the Latin translators did not distinguish the periods, and, because this star is now the most northerly, corrupted this text and put "most northerly" in place of "most southerly", as Mercator, Montanus [?] and Magini did;

[Margin: Lapse of Mercator, Magini and others in the text of Ptolemy.]

because of whose authority our own Guldin [Guldinus] also hesitates here, book 2 of the Refutation of the *Elenchus* of Calvisius, ch. 10. But these men are to be corrected from the genuine Greek edition, and from a similar passage of Strabo, book 2, who says: *For the bright star at the end of the tail, which is the most southerly, is placed on the Arctic circle itself, so that it touches the horizon.* Marinus of Tyre in Ptolemy also alludes to this, saying above that the whole of Ursa Minor is enclosed by the visible circle of that region which lies 500 stadia, or one degree, north of Ocele; that the parallel of Ocele is raised 11° 24′; and that

the last star of the tail of Ursa Minor is 12° 24′ from the Pole. Magini, however, errs less here, because, although he retains the corrupt Latin edition of Ptolemy, in which it reads "most northerly", he nevertheless admits that in Hipparchus's age it was the most southerly.

Hyginus, on the contrary, writes in book 3 about Cynosura: *But among the first stars of the tail there is one from which the pole is named, as Eratosthenes says, through which place the World itself is thought to turn; and the two others are called* χορευταὶ [Greek: choreutai, "dancers"]*, because they turn around the pole.* The old scholiast on Aratus also affirms this, but confuses the seven bright stars of Ursa Major with the stars of Ursa Minor. This error, however, flowed from Aratus, or rather perhaps from Eudoxus, about whom Hipparchus of Bithynia writes thus, on Aratus's *Phenomena*, book 1, no. 5 in Pétau: *On the north pole, however, Eudoxus is mistaken, writing thus: (There is a certain star, standing always in the same place, which indeed is the pole of the World:) for no star is situated at the pole itself. But there is an empty place, beside which lie three stars, with which the point of the pole makes a four-sided figure, as Pytheas of Massalia also says.* And he goes on to refute various errors of Aratus and Eudoxus about the positions of the Fixed Stars, even though Pétau, book 3, ch. 3, tries to vindicate Eudoxus too against Hipparchus, on the ground that he spoke about another star. The author of the fragment falsely inscribed with Eratosthenes's name also says: *They name the ends of the axis of the world poles, which some have said are tiny stars, others points existing in thought alone, as does Aratus too.* And Martianus Capella, book 8, the chapter on the northern circle: *that in the very hinge of the world there is a brighter star.* Yet none of these three said which star this was. Perhaps it was either the next-to-last star of Draco or the bright shoulder of Ursa Minor, which were then about 7° from the North Pole; for no other nearer one presents itself for that time, unless you gratuitously imagine that a new star appeared in that age at the very pole and afterwards vanished. Pétau, however, in book 3 of the *Uranologion*, ch. 5, thinks that Eudoxus spoke in a popular sense rather than because he really judged it so.

4. It is established, then, from Pytheas of Massalia, from both Hipparchuses, from Strabo, Marinus of Tyre and Ptolemy, that the last star of the tail of Ursa Minor was also the most southerly of the stars of Cynosura, and was not at the pole of the world. These authors are surely to be believed rather than Eudoxus, an astronomer of a cruder age and perhaps speaking in popular terms, and Aratus, who drew from him, or the fictitious Eratosthenes, and Hyginus the Grammarian, or Capella; especially since astronomical calculation proves it. For today the last star of the tail of Ursa Minor is 2° and nearly 36′ from the Pole, as I shall show below; and there is no hypothesis of any distinguished astronomer on the motion of the Fixed Stars that does not show this star, 1,700 years ago and more, when Hipparchus of Rhodes flourished, as then the farthest from the pole of all the stars in Cynosura. And if we abide by the report of Ptolemy mentioned above, it was then 12° 24′ distant. Assuming a motion of the

Fixed Stars of one degree in 72 years, and an obliquity reckoned for that time at nearly 24°, Pétau, book 3 of the *Uranologion*, ch. 3, gathers the distance from the Pole of the following stars of Cynosura, as in this little table.

Stars of Cynosura	Distance from the Pole in the time of Eudoxus	Distance from the Pole in the time of Hipparchus
Last of the tail	14° 4′	12° 24′
Middle of the tail	12° 37′	11° 10′
Antepenultimate of the tail	11° 24′	10° 22′
Shoulder of Ursa Minor	7° 26′	8° 7′
Upper following star	9° 16′	8° 54′

[Margin: Scaliger's fabrication.]

5. Despite all this, Joseph Justus Scaliger, in the *Diatriba* on the Equinoxes and in book 4 of *De emendatione temporum*, p. 284, relying on Hyginus and on Aratus or his scholiast rather than on Pytheas, Hipparchus, Strabo, Marinus and Ptolemy, asserts that the last star of the tail of Ursa Minor both is now and formerly always was at the pole of the world. He asserts that the stars do not change their declinations with respect to this pole, but that the poles of the Equator, which he imagines as different from the poles of the world, and movable, approach the stars; that the position of the meridian line changes; and that the Fixed Stars stand still, and it is rather the equinoctial points of the Equator that move against the order of the signs [in prȩcedentia]. In a word, he overturns the entire doctrine of the motion of the eighth sphere on the emptiest and slightest of grounds, which it is not worth the trouble to report and refute here. Clavius did that, in few words, in the *Sphaera*, p. 62, but at greater length Denis Pétau in the Dissertations of the *Uranologion*, the whole of book 3, and Paul Guldin in the Refutation of the *Elenchus* of Calvisius written against the Gregorian Calendar, book 2, chs. 9 and 10. It is enough for us, as more proper to this place, to show from the distances of the last star in the tail of Ursa Minor from the Pole, observed by the highest and lowest meridian altitudes, the change of declination and the approach to the pole of the world, perceptible in this and the preceding century, let alone over several. Whether this star or another has ever been or ever will be at the very pole of the world, see below, ch. 19, Problem 5.

Obseruationes Decem Stellæ Polaris

Eiusque accessus his sæculis ad Mundi polum Borealem.

Ten observations of the Pole Star, and of its approach in these centuries to the north pole of the world.

[Margin: 1. Observation.]

6. Gemma Frisius, as he relates in the *Catholic Astrolabe*, ch. 9, observed at Leuven, in the year of Christ 1547 December 13, the greatest meridian altitude of the Pole Star as 53° 58′ and the least as 47° 43′, from which he deduced its distance from the Pole as 3° 7′ 30″. But [sed sed] according to the Tychonic approach it should have been 3° 8′ 50″.

[Margin: 2. Observation.]

Pedro Nunes [Petrus Nonius], book 2 of *De observatione*, ch. 7, after he too has censured the error of those who contend that this star was the most northerly in Hipparchus's age, since according to Ptolemy's *Geography* and the accurate version of it made by Vuernerus [Johannes Werner] and Bilibaldus [Willibald Pirckheimer] it was the most southerly, adds that in the year 1500 sailors observed it to be distant from the Pole not 4° 9′, as the Alphonsine calculation required, but 3° 30′. By Tycho's reckoning, however, it should have been 3° 24′ 40″; but those sailors may have observed with an instrument not so finely divided.

[Margin: 3. Observation.]

Paul Hainzel, as Tycho relates in *Progymnasmata*, vol. 1, p. 347, observed at Göggingen near Augsburg, in the year 1572, with a huge Quadrant, the greatest meridian altitude of the Pole Star as 51° 22′ 15″ and the least as 45° 21′ 45″, and therefore its distance from the Pole as 3° 0′ 30″.

[Margin: 4. Observation.]

Tycho himself, in the same place, p. 362, reports from both altitudes these observed distances of the Pole Star from the Pole; from which, and from Paul's observation, he concluded that it approaches the pole of the world by 20″ each year.

Year	Distance from the Pole
1577	2° 58′ 51″
1581	2° 57′ 30″
1586	2° 56′ 10″
1589	2° 54′ 50″

[Margin: 5. Observation.]

Nor does Rothmann's observation, made at Kassel in the year 1586, stand against these, in which he had taken its greatest altitude as 54° 16′ and its least as 48° 24′. For, as is evident from Tycho's letters, pp. 11, 30 and 82, and from Willebrord Snel in the *Hessian Observations*, Rothmann, having corrected his plumb line and set the instrument more exactly, found the altitude of the pole at Kassel to be 51° 19′ 20″, and hence the distance of this star from the pole 2° 55′ 40″.

[Margin: 6. Observation.]

Jacob Christmann, in his commentaries on al-Farghānī, confirms that the Pole Star approaches the pole of the world by 20″ each year, and that in the year 1618 it was 2° 44′ 30″ from it; even though he had earlier said, in book 1 of

the *Solar Observations*, ch. 4, that in the year 1596 it was 2° 51′ 50″ away, when by Tycho's reckoning it should then have been 2° 52′ 30″ away. For by a less accurate observation he had taken its greatest meridian altitude at Heidelberg as 52° 13′ 50″ and its least as 46° 30′ 10″.

[Margin: 7. Observation.]

Pierre Gassendi, in the *Judgement on the nine stars seen around Jupiter and on the reciprocation of the pendulum*, asserts that in the year

1633, toward the end of the year, at Digne, at 6^h in the morning, he observed the lowest altitude of the Pole Star as 41° 25′ 30″, and toward 6^h in the evening the highest altitude as 46° 46′, and therefore the distance as 2° 40′ 15″ and the altitude of the pole at Digne as 44° 5′ 45″. I afterwards found this observation in our Father Fournier, *Hydrographie*, book 10, ch. 27.

[Margin: 8. Observation.]

Andreas Garcia Cespedius [Andrés García de Céspedes], in the book entitled *Regimento della Navigation*, printed at Madrid in the year 1606, relates on p. 87 that he observed at Madrid in the year 1598 the greatest meridian altitude of the Pole Star as 43° 23′ and the least as 37° 24′, and therefore the difference as 5° 59′, and the half-difference, that is, the distance of the star from the Pole, as 2° 59′ 30″. But according to the Tychonic approach it should have been only 2° 51′ 50″. So Céspedes's instrument or observation was not so accurate, and neither was the observation of Rodrigo Zamorano, which the same Céspedes reports on p. 87 from Zamorano's *Breviary of Navigation*, and, from both of them, Father Fournier, *Hydrographie*, book 10, ch. 27. For Rodrigo says that he observed in the year 1584 the distance of the Pole Star from the Pole as 3° 8′, whereas from Tycho's observations it should have been 2° 56′ 30″. For ship-masters usually employ Astrolabes or hanging Rings of no great size, and a meridian line found by the magnetic needle or otherwise, but not so corrected as it should be.

[Margin: 9. Observation.]

Father Stephanus Ostoul [?], a Minim, prompted by Father Théophile Raynaud at my request, observed at Avignon in the year 1643, on January 6, 7, 8 and 9, the greatest meridian altitude of the Pole Star, in the evening, as 46° 58′, and the least, in the morning, as 40° 45′ 20″, and half the difference, that is, the distance from the Pole, as 3° 6′ 20″, from which he deduced the altitude of the pole as 43° 51′ 40″. But from Tycho's observations and ours that distance should have been 2° 36′ 30″. So there was an error of 30′ in his observation, owing to some pyramid or other that he devised as an instrument for observing.

[Margin: 10. Observation.]

[Margin: Altitude of the pole of Bologna, but at our observatory; at the middle of Bologna it would be 44° 30′.]

We, finally, at the end of the year 1641 and the beginning of 1642, with observations repeated more than forty times, in order to establish most evidently for myself and my companions the altitude of the pole of Bologna in Italy, observed with large Quadrants the least meridian altitude of the Pole Star, in

the morning, as 41° 52′, and the greatest, in the evening, as exactly 47° 7′; from which the altitude of the pole is 44° 29′ 30″ and the distance of the Star from the Pole 2° 37′ 30″, exactly as the Tychonic approach required, although while observing I was giving no thought to this. Moreover, in the year 1643 December 26, with a very large bronze Quadrant set up in the new observatory, I took this star's greatest meridian altitude as 47° 6′ 40″, and in the morning its least as 41° 52′ 20″, from which a distance from the Pole of 2° 36′ 50″ is gathered, exactly by Tycho's reckoning; I rejoiced greatly at this marvellous agreement.

[Margin: Magini's error.]

I found, moreover, in the *Ephemerides* of Nicolò Simi, mathematician of Bologna, and of Pietro Pitati, and in Biancani, the altitude of the pole of Bologna as 44° 30′. The error of Magini, therefore, who puts it at 44° 12′, came from the faulty observation of Egnazio Danti through the shadow of a Gnomon at the Equinox, in which neither the visible semidiameter of the Sun was subtracted from the Sun's altitude, nor the northern declination of about 2′, since the Equinox took place two hours before noon, as I shall teach elsewhere.

[Margin: 3. Draco.]

7. DRACO, guardian of the Hesperides, killed by Hercules and raised into heaven by Juno. In Arabic it is *Eltanin*; and in al-Ṣūfī, Mathematician of the Persians, in place of a Dragon there are five Dromedaries and two Wolves, *Abeen* or *Taeben*. It has 31 stars in Ptolemy, 33 in Bayer, 32 in Kepler. Of these the antepenultimate of the tail is of the second magnitude; and the one called the bright star of the head, which is of third rank, is called *Ras Eltanin* or *Rasaben*. There are some, as Stöffler reports, who imagine that Draco was thrown at Minerva by the Giants, but was seized by her, twisted, and flung to the heavens, and has stuck there, always entwined.

[Margin: 4. Cepheus.]

8. CEPHEUS, Κήφευς [Greek: Kēpheus], *Ceginus*, *Iasides*, Lord of the Sun, πυκαρεὺς [Greek: pykareus] *Cancaus*, and in Nonnus *Vir regius*, the Kingly Man; in Arabic, from the corrupted Greek, *Keiphus*. It has 11 stars in Ptolemy, with 2 unformed, 17 in Bayer, 11 in Kepler. Of these three are brighter, one on the left shoulder, called by the Arabs *Aderaimin*. Kircher says that three stars near the left shoulder are called in Arabic *Raar*, *Kelds* and *San*, that is, the Shepherd, the Dog and the Sheep. On the tale of Cepheus, see below, where Cassiopeia is treated.

[Margin: 5. Bootes.]

9. BOOTES, Βοωτὴς [Greek: Boōtēs, "ox-driver"], or Αρκτοφύλαξ [Greek: Arktophylax, "bear-guard"], Arctophylax, that is, guardian of the Bears; *Bubulus*, *Bubulcus*, the Oxherd; in Arabic *Theguius*, as though weeping or crying out, or *Ariamech* or *Alramech*; on the Turkish map Οἰστοφόρος [Greek: Oistophoros, "arrow-bearer"], that is, *Lanceator* or *Sagittifer*, Lancer or Arrow-bearer; in others *Lycaon*, father of the Bears, although

he is rather the son of Ursa Major; on the Persian map *Kontaratus*, and in Avenezra [Avraham ibn Ezra] *Canis latrans*, the Barking Dog. Isidore calls him the lesser Arcturus, but Hesychius calls him Orion. He carries, as Virgil sings, a crook *handsome with even knots*, that is, with stars; or a spear, as Ptolemy has it, κολόρροβον [Greek: kolorrobon]; Hesychius and the Greeks have καλαύροπον [Greek: kalauropon, "shepherd's staff"]; Hyginus ῥόπαλον [Greek: rhopalon, "club"], that is, a club; the Arabs *Incalurum* or *Alkalurops*, by a corrupted Greek word. His belt, moreover, the Arabs call *Mezer* or *Mirach*. In all, it consists of 23 stars in Ptolemy, 34 in Bayer, 28 in Kepler. Among these is one of the first magnitude, called *Arcturus*, of which I shall speak shortly, and which Ptolemy places among the unformed stars; it hangs from the belt between the knees, as Ptolemy and Proclus have it. And so Vitruvius says in book 9, ch. 6, *the middle of the knees of the guardian of the Bear* [custodis arct.], although others fasten it to the belt, with Rufus Festus, in this verse:

Where the golden belts bind the upper garments

and with Germanicus:

They call the star Arcturus where the bands make their knots.

The first star of the sickle, which he carries in his left hand, is called *Marrha*, and in Pliny the Elder *Falx Italica*, the Italian Sickle.

[Margin: Tale.]

He was not Lycaon, but the son of Jupiter and Callisto, cut into pieces by Lycaon and set before Jupiter, his guest, to eat; but he was restored by Jupiter and taken up among the stars, out of compassion, because, having pursued his mother, unrecognised under the form of a Bear, right into the temple of Lycaean Jupiter, which was a capital crime, he was to be put to death.

[Margin: Arcturus.]

ARCTURUS, Αρκτοῦρος [Greek: Arktouros], as though the tail of the Bear, since in Greek a tail is ὄυρα [Greek: oura, "tail"]; and in Homer Οψεδύων [Greek: Opsedyōn, "late-setting"]; in Isidore *Arctuzona*; in Arabic *Alkameluz* or *Kolanza*, *Alramech*; the sword or dagger of Bootes; in Pliny the Elder the *sidus horridum*, the bristling star. It is a star of the first magnitude, hanging, as I said, from the belt between the knees of Bootes.

[Margin: What is Arcturus in Amos and Job, and in the sacred interpreters?]

Now I must explain those words of the prophet Amos, ch. 5, verse 8, who praises God's power in stirring up storms: *Who makes Arcturus and Orion, and turns darkness into morning, and changes day into night, who calls the waters of the sea and pours them out upon the face of the Earth: the Lord is his name.* Our own Cornelius à Lapide expounds this passage learnedly. In Hebrew it reads: *who makes Kima and Kesil*, or *Chimà and Chesil*, or *Cecil*. Likewise those words of Job 9, verses 8 and 9: *Who commands the Sun and it does not rise, who shuts up the stars as under a seal; who makes Arcturus and Orion and the Hyades and the inner parts of the South.* In Hebrew: *who makes Nghais, Chesil and Chimà*. And those words of God himself to Job, 38, verse 31: *Will you be able to join the glittering*

stars, the Pleiades, or will you be able to break up the circuit of Arcturus? Here the name of Arcturus in Hebrew is *Chesil*, which in the same place Pagninus [Sante Pagnini] and the Zurich Bible [Tigurina] translate as Orion.

The translator of the Vulgate, therefore, renders as Arcturus now the name *Nghas* or *Nghais*, as in Job 9, now *Chesil*, as in Job 38, now the name *Chimà*, as in Amos 5. Nor is this surprising, since the Hebrew names of Animals, Plants and Stars take their origin from some property common to several species. The name *Nghas*, or *Nghais*, or *Ghas*, from the verb *Nghus*, which means "I gather", is rightly suited to any constellation aggregated from several stars, but especially to Arcturus, which not only consists of its own stars but besides seems to gather the Wagons and Bears around the Arctic pole; just as the name *Cocaû* generically signifies a star and *Cocacuim* stars. But the name *Chesil*, from the verb *Chacal*, signifies being inconstant and variable, which the Vulgate translator rightly applied to Arcturus in Job 38 because of the variability of the weather, but more rightly to Orion in Job 9 and Amos 5, because Orion is not only variable and inconstant on account of the storms it stirs up by its rising in the month of November, which from this inconstancy is called *Kasleu*, but it also sparkles with an inconstant gleam. Finally, those versed in Hebrew say that the name *Kimà* is a constellation or knot consisting of seven stars, as Pineda affirms on Job 9. Hence, therefore, the Vulgate translator not inappropriately renders this name as Hyades in Job 9 and as Pleiades in Job 38, since each of these constellations consists of seven stars; and as Arcturus in Amos 5, since Arcturus, taken figuratively for Bootes, presides over the governing of the seven stars of Ursa Minor and Major, each of which consists of seven principal and better-known stars. Although other translators have varied on these three names, they in no way conflict, however, with the generic or specific meaning. For any constellation can be called *Nghais* in Hebrew, insofar as it is gathered from several stars. If, however, it consists of seven more notable stars, as do both Bears and the Pleiades and the Hyades, it can be called *Chimà*; or if at least it comes closer to these. Finally, every star that either twinkles inconstantly or causes inconstancy and variability in the weather can be called *Chesil*. Of this kind are Orion, as we shall say in its place, and the Hyades, named from rains, as we explained in the preceding Chapter, number 4, and Arcturus, of which Pliny the Elder says in book 2, ch. 39: *The star of Arcturus hardly ever rises without stormy hail*; and in book 18, ch. 28, speaking of storms and hail, which he calls the greater force, he says: *These will come from the bristling stars, as we have said more than once, such as Arcturus, Orion and the Kids.* And before him Plautus in the *Rudens*:

Arcturus am I, of all signs by far the fiercest, Violent when I rise, more violent still when I set.

And Horace, *Odes* 2, ode 1:

The man who desires what is enough is troubled Neither by the tumultuous sea Nor by the savage onset of setting Arcturus Or of the rising Kid.

And Virgil, *Aeneid* 1:

From where come rain and fires, Arcturus and the rainy Hyades and the twin Triones.

Rightly, therefore, both Amos above and Job ch. 9 praise God's power by his ability to stir up storms at will and to vary the weather at his nod; for this is what it is to make Arcturus and Orion and the Hyades, as Pineda and Cornelius à Lapide, with most others, expound those passages. So too Job ch. 37, verse 9 says: *Out of the inner parts a storm will come forth, and cold from Arcturus*; meaning there, and in ch. 9, the inner parts of the South, from which rain-clouds and rains come, and, by the name of Arcturus, the north wind that scatters the clouds. For the Hebrew has *Mazar* or *Zarah*, which means "I scatter and winnow"; and the north wind blows from the Septentriones, which are figuratively designated by the name of Arcturus; see Pineda there.

[Margin: The opinions of the holy Fathers on these names.]

I do not know, however, from where St Thomas Aquinas on Job ch. 38, and St Gregory in the same place, book 29, ch. 29, took what they understood by the name of Arcturus: the former Ursa Major, the latter the Bears without distinction, which no one can prevent from revolving around the pole in their gyre, just as there is no one who could have composed the Pleiades, so tightly, coherently and constantly joined, as GOD did. St Basil too, on Isaiah ch. 13, verse 10, explaining the words *For the stars of heaven and their splendour will not spread forth their light*, where the Septuagint translators put Orion in place of splendour, affirms that on certain globes Orion is the same as Bootes and consists of 22 stars, or that Arcturus is placed in the middle of Orion. And St Cyril in the same place says that Isaiah *mentioned Orion or Arcturus, so as to signify by this some one of the most notable of the stars*. Less in accord, however, with the more recent nomenclatures and positions of the stars is what Pineda says on Job ch. 38, namely that the Pleiades are northern and Arcturus southern. See St Gregory, *Moralia* book 9, ch. 9, where by Arcturus he understands the Church, which never sets or sinks, though it may suffer persecutions; by Orion the holy Martyrs; and by the Hyades the holy Doctors, etc. Here now is a synopsis of the already mentioned names as used in the sacred writings, with the interpretations according to the versions noted beside them.

Passage	Name	Rendering	Authority
Job 9, verse 9	*Ng-has*	Arcturus	Vulgate
		Pleiades, or Tail of the Ram	Rabbi Mardochaeus
	Chesil	Orion	Vulgate
	Chimà	Hyades	Vulgate
		Arcturus	Septuagint
Job 37, verse 9	*Mazar*	Arcturus	Vulgate
		North wind [Aquilo]	Rabbi David and Levi, Pagninus, Vatablus [François Vatable], Zurich Bible
Job 38, verse 31	*Chimà*	Pleiades	Vulgate

Passage	Name	Rendering	Authority
	Chesil	Arcturus	Vulgate and Septuagint
		Orion	Zurich Bible, Pagninus
Isaiah 13, verse 10	*Chesil*	Splendour	Vulgate
		Orion	Septuagint
Amos 5, verse 5	*Chimà*	Arcturus	Vulgate, Vatablus, Pagninus, Arias [Benito Arias Montano]
		Pleiades	Symmachus and Theodotion
		Hyades	Chaldean
		Cynosura	Zurich Bible
	Chesil	Orion	Vulgate and Syriac
		Gemini	Arabic

[Margin: 6. Corona.]

10. CORONA Borea, the Northern Crown, or the Gnossian Crown of Theseus or of Ariadne; πρώτος στέπανος [recte: στέφανος] [Greek: prōtos stephanos, "first crown"]; in al-Ṣūfī *Parma*, the Shield; in Arabic *Elkleilchemali*, namely the Northern Crown; in Chaldean *Malphelcarte*, which means *sertum pupillae*, the garland of the *pupilla*; in the Persian table πινάκις κεκλασμένος [Greek: pinakis keklasmenos, "broken dish"], *Discus contractus*, the Contracted Disc. It has 8 stars by Ptolemy's reckoning, 20 in Bayer, and in Kepler 8 observed by Tycho. Among these one of the second magnitude is notable, called *Lucida Coronae*, the Bright Star of the Crown; in Ptolemy λαμβρὸς ἀστὴρ [Greek: lambros astēr, "bright star"]; *Alphetal* or *Alphecca*, that is, "opening", in Arabic; and *Mumir*, that is, *pupilla*. Some depict this crown as of laurel, others as of myrtle, and Bayer as of ivy with clusters of berries, from the coins of Magna Graecia and from Manilius, book 5, and Capella. For Bacchus presented his wife Ariadne with such a garland, and it is called *Alphecca* because it breaks through walls; although the tales say that a crown made in its likeness by Vulcan out of gold and gems was given to her at the wedding and afterwards set in the sky.

[Margin: 7. Hercules.]

11. HERCULES, Ενγόνασι [Greek: Engonasi, "on the knees"], that is, one who is ἐν γόνασι [Greek: en gonasi, "on the knees"], namely *in genibus*; and therefore *Ingeniculus* in Vitruvius, book 9, ch. 6, and *Nixus genu* or *genibus*, kneeling on the knee or knees, in Manilius, book 5, and in Ovid, *Metamorphoses* 8. In Arabic it is *Algethi*, or *Elzegeziale*, or *Elhathi*, that is, *geniculator*, the Kneeler; among the Persians, however, *Ternuelles*. It has 28 stars in Ptolemy, with one unformed; 48 in Bayer; in Kepler 28 observed by Tycho. Of these 9 are of the third magnitude, among which the one on the head is called *Ras-Algethi* or *Ras-elbathi*; the middle one on the left hand is called in Arabic *Marfic*, and the one on the right elbow *Maasym*. There are some who would have this be the image of Theseus,

or of Ixion, or of Thamyris, blinded by the Muses, and for that reason on his knees like those who supplicate and beg to be spared punishment; or of Orpheus, or of Prometheus.

[Margin: 8. Lyra.]

12. LYRA, or *Vultur cadens*, the Falling Vulture; in Greek χέλυς [Greek: chelys, "tortoise"] or γύψ κατειμένος [Greek: gyps kateimenos, "vulture let down", i.e. descending]; or *Deferens Psalterium*, the Bearer of the Psaltery; in Chaldean *Asanges*, or rather *Mesanguo*; in Arabic *Albegalà* or *Alahore*: whether this lyre be Apollo's or Orpheus's, according to Ovid, *Metamorphoses*, books 10 and 11. It contains 10 stars in Ptolemy, as many, that is, as there are strings on the ten-stringed psaltery; but in Bayer there are 13 and in Kepler 11. Among them the most brilliant, and of the first magnitude, is the one called *Fidicula* or *Lucida Lyrae*, the Bright Star of Lyra, and in Arabic *Brinek* or *Vuega* or *Vagieh*, that is, face.

[Margin: 9. Cygnus.]

13. CYGNUS, κύκνος [Greek: kyknos, "swan"] or ὄρνις [Greek: ornis, "bird"]; in Ptolemy *Gallina*, the Hen, but in Ovid *Miluius*, the Kite; in Arabic *Eldegiagich*, that is, *Gallina*, or corruptly *Adigege*, in others *Degige* or *Hierezim*, as if fragrant of a rose or lily. It has 17 stars in Ptolemy, with 2 unformed; 36 in Bayer; in Kepler 27 Tychonic stars. Among these one of the second rank is notable, on the Tail, called *Deneb Adigege* or *Arided*; the one on the beak is called *Albireo*, and the one at the tip of the tail *Azelfage*.

[Margin: New star in Cygnus.]

On the Breast of this Swan, in the year 1600, a new star of the 3rd magnitude appeared, having a northern latitude of 55° 37′ and a longitude of 16° 18′ of Aquarius; see Biancani, part 3 of the *Sphaera*, treatise 13. It lasted until the year 1621.

[Margin: Little tale.]

Further, Leda, by Jupiter turned into a Swan, bore an egg, from which came Helen, Castor and Pollux; for that reason the Swan was placed in the heavens, in the Milky Way.

[Margin: 10. Cassiopeia.]

14. CASSIOPEIA, among the Greeks *Cathedra* or *Thronus*, the Chair or Throne, or *Sedes regia*, the Royal Seat, or *Mulier sedis cum Siliquastro*, the Woman of the Seat with the Chair; the seat itself is called in Arabic *Dath Elkarsi*. It has 13 stars in Ptolemy, 25 in Bayer, but Tycho observed 45, besides the new one, of which shortly. Among these 5 of the third magnitude are more notable, of which the one on the breast is called in Arabic *Schedar* or *Seder*, that is, breast, and by the Persians the dyed hand, χεὶρ βεβαμμένη [Greek: cheir bebammenē, "dyed hand"].

[Margin: New star in Cassiopeia.]

On 1572 November 9 [ad 5. Idus Nouemb.] a new star appeared in Cassiopeia, equal to Venus in visible size. Through December it rivalled the star

of Jupiter. In 1573 January it was a little greater than stars of the first magnitude, but equal to them in February and March; equal to stars of the second magnitude in April and May; in June and July it was equal to stars of the third rank; and at the end of the year it scarcely exceeded the fifth magnitude. At last, in 1574 March, it vanished. At its beginning it had a northern latitude of 55° 45′ and a longitude of 6° 54′ of Taurus. Now if it had no sensible parallax, at its beginning it was at least 361 times greater than the Earth and 2 2/[?] times greater than the Sun, according to Tycho, who has more on it in volume 1 of the *Progymnasmata*, from p. 301; on it see also Biancani in the *Sphaera*, part 3, treatise 13, and Claramontius [Scipione Chiaramonti], *De Novis Stellis*.

[Margin: Little tale.]

Cassiopeia is said to have been the mother of Andromeda and the wife of Cepheus, King of the Ethiopians. When she boasted that the Nereids were surpassed by her in beauty, she was carried away from here and placed among the stars as a warning, sitting shamefully with her head thrown back, in her chair. Cepheus too was placed there, by the favour of Minerva, with Andromeda and Perseus, so that their whole family might be immortal.

[Margin: 11. Perseus.]

15. PERSEUS, *Inachides*, *Cyllenius*; in Arabic *Chelub* or *Cheleub*. It has 26 stars in Ptolemy, with 3 unformed; in Bayer there are 38, in Kepler 33. Among these only one is of the second magnitude, shining on the flank, called *ElGenab*, that is, flank, or corruptly *Genib* or *Chenib*. For the one that shines on the shield, called *Raas Algol*, that is, head of the Demon, or *Aloue*, or Head of Medusa, and set at the second magnitude by Ptolemy and Bayer, is in reality now of the third magnitude to Tycho and to us when we inspect it. The Nubian astrologers call it head of the Demon from its malign effects, for they say it threatens hanging or the cutting off of the head or hand, as Ptolemy has it in the *Centiloquium*, aphorism 73.

[Margin: Tale.]

Perseus was the grandson of Acrisius, King of the Argives, and the son of Danaë and Jupiter. He was carried up to heaven with the help of Minerva because he had conquered the Gorgon and also, the marriage having been agreed, had freed Andromeda, who because of her mother Cassiopeia's boasting had been exposed to the sea-monster Cetus and bound near a rock, by killing Cetus. All of these were added to the heavens, but with Cetus banished to the South.

[Margin: 12. Auriga.]

16. AURIGA, or *Erichthonius*, *Myrtilus*; among the Arabs *Mulus clitellatus*, the Saddled Mule; Driver of chariots; ἡνίοχος [Greek: hēniochos, "rein-holder"], *Heniochus*; in Isidore *Mavors*, in others *Maforte*. It consists of 14 stars in Ptolemy, 32 in Bayer, 27 in Kepler. Among them the best known and of the first rank is *Capella Olenia*, the Olenian She-goat, or *Capra Amalthea*, the Goat Amalthea, nurse of Jupiter, called in Arabic *Albaiot* or

Albatod; with the two Kids it imitates the figure of an acute-angled and oblong isosceles triangle. After it the famous one is the star of the second magnitude on the following shoulder; for the one under the foot, likewise of the second rank, belongs rather to the tip of the northern Horn of Taurus. Jupiter took this man into the heavens for his invention of the four-horse chariot: read Ovid, *Metamorphoses* book 2, and St Augustine, *City of God* book 18, ch. 12. Pliny the Elder has more on Capella in book 18, chs 26, 27, 28, 29; for Capella is a stormy star to Rufus Avienus, or, as Germanicus sings here, is hostile to sailors.

[Margin: 13. Serpentarius.]

17. SERPENTARIUS, or Ophiuchus, Ὀφιοῦχος [Greek: Ophiouchos, "serpent-holder"]; Aesculapius; in Aratus Μογερὸς [Greek: Mogeros, "toiling one"]; *Alhague* or *Alangue*; among the Moors the Crane, or the Stork standing on a serpent. It has 24 stars in Ptolemy, with 5 unformed; but in Bayer 30, in Kepler 37. Of these only one is notable, of the second magnitude, the more northerly one on its Head, called in Arabic *Raas alangue* or *Ras alhauge*. But for how wrongly several stars of this constellation are drawn on globes, with their positions interchanged, see Kepler, the Rudolphine Tables, p. 68.

[Margin: New star in Serpentarius.]

In this constellation, on 1604 October 9, a new star appeared, wonderfully ruddy, of almost 2° northern latitude and at 18° of Sagittarius, with no parallax, equal to Venus in apparent size; and it vanished from sight in 1606, at the beginning of February. Kepler has much on this star in his book *De Nova Stella in Serpentario*: see also [?] Biancani, part three of the *Sphaera*, treatise 13, and Chiaramonti, *De Novis Stellis*. It is a remarkable thing that the new star of Cassiopeia, of Cygnus and of Serpentarius appeared in the Milky Way or at its border.

[Margin: Tale.]

Aesculapius, moreover, was the son of Apollo and Coronis, called up to heaven to immortality because by the art of medicine, especially by means of a herb shown him by a snake, he restored people to life, whether dead, like Glaucus, or half-dead.

[Margin: 14. Serpens.]

18. SERPENS of Ophiuchus, Ὄφις [Greek: Ophis, "serpent"], *Alangue*. It has 18 stars in Ptolemy, with 5 unformed; but 37 in Bayer, and 13 Tychonic stars in Kepler. Of these the bright one of the Neck is of the second magnitude, but in Ptolemy of the third.

[Margin: 15. Sagitta.]

19. SAGITTA, Οἰστὸς [Greek: Oistos, "arrow"]; in Arabic *Schaham* or *Alhance*; among the Turks *Orfercalem*. It has 5 stars in Ptolemy, 8 in Bayer, 8 in Kepler.

[Margin: Tale.]

This was the arrow with which Hercules killed the vulture that was eating Prometheus's liver; for when Prometheus had been received back into favour by Jupiter, Jupiter willed that the arrow be set in the sky. In Cicero it is called *Musator*, in others *temo meridianus*, the southern Wagon-pole.

[Margin: 16. Aquila.]

20. AQUILA, or *Vultur volans*, the Flying Vulture, abductress of Ganymede, Αετὸς [Greek: Aetos, "eagle"]; in Arabic *Altair* or *Atair*, that is, bird. It contains 9 stars in Ptolemy, 32 in Bayer, because he adds Ganymede; but Kepler gives 12. Of these the bright one on the shoulders, or at the projection of the neck, is of the second magnitude. In the Persian Tables it is γὺψ πετόμενος [Greek: gyps petomenos, "flying vulture"], *vultur volans*.

[Margin: 17. Antinous.]

21. ANTINOUS, in place of Ganymede, has 7 stars in Kepler, 11 in Bayer. He was the darling of the Emperor Hadrian for his beauty, was born at Claudiopolis in Bithynia, and was given celestial honours.

[Margin: 18. Delphinus.]

22. DELPHIN, Delphinus, carrier of Arion; in Pliny the Elder *Hermippus*; Δελφὶν [Greek: Delphin, "dolphin"] or δελφὶς [Greek: delphis, "dolphin"]; *Rhomboides*. It consists of 10 stars in Ptolemy, and as many in Bayer and Kepler. Cicero calls it *Currus*, the Chariot; the Arabs, borrowing the name from the Greeks, say *Dalphin*.

[Margin: 19. Equiculus.]

23. EQUULEUS, the Lesser Horse; in Arabic *Alpharas Elmac*. It has only 4 stars, of the fourth magnitude, and those faint. In Proclus it is προτοπὴ [recte: προτομὴ] τοῦ ἵππου [Greek: protomē tou hippou, "forepart of the horse"], *sectio equi*, the section of the horse, or *Equiculus*.

[Margin: 20. Pegasus.]

24. PEGASUS, the Greater Horse, *Medusaeus*, *Gorgoneus*, *Bellerophonteus*, *Alpheratz*. It has 20 stars in Ptolemy, 23 in Bayer, likewise 23 in Kepler, of which 4 are of the second magnitude. Of these the one on the shoulder of the preceding wing is called *Markab*, that is, chariot; the one at the tip of the wing *Algenib*; the one at the projection of the leg *Scheat Alpheraz*; and the one on the navel, which is shared, is the Head of Andromeda: Ομφαλος ἵππου [Greek: Omphalos hippou, "navel of the horse"], navel of Pegasus.

[Margin: 21. Andromeda.]

25. ANDROMEDA, in Arabic *Marat musalseleth*, that is, the Chained Woman; on her, see under Cassiopeia. In all it has 23 stars in Ptolemy and as many in Kepler, but Bayer has 27. Among these three are noteworthy and of the second magnitude, though in Ptolemy they are of the third: the first on the Head, which is also called the navel of Pegasus; the second on the belt or navel, called *Mizar* or *Mirach*; the third on the southern foot, called *Allamak* by the Arabs.

[Margin: 22. Triangulum.]

26. TRIANGULUM Boreale, the Northern Triangle, Δελτῶτον [Greek: Deltōton, "delta-shaped"], or τρίγωνος [Greek: trigōnos, "three-cornered"]; Gift of the Nile; Δέλτα [Greek: Delta]; in Arabic *Mutlathum* or *Mutlat*. It has 4 stars by Ptolemy's reckoning, 5 in Bayer, 4 in Kepler.

[Margin: 23. Coma Berenices.]

27. COMA BERENICES, in Bayer *Spicarum manipulus*, the Handful of Ears of Grain, and τρίχες [Greek: triches, "hairs"], or *crines*, hair. It has 7 stars in Proclus and Stöffler, 15 in Kepler.

[Margin: Little tale.]

This Berenice was the wife of Ptolemy Euergetes. She vowed that if her husband returned victorious from Asia she would cut off her hair and hang it in the temple of Venus. When she had done so, and the next day it had not appeared, Conon the mathematician, to console the king, showed the hair set among the stars; and so Callimachus the poet, in Olympiad 136, and afterwards Catullus, wrote a poem on the hair of Berenice. Pliny the Elder, however, seems to place the Berenicean hair among the southern constellations, book 2, ch. 72. Further, in Ptolemy the three stars he calls τρίχες, that is, *crines*, or *Plocamos*, that is, *cincinnus*, a lock, outside the constellation of Leo, at its tail toward the north, together with four others observed by Conon, are the hair of Berenice, to which more recent authors have added another 8.

CAPVT V.

Chapter 5.

De Astris extra Zodiacum Australibus, præcipuè de Canicula, & de nominato in sacris literis Orione.

On the Southern Constellations outside the Zodiac, especially on the Dog Star, and on the Orion named in the sacred writings.

[Margin: 1. Cetus.]

1. CETE, or Cetus, Κῆτος [Greek: Kētos, "sea-monster"], Whale, *Pistrix*, πρῆστις [Greek: prēstis, a sea-monster], Sea Beast, Sea Lion or Sea Bear, *Orphas*, Ὀρφὼς [Greek: Orphōs]; in Arabic *Elkaitos* or *Alkeitos*. It has 22 stars in Ptolemy, 27 in Bayer, and in Kepler 21 Tychonic and 4 semi-Tychonic. Of these the bright one on the jaw or nostril, called in Arabic *Menchar* or *Menkar Elkaitos*, that is, beak of Cetus, and the brighter and more southerly one on the tail, called in Arabic *Demeb Kaitos*, are in reality now of the second magnitude, although in Ptolemy's table they are placed at the third magnitude. The middle, more northerly one of the belly is called *Baten Elkeitus*, belly of Cetus.

This Beast was sent by Neptune to devour Andromeda, but it was killed by Perseus: see what we said under Andromeda, and Manilius, who in book 5, ch. 40, describes the fight of Perseus with Cetus.

[Margin: 2. Orion.]

2. ORION, Ωριων [Greek: Ōriōn], or Ωάριων [Greek: Ōariōn], *Hyriades* or *Hyrides*, from his parent Hyreus; the Hunter; *Iugula* in Plautus and Varro, but in Manilius, book 5, *Iugulae*; in Hebrew *Chesil* or *Kesil*; in Arabic *Elgeuze* or *Almahbarrab*, that is, mighty warrior; and, from hunting or searching out, *Algebra*; or *Elgebar*, that is, Giant. He is called Orion as if Urion, from urine, which in Greek is οὖρορ [recte: οὖρον] [Greek: ouron, "urine"], because of the little tale that follows shortly; or from ὀρίνειν [Greek: orinein], which means to disturb. It has 38 stars in Ptolemy, 49 in Bayer, and in Kepler 62 Tychonic stars, which I too once counted. Among them two are of the first magnitude: one on the following shoulder, called in Arabic *Bectelgeuze*, that is, house of the Giant, or *Bedalgeuze*, which Aratus calls γλήνεαν [Greek: glēnean]; the other at the tip of the right foot, called *Rigel* or *Regel Elgebar*, that is, foot of the Giant. The one on the preceding shoulder, of the second magnitude, is called *Bellatrix*, to which Kepler makes the bright one of the following shoulder equal in size. In the Persian Tables translated by Chrysococca the foot of Orion is called ποῦς Διδύμων [Greek: pous Didymōn, "foot of the Twins"], and the bright one of the following shoulder ὦμος Διδύμων [Greek: ōmos Didymōn, "shoulder of the Twins"]. The three of the belt, or, as they are commonly called, the staff of St James, are of the second magnitude.

[Margin: A huge multitude of stars detected by the telescope.]

Further, Galileo, as he relates in the *Sidereus Nuncius* from p. 16, having undertaken to draw the whole constellation of Orion with the spyglass, was deterred by the huge abundance of stars and, for lack of time, put off the work; and he adds: *For more than five hundred stand beside and around the old ones, scattered within the limits of one or two degrees: therefore to the three in the belt and the six in the sword, noted long since, we have added eighty others adjacent to them, recently seen; and we have preserved their intervals as exactly as we could.*

[Margin: Little tale.]

Now from Ovid, *Fasti* book 5, Hyginus and others, the tale is told that Orion, otherwise Urion, at the prayers of the childless Hyreus, was born from the urine of three Gods whom Hyreus had received as guests, namely Jupiter, Neptune and Mercury, collected in a leather vessel; that he was an outstanding hunter and companion of Diana, but suspect to Apollo for his excessive familiarity with Diana; and that Apollo therefore challenged Diana to aim at a certain black target emerging from the sea, which was in fact the head of Orion, swimming. And so Orion was pierced with arrows, but was received into heaven to console Diana, and between the Dog and the celestial Hare he seems even now to be hunting. It is, moreover, a stormy constellation, according to that line of Virgil, *Aeneid* 1:

When suddenly, rising on the swell, stormy Orion

and of Horace, *Odes* book 1, where he calls the rainy south wind the companion of setting Orion:

The south wind, swift companion of declining Orion.

[Margin: What is Orion in Hebrew and in the sacred writings?]

In Hebrew it is called *Kesil* or *Chesil*, from the verb *Cacal*, which means to be varied and inconstant. And Orion either twinkles inconstantly because of its very ruddy sparkling, or rather causes varied and inconstant weather at its rising or setting, especially in the month of November, a month which for that reason is called *Kasleu*, from the same root. Hence in the sacred writings the power of GOD is praised in stirring up storms at his pleasure and varying the weather of the year, as when it is said in Job 9, verse 9: *Who makes Arcturus and Orion and the Hyades*, etc., and in the Prophet Amos, ch. 5, verse 5, where he praises God as *Making Arcturus and Orion*. In both places, however, the Hebrew has *Kesil*, although, as we said in ch. 4, no. 9, they are confused with Arcturus by some sacred writers. Yet, as I said, *Kesil* can be drawn to the variability of the sparkling and splendour with which Orion twinkles, since in Isaiah 13, verse 10, where the Vulgate has *For the stars of heaven and their splendour will not give their light*, the Septuagint translators render the name *Kesil*, in place of splendour, as Orion, according to that line of Virgil, *Aeneid* 3:

And he looks around at Orion, armed with gold

and of Lucan, book 1:

The flank of sword-bearing Orion shines too brightly.

Finally, one should see St Gregory, *Moralia* book 9, ch. 9, where by the name of Orion he understands the holy Martyrs; Pineda on Job ch. 9, and Cornelius à Lapide on Amos ch. 5; and, on the power of Orion, Pliny the Elder, book 18 throughout, especially ch. 28, and Manilius, book 5, from the verse *Maximus Orion*, Greatest Orion, etc.

[Margin: 3. Eridanus.]

3. ERIDANUS, the river Po, ποταμὸς [Greek: potamos, "river"]; in others the Nile, Gyon; among the Fetzani *Vardi*, that is, River; among the Mauritanians *Guad*; in Arabic *Nahar*. It has 34 stars in Ptolemy, 43 in Bayer, and in Kepler 19 Tychonic and 20 semi-Tychonic. Among these one is notable and of the first magnitude, at the end of the river, called *Acharnahar*, that is, the end of the river, or *Acarnaharim*. Its southern latitude, for navigators, is 59° 30′, and its longitude for the year 1600 is 9° 45′ of Pisces; and so it cannot be observed on our horizon. The constellation has no stars of the second magnitude. The last star of Eridanus is called in the Persian Tables of Chrysococca αὖλαξ [Greek: aulax, "furrow"], that is, furrow, as Boulliau shows at the end of his *Astronomia*. But the one at the bend of Eridanus is called in Arabic *Argentenar*.

Those who recognise this constellation as Eridanus, with Ovid, *Metamorphoses* book 2, place it in the heavens because, when Phaethon was plunged into it, the burning of the world was extinguished; those who think it the Nile

judged it worthy of an image in the heavens for the outstanding benefits it brings to Egypt.

[Margin: 4. Lepus.]

4. LEPUS, λαγωὸς [Greek: lagōos, "hare"], *Levipes*, Light-foot; among the Sicilians λέπορος [Greek: leporos]; in Nicander δερκευνὴς [Greek: derkeunēs]; in Arabic *Harneb* and *Elharneb*. It consists of 12 stars in Ptolemy, 13 in Bayer, 13 in Kepler, and has none of the first or second magnitude. It was put in the sky either for its speed, or because Orion, to please Diana, who delighted in hare's blood, took the greatest delight in hunting the hare.

[Margin: 5. Canis Maior.]

5. CANIS Maior, *Laelaps*; in Arabic *Scheer Eliemini*, from which in the Persian Tables σιάηρ ἰαμανῆ [Greek: siaēr iamanē]; and in Homer, *Iliad* book 10, ἀστὴρ ὀπώρινος [Greek: astēr opōrinos, "autumn star"], the star near autumn, or the one ending the summer. It has 18 stars in Ptolemy, with 11 unformed; 19 in Bayer; in Kepler 13 Tychonic and 16 others semi-Tychonic. Among them there is one which, as far as appearance goes, is the greatest of the fixed stars and equal to Jupiter at perigee, namely the one that shines on the cheek or tongue of the Dog, called *Sirius*, in Arabic *Alhabor* or *Elscheer* or *Elkabar*; but the one that glows red at its left ear is called *Isis*.

[Margin: Little tale.]

Some say that both dogs belonged to Orion the hunter and were carried up to Heaven with him by the prayers of Diana; others that this one was given to Cepheus by Aurora and endowed with such speed that it outran all wild beasts, but that, when it was about to encounter at Thebes a fox endowed by Jupiter with the same speed, it was raised to heaven so that the fates should not be made void.

[Margin: Sirius: what it is and where the name comes from.]

That splendid star, further, was called Σείριος [Greek: Seirios], either from σείρειν [Greek: seirein], which means to gape, because under this star the ground is made to gape open from dryness; or from σειριάω [Greek: seiriaō], which means I dry up. For this reason also the Sun itself is called Sirius by Hesiod in book 2 of the *Works and Days*, according to the common opinion of the interpreters; and Hesychius says expressly Σείριος, ὁ ἥλιος, καὶ ὁ τοῦ κυνὸς ἀστὴρ [Greek: Seirios, ho hēlios, kai ho tou kynos astēr], that is, *Sirius is the Sun, and the Dog Star*; and he adds that the word is used by Archilochus for the Sun, and by Ibycus for any star whatever.

[Margin: The Sothic period and the Canicular Year.]

This Dog the Egyptians called Sothis, and they gave it first place among the stars, and from its rising they drew conclusions about the rise of the Nile and the weather of the whole year, as Horus, Apollo and Hephaestio report. Indeed, from it they named that great Sothic period, or great Cynic or Canicular year; and, beginning it from its rising on the first day of the first month, Thoth, they

defined it as 1461 Egyptian years, at the end of which the first day of the month Thoth returned to the same degree of the Zodiac, and so, as they themselves thought, to the same rising of the Dog; for they had not yet learned that the Fixed stars are moved forward in the order of the signs. See what we said on the Canicular year and its Epoch in book 3, ch. 13, no. 9. Whether Sirius is the Canicula for everyone, and whether the effects of the dog days are to be attributed to it, will be argued shortly, after the explanation of Canis Minor. On what days it used to rise and set in former times, and rises and sets now, we shall discuss at length in ch. 22, under the word *Canicula*.

[Margin: 6. Canis Minor.]

6. CANIS Minor, the Little Dog, *Procyon*, or *Procynis*, or *Praecanis*; in Cicero *Anticanis*, in that verse:

Anticanis, who is called by the Greek name Procyon;

in Arabic *Kebelazguar*. It has 2 stars in Ptolemy, 8 in Bayer, 5 in Kepler. Of these the bright one of the breast or thigh is called, from the name of the whole constellation, *Procyon*; in Arabic *Algomeiza* or *Algomisa*. To Ptolemy and Bayer it is of the first magnitude, but to Tycho of the second; certainly if it is compared with Sirius, Lyra and Arcturus, not, however, if with the tail of Leo. On its rising and setting too there is more below, in ch. 22.

[Margin: Little tale of the Dog.]

Some, moreover, have told the tale that this dog was carried up into heaven with Erigone, that is, the Virgin, because it had wasted away with grief for its master Icarius, killed by drunken peasants, and for Erigone, who had hanged herself because of the murder of her father Icarius,

Vter Canum sit Canicula, & quinam & vnde sint effectus dierum Canicularium.

Which of the Dogs is the Canicula, and what the effects of the Dog Days are and where they come from.

[Margin: Authors who recognize Canis Minor as the Canicula.]

The name of the Canicula is as famous as it is ambiguous. At first sound it seems to suit the smaller dog, which is taken for the Canicula by the Alphonsine Tables; by Bede in his little work on the sphere; by Adrianus Turnebus [Adrien Turnèbe] in his *Adversaria*; by Raderus [Matthäus Rader] on Martial, book 11, epigram 49; by Carolus Stephanus [Charles Estienne] in his *Poetic Dictionary*; and by Kepler in the *Epitome of Copernican Astronomy*, p. 391. Hyginus also favours this when he attributes to Procyon what Germanicus attributes to Sirius, namely conjunction with the Sun in the centre of the sky. For whether you take the centre of the sky to mean the solstitial point, or the culmination on the meridian, or the zenith in a barbarian horizon, Procyon was then both nearer to the beginning of Cancer and culminated earlier with the Sun and as the nearer star in its passage across the meridian; and because of its northerly declination it can appear, and could appear, closer to the zenith than Sirius for

more people on this side of the Equator. Horace chimes in with these, book 3, ode 29:

> … Now Procyon rages, And the star of frenzied Leo, As the Sun brings back the dry days.

[Margin: Pliny the Elder's opinion.]

But Pliny the Elder says so much more clearly in book 18, ch. 28, in these words: "In Egypt Procyon is hot in the morning; this star has no name among the Romans, unless we wish this one to be understood as the *canicula*, that is, the lesser Dog, as indeed it is depicted among the stars." He confirms this from its relevance to, and nearness with, the rising of the greater Dog, for he adds at once: "But it is very relevant, as we shall show a little later: on the 3rd day before the Nones [III. Nonas] the Crown sets in the morning for the Chaldeans; for Attica the whole of Orion rises on that day. On July 14 [Pridie Idus Iulij] Orion finishes rising for the Egyptians. On July 17 [XVI. Kalend. Augusti] Procyon rises for Assyria; then on the following day comes the star agreed on among all peoples almost everywhere, which gives the signal we call the rising of the Dog, when the Sun has entered the first part of Leo." And in ch. 29 he distinguishes the Canicula from Canis Major more plainly, saying: "By the varying observation of the nations the Dog sets on April 28 [IV. Calendas Maij], a star both violent in itself and one before which the Canicula must set." Granted that our Pétau, in book 7 of the *Dissertations* of the *Uranologion*, ch. 2, because Procyon does not set before the Dog in any setting but after it, may take this passage to concern not the heavenly *canicula* but an earthly red bitch, which the Romans used to kill at the Catularia gate, as Festus attests, to appease the star of the Canicula. The Rubigalia, moreover, were held on April 25 [VII. Cal. Maij] to turn rust away from the crops, as Pliny the Elder relates in the same place.

[Margin: For whom both Dogs are the Canicula?]

The old interpreter of Aratus, however, and Bayer in his *Uranometria* call both dogs the Canicula.

[Margin: Authors who recognize Canis Major as the Canicula.]

Yet more others understand by the name Canicula Sirius, the most brilliant part of Canis Major: first of all Germanicus and his commentator Bassus; Iulius Firmicus [Firmicus Maternus], book 8; Apian, Magini and Argolus [Andrea Argoli] in their catalogues of stars; Pierius Valerianus [Pierio Valeriano], *Hieroglyphica*, book 49; Stöffler on Proclus's *Sphere*, p. 125; Henricus Stephanus [Henri Estienne] in the *Thesaurus linguae Graecae*; the author of the *Thesaurus linguae Latinae*; Pétau in the *Uranologion*, book 2, *Dissertations*, ch. 10, book 5, chs 5 and 6, and book 7, ch. 2; and finally those who attribute the canicular changes to the rising of the Dog or of Sirius. For although both Dogs rise, both cosmically and heliacally, in the summer season and with the summer already advanced, and although greater heat arises from the Sun's approach to both, or even to Regulus, still this assessment appears to come more manifestly from

the heliacal rising of Sirius; and it was certainly then that the Nile used to swell more abundantly.

[Margin: Effects of the Canicula [?].]

Further, on the effect of the Dog Days, and on their observance, which Hippocrates and Aëtius urge, there are discussions, besides the physicians, by Pierius, *Hieroglyphica*, book 43; by Simon Maiolus [Simone Maioli] in the preface to his work on the Dog Days; by Delrius [Martin Del Rio] on the first act of the *Oedipus*; by Laelius Bisciolius [Lelio Bisciola] in his *Horae subsecivae*, volume 2, book 12, ch. 2; and by the commentators, both on Persius, satire 3, at this verse:

> See, what are you doing? The frenzied Canicula, the dry harvests, etc.

and at this verse of Horace, book 3, ode 13:

> You the fierce hour of the blazing Canicula

and on this from Ovid, *Fasti* 5:

> There is a Dog, they call it Icarian, at whose star's rising The scorched earth thirsts and the crop is snatched away. In place of the starry Dog, this dog is laid on the altars; And why it is done has nothing but the name.

Let Pliny the Elder stand for all, book 18, ch. 28: "Then on the following day comes the star agreed on among all peoples almost everywhere, which gives the signal we call the rising of the Dog, when the Sun has entered the first part of Leo. This happens on the 23rd day after the solstice. Seas and lands feel it, and many wild beasts too, as we have said in their places; nor is the veneration of it less than that of the stars assigned to the gods; and it kindles the Sun and is a great cause of the heat." For in book 2, ch. 40 he had said: "For who does not know that the Sun's vapours are kindled at the rising of the Canicula? The effects of this star are felt most widely on earth: seas seethe as it rises, wines surge in the cellars, pools are stirred. Egypt gives the name oryx to a wild beast which, it reports, stands facing the star at its rising and gazes at it, and as it were worships it when it has sneezed. As for dogs, there is no doubt that throughout that whole period they are driven most of all to madness." And in book 9, ch. 16 he says of the silurus, a fish: "Among river fish the silurus is stricken at the rising of the Canicula, and at other times is stunned by lightning. They think this also happens at sea to the cyprinus; and in any case the whole sea feels the rising of that star, which is most apparent in the Bosphorus. For seaweed and fish are carried to the surface, and everything is turned over from the bottom." For this reason Hippocrates forbade purging medicines during these days, saying: "Under the Dog and before the Dog treatments are difficult."

[Margin: Abundance and excellence of honey at the rising of Sirius.]

Yet the Canicula by its rising brings this benefit, that a greater quantity of honey is then produced, as Mercurialis [Girolamo Mercuriale], *Variae lectiones*, book 2, ch. 24, gathers from Aristotle, *History of Animals*, book 5, ch. 22. He brings forward the text from an ancient codex of Scipio Garteromachus

[Scipione Forteguerri], in which it is read that honey falls from the air μαλίστα ἐν ταῖς τῶν ἄστρων ἐπιτολαῖς, καὶ ὅταν κατασκήψη ὅ ξείριος [recte: ὁ Σείριος] [Greek: malista en tais tōn astrōn epitolais, kai hotan kataskēpsē ho Seirios], that is, especially at the risings of the stars, and when Sirius is seen; for in great dryness and a clear sky this aerial nectar exudes onto the flowers. Pliny the Elder states this expressly in book 11, ch. 14: "A second kind is summer honey, which is called *horaeum* from its especially good season, when Sirius itself blazes out, about 30 days after the solstice"; and a little later: "But if this is kept when Sirius is rising, and if the rising of Venus, or of Jupiter or Mercury, happens to fall on the same day (as often), its sweetness and its power for calling mortal ills away from death prove to be nothing other than those of divine nectar." So the saliva of the heavenly dog is then sweet and life-giving, while the saliva of earthly dogs turned to madness is poison.

[Margin: Singular opinion of Geminus and Petavius.]

Notwithstanding all this, Geminus in the *Elements of Astronomy*, ch. 14, and with him, more or less, Pétau in the *Uranologion*, book 2, ch. 10, contend that the effects already mentioned are indeed signified, but not produced, by these or other rising stars, being produced rather by the Sun, which is stronger at that time and falls in the days of such risings. But this is to struggle against the stream, or rather the torrent, of authors, and to make far too idle the creation and arrangement, divinely accomplished, of so many stars.

[Margin: 7. Argonavis.]

7. ARGONAVIS, the Ship of Jason; in Catullus *Currus volitans*, the Flying Chariot; Noah's Ark; *Markeb*. It comprises 45 stars in Ptolemy, 63 in Bayer, and in Kepler 11 Tychonic and another 42 semi-Tychonic. Of these only one, at the end of the rudder, is of the first magnitude, called Κάνωβος [Greek: Kanōbos], *Canobus* in Proclus, or *Canopus*, and in the Persian Tables *Soail Iamani*, σοαὶλ ιαμανῆ [Greek: soail iamanē]; in Arabic *Suhel*. At Rhodes it seems to graze the horizon, perhaps because hills stand in the way, as Snel conjectures in *Eratosthenes Batavus*, book 1, ch. 16. Kepler, on the contrary, in the *Astronomia Optica*, thinks that it could not appear even at Rhodes except by the benefit of refractions; on which I shall speak in volume 2 of the *Almagest*, book 4. This constellation has besides 6 stars of the second magnitude in Ptolemy, 7 in Bayer and Kepler.

[Margin: 8. Centaurus.]

8. CENTAURUS, Chiron, the son of Philyra, who died from an arrow of Hercules falling by accident; Minotaur; *Albeze* or *Asmeat*. It consists of 37 stars in Ptolemy, 40 in Bayer, and in Kepler 4 observed by Tycho and the remaining 52. Of these 5 are of the second magnitude; and for Kepler and Ptolemy one is of the first magnitude, namely the one at the top of the forward foot, while the one on the hip of the hind foot is likewise of the first magnitude for Bayer. The Cross, moreover, commonly *el Crosiero*, has its top and bottom stars of the second magnitude and its side

stars of the third magnitude, and it is set on the hind feet of the Centaur. The Centaur's spear was called *Thyrsus* or *Thyrsolochus*, according to Proclus and Bassus.

[Margin: 9. Lupus.]

9. LUPUS, the Beast of the Centaur; in Capella the Panther; among the Persians *Bridemif*; in Arabic *Asida*. It has 19 stars in Ptolemy, 20 in Bayer, 19 in Kepler, none of them of the second rank.

This wolf the Centaur is said to have sacrificed to the gods as a victim, but above all to Bacchus.

[Margin: 10. Hydra.]

10. HYDRA, ἀσβία [Greek: asbia], *Asbia*; in Arabic *Elhauich*. It has 25 stars in Ptolemy, with 7 unformed; 29 in Bayer; in Kepler 24 Tychonic and the remaining 9. Of these the one that shines on the Heart, called *Alphard*, is of the first magnitude to Tycho and most others, but of the second in Ptolemy's table. This Hydra is not a trophy of Hercules, but was added by Apollo to frighten the raven, suffering from thirst, away from the water.

[Margin: 11. Crater.]

11. CRATER, the Bowl, κρήτηρ [Greek: krētēr, "mixing bowl"]; in Arabic *Elkis* or *Eluarad* or *Pharmaz*. It has 7 stars in Ptolemy, 11 in Bayer, 8 in Kepler, none of the third magnitude, let alone of the second or first. Is this the cup of Bacchus? Or of Apollo, as Hyginus prefers, which Apollo gave to the Raven to fetch water?

[Margin: 12. Corvus.]

12. CORVUS, Κόραξ [Greek: Korax, "raven"]; in Arabic *Algorab*. It has 7 stars in Ptolemy, and likewise in Bayer and in Kepler. This raven was carried up into heaven by Apollo. See Hyginus.

[Margin: 13. Thuribulum.]

13. THURIBULUM, the Censer; *Lar*; *Acerra*; in Arabic *Almegrameth*; in others *Ara*, or altar, made by the Cyclopes, on which the gods are said first to have made sacrifice and their conspiracy against the Titans. It has 7 stars in Ptolemy and Kepler, but 8 in Bayer.

[Margin: 14. Corona Australis.]

14. CORONA Australis, οὐρανίσκος [Greek: ouraniskos, "little heaven"], *parvum caelum*, the Little Sky; in Arabic *Ekleil Elgenubi*; *Rota Ixionis*, the Wheel of Ixion; in Hipparchus the Caduceus; in Proclus κηρυκεῖον [Greek: kērykeion, "herald's staff"]. It has 13 stars in Ptolemy, Bayer and Kepler. But if the star of the second magnitude in front of the knee of the left foot of Sagittarius is assigned to it, as it conveniently can be, this Crown too will have its bright gem, as Corona Borealis has. This Crown was carried down to the underworld by Bacchus.

[Margin: 15. Piscis Notius.]

15. PISCIS Notius, the Fish of Capricorn. It has 12 stars in Ptolemy and Bayer, who count among these *Fomahant*, a star of the first rank; but we

have counted that one in the outflow of Aquarius. Ptolemy adds another 6 unformed; in Kepler there are 17. This fish is said to swim in the sky because it saved Phacetis, daughter of Venus, who had fallen into the pool of Boëth. [?]

Sequuntur Duodecim noua Astra Australia, partim ab Americo Vespucio, partim ab Andrea Corsalio, & Petro Medinensi obseruata & à Petro Theodori Nauclero peritissimo, Friderico Houtmanno, ac Iacobo Barthschio ad normam Astronomicam redacta.

The twelve new southern constellations follow, observed partly by Amerigo Vespucci, partly by Andrea Corsali and Pedro de Medina, and brought to an astronomical standard by that most expert navigator Petrus Theodori [Pieter Dirkszoon Keyser], by Frederik de Houtman, and by Jakob Bartsch.

[Margin: 16. Grus.]

16. GRUS consists of 13 stars in Kepler and Bayer, of which three are of the second magnitude: one on the head, another at the start of the tail, the third on the more southerly wing.

[Margin: 17. Phoenix.]

17. PHOENIX, of 15 stars, with only one of the second rank, on the neck, and two nebulous ones.

[Margin: 18. Indus.]

18. INDUS, of 12 stars, in human form.

[Margin: 19. Pavo.]

19. PAVO has 16 stars in Bayer, 23 in Kepler with the unformed ones; among these is one on the head of the second magnitude, and two nebulous ones.

[Margin: 20. Apus.]

20. APUS, or *Avis Indica*, the Indian Bird, of 12 stars in Bayer, 11 in Kepler.

[Margin: 21. Apis.]

21. APIS, or *Musca*, of only 4 stars.

[Margin: 22. Triangulum Australe.]

22. TRIANGULUM Australe, with five stars, of which the three at the vertices or angles are put at the second magnitude by Bayer, at the third by Kepler.

[Margin: 23. Chamaeleon.]

23. CHAMAELEON, of 10 stars in Kepler, 9 in Bayer; all are of the fifth rank.

[Margin: 24. Piscis volator.]

24. PISCIS volans, the Flying Fish, or *Passer*, of 7 stars.

[Margin: 25. Dorado.]

25. DORADO, the Swordfish [Piscis Xiphias], with 6 stars, but of these two belong to the nearby little cloud. The star of the belly was distant from

the pole of the ecliptic in the year 1600 by 1° 48′, and it is of the fifth magnitude.

[Margin: 26. Anser Americanus.]

26. ANSER Americanus, the American Goose, called *Toucan*, of 8 stars, of which four are notable and of the second magnitude in Bayer, of the third in Kepler: one on the head, another on the beak, the third on the rump, the fourth on the wing or breast.

[Margin: 27. Hydrus.]

27. HYDRUS, of 15 stars in Bayer, 20 in Kepler besides the little cloud. Of these one, on the head, is of the second magnitude in Bayer, of the third in Kepler. The one almost at the tip of the tail, closest to the Antarctic pole of the world, is of the fifth magnitude; it was distant from that pole in the year 1600 by about 2° 30′, and now it is less distant.

CAPVT VI.

Chapter 6.

De Numero Astrorum & Stellarum in illis aut extra illa, tum relatiuè ad sex magnitudinis apparentis classes, aut ad Mundi Plagas, tum absolutè: & de Figuris ac Nominibus situue eorum mutandis.

On the number of the constellations and of the stars in them or outside them, both relative to the six classes of apparent magnitude or to the quarters of the world, and absolutely; and on changing their figures and names, or their position.

[Margin: Number of the constellations according to the moderns.]

1. The first question is how many constellations [Astra seu Constellationes] there once were and how many there are now. I reply briefly that the ancient ones are 50 and the new ones 12, and so 62 in all. Among them are the 12 Signs or constellations of the zodiac, reviewed in ch. 3; the 23 northern constellations named in ch. 4; and the 27 southern ones related in ch. 5. Among the older writers, however, the number is smaller or larger, whether from the omission of some whole constellation, or from the reduction of two to one, or from the division of one into two or more; and all the ancients left out the 12 new ones.

[Margin: 43 constellations.]

Ausonius and Bede, in the little work on the sphere and in the *Eclogarium* on the heavenly signs, list 43, with Equuleus, Lupus, Crater, Corvus, Serpens, Coma Berenices and Antinous omitted or merged with others.

[Margin: 44 constellations.]

Germanicus Caesar, even though he is the interpreter of Aratus, sets down 44, with Sagitta, Corona Australis, Procyon, Serpens, Coma Berenices and Antinous omitted; perhaps some fragments of his have been lost.

[Margin: 45 constellations.]

Vitruvius, book 9, chs 6 and 7, lists 45, with Equuleus, the Vulture, Corona Australis, Coma Berenices and Antinous omitted; but the man who added pictures to Vitruvius set down 48.

[Margin: 46 constellations.]

Manilius, *Astronomica* book 1, Avienus, Hyginus and Apian count 46, with Equuleus, Coma Berenices, Antinous and Corona Australis omitted. Tycho, volume 1 of the *Progymnasmata*, p. 258, and Lansbergen in his tables, p. 161, agree on this number, having deliberately passed over the southern Lupus, Ara, Corona and Piscis, because these cannot be observed in their climate.

[Margin: 47 constellations.]

Martianus Capella, *De Nuptiis Mercurii et Philologiae*, book 8, says that there are 35, and with the zodiacal ones 47; but he gives the names of only 46, leaving out Serpens, Equuleus, Coma Berenices and Antinous.

[Margin: 48 constellations.]

Ptolemy, book 7, ch. 5, with the Platonists, counts 48, with Equuleus omitted, which he reduces to Pegasus, and Antinous, which he puts among the unformed stars of Aquila, and Coma Berenices, three of whose stars, however, he puts among the unformed ones around the tail of Leo, under the name τρίχες [Greek: triches, "hairs"] or πλόκαμους [Greek: plokamous, "locks"], namely of hair or of a curl. Ptolemy was followed by Alfonso, Copernicus, Piccolomineus [Alessandro Piccolomini], Iunctinus [Francesco Giuntini] and Clavius in their catalogues.

[Margin: 50 constellations.]

Griembergerus [Christoph Grienberger], after his catalogue of the fixed stars, sets down 50 figures, adding Antinous and Coma Berenices to the Ptolemaic ones; but in the catalogue he reviews only 48.

[Margin: 52 constellations.]

Proclus in the *Sphere* counts 52, adding to the Ptolemaic ones Coma Berenices, the Water of Aquarius, Thyrsolochus, namely the spear of the Centaur, and the Caduceus, a constellation he set down following Hipparchus of Nicaea, and which is thought to consist either of 6 stars of Corona Australis set in a straight line, or of five of Eridanus likewise set in one straight line, as Stöffler explains on Proclus, p. 133.

[Margin: 60 constellations.]

Johann Bayer in his *Uranometria* sets down 48 Ptolemaic ones and 12 of the recent navigators.

[Margin: 62 constellations.]

Johannes Kepler in the Rudolphine table of stars, p. 105, sets down 50 of the older constellations, adding Coma Berenices and Antinous separately to the Ptolemaic ones. He then adds 12 new constellations observed or set in order by navigators who crossed beyond the Equator, namely Amerigo Vespucci, Andrea Corsali and Pedro de Medina, but above all Frederik de Houtman, who observed them on the island of Sumatra; all of them, however, were put in order

by Petrus Theodori and Jakob Bartsch, who were followed by the makers of star globes, Iansonius [?], Hondius and Jacob Floris van Langren. So for these men the constellations are 62, a number accepted by Biancani in the *Sphaera*, book 17, and by Boulliau in his tables, p. 180.

[Margin: 72 constellations.]

Pliny the Elder, however, in book 2, ch. 41, counts 72. But he passed over their names with too dry a foot, says Stöffler on Proclus, p. 82; and he seems to have counted parts of constellations as whole constellations: for instance the Kids as distinct from Auriga, the Head of the Gorgon or Medusa as distinct from Perseus, Arcturus from Boötes, the Pleiades and Hyades as distinct from Taurus, the Aselli from Cancer, Canopus from Argonavis, and the Urn from Aquarius. But perhaps Pliny the Elder had something else in mind.

[Margin: Should the names and figures of the ancients be changed in the constellations?]

2. From this arises another question: whether it is permissible, or even expedient, to change over to other figures and forms of the stars, which sailors, farmers and beginners in astronomy could more easily observe and commit to memory, or at least to change their profane names into sacred ones, the sky being purged, so to speak, and the minds of Christians drawn away from the turpitude or vanity of the ancient tales.

[Margin: Ptolemy's example in this.]

For indeed Ptolemy was allowed to alter the Hipparchean figures, as he himself testifies in the *Almagest*, book 7, ch. 5, saying: "In many places, therefore, assigning names better suited to the figures themselves, we have changed the usage of the ancients, as for example the figures which Hipparchus places on the shoulders of Virgo etc." Tycho was allowed to bring the stars which in Ptolemy are σποράδες [Greek: sporades], that is, Scattered, or ἀμόρφωτοι [Greek: amorphōtoi], that is, Unformed, within the forms of a nearer constellation.

[Margin: Bede's attempt.]

Bede too began from the constellations of the zodiac, and gave a sample of the way in which one ought to substitute sacred names and holier figures for profane ones, in that trochaic poem which Stöffler also reports on Proclus, p. 86, and whose opening is:

> Truly astonishing and savage is the madness of the pagans, Who
> transferred such diverse beasts into the sky, When it is agreed that
> on Olympus are the ranks of the Angels etc.

[Margin: Schiller's invention.]

Kepler too, in the Rudolphine Tables, p. 118, indicates that Jacob Bartsch of Lusatia took his globe from the *Uranographia* of Christian figures by some Schiller or other [Julius Schiller], who had ordered its publication in his will.

[Margin: Copernicus's opinion.]

Nevertheless Copernicus, book 2, ch. 14, indicates that the old forms and ancient names are to be retained, in these words: "For the stars were formed into images, according to the opinion of Theon the Younger in his exposition

of Aratus, for no other reason than that so great a multitude of them should be distinguished part by part and could be designated part by part with certain names; an institution ancient enough, since it is agreed that even in Job some were already named, and we also read the Pleiades, the Hyades, Arcturus and Orion expressly named in Hesiod and Homer. Therefore in their etc."

[Margin: Tycho's view.]

But Tycho says it more clearly, in volume 1 of the *Progymnasmata*, p. 256, affirming that these ancient names and figures are to be retained, even though they smell of heathenism and of the tales of the poets, for three reasons: first, because under their wrappings they are not without a certain abstruse knowledge; second, because some of them are mentioned not only in the most ancient poets but also in the holy Job and Amos; third, because "It is not fitting lightly to abolish and cancel what has been confirmed by long approval, unless something better is ready at hand to be put back in their place. And it is to be feared that, if the old names of the stars are set aside because they rest on fictions and tales, it may not be possible to introduce others anew, unless here too one is allowed to invent and shape whatever one pleases. For the true names of the stars, by which the supreme Maker calls each of them, as David testifies in Psalm 146, are entirely unknown to us; perhaps something about these was known to Adam and the Fathers, or at least they used more solid and truer appellations for them."

Nor is there any doubt that, if we knew the properties of the constellations, it would be best to seek a nomenclature from them.

[Margin: Our view.]

It is false, however, what Copernicus and Tycho suppose, that the names of the Pleiades, the Hyades, Arcturus and Orion, as they sound among us, are in the Hebrew text, since the names there are different, namely *Nghais*, *Kimà*, *Kesil*; in their place the Vulgate and other versions have put those names which had already gained currency among the Greeks and Latins, as is clear from what was said in chs 3, 4 and 5 where those constellations were treated. And so, if the necessity did not bind us to retain the ancient names of the stars after all, so that ancient observations can be compared with more recent ones and the motion of the fixed stars established, I would come close to abolishing most of them and to coining new names and new forms from a holier store. Perhaps, however, I shall indicate names, in case anyone outside the business of astronomy should wish to use them at some time, where I set out the catalogue in the tables.

[Margin: Position.]

3. But you must necessarily be warned, Reader, that the parts of the celestial figures which hold the right-hand position in some authors are on the left in others, and that those which are upper for some are lower for others, according to how the viewer is imagined to contemplate them, turned towards this quarter or that, either from beneath the concavity of the sky or from above the convex surface of their globe. The illustrations of Bayer, moreover, the painter or engraver represented with their position

interchanged and inverted, against the will and to the grief of the author, as Kepler says in the book *De Stella Nova*, p. 68. Our Grienberger, however, in his catalogue of the fixed stars, added a double perspective of the celestial figures, one from the poles of the world and the other from the centre of the world, and represented them in both ways.

[Margin: The number of stars seen with the naked eye?]

4. The number of stars seen without the telescope differs among authors. First, because of the different climates in which they were observed: and so Tycho and Lansbergen, who noted only those observable in Denmark and Zeeland, have fewer than others, and all the older authors present fewer than the more recent, since observations made beyond the Equator by the explorers of the New World were lacking. Second, because of the different season of the year, since on clear winter nights more seem to appear; or because of greater or lesser diligence and circumspection in counting the stars and in not confusing them with stars already counted in another, nearer asterism. Third, because of the greater or lesser sharpness of the eye: for how many there are who cannot make out Alcor in the tail of Ursa Major, or the seventh of the Pleiades, or other little stars of this kind! Fourth and last, because of errors of calculation, or printers' mistakes.

Now, to bring the variety of opinions into a brief synopsis, I have chosen four catalogues out of very many. The first is Ptolemy's, followed by al-Battānī, Alfraganus [al-Farghānī], Alfonso, Copernicus, Apian, Piccolomini, Giuntini and Clavius, who corrects the text of Ptolemy from a manuscript codex, as well as the errors that crept into the Arabic versions, which Alfonso followed, or into the translation of Georgios Trapezountios, even though it was revised by Luca Gaurico. The second is that of our Christoph Grienberger, which he put together both from the catalogue of Tycho, in which there are 767 stars most accurately observed and arranged; and from that of Francesco Pifferi, who from a double manuscript of Tycho has another 218, not so accurate, nor polished by Tycho's final file; and from Clavius, supplying the remaining 240 omitted by Tycho. The third is that of Johann Bayer, who compiled his *Uranometria* from Ptolemaic, Tychonic, Arabic and Turkish catalogues or maps, and from the more recent navigators. The fourth is that of Kepler, and after him of Boulliau, which is divided into three parts. The first part has a thousand more accurate Tychonic stars from Tycho's papers, whereas in the published catalogues of Longomontanus and Tycho no more than 858 are recorded. The second contains both a few other, less accurate Tychonic stars, and the Ptolemaic stars omitted by Tycho and corrected from the Greek codex rather than from the Arabic version, those which, namely, Ptolemy put in order and emended from the old catalogue of Hipparchus. The third part presents the stars that cannot be observed in our temperate zone but were observed by the recent navigators, with the addition of those Bayer did not know.

[Margin: Opinion of Pliny the Elder and others on the number of the stars.]

In the summaries that follow, moreover, you will see four opinions on the number of stars seen with the naked eye, to which add Rabbi Kimhi in Bayer, who counted 1,089. But it seems certain that there are many more, since Pliny the Elder says in book 2, ch. 41: "The immense vastness of the sky pleads for it, its extent being divided into 72 signs [duo atq. LXX.]. These are the images of things or of living creatures into which the experts have arranged the sky. In these they have recorded 1,600 stars, those namely that are notable for their effect or their appearance." So if the rest are added, which are not so notable to sight, and those which were always hidden from those early observers who lived on this side of the Torrid Zone, they will become far more than 1,600. What if those very constellations we have reviewed should be observed by very sharp eyes? For, as Kepler relates in the *Dissertatio cum Nuncio Sidereo*, p. 9, Mästlin counted in the Pleiades 14 stars without the tube, which others scarcely count as 6 or 7; and he tells of a man in religious orders known to him who on a moonless night counted more than 40 in the Shield of Orion, in which others note scarcely 11 or 12; and the Chinese have far more on their count than we do. But as for the Hebrews counting, as Kepler says on the same p. 9, more than twelve thousand, or, as Bayer reports at the end of the *Uranometria*, as the *Cabela in Drach* [?], cited on Isaiah ch. 49, nu- mber 29,000 myriads of stars and 140 besides, that has been derived from cabalistic fabrications rather than from observation by the eye. Conversely, when Clavius, on ch. 1 of the *Sphere*, p. 140, contends that the stars contained within the six common magnitudes are no more than 1,022, because of the diligence he thinks astronomers have applied in counting them, and that sight is deceived when in winter it counts more around the North Pole than at other times, owing to the greater scintillation by which many seem to arise from one, he must be understood as speaking of stars observed in the northern zones. Otherwise he does not deny that all the stars, counting those smaller than the sixth magnitude, are innumerable.

[Margin: Total of all.]

V. To anyone who asks about the absolute number of all the stars, I reply that they are indeed not infinite, as Iordanus Brunus [Giordano Bruno] contends in the book *De infinito et innumerabilibus*, saying that there are as many worlds as stars, and that these are infinite in number; against him, Kepler in the book *De Stella Nova*, ch. 21. But I reply that they are nevertheless beyond counting by human beings. First, because even if they are viewed with the naked eye, yet, given the differing keenness of eyes, and endurance and diligence, there will always be someone who notes a different number from the others; and so they are not numerable in such a way that there is a settled number of them on which all finally agree. Second, because it is now clear from the telescope that there are far more than those observed with the naked eye. For Galileo, as we have already reported from the *Sidereus Nuncius*, detected with the glass 21 stars in the nebula of Orion, and 36 in the nebula of Praesepe, and more than

40 in the asterism of the Pleiades, and at least 80 within the space of the belt and sword of Orion; and within the space of one degree or another he counted more than 500 in Orion, so much so that he was deterred from observing the whole constellation of Orion, which he had decided to draw. And of the Galaxy, or milky circle, he says: "For the Galaxy is nothing other than a mass of innumerable stars planted together in clusters: to whatever region of it you direct the spyglass, at once a vast crowd of stars presents itself to view, many of which appear quite large and very conspicuous, but the multitude of the small ones is wholly beyond exploring." From this he concludes that the Milky Way, and other small areas like it, and the nebulous stars are nothing other than a mass of stars. Kepler endorses this in the *Dissertatio*, p. 9½, as do Blancanus [Giuseppe Biancani] in book 17 of the *Sphere*, ch. 2, and Mastrius [Bartolomeo Mastri], disputation 2 *De caelo*, no. 87. Nor does Galileo doubt that the stars go beyond ten thousand. Add Antonín Maria Šírek, who on p. 197 of his *Radius Sidereomysticus* affirms that in Orion alone about two thousand stars were counted by him with a Belgian telescope, and Father Giovanni Battista Zupi, who with Fontana's telescope counted more than 50 in the Pleiades and about as many in the Sword of Orion and in the Hyades.

[Margin: Whether the stars are infinite?]

[Margin: The innumerability of the stars. First argument.]

[Margin: Second argument, from the telescope.]

[Margin: What the Galaxy is.]

Now if Orion occupies very nearly 500 square degrees of the sky, as will be evident to anyone measuring its area on an Aratean globe, and if within a square space whose side is 2 degrees there are at least 500 stars, as Galileo noted, there will be 62,500 stars in the whole of Orion; but let us set 60,000. Again, suppose that as the 63 stars of Orion seen with the naked eye stand to the roughly 60,000 that would be revealed by the telescope, if one had the leisure and did not mind counting them, so the number of any constellation counted with the naked eye, and set down in the last columns of the preceding table, stands to the number of stars observable by telescope: then more than a million stars will be gathered, not counting those in the Milky Way. And so if anyone should think that there are more than two million stars, he will, to my mind at least, have imagined nothing unbelievable.

[Margin: Third argument, from sacred authority.]

Finally, this seems to agree very well with the assertion of God himself, in Genesis 12, saying to Abraham: "Look up at the sky and count the stars if you can." And in ch. 22: "I will bless you and multiply your seed like the stars of the sky and like the sand that is on the seashore." Mindful of this promise, the holy Patriarch said in Genesis 32: "You said that you would do me good and spread my seed like the sand, which for its multitude cannot be counted." And lastly it is said in Jeremiah 33: "As the stars of the sky cannot be counted and the sand of the sea cannot be measured, so I will multiply the seed of David my servant." For although some think that these things were said to suit the understanding

of the common people, and of a number of stars that human beings cannot easily take in one or a few looks, yet since no necessity compels us to depart from the sense the letter conveys, and the majesty of the Creator requires of us that we think magnificently of his works, we shall do much better to interpret these passages of some huge number of stars, and so great that it is not smaller than either the number of the elect or that of the whole stock of Abraham and David signified in those promises; and thus we shall proclaim with the Psalmist, in Psalm 146, that God alone is he "who counts the multitude of the stars, and calls them all by name."

[Margin: Whether there are more stars toward the north or toward the south?]

VI. Therefore, if you ask further whether there are more stars in the northern or in the southern hemisphere: if you are asking about all of them together, including those invisible to us, you ask in vain, and it would be no less rash for any of us to determine this than whether their number is odd or even. But if you are asking about those counted by astronomers, I reply that according to all authors there are more in the northern than in the southern region; according to Kepler and Boulliau, however, there are about as many in each, and a little more in the northern, although Amerigo Vespucci affirms that more are noted beyond the equator than on this side of it.

[Margin: Stars of first magnitude.]

VII. Moreover, the stars of the first rank or magnitude (for their number is usually sought with special care) are at least 15 in all authors, and 18 in Bayer, but they are not the same in all. Such without dispute are:

[Margin: Certain.]

1. Acarnar, which lies at the end of Eridanus. 2. Aldebaran, or the southern eye of Taurus. 3. Arcturus, or the boss of the fringe of Bootes. 4. Canopus, on the rudder of Argonavis. 5. Capella, on the shoulder of Auriga. 6. The topmost of the Centaur, on the right forefoot. 7. Fidicula of Lyra. 8. Fomahant, or the last in the outpouring of Aquarius, which Piscis Notius appears to swallow. 9. The tail of Leo. 10. The heart of Leo, or Regulus. 11. Rigel, on the foot of Orion. 12. Sirius, or Alhabor, in the mouth of Canis maior. 13. Spica.

[Margin: Disputed.]

The disputed ones, however, are: 1. Antares, or the Heart of Scorpius, for it is of first magnitude to Ptolemy and his followers, of second to others. 2. The bright one of the Centaur on the hind hip, which to Bayer is of first rank, to others of second. 3. The heart of Hydra, which to Ptolemy is of second brilliance, to others of first. 4. The following shoulder of Orion, which to Ptolemy and Bayer is of first class, to others of second. 5. Procyon, which for Ptolemy and Bayer stands among the first, among others in the second, and to me seems no larger than the bright star of Aquila. On this, moreover, depends the variation in the arc of the Sun's depth that Ptolemy assigned for the heliacal

rising and setting of the fixed stars, which varies among the stars with their varying apparent magnitude and brilliance.

[Margin: How many nebulous stars?]

VIII. Finally, one could ask about the number of the nebulous stars by themselves. On this I reply that there are at most 14, and they are: 1. The nebulous star on the breast of Cancer, called Praesepe. 2. The nebulous star on the sting or behind the sting of Scorpius. 3. The double nebulous star in the eye of Sagittarius; and on these all agree. To them Ptolemy and his followers add 4. a nebulous star on the head of Perseus, or at the tip of the right hand, as Grienberger has it, and 5. one on the head of Orion, not placed there by others. Grienberger and Kepler, moreover, add to these 6. one at the tip of the foot or on the calf of Hercules, 7. one on the forehead of Capricorn, 8. one on the eastern horn, and 9. one on the western horn of Capricorn. Finally Kepler adds to these 10. one in Capricorn, 11. and 12. in Phoenix, and 13. and 14. in Pavo, to say nothing of the two small clouds near the Antarctic Pole. So there are about as many nebulous stars as stars of first magnitude; but in Kepler 13, in Grienberger 8, in Ptolemy and Clavius 5, though 14 with the obscure ones. Bayer, however, being less careful in distinguishing these, lists only the nebulous stars of Hercules, Cancer and Sagittarius.

SCHOLIA.

Scholia.

I. M. Manilius describes all the constellations in order, but in many verses, in book 1 of the *Astronomica*, ch. 4. In elegance in describing the signs of the zodiac, as I reported in ch. 3, he surpasses Ausonius; but Ausonius surpasses Manilius in the brevity with which he reviews all the signs of his age, which he does in the *Eclogarium* in the following verses:

> *Ad Boreæ partes Arcti iunguntur & Anguis; Poſt has Arctophylax, pariterq. Corona, Genuq. Prolapſus, Lyra, Auis, Cepheus, ac Caſſiopea: Auriga, & Perſeus, Deltoton & Andromedæ aſtrum, Pegaſus, & Delphin, Telūq. Aquila, Anguitenenſq. Signifer inde ſubeſt, bis ſex quem ſidera complent. Hic Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libraque, Scorpius, Arcitenēs, Capricornus, & Vrnam Qui tenet, & Piſces. Hi ſunt in partibus Auſtri: Orion, Procyon, Lepus, ardens Sirius, Argo, Hydrus, Chiron, Thuribulum quoq. Piſcis, & ingens Hunc ſequitur Piſtrix, ſimul Eridaniq. fluenta.*

To the regions of Boreas the Bears are joined, and the Serpent; after these Arctophylax, and likewise the Crown, and the one fallen on his knee, Lyra, the Bird, Cepheus and Cassiopea; Auriga, and Perseus, Deltoton and the constellation of Andromeda, Pegasus, and the Dolphin, the Arrow, the Eagle, and the Serpent-holder. Then below lies the zodiac, which twice six constellations complete. Here are Aries, Taurus, Gemini, Cancer, Leo, Virgo, and Libra, Scorpius, the Archer, Capricorn, and he who holds the Urn, and Pisces. These

are in the regions of the south: Orion, Procyon, Lepus, blazing Sirius, Argo, Hydrus, Chiron, the Censer too, the Fish, and huge Pistrix follows this, together with the streams of Eridanus.

II. Since there was an old opinion, passed down from Ptolemy onward, that the stars in all are 1,022, Erycius Puteanus [Erik van der Putte] left to posterity, as a monument of his piety and talent, this most ingenious line:

Tot tibi ſunt dotes Virgo, quot ſidera cælo.

You have as many gifts, O Virgin, as there are stars in the sky.

This verse, with the quantity of its syllables preserved and the meaning of the same thought kept, is converted into 1,022 verses by transposing the words, to each of which he added its own particular gift befitting the Mother of God. Nobody will find this difficult, if he knows how many combinations or different arrangements can be made even of a few terms, since the combination of the immediately preceding number, multiplied by the next number of terms, yields the combination of the following number. For example, because two terms have a twofold arrangement, so that if A and B are given the orders AB and BA can be made: if three terms are given, these multiplied by 2 make 6, that is, the number of ways in which six [recte: tres] terms can be arranged; and so on with the rest, as Clavius teaches in the *Sphere*, p. 34. For these, here for you in a small table are the numbers of combinations corresponding to the number of terms, up to 12.

[Margin: Rule of combinations.]

Terms [Termini]	Possible combinations [Combinationes Poſſibiles]
2	2
3	6
4	24
5	120
6	720
7	5040
8	40320
9	362880
10	3628800
11	39916800
12	479001600

[Margin: Protean verses.]

So if verses are made of the kind that from their capacity for turning are called Protean, which have the first or last syllable common and consist of as many monosyllables as possible, the same verse could be permuted, with the laws of grammar intact, into so many others of the same metre and meaning that they exceed the number of all ver- ses that Greek and Latin poets alike once composed. Let a specimen of such verses be, especially in the second line, the following distich, which we put together on another occasion:

Vi metri tibi me en nunc hîc Tethy Prothea ſacro; Sum Strix, Glis, Grus, Sphinx, Mus, Lynx, Sus, Bos Capra & Hydrus.

By the force of metre, behold, here and now, Tethys, I consecrate myself to you, a Proteus; I am screech-owl, dormouse, crane, sphinx, mouse, lynx, sow, ox, goat and water-snake.

Here you see that before those names Capra and Hydrus there are 9 monosyllables that can be freely permuted, so that 362,880 verses can be made. Again, they can be ended in such a way that a dactyl and a spondee stand in last place, *Bos Hydrus & Mus*, beginning the verse *Sum Capra*, etc.; and so with innumerable others, which it may suffice to have indicated.

CAPVT VII.

De Loco & Diſtantia Fixarum à Terra, adeòq. de illarum Parallaxi, & de Infinitate huius diſtantiæ, ac velocitate Fixarum.

Chapter 7. On the place and distance of the fixed stars from the Earth, and hence on their parallax, and on the infinity of this distance, and on the speed of the fixed stars.

I. Just as it is God who counts the multitude of the stars, so he is the same who has measured their distance from the Earth and knows it with certainty. For so it is asserted in Ecclesiasticus, ch. 1: "Who has measured the height of the sky, and the breadth of the Earth, and the depth of the abyss?" And again in ch. 17: "He himself sees the power of the height of the sky." For this reason the warning of the same book in ch. 3 seems able to apply here: "Do not seek things higher than yourself." And so, in order to separate here what is certain from what is uncertain, we must first set out the methods by which parallax, and from it, by Problem 1 of ch. 7 of Book 3, the altitude of the fixed stars, seems able to be investigated by observations.

[Margin: First method of observing the distance of the fixed stars from the Earth.]

The first method is the one I spoke of in Book 3, ch. 7, no. 5: namely, if someone placed under the equator, with a very exact pendulum whose oscillations correspond exactly to single seconds of time of the primum mobile, were to count the time from one altitude of a star placed on the equator to another altitude, taken with a huge quadrant showing single seconds, provided that the altitudes lie beyond the hazard of sensible refractions. For if the seconds of the counted time are equal to the intercepted arc, that is, to the difference of the altitudes converted into seconds of time, there will be no sensible parallax; but if that difference is greater than the time counted, the excess will give the parallax, or at least the difference of parallax. But when will all those requirements ever come together: that someone be certain both that he is precisely under the equator, and that the fixed star is on the equator itself, and that it lies beyond the hazard of refractions, independently of parallax, and that he have a quadrant showing single seconds, and a pendulum that does not stray by even one second of time after a count of several hours? Certainly never.

[Margin: Second method.]

The second is by means of two meridian altitudes of a star circling the Pole of the World, if the altitude of the pole were known from elsewhere, independently of the fixed stars, without any sensible error, and the star at both places were beyond all sensible refraction, and the altitude were taken with a quadrant showing single seconds, and the meridian line were very exact. For with these things coming together, if, for example, the distance of the same star from the Pole of the World were found to differ in one of the meridian altitudes, it would furnish a difference of parallax and some evidence of parallaxes. But neither will all these things ever come together; and let the same judgement be made of the other methods, which depend on an altitude taken of a star, or on a motion of the fixed stars known beforehand independently of what we are seeking.

[Margin: Third method.]

The third method is from the difference of refractions, which have been found to be smaller in the fixed stars than in the planets. But since refraction is not known precisely, except either with the parallax computed, which it cancels, or with no parallax assumed, parallax itself cannot be known from refraction alone; although from this, as we shall say, I may have drawn a sufficient argument against the infinity of the distance, and indeed against the huge distance asserted by some Copernicans. Let the following theorem therefore stand as certain, namely:

The parallax and distance of the fixed stars cannot be grasped by human means through certain and evident observation.

This will be further confirmed from what was said of the uncertain parallax and altitude of the Sun itself, namely in Book 3, ch. 7, in the scholium.

[Margin: The fixed stars are above Saturn.]

II. Yet it seems certain that those stars that are occulted from us by some planets, as are almost all those within the zodiac, are higher than the planets, at least at the time when they are occulted by them. Hence, from the constancy of the distance that the fixed stars perpetually keep among themselves, and from the same measure of motion, it becomes very probable that all the fixed stars are higher than Saturn; and this indeed is the common view of all, both astronomers and natural philosophers, in their books on the heavens. But it is uncertain whether some or all of the fixed stars lie immediately above the heaven of Saturn, or whether there is a notable interval between Saturn and the fixed stars and how great; and whether all lie on the same spherical surface described from the centre of the world, or whether some are higher than others. All those who determine altitudes of the fixed stars rely on mere conjectures and on the choice of hypotheses, within the limits of probability.

[Margin: The opinion of the ancients on the equal distance of the fixed stars.]

Now, as regards the equality of the distance of the fixed stars from the Earth: Xenocrates held that the stars move along one surface, while the other Stoics

held that some are lower and higher than others, as Plutarch relates in *De placitis philosophorum*, book 2, ch. 15.

[Margin: Tycho's opinion on the unequal distance of the stars.]

The opinion of the Stoics has been followed above all by Tycho in vol. 1 of the *Progymnasmata*, p. 470, where he says: "It can therefore happen that some that appear smaller to us are equal to some that in truth appear larger, even though they appear smaller to us because of their higher position." And more clearly on p. 481: "Since it seems more likely that some are placed higher and others lower."

[Margin: And Galileo's.]

Galileo too agrees, in Dialogue 3 on the world system, saying: "For I do not believe that the stars are scattered on a spherical surface equally distant from the centre; rather, I think that their distances from us are so varied that some can be two or three times more remote than others. Therefore if at some time a very small star were found with the telescope, very close to some larger one, and yet that one were very high, it could happen that some sensible change would occur between them, corresponding to the change of the superior planets."

[Margin: And Kepler's.]

Kepler agrees with both, in the book *De Stella Nova*, ch. 21, and in the *Epitome of Copernican Astronomy*, book 1, part 2, from p. 34 on, where he thinks it probable that some fixed stars look smaller than others because they are farther from us. To this applies the line of Manilius in book 1 of the *Astronomica*, ch. 4, who says that the nebulous or obscure stars on the forehead of Orion look that way

Non quòd Clara minùs, ſed quòd magis alta recedant.

not because they are less bright, but because they recede higher up.

Yet Kepler judges it more probable that all the stars that appear to us of equal magnitude are equally distant from us, and form a concave surface around us. And in that ch. 21 he does not indeed affirm, but concedes as not absurd, that all the stars are of equal magnitude, yet that some look smaller because of their lesser distance from the Earth. At greater length, however, he contends in both treatises that the sphere of the fixed stars is so bounded toward us that the space between us and the nearest fixed stars is nevertheless very ample, and that we are, as far as sense can tell, in the middle of it, and see equally the hemispheres of stars divided by the Milky Way. Al-Farghānī too puts as much from the concave of the firmament and the least distance of the fixed stars to the convex as there is from the Earth to the concave of the firmament, as Clavius has it in the *Sphere*, p. 21[?], although others, of whom see the end of no. 6, put a smaller thickness.

[Margin: Whether the distance of the fixed stars is infinite.]

III. But is the distance from us of all, or of some, of the fixed stars visible to the naked eye or the eye equipped with telescopes infinite? This is much the same as if you asked whether this visible world is of infinite bulk. For, as Plutarch relates in *De placitis philosophorum*, book 2, ch. 1, Seleucus thought

the world infinite; Diogenes thought the universe infinite but the world finite; just as, in the same place, the Stoics held that the universe is infinite, counting in it the void or empty, but that the world, subsisting apart from the empty, is finite. Pliny the Elder, however, speaks very ambiguously in book 2, ch. 1, when he says: "The world, and this which it has pleased us to call by another name the sky, by whose encircling all things are covered, etc., is sacred, eternal, immense, whole in the whole, nay rather itself the whole: finite and like the infinite." Here Milich explains that it is like the infinite because of its immense bulk and the distance of the highest heaven from human beings, which is incomprehensible. But Giordano Bruno, in the book *De Maximo & Immenso*, and in *De Infinito & innumerabilibus*, argues for this infinity, which Aristotle in Book 1 of *De caelo* reports was the view of some of the ancients. Aristotle refutes them from text 33 to 75 with the well-worn argument from motion. For if stars, say A and B, were an infinite interval from the Earth's centre C, then the straight lines drawn to them from the centre of the world C, namely AC and CB, would be of infinite length; and so the chords subtending the arc AB would be infinite, and the arc AB itself infinite, let alone the whole circumference. Therefore its infinite space could not be traversed in a finite time. But we see, says Aristotle, that the whole sky with its stars moves in the finite time of 24 hours. Therefore neither the sky nor the distance of the stars is infinite.

Diagram. Set into the left column beside the argument from motion: two concentric circles about a centre, with two straight lines drawn from the centre out through the inner circle to the outer, forming a V.

- A (upper left, on the outer circle, at the end of the left-hand line)
- B (upper right, on the outer circle, at the end of the right-hand line)
- M (on the left-hand line, at the inner circle)
- N (on the right-hand line, at the inner circle)
- C (the centre, at the vertex of the two lines)

Someone might perhaps evade this argument by saying that an infinite space can be traversed in a finite time, but by the force of an infinite power and with infinite velocity in the mover; or, with the Copernicans, by denying that the sky or the fixed stars move, and assigning the daily motion to the Earth rather than to the sky and the fixed stars. Others therefore reason better as follows. Since arcs of circles described from the same centre and enclosed within the same straight lines drawn from the centre are similar or proportional, there will then be some infinite arc AB similar to a finite arc MN; and this seems absurd, unless one says that proportions of this kind demonstrated by geometers hold so long as one stays within the limits of finite quantity, but do not hold in the infinite. Others will say that it is impossible either for images and lights to reach our eye from an infinite interval, decreasing in a uniformly difform manner; or for the infinite distance between two stars to be seen under a finite angle; or, with Kepler in ch. 21 of *De Stella Nova*, that what is seen as having a shape, and so is enclosed within certain boundaries, as the stars are, cannot

be infinite. These and similar arguments we once discussed in physics, and we now leave them to the natural philosophers to treat at greater length. The argument that seems to me more astronomical, though with the help of optics, is the one supplied by refractions, of which I shall speak in Scholium 3.

[Margin: 1. The opinion of Pliny the Elder.]

IV. The first and truest opinion is that of Pliny the Elder, who holds that the distance of the fixed stars is uncertain, as we too have taught in number 1. Indeed he adds that it is rash to want to define it. For in Book 2, ch. 1, after saying of the world: "It is finite and like the infinite," he goes on: "It is madness that certain people have turned its measure over in their minds and have dared to publish it." And soon after: "It is madness, truly madness, to go out of it and, as if its interior were by now fully known, to search in this way what lies outside: as if someone could take the measure of anything who does not know himself, or the mind of man could see what the world itself does not contain." And below, in ch. 23, when he was offering a conjecture on the distance of the Sun, saying: "Not as a measure, for to want that is the mark of an almost demented leisure, but only so that an estimate for conjecture may stand in the mind," he added: "It is astonishing how far the shamelessness of the human heart goes, lured on by some tiny success, as in the matters above reason supplies an occasion for impudence: and having dared to divine the distances of the Sun to the Earth, they do the same for the sky, since the Sun is in the middle, so that straightway the measure of the world itself too comes to their fingers, etc., as if the measure of the sky were established quite by the plumb line."

[Margin: 2. The opinion of the Pythagoreans, and their method from harmonic intervals.]

V. The second opinion and method is that of the Pythagoreans, who determine the distance of the stars from harmonic intervals. For Pliny the Elder reports it thus in Book 2, ch. 21, saying: "But Pythagoras, a man of shrewd mind, inferred that from the Earth to the Moon is one hundred and twenty-six thousand stadia; from her to the Sun double that; from there to the twelve Signs three times that: and Gallus Sulpicius too was of this opinion." Then in ch. 22 he adds: "But Pythagoras sometimes, on a musical principle, calls the distance of the Moon from the Earth a tone; from her to Mercury half of that space; and from him to Venus about the same; from her to the Sun one and a half times. From the Sun to Mars a tone, that is, as much as from the Earth to the Moon; from him to Jupiter a half; and from there one and a half times to the zodiac [Signiferum]: thus seven tones are produced, the harmony they call diapason, that is, the totality of concord." Censorinus, *De Die Natali*, ch. 11, is in accord with Pliny the Elder's account. I shall quote that passage whole, since it also serves for the intervals of the planets. He says, then:

"So Pythagoras held that from the Earth to the ☾ is about 126 thousand stadia (understand: Italian ones), and that this is the interval of a tone; and from the Moon to the star of Mercury, which is called [Greek: στίλβων (stilbōn, "the

gleaming one")], half of that, like a [Greek: ἡμιτόνιον (hēmitonion, "semitone")]; from there to [Greek: φόσφορον (phosphoron, "the light-bearer")], which is the star of Venus, about the same, that is, another semitone [ἡμιτόνιον]; then further on to the Sun three times as much, as it were a tone and a half: so that the star of the Sun is three and a half tones from the Earth, which is called Diapente; and two and a half from the Moon, which is Diatessaron; and from the Sun to the star of Mars, whose name is [Greek: πυρόεις (pyroeis, "the fiery one")], there is as much interval as from the Earth to the Moon, and this makes a tone [τόνον]; from there to the star of Jupiter, which is called [Greek: φαέθων (phaethōn, "the blazing one")], half of that, which makes a semitone [ἡμιτόντον] [recte: ἡμιτόνιον]; the same from Jupiter to the star of Saturn, whose name is [Greek: φαίνων (phainōn, "the shining one")], that is, another semitone [ἡμιτόνιον]; from there to the highest sky, where the Signs are, likewise a semitone [ἡμιτόνιον]; and so from the highest sky to the Sun the interval [diastema] is a Diatessaron, that is, two and a half tones, and to the summit of the Earth from the same sky there are six tones; in which there is the concord [Symphonia] [Greek: διὰ-πασῶν (dia pasōn, "through all")]. Besides this he related many things that musicians discuss: he showed that the stars and this whole world are [Greek: ἐναρμόνιον (enarmonion, "harmonious")]. For this reason Dorylaus wrote that the world is the instrument of God."

[Margin: The world, the instrument of God.]

So dividing the 126000 stadia by 8 gives 15750 Italian miles. On this basis the distances of the stars from the Earth and from one another, according to Pythagoras's opinion, are those we have gathered into the following table.

[Margin: The Pythagorean intervals of the stars.]

INTERVALLA SIDERVM PYTHAGORICA

The Pythagorean intervals of the stars

Order of the stars	Distance from the Earth, in Italian miles	Distance between them, in Italian miles
☾	15750	15750 Tone
☿	23625	7875 Semitone
♀	31500	7875 Semitone
☉	55125	23625 Tone and a half [Sesquitonus]
♂	70875	15750 Tone
♃	78750	7875 Semitone
♄	86625	7875 Semitone
✶	94500	7875 Semitone

But since an excessive parallax follows from this, especially in the fixed stars, which would be no further from the Earth than about 24 semidiameters of the Earth, one of which contains 4139 modern Italian miles [Milliaria Italica recentia], from what was said in Book 2, ch. 7, their parallax would be 2° 23′; and it is certain that the lunar parallax itself is not so great. For that reason both this and the Archimedean measurement of the intervals were rejected by the Platonists, as Macrobius asserts in Book 2 on the *Dream of Scipio*, ch. 3. If

only he had set out the Archimedean measures for us! For he says only: "This measurement of Archimedes, however, was rejected by the Platonists, as not keeping the double and triple intervals: and they laid down that this is to be believed: that as far as it is from the Earth to the Moon, it is twice that from the Earth to the Sun; and as far as it is from the Earth to the Sun, it is three times that from the Earth to Venus; and as far as it is from the Earth to Venus, it is four times as much from the Earth to the star of Mercury; and as far as it is to Mercury from the Earth, it is nine times as much from the Earth to Mars; and as far as it is from the Earth to Mars, it is eight times as much from the Earth to Jupiter; and as far as it is from the Earth to Jupiter, it is twenty-seven times as much to the orb of Saturn." Therefore if we take the Pythagorean distance of the Moon, which is about 4 semidiameters of the Earth, or the Ptolemaic, which runs at about 60 (for this roundness of numbers is enough for what we intend), the intervals of the stars would have to be arranged according to the Platonists as you see in the following table, in which, however, Macrobius puts ☿ higher than Venus at apogee.

[Margin: The Platonic intervals of the stars.]

INTERVALLA SIDERVM PLATONICA

The Platonic intervals of the stars

Order of the stars	If the distance of the ☾ from the Earth is 4: distance from the Earth, in semidiameters of the Earth	But if it is 60: distance from the Earth, in semidiameters of the Earth
☾	4	60
☉	8	120
♀	24	360
☿	96	1440
♂	864	12960
♃	69125	103680
♄	1866375	27993654

Finally our Bettini, drawing the harmonic intervals from another source, from the divisions of the octochord, in *Apiarium* 10, Progymnasma 1, propositions 1 and 3, gives the distances that you have here, copied from him, in the following table.

INTERVALLA SIDERVM AC CÆLORVM IVXTA BETTINVM

The intervals of the stars and heavens according to Bettini

Distances from the Earth, in semidiameters of the Earth	Semidiameters of the Earth	Names of the musical intervals, and proportions:			Of the whole interval
The Earth					
☾ Apogee	381 6/9	Fà fà	Nete	Major tone	9th part
♀ Perigee	687	Mì mì	Paranete	Major ditone	5th part

Distances from the Earth, in semidiameters of the Earth	Semidiameters of the Earth	Names of the musical intervals, and proportions:			Of the whole interval
☿ Perigee	858 3/4	Rè rè	Trite	Diatessaron	4th part
☉ Mean	1145	Sol	Paramese	Diapente	3rd part
♂ Mean	1374	Fà	Mese	Major hexachord	Two-fifths
♃ Perigee	1603	Mì	Lycanos	✝	Seven-fifteenths
♄ Perigee	1717 1/2	Rè	Parhypate	Diapason	A half
✶ Fixed stars	2290	Ut	Hypate	Diapason-diapente	Two-thirds
Crystalline heaven	2574 3/4			Disdiapason	Three-quarters
Empyrean	3435				The whole interval

But just as the distance of the Moon is absurd and too great, against the evident observations of the lunar parallaxes, and destroys all lunar eclipses, as we said in Book 4, ch. 14, Scholium 2, so the distance of the fixed stars is too small, and it subjects the fixed stars to a parallax of 1′ 30″ [sesquiminuti], which not even the Sun has in the truer opinion, although no instruments have yet been able to detect this parallax of the fixed stars. A truer astronomy also requires the distance of ♃ to be about five times, and that of ♄ about ten times, the Sun's distance from the Earth, etc. So you see how uncertain, and in some places how evidently deceptive, is a distance of the stars devised from harmonic intervals alone. I pass over for now the harmonic intervals of the planets established by Kepler, since they are more fittingly dealt with in the book of the Systems, where the Harmonic System is treated.

[Margin: Bettini's error in the intervals of the stars.]

[Margin: 3. Opinion and method.]

VI. The third opinion and method rests on the distance of Saturn at apogee from the Earth, than which the distance of the fixed stars is agreed to be greater. How the distance of Saturn is investigated from the hypothesis and theory of its motions will have to be told in the next book, although all astronomers concur in this, that Saturn's distance from the Earth is about ten times the distance of the Sun from the Earth. So here we shall only add the authors who have determined the distances of the fixed stars by this method. They are:

[Margin: Authors who have used this third method.]

al-Battānī, ch. 50; al-Farghānī, chapter [differentia] 21; Jean Fernel, *Cosmotheoria*, Book 1, ch. 11; Erasmus Reinhold on Peuerbach's *Theoricae*; Francesco Maurolico at the end of the *Cosmographia*; Giovanni Antonio Magini in the *Primum Mobile*, Book 11, Problem 29; Christoph Clavius on the *Sphere*, p. 215;

Tycho, *Progymnasmata*, vol. 1, p. 481, and vol. 2, p. 465, and in the *Epistolae Astronomicae*, p. 167; Longomontanus, *Astronomia Danica*, Book 1, *Theorica*, ch. 1; Francesco Giuntini on the *Sphere*, and from him Baranzanus [Redento Baranzano], *Uranoscopia*, p. 120; Barocius [Francesco Barozzi], *Cosmographia*, Book 1, p. 49; and Giuseppe Biancani, *Sphaera*, Book 17, ch. 14.

Among these, al-Battānī and al-Farghānī declare that they deduced the distances from the Ptolemaic hypothesis. But al-Farghānī doubles the least distance to obtain the thickness of the eighth sphere, or the greatest distance of the fixed stars; and he sets the former at 20220 semidiameters of the Earth and the latter at 40440. Fernel, Barozzi, Magini and Clavius follow these numbers fairly closely, while Giuntini follows al-Battānī. Tycho, however, and following him Longomontanus, Biancani and Baranzano, do not double the distance; yet they assign a greater distance to some stars and a lesser to others, and they define the least as 13000 and the greatest as 14000 semidiameters of the Earth. But we shall set out their opinions at the end of number 14, in a table together with others.

[Margin: 4. Opinion of Copernicus.]

VII. The fourth opinion is that of Copernicus. In Book 1, ch. 10, he places the Sun at the centre of the world and the Earth as movable around the Sun, with an annual motion through the same orbit through which the Ptolemaics carry the Sun round. So that no sensible parallax should arise from such a hypothesis in observations of the fixed stars, through the Earth's approach to the fixed stars or its recession from them, he holds the distance of the fixed stars from the centre of the world to be so great that the diameter of the Earth's annual orb has no apparent or sensible difference and proportion to the diameter of the sphere of the fixed stars. And thus he acknowledges a certain vast space empty of stars between Saturn and the fixed stars, which he confirms in the same ch. 10 in these words: "For that there is still a very great space from Saturn, the highest of the wanderers, to the sphere of the fixed stars, is shown by their twinkling lights. By this sign above all they are distinguished from the planets; and between things moved and things not moved there had to be the greatest difference. So great indeed is this work of the Best and Greatest." For he makes the fixed stars immobile and the daily motion the Earth's; and the apparent motion of the fixed stars in longitude towards the east he assigns to a motion of the equinoctial points towards the west, by which the intersections of the terrestrial equator with the celestial ecliptic are advanced towards the setting, as we have already set out in Book 3, ch. 28. But how great that distance is, Copernicus nowhere determined.

To show the reasoning for so vast a distance in the Copernican hypothesis, let the vertical line AB in the following figure be drawn through the centre of the world C, where Copernicus places the Sun immobile, and around this centre let the Earth move with the annual motion in the great orbit, whose semicircle is DEF and its diameter DF. And about the same centre C let the

semicircle of the sphere of the fixed stars AIB be described, in which let there be a star G or H, on the meridian or on some other vertical AIB.

Diagram. Set into the right column at the left of the text: a vertical diameter AB with a large semicircle running from A round to the right down to B, and a small semicircle about the same centre on the diameter's middle part, bulging right from D to F. Straight lines run from D to G, to H and to I; from F to G, to H, to I and to K; and from C to I. G and H are drawn as stars.

- A (top of the vertical line)
- G (on the large semicircle, upper right, star)
- H (on the large semicircle, right of G and below it, star)
- D (on the vertical line, upper end of the small semicircle)
- E (on the small semicircle, at its right, among the lines)
- C (on the vertical line, the centre)
- I (on the large semicircle, at the right, level with C)
- F (on the vertical line, lower end of the small semicircle)
- K (on the large semicircle, below I, level with F)
- B (foot of the vertical line)

Now let the Earth be at F, and its sensible horizon FK; and let the distance of the star G from the zenith A, which is the arc AG, be taken with some instrument, the angle AFG on the instrument measuring it. Then six months later let the Earth be at D, and from there again, if not on the same meridian or vertical, at least on a vertical standing off from the meridian line by an equal azimuth, let the distance of the same fixed star G from the zenith be taken through the angle ADG. For if the diameter of the annual orb DF has a sensible proportion to FG, the distance of the fixed stars, some sensible parallax will certainly appear in the distance of the fixed star G, and it will seem greater when viewed from D than from F, because the angle ADG, being exterior, is greater than the interior AFG, by proposition 32 of Euclid's first book; and that parallax will be the angle G, by which, by the same proposition 32, the angle ADG differs from the angle AFG, and this is called the parallax of the annual orb. Similarly, the star H, which seen from the Earth placed at D would appear on the physical horizon DH, would appear, seen from the Earth placed at F, raised above the physical horizon FK by the whole arc HK. Moreover, if the distance GH of two stars G and H were taken with some large sextant from the Earth at D, through the angle GDH, and then the distance of the same stars were taken from the Earth placed at F, through the angle GFH, then, if their distance from the Earth were of sensible proportion to the diameter DF, their distance would appear greater to the eye nearer at D than to the eye more remote at F, according to the laws of optics, because the angle GDH would easily be shown to be greater than the angle GFH. But since it is commonly assumed by astronomers that no parallax in the fixed stars has been observed or is observable with any instruments, whether their declination through meridian altitudes, or through armillary spheres, or their mutual distance, or the altitude of the pole is taken with them, the Copernicans, so that no observable parallax

from the Earth's annual motion can perhaps be demonstrated, lay it down that the diameter DF has no apparent ratio to the distance of the fixed stars FA or FB, and that the annual orb itself is like a point with respect to the sphere of the fixed stars.

VIII. So, supposing now the hypothesis of the Earth carried round through the annual orb, let us see how great the distance of the fixed stars from the Earth, say FH, must be, for the parallactic angle H to vanish to the senses and to be observable by no human instruments. For some put it greater, others smaller. [Margin: The Copernican distance of the fixed stars, from Magini.] First, Magini says in the *Primum Mobile*, Book 11, Problem 29: "To leave aside the opinion of Copernicus, who maintains that between the sphere of Saturn and the eighth there is so immense a vastness that the eighth sphere is removed from the Earth by at least 7,850,000 semidiameters." I do not recall having read this anywhere in Copernicus; but I think it was deduced from his hypothesis by Tycho, from whom Magini may have drawn it. [Margin: And from Tycho.] For Tycho says in the letter to Christoph Rothmann of 1589 November 24: "As for the Earth's other motion, the annual one, which would remove the eighth sphere so far that the orbit this motion traces vanishes with respect to it, explain whether it seems likely to you here that the space from the Sun, then the centre of the universe, to Saturn is contained more than 700 times between Saturn and the sphere of the fixed stars [Affixarum]; and all of that filled with no stars. Yet this must happen, if the Earth's annual orb is to appear even the size of 1′. Indeed, even then the fixed stars of the third magnitude, which have 1′ in diameter, will necessarily be equal to this whole annual orb: that is, they will take in 2284 semidiameters of the Earth in their diameter; for they will be very nearly 7,850,000 of the same semidiameters distant. What shall we say of the stars of the first magnitude, some of which occupy 2′ and some nearly 3′ in visible diameter? And what if the eighth sphere were removed still higher, so that the Earth's annual motion vanished there altogether?"

[Margin: From Longomontanus.] Nor does Longomontanus depart much from this measure, in the *Theorica*, Book 1, ch. 1, where he draws a second argument against the annual motion of the Earth from the incredible gap between the sphere of the fixed stars and the Earth, which the Copernican hypothesis brings in. For in the preceding figure, if the angle DIF, the parallax of the annual orb, were 1′, and the angle CID ½′ [semiminuti], then with CD, the semidiameter of the annual orb, that is, the Tychonic mean distance of the Sun, put at 1150 semidiameters of the Earth, he deduces by the doctrine of triangles the distance CI as 7,906,818 semidiameters of the Earth. If you subtract from this the distance of Saturn, which is about 12000 semidiameters of the Earth, there remains, he says, between Saturn and the fixed stars a gap of 7,894,818 semidiameters of the Earth, utterly empty. Moreover, from almost the same figure, if a star is taken to be FED, and its apparent semidiameter under the angle CID is 1′, as in stars of the first magnitude, and the distance CI 7,906,818, he infers DC, the true semidiameter of the star, as 2300 semidiameters

of the Earth, and the diameter DF as 4600. But of these things below, where the true size of the fixed stars is treated.

[Margin: Two distances of the fixed stars in the hypothesis of Copernicus, from Scheiner.]

IX. But our Scheinerus [Christoph Scheiner], in the *Disquisitiones Mathematicae*, number 13, taking from Michael Mästlin's appendix to Rheticus the semidiameter of the annual orb as 1208 semidiameters of the Earth, and the distance of Saturn as 10872, makes: as the Earth's semidiameter 1 is to Saturn's distance 10872, so the semidiameter of the annual orb 1208 is to the distance of the fixed stars, 13,133,376 semidiameters of the Earth, so that in this way the parallax of the fixed stars at the extremes D and F of the annual orb vanishes. And in the triangle CID, from CD 1208 and CI 13133376, there follows the angle CID 20″, and the whole parallax of the annual orb DIF 40″. [Margin: The parallax of the annual orbit from this distance.] But if, according to Tycho, *Progymnasmata*, vol. 1, p. 480, the distance of Saturn is 12900, and this has to be multiplied about eight hundred times, so that in the hypothesis of Copernicus the semidiameter of the annual orb vanishes with respect to the semidiameter of the sphere of the fixed stars, then, as Scheiner infers, the distance of the fixed stars will be 10,320,000, multiplying 12900 by 800; from which there results CID 24″, and the whole parallax DIF or DFH 48″.

[Margin: The Copernican distance of the fixed stars, from Galileo.]

X. But Galileo, in Dialogue 3 of the *De Systemate Cosmico*, infers the distance of the fixed stars from the proportion of the periodic motions, thus. If Saturn's motion of 30 years requires a distance of Saturn from the Earth nine times greater than the greatest distance of the Sun from the Earth, whose motion is of one year, then the motion of the fixed stars, which in Ptolemaic terms is of 36000 years, requires a distance of the fixed stars 10800 times greater than the distance of the Earth from the Sun. For as 30 is to 9, so 36000 is to 10800. Multiplying by these the Earth's distance from the Sun, 1208, as Galileo uses it here, the distance of the fixed stars from the Earth becomes 13,046,400 semidiameters of the Earth, and hence the angle DIC 20″, but the whole parallax of the annual orb DIF or DHF 40″.

[Margin: The distance of the fixed stars, from Kepler.]

XI. With similar ingenuity Kepler, in the book *De Stella Nova*, ch. 16, and in the *Epitome of Copernican Astronomy*, p. 490, investigates the distance of the fixed stars. Having placed the Sun immobile at the centre of the world and as the source of planetary motion, and the sphere of the fixed stars as immobile, as the place containing all things, he says that the Movable, that is, the interval of the planets, or the distance of highest Saturn, is the mean proportional between the mover and the immobile place. He gives the Sun's semidiameter 6 semidiameters of the Earth, and the distance of the Earth from the Sun 1432 semidiameters of the Earth, and to the distance of Saturn ten times this, namely 14320. On this basis he makes: as 6 is to 14320, so 14320 is to 34,077,066 2/3, the distance of the fixed stars; from which he denies that a

parallax of the annual orb greater than 9″ follows, and the perception of that he grants to none of the astronomers. [Margin: Kepler's slip on the parallax of the annual orbit.] But he is mistaken. For although the parallax CID, which the Earth's motion makes when it has completed a quadrant of the zodiac, is 8″ 27‴, yet after the semicircle FED is completed the whole DIF or DHF is 16″ 54‴.

But in the *Epitome*, p. 479, he gives the Sun's semidiameter 15 semidiameters of the Earth, and the distance of the Earth from the Sun 3469, so as to make the Sun's parallax almost insensible. Saturn's distance, however, he makes a little less than ten times the Earth's distance from the Sun, that is, in round figures 30000 semidiameters of the Earth; and he makes this same distance the mean proportional between the Sun's semidiameter and the distance of the fixed stars. Accordingly he makes: as 15 is to 30000, so 30,000 is to 60,000,000 semidiameters of the Earth, namely to the distance of the fixed stars; from which he denies that a parallax of the annual orb greater than 12″ follows, and on this he says that no practitioner who asserts that 12″ can be perceived with instruments is to be believed. [Margin: Kepler's second slip on the same parallax.] But here too he is mistaken, or perhaps conceals the error. For granted that the parallax CID comes to 11″ 56‴ from these measures, yet the whole parallax DIF or DHF is 23″ 52‴, and greater than the preceding, because of the far greater distance of the Earth from the Sun assumed here than there.

Further, to show that the distances he assumes do not conflict with Tycho's observations, he recounts that in 1586, at midnight after the autumn equinox, Tycho found the greatest altitude of the pole star to be 58° 51′, and that he found the same on December 26, in the evening at about the sixth hour, near the solstice, although the Earth had then completed the quadrant ED, and the horizon DH in the later observation was higher than the horizon CI in the earlier by the whole semidiameter CD of the annual orb. Therefore, if Tycho did not perceive a parallax of even 1′, much less can a parallax of 12″ be perceived. [Margin: Kepler disparages Tycho's instruments.] Yet Tycho in his *Mechanica Astronomica* asserted that with his largest quadrant a sixth part of 1′, that is, 10″, can be perceived in the altitudes of the stars; so much the more, then, 24″. And in *Progymnasmata*, vol. 1, pp. 347 and 362, he recounts the altitude of the pole star observed down to these seconds.

[Margin: Two distances of the fixed stars, from Lansbergen.]

XII. Let us now hear Philips van Lansbergen, and with him Hortensius [Maarten van den Hove], who is itching to be a Copernican [Copernicoturientem]. Formerly Lansbergen, in his commentaries on the motion of the Earth, supposing a parallax of the annual orb of 30″, had inferred the distance of the fixed stars as 68,754,937 parts of which the radius of the annual orb is 10000, that is, 10,312,227 semidiameters of the Earth; since the semidiameter of the annual orb, or the mean distance of the Earth from the Sun, is according to Lansbergen 1498 1/2 semidiameters of the Earth, from what was said in Book 3, ch. 7. Later, in the *Uranometria*, he chooses a distance of the fixed stars of 280,000,000 parts of which the radius of the annual orb is 10000, [Margin:

Book 3, Element 7.] that is, 41,958,000 semidiameters of the Earth; from which he deduces the parallax of the annual orb as 7″ 22‴. This is true indeed, if one is speaking of the parallax CID made by the semidiameter of the annual orb; [Margin: Lansbergen's slip on the parallax of the annual orbit.] but if of the whole DIF or DHF, made by the diameter, it is 14″ 44‴. Lansbergen's basis is, first, that if a smaller distance is assumed, the parallax of the fixed stars caused by the Earth's annual motion will turn out sensible, "contrary to the experience of every age"; and second, that he puts the revolution of the fixed stars at 28000 years, and reasons thus: "As the periodic time of the Earth, of one year, is to the radius of its orbit, 10000, so the periodic time of the fixed stars, of 28000 years, is to the radius of their sphere, 280,000,000." He adds that between Saturn and the fixed stars there is a space of 279,900,696 parts of which the radius of the an- nual orbit is 10000, empty of stars. From this it comes about that, just as the Sun, the centre of the world, is a point with respect to the sphere of the highest planet, so the sphere of the planets is a point with respect to the sphere of the fixed stars, and, viewed from the fixed stars, does not appear greater than 1′ 49″; and that this befits the immensity and infinity of God the Architect. Nor does he blush to say *that the ancient and more recent astronomers have erred by the whole heaven*, who made out of the sphere of the planets and that of the fixed stars one heaven, or a contiguous one, although these are separated from each other by a vast interval. But this reasoning comes down to this: the distance of the fixed stars is 28000 semidiameters of the annual orb because the period of the fixed stars is 28000 years. To be consistent, then, the distance of Saturn ought to have been 30 semidiameters of the annual orb, because the period of ♄ is 30 years. And yet in Book 3 of the *Uranometria*, Element 6, he makes it 11½ parts of which the radius of the annual orb is 1. But if the parallax of ♄ stands in the way of the proportion between the distance and the period of ♄, what if a parallax of the fixed stars, known to God, stands in the way of the proportion between their distance and period?

[Margin: Hortensius's opinion on the distance of the fixed stars, and his lapse on the parallax of the annual orbit.]

XIII. I come to *Hortensius*, who, in his dissertation with Gassendi, chooses Lansbergen's earlier opinion on the distance of the fixed stars: 68,754,937 parts of which the radius of the annual orb is 10000, that is, 10,312,227 terrestrial semidiameters. This is because from it, he says, there follows a parallax of the annual orb of only 30″, which he thinks can be admitted without any evident conflict with the observations. Yet the whole parallax DHF, or DIF, is 1′, a full minute, even granted that its half, CID, is 30″.

[Margin: Hérigone's opinion on the distance of the fixed stars.]

XIV. *Pierre Hérigone* has a stronger stomach. In volume 5 of the *Cursus Mathematicus*, p. 615, he assumes that the semidiameter of the annual orb, or the distance of the Earth from the Sun, which he makes 1200 semidiameters of the Earth, is the mean proportional between the semidiameter of the Earth and the semidiameter of the sphere, or the distance of the fixed stars, which

he accordingly makes 144000 [recte: 1440000, per the book's errata; on this copy a hand has also added the final 0]. From this he infers that the parallax of the fixed stars produced by the annual orb is as great as the greatest parallax of the Sun, namely 3′. He denies, however, that it can be perceived, except in stars near the pole of the zodiac, and only after an interval of six months. But because, he says, after this interval, if it was night at the first observation it will be day at the second, it therefore cannot be perceived absolutely, since the fixed stars are then hidden.

[Margin: Hérigone's twofold error.]

But he errs twice over. *First*, because the parallax CID, in the figure of no. 7, is indeed 3′, given CD 1200 and CI 144000 [recte: 1440000, per the book's errata]; but the whole parallax DIF, or DHF, produced by the Earth's annual motion of six months through the semicircle DEF, is 6′. *Second*, because the altitude of the Pole Star can be observed both in the evening near the summer solstice and in the morning near the winter solstice, with an interval of six months between them; and in this way that great parallax, not only of 3′ but even of 6′, would certainly be perceived. I do not know with what stomach Hérigone would swallow that.

[Margin: Corollary against the asserters of the Copernican hypothesis.]

XV. All these asserters or supporters of the Copernican hypothesis, then, have concealed from us half of the parallax of the annual orb, whether by deceit or rather through inadvertence, so that they would neither lose the beauty of their analogies nor, in keeping those analogies, end up with a parallax of the fixed stars too great against the observations. And what deceived them, I believe, was the way of deriving the Sun's horizontal parallax, for which we usually employ only the Earth's semidiameter, since of course we are seeking that variation of view which arises with the eye supposed now at the centre, now on the surface of the Earth. But if we were seeking the variation of view that the whole diameter of the Earth produces for us and our Antipodes, or would produce for us if we walked around a semicircle of the Earth, it would certainly be twice as great as that from the centre to the surface. For my part, in the hypothesis of Copernicus, I would not admit a parallax of the annual orb in the fixed stars greater than 10″, since this difference, and indeed even a smaller one, can be clearly perceived with exactly divided instruments, using the very fine threads of the dioptras, set far from the eye. Below, therefore, in the last table, I shall give the distance of the fixed stars required so that the parallax DHF does not come out greater than 10″, according to the doubled distance of the Earth from the Sun, or DF, the diameter of the annual orb asserted by the supporters of the Copernican hypothesis.

[Margin: 5. Rheita's method: his opinion and fallacy.]

XVI. The fifth opinion and method is that of *Antonín Maria Šírek de Rheita*, who on p. 193 of his *Radius Sidereomysticus* derives the distance of the Sun and of the fixed stars. He says that he observed the Sun's diameter to be 34′ 41″, whose sine is 100 of the parts of which the radius in the tables of sines is

10000. Therefore, he says, the Sun's diameter is to the distance of its orbit as a square root is to its square. Then he adds that just as the Earth's diameter is contained a thousand times in the radius of the Sun's orbit, so the diameter of the Sun's body is contained a thousand times in the radius of Saturn's orbit, and the diameter of Saturn's sphere a thousand times in the radius of the sphere of the fixed stars; so that the radius of the fixed stars contains 1,000,000 diameters of the Sun and 10,000,000 diameters of the Earth, and the distance of the fixed stars is therefore 20,000,000 semidiameters of the Earth. But earlier, on the same p. 193, he had gratuitously assumed that the Earth's diameter is to the true diameter of the Sun as 10 to 100. No less gratuitously does he assume the other analogies already mentioned, since other analogies no less probable can be invented, as is now clear from the preceding opinions.

[Margin: 5 principal methods are weighed.]

XVII. Of all the ways brought forward so far, five might seem the most probable of all, setting aside those that rest on the mobility of the Earth.

[Margin: 1. Method from the smallest of the perceptible parallaxes.]

The *first* is to posit a distance of the fixed stars at least as great as a parallax of 2″ or 3″ requires, within which it is certain that all the refinement of observations lies. For although instruments for taking the altitudes of stars can be built so large that, by transversal lines, they admit a subdivision of each minute into 2″ or 3″ each, yet the cylinders or strings of the dioptras cannot be so fine as to make us certain of any greater refinement in sighting at the centre of the stars. And the instrument and the observer must be very exquisite indeed if one is to be certain of not having committed an error of 5″, let alone 3″ or 2″. Now if in a right-angled rectilinear triangle the Earth's semidiameter is assumed as 1, and the parallactic angle opposite it as 2″, there will come out, for the base, a distance of the fixed stars from the Earth of at least 100000 semidiameters; which seems very probable to me, supposing the distance of Saturn, of which more below.

[Margin: 2. Method from the proportion of the motions.]

The *second* method rests on the proportion of the more certain periodic motions and distances. Now no star's distance is more certain than the Moon's, because of the evidence of its parallaxes. For us that distance is 59 semidiameters of the Earth, while its revolutions in one Julian year are 12⅓. One revolution of the fixed stars, on the other hand, requires 26000 years in our opinion, in which there are 321360 lunar months. So if we form the proportion, as 1 month to the distance of 59 semidiameters of the Earth, so 321360 months to another, there will be 18,960,240 semidiameters of the Earth. But if we used the distance of the Sun, not now our own but the smallest among those that can be entertained, which is at least 1000 semidiameters of the Earth, and formed the proportion, as 1 year to 1000, so 26000 years to another, the distance of the fixed stars would be 26,000,000 semidiameters of the Earth. That is very enormous and absurd, as is the former, because of the excessive gap between the fixed stars and Saturn;

for between them and the system of the planets there would be an immense space, empty of stars and idle.

[Margin: 3. Method from the difference of refractions.]

A *third* method could rest on the difference of refractions, of which we shall speak again in Scholium 8. For the Moon's horizontal refraction is greater than the Sun's refraction by very nearly 1′, and the difference of the intervals of the Moon and the Sun from us is 7268 terrestrial semidiameters; while the refraction of the fixed stars is less than the solar by 4½′ at the horizon. If we form the proportion, as the difference of refraction, 1, to the difference of distance, 7268, so 4½ to another, the difference of distance between the Sun and the fixed stars will be 32706; and if you add to it the Sun's mean distance, 7327, the distance of the fixed stars will be 40033 semidiameters of the Earth. But although a probable argument can be taken from this for their finite distance, it is hardly very probable for the determinate measure of that distance, both because of the headlong increase of refractions near the horizon, which does not follow the decrease of the inclination, and because our distance of the Sun from the Earth rests on a more solid foundation, and from it is derived a distance of Saturn, and hence of the fixed stars, far greater than 40033 semidiameters of the Earth.

[Margin: 4. Method from the distance of Saturn.]

The *fourth* method, then, the most likely of all those reported so far, uses the distance of Saturn alone, giving no thought meanwhile to its shadow. Now it is established from the parallaxes of the annual orb, and from the equations necessary to reconcile Saturn's mean motion with its true motion and with the places observed by instruments, that the distance of Saturn from the Earth is ten times the distance of the Sun from the Earth, or less than that by an imperceptible small difference, so that for this purpose we may safely use the tenfold ratio; *Kepler* too noted this in the *Epitome of Copernican Astronomy*, Book 4, p. 455. Now the Sun's mean distance, for us, is in round figures 7300 semi- diameters of the Earth; tenfold that, then, which is the distance of Saturn, will be 73000. This should not seem too much to anyone who examines the foundations prudently, especially since for Posidonius and Wendelen, for whom the Sun is distant from the Earth by about 15000 terrestrial semidiameters, Saturn must be raised to nearly 150000 semidiameters. For this reason we cannot assign the fixed stars a distance less than 73000 semidiameters of the Earth, even if we give no thought to the shadow of Saturn. But the greatest distance of ♄ is, for us, 90000 and more; therefore the least distance of the fixed stars is about 100000.

[Margin: 5. Method from the distance and shadow of Saturn.]

The *fifth* method, a very probable one, joins the distance of Saturn with the length of Saturn's shadow. Though that shadow is one length for Biancani and another for others, as we shall say in Book 7, section 6, ch. 14, for me it is 118680 semidiameters of the Earth, from what will be said there. So when my greatest distance of Saturn, 90155, and the axis of Saturn's shadow are joined, the distance of the fixed stars will be not less than 200000 semidiameters of the Earth, and at least 208835; that is, so that it lies beyond all hazard of Saturn's shadow.

For although there can be no fear for the fixed stars from that shadow, since they shine of themselves and not from the Sun, whatever *Biancani* may have suspected about their eclipse in Book 15 of the *Sphaera*, ch. 2, it is nevertheless probable that God raised them beyond this limit; especially since the ascents of comets, as *René Descartes* notes in part 3 of his new *Philosophy*, or new stars, seem to require a great space between the planets and the fixed stars. For us, then, let the minimum be 210000 semidiameters of the Earth, a little above the shadow of Saturn with its companions, while the maximum is uncertain; for the thickness of the heaven of the fixed stars is uncertain, in which they are unequally removed from us, in their lowest part as well as in their centre.

FIXARVM DISTANTIA A TERRA

The distance of the fixed stars from the Earth

[52] In Hérigone's row, the final 0 of the distance and the figures 3 and 0 of the half parallax are written by hand on this copy, over the print. Under the pen 3 the type is a printed 0, to which the hand has added a hook and a tail; the type under the pen 0 of the seconds was not made out. The figure 1440000, given twice in the text on p. 418, ends in a similar dark, slanted 0 run up against the next word, and has received the same hand's added 0: the type prints 144000 at both places.

Velocitas Fixarum.

The speed of the fixed stars.

[Margin: Method of deriving the speed of the fixed stars.]

XVIII. Double the greatest distance of the fixed stars from the Earth, and you will have the diameter of the sphere of the fixed stars. Multiply it by 314 and divide the sum by 100, and you will have the circumference, or perimeter, in semidiameters of the Earth, which the fixed stars traverse in one day by the diurnal motion. Divide these by 24, and you will have the number of terrestrial semidiameters that the fixed stars traverse in one hour. Divide these again by 60, and you will have the number of them that they complete in one minute. Finally divide these by 60, and you will have the number of terrestrial semidiameters that the fixed stars complete in one horary second. If you want to express this speed in miles, consult Book 2, ch. 7, and multiply these semidiameters by the miles contained in a semidiameter of the Earth.

Fixarum Velocitas in motu Primi Mobilis, expreſſa in Semidiametris terræ, quas Fixa quælibet in Æquatore poſita, & in maxima ſui à terra diſtantia percurrit.

The speed of the fixed stars in the motion of the primum mobile, expressed in semidiameters of the Earth, which any fixed star placed on the equator, and at its greatest distance from the Earth, traverses

Authors	1 hour: semidiameters of the Earth	1 minute: semidiameters of the Earth	1 second: semidiameters of the Earth
Ptolemy according to Fernel	11834	197 1/4	3 17/60
al-Battānī according to Giuntini	4972	82 5/6	1 25/60
al-Farghānī according to Maurolico	5240	87 1/3	1 27/60
al-Farghānī according to Clavius	11834	197 1/4	3 17/60
al-Farghānī according to Barozzi	10582	176 1/3	2 56/68 [recte: 2 56/60]
Tycho	3663	61	1 0
We	549500	9158 1/3	152 2/3

If you want these measures in miles or stadia, consult Book 2, ch. 7. The remaining authors either did not determine the distance of the fixed stars, or denied this motion to them.

SCHOLIA.

Scholia.

[Margin: Whether a parallax of the pole and of the fixed stars is to be feared in the hypothesis of Copernicus; and in which stars it is greater.]

I. Since the hypothesis of Copernicus admits an infinite distance of the fixed stars, there is no danger in it that any parallax be detected in the altitude of the pole, observed by means of the altitudes of stars in the same place on the Earth but at different times of the year, because in that hypothesis the meridian altitude of the fixed stars does not vary perceptibly. It should be noted, however, from Galileo, Dialogue 3 on the System of the World, that in this hypothesis the equator and its axis and poles are in the Earth itself, and that only in imagination are the poles of the equator feigned in the heaven at those points where the terrestrial axis of the equator would fall, if it were produced as far as the highest heaven. Now since in this hypothesis this axis always remains parallel to itself, and describes a cylindrical surface with an inclination of 23½° to the plane of the ecliptic, it follows: first, that wherever the Earth is in the annual orb, the elevation of the feigned pole in the heaven is always the same; second, that the parallax in the altitude of the fixed stars is indeed imperceptible, given their Copernican distance, but is nevertheless greater in stars nearer the pole of the ecliptic, smaller in those more remote, and smallest in stars of the ecliptic; third, that the parallax of the apparent size of the fixed stars is indeed imperceptible, but is nevertheless greater in stars of the ecliptic than in stars nearer the pole of the ecliptic, as Galileo notes in the same place. He adds, however, that the parallax of the fixed stars is imperceptible with customary instruments; but if instruments were used whose side contained several miles, say 50 or 60, so that each degree would be 1 mile, each minute about 50 cubits, and each second nearly 1 cubit, perhaps that parallax would become perceptible. See what we said in the preceding chapter, nos. 12 and 13.

II. Now we must show what I promised in no. 3: that from the refractions of the fixed stars neither can their distance be determined demonstratively, nor can the infinity of their distance be solidly undermined. For this purpose, let AB be a quadrant of the terrestrial meridian described from the Earth's centre C; and from the same centre, in the same plane, let there be described a quadrant DE of the atmosphere suited to refracting the rays of the stars perceptibly, and a quadrant FH of the celestial meridian in the sphere of the fixed stars, with a small appendage HV. Let the observer's eye be at A, and his sensible horizon AG, but the rational horizon CH, each of which makes right angles with the perpendicular CF, produced as far as the zenith F. This being laid down, I shall show that, even if the refraction of the fixed stars is said to be known, and the altitude of the refractive air, and the Earth's semidiameter, and the true altitude of the star, then, as long as the parallax is unknown separately from the refraction, or is supposed to be nil, the distance of the fixed stars cannot be known, nor can the infinity of their distance be convicted of falsehood by this means. I demonstrate this first *a posteriori*, from three cases that seem best suited to it, and then *a priori*.

Diagram. Set into the left column, with the text of para II running down its left side. A vertical line rises from the centre C at lower left to F at the top; a large arc, the celestial quadrant, runs from F down the right side through N,

P, K and G to H, and continues below H to V. From C a horizontal line runs to H, and another line slants down to V. A horizontal line runs from A to G. Two smaller concentric arcs stand about C, one from the region of T to B and one from the region of I and O to E. Straight lines run out from C through I towards L and through O towards M, and lines run from A towards K and towards G, from I to H, and from O to V. Two dotted lines run up and to the left from the region of I and O to R and S on the vertical line.

- F (top of the vertical line)
- N (a star on the arc, just right of F)
- P (on the arc, upper right)
- K (a star on the arc, right)
- G (a star on the arc, at the end of the horizontal from A)
- H (a star on the arc, at the end of the horizontal from C)
- V (a star at the lower end of the arc, below H)
- S, R, D (on the vertical line, in that order downward, above A)
- A (on the vertical line, the observer's eye)
- C (the centre, at the foot of the vertical line)
- T (on the small arc, just right of A)
- B, E (below the horizontal CH, on the two smaller arcs)
- I (intersection point, below L)
- L, M (above I and O, on the lines from C)
- O (intersection point, right of I and lower)

[Margin: First case.]

III. *First*, let the altitude of the pole P, the arc PH, be exactly 45°, and let a fixed star also have a declination of 45°, so that in culminating it passes through the zenith itself, F. For 12^h before or after the culmination you will be certain that it is at H, a point of the rational horizon. About that time, with the instrument now placed in the meridian line, let its apparent altitude be observed; for unless more opaque vapours obstruct, it will appear at K, by the force of a refraction of about 30′, which may become known from this or a similar observation. So the ray HI, drawn into the denser air, does not go straight to R but, refracted at the point I, is carried to the eye A, so that the refracted ray is IA, along which, produced to K, the star is seen at K; and let the angle of refraction of 30′ be RIA, to which, by proposition 15 of Book 1 of Euclid, the angle KIH is equal. For the star's apparent distance from the zenith, to the eye A, by the instrument, will be the angle FAK, 89° 30′, and therefore the angle IAC, by proposition 13 of Book 1 of Euclid, will be 90° 30′. Now through the point of incidence I, from the Earth's centre C, let the straight line CIL be drawn, so that the triangle ACI arises, in which the angle CAI, 90° 30′, is now given. Also given is the Earth's semidiameter AC, to which CT is equal, of 4139 Bolognese miles, from what was said in Book 2, ch. 7. And let TI, the altitude of the refractive air, be assumed to be at most 100 miles (for it is much less, as is clear from what was said in Book 1, ch. 31), so that the whole of CI is 4239 miles. For from these three givens you will derive, by the doctrine of

triangles, the angle ACI, 11° 58′ 48″, and AIC, that is, its vertical angle LIK, 77° 31′ 12″. This, joined to the angle KIH, 30′, makes the angle LIH, namely the angle of inclination, 78° 1′ 12″. But ICH will be found equal to this, as is clear to anyone subtracting the angle ACI, 11° 58′ 48″, from the right angle ACH. So IH and CH will be parallel, by proposition 28 of Book 1, and will not meet at H, as otherwise they ought to meet; nor will the triangle CIH be formed, in which, from the givens CI and the angles at C and I, the distance CH could be derived or demonstrated to be finite. The reason for this parallelism is that the parallactic angle H is supposed nil, and therefore is not reckoned in the angle FAK, and the apparent distance from the zenith is taken by the force of the refraction raising the star, just as if no parallax at all depressed it below H. And so that you do not think this happens from things wrongly assumed, vary what is assumed, for in any case you will find the angle LIH equal to the angle ICH. For instance, if with Kepler, p. 287 of the *Optics*, you assume the altitude TI to be only 2 Italian miles, so that the whole of CI becomes 4141 miles of which CA is 4139: then, keeping the refraction at 30′, you will find the angles ACI, 1° 20′ 58″ 30‴, and AIC, that is LIK, 88° 9′ 1″ 30‴, and hence LIH, 88° 39′ 1″ 30‴. But ICH will be equal to this, namely when ACI is taken from the right angle ACH; and so for the rest.

[Margin: 2nd case.]

IV. *Second*, let there be a star N which, as its declination has it, when it has returned to the meridian below the rational horizon and is at V, nevertheless appears, by the force of refraction, at G, a point of the physical horizon, so that its true ray VO does not go straight to S, but is refracted at O and carried to A, the refracted ray being AO, along which the star is seen at G. And through O let the straight line COM be drawn, and let there be supposed known both the straight lines AC and CO, as above, and the angle of refraction SOA, that is VOG, known from elsewhere, 30′. For in the triangle CAO, right-angled at A, one can find both the angle ACO, and when this is taken from the right angle ACH, OCH will be known; and also the angle AOC, that is MOG, which, joined with the angle of refraction GOV, will give the angle MOV; and this, subtracted from two right angles, will give the angle COV, in the triangle OCV, in which OC is supposed known. From the star's declination, moreover, its distance from the pole of the world will be known; and from the altitude of the pole, here too presupposed, the arc HV becomes known, namely by taking the altitude of the pole HP from the star's distance VP from the pole. Hence the angle HCV becomes known, which, added to OCH already found, will give the angle OCV. In the triangle OCV, then, nothing seems to be lacking for finding the distance CV of the fixed star V, since CO and the angles OCV and COV are given. Let us come to an example, and take Capella, whose northern declination in the year 1644 was 45° 34′, and hence its distance from the pole 44° 26′. Let its horizontal refraction according to Tycho be 30′, represented by the angle VOG, and at an altitude of the pole of 43° 56′ 10″ let it appear on the physical horizon, or at the point G, when its true place is at V. For when

the altitude of the pole HP is taken from the star's distance from the pole VP, there will remain the arc HV, and the angle HCV, 29′ 50″, which is to be set aside. Next, in the triangle ACO, let the side AC be 4139 miles and the base CO 4239. The angle ACO will be 12° 28′ 41″, and AOC, that is MOG, 77° 31′ 19″. So when the refraction of 30′, that is, the angle VOG, is added, the angle MOV becomes 78° 1′ 19″, and COV 101° 58′ 41″. And when ACO is taken from the right angle ACH, there remains OCH, 77° 31′ 19″; if you add to this HCV, 29′ 50″, the angle OCV becomes 78° 1′ 9″. The sum of the angles OCV and COV will then be 179° 59′ 50″, and accordingly the angle V is 10″. With this laid down, the distance CV will be derived as 87,323,400 miles of which CO is 4239, or 21097 terrestrial semidiameters. But if you had assumed with Kepler an altitude of the refractive air of only 2 miles, CV would finally come to about 20630 miles. We are certain, however, that the altitude of that air neither exceeds 100 miles nor falls short of 2 miles.

and so that the distance of the fixed stars deduced from this hypothesis does not exceed 22000 of the Earth's semidiameters, and indeed does not even reach them. But what uncertainty lies hidden in the hypothesis I shall soon reveal.

[Margin: The uncertainty of the second case.]

V. In the hypothesis of the second case proposed, it is supposed without warrant that the star's declination and the altitude of the pole were observed elsewhere independently of the parallax of the fixed stars; that the star can appear on the physical horizon itself by force of refraction, so that it can be seen in spite of the thickness of the vapours, and does not need, as usually happens, a greater altitude in order to be seen; and that its refraction, or that of another fixed star, was observed from some other source. Indeed, refraction is not known beforehand separately from parallax; otherwise we could obtain the distance at once from the parallax alone. Therefore the refraction is not exactly known either. From the star's declination, the altitude of the pole and the star's appearance on the physical horizon one can conclude that the refraction is greater than the arc HV of true depression below the rational horizon, but one cannot know how much greater it is, that is, how great is the arc HG, which is the difference of the physical horizon from the rational, and is always as great as the star's horizontal parallax. Tycho, moreover, and anyone else to whom the parallax or distance of the fixed stars was not known beforehand, could not, and will not be able to, determine their refraction from observation except by neglecting the parallax and supposing it to be nil; and on that supposition there is likewise no certain limit of a finite distance. And so in our case nothing else could be concluded from those three givens [Greek: διδόμενοις (didomenois, "things given")] than that the refraction is greater than 29′ 50″, even granting that by hypothesis it is assumed to be 30′.

[Margin: An argument from refraction against the annual motion of the Earth, but an invalid one.]

VI. Still, someone could argue *ad hominem*, as the dialecticians say, against Kepler, Lansbergen, Boulliau and others who accept the annual motion of the

Earth and yet receive the declinations and refractions of the fixed stars as exactly known, in this way. The declination of Capella in the year 1560 was 45° 26′. Therefore, at a pole altitude of 44° 4′ 10″, it had to be, at the lowest point of the meridian, below the rational horizon by the arc HV, 29′ 50″. Now if its horizontal refraction, by force of which it appears at G unless the opacity of the vapours obstructs sight, is 30′, as Kepler and Boulliau lay down with Tycho, then the arc HG, that is, the horizontal parallax, is 10″. Given this, it follows that the distance of the fixed stars is less than 22000 terrestrial semidiameters; and from this and Kepler's diameter of the annual orb there would follow a parallax of the annual orb of several degrees, whereas none is observed. But the Copernicans will deny that the arc HG is 10″, not only because the angle GOV does not measure the arc VG, but because it is feigned without warrant that a star of so great a declination appears on the horizon and on the meridian at the same time. This is also to be noted in the example set out above.

[Margin: 3rd case.]

VII. There remains the third case, in which the star, as to its true place at its lowest altitude on the meridian, is neither on the rational horizon, as in case 1, nor below it, as in case 2, but above it, say at G or some other nearer point, and by force of a known refraction appears higher, as at K; and from its declination and the altitude of the pole its true altitude is known. But in this case too, so long as the parallax of the fixed stars, or the angle K, is supposed nil, the angle LIK will be found equal to the angle ICK, and the triangle ICK cannot be formed so that the distance CK may be derived from it. Instead, IK and CK will be parallel, and an infinite distance cannot be overthrown.

[Margin: An argument for the finite distance of the fixed stars from the difference of the refractions.]

VIII. But surely a great, if not an evident, argument for the finite distance of the fixed stars, and for its proportion with the finite distance of the Moon and the Sun, seems to be the proportion of the refractions. For the horizontal refraction of the Moon is greater than the refraction of the Sun by one or two minutes, granted that Tycho (*Progymnasmata*, vol. 1, pp. 79 and 124) makes the Moon's refraction at one time greater, at another smaller, than the Sun's, as Kepler also does in the Rudolphine Tables, p. 115, while Lansbergen, p. 46, makes them equal. But the refractions of the fixed stars are, for Tycho (p. 280) and for Kepler (p. 124), smaller than the solar ones by 4½′. Now it is certain that where the inclination of a ray from the perpendicular is smaller, the refraction is smaller; and it is likewise certain that, other things being equal, the inclination of a ray from a star more remote from the Earth is smaller, and hence its refraction smaller, than that of a nearer star, as the more expert writers on optics concede, and as we shall show in the Optical Book, which is the third of volume 2 of the *New Almagest*. Therefore, just as the difference of one or two minutes in the refractions of ☾ and ☉ arises from the difference of distance, a difference that is great but nevertheless finite and known within definite limits, so the difference of 4½′ between the refractions of the Sun and

of the fixed stars seems to arise from a difference of distance that is, however great, in the end finite. But see above, no. 17, why I rejected the distance of the fixed stars badly deduced from this proportion.

CAPVT VIII.

Chapter 8.

De Refractionibus Siderum Inuestigandis earumque vſu.

On investigating the refractions of the stars, and on their use.

I. By all those methods by which we taught the refractions of the Sun to be observed, in Book 3, chapter 9, from number 2 to number 5, the refractions of the fixed stars can be observed more easily, since there is no need to wait, as there, for the solstitial days, and it suffices that the altitude of the pole and the star's declination be known beforehand. But for stars to appear on the physical horizon itself, the horizon must be clear of the thicker and more opaque vapours; otherwise the stars will not appear unless they have risen by several degrees. Beyond the methods just mentioned there are now three others, indicated in the Scholia of the preceding chapter, and the figure set out there is to be taken up again from them.

[Margin: First method of observing the refractions of the stars.]

II. *First*, then, where HP, the altitude of the pole P, is exactly 45°, and the declination of some fixed star, such as F, is likewise 45°, so that its distance from the pole, namely the arc FP, or HP, is 45°, you will be certain that when it has reached the bottom of the meridian FPH it will be at H, a point of the rational or astronomical horizon. So observe from A, with an instrument, its apparent distance from the zenith, namely the arc FK, by means of the angle FAK; for it will most certainly appear above the physical horizon AG, unless the thickness or opacity of the vapours hinders the view of it. For the difference of the apparent distance from a whole quadrant, that is, the amount by which it falls short of 90°, will be the refraction sought, and it will be as great as the arc HK, on the supposition, as is supposed for the fixed stars, that the arc GH and their parallax are nil or insensible. But it will rarely happen that these three things coincide, namely the altitude of the pole and the declination of the star exactly equal, and a clear horizon.

[Margin: 2nd method.]

III. *Second*, if the distance of some fixed star from the pole is greater than the altitude of the pole, but does not exceed it by more than 28′ or 30′, it will be able to appear above the physical horizon at its lowest depression, as at K. Let there be, then, a star N of this kind, whose distance from the pole, namely the arc NP, is known from its declination and the altitude of the pole; and let the altitude of the pole HP be, for example, as at Bologna, 44° 29′ 30″, and the distance of the star from the pole 44° 59′; and on a night longer than 12 hours let the star culminate in the evening at N, for in the morning, 12 hours

later, it will be at the lowest point of the meridian, V. Or if it culminates in the morning, it will be at the lowest point V after sunset, and it will not be difficult to know the time of the lowest depression. At that time, then, observe its apparent distance from the zenith, namely the angle FAK; subtract this from 90°, and to the remainder add the arc HV, that is, the star's true depression below the rational horizon, which becomes known by subtracting the altitude of the pole HP from the star's true distance from the pole, which is the arc VP. For the sum of the arc HV, or the angle HCV, and the remainder of the apparent distance from the zenith will be the star's refraction, its parallax being neglected here too as insensible.

[Margin: 3rd method.]

IV. *Third*, choose a star whose distance from the pole is less than the altitude of the pole, but by as few minutes as possible, so that at its lowest meridian depression it is above both horizons, and then observe its apparent altitude; for its excess over the true altitude will be the refraction sought. Its true altitude becomes known by subtracting its distance from the pole, or the complement of the declination, from the altitude of the pole. Such a star was Capella in the year 1644 at Bologna: its declination was 45° 34′ and the complement of the declination 44° 26′. When this was taken from the pole altitude of 44° 29′ 30″, there remained its true altitude above the horizon, 3′ 30″. With its apparent altitude set at 32′ 30″, the refraction was 29′, which belongs to fixed stars at a true altitude of 3′ 30″.

[Margin: The use of refractions.]

V. The use of the refraction of the fixed stars is frequent and necessary for correcting their altitudes, by subtracting, that is, the refraction from the apparent altitude so that the true altitude remains, but chiefly in observing the declinations of those fixed stars which at their highest meridian altitude are subject to a sensible refraction. Of this kind are undoubtedly Sirius and Antares on the horizon of Denmark; and then in correcting the apparent distances of the minor planets from fixed stars nearer the horizon, when other stars cannot be used, so that the places of the planets may be observed by means of the fixed stars. How this is to be done we shall say in Book 7. Meanwhile, from many observations of ours, no necessity is established for departing sensibly from the refractions which Tycho observed in Denmark, although some of them have indicated some difference. So, before we weigh many other observations, which are to be brought forward in volume 3 of the *Almagest*, we shall use the little table of refractions that Tycho provided in *Progymnasmata*, vol. 1, p. 280.

CAPVT IX.

Chapter 9.

De Apparenti & Vera Magnitudine Fixarum.

On the apparent and true magnitude of the fixed stars.

I. We are not inquiring in this place into how many classes the apparent magnitudes of the fixed stars are divided, and which stars are of the first magnitude, which of the second, and so on, for enough has been said of this in chapter 6. We ask rather how many minutes and seconds in the heavens their apparent diameter contains, whose measurement and observation are very difficult, because of the stars' apparent smallness and the scintillation of their rays. Yet both the attempts of others and our own must be set out. But first, Reader, you must be warned that stars appear larger than usual, or than others, for six reasons.

[Margin: The causes for which stars appear larger or smaller than they should.]

First, on the horizon, because of a double refraction or because of a deception of the imagination. *Second*, when the sky has cleared after rains, or when east winds are blowing, as Aristotle noted in the *Meteorologica*, Book 3, t. 18, and in the *Problems*, section 26, q. 54, and from him Kepler in the *Optics*, from p. 133. *Third*, because of a white colour: thus Sirius, because it is whiter than Arcturus, appears far larger than Arcturus to the naked eye, through the predominance of the image of whiteness in the eye, than when both are observed with a telescope, as Scheiner too noted in the *Disquisitiones Mathematicae*. *Fourth*, because of weakness of sight: thus the same Sirius seemed to Kepler equal to the Moon, when the rays glittering around it were counted in, as he himself admits in the *Dissertatio cum Nuncio Sidereo*, p. 9. *Fifth*, they vary because of the curls and hair of the rays, by which the disc of the stars seems to be enlarged, whether from innate scintillation, or from the vaporous sphere, or from some other source. *Sixth*, in the case of the planets, because of their approach to and withdrawal from the Earth. For the contrary reasons, or because of the nearness of a greater brightness, they appear smaller, as do stars viewed at dawn or near the full Moon. With this laid down, we must give the methods of observing the diameters of the fixed stars and of the minor planets, next of deriving from them the true magnitude, and finally the opinions on both.

[Margin: 1st method of observing the diameters of stars.]

II. The *first* method of observing the diameters of stars rests on estimation by eye and on comparison either with the Moon's diameter or, lest its brightness interfere, with the distance from one another of the Pleiades, the Hyades or the Kids, otherwise known: one considers, that is, how many such stars would be required to fill that interval. This conjecture is undoubtedly exposed to error, especially because of the extraneous rays that enlarge the stars and diminish the intervals, so much so that the star in the middle of the tail of Ursa Major seems a single star, though there are in fact two, as the telescope has disclosed. For that reason Galileo, in Dialogue 3 of the *De Mundi systemate*, judges it better that diameters be observed in luminous surroundings, near the Sun or the Moon, because they are then stripped of those spurious rays, as appears in Venus seen by day and in the little flames of lamps seen from afar by day; and I have quite often found this by experience at full Moons.

[Margin: 2nd method.]

The *second* method, which al-Battānī indicates in chapter 50, is by two apertures in dioptras, of which the one to which the eye is applied is very narrow, like a point, while the other, remote from the eye, is somewhat wider, but exactly as wide as the apparent diameter requires. For from the distance of the dioptras, and from the semidiameter of the wider aperture, known in the same parts, the angle subtending the semidiameter of the star is derived: namely, if one makes, as the distance of the dioptras is to the radius, so the semidiameter of the wider aperture to the tangent of the angle already mentioned; or if the logarithm of the semidiameter of the aperture and the residual of the logarithm of the distance are added together, so that the sum is the mesologarithm of the angle already mentioned. Besides the fact, however, that the visual angle is formed not at the smaller aperture but in the middle or at the back of the eye, the distance of the dioptras can be varied by many spans and yet the other aperture be seen to match exactly the diameter of the star, as I said in a similar case about Hipparchus's dioptra in Book 3, chapter 10, number 4.

[Margin: 3rd method.]

III. A *third* method is given by Galileo in Dialogue 3 of the *De systemate Cosmico*, though he admits that it is not wholly exact. Hang up, he says, a thread opposite some star (he himself used the bright star of Lyra), and by moving towards and away from it seek the position in which the thickness of the cord exactly covers the star; and measure the distance of that position from the cord in very small parts, say in hundredths of the inches of a known foot. Next wind the cord around a plate an inch wide, so that you may know how many cords exactly cover one inch: for from this you will derive what fraction of an inch matches the thickness of the thread, and half of it will be the semidiameter of the thread. With this and with the distance just mentioned, as the sides about a right angle, you will find the angle subtending the star's apparent semidiameter. But Galileo adds that this distance must be somewhat increased, because the meeting of the rays that forms the angle occurs, on account of refractions, not in the eye but beyond the eye; and he gives a method of finding this meeting point, of which we shall speak in the Optical Book, comparing it with the method of Archimedes and of Kepler. For I do not wish to be needlessly longer here, since this method is subject to the same uncertainty and fallacy as the second, and you can move several feet towards and away from the thread with no sensible difference as regards covering the star exactly. What is the point, then, of that scruple over a little addition to the distance on account of the meeting of the rays beyond the eye, when we are uncertain of the proper distance between the thread and the eye, and the suspicion of an error of anything short of whole feet makes this practice uncertain? I have found, however, that it is carried out somewhat more perfectly if the thread is not fibrous and is lit by a rather near small lamp, whose glare must nevertheless not strike your eyes. Now Galileo asserts there that the apparent diameter of the bright star of Lyra, which Tycho estimated at no less than 2′, was found by him in this way to be not greater

than 5″, and from this he accuses Tycho and others of a notable error, arising, as he thinks, from the rays spread about the discs of the stars in the manner of a curl, which, he says, the thread in covering the star takes away not from the star but from the eye, to which they are proper. But in truth Galileo's observation is suspect to me, both because of the fallacy already explained and because he is wholly bent on building up the probability of the Copernican hypothesis; and lest an incredible bulk of the fixed stars should follow from it on account of their insane distance, he studiously diminishes their diameters, or more willingly embraces observations that favour that diminution.

[Margin: 4th method.]

IV. A *fourth* method is estimation by eye, but with the stars viewed through a fine telescope, for this shows the discs of the stars shorn of the hair of adventitious rays. Galileo tells us that he used this method, in Dialogue 3 of the *De systemate Cosmico* and in the *Sidereus Nuncius*, where, on p. 16, he rightly advises that stars viewed through the spyglass [Perspicillo] are by no means enlarged in the same proportion as other objects; for if other objects are enlarged a hundredfold, the stars are enlarged barely fourfold. The cause, he says, is that before the use of the spyglass we were accustomed to view the stars radiant and hairy with certain brightnesses, especially as night deepens, and the visual angle is then bounded not by the star's little body alone but also by the splendour poured around it. Since, then, in darkness and to the naked eye the stars, unshorn, are seen so large, it is no wonder if through the telescope they are not seen so large, since it enlarges only the disc of the stars and not those extraneous rays, which are in reality not in the object but in our eye. He admits, however, that the planets do appear exactly round by means of the telescope, except when Venus appears horned; but that the fixed stars are by no means shown bounded by a circular periphery, but as flashes, darting rays all around, though now their own, yet so that their disc appears much larger than to the naked eye, so much so that a little star of the fifth or sixth magnitude seems to equal Sirius (if, however, you place over the lens farther from the eye a thin plate perforated in the middle with a small hole, you will see them round). Kepler subscribes to this in the *Dissertatio cum Nuncio Sidereo*, p. 9, as do Scheiner and Hortensius, as regards this effect of the telescope in shearing off the hair of adventitious rays. And Kepler adds, in the *Epitome of Copernican Astronomy*, p. 498, that fixed stars viewed through more perfect telescopes look like radiant points.

[Margin: The diligence of Martinus Hortensius in exploring the capacity of the tube.]

Martinus Hortensius, as he himself reports in his dissertation with Gassendi, explored the capacity of his telescope in order to estimate the diameters of the stars better, by the method treated in Book 7, section 6, chapter 10, scholium 4. Comparing other distances with this capacity, he found two contiguous stars in Capricorn to be distant from each other by one eighth part of the tube, that is, 5′ or 5½′; the contiguous stars of the Hyades about 5′ or 4½′; and two of the Pleiades 31′. Comparing the discs of the planets and fixed stars, viewed through

the tube, with these distances, he estimated their diameters. We, for our part, found the capacity of our tube to be 30′, because it took in the Moon from its eastern limb as far as the middle of the Caspian spot when the Moon's diameter was 33′.

[Margin: 5th method.]

V. The *fifth* method, used by the same Hortensius on Jupiter, by Scheiner on Venus and by Gassendi on Mercury, is by receiving the bright image of these planets, passed through the lenses of the telescope, onto very clean paper; by measuring the diameter of that image, or, if Mercury is under the Sun, of its little shadow; and by comparing it with the Sun's diameter, taken in the same way. But Hortensius admits that the edges of the image of Jupiter appear somewhat fainter. Further, with Jupiter's diameter now obtained, Hortensius compared the diameters of the fixed stars viewed directly through the tube, and found Sirius six times smaller than Jupiter.

[Margin: The danger of deception in this method.]

But this estimate, like the previous one, is exposed to the danger of error unless you very carefully distinguish the magnitude of the circle viewed from the magnitude of the diameter alone. For if Sirius, for example, appears eight times smaller than Jupiter as to its whole disc, it is easy for us to estimate its diameter also as eight times smaller than Jupiter's, when in such a case it would be only twice smaller; for circles are to one another as the squares of their diameters, by proposition 2 of the twelfth book of the *Elements*. So if the diameter of Sirius is 2 and that of Jupiter 5⅘, Sirius would appear eight times smaller than Jupiter, that is, as many times as 4, the square of 2, goes into the number 32, which is approximately the square of the number 5⅘.

[Margin: 6th method.]

VI. The *sixth* method, our own, is by radii made of black plates, these being fixed at right angles to a small beam of 15 Roman feet, which turns up and down and crosswise, as is done in the supports of telescopes. The first radius, which I call triangular, is a black plate ABC, formed into an isosceles triangle, but much narrower than in this diagram. Its base AC was of 11 particles, of which an inch of the Roman foot contains 200, and so it subtended an angle of 2′ when viewed from a distance of 15 feet, as is established from trigonometry. The little white line DE, marked on the black of the plate, was of 9 particles, so as to subtend an angle of 1′ 40″; the little line FG, of 7 particles, subtending 1′ 20″; the little line HK, of 6 parts, subtending 1′ 0″; and the little line LM, of 4 particles, subtending 40″. In the same way the plate NPO of the other, stepped radius [scalaris] was cut so that QR contained 11 parts, ST 9, and so on. Now, with the plates already mentioned turned towards the stars, and by raising or lowering the small beam, you will observe by which of their breadths they exactly cover the stars: whether by the first, AC or QR, or by the second, DE or ST, and so on for the others, or by a breadth intermediate between these. In this way you will observe that the apparent diameters of all the fixed stars, and also of the superior planets, are covered by a portion of the plate DE, and hence

that the apparent diameter of none of these exceeds 1′ 40″; and that by the breadth HK no planet of the three superior ones, placed at perigee, is wholly covered. But a lamp is needed at the edges of the plates, whose splendour, however, must not strike the eyes of the observer.

Diagram. Two solid black woodcut figures side by side, set into the left column with the text wrapped at their left. On the left, a tall narrow isosceles triangle, the triangular radius, crossed by four thin white horizontal lines. On the right, a stepped pyramid of black, the stepped radius, narrowing upward through a series of steps to a narrow column at the top.

- Triangle, apex: B
- Triangle, foot of base, left and right: A, C
- Triangle, white lines from the base upward, left and right ends: D, E; F, G; H, K; L, M
- Stepped figure, top: P
- Stepped figure, foot, left and right: N, O
- Stepped figure, steps from the foot upward, left and right ends: Q, R; S, T; V, X; Y, Z

[Margin: 7th method, the best of all.]

VII. The *seventh* method, which first came to the mind of Father Francesco Maria Grimaldi S.J., on a truly happy occasion, and was used by Don Vicenç Mut, who also devised it by his own ingenuity at quite the same time, is by the apparent diurnal motion of Jupiter and Saturn, and by the distance of its limb from a fixed star, estimated with the telescope, some hours, or even a day, immediately before and after its conjunction with that star, such that both the planet and the fixed star fall within the capacity of the tube. But since this method is proper to these two planets only, and must be explained by use itself, we shall set it out more fully in Book 7, section 6, chapter 10, and illustrate it with examples in the same place, nos. 2 and 9.

[Margin: 8th method, the best after the 7th.]

VIII. The *eighth* method, the best after the seventh, and presupposing either it or the fourth, is carried out by drawing on paper several little circles of different sizes, viewing the stars through the telescope, and at once looking back repeatedly at those circles, until it is evidently established which of them most nearly matches the disc of the star viewed. When this has been done, first with Jupiter or Saturn, whose diametral size will already have been established by method 7 or 4, and then with other stars, the diameter of Jupiter or Saturn is divided into very tiny equal particles, a division that comes out clearer if it is made by transversal lines. Finally, with a very sharp pair of compasses taking in the diameter of the circle that matches the star's disc, one investigates what proportion it has to the diameter of Jupiter or Saturn.

[Margin: Why the observations of the diameter of the fixed stars are deferred to Book 7.]

We, therefore, have established the apparent diameters of the planets, and next of the fixed stars, chiefly by methods 4, 7 and 8. Their observations,

because of the dependence which the fixed stars have in this on the planets, we shall present in Book 7, section 6, chapter 11; and it will be enough here, taking those as supposed, to give in this place the tables of the apparent and true magnitude of the fixed stars.

Problema. Data diſtantia & ſemidiametro apparenti Stellæ, Veram eius Magnitudinem inquirere.

Problem. Given the distance and apparent semidiameter of a star, to find its true magnitude.

IX. With the apparent diameter known, and the distance of the fixed stars assumed from what was said in chapter 7, the true magnitude is derived by Problem 1 of chapter 11 of Book 3. For let the star be HDFE, the eye on the Earth G, the straight line passing through the centre of the eye and of the star HBG, and let the portion of the heavens in which the star's centre lies be ABC; and let two rays, GD and GE, be drawn touching the globe of the star at D and E. For by proposition 18 of the third book of Euclid they will make a right angle at the contact with the semidiameters BE or BD. Therefore, in the triangle GBD, right-angled at D, given the angle DGB, subtending the star's apparent semidiameter, and the distance BG as base, the true semidiameter BD will become known in parts of which GB was given. The semidiameter doubled will give the diameter; and when this is multiplied by 314 and the product divided by 100, you will obtain the circumference, according to what was said in Book 1, chapter 4. Again, if the distance BG, and hence the star's diameter, is known in diameters of the Earth, you will easily find the volume of the star, since spheres are in the triplicate ratio of their diameters, from what was said in Book 1, chapter 6.

Diagram. A woodcut set at the right of the right column, with the text wrapped at its left. A circle, the star's globe, stands above a point on the Earth. A vertical straight line runs from the top of the circle through its centre and down to the point below; two straight lines rise from that point to touch the circle on either side, and a curved line crosses the circle through its centre and runs out on both sides.

- Top of the circle: H
- Centre of the circle: B
- Left and right on the circle, where the tangents touch: D, E
- Bottom of the circle: F
- Curved line, far left and far right ends: A, C
- Point below, where the tangents meet: G

X. Before I cast into tables the opinions on the apparent and true magnitude of the fixed stars, the authors from whom we have taken them must be indicated. Among them there is a remarkable diversity, arising partly from the varying distance of the fixed stars, on which see the table in chapter 7, and partly from differing estimates of the diameter of the stars, made by Tycho and the older

authors with the naked eye, and by other, more recent ones with the telescope; nor all of them the apparent, but only the true magnitude do they report.

[Margin: Authors on the true or the apparent diameter of the fixed stars.]

These authors are as follows. Al-Battānī, chapter 50. Al-Farghānī, difference 22. Maurolico, at the end of the dialogues of his *Cosmographia*, from al-Farghānī. Fernel, *Cosmotheoria*, Book 1, chapter 11. Clavius, in his *Sphere*, p. 187, from Maurolico. Barozzi, *Cosmographia*, Book 1, at the end, from Clavius and Maurolico, though content with round numbers. Magini, *Theoricae Planetarum*, Book 1, chapter 19, and in the *Isagoge* to his *Ephemerides*, p. 19. Tycho, *Progymnasmata*, vol. 1, p. 481, and from him Biancani, at the end of his *Sphere*, and Bayer, *Uranometria*, table 31, and from the same source Hérigone, *Cursus Mathematicus*, vol. 5, Book 2 of the *Theorica*, p. 619, although in vol. 4, in the *Sphere*, chapter 4, he reports the opinion of Hortensius. Galileo, *Sidereus Nuncius*, p. 16, and dialogue 3 on the Cosmic System. Kepler, in the book *De Stella Nova*, chapters 16 and 21, before the use of the telescope, and in the *Epitome of Copernican Astronomy*, p. 484. Longomontanus, *Theorica*, Book 1, chapter 1. Lansbergen, *Uranometria*, Book 3, from element 20 to 31. Martinus Hortensius, in his dissertation with Gassendi on Mercury seen under the Sun; with him Gassendi, *Institutio Astronomica*, Book 3, chapter 11. Baranzano, *Uranoscopia*, part 2, from p. 114 to 119, reporting the tenets of the ancients and of Tycho. For our own opinion, see the end of the tables that follow.

[Margin: Hortensius, however, assigns 10″ to Sirius. Galileo gives 5″ to the bright star of Lyra.]

If you want the magnitude of the fixed stars for a distance of the fixed stars asserted, or to be asserted, by the Copernicans, consult the tables below, Book 7, Section 6, chapter 11, at the end.

SCHOLIA.

Scholia.

I. Galileo, in dialogue 3 on the Cosmic System, says more than once that the fixed stars are so many Suns, of the same kind as our Sun. Giordano Bruno also held this, in the book *De maximo & immenso*, and so did Kepler, in the *Dissertatio cum Nuncio Sidereo*, p. 9. How true this is becomes clear from their bulk, treated in the preceding small tables, when it is compared with the bulk of the Sun, treated in Book 3, chapter 11; for the Sun, at least in our opinion, is much larger than any fixed star.

II. Now if you should ask how many stars of the size of Arcturus or Aldebaram, for example, could fill the hollow surface of the firmament while touching one another, you will obtain it as follows. Make, as the diameter of a fixed star is to 1, so the diameter of the firmament, that is, the doubled distance of the fixed stars, to another number; and you will have the number of stars contained in the diameter of the firmament. Next make, as 100 is to 314, so the number of stars of the diameter of the firmament to another number, and you will have the number of stars contained in the circumference of the firmament. Multiply this by the stars of the diameter of the firmament, and you will have the number of stars filling the spherical surface of the firmament, according to the rules given in Book 1, chapters 4 and 6. So, if on our opinion you assume stars such as Arcturus, and a distance of 100000, the diameter of the firmament will contain

2273 Arcturuses, the circumference 7137, and the whole concavity 16,222,401. But Clavius, in his *Sphere*, p. 189, using a diameter of the firmament of 22612 1/2 diameters of the Earth, and assigning with Maurolico 4 3/4 diameters of the Earth to stars of the first magnitude, gathers 4760 stars in the diameter of the firmament, 14960 in the circumference, and 71,209,600 on the concave surface.

[Margin: To whom the infinite bulk of the stars?]

III. Giordano Bruno, in *De Infinito & innumerabilibus*, asserts that the fixed stars are infinite in number. Kepler rises against him in the book *De Stella Nova*, chapter 21, inferring from this that any one of them is of infinite magnitude, and yet, because they are shaped and bounded on all sides, that they are finite, and so their infinite distance cannot stand. But it is not our task at this point to settle this controversy about the infinite, and we have indicated our opinion sufficiently in physics.

[Margin: The magnitude of the fixed stars on the Copernican hypothesis.]

IV. Among the arguments with which the Copernican hypothesis, requiring an enormous distance of the fixed stars, is usually attacked is the insane bulk of the fixed stars that follows from it. For thus Longomontanus, *Theorica*, Book 1, chapter 1, assigning to the Copernican hypothesis a distance of the fixed stars of 7,906,818 semidiameters of the Earth, and to fixed stars of the first magnitude 2′ of apparent diameter, teaches that one star of the first magnitude would be so large as to contain the Earth 12,167,000,000 times, and the Sun at least 86,907,143 times. But Scheiner, in the *Disquisitiones Mathematicae*, p. 26, from the distance of the fixed stars on the Copernican hypothesis, which he thinks is 13,133,376, and from an apparent diameter of fixed stars of the first magnitude of 2′, has the diameter of any such fixed star containing 7972 semidiameters of the Earth, and the diameter of the great orb more than 3 times, and the volume of the great orb more than 33 times. But more on this argument in Book 9. Meanwhile I say that such a bulk does not follow from our distance of the fixed stars, but with our diameters of the stars posited; indeed, with those very diameters diminished, as Galileo and Hortensius do, it does not follow. Now if anyone wishes to know the ratio of the great orb to any fixed star, let him consult Hortensius in the dissertation with Gassendi, and Gassendi himself in the *Institutio Astronomica*, Book 3, chapter 11. From these, take the small table set below.

STAR of magnitude	Smaller than the great orb according to Lansbergen, in Hortensius	Smaller than the great orb according to Hortensius	But for Lansbergen himself it was once larger
Sirius	☩	217	
1	6 1/3	422	20053
2	15	1012	5935

CAPVT X.

Chapter 10.

De Diſtantijs Fixarum Stellarum inter ſeſe, quarum multæ à Tychone, plures à nobis, paucæ à Metio, aut Naucleris recentioribus obſeruatæ, & nonnullæ calculo inuentæ ab Herigonio vel alijs.

On the distances of the fixed stars from one another, of which many were observed by Tycho, more by us, a few by Metius or by recent navigators, and some found by calculation by Hérigone or others.

[Margin: Why they are called fixed stars.]

I. It is now admitted among astronomers that all the non-wandering stars keep the same distance from one another perpetually, and that saying of Ptolemy's in *Almagest*, Book 7, chapter 1, is well known: *Before all else, then, it must be asserted that this name rightly suits these stars, so that they are called non-wandering, because they are always seen to preserve both similar alignments and figures and equal distances from one another.*

[Margin: The constancy of the fixed stars in the immutability of their distance.]

Ptolemy shows this in the same place, from the fact that in his own time they stood in the same position relative to one another in which they had been seen by Hipparchus, and indeed by Aristyllus and Timocharis, that is, over more than 400 years. Nor did Hipparchus hold the opposite. For although, on account of the few observations before him, which Ptolemy above calls *insufficiently explained and ambiguous*, he suspected that the stars of the zodiac alone among themselves, and the rest among themselves, but not with the stars of the zodiac, keep the same distance, he afterwards followed a different hypothesis, as is gathered from the same chapter 1 of Ptolemy. But this truth became evident much more clearly when, after so many centuries, they were found in the same position, figure and distance that is deduced from the tables and delineations not only of Aratus and Hyginus but also of Hipparchus and Ptolemy, by Tycho, as he himself attests on p. 43 of the *Epistolae Astronomicae* and in *Progymnasmata*, vol. 1, p. 233, and by us and others who have been seized by some care and ardour for observing the sky. But so that we do not leave posterity without any specimen of this matter, we will list some stars that are now in the same line, or very nearly so, as they once were in the age of

Hipparchus and Ptolemy, so that a similar judgement may be made about the others. Then we will set out a Table of Distances for the more notable stars.

[Margin: Examples of the constancy already mentioned.]

In the same line, then, or very nearly the same, are the 2 more northerly stars of the head of Aries, the bright star on the knee of Perseus, and Capella. Likewise the leading shoulder of Aquarius, the brighter of the 2 on the neck of the Horse, and the Head of Andromeda. Likewise the bright star on the breast of the Horse, the one at the gape of the Horse, the one at the gape of the Southern Fish, and the bright star on the shoulders of the Horse. Likewise the Goat, the one on the northern horn of Taurus, and the leading shoulder of Orion. Likewise the 3 in the belt of Orion. Likewise the bright star on the neck of Hydra and the 2 bright stars on the heads of Gemini. Likewise Spica and the 2 on the wings of Corvus. Likewise the middle star of the tail of Ursa Major, Arcturus, and the bright southern star on the forehead of Scorpius; and so for many others that Ptolemy lists.

[Margin: On the distances of the fixed stars observed by us.]

II. I come now to the distances observed by us. When I considered, then, that these were to be preferred to all observations of the fixed stars, inasmuch as they are perpetual and, once accurately determined, could always serve for deducing more exactly the positions of the planets through the Problems to be given in Books 7 and 10, I selected 70 more notable stars, that is, all those of the first and second magnitude and some others more worthy of note that can be viewed on our horizon, especially beyond the hazard of sensible refractions (for the distance of very few, seen within the refractions, had to be converted into the true one by Problem 8, to be given in chapter 11). These I observed not merely once or twice but repeatedly, with 2 different large sextants, and sometimes with a quadrant or a hemicycle, together with my most diligent colleague, highly practised in this, Father Francesco Maria Grimaldi, over 4 years, with incredible patience, so that the distances of stars of the first and second magnitude were repeated 10 times, 12 times, and some more often, in a very convenient position. Any that we observed only once or twice, or in a less favourable position, I have distinguished from the others by adding an asterisk, and I do not consider them so certain that an error of about 2′ or 3′ could not underlie them. I used not these but others in deducing, along with the declination, the equatorial distance; just as I also did not use distances taken in the past under a sky that was not quite clear. For example, Sirius and Procyon, amid reddish half-vapours, seemed to be 25° 39′ or 40′ apart, but 25° 42′ when the sky was thoroughly clear. Likewise Spica, when lower, appeared to be 34° 58′ from the Tail of Leo, whereas when higher it was 35° 2′ distant. This difference arose from the variation of refraction.

[Margin: On the Tychonic distances.]

III. As for the Tychonic distances collected from Tycho's *Epistolae Astronomicae*, p. 50, and *Progymnasmata*, vol. 1, chapter 2, no one should be surprised if they sometimes disagree with ours, especially in stars lower on the Danish

horizon, since Tycho himself was sometimes inconsistent on this. For the heel of Gemini is distant from Regulus, for Tycho, now 54° 35′, in the *Epistolae*, p. 50, now 54° 33′ 45″, in the *Progymnasmata*, p. 198. Moreover, as Willebrord Snel relates in the observations, Tycho saw Spica distant from Regulus by 54° 2′ at Uraniborg, but near Prague by 54° 1′ 30″. And the bright star of Aries is placed in the *Epistolae* at 41° 19′ 30″ from the bright star of the Chair, but in the first volume of the *Progymnasmata* at 41° 20′ 40″. Next, the Northern Scale and Antares are, for Tycho, 24° 10′ apart, and the Scales from one another 9° 8′ 20″, although from their Tychonic longitude and latitude Gassendi derives the former as 24° 9′ 12″ and the latter as 9° 12′. Spica also and Antares are, for Tycho, 45° 51′ 30″ apart, but Magini, in the *Primum Mobile*, gathers from the Tychonic longitude and latitude a distance of 45° 52′, whether refraction produced this or something else in observing. Finally, I advise the reader that, after deriving from declination and distance the differences of right ascension by the Problems of the primum mobile, I then made the return, and from the difference of right ascension and the declination confirmed the distance by analysis of triangles, and I have found that these differ from one another by no seconds or by very few. So the following table, unless love of my own work deceives me, is to be held in great value. When I say *for Tycho* [Tychoni], know that the distance was observed with instruments by Tycho; when I say *Tychonically* [Tychonicè], that it was derived from data given by Tycho.

TABVLA DISTANTIÆ FIXARVM Inter se.

Table of the distances of the fixed stars from one another.

Stars in alphabetical order	Distance
ANDROMEDÆ — *of Andromeda*	
Head from the bright star of Aries, *for me*	27° 9′ 0″
for Tycho	27° 7′ 30″
Head from Markab of Pegasus, *for me*	20° 11′ 35″
Head from the southern foot of Andromeda, *for me*	26° 40′ 0″
Bright star of the belt from the bright star of Aries, *for me*	17° 27′ 40″
for Tycho	17° 27′ 15″
Bright star of the belt from the Head of Andromeda, *for me*	14° 29′ 30″
Bright star of the belt from the southern foot, *for me*	14° 26′ 0″
Southern foot from Aldebaran, *for me*	41° 24′ 0″
Southern foot from the bright star of Aries, *for me*	18° 48′ 30″
for Tycho	18° 48′ 0″
ANTINOI — *of Antinous*	
Leading hand from the bright star of Aquila, *for me*	10° 57′ 0″
for Tycho	10° 56′ 0″
AQVARII — *of Aquarius*	
Fomahant [Fomalhaut] from the bright star of Aries, *for me*	70° 0′ 0″
Fomahant from the bright star of Aquila, *for me*	59° 5′ 20″
Leading shoulder from the following one, *for me*	10° 0′ 0″
for Tycho	10° 1′ 0″
Leading shoulder from the bright star of Aquila, *for me*	29° 1′ 0″

Stars in alphabetical order	Distance
Leading shoulder from the northern horn of Capricorn, *for Tycho*	19° 25′ 0″
Leading shoulder from the southern horn of Capricorn, *for Tycho*	19° 37′ 0″
Right shoulder from the bright star of Aquila, *for me*	34° 54′ 0″
for Tycho	34° 53′ 30″
Right shoulder from Markab of Pegasus, *for me*	21° 1′ 0″
Leading hand, from the right shoulder, *for Tycho*	21° 27′ 30″
AQVILÆ — *of Aquila*	
Bright star from Spica, *for Tycho*	97° 50′ 0″
Bright star, from the bright star of Lyra, *for me*	34° 9′ 0″
and for Tycho	34° 9′ 0″
Bright star from the tail of Cygnus, *for me*	38° 4′ 0″
for Tycho	38° 4′ 30″
Bright star from Antares, *for me*	60° 14′ 0″
from the bright star of Aries, *for Tycho*	90° 15′ 0″
✶ Bright star from the northern one of the wing, *for me*	2° 7′ 0″
✶ Bright star of the throat from the southern bright one, *for me*	2° 33′ 0″
ARIETIS — *of Aries*	
First in the leading horn from Aldebaran, *for me and for Tycho*	38° 36′ 0″
Following one in the horn from the belt of Andromeda, *for me*	17° 44′ 0″
Following one in the horn from Aldebaran, *for Tycho*	38° 21′ 40″
The one above the tail from Aldebaram, *for Tycho*	26° 45′ 0″
Bright star of ♈ from the bright star of the Pleiades: see Taurus	
Bright star of Aries from Aldebaram, *for me*	35° 32′ 0″
for Tycho in the *Epistolae*	35° 32′ 0″
but in the *Progymnasmata*, page 200	35° 32′ 10″
Bright star of Aries from Capella, *for me*	44° 5′ 0″
for Tycho	44° 6′ 36″
Bright star of Aries from the foot of Andromeda, *for me*	18° 48′ 30″
for Tycho	18° 48′ 0″
Bright star of Aries from the Head of Andromeda, *for me*	27° 9′ 0″
for Tycho	27° 7′ 30″
Bright star of Aries from Fomahant, *for me*	70° 0′ 0″
AVRIGÆ — *of Auriga*	
Capella from the bright star of Aries, *for me*	44° 5′ 0″
for Tycho	44° 6′ 30″
Capella from Aldebaran, *for me*	30° 42′ 30″
Capella from Procyon, *for me*	51° 7′ 0″
Capella from the bright shoulder of Orion, *for me*	39° 29′ 0″
Capella from the head of Pollux: see Pollux	
Right shoulder from Procyon, *for me*	45° 10′ 40″
Right shoulder from the bright star of the Pleiades, *for me*	33° 57′ 30″
Right shoulder from Capella, *for me*	7° 42′ 30″
✶ Leading foot from Procyon, *for me*	46° 48′ 0″
✶ The same foot from the bright shoulder of Orion, *for me*	29° 6′ 0″
The same foot from the head of Pollux, *for Tycho*	36° 23′ 30″
✶ Foot or tip of the Kids from the Goat, *for me*	3° 6′ 0″
✶ The same from the bright foot of ♊, *for me*	34° 9′ 0″
BOOTIS — *of Boötes*	
Arcturus from Regulus, *for me*	59° 49′ 0″

Stars in alphabetical order	Distance
Arcturus from the Tail of Leo, *for me*	35° 25′ 30″
Arcturus from Spica Virginis, *for me*	33° 2′ 0″
Arcturus from the bright star of Lyra, *for me*	58° 52′ 30″
✶ Bright star on the hip from Arcturus, *for me*	10° 13′ 0″
✶ Unformed star between Arcturus and Ursa Major, of the 2nd magnitude, from Arcturus	9° 57′ 0″
✶ The same from the bright star of the Crown, *for me*	11° 0′ 0″
CANCRI — *of Cancer*	
Northern Ass from Regulus, *for Tycho*	22° 29′ 30″
Northern Ass from the bright foot of ♊, *for Tycho*	30° 4′ 39″
✶ Southern arm from the Tail of ♌, *for me*	19° 0′ 0″
✶ The same from the bright star of Hydra, *for me*	16° 41′ 0″
CANIS MAIORIS — *of Canis Major*	
Sirius from Procyon, *for me*	25° 42′ 0″
for Tycho	25° 41′ 30″
Sirius from Regel of Orion, *for me*	23° 42′ 0″
for Tycho	23° 41′ 40″
Sirius from Aldebara, *for Tycho*	45° 57′ 30″
CANIS MINORIS — *of Canis Minor*	
Procyon, from Regel of Orion, *for me*	38° 38′ 0″
for Tycho	38° 37′ 30″
Procyon from Sirius, *for me*	25° 42′ 0″
for Tycho	25° 41′ 30″
Book 8 of the *Primum Mobile*, from Tycho's data, *for Magini*	25° 40′ 0″
Procyon from Regulus of Leo, *for me*	37° 20′ 0″
for Tycho	37° 19′ 30″
Procyon from Aldebaram, *for me*	46° 22′ 0″
and Tychonically	46° 22′ 0″
Procyon from the Heart of Hydra, *for me and for Tycho*	30° 20′ 0″
Procyon from Capella, *for me*	51° 7′ 0″
✶ Procyon from the bright shoulder of Orion, *for me*	26° 2′ 0″
✶ Bright star in the Neck of Canis Minor from the bright foot of Gemini, *for me*	14° 30′ 0″
CAPRICORNI — *of Capricorn*	
Leading horn from Fomahant, *for me*	40° 37′ 0″
Leading horn from the left shoulder of Aquarius, *for Tycho*	19° 25′ 0″
Leading horn from the bright star of Aquila, *for me*	22° 24′ 30″
for Tycho	22° 25′ 0″
Southern horn from Fomahant, *for me*	39° 5′ 0″
The same from the left shoulder of ♒, *for Tycho*	19° 37′ 0″

TABVLA DISTANTIÆ FIXARVM Inter se.

Table of the distances of the fixed stars from one another.

CAPRICORNI — *of Capricorn*	Distance
The same horn from Scheat of Pegasus, *for me*	50° 29′ 0″
The following star of the tail, from the bright star of Aquila, *for me and for Tycho*	38° 5′ 0″
CASSIOPEÆ — *of Cassiopeia*	
Head from Capella, *for me*	43° 49′ 0″

CAPRICORNI — *of Capricorn*	Distance
from the belt of Cassiopeia, *for Tycho*	4° 17′ 0″
from Schedar, *for Tycho*	2° 41′ 0″
from the hollow of the knee of Cassiopeia, *for Tycho*	9° 6′ 0″
from the haunch of Cassiopeia, *for Tycho*	13° 53′ 0″
from the tip of the foot, *for Tycho*	18° 54′ 0″
Schedar in the breast of Cassiopeia, from the bright star of Aries, *for me*	36° 39′ 0″
for Tycho	36° 38′ 45″
The same from the tail of Cygnus, *for me*	37° 59′ 50″
from the Pole Star, *for Tycho*	32° 47′ 45″
from the head of Pollux, *for Tycho*	75° 11′ 15″
from the belt of Cassiopeia, *for Tycho*	1° 42′ 0″
and in the *Epistolae*	1° 40′ 0″
from the bend, *for Tycho*	4° 40′ 0″
from the hollow of the knee of Cassiopeia, *for Tycho*	6° 56′ 0″
from the leg of Cassiopeia, *for Tycho*	11° 33′
Belt from the hollow of the knee of Cassiopeia, *for Tycho*	5° 19′ 30″
from the leg of Cassiopeia, *for Tycho*	9° 53′ 0″
from the tip of the foot, *for Tycho*	14° 45′ 0″
from Schedar, *for Tycho*	1° 42′ 0″
Flank of Cassiopeia from the head of Cassiopeia, *for Tycho*	7° 20′ 0″
from the belt, *for Tycho*	3° 3′ 0″
from the hollow of the knee, *for Tycho*	3° 35′ 0″
from the leg, *for Tycho*	7° 19′ 0″
from the Pole Star, *for Tycho*	28° 36′ 0″
Upright of the seat from the head, *for Tycho*	9° 3′ 0″
from the belt, *for Tycho*	5° 23′ 0″
from the hollow of the knee, *for Tycho*	6° 48′ 38″
from the leg, *for Tycho*	9° 5′ 30″
from the Pole Star, *for Tycho*	26° 26′ 0″
Leg of Cassiopeia from Schedar, *for Tycho*	11° 33′ 0″
from the tip of the foot, *for Tycho*	5° 9′ 0″
from the hollow of the knee, *for Tycho*	4° 50′ 0″
from Aldebaran, *for Tycho*	55° 23′ 30″
Bright star of the Chair from the bright star of Aries, *for Tycho*	41° 20′ 40″
but in the *Epistolae*	41° 19′ 30″
from the Pole Star, *for Tycho*	30° 13′ 30″
from the head of Cassiopeia, *for Tycho*	6° 33′ 30″
from the foot of Cassiopeia, *for Tycho*	13° 18′ 0″
from Schedar, *for Tycho*	4° 59′ 0″
but in the *Epistolae*	4° 57′ 30″
from the belt, *for Tycho*	5° 19′ 0″
but in the *Epistolae*	5° 17′ 30″
from the hollow of the knee, *for Tycho*	9° 42′ 0″
but in the *Epistolae*	9° 41′ 0″
Bright star of the Chair from the tail of Cygnus, *for me*	33° 32′ 0″
Bright star of the Chair from the Head of Andromeda, *for me*	27° 57′ 0″
Left knee of Cassiopeia from the bright star of Aries, *for Tycho*	37° 27′ 0″
from Aldebaran, *for Tycho*	55° 23′ 30″
from the Head of Andromeda, *for Tycho*	33° 40′ 0″

CAPRICORNI — *of Capricorn*	Distance
from the bend, *for Tycho*	3° 35′ 30″
CENTAVRI — *of Centaurus*	
✶ Leading shoulder from Antares, *for me*	41° 0′ 0″
✶ Following shoulder from Antares, *for me*	31° 41′ 0″
CEPHEI — *of Cepheus*	
Belt from the tail of Cygnus, *for me*	25° 56′ 30″
from the bright star of Lyra, *for me*	38° 42′ 50″
Right shoulder from the bright star of Lyra, *for me*	33° 59′ 0″
from the tail of Cygnus, *for me*	18° 4′ 0″
CETI — *of Cetus*	
Jaw from the bright star of Aries, *for me*	23° 33′ 0″
from Aldebaram, *for me*	26° 17′ 30″
from Regel of Orion, *for me*	35° 17′ 40″
from the bright shoulder of Orion, *for me*	43° 18′ 0″
and for Tycho	43° 18′ 0″
CETI — *of Cetus*	
Northern star in the tail, from the bright star of ♈, *for me*	41° 37′ 40″
Southern star in the tail, from Fomahant, *for me*	26° 45′ 0″
from the bright star of Aries, *for me*	46° 14′ 30″
from the jaw, *for me*	40° 38′ 0″
CORONÆ Borealis — *of Corona Borealis*	
Bright star from Arcturus, *for me*	19° 26′ 0″
from the bright star of Lyra, *for me*	39° 40′ 30″
from Spica Virginis, *for me*	49° 5′ 0″
CORVI — *of Corvus*	
✶ Beak from Spica, *for me*	21° 20′ 0″
✶ Leading wing from Spica, *for me*	17° 58′ 0″
✶ Following wing from Spica, *for me*	14° 27′ 0″
✶ Breast from Spica, *for me*	17° 15′ 0″
CYGNI — *of Cygnus*	
Beak from the tail of Cygnus, *for me*	22° 16′ 0″
from Scheat of Pegasus, *for Tycho*	46° 36′ 40″
from the bright star of Aquila, *for me*	19° 39′ 30″
for Tycho	19° 40′ 0″
Breast of Cygnus from the bright star of Aquila, *for me*	32° 10′ 30″
from Scheat, *for Tycho*	35° 12′ 30″
Tail of Cygnus from the Pole Star, *for Tycho*	44° 39′ 30″
from the bright star of Aquila, *for me*	38° 4′ 0″
for Tycho	38° 4′ 30″
from the bright star of Lyra, *for me*	23° 51′ 40″
for Tycho	23° 53′ 0″
Middle star in the left wing, from Scheat, *for Tycho*	46° 1′ 30″
✶ Elbow [Ancon] of the northern wing, from Aquila, *for me*	28° 8′ 0″
✶ Elbow of the southern wing, from Aquila, *for me*	36° 23′ 0″
DRACONIS — *of Draco*	
Leading bright star of the head, from Lyra, *for me*	17° 44′ 0″
ERIDANI — *of Eridanus*	
✶ The one at the feet of Orion, from Sirius, *for me*	26° 24′ 0″
✶ from Aldebara, *for me*	23° 2′ 0″

CAPRICORNI — *of Capricorn*	Distance
✶ Lowest of the brighter ones, from Regel, *for me*	19° 36′ 0″
from the bright shoulder of Orion, *for me*	35° 50′ 0″
GEMINORVM — *of Gemini*	
Head of Castor from Aldebaram, *for me*	43° 12′ 0″
for Tycho	43° 12′ 30″
from Regulus, *for Tycho*	40° 32′ 0″
from Procyon, *for me*	26° 37′ 0″
from Capella, *for me*	29° 58′ 0″
from Rigel of Orion, *for me*	52° 9′ 15″
from the bright shoulder of Orion, *for me*	33° 38′ 10″
from the head of Pollux, *for me*	4° 32′ 0″
Head of Pollux from Procyon, *for me*	22° 44′ 0″
from Regel of Orion, *for me*	51° 26′ 50″
from Aldebaran, *for Tycho*	45° 5′ 0″
from Regulus, *for me and for Tycho*	36° 59′ 40″
but in the *Progymnasmata*, page 200	36° 59′ 30″
from the heel of the foot, *for Tycho*	19° 28′ 0″
from the tip of the foot of ♊, *for Tycho*	21° 14′ 0″
from Saica [?], *for Tycho*	90° 46′ 20″
from Capella, *for me*	34° 19′ 30″
for Tycho	34° 18′ 30″
from the bright shoulder of Orion, *for me*	33° 15′ 0″
for Tycho	33° 16′ 0″
from the bright star of Aries, *for Tycho*	74° 45′ 30″
Bright foot of Gemini from the Goat, *for me*	34° 6′ 0″
from Procyon, *for me*	18° 49′ 0″
from Regulus, *for Tycho*	51° 11′ 0″
from Aldebaran, *for me and for Tycho*	29° 9′ 0″
from the northern horn of Taurus, *for me*	20° 27′ 20″
from the bright star of Aries, *for Tycho*	58° 22′ 0″
Left heel of Castor, from Aldebara, *for me and for Tycho*	25° 53′ 0″
from Pollux, *for me and for Tycho*	19° 29′ 0″
from Regulus, *for Tycho*	54° 33′ 45″
but in the *Epistolae*, page 50	54° 35′ 0″

TABVLA DISTANTIÆ FIXARVM Inter se,

Table of the distances of the fixed stars from one another.

GEMINORVM — *of Gemini*	Distance
✶ The same heel from the Dog Star [Canicula], *for me*	25° 15′ 0″
Propus on the foot of Castor, from Aldebaran, *for Tycho*	24° 3′ 30″
Tip of the foot of Pollux from the head of Pollux, *for me*	21° 14′ 0″
from Regulus, *for Tycho*	56° 26′ 30″
HERCVLIS — *of Hercules*	
Head from the bright star of Lyra, *for me*	30° 23′ 0″
from the bright star of Aquila, *for Tycho*	38° 32′ 30″
HYDRÆ — *of Hydra*	

GEMINORVM — *of Gemini*	Distance
Heart from Procyon, *for me*	30° 20′ 0″
and for Tycho	30° 20′ 0″
from Spica, *for me*	58° 27′ 45″
from Regulus of Leo, *for me*	23° 0′ 20″
LEONIS — *of Leo*	
Heart, Regulus, from Spica, *for me*	54° 1′ 20″
and for Tycho	54° 2′ 0″
from Procyon, *for me*	37° 20′ 0″
and for Tycho	37° 19′ 30″
from the Tail of Leo, *for me*	24° 39′ 0″
for Tycho	24° 39′ 45″
from Arcturus, *for me*	59° 49′ 0″
from the Heart of Hydra, *for me*	23° 0′ 20″
Tail of Leo, from Arcturus, *for me*	35° 23′ 40″
for Tycho	35° 24′ 40″
from Spica Virginis, *for me*	35° 0′ 30″
for Tycho	35° 1′ 45″
from Regulus: see above	
Bright star of the mane from Spica, *for me*	55° 10′ 0″
for Tycho	55° 12′ 0″
from the Tail of Leo, *for me*	22° 0′ 10″
from Pollux, *for Tycho*	35° 59′ 0″
from Vindemiatrix, *for Tycho*	40° 3′ 10″
Bright star of the loins from Spica, *for me*	45° 11′ 20″
from Regulus, *for me*	17° 54′ 45″
from the Tail of Leo, *for me*	10° 17′ 40″
from the bright star of the mane, *for me*	12° 43′ 0″
for Tycho	12° 44′ 0″
Hip and Heart of Leo, *for Tycho*	17° 51′ 0″
Hip and neck of Leo, *for Tycho*	8° 31′ 0″
Hip and thigh of Leo, *for Tycho*	12° 44′ 0″
LEPORIS — *of Lepus*	
✶ Brighter star of the back from Sirius, *for me*	17° 27′ 0″
✶ from Rigel of Orion, *for me*	10° 0′ 0″
LIBRÆ — *of Libra*	
Northern Scale from Spica, *for me*	27° 33′ 0″
for Tycho	27° 34′ 0″
from Antares, *for me*	24° 10′ 0″
and for Tycho	24° 10′ 0″
from the bright star of Aquila, *for Tycho*	70° 27′ 0″
from the Head of Ophiuchus, *for Tycho*	40° 41′ 30″
from the Southern Scale, *for Tycho*	9° 8′ 20″
but for Gassendi, from the Tychonic longitude and latitude	9° 12′ 0″
Southern Scale from Spica, *for me*	21° 22′ 0″
and for Tycho	21° 22′ 0″
from Antares, *for me*	25° 7′ 40″
LYRÆ — *of Lyra*	
Bright star from Arcturus, *for me*	58° 52′ 30″
from the bright star of Aquila, *for me*	34° 9′ 0″

GEMINORVM — *of Gemini*	Distance
and for Tycho	34° 9′ 0″
from data given by Tycho	34° 10′ 20″
from the tail of Cygnus, *for me*	23° 51′ 40″
for Tycho	23° 53′ 0″
from Scheat of Pegasus, *for Tycho*	55° 30′ 40″
for Longomontanus	55° 31′ 0″
OPHIVCHI — *of Ophiuchus*	
Head from the bright star of Lyra, *for me*	29° 33′ 34″
from the bright star of Aquila, *for me*	33° 33′ 0″
OPHIVCHI — *of Ophiuchus*	
Head from Arcturus, *for me*	48° 2′ 20″
from the bright star of the Crown, *for me*	31° 30′ 10″
from the Northern Scale, *for Tycho*	40° 41′ 30″
from the northern hand of Ophiuchus, *for Tycho*	25° 46′ 0″
More southerly star of the left hand of Ophiuchus, from Aquila, *for Tycho*	55° 17′ 20″
from Spica, *for Tycho*	42° 33′ 0″
More northerly star of the left hand, from Spica, *for Tycho*	42° 33′ 30″
from Aquila, *for Tycho*	55° 17′ 0″
ORIONIS — *of Orion*	
Rigel, or the left foot, from Procyon, *for me*	38° 38′ 0″
for Tycho	38° 37′ 30″
from Sirius, *for me*	23° 42′ 0″
for Tycho	23° 41′ 40″
from Aldebaram, *for me*	26° 36′ 0″
for Tycho	26° 32′ 0″
from the head of Castor, *for me*	52° 9′ 15″
from the head of Pollux, *for me*	51° 26′ 50″
Leading shoulder from Procyon, *for Tycho*	33° 13′ 0″
from the bright star of Aries, *for Tycho*	50° 31′ 20″
✶ from Aldebaran, *for me*	15° 45′ 0″
Following and brighter shoulder of Orion from Regel, *for me*	18° 45′ 0″
from the head of Castor, *for me*	33° 38′ 10″
from Procyon, *for me*	26° 2′ 0″
and for Tycho	26° 2′ 0″
from the head of Pollux, *for me*	33° 15′ 0″
for Tycho	33° 16′ 0″
from Aldebaran, *for me*	21° 24′ 50″
for Tycho	21° 23′ 0″
First star of the belt of Orion, from Aldebaran, *for me*	21° 54′ 0″
but note, *for Tycho*	21° 49′ 30″
from the bright star of Aries, *for Tycho*	55° 7′ 40″
✶ from the bright shoulder of Orion, *for me*	9° 43′ 0″
✶ from Sirius, *for me*	22° 57′ 0″
Middle star of the belt from Procyon, *for me*	31° 25′ 0″
✶ from Aldebara, *for me*	23° 6′ 0″
✶ from Sirius, *for me*	22° 56′ 0″
✶ from the bright shoulder, *for me*	9° 48′ 0″
Last star of the belt, from Aldebaran, *for me*	24° 24′ 0″
✶ from Sirius, *for me*	21° 38′ 30″

GEMINORVM — *of Gemini*	Distance
✶ from the bright shoulder, *for me*	10° 50′ 0″
Brighter star of the sword ✶ from Aldebaran, *for me*	26° 46′ 40″
✶ from Sirius, *for me*	20° 10′ 0″
Right knee ✶ from Aldebaran, *for me*	31° 36′ 0″
✶ from Sirius, *for me*	15° 42′ 0″
PEGASI — *of Pegasus*	
Markab, from the bright star of Aries, *for Tycho*	43° 37′ 15″
from the Head of Andromeda, *for me*	20° 11′ 36″
from the bright star of Aquila, *for me*	47° 48′ 40″
for Tycho	47° 49′ 40″
from Algenib, *for me*	16° 29′ 0″
from the right shoulder of Aquarius, *for me*	21° 1′ 0″
Algenib from the bright star of Aries, *for me*	28° 2′ 0″
✶ from the Head of Andromeda, *for me*	13° 57′ 0″
✶ from Scheat, *for me*	20° 34′ 0″
Scheat of Pegasus, from the bright star of Aquila, *for me*	49° 14′ 45″
from the bright star of Aries, *for Tycho*	41° 16′ 30″
from the bright star of Lyra, *for Tycho*	55° 30′ 40″
from the beak of Cygnus, *for Tycho*	46° 36′ 30″
from the breast of Cygnus, *for Tycho*	35° 12′ 30″
Mouth of Pegasus from the bright star of Aquila, *for me*	27° 57′ 0″
Knee of Pegasus, from the Head of Andromeda, *for Tycho*	18° 28′ 0″
PERSEI — *of Perseus*	
Bright side, from Aldebaran, *for me*	36° 14′ 40″
from Capella, *for me*	18° 56′ 0″
Head of Medusa from Aldebara, *for me*	30° 54′ 0″
and for Tycho	30° 54′ 0″
from Capella, *for Tycho*	23° 37′ 0″
✶ from the foot of Andromeda, *for me*	12° 0′ 0″
✶ Leading right foot from Aldebaran, *for me*	30° 53′ 0″

TABVLA DISTANTIÆ FIXARVM Inter se.

Table of the distances of the fixed stars from one another.

PISCIVM — *of Pisces*	Distance
The one of the third magnitude at the knot of the line, from Aldebaran, *for me*	40° 13′ 30″
for Tycho	40° 13′ 45″
The leading one on the back, from Aquila, *for Tycho*	53° 55′ 0″
Head of the southern Fish, from Aquila, *for Tycho*	51° 32′ 0″
Mouth of the southern Fish, from Aquila, *for Tycho*	48° 16′ 30″
The leading one in the jaw, from the mouth of Pegasus, *for me*	20° 41′ 0″
SAGITTARII — *of Sagittarius*	
Middle star of the head, from Antares, *for me*	35° 37′ 30″
✶ Hand from the Head of Ophiuchus, *for me*	43° 22′ 0″
✶ from Aquila, *for me*	37° 22′
✶ from Antares, *for me*	32° 34′
SCORPII — *of Scorpius*	

PISCIVM — *of Pisces*	Distance
Heart, Antares, from Spica, *for me*	45° 54′ 0″
for Tycho	45° 51′ 30″
from Arcturus, *for me*	56° 4′ 10″
from the Southern Scale, *for me*	25° 7′ 40″
from the Northern Scale, *for me*	24° 10′ 0″
and for Tycho	24° 10′ 0″
from Aquila, *Tychonically*	60° 10′ 0″
for me	60° 14′ 0″
Northern star in the forehead of Scorpius, from Spica, *for me*	39° 28′ 40″
for Tycho	39° 26′ 30″
✶ from the Southern Scale, *for me*	18° 2′ 0″
Southern star in the forehead of Scorpius, from Spica, *for me*	39° 8′ 40″
for Tycho	39° 6′ 30″
✶ from Antares, *for me*	6° 52′ 0″
Middle star in the forehead of Scorpius, from Spica, *for me*	38° 39′ 30″
for Tycho	38° 40′ 0″
✶ from the Southern Scale, *for me*	17° 34′ 0″
✶ Region of the heart [Præcordium] from the Southern Scale, *for me*	23° 12′ 0″
✶ In the bend of the tail, from the point of ♐, *for me*	16° 18′ 0″
✶ The same from the lowest star of Sagittarius, *for me*	19° 17′ 0″
SERPENTIS — *of the Serpent*	
Bright star of the neck from Arcturus, *for me*	24° 50′ 0″
from the bright star of Lyra, *for me*	50° 29′ 40″
✶ from Spica, *for me*	38° 46′ 0″
✶ from the bright star of the Crown, *for me*	20° 23′ 0″
✶ The one in the temples of the Serpent, from Aquila, *for me*	55° 10′ 0″
TAVRI — *of Taurus*	
Aldebaran, or the southern eye	
from the bright star of Aries, *for me and for Tycho*	35° 32′ 0″
from Procyon, *for me and for Tycho*	46° 22′ 0″
from the Head of Medusa, *for me and for Tycho*	30° 54′ 0″
from the bright foot of ♊, *for me and for Tycho*	29° 29′ 0″
from the left heel of ♊, *for me and for Tycho*	25° 53′ 0″
from Sirius, *for me*	45° 59′ 0″
for Tycho	45° 57′ 30″
from the first star of Aries, *for me*	38° 37′ 0″
for Tycho	38° 36′ 0″
from the head of Castor, *for me*	43° 12′ 0″
for Tycho	43° 12′ 30″
from the knot of the line of Pisces, *for me*	40° 13′ 30″
for Tycho	40° 13′ 45″
from the bright shoulder of Orion, *for me*	21° 24′ 50″
for Tycho	21° 23′ 0″
from the first star of the belt of Orion, *for me*	21° 54′ 0″
for Tycho	21° 49′ 0″
from Capella, *for me*	30° 42′ 30″
from the jaw of Cetus, *for me*	26° 17′ 30″
from the bright side of Perseus, *for me*	36° 14′ 40″
from the southern foot of Andromeda, *for me*	41° 24′ 0″

PISCIVM — *of Pisces*	Distance
from Propus of Gemini, *for Tycho*	24° 3′ 30″
from the head of Pollux, *for Tycho*	45° 5′ 0″
from the northern foot of Auriga, *for Tycho*	33° 3′ 30″
from Regel of Orion, *for me*	26° 36′ 0″
for Tycho	26° 32′ 0″
Northern horn from the bright foot of Gemini, *for me*	20° 27′ 20″
TAVRI — *of Taurus*	
The same horn from the bright star of Aries, *for Tycho*	33° 8′ 30″
from the head of Pollux, *for Tycho*	30° 48′ 0″
✶ from Aldebaran, *for me*	16° 45′ 0″
✶ from Capella, *for me*	17° 30′ 0″
✶ from the Dog Star, *for me*	39° 14′ 0″
✶ from Regel of Orion, *for me*	36° 58′ 0″
✶ Southern horn of Taurus from Aldebaran, *for me*	17° 16′ 0″
✶ from Capella, *for me*	13° 24′ 0″
✶ from the Dog Star, *for me*	46° 53′ 0″
✶ Northern eye from Aldebara, *for me*	3° 9′ 0″
for Tycho	3° 10′ 0″
✶ from the bright star of Aries, *for me*	33° 8′ 0″
✶ Twin star of the Hyades from Sirius, *for me*	46° 56′ 0″
✶ Middle star of the Hyades from Sirius, *for me*	49° 2′ 0″
✶ Last star of the Hyades, in the nostrils, from Sirius, *for me*	48° 14′ 0″
Bright star of the Pleiades from Aldebara, *for me*	13° 43′ 0″
from the bright star of Aries, *for me*	22° 56′ 0″
for Tycho	22° 56′ 30″
from the Head of Medusa, *for Tycho*	18° 44′ 0″
✶ from Capella, *for me*	28° 24′ 0″
✶ from the bright shoulder of Orion, *for me*	34° 50′ 0″
VIRGINIS — *of Virgo*	
Spica, from Arcturus, *for me*	33° 2′ 0″
from Antares, *for me*	45° 54′ 0″
for Tycho	45° 51′ 30″
from Regulus, *for me*	54° 1′ 20″
for Tycho at Uraniborg	54° 2′ 0″
for Tycho at Prague	54° 1′ 30″
for Magini, Tychonically	54° 2′ 0″
Spica from the tail of Leo, *for me*	35° 0′ 30″
for Tycho	35° 1′ 45″
from the mane of Leo, *for me*	55° 10′ 0″
for Tycho	55° 12′ 0″
from the bright star of the loins of Leo, *for me*	45° 11′ 20″
from the Heart of Hydra, *for me*	58° 27′ 45″
from the Southern Scale, *for me*	21° 22′ 0″
from the Northern Scale, *for me*	27° 33′ 0″
for Tycho	27° 34′ 0″
Spica from the northern star in the forehead of Scorpius, *for me*	39° 26′ 0″
from the southern star in the forehead of Scorpius, *for me*	36° 6′ 0″
for Tycho	36° 6′ 30″
Vindemiatrix from Arcturus, *for me*	20° 24′ 0″

PISCIVM — *of Pisces*	Distance
from the Tail of Leo, *for me*	17° 57′ 0″
Tip of the left wing from Spica, *for me*	14° 29′ 0″
and for Tycho	14° 29′ 0″
Third star of the southern wing, from Spica, *for Tycho*	14° 39′ 15″
from Regulus, *for Tycho*	40° 22′ 0″
VRSÆ MAIORIS — *of Ursa Major*	
Of the leading stars, the one in the quadrilateral nearer the pole of the world, from Regulus, *for me*	50° 47′ 0″
from Arcturus, *for me*	53° 46′ 0″
Of the leading stars in the quadrilateral, the one that is nearer the equator, from Regulus, *for me*	45° 35′ 0″
from Arcturus, *for me*	51° 34′ 30″
Of the following stars in the quadrilateral, the one that is nearer the pole of the world, from Regulus, *for me*	51° 58′ 0″
from Arcturus, *for me*	42° 18′ 0″
Of the following stars in the quadrilateral, the one nearer the equator, from Regulus, *for me*	46° 37′ 36″
from Arcturus, *for me*	43° 49′ 0″
First star of the tail from Regulus, *for me*	54° 22′ 0″
from Arcturus, *for me*	39° 42′ 30″
✶ from the Pole Star, *for me*	34° 45′ 0″
Middle star of the tail, from Regulus, *for me*	57° 23′ 10″
from Arcturus, *for me*	36° 24′ 20″
✶ from the bright star of the Crown, *for me*	36° 52′ 0″
Last star of the tail, from Regulus, *for me*	58° 20′ 30″
from Arcturus, *for me*	30° 29′ 0″
✶ from the bright star of the Crown, *for me*	30° 35′ 0″

TABVLA DISTANTIÆ FIXARVM Inter ſe.

Table of the distances of the fixed stars from one another.

VRSÆ MINORIS. — *of Ursa Minor*	Distance
Polaris, now the last star of the Tail, from Capella, *for me*	43° 23′ 20″
from Arcturus, *for me*	71° 19′ 20″
from the bright star of Lyra, *for me*	51° 36′ 40″
for Tycho	51° 34′ 40″
from the last star of the Tail of Ursa Major, *for me*	41° 22′ 40″
from the Tail of Cygnus, *for Tycho*	44° 39′ 30″
from Schedar of Cassiopeia, *for Tycho*	32° 47′ 45″
or	32° 48′ 30″
from the bright star of the Chair, *for Tycho*	30° 13′ 30″
Bright star of the shoulder, from Arcturus, *for me*	55° 0′ 10″
Tychonically	55° 0′ 46″
from the bright star of the Crown, *for me*	47° 51′ 30″

APPENDIX DISTANTIARVM Quas ex Longitudine & Latitudine *Tychonica*, deduxit *Henrico Gallus*

Appendix of distances, which Henrico Gallus [?] derived from the Tychonic longitude and latitude.

Stars	Distance
Aldebaran, from the first of Aries	38° 39′ 0″
from the bright star of Aries	35° 32′ 10″
from the head of Pollux	45° 5′ 0″
from the head of Castor	45° 12′ 30″
from the heel of the foot of Gemini	25° 53′ 0″
from the bright foot of Gemini	29° 9′ 0″
from the Propus of Gemini	24° 3′ 30″
from the bright shoulder of Orion	21° 23′ 0″
from Rigel of Orion	26° 32′ 0″
from the bright star of the Pleiades	13° 29′ 0″
from Canicula, that is, Procyon	46° 22′ 0″
from the head of Medusa	30° 54′ 0″
from the bright star of the knot of Pisces	40° 13′ 45″
from Sirius	45° 57′ 30″
Bright star of Aquila, from the bright star of Lyra	34° 9′ 0″
from the tail of Cygnus	38° 4′ 30″
from the bright star of the tail of Capricorn	22° 25′ 0″
from the upper horn of Capricorn	20° 25′ 0″
from the right shoulder of Aquarius	34° 55′ 30″
from the left shoulder of Aquarius	29° 0′ 30″
from the hand of Antinous	10° 56′ 0″
from the head of Hercules	38° 32′ 30″
from the hand of Ophiuchus	55° 17′ 20″
from the Northern Scale	70° 27′ 0″
from the bright star of Aries	90° 15′ 0″
Arcturus, from the bright star of the Crown	19° 26′ 0″
from the tail of Leo	35° 24′ 40″
from Spica Virginis	33° 2′ 0″
Capella, from the bright star of Aries	44° 6′ 36″
from the head of Cassiopeia	43° 44′ 30″
from the head of Medusa	23° 37′ 0″
from the head of Pollux	34° 18′ 30″
The Scales of Libra, from each other	9° 8′ 20″
Northern Scale, from Spica Virginis	27° 34′ 0″
Southern Scale, from Spica	21° 22′ 0″
Northern Scale, from the head of Ophiuchus	40° 41′ 30″
Northern Scale, from Antares	24° 10′ 30″
Bright star of Aries, from Schedar	36° 38′ 45″
from the head of Pollux	74° 45′ 30″
from the heel of the foot of Gemini	58° 22′ 0″
from Scheat of Pegasus	41° 16′ 30″
from the head of Andromeda	27° 7′ 30″
from the left shoulder of Orion	50° 31′ 20″
from the bright star of the Pleiades	22° 56′ 30″
Bright star of Lyra, from the bright star of Aquila	34° 9′ 0″

Stars	Distance
from the Pole Star	51° 34′ 40″
from Scheat of Pegasus	55° 50′ 40″
from the tail of Cygnus	25° 53′ 0″
The shoulders of Orion, from each other	7° 30′ 40″
Right shoulder of Orion, from Pollux	33° 16′ 0″
the same from Procyon	26° 2′ 0″
the same from the jaw of Cetus	43° 8′ 0″
Procyon, from Sirius	25° 41′ 30″
from Regel of Orion	28° 37′ 30″
from Aldebaran	46° 22′ 0″
Procyon, from the left shoulder of Orion	33° 13′ 0″
from the bright star of Hydra	30° 20′ 0″
Regulus, from the tail of Leo	24° 39′ 45″
from Procyon	37° 19′ 30″
from the head of Castor	40° 32′ 0″
from the head of Pollux	36° 59′ 40″
from the bright star of the foot of Gemini	51° 11′ 0″
from the Northern Ass	22° 29′ 30″
Polaris, from the tail of Cygnus	44° 39′ 30″
from Schedar of Cassiopeia	32° 47′ 45″
Sirius, from Procyon	25° 41′ 30″
from Regel of Orion	23° 41′ 40″
from Aldebaran	45° 57′ 30″
Spica Virginis, from Regulus	54° 2′ 0″
from the bright star in the mane of Leo	55° 12′ 0″
from the northern star in the forehead of Scorpius	39° 26′ 30″
from the southern star in the forehead of Scorpius	39° 6′ 30″
from the middle star of the forehead of Scorpius	38° 40′ 0″
from the bright star of Aquila	97° 50′ 0″
from Pollux	90° 46′ 20″
from the northern star in the left hand of Ophiuchus	42° 33′ 30″
from Arcturus	33° 2′ 0″
from Antares	45° 51′ 30″

DISTANTIÆ per Radium captæ ab *Hadriano Metio*, ex libro eius 3. de vſu globi.

Distances taken with the radius by Adriaan Metius, from his third book on the use of the globe.

Stars	Distance
Antares, from the Northern Scale	24° 10′ 0″
Capella, from the head of Cassiopeia	43° 49′ 0″
Capella, from the heel of the foot of Gemini	27° 1′ 0″
Capella, from the bright star of Aries	44° 6′ 0″
The mane of Leo, from Pollux	36° 0′ 0″
Bright star of Aquila, from the left shoulder of Aquarius	20° 0′ 0″
Bright star of Aries, from the northern eye of Taurus	33° 8′ 0″

Stars	Distance
Bright star of Aries, from Aldebaran	35° 32′ 0″
Markab of Pegasus, from the left shoulder of Aquarius	31° 3′ 0″
Regulus, from the bright foot of Gemini	51° 11′ 0″
Spica, from the Northern Scale	27° 34′ 0″

DISTANTIÆ aliquot Stellarum inſignium à Naucleris obſeruatæ in noſtro Horizonte latentium.

Distances of some notable stars hidden below our horizon, observed by navigators.

Stars	Distance
Canobus, from Sirius, by the radius	36° 50′ 0″
Canobus, from the bright star of Hydra	57° 52′ 0″
Right forefoot of the Centaur, of the first magnitude, from Antares	38° 20′ 0″
The same foot of the Centaur, from Spica	52° 10′ 0″
Haunch of the Centaur, of the 2nd magnitude, from Spica	44° 40′ 0″
the same from the bright star of Hydra	54° 26′ 0″
Top of the Cross, of the 2nd magnitude, from Spica	48° 20′ 0″
the same from Antares	51° 25′ 0″
Foot of the Cross, from Spica, of the 2nd magnitude	52° 50′ 0″
the same from Antares	53° 15′ 0″
Leading arm of the Cross, from the following arm	3° 55′ 0″
the same from the foot of the Cross	4° 25′ 0″
Following arm of the Cross, from the foot of the Cross	4° 54′ 0″
Left knee of the Centaur, of the 2nd magnitude, from Antares	44° 0′ 0″
the same star from Spica	49° 30′ 0″
Eye of the Peacock, of the 2nd magnitude, from Antares	51° 45′ 0″
the same from the right forefoot of the Centaur	40° 25′ 0″
Bright star of the Southern Crown, from Antares	36° 10′ 0″
the same, of the 2nd magnitude, from Aquila	50° 45′ 0″
Foot of Sagittarius, of the 2nd magnitude, from Antares	38° 40′ 0″
the same from the bright star of Aquila	55° 10′ 0″
Northern wing of the Crane, of the 2nd magnitude, from the eye of the Peacock	18° 15′ 0″
the same from the bright foot of Sagittarius	29° 5′ 0″
Breast of the Crane, of the 2nd magnitude, from the eye of the Peacock	23° 18′ 0″
the same from the bright foot of Sagittarius	34° 50′ 0″
Head of the Crane, from the eye of the Peacock	24° 20′ 0″
the same, of the 2nd magnitude, from the foot of Sagittarius	29° 55′ 0″
First of Eridanus, of the first magnitude, from the eye of the Peacock	39° 25′ 0″
Alcarnar, the same star, from Fomahant	39° 45′ 0″

Vltimæ quæ per Radium captæ ſunt à Naucleris, vellem iterum per Sextantes caperentur.

I should like these last distances, which the navigators took with the radius, to be taken again with sextants.

CAPVT XI.

Chapter 11.

De Fixarum Declinatione & Aſcenſione Recta obſeruandis, aut ex obſeruatione colligendis.

On observing the declination and right ascension of the fixed stars, or deriving them from observation.

[Margin: What is declination?]

I. The declination of a star is its distance from the equator along an arc of a great circle drawn through the poles of the equator and the centre of the star; in other words, it is the arc of a great circle drawn through the poles of the equator, intercepted between the centre of the star and the equator. It can be observed with equatorial and declination armillaries [Armillas Æquatorias ac Declinationum], as we shall teach in the *Liber Organicus*. Yet the simplest and most certain way of all to observe it is by altitudes, especially true meridian altitudes, taken with large quadrants that show at least single minutes and tens of minutes.

[Margin: Method of observing the declinations of the fixed stars.]

And at the centre of the instrument it is better to use either a very fine needle or threads of cithara strings, set up perpendicular to the plane of the quadrant and lit by a lamp placed close by, in such a way that a lantern keeps back the glare that would otherwise hinder the observer's eyes, than to use Tycho's cylinders, as I shall teach at greater length in the *Liber Organicus*. I said *true meridian altitudes* because if the altitude of the observed star is less than 20°, it is subject to sensible refraction, which must be subtracted from its apparent altitude so that the true altitude remains. With these things laid down, let there be:

Problema 1. Data Vera Altitudine Meridiana Sideris, & Altitudine Poli, Declinationem eiuſdem Sideris Inquirere.

Problem 1. Given the true meridian altitude of a star and the altitude of the pole, to find the declination of the same star.

II. In the present figure let the horizon be HR and the meridian HZRN, on which let the zenith be Z and the nadir N, and let there be the pole of the equator AQ, the northern being B and the southern P. Let the altitude of the north pole be the arc BR, to which the arc AZ, namely the distance of the equator from the vertex, is always equal; and let the complement of the altitude of the pole to a quadrant be the arc BZ, to which the altitude of the equator HA is always equal.

Diagram. A small circle standing as the meridian, set into the left column at the right of the text of paragraph II. Straight lines cross at its centre: the

horizon from H to R, the equator from A to Q, and the axis from B to P. Small stars are drawn at K, G, C and M on the circumference.

- K (top, left of Z): star position, with a small star
- Z (top): zenith
- G (top, right of Z): star position, with a small star
- A (upper left): end of the equator
- C (left, below A): star position, with a small star
- H (left): end of the horizon
- B (upper right): north pole
- M (right, below B): star position, with a small star
- R (right): end of the horizon
- Q (lower right): end of the equator
- N (bottom): nadir
- P (lower left): south pole

Labels read: K, Z, G, A, C, H, B, M, R, Q, N, P. Labels not read: none.

[Margin: Seven cases of the meridian altitude.]

There are seven cases of the true meridian altitude of a star. First, if it equals the altitude of the equator HA, as when the star is at A, the star has no declination. Second, if the star is at the zenith Z itself, that is, if its altitude HZ is 90°, the declination AZ equals the altitude of the pole. Third, if it were at the pole B or P itself, its declination would be 90°, northern in the one case and southern in the other. Fourth, if the star's true altitude is less than the altitude of the equator, that is, less than the complement of the altitude of the pole, as when it is at C, subtract the star's altitude HC from the altitude of the equator HA, and the star's declination AC will remain, southern. Fifth, if the star's altitude is greater than the altitude of the equator but towards the south, as when the star is at K, subtract the altitude of the equator HA from the star's altitude HK, and the star's declination AK will remain, but northern. Sixth, if the star is beyond the zenith towards the pole B, and its true meridian altitude is less than the altitude of the pole, as when the star is at M, its altitude will be not the greatest but the least. So by doubling its distance BM from the pole you will have the arc MG, which added to the least altitude RM will give the greatest, RG; work with this as in case 7. Seventh, then, if the altitude towards the pole B is greater than the altitude of the pole, as when the star is at G, subtract from it the altitude of the pole, and its distance from the pole, namely the arc GB, will remain; subtract this from the 90° of the arc AB, and the star's northern declination AG will remain. Work similarly for stars around the southern pole P.

EXEMPLVM.

Example.

[Margin: Example in the southern eye of Taurus.]

On 1642 February 12, 13, 14 and 16, the meridian and true altitude HK of Aldebaran at K was observed by us, with the instruments in agreement, as 61° 14′ 40″, at Bologna, where the altitude of the equator HA, observed by us more than 40 times, is 45° 30′ 30″. When this was subtracted from the altitude of Aldebaran, there remained its northern declination AK, 15° 44′ 10″.

Problema 2. Declinationem Sideris Inueſtigare, Data Poli Altitudine, & obſeruatis Sideris Altitudine & Azimutho vero.

Problem 2. To investigate the declination of a star, given the altitude of the pole, with the star's altitude and true azimuth observed.

III. Let the horizon be HR and the meridian HZR, on which let there be the zenith Z and the pole of the equator P, and let the given altitude of the pole be PR, whose complement to the quadrant RZ is the distance of the pole from the zenith, that is, the arc PZ. Let the equator be EQ, and the vertical circle, or circle of altitude, AZ. Let AB be the star's altitude, observed free of sensible refraction, for its complement to a quadrant will be the arc BZ. And finally let the azimuth of the star B be the arc HA of the horizon, for this measures the angle HZA, since it is described from the pole of the horizon. When this angle is subtracted from two right angles, that is, from 180°, the angle BZP will be known. So in the spherical triangle BZP we are given the vertical angle at Z and the sides containing it, namely ZP, the distance of the pole from the zenith, and BZ, the true distance of the star from the vertex. Therefore, by the analysis of triangles the base BP will not stay hidden; in this example it is the complement of the northern declination (if P is the north pole). So when BP has been subtracted from 90°, the star's declination BN will be known.

Diagram. A small circle standing as the meridian, set into the right column at the right of the text of paragraph III. The horizon runs from H to R, the equator from E to Q, a line runs from Z down to A through B and the crossing near G and C, and arcs run from P to N, G and I.

- Z (top): zenith
- E (upper left): end of the equator
- B (top, inside the circle): the star
- P (upper right): the pole
- N (inside, just below E): foot of the star's declination
- G (inside, centre left): point of the equator
- C (inside, right of G): foot of the declination of the star at I
- I (inside, below G): second position of the star
- H (left): end of the horizon
- A (inside, just below the horizon near H): foot of the vertical circle
- R (right): end of the horizon
- Q (lower right): end of the equator

Labels read: Z, E, B, P, N, G, C, I, H, A, R, Q. Labels not read: none.

But if that base came out as PG, exactly 90°, the star would be at G, a point of the equator, and would have no declination. If, however, the star were at I and its true altitude were AI, the base would be PI, and would be found greater than a quadrant, that is, than 90°. So with those 90° subtracted from the base PI, the star's declination CI would remain, but towards the other pole, that is, southern, if P is the north pole.

[Margin: Warning about refraction.]

If the star's observed altitude is less than 20°, and so subject to sensible refraction, while the refraction of the fixed stars is known from elsewhere, as when the star's apparent place would be at B but its true place at C, subtract the refraction, that is, the arc CB, from the apparent altitude, and the true altitude AC will remain; then do the rest as above.

[Margin: Method of observing azimuths.]

You will observe the star's azimuth most exactly if you set the plane of our thread triangle (on which see Book 5, chapter 15, no. 16) at a determined degree of distance from a most exact meridian line, and notice that the star's centre is going to reach it shortly. As soon as the star's centre is in that plane, let the star's altitude be taken by yourself or by another most skilled observer, with the instrument already directed there and set up by the plumb line on a separate observing table, but in the same azimuth. Otherwise, an observation of azimuths made by other methods is unreliable.

Problema 3. Declinationem Sideris Inquirere, Data Poli Altitudine, & obſeruatis aut Altitudine vera & momento Temporis; aut Azimutho & momento Temporis.

Problem 3. To find the declination of a star, given the altitude of the pole, with either the true altitude and the moment of time observed, or the azimuth and the moment of time.

IV. In the figure set out above, let the star be at B. For in the triangle BZP, ZP is given, the complement of the altitude of the pole. So if BZ, the complement of the true altitude AB, is given, and the angle BPZ, from the time before or after noon converted into degrees of the equator, three sufficient quantities will be given, so that the arc BP can be derived by the rules of spherical triangles. But if in the same triangle, besides ZP and the angle BPZ known from the time, the angle BZP is given, which is the complement to two right angles of the angle HZA, that is, of the observed azimuth, then by the rules of the same triangles the arc BP will not stay hidden, and this is the complement of the declination. So when it has been subtracted from 90°, the star's declination NB will become known; it will be northern if the pole P is northern, and southern if P is southern. But if the arc found were GP, of 90°, the star would be at the point G of the equator, lacking all declination; and finally, if the arc found were greater than 90°, as the arc PI is, the star would be at I, beyond the equator, and so when 90° are subtracted from the arc PI, the star's declination IC would

remain, southern if the pole P is northern, and so on. How the moment of time is observed, whether by the altitude of another known fixed star, or by the count of time with the help of our pendulum (on which see Book 2, chapter 20), counted from the transit, or before the transit, of a known fixed star through the midheaven, or from an altitude of the Sun taken before its setting, or before an altitude of the Sun to be taken after its rising, we shall say in the Problems of the primum mobile, Book 10.

[Margin: Problem 1 is preferred to the others.]

But I advise you to take the declinations of the fixed stars by Problem 1, as we have done, rather than by 2; or, if at any time you cannot use that one, to use the second rather than the third. The remaining problems that belong here do not depend on direct observation but on other data that presuppose observations, or else they are more deceptive. Here, however, we set out only those that are resolved by the first and simpler principles of observations.

Problema 4. Differentiam Aſcenſionis Rectæ inter duo Sidera, Data illorum Declinatione & Diſtantia, Inueſtigare.

Problem 4. To investigate the difference of right ascension between two stars, given their declination and distance.

[Margin: Four cases of the Problem.]

V. In the following figure let the south pole of the equator be A and the north pole B, from which let the arc EQ of the equator be described, which the angle B or A therefore measures. First, let one star be at C and the other at D, through which let the declination circles BCA and BDA be drawn; and let their distance CD be given, either from observation or from our table in the preceding chapter. For in the spherical triangle CBD three sides will be given, namely the distance CD and the arcs CB and BD, which are the complements of each star's own declination to a quadrant. So by the rules of triangles the angle B will become known, which measures the equatorial distance EQ, that is, the difference of right ascension between the stars C and D.

Diagram. A pointed lune between two curved sides meeting at B above and A below, set into the left column at the right of the text of paragraph V. Across it the straight line EQ joins the two sides at the middle. Further lines run between the sides: from C to D, from C down to F, from E down to F, and from G to F.

- B (top vertex): north pole
- D (right side, upper): star
- C (left side, upper): star
- E (left side, middle): end of the equator
- Q (right side, middle): end of the equator
- F (right side, lower): star
- G (left side, lower): star
- A (bottom vertex): south pole

Labels read: B, D, C, E, Q, F, G, A. Labels not read: none.

But if the stars were G and F, and the declination of both southern, the triangle GAF would have to be solved, from the given distance GF and the complements of the declinations AG and AF; and the angle A, once found, would be the measure of the difference of right ascension. If, however, one star is at E, lacking declination, and the other at F, solve the triangle EAF, seeking the angle A from the given distance EF, the arc FA, which is the complement of the declination of star F, and the quadrantal arc AE, that is, of 90°. Finally, if both stars lacked declination, and one were at E and the other at Q, their distance itself would be the arc EQ of the equator and the difference of right ascension.

Problema 5. Aſcenſionem Rectam Stellæ alicuius Fixæ more Antiquiorum Aſtronomorum Obſeruare.

Problem 5. To observe the right ascension of some fixed star in the manner of the older astronomers.

[Margin: First method, most deceptive.]

VI. The first method, an ancient one but now antiquated, was by a count of time made with the help of clepsydras, from the transit of the Sun or the Moon through the middle of the sky up to the transit, or the rising or setting, of the star. They converted that time into an arc of the equator, and added that arc of the equator to the right ascension of the Sun or the Moon if the star was further east than they were, and subtracted it if further west, and the sum or remainder was the right ascension of the star. But enough has been said about the deceptiveness of clepsydras in Book 2, chapter 20, proposition 15, and Book 3, chapter 10, no. 6.

[Margin: Second method, but deceptive.]

The second method, used by Hipparchus and Ptolemy (*Almagest* Book 7, chapters 2 and 4), by al-Battānī (chapter 51), by Regiomontanus and Bernhard Walther (as found in their observations), and by Copernicus (Book 2, chapter 14), was by the equatorial distance of the Moon from the Sun, taken with the Sun near the horizon at a definite moment of time known from the Sun's altitude or from a sundial; and then by the equatorial distance of the Moon from a fixed star, taken at night with the armillary spheres of the astrolabe. For from the first observation they deduced the right ascension of the Moon, and from the second the right ascension of the fixed star, through the difference of right ascension, in the first case between the luminaries, in the second between the Moon and the fixed star; and this difference was known from the arc of the equator taken between the stars. But Tycho rightly rejects this method (*Progymnasmata* volume 1, chapter 2, from p. 140): both because of the deceptiveness of the armillary spheres and their division carried no further than tens of minutes, on which we say more in our *Liber Organicus*; and because of the refractions of

the Sun when closer to the horizon, unknown to the ancients or neglected by them; and because of the complications of lunar parallaxes.

[Margin: Third method, likewise deceptive.]

The third method, used by Walther and Cardanus [Girolamo Cardano], was by the distance of a fixed star from Venus, after first verifying the place of Venus and the right ascension of Venus relative to the Sun, since Venus can be seen within the same natural day both by day and by night. But because they obtained that distance with the astrolabe and armillary spheres in the old manner, the observation was not so exact. And so for this reason, or perhaps from inexperience in observing the places of the stars exactly, or from neglected refractions and parallaxes, Cardano erred by 1° 40′ in fixing the place of the Southern Scale by means of Venus, more than the Alphonsine calculation required, which he was nevertheless striving to correct, as Tycho reports (*Progymnasmata* volume 1, chapter 2).

Problema 6. Aſcenſionem Rectam Stellæ Fixæ Tychonis more obſeruare, cum correctione Obſeruationis Tychonicæ.

Problem 6. To observe the right ascension of a fixed star in Tycho's manner, with a correction of the Tychonic observation.

VII. So Tycho, rejecting the preceding methods, used the distance of the Sun from Venus, sometimes morning and sometimes evening, taken with his sextants, and then the difference of right ascension taken with the equatorial armillaries, or the distance of Venus from a fixed star taken at night. The moments of both times were observed, with the altitudes and declinations of the Sun and Venus; the declination of that fixed star was known, or observed shortly afterwards; and both places of the planet were corrected, with parallaxes and refractions taken into account. It is better, however, to teach this practice by an example than by a longer precept. So let the example be taken from Tycho's *Progymnasmata*, volume 1, chapter 2, on the bright star of Aries, observed in 1586 on December 27 of the Julian calendar, but on January 6 of 1587 of the Gregorian. On that day the earlier observation, from the true altitude of the Sun, was made at Uraniborg at $2^h\ 48^m$ after noon, and the later at $4^h\ 58^m$, by Tycho's clock.

EXEMPLVM.

Example.

Ex Tychone tomo 1. Progymn. pag. 176. — *From Tycho, Progymnasmata volume 1, p. 176*	Value
At $2^h\ 48^m$, altitude of the Sun	3° 30′ 0″
Altitude of ♀	23° 0′ 0″
Distance of ♀ from the centre of the Sun, taken with the sextant	46° 22′ 0″
Southern declination of ♀, taken with the armillary spheres	10° 49′ 30″
Southern declination of ☉, from Tycho's tables	22° 34′ 37″

Ex Tychone tomo 1. Progymn. pag. 176. — *From Tycho, Progymnasmata volume 1, p. 176*	Value
Place of ☉ from the same tables, in Capricorn	15° 52′ 34″
Right ascension of the Sun, from the same tables	287° 14′ 1″
So the difference of right ascension between the Sun and Venus, by Problem 4	47° 3′ 6″
So the right ascension of ♀, which was further east than the Sun, was	334° 17′ 7″
Then, at 4^h 48^m after noon, the equatorial distance between ♀ and the bright star of Aries, taken with the armillary spheres, was	51° 32′ 0″
Altitude of ♀	20° 0′ 0″
Time elapsed between the observations, of hours	2^h 0^m 0^s
Motion of ♀ corresponding to the preceding time	0° 4′ 5″
So the right ascension of ♀, increased by 4′ 5″, was	334° 21′ 12″
Add the equatorial difference of ♀ and the bright star of Aries, the further east, and the result is	385° 53′ 12″

	Value
Subtract the whole circle, and there remains the right ascension of the bright star of Aries	25° 53′ 12″

With 50″ subtracted for the almost entire year, however, the right ascension of the bright star of Aries at the end of 1585 remains 25° 52′ 22″.

[Margin: Tycho's caution.]

But in observations of this kind both the Sun and, not rarely, Venus undergo a sensible refraction because they are close to the horizon, the Sun more so, and the Sun's greater refraction reduces the true distance of the Sun from Venus. As a result the right ascension of ♀ in the morning, being then further west, is apparently increased, and that of ♀ in the evening, being then further east than the Sun, is decreased. For this reason Tycho, in his *Epistolae Astronomicae*, p. 96, prudently advises that several observations be made by way of Venus, both morning and evening, with ☉ and ♀ at the same altitude as nearly as possible, so that the defect of right ascension arising from the evening refractions may be offset by the excess arising from the morning ones and, once the arithmetic mean has been chosen, a more correct right ascension of the star may be obtained. So the same Tycho, as stands in *Progymnasmata* volume 1, chapter 2, p. 193, from fifteen observations of the bright star of Aries by way of morning Venus and as many by way of evening Venus, made from 1582 to 1588, derived for the end of 1585 a right ascension of the bright star of Aries of 26° 0′, with the seconds at the least 4″ and at the most 44″. He therefore chose 26° 0′ 30″, which differs insensibly from the 26° 0′ 24″ derived from the arithmetic mean.

[Margin: Tycho's method suspected by Kepler.]

However, the morning and evening refractions, and the altitudes of ☉ and ♀, are rarely equal, and only very rarely is Venus, at the same distance from the horizon, at the same distance from the centre of the Earth. For that reason Kepler, in the prologue to his *Ephemerides*, p. 15, held this method suspect, and it is certainly a too scattered labour, because of the stretch of time needed to get two observations suitable for offsetting the excess of one with the defect of the other. Kepler's words are these: *"There remains the matter of the six minutes*

of the Sun's motion from the fixed stars, a dispute between the Landgrave and Brahe left undecided, and the testimonies waver this way and that. For the parallax of Venus cannot be as great as Brahe assumed in the Progymnasmata*, adapted to the parallax of the Sun handed down by the ancients, which is without doubt smaller; and even if we suppose the parallax of Venus to be that great, its two parallaxes at the same altitude from the horizon are still not exactly offset, unless the interval of Venus and of the Earth is also the same."*

Problema 7. Aſcenſionem Rectam Stellæ Fixæ per diſtantiam eius ab vno trium Superiorum Planetarum, ſed præcipuè Saturno aut Ioue Stationarijs, Quorum tranſitus per M. C. paulò ante vel poſt obſeruatus ſit, Inuenire.

Problem 7. To find the right ascension of a fixed star by its distance from one of the three superior planets, but especially from Saturn or Jupiter when stationary, whose transit through the M. C. has been observed a little before or after.

VIII. Saturn or Jupiter, nearly stationary, should be chosen: not indeed of necessity, but so that a smaller and insensible error may enter into its right ascension because of the different moment at which the distance of the fixed star was observed, since when they are stationary their proper motion varies insensibly over several hours. But it is necessary that the planet's meridian altitude can be observed that same night, that from this, with the altitude of the equator, its declination be made known by Problem 1, and that from the declination and its latitude, on which the astronomers' tables usually agree very closely, the right ascension of the same planet be derived by the problems of the primum mobile. For by its distance, taken on the same night, from whatever fixed star you prefer, and by the declination of that fixed star, already observed or to be observed by Problem 1, there is easily found by Problem 4 the difference of right ascension, to be added to the planet's right ascension if the planet is further west than the fixed star and subtracted if it is further east, so that the right ascension of the fixed star results or remains. We carried this out, on both the bright star of Aries and Aldebaran, by way of Jupiter in 1643, on the very clear night preceding August 15, with Jupiter close to its station, since it had begun to be retrograde on the 12th. The altitude of Jupiter was taken with three different quadrants, while the declination of the bright star of Aries was taken at the end of August, and that of Aldebaran at the beginning of October of that year.

EXEMPLVM DVPLEX.

Double Example.

Anno 1643. Auguſti 15. illuceſcente — *1643, as August 15 was dawning*	Value
True meridian altitude of Jupiter	53° 50′ 30″

Anno 1643. Auguſti 15. illuceſcente — *1643, as August 15 was dawning*	Value
Altitude of the equator at Bologna	45° 30′ 30″
Therefore the true northern declination of ☊	8° 20′ 0″
True latitude of ☊ at that time, southern	1° 28′ 0″
And the true place of ☊	♈ 24° 34′ 0″
Therefore the right ascension of ☊	23° 43′ 28″
Distance of the bright star of Aries from ☊, as taken	13° 43′ 0″
Distance of Aldebaran from ☊, as taken	39° 53′ 0″
Northern declination of the bright star of Aries	21° 45′ 36″
Northern declination of Aldebaran	15° 44′ 25″
Therefore, by Problem 4, the difference of right ascension between ☊, the further west, and the bright star of Aries	3° 5′ 32″
And between ☊, the further west, and Aldebaran	40° 10′ 10″
Therefore the right ascension of the bright star of ♈	26° 49′ 0″
And the right ascension of Aldebaran	63° 53′ 38″
But at the end of 1644, the right ascension of the bright star	26° 50′ 8″
And the right ascension of Aldebaran	63° 54′ 47″

Assuming the advance of these fixed stars, on which Tycho, *Progymnasmata* volume 1, p. 276, and we ourselves below.

[Margin: Right ascension of the bright star of Aries and of Aldebaran at the end of 1644.]

Problema 8. Aſcenſionem Rectam Sirij per diſtantiam eius à Sole acquirere.

Problem 8. To obtain the right ascension of Sirius by its distance from the Sun.

[Margin: Sirius seen by day.]

IX. Sirius is so bright that in this century, around the equinoxes, it can be seen eight minutes and more before sunset in March and after sunrise in September, and its distance from the centre of the Sun can be taken with a quadrant or a hemicycle, since sextants are not sufficient. From the altitude of the Sun then observed, and corrected by adding parallax and subtracting refraction, the true altitude is derived, and from that the moment of time. From the Sun's meridian altitude immediately preceding or following are derived both the declination and the right ascension of the Sun, the altitude of the pole and the obliquity of the ecliptic being now given; these are adjusted to the time of the observed distance between the Sun and Sirius, according to the difference of time before or after noon converted into degrees of the equator. Next, from the altitudes of the Sun and Sirius converted into true ones, the true distance is derived by the method to be given shortly, by correcting the apparent or observed distance. Finally, from the true distance and the declination of the Sun and of Sirius, taken or to be taken by Problem 1 near the time of this observation, the difference of right ascension between the Sun and Sirius is derived by Problem 4. This, added to the Sun's right ascension if Sirius is

further east, or subtracted if further west, gives the right ascension of Sirius for that time.

[Margin: Method of converting an apparent distance into a true one.]

Now let Sirius appear at C but truly be at F, and let the Sun appear at D but truly be at G. Through their centres let the vertical circles VCA and VDB be drawn from the zenith V down to the horizon. Let the observed altitude of Sirius be AC, whose complement will be the arc CV, and the apparent altitude of the Sun BD, whose complement is the arc DV, and let the apparent distance between Sirius and the Sun be CD. For from the three sides of the spherical triangle CVD you will easily derive, by the analysis of triangles, the angle CVD, which is the same as the angle FVG. Therefore in the triangle FVG, with the already mentioned angle known and the complements of the true altitudes, FV for Sirius and GV for the Sun, you will derive by the rules of the same triangles the base FG, that is, the true distance between the Sun and Sirius.

Diagram. A woodcut set into the right column against the words of this paragraph: a tall, narrow spherical figure with its point at the top right. One curved side runs from V down and to the left through C and F to A and on to H; the other runs from V almost straight down through D, G and B to R. Two arcs cross the foot: AB, and below it HR. Fine lines cross the interior from C and F towards D and G, and a long line runs from F down to R. The course of the fine lines is described only as far as seen on the scan.

- V (top right): point of the figure, the zenith in the text
- C (left side, upper): Sirius apparent
- F (left side, just below C): Sirius true
- D (right side, upper): the Sun apparent
- G (right side, below D): the Sun true
- A (left side, lower): foot of the vertical circle VCA, on the arc AB
- B (right side, lower): foot of the vertical circle VDB, on the arc AB
- H (bottom left): end of the lowest arc
- R (bottom right): end of the lowest arc, the Sun's place when below the horizon

But if Sirius suffers no sensible refraction, being higher than 20°, and is at C, its true place, then to derive the angle at V use the complement of the true altitude, CV, and the remaining items as above. Then in the triangle CVG, with the angle at V known, again use the arc CV and, as above, the arc VG, and derive the true distance CG. It can happen, however, that the Sun's true place is below the horizon AB, as when the Sun is at R but appears at G, and then the arc VR, greater than a quadrant, must be used. Finally, the apparent place of one may be at F and, because of parallax, the true place at C, without any refraction, and yet the apparent place of the other may be at D, higher than the true place G, because of refraction. In this case the apparent distance would be FD, and the true distance CG.

[Margin: Method of making up for the observation of the distance.]

But if you cannot observe the distance for lack of instruments, at least take the altitudes and the azimuths of both, since the difference of the azimuths will be the angle V. With this, and with the complements of the altitudes, work as above to find the true distance.

Now let the example be from our own observation of 1644 September 13, in the morning, with a very clear horizon. The declination of Sirius was observed repeatedly on the days following the autumnal equinox.

EXEMPLVM.

Example.

Anno 1644. Septembris 13. manè — *1644 September 13, morning*	Value
Apparent altitude of the Sun	0° 16′ 0″
⊙, our parallax	0° 0′ 28″
⊙, refraction	0° 31′ 0″
True depth of the Sun below the horizon	0° 14′ 32″
Apparent distance of Sirius and ⊙	75° 35′ 0″
Time before noon, in hours	7^{h} 1^{m} 0^{s}
True northern declination of the Sun at that time	3° 41′ 0″
True right ascension of the Sun at that time	171° 29′ 40″
True altitude of Sirius	25° 0′ 0″
True distance of Sirius from ⊙	75° 47′ 30″
Southern declination of Sirius	16° 17′ 20″
Difference of right ascension	74° 2′ 6″
Therefore the right ascension of Sirius	97° 27′ 30″
But at the end of 1644	97° 27′ 40″
For converting the apparent distance into the true one:	
FV, complement of the altitude of Sirius	65° 0′ 0″
GV, complement of the apparent altitude of ⊙	89° 44′ 0″
FG, apparent distance of Sirius from ⊙	75° 35′ 0″
Therefore the angle FVG	74° 11′ 0″
Again FV	65° 0′ 0″
And the arc VR	90° 14′ 32″
And the angle FVR	74° 11′ 0″
Therefore the true distance FR	75° 47′ 30″

Problema 9. Aſcenſionem Rectam Fixarum adipiſci per tempus numeratum inter tranſitum earum per Meridianum, & Momentum obſeruatæ Aſcenſionis Rectæ Solis.

Problem 9. To obtain the right ascension of the fixed stars by the time counted between their transit through the meridian and the moment of the observed right ascension of the Sun.

X. The counting of the time is to be carried out with our pendulum, on which see Book 2, chapter 20, Propositions 11 and 12, and the transits of the fixed stars through the meridian are to be observed with the thread triangle

already described by us in Book 5, chapter 15, number 16, since otherwise the observation can hardly be exact. Furthermore, a time should be chosen at which the fixed star passes through the meridian near sunrise or sunset, not a whole hour away from it, so that the count of the time between the star's culmination and the Sun's altitude, taken or to be taken, may be as short as possible and exposed to as little tedium and risk of error as possible. For an error of 4^s in the time produces an error of a whole 1′ in the right ascension of the stars. In addition, at the nearest noon the Sun's meridian altitude is to be taken with large quadrants and corrected by adding parallax, so that from the true altitude and the altitude of the equator the declination of ☉ may become known by Problem 1. From the declination of the Sun and the obliquity of the ecliptic the right ascension of the Sun is to be derived by the solution of a right-angled spherical triangle.

So if the time is counted between the star's transit through the M. C. before morning and the following noon, or between the star's transit towards evening and the preceding noon, that time, converted into degrees of the equator, will give the difference of right ascension, to be subtracted in the first case and added in the second to the Sun's right ascension, so that the right ascension of the star is obtained. But it is advantageous to count the time between the fixed star's transit through the M. C. and the altitude of the Sun taken a little before sunset or after sunrise, and, with the Sun's altitude corrected, to derive from it the moment of time, and for that moment the Sun's right ascension, from the difference of time between the nearest noon and the moment at which the solar altitude was taken near the horizon.

In this way, with incredible endurance on our part and that of our colleagues, whom we found most practised and most trustworthy, we observed at Bologna the right ascension of the following stars, together with their declination by Problem 1. These we reduced to the end of 1644 by Tycho's table in *Progymnasmata* volume 1, p. 276, on which see below, that is, by the proportional part owed to the difference of right ascension and declination arising in this century over an interval of 100 years. To give at least one example, let it be on the bright star of Aries, which Tycho takes as the foundation for the others.

EXEMPLVM.

Example.

In 1643, on August 24, in the morning before sunrise, the meridian altitude of the bright star of Aries was taken with three quadrants as 67° 16′ 10″ at Bologna, where the altitude of the equator is most certainly 45° 30′ 30″. Therefore the star's northern declination at that time was 21° 45′ 40″. From the transit of the bright star of Aries through the meridian up to the apparent altitude of the risen Sun, 1° 25½′, the most thoroughly corrected times of $1^h\ 5^m\ 55^s$ were counted with the pendulum (on which see Book 2, chapter 20, Proposition 11), to which 16° 28′ 50″ of the equator correspond. But when the count of

oscillations was continued up to noon, they came to $8^h\ 25^m\ 17^s$, to which 126° 19′ of the equator correspond. At noon the apparent altitude of the Sun was 56° 38′, but the true altitude by our parallax was 56° 38′ 10″. Therefore the Sun's northern declination was 11° 7′ 40″, and so, from our obliquity of the ecliptic, the Sun's right ascension at noon was 153° 8′. If you take from this those 126° 19′, there remains 26° 49′ as the right ascension of the bright star of Aries.

Again, because the apparent altitude was 1° 25′ 30″, but with nearly 30″ of parallax added it was 1° 26′, and with 26′ of refraction subtracted the true altitude was exactly 1°, it was therefore then exactly $7^h\ 19^m\ 20^s$ before noon, to which 109° 50′ of the equator correspond. With these taken from the right ascension of the following noon, there remains 43° 18′ as the right ascension of the Sun observed a little after sunrise. Subtracting from this the arc of the time elapsed, which was 16° 28′ 50″, there remains 26° 49′ 10″ as the right ascension of the bright star of Aries. This value we chose, because in the oscillations of the pendulum over 1 hour a far more insensible error could creep in than in the oscillations over 8 hours and more. From that time to the end of 1644 there are 16 months, for which 68″ must be added, from Tycho's small table in *Progymnasmata* volume 1, p. 276. So the right ascension of the bright star of Aries at the end of 1644 was 26° 50′ 18″. But from the same small table, at the end of 1600, according to Tycho's observations, it was 26° 13′, and at the end of 1700 it will be 27° 38′. Therefore at the end of 1644, according to Tycho, it was 26° 50′ 24″, greater than ours by 6″.

Problema 10. Aſcenſionem Rectam Stellæ Fixæ per Aſcenſionem Rectam alterius ſtellæ vicinæ cognitam, Obſeruare.

Problem 10. To observe the right ascension of a fixed star by the known right ascension of another star nearby.

XI. The principal method is by the distance of the stars and their declination, on which see Problem 4. The secondary one is as follows. With the oscillations of a pendulum, but one exhibiting exactly the times of the primum mobile, of the kind we treat in Book 2, chapter 20, Proposition 12, count the time between the transit through the meridian of the star whose right ascension is known and the transit of another nearby star through the same meridian. Let this time be converted into an arc of the equator, and let that arc be added to the right ascension of the known star if this star is further west, and subtracted if it is further east, and the desired right ascension of the star will become known. But the transit through the M. C. is to be observed by our thread triangle, on which see Book 5, chapter 15. A nearby star should be used, so that the intervening time does not reach an hour, or exceeds it only slightly, lest a small error in the pendulum's times become more sensible over a longer stretch of time; and stars closer to the equator should be used, since they cross more quickly and do not seem to stick on the meridian, as those nearer the poles do. See, moreover, what we said in Book 2, chapter 20, in the examples to Proposition 11.

By this technique, with the colleagues indicated in the same place, I observed the difference in right ascension of all the fixed stars of the first and second magnitude visible in our climate, and of many also of the third and fourth rank, using in succession stars closer to one another. We bore this labour over many nights, and in three different years we summoned the whole starry circuit of the sky to this count, so that in this way at least their right ascension should be as nearly certain as possible, until it could be brought to a more certain polish by distances and declinations, according to the method given in Problem 4. I have thought it superfluous, however, to fill pages with those observations or with the meridian altitudes of the stars, since all of them are in the end contained in effect in the table to be given in Chapter 14.

[53] B and A in the last column stand as printed: B northern (*Borea*), A southern (*Australis*). The leaf sets no key to the two letters.

Problema 11. Data Longitudine & Latitudine ſideris Quærere illius Aſcenſionem Rectam & Declinationem.

Problem 11. Given the longitude and latitude of a star, to seek its right ascension and declination.

XII. On this, see Chapter 12, Problem 3.

SCHOLIA.

Scholia.

[Margin: Tycho's diligence.]

I. Tycho, in *Progymnasmata* volume 1, chapter 2, from p. 195, examines the right ascensions of selected fixed stars from the sum of the differences of right ascension, which he derives, by our Problem 4, from their mutual distances and from their declinations as observed by him in 1585. He asks, namely, whether their sum exactly equals the circuit of the whole equator; and he does this in a threefold combination, which it pleases me to show in the following small table, in which the declinations are northern except for Spica and the hand of Ophiuchus.

Ordo Stellarum — *Order of the stars*	Distance from the preceding star	Declination of 1585	Difference from the preceding right ascension
Bright star of ♈	☩	21° 28′ 30″	☩
Southern head of ♊	74° 45′ 30″	28° 57′ 0″	83° 57′ 33″
Spica ♍	90° 46′ 20″	8° 56′ 20″	85° 54′ 18″
Bright star of the Vulture	97° 50′ 0″	7° 51′ 20″	96° 45′ 9″
Bright star of ♈	90° 15′ 0″	21° 28′ 30″	93° 22′ 58″
1. Sum of the differences of right ascension			359° 59′ 58″
Bright star of ♈	☩	21° 28′ 30″	☩
First of the wing of Pegasus	43° 37′ 15″	13° 0′ 40″	44° 58′ 0″
Bright star of the Vulture	47° 49′ 40″	7° 51′ 20″	48° 25′ 0″
Spica ♍	97° 50′ 0″	8° 56′ 45″	96° 45′ 9″
Heart of Leo	54° 2′ 0″	13° 58′ 0″	49° 19′ 20″
Heel of the foot of ♊	54° 33′ 45″	22° 38′ 30″	57° 4′ 10″
Bright star of ♈	58° 22′ 0″	21° 28′ 30″	63° 28′ 30″
2. Sum from the differences of right ascension			360° 0′ 9″

Ordo Stellarum — *Order of the stars*	Distance from the preceding star	Declination of 1585	Difference from the preceding right ascension
Bright star of ♈	☩	21° 28′ 30″	☩
Eye of ♉	35° 32′ 10″	15° 36′ 15″	37° 3′ 15″
Southern head of ♊	45° 5′ 0″	28° 57′ 0″	46° 53′ 53″
Heart of Leo	36° 59′ 30″	13° 58′ 0″	36° 34′ 47″
Spica ♍	54° 2′ 0″	8° 56′ 20″	49° 19′ 20″

Ordo Stellarum — *Order of the stars*	Distance from the preceding star	Declination of 1585	Difference from the preceding right ascension
Northern left hand of Ophiuchus	42° 33′ 30″	2° 33′ 15″	42° 19′ 20″
Bright star of the Vulture	55° 17′ 20″	7° 51′ 20″	54° 26′ 21″
First of the wing of Pegasus	47° 49′ 40″	13° 0′ 40″	48° 25′ 0″
Bright star of ♈	43° 37′ 15″	21° 28′ 30″	44° 58′ 0″
3. Sum from the differences of right ascension			359° 59′ 56″

[Margin: Tycho's semi-paralogism.]

II. Since, then, the first sum falls short by only 2″ and the third by 4″, while the second exceeds the equator by 9″, an imperceptible difference, Tycho asserts that the places of the stars are clear evidence both of rightly established right ascensions and of his instruments' being free of every fault in observing distances and declinations. I, however, say that this is indeed very probable, but by no means evident. For the defect of one star, however large and sensible, could have been offset by an equal excess of another, or of other stars, with the integrity of the equator, as represented by the sum, still preserved.

CAPVT XII.

De Longitudine ac Latitudine Fixarum Obſeruanda aut ex Obſeruatione deriuanda, & inde Aſcenſione Recta ac Declinatione ad alios multos annos extendenda. Cum 8. Problematibus ad id ſpectantibus.

Chapter 12. On observing the longitude and latitude of the fixed stars, or deriving them from observation, and then extending the right ascension and declination to many other years. With 8 problems relating to this.

[Margin: Three methods of observing the longitude and latitude of the fixed stars.]

I. There are chiefly three methods of obtaining by observation the longitude and latitude of the fixed stars and of other stars. The first is by the zodiacal armillaries enclosed in the astrolabe, on which see Ptolemy, Book 7, chapter 2; the older astronomers used it from Ptolemy up to Tycho. But on the insufficiency of those armillaries for showing the exact place of the stars, enough has been said by Tycho, in *Progymnasmata* volume 1, chapter 2, pp. 140 and 204, and by us in the *Liber Organicus*. The second is by the applications of the Moon's horns or edges to the stars, of which we have not a few examples, partly in Ptolemy and Copernicus, partly in Lansbergen, in Class 7 of the lunar observations in the *Treasury of Observations*. But this method is both entangled in the intricacies of the parallaxes, which have to be resolved into longitude and latitude, and serves only for stars placed near the zodiac; and it serves rather for establishing the Moon's place by the already known places of

the fixed stars than for discerning the places of the fixed stars themselves by the Moon, unless perhaps the Moon's appulse to some fixed star occurs in a total eclipse of the Moon, during which even the smallest stars appear. This method, approved by Cardanus [Girolamo Cardano], Tycho all but rejected in *Progymnasmata* volume 1, p. 146. The third is by the star's declination and right ascension, given or already found, or by the star's distance from two stars of already known longitude and latitude; this is the most universal and most exact of all. The others will be indicated in the problems of the primum mobile. But here, where the most certain foundations of the fixed stars are to be laid, only the third is to be chosen and set out by us, somewhat more accurately than the other astronomers before us have done. For Copernicus, in Book 2, chapter 4, and our Petavius [Denis Pétau], in Book 1, chapter 6, of the dissertations of the *Uranologion*, rather from a given longitude and la- titude teaches how to find the right ascension and declination, as if the former were established by observation more certainly and earlier than the latter. Tycho, however, who handed down this method most diligently of all in vol. 1 of the *Progymnasmata*, chapter 2, from p. 203 to 205, Kepler in the *Epitome of Copernican Astronomy*, p. 357, Longomontanus in Book 2 of the *Sphaerica*, chapter 2, Magini in Book 8 of the *Primum Mobile*, Problems 13 and 14, Osualdus [Erasmus Oswald Schreckenfuchs], and the others who have touched on this method have not covered all the cases. For there are 22 of them, of which 10 do not need trigonometry. The rest do need it, unless someone were to try to solve them by mechanical use of the compasses or of armillary spheres, with large planispheres or globes showing minutes and some subdivisions of minutes, by an insane mass of instruments, and were to spare no expense in order to escape the labour of trigonometry. For these, then, let the following diagram serve.

Problema 1. Longitudinem ac Latitudinem Stellæ Inquirere, datis Declinatione Aſcenſione Recta, & Obliquitate Eclipticæ.

Problem 1. To find the longitude and latitude of a star, given the declination, the right ascension and the obliquity of the ecliptic.

II. Let ABCD be the solstitial colure, in which B is the north and D the south pole of the equator, from which let the equator A♈C be described, and through which let the circle of declination BSDZB be drawn. In the same colure let G be the north and H the south pole of the ecliptic, from which let the ecliptic E♈F be described, and let arcs of a circle of latitude be drawn through the centres of the stars, as will be said below. And let the distance of the poles, BG or HD, be given, which is as great as the angle of the ecliptic and the equator, A♈E or F♈C; and equal to this is the greatest declination of the ecliptic, namely the arcs AE and CF. In our opinion this is always 23° 30′.

Diagram. A circle (the solstitial colure ABCD) set in the left column, crossed by the equator from A to C and by the ecliptic from E to F, which meet at the

centre at ♈. Curved arcs run from the poles at the top (B, G) to the poles at the foot (D, H), two of those from G in dotted line. Stars are marked by small star signs at several lettered points.

- B (top of the circle): north pole of the equator
- G (top, right of B): north pole of the ecliptic
- K (upper left, with star sign)
- E (left, on the circle), with the sign ♋ beside it
- P (upper interior, with star sign)
- M (right, with star sign)
- I (left, with star sign)
- R, X, S, T (interior, left of centre, close together)
- A (left, on the equator)
- λ, V (interior, below the equator, left of centre)
- ♈ (centre), with a sign like ♎ directly below it
- C (right, on the equator)
- N (right, with star sign)
- L (lower left, with star sign)
- Y (lower interior, with star sign)
- ♑ and F (right, at the end of the ecliptic)
- O (lower right, with star sign)
- H (foot, left of D): south pole of the ecliptic
- D (foot): south pole of the equator
- Z (upper right interior, with star sign)
- Q (on the ecliptic between E and R, italic)
- δ, θ (on the equator, right of centre)
- ε (interior, right of centre, below the equator, with star sign)
- β, μ (interior, right of centre, just below the ecliptic)

[Margin: 5 cases, when the right ascension of a star is 90°.]

III. With this established, if the given right ascension of the star is exactly 90°, its longitude is the very beginning of ♋, and the colure is at once a circle of declination and of latitude. So either the star is at A, lacking all declination, and then its south latitude is AE, and as great as the obliquity of the ecliptic; or it is at E, with declination AE equal to the obliquity of the ecliptic itself, and then it has no latitude; or it is at I, having a north declination AI, less than the obliquity of the ecliptic, and then, with the declination subtracted from the obliquity of the ecliptic, its south latitude EI will be known; or it is at K, having a north declination AK, greater than the obliquity of the ecliptic, and then, with the obliquity of the ecliptic subtracted from the declination, the north latitude EK will be known; or finally it is at L, having a south declination AL, and this, added to the obliquity of the ecliptic AE, will make up the south latitude EL.

[Margin: 5 other cases, when the right ascension is 270°.]

But if the star's right ascension is exactly 270°, it will be at the beginning of ♑ as regards longitude, and the solstitial colure will likewise be a circle of

declination and of latitude. So either the star is at C, free of all declination, and then its latitude is north, FC, and as great as the obliquity of the ecliptic; or it is at F, having a south declination equal to the obliquity of the ecliptic, and then it has no latitude; or it is at N, having a south declination less than the obliquity of the ecliptic, and the former subtracted from the latter will give the latitude NF, north; or it is at M, with a north declination, and the obliquity of the ecliptic, or the arc CF, added to this makes up the north latitude FM; or finally it is at O, with a south declination greater than the obliquity of the ecliptic, and the latter subtracted from the declination leaves the south latitude FO. And these are the ten cases in which there is no need for the analysis of triangles: rare indeed, but such as ought not to have been passed over altogether.

[Margin: On the 12 cases to be solved by trigonometry.]

IV. The remaining 12 cases arise from the difference of the 4 quadrants of the equator in which the right ascension is reckoned. In any one of these the star can be either with no declination, or with a north one, or with a south one; and so, the three cases of declination being multiplied by the 4 quadrants, 12 result. For we do not enumerate here the cases that concern the conclusions rather than the data, though we shall nevertheless point them out. A star belongs to the first quadrant of the circle when it is within 90°, to the second when it is beyond 90° but short of 180°, to the third when it is beyond 180° but short of 270°, to the fourth when it is beyond 270°. With this known beforehand:

[Margin: Case 1, in quadrant 1, without declination.]

First, let the star be at V, a point of the first quadrant of the equator, without any declination, and through it, from either pole of the ecliptic, say from H, let the arc of latitude HX be drawn as far as the ecliptic. There will then be a triangle VX♈, right-angled at X, in which the angle at ♈ is given, which is the obliquity of the ecliptic, and the base V♈, which is the right ascension itself. Therefore by the rules of right-angled spherical triangles both the longitude ♈X and the south latitude VX will become known.

[Margin: Case 2, of quadrant 1, with north declination.]

Second, let the star be at P, whose right ascension is λ♈, marked at λ by the arc of declination BPλ drawn through the star, and let it belong to the first quadrant of the equator. For the complement of the right ascension to the quadrant, that is the arc λA, measures the angle ABλ; and this subtracted from 180° gives the angle PBG. Therefore, with the arc of latitude GPQ drawn, in the triangle PBG the angle at B will be known, and the side BG, the distance of the poles, and BP, the complement of the north declination Pλ. So the base PG will not remain hidden, which is the complement of the north latitude PQ; nor will the angle BGP, which is the measure of the arc of the ecliptic EQ, whose complement to the quadrant will be the longitude sought. But if the base opposite angle B were of 90°, as is the arc GR, the star would have no latitude, and the longitude would be the arc R♈, that is the complement of the arc RE, known from the angle RGB. Finally, if it were greater than 90°, as is the arc GS, the star would be at S, and the excess above 90°, namely the arc ST,

would be the south latitude, and the longitude would be the arc T♈, that is the complement of the arc TE, known from the angle SGB. Understand these cases to be possible also in the other three quadrants.

[Margin: Case 3, of quadrant 1, with south declination.]

Third, let the star be at Y, with south declination Yλ and right ascension λ♈. For when this is subtracted from 90° the arc Aλ, or the angle ADλ, will become known; and when the arc of latitude HYX has been drawn through the star, the triangle HYD will arise, in which, as I said, the angle HDY will be known, and the side HD, the distance of the poles, and DY, the complement of the declination. And therefore by means of trigonometry the base HY will become known, which is the complement of the south latitude to the quadrant, and the angle YHD, that is XHF. So when 90°, that is the arc F♈, is removed, the arc ♈X will remain, which will be the star's longitude.

[Margin: Case 4, in quadrant 2, with no declination.]

Fourth, let the star be at V, but as a point of the second quadrant, without any declination. For in the triangle VX♎, right-angled at X, the angle X♎V will be given, which is the obliquity of the ecliptic, and the base V♎, which is the complement of the right ascension to the semicircle; and therefore the arc VX, of south latitude, will become known, and X♎, which, subtracted from the semicircle or from 180°, will leave the star's longitude.

[Margin: Case 5, in quadrant 2, with north declination.]

Fifth, let the star be at P, with north declination Pλ, but let the right ascension belong to the second quadrant of the equator. For this, subtracted from 270°, will give the angle PBG of the triangle PGB, in which BG, the distance of the poles, is given, and BP, the complement of the declination. So the base GP will become known, which subtracted from 90° will give the north latitude PQ; and the angle PGB will become known, measuring the arc EQ, which is to be added to 90° to obtain the star's longitude from ♈.

[Margin: Case 6, in quadrant 2, with De]

Sixth, let the star be at Y, but with the right ascension belonging to the 2nd quadrant, with south declination Yλ. For the excess of the right ascension above 90°, that is the arc

[Margin: clination, south.]

Aλ, will give the angle HDY in the triangle HYD, in which HD, the distance of the poles, is given, and DY, the complement of the declination. So the base HY will become known, the complement of the south latitude, and the angle YHD, which, subtracted from 270°, will leave the star's longitude.

[Margin: Case 7, in quadrant 3, with no declination.]

Seventh, let the star be in quadrant 3 with no declination, as at δ. For when an arc of latitude, say Gδβ, has been drawn through it from either of the poles of the ecliptic, there will be a triangle ♎δβ, right-angled at β, in which the angle at ♎ is the obliquity of the ecliptic, and ♎δ, the base, is the excess of the right ascension above the semicircle. So by analysis of this triangle the north

latitude βδ will easily become known, and the arc ♎β, which, added to 180°, will make up the star's longitude.

[Margin: Case 8, in quadrant 3, with north declination.]

Eighth, let the star be at Z, with north declination Zθ, and let its right ascension belong to the 3rd quadrant. For this, subtracted from 270°, will make known the angle ZBG. So when the arc of latitude GZβ has been drawn, there will be a triangle BGZ, in which the already mentioned angle at B will be known, with the sides enclosing it, namely BG, the distance of the poles, and BZ, the complement of the declination. So the base GZ will become known, which, subtracted from 90°, will give the north latitude Zβ, and the angle BGZ, measuring the arc of the ecliptic Eβ; if you add 90° to this, you will have the star's longitude.

[Margin: Case 9, in quadrant 3, with south declination.]

Ninth, let the star be at ε, with south declination εθ, and through the centre of the star let the arc of latitude Hμε be drawn. For the triangle HεD will then arise, in which the side HD, the distance of the poles, is given, and Dε, the complement of the declination; and the angle HDε becomes known by subtracting 90° from the right ascension. So the base Hε will not remain hidden, which in our case is greater than a quadrant, and therefore the excess με above the quadrant will be the north latitude. In other cases, however, it can be either a quadrant, as if the star were at μ, without latitude, or less than a quadrant, with south latitude. The angle εHD will also become known, which measures the arc μF, and which, subtracted from 270°, leaves the star's longitude.

[Margin: Case 10, in quadrant 4, without declination.]

Tenth, let the star be at δ, but as a point of the fourth quadrant, without any declination. For in the triangle ♈βδ, right-angled at β, the angle at ♈, the obliquity of the ecliptic, is given, and the base ♈δ, which becomes known when the right ascension is taken from 360°. So the north latitude βδ will not remain hidden, nor the arc ♈β; when this is subtracted from 360° the longitude will be known.

[Margin: Case 11, in quadrant 4, with north declination.]

Eleventh, let the star be at Z, with north declination Zθ and with right ascension belonging to the 4th quadrant. For by subtracting 270° from it the arc θC will be known, that is the angle ZBG of the triangle BGZ. Since in this triangle BG, the distance of the poles, is given, and BZ, the complement of the declination, the base GZ will also become known, which, subtracted from 90°, will give the north latitude Zβ, and the angle BGZ, which measures the arc Eβ. So its complement to 180°, added to 270°, will make up the star's longitude.

[Margin: Case 12, in quadrant 4, with south declination.]

Twelfth, let the star be at ε, and the rest as above in case 9, but with right ascension belonging to the 4th quadrant. For if 270° is taken from the right ascension, the angle εDC will be known, whose complement to 180° will give the angle HDε in the triangle HεD. In this triangle, with HD, the distance of the poles, and Dε, the complement of the declination, now given, the base Hε will

become known. Since in this figure it is greater than a quadrant, its excess με above the quadrant will be the star's north latitude. That base could, however, be a quadrant, without latitude, or less than a quadrant, and the complement of a south latitude. Finally the angle εHD will become known, which measures the arc μF, and which, added to 270°, will make up the star's longitude that was sought.

Problema 2. Longitudinem ac Latitudinem Stellæ Inquirere, Data eius diſtantia à duabus ſtellis notæ Longitudinis, Latitudinis, & Diſtantiæ mutuæ.

Problem 2. To find the longitude and latitude of a star, given its distance from two stars of known longitude, latitude and mutual distance.

V. We anticipate this problem here from our Book 10, and from Regiomontanus's *Epitome of the Almagest*, from prop. 7, because it serves marvellously not only for the fixed stars but also for planets whose distance has been observed from two stars of known latitude, longitude and mutual distance, either from observation or from the table of chapter 10.

So in the figure below let A be the south pole of the ecliptic and B the north; let EC be a portion of the ecliptic, and let the three semicircles of latitude be BEA, BHA and BCA.

Diagram. A lens-shaped figure set at the right of the right column, formed by two curved arcs that meet at the top and the foot, with a straight vertical line between them from top to foot and a horizontal line across the middle. Further arcs join the lettered points in the upper half and run down to the lower right. A small dot stands in the lower interior. No star signs.

- B (top)
- G (upper interior, on the vertical line)
- F (upper right, on the arc)
- D (left, on the arc, above E)
- E (left end of the horizontal line)
- H (centre)
- C (right end of the horizontal line)
- K (lower right, on the arc)
- A (foot)

[Margin: Case 1, a star at D, and stars G and F.]

First, let the star be at D, whose observed distance is DG from the star G and DF from the star F, both of north latitude. Let the latitude of these be known, HG, and hence its complement GB; and the latitude FC, and therefore its complement FB; and the distance GF. From the difference of longitude, moreover, let the arc HC be known, or the angle HBC. So in the triangle DGF, from the three given sides, which are the three distances, find the angle DGF. Then in the triangle BGF, from the given distance FG, the complement of latitude BF, and the angle GBF, which is the same as the angle HBC, find the

angle BGF. Join this to the angle DGF that was found, and subtract the sum from four right angles, or from 360°. For there will remain the angle DGB, with which, in the triangle DGB, and with the distance DG and the complement of latitude GB, find both the base BD, which will be the complement of the latitude of the star D, and the angle GBD, which will be the difference of longitude, to be added to the longitude of the star G if that star were more westerly, or subtracted if more easterly, so that the longitude of the star D may be known.

[Margin: Case 2, a star at F, and stars D and G.]

Second, let the star for which the work is being done be at F, and the two other stars D and G. For in the triangle DGF, from the three distances, gather the angle DGF as above; and in the triangle DBG, from the distance DG, the complement of latitude BD, and the angle DBG, which is the difference of longitude of the stars D and G, find the angle DGB. Subtract the sum of this and the angle DGF from 360°, and the angle BGF will be known. With this, and with the complement of latitude BG and the distance GF, find the base BF, for it is the complement of the latitude of the star F, and the angle GBF, which measures the arc HC, to be added, etc., to the longitude of the star G, so that the longitude of the star F may become known.

[Margin: Case 3, a star at G, and stars D and F.]

Third, let the star for which the work is being done be at G, and the other stars at D and F. First, then, in the triangle DGF, from the three distances given or observed, find the angle DFG. Then in the triangle DBF, from the three given sides, DF, the distance of the stars, and DB and FB, the complements of the latitudes, or from the given angle DBF, which is their difference of longitude, find the angle DFB. From this subtract the DFG that was found, and the remaining GFB will become known. With this, in the triangle GFB, and with the distance GF and the complement of latitude BF, find both the side BG, which is the complement of the latitude of the star G, and the angle GBF, which measures the arc HC, that is the difference of longitude to be subtracted from the longitude of the star F, so that the longitude of the star G may be known.

[Margin: Case 4, a star at D, and stars G and K.]

Fourth, let the star you are concerned about be at D, and one of the known stars at G, to the north, the other at K, to the south. First, then, in the triangle DGK, from the three known distances, find the angle DGK. Then in the triangle GKB, from the known distance GK and the side BK, which is the aggregate of the latitude CK and the quadrant BC, and with the angle GBK, that is HBC, which is the difference of longitude of the stars G and K, investigate the angle BGK. Join this to the angle DGK, take the sum of these from 360°, and the angle DGB will become known. With this, finally, in the triangle DGB, with the distance DG and the complement of latitude BG, find both the base BD, which is the complement of the latitude of the star D, and the angle

DBG, which measures the difference of longitude, to be subtracted from the longitude of the star G, so that the longitude of the star D may become known.

[Margin: Case 5, a star at G, and stars D and K.]

Fifth, let the star you are after be at G, and one of the known stars at D, to the north, the other at K, to the south. First, in the triangle DAK, from the angle DAK, which is the difference of the known longitudes, the distance DK and the complement of latitude AK, find the angle KDA. Afterwards in the triangle DGK, from the three known distances, find the angle GDK. Join this to the angle ADK, subtract the sum from two right angles, or from 180°, and the angle BDG will remain. With this, finally, in the triangle DGB, with the distance DG and the complement of latitude DB, find both the base BG, which is the complement of the latitude of the star at G, and the angle DBG, which is the measure of the difference of longitude, to be added to the longitude of the star D, so that the longitude of the star G may become known.

[Margin: Case 6, a star at D, and stars at F and K.]

Sixth, let the star be at D, and the other two of the same longitude, but one of north latitude at F, the other of south latitude at K. So in the triangle DFK, in which the distances DF and DK are given, and FK, either as a distance or as the aggregate of the latitudes of the stars F and K, find the angle DFK, which, subtracted from 180°, will give the angle DFB in the triangle DFB, in which the distance DF and the complement of latitude BF are given. So in that triangle investigate both the base DB, namely the complement of the latitude of the star D, and the angle DBF, namely the difference of longitude to be added to the longitude of the stars F and K if the star is, as in our figure, more easterly, so that the longitude of the star D may be known.

[Margin: Use of the table of Chapter 10.]

From these six principal cases, moreover, it will not be difficult to shape figures for the other cases, and in them to find the longitude and latitude of the star wanted. But if the distance of the two stars adopted here were neither observed nor given, one would have to hunt it out by solving one or another further triangle, and carry out the rest as above. So our table in chapter 10, showing so many distances of the fixed stars, relieves us of this labour.

Problema 3. Data Longitudine ac Latitudine Stellæ Fixæ, Inquirere Aſcenſionem Rectam & Declinationem eiuſdem.

Problem 3. Given the longitude and latitude of a fixed star, to find its right ascension and declination.

VI. It will be useful to read here, in advance, the rules for the angles at the poles, which we shall set down in chapter 13, no. 4. Then let the figure set out and explained in Problem 1 be repeated here, and let everything be done that we said was to be done in that problem, but use latitude in place of declination, or the complement of latitude in place of the complement of declination, and the arc or angle of longitude in place of the arc or angle of right ascension, in

adapting the data, and in this way you will dispatch all 22 cases. For example, if the star is at P, and its latitude PQ is given, and the star is in the first quadrant of the ecliptic, the angle PGB will be known from the complement of the longitude to the quadrant. So with it, and with the complement of latitude PG and the distance of the poles BG, find both the base BP, which will be the complement of the north declination Pλ, and the angle PBG, which measures the arc λC. So when 90°, or the arc ♈C, is subtracted, λ♈ will remain, namely the right ascension of the star P; and so for the others. For to someone already practised in that figure and in the theory of triangles the remaining cases will not remain hidden. For these, remember that a star is in the 1st quadrant of the ecliptic if its longitude is less than 90°, but in the 2nd if greater than 90° and less than 180°, in the 3rd if greater than 180° but less than 270°, and in the 4th if greater than 270°. But if it is exactly 90° or 270°, that is at the beginning of Cancer or Capricorn, the solstitial colure will be at once a circle of latitude and of declination, and from the latitude alone and the declination of the tropics the star's declination can be gathered, without trigonometry.

Diagram. The figure of Problem 1 (p. 514) printed again in the left column, as the text calls for: the solstitial colure as a circle, crossed by the equator from A to C and by the ecliptic from E to F, which meet at ♈, with arcs from the poles at the top (B, G) to those at the foot (D, H), two of those from G in dotted line, and star signs at several lettered points.

- B, G (top)
- K (upper left, with star sign)
- E (left, on the circle), with the sign ♋ beside it
- P (upper interior, with star sign)
- M (right, with star sign)
- I (left, with star sign)
- R, X, S, T (interior, left of centre, close together)
- A (left, on the equator)
- λ, V (interior, below the equator, left of centre)
- ♈ (centre), with a sign like ♎ directly below it
- C (right, on the equator)
- N (right, with star sign)
- L (lower left, with star sign)
- Y (lower interior, with star sign)
- ♑ and F (right, at the end of the ecliptic)
- O (lower right, with star sign)
- H, D (foot)
- θ (interior, right of centre, above the equator)
- ε (interior, right of centre, below the equator, with star sign)
- β (interior, right of centre, below the ecliptic)
- Z (upper right interior, with star sign)
- Q (on the ecliptic between E and R, italic)
- δ (on the equator, left of θ)

• μ (right of β, just below the ecliptic, below ε)

Problema 4. Data Longitudine, ac Declinatione Stellæ, cum Polorum Diſtantia, ſeu Obliquitate Eclipticæ; Latitudinem & Aſcenſionem Rectam Inquirere.

Problem 4. Given the longitude and declination of a star, with the distance of the poles or the obliquity of the ecliptic, to find the latitude and right ascension.

VII. In the same figure of Problem 1 let the star be at P, and let the complement of the declination BP and the distance of the poles BG be known, and, from the star's longitude, not greater than 180°, its distance from the beginning of Cancer, namely the arc EQ, or the angle PGB. For from these three data in the triangle PBG trigonometry will make known to you the base PG, which is the complement of the latitude, and the angle PBG, which is the argument of the right ascension: for it measures the arc of the equator λC. When the arc ♈C, of 90°, is subtracted from this, λ♈ will remain, the right ascension, if the star is in the first quadrant. But if it is in the 2nd, subtract λ♈ from 180°, and the right ascension will remain. But if the star were at Z, the triangle suited to the purpose would be BGZ, and the complement of the declination BZ, and from the longitude the angle BGZ would be known, as in case 8 of Problem 1, and hence GZ, the complement of the latitude, and ZBG, the argument of the right ascension, etc.

Problema 5. Data Aſcenſione Recta & Longitudine cum Diſtantia Polorum, Inuenire Declinationem & Latitudinem ſideris.

Problem 5. Given the right ascension and longitude, with the distance of the poles, to find the declination and latitude of the star.

VIII. In the same figure of Problem 1 let the star be at P. For in the triangle BPG, given the distance of the poles BG, the angle PBG from the right ascension, and the angle BGP from the longitude, by the distance from the equinoctial or solstitial points, both BP, the complement of the declination, and GP, the complement of the latitude wanted, will easily be found. When these are subtracted from 90°, the declination and latitude will be known: and so in the other 12 cases, on which see Problem 1.

Problema 6. Data Aſcenſione Recta & Latitudine Stellæ, cum Diſtantia Polorum, Longitudinem ac Declinationem eius Indagare.

Problem 6. Given the right ascension and latitude of a star, with the distance of the poles, to search out its longitude and declination.

IX. In the same figure of Problem 1 let the star be at P. For in the triangle PBG, given BG, the distance of the poles, GP, the complement of the latitude, and the angle PBG from the right ascension, by the equatorial distance from the solstitial or equinoctial points, BP, the complement of the declination, and the angle PGB, the argument of the longitude, cannot remain hidden from the trigonometer: and so in the other cases, on which see Problem 1.

Problema 7. Data Latitudine ac Declinatione cum Diſtantia Polorum, & Quadrante ad quem Stella pertinet, Longitudinem atque Aſcenſionem Rectam eius deducere.

Problem 7. Given the latitude and declination, with the distance of the poles and the quadrant to which the star belongs, to deduce its longitude and right ascension.

X. In the same figure of Problem 1 let the star be at P. For in the triangle PGB, given the distance of the poles BG, the complement of the latitude GP and the complement of the declination BP, the analysis of triangles will yield the angle at the pole of the world B, which is the argument of the right ascension, and the angle at the pole of the ecliptic G, which is the argument of the longitude: and similarly in the other cases of Problem 1.

Problema 8. Conſtituta Aſcenſione Recta, & Declinatione Fixarum pro aliquo tempore, ad alia tempora intra vnum circiter ante vel poſt ſæculum eam Extendere.

Problem 8. Given the right ascension and declination of the fixed stars as established for some time, to extend it to other times within about one century before or after.

XI. For example, let the right ascension and declination of Spica be established for the end of the year 1600 as a root, together with its longitude and latitude, by Problem 1 or 2, and suppose you wish to extend it to any time within this century, up to the end of the year 1700. First, then, in accordance with the opinion you have chosen on the motion of longitude, add to the longitude of Spica for the completed year 1600 the motion appropriate to 100 years, and you will have the longitude of Spica at the end of the year 1700. The latitude, however, will of itself be the same, unless perhaps it varies because of a variation in the obliquity of the ecliptic. Therefore by Problem 3, from the longitude and latitude of the year 1700, find the right ascension and declination of Spica, and the difference of each from the right ascension and declination of the year 1600, subtracting the smaller from the greater, etc. For that difference, distributed by proportional part over the intervening time, added to the root if the right ascension or declination increases and subtracted if it decreases, will give the right ascension and declination wanted, although the result is had more exactly by trigonometry and Problem 3. By this device Tycho, in vol. 1 of the *Progymnasmata*, p. 276, constructed a table of the right ascension

and declination of selected fixed stars for the end of the years 1600 and 1700, inserting the secular difference appropriate to them.

CAPVT XIII.

Chapter 13.

In quo Regulæ Incrementi & Decrementi in Aſcenſione Recta, & Declinatione Fixarum, cum aliquot Proprietatibus earumdem.

In which the rules for the increase and decrease in the right ascension and declination of the fixed stars, with some of their properties.

I. We suppose here that the fixed stars move not only by the diurnal motion, that of the primum mobile, on the poles of the equator, describing diurnal arcs parallel to the equator, but also by a proper motion in longitude towards the east, on the poles of the ecliptic, as will be said in chapter 16; and that meanwhile they perpetually keep among themselves the same distance that they once obtained from the beginning by divine act, as was said in chapter 10. So it comes about that by this motion they describe arcs parallel to the ecliptic, always keeping the same latitude, either with respect to the mean ecliptic or with respect to the temporary ecliptic, if that changes its obliquity; on this subject, chapter 15. With these things laid down, we must give the rules for telling whether the right ascension and declination increase or diminish as the longitude increases.

II. As regards declinations, from the suppositions made above and from inspection of the globe itself there arise the following propositions, which can serve as very certain rules for practice.

Proposition 1. *For fixed stars moving by their motion in longitude from Capricorn through ♈ to Cancer, north declination increases and south declination decreases.* Ptolemy, Book 7, chapter 3. *Reinhold*, in the *Theorica* of the eighth sphere, p. 230.

Proposition 2. *For fixed stars moving by their motion in longitude from Cancer through ♎ to Capricorn, north declination decreases, but south declination increases.*

[Margin: Error of certain astronomers.]

III. As regards right ascension, it has seemed to some that it increases continually as the longitude of the fixed stars increases. But this is false, since there are some stars whose right ascension decreases for many years as their longitude increases, although at other times it increases. Such in this century is the bright star in the Wain, or shoulder, of Ursa Minor. For its right ascension in the year 1600 was 222° 59′ 12″, and yet it was found by us in the completed year 1644 to be 222° 54′, and for the year 1700, 222° 47′ 7″, as will be clear to anyone deriving it trigonometrically by Problem 3 of the preceding chapter from its longitude and latitude, even though those are Tycho's. For its longitude in the

year 1600 was ♌ 7° 16′ 30″, and in the year 1700 it will be ♌ 8° 41′ 30″, while its north latitude at both times is 72° 51′ 30″.

[Margin: A suspicion about the hesitation of Tycho or of the Tychonians.]

From this I suspect it came about that Tycho or his calculators, when they had come upon this star, found its right ascension smaller in the year 1700 than in the year 1600, and yet believed that it too must increase as the longitude increases, chose to cut this knot, by cutting the shoulder of Ursa Minor out of the catalogue of right ascensions, rather than set about untying it. For no more probable cause can be offered for their having passed over this star, which is of the second magnitude and very conspicuous.

The rules of this increase and decrease, together with other propositions most worth knowing, will be given more conveniently and demonstrated in chapter 19, in the Corollaries of the last Problem.

[Margin: Rule on the angles at the poles.]

IV. Since, however, the angles at the pole of the ecliptic made by the solstitial colure and by a circle of latitude, or the angles at the pole of the equator made by the same colure and by a circle of declination, often come into use in the Problems of the preceding chapter and elsewhere, take the rules for these angles, in which the given right ascension is taken for the angle at the pole of the equator, and the longitude for the angle at the pole of the ecliptic. When the longitude or the right ascension is exactly 0°, 180° or 360°, the angles, each at its own pole, are right on both sides; otherwise one is acute and the other obtuse; but at 90° and 270° there is no angle.

De Angulis ad Polum Ecliptic æ factis à Coluro Solſtitiorum & à Circulo Latitudinis.

On the angles at the pole of the ecliptic made by the solstitial colure and by a circle of latitude.

Rule 1. In the first quadrant of the ecliptic, namely from the beginning of ♈ to the beginning of ♋, subtract the longitude from 90°, and the acute angle at the pole of the ecliptic will be left. Add 90° to the longitude, however, and the obtuse angle will result.

Rule 2. In the second quadrant, subtract 90° from the longitude, and the acute angle will be left; subtract the longitude from 270°, however, and the obtuse angle will remain.

Rule 3. In the third quadrant, subtract the longitude from 270°, and the acute angle will be left; subtract 90° from the longitude, however, and the obtuse angle will result.

Rule 4. In the fourth quadrant, subtract 270° from the longitude, and you will have the acute angle; subtract the longitude from 450°, however, and you will have the obtuse angle.

De Angulis ad Polum Æquatoris.

On the angles at the pole of the equator.

Do everything as in the preceding rules, but in place of the longitude use the right ascension of the star.

CAPVT XIV.

Chapter 14.

De Tabula Aſcenſionis Rectæ, Declinationis, Longitudinis, ac Latitudinis ſelectarum Fixarum à nobis conſtituta, eiuſque diſcrimine à Tychonica & ab alijs.

On the table of right ascension, declination, longitude and latitude of selected fixed stars established by us, and its difference from Tycho's and from others.

I. Since from Chapter 11 up to this point we have set out the method of constructing a table of this kind, and its most solid foundations were laid by us in chapters 11 and 12, it remains for us to present the table of selected fixed stars, which indeed differs only very slightly from Tycho's. It is no wonder, moreover, that so small a divergence has arisen between our observations and those of that great astronomer, or the conclusions drawn from the observations, since we did not use his dioptras but our own, which we shall describe in the *Liber Organicus*, and which, in the judgement not only of ourselves but of those who were present when we were observing and to whom we showed both the Tychonic method and our own, give a somewhat clearer and finer observation.

[Margin: The cause of the disagreement indicated.]

Indeed, a greater difference is found between Tycho and the Landgrave of Hesse. In addition, Tycho uses a greater parallax of the Sun and a greater obliquity of the ecliptic than we do; and so a slight difference has arisen in the right ascension of the Sun, on which the ascension of the fixed stars depends. Let us indeed hear Tycho himself, on p. 93 of the *Epistolae Astronomicae*, writing thus to the Landgrave of Hesse: *"That we nevertheless differ in the longitudes of the stars by about five minutes, by which mine are found to stand further forward, deserves its excuse among those who have sufficiently surveyed the perplexing labyrinths of this subtle inquiry, etc.*

since those ancient leaders of astronomy hardly attained the truth in these matters to within a sixth part of a degree." These, then, are those five or six minutes about which Kepler said, in the groundwork of his *Ephemerides*, p. 15: *There remains undecided, concerning six minutes of the Sun's motion from the fixed stars, a dispute between the Landgrave and Brahe, and the testimonies waver this way and that. For the parallax of Venus cannot be as great as Brahe assumed in the* Progymnasmata*, fitted to the parallax of the Sun handed down by the ancients.* For we have already seen in chapter 11, Problem 6, that Tycho observed the right ascension of the bright star of ♈, with which he began the others, by its distance from

Venus. Accordingly Longomontanus, who uses a smaller parallax of the Sun than Tycho, always falls short of Tycho's catalogue in his catalogue of fixed stars by a single minute in their longitude, as he himself also attests in Book 1 of the *Theorica*, chapter 4, saying: *In restoring the fixed stars, observations repeated where needed, until they settled at as nearly as possible the same minutes; and because we had diminished the mean longitude of the Sun by more than a minute, we subtracted as much, star by star, from the longitude of the stars in Tycho's canon.* Granted, Kepler sets down Tycho's numbers in his catalogue, notwithstanding the reduction of the parallax.

[Margin: Examples of the disagreement among the older astronomers on the places of the fixed stars.]

But far greater is the disagreement among the older astronomers, both with one another and with the more recent ones. Noticing this, that shrewd man Petrus Nonius [Pedro Nunes] says in Book 2, *De Observatione*, p. 49: *But either through the deceptiveness of their instruments, or because the latitudes of the places where they made their observations were not sufficiently ascertained, they disagree among themselves. For Vernerus [Johannes Werner] found Spica at 16° 54′ of Libra, but Copernicus, using the same method, at 17° 14′ of the same sign; and Girolamo Cardano says that in Italy, twenty-two years later, he found the same star again, by eleven observations he himself made, at 16° 18′ of Libra. We meanwhile, although we make constant observations of the stars, since we do not yet have such instruments as we could confidently use, affirm nothing for certain and hold with al-Battānī.* But as a specimen of this disagreement, let there stand the longitude and latitude of ten of the more notable stars observed in the years 1585 and 1586 by the Landgrave of Hesse and by Tycho, with the Alphonsine and Copernican calculation, as found in Tycho, in the *Epistolae Astronomicae*, pp. 39, 52, 55. To these I have added the place owing to the same stars by the calculation of Ptolemy, who fixes his roots in the year of Christ 132, and of al-Battānī, in the year 880; of these the former requires 100 years for one degree, the latter only 66.

[Margin: A specimen of the same disagreement in 10 stars.]

Longitude of the fixed stars from the beginning of Aries (the first six value columns); latitude (the last three).

In the year of Christ 1586. 10 stars	Long.: Ptolemy	Long.: al-Battānī	Long.: Al-fonso	Long.: Coper-nicus	Long.: Land-grave	Long.: Ty-cho	Lat.: Ptolemy, al-Battānī, Alfonso, Copernicus	Lat.: Land-grave	Lat.: Ty-cho

There also exists, at the end of the works of Cardinal Cusanus, a table of 53 fixed stars verified to the year 1440 from his own observation and that of the Cardinals of Nicaea and of Ailly, which departs not a little from the Alphonsine and from the truth.

[Margin: Authors of the catalogue of right ascensions and declinations. ✳]

II. The principal authors who set out catalogues of the fixed stars with right ascensions and declinations are: Io. Stadius [Johannes Stadius], p. 215 of the *Canones Bergenses*; Magini, in the *Introduction to the Ephemerides*, part 4, chapter 5, from the Prutenic Tables for the year 1581, together with the mediations of the heaven [Mediationibus cæli]; Origanus, vol. 1 of the *Ephemerides*, p. 204, from Copernicus and Tycho, with the mediations of the heaven, for the year 1620; Grienberger, in his catalogue from p. 57, from Tycho, Piffero [?] and Clavius, for the year 1600; Argoli, in the *Canones* of his *Ephemerides*, after chapter 29, from Tycho, for the year 1640; Francesco Montebruni, at the end of his *Ephemerides*, partly from Tycho and partly from Lansbergen, for the year 1650; Tycho himself, vol. 1 of the *Progymnasmata*, p. 276. On the observations of declinations made by Aristillus, Timocharis, Hipparchus and himself: Ptolemy, Book 7, chapter 3; Tycho, vol. 1 of the *Progymnasmata*, especially pp. 155, 276, 361, chapter 2 passim, and in the *Epistolae Astronomicae*, p. 52; and Lansbergen in the *Treasury of Observations*, Class 7.

Our table of 70 stars, verified to the completed year 1644, with right ascension, declination, longitude and latitude, and with an equation to be added or subtracted so that it may serve back to the year 1500 and forward to 1800, is at the end of this Sixth Book, so that it may be found more readily.

CAPVT XV.

Chapter 15.

An Stellæ Fixæ Latitudinem mutent per ſe, aut per accidens ad mutationem Obliquitatis Eclipticæ.

Whether the fixed stars change their latitude of themselves, or incidentally, with a change in the obliquity of the ecliptic.

I. It is an old opinion, held ever since Hipparchus, that the non-wandering stars move by a proper motion in circles parallel not to the equator but to the ecliptic, and described from the poles of the ecliptic. Hipparchus and Ptolemy thought it a sufficient argument for this that they had moved in longitude,

according to the succession of the signs, in such a way as always to keep the same distance from the ecliptic in the circles of latitude, that is, the same latitude.

[Margin: Hipparchus's opinion on the immutable latitude of the fixed stars.]

And of Hipparchus, indeed, Ptolemy says as follows in Book 7 of the *Magna Syntaxis*, chapter 3: *Hipparchus too appears to have agreed that this motion takes place about the poles of the zodiac. For in his treatise on the displacement of the solstitial and equinoctial points he gathered, from the observations of Timocharis and his own, that Spica has kept the size of its distance in latitude with respect not to the equinoctial circle but to the ecliptic, and that both formerly and afterwards it was 2° farther south than the circle through the middle of the signs. For this reason, in his treatise on the length of the year he assumes that this motion takes place on the poles of the zodiac. Yet he was in doubt (as he himself admits), since he neither regarded the observations made in the time of Timocharis as certain, because they had been taken too crudely, nor was the time that had elapsed in the meantime sufficient for a perfect understanding of this matter.* Adding his own opinion straight after these words, he goes on to say: *But we, finding this through observations over a longer time, and in nearly all the non-wandering stars, affirm that their motion takes place on the poles of the zodiac:*

for observing their distances from the zodiac in latitude, in a great circle described through the poles of the zodiac, we find them nearly the same as and equal to those gathered and written down by Hipparchus, or with the smallest difference, such indeed as can creep in through error on the part of any observer. And a little later: *But from all of these the same latitude with respect to the circle through the middle of the signs is found.* He confirms this, first, from the third, or middle, following star of the Pleiades, whose north latitude was observed both by Timocharis at Alexandria in the year of Nabonassar 465 and by Agrippa in Bithynia in the year of Nabonassar 840, and was found by both to be 3° 40′. Second, from Spica, whose south latitude, very nearly 2°, was observed both by Timocharis in the year of Nabonassar 466 and by Menelaus at Rome in the first year of Trajan, that is, of Nabonassar 845. Third, from the northern star in the brow of Scorpius, whose north latitude of 1° 12′ he says was observed both by Timocharis in the year 454 of Nabonassar and by Menelaus in the year 845 of Nabonassar; although he also uses these three pairs of observations to confirm the motion of 1° in 100 years.

[Margin: Al-Battānī's opinion in favour of the immutability of latitude.]

II. This is the opinion of Ptolemy, to which al-Battānī subscribed, who, though nearly a thousand years after Hipparchus, nevertheless found no variation in the latitude of the fixed stars. For he says in chapter 51: *The motion of the fixed stars has been found to be on the two poles of the circle of the signs; and since the time their motion was detected it has in no way departed from this, nor have their latitudes been altered.* [Margin: And Alfonso's.] So too Alfonso in his Tables assigned to the fixed stars the same latitude as Ptolemy. [Margin: Regiomontanus's.] Regiomontanus holds the same in the *Epitome of the Almagest*, Book 7, Proposition 3, and [Margin: Peuerbach's.] Peuerbach with all

his commentators, in the *Theorica* on the motion of the eighth sphere, among whom [Margin: Reinhold's.] Reinhold says, p. 230: *These stars are gradually carried to other places on the poles of the ecliptic, not of the equator. A clear argument of this is that in that progress they change their declination, not their latitude.* [Margin: Copernicus's.] Nor did Copernicus himself think otherwise, since he took all motion away from them, and in Book 2, chapter 14, attributed to the fixed stars the same latitudes as Ptolemy, and in Book 3, chapter 2, asserted this immutability of latitude as beyond doubt. Finally, Augustinus Riccius [Agostino Ricci] defends the same immutability in his treatise on the motion of the eighth sphere, p. 31, and Kepler in the Rudolphine Tables, chapters 12 and 34, precept 195, whose words we shall give below. But Boulliau, in Book 5 of the *Astronomia Philolaica*, chapter 4, whose words and reasons we shall likewise adduce shortly, pronounces it uncertain.

[Margin: By whom a change in the latitude of the fixed stars has been asserted.]

III. The contrary opinion, however, was first discovered, so far as I know, by Pomponius Gauricus [Pomponio Gaurico], or rather by Thebit [Thābit ibn Qurra] and Regiomontanus in the treatise on the motion of the eighth sphere. [Margin: The opinion of Pomponio Gaurico.] Praising them, Gaurico affirms that the north latitudes of the fixed stars have decreased since the time of Ptolemy by two-fifths of a degree, and that the south latitudes have increased by the same amount. [Margin: The doubt of Stadius.] So Io. Stadius reports in his Commentary on the fixed stars, chapter 1, adding his own opinion in these words: *But this will have to be ascribed either to the obliquation of the ecliptic, narrower by two-fifths since the time of Ptolemy up to now, or the matter itself, otherwise of doubtful credit, was to be propped up by observations, and hence by geometrical demonstrations.*

[Margin: Christoph Rothmann's.]

These were succeeded by Christoph Rothmann, who, as Tycho reports in a letter to the Landgrave of Hesse dated 1587 January 18 and in another to Rothmann dated January 20 of the same year, affirmed that the latitudes of the fixed stars had been detected by him to have varied from the amount assigned to them in antiquity.

[Margin: The opinion of Tycho, Longomontanus and Lansbergen.]

Tycho himself, however, in the same place and in vol. 1 of the *Progymnasmata*, chapter 2, pp. 233 and 247, as also Longomontanus at the end of his commentary on the fixed stars, and Lansbergen in his tables, precept 12 and Canon 3, which is found on p. 103, and in the *Theorica motuum*, chapter 8, consider that the fixed stars have undergone no change of latitude other than what comes to them from an external cause and incidentally, through the approach or withdrawal of the ecliptic as it changes its obliquity. If any greater change is found in their latitude than the change of the ecliptic allows, Tycho thinks this is to be ascribed partly to less exact observation, partly to calculation and a slip in solving the triangles, partly to the negligence of copyists, or to inexperience in

a matter of such subtlety. And he attests that Rothmann himself was of the same opinion, in the letter already mentioned, p. 65, in these words: *That you have noticed that the fixed stars change their latitudes, and this proportionally, according to the variation of the obliquity of the ecliptic, pleases me greatly. For I too had long been gathering to myself that something of the kind had happened:* etc. And a little later: *And since this matter is of great moment, and has been noticed by no one else, so far as I know, except you alone,* etc. But Tycho is mistaken, if what Stadius reports from Thābit about Gaurico is true, that he long ago caught the scent of this variation.

[Margin: Tycho's foundations and method.]

IV. Tycho's foundation, in that second letter and in the *Progymnasmata*, and his method of establishing this change, are as follows. First, because he held suspect the numbers noted in the table and in the common version of Ptolemy, on the ground that they do not agree with the unvarying distance of the fixed stars, he chose Spica, as more certainly observed by Timocharis, Hipparchus and Ptolemy, both because of its nearness to the equinoctial point and because Ptolemy often mentions it. And from the declinations of Spica observed by them, which Ptolemy gives in Book 7, chapter 3, assuming the obliquity of the ecliptic in that age as 23° 51′ 20″ and the south latitude of Spica as 2°, he deduced the longitude of Spica by triangles, as in the following small table [laterculo].

With the obliquity of the ecliptic set at 23° 51′ 20″ and the south latitude of Spica at 2°.

And with the observed declination of Spica, for	Declination	Longitude of Spica
Timocharis	1° 24′ Bor.	♍ 21° 53′
Hipparchus	0° 36′ Bor.	♍ 23° 53′
Ptolemy	0° 30′ Austr.	♍ 26° 38′

Second, from the difference in longitude of several selected stars from the longitude of Spica, observed by himself, he gathers their longitude appropriate to the time of Timocharis, Hipparchus and Ptolemy. Third, from that longitude, together with their declination observed by the same men and reported by Ptolemy in Book 7, chapter 3, and with the distance of the poles, or the obliquity of the ecliptic, appropriate to their age, he computes their latitudes by Problem 4 of our Chapter 12. Comparing these with one another and with the latitude appropriate to them in the year of Christ 1600, he gathers that as great a difference has arisen in it as the change in the obliquity of the ecliptic requires, apart from Aldebaran, Sirius and the bright star of the Vulture. Thus, for example, the Head of Castor is distant in longitude from Spica 93° 35′ by Tycho's observation; therefore in the time of Timocharis it was in ♊ 18° 18′, since Spica was then in ♍ 21° 53′, etc. But so that Tycho's principles and conclusions can be surveyed at one glance, here is a table put together from p. 69 of his *Epistolae Astronomicae* and from vol. 1 of the *Progymnasmata*, from

p. 236, in which, however, he sets the ancient latitude of the bright star of the Pleiades and of the more northerly star in the brow of Scorpius from the very observation of the ancients and the calculation of Ptolemy, Book 7, chapter 3, not from his own.

Synopsis of Tycho's calculation for the change in the latitude of the fixed stars.

Names of the stars	Observing astronomers	Tychonic longitude	Observed declination	Deduced latitude	Difference of latitude from the Tychonic
Head of Castor	Timocharis	♊ 18° 18′	33° 0′ B	9° 43′ B	19′
	Hipparchus	♊ 20° 18′	33° 10′ B	9° 42′ B	20′

[Margin: Tycho's foundation is shaken.]

V. Yet this whole great apparatus of 11 stars has only four that favour Tycho's opinion: namely the Head of Castor, the Bright star of the Pleiades, the northern star of Scorpius and, if you stand by the Tychonic reduction, the Bright star of the Vulture. For the ancient latitude of these stars differs from the Tychonic, and very nearly from ours, by as much as the obliquity of the ecliptic is said to have been greater at those times, namely 19′ or 20′, or, if we are speaking of the times of Agrippa and Menelaus, 15′. It has two stars, though, that protest strongly against Tycho, namely the Heart of Leo and Aldebaran, whose ancient latitude differs from that of our own time by no more than 2′ or 3′, if for the former you follow Timocharis and for the latter Hipparchus. The remaining five, since they do not keep the proportion owed to the variation of the obliquity, but have a greater difference of latitude when the difference of obliquity was less, and a lesser one when it was greater, certainly do not vote for Tycho, but rather against him.

Further, to draw the 7 stars that resist him round to what he wishes, Tycho tries to cast suspicion on the declinations observed by the ancients, or on the figures for them reported by Ptolemy; and in some places he does this with a probable conjecture. But why does he not call into suspicion the declinations of the four former stars? Surely because, taken as they stand, they support his opinion. I ask likewise why he rejects those noted by Ptolemy and substitutes others, sought out by his own calculation, in their place, and yet accepts the latitudes of the Bright star of the Pleiades and of the northern star in the brow of Scorpius as Ptolemy reports them, just as he accepts the latitude of Procyon on p. 71 of the *Epistles*? Certainly for no other reason than that the former harm an opinion he has already formed, while the latter favour it. So Tycho concludes with too much exaggeration, on p. 246 of the *Progymnasmata*, that *through the stars listed it has been proved by sufficiently evident testimony that the latitude of the fixed stars changes according to what the change in the obliquity of the ecliptic requires.*

VI. To give my own view on this matter, then, I shall set it out distinctly in three propositions.

[Margin: 1st conclusion.]

Propoſitio 1. Si Obliquitas Eclipticæ mutatur, Latitudines tamen Fixarum non mutantur neceſſariò.

Proposition 1. If the obliquity of the ecliptic changes, the latitudes of the fixed stars nevertheless do not necessarily change.

This is proved. For if the fixed stars by their proper motion describe circles parallel to the ecliptic, they can certainly direct their course by the moving ecliptic and its poles, that is, by the ecliptic that the centre of the Sun describes at the time by its annual motion. Indeed, it is necessary to use this moving ecliptic whenever the latitude and longitude of the fixed stars are deduced from their right ascension, as observed through the distance from the Sun: for then the right ascension of the Sun, which is sought as the foundation for those quantities, depends on the obli- quity of the current ecliptic, and is deduced trigonometrically from its angle and the declination of the Sun.

[Margin: 2nd conclusion.]

Propoſitio 2. Si Obliquitas Eclipticæ Solaris mutatur, & pro ratione huius mutationis mutatur Latitudo Fixarum, ob Eclipticæ acceſſum ac receſſum ad ſtellas Fixas; Ecliptica cui Fixæ parallelῶs incedunt, diuerſa eſt ab Ecliptica ſolari.

Proposition 2. If the obliquity of the Sun's ecliptic changes, and the latitude of the fixed stars changes in proportion to this change, because the ecliptic approaches and recedes from the fixed stars, the ecliptic to which the fixed stars run parallel is different from the solar ecliptic.

This is proved, because if the fixed stars by their motion in longitude described a path parallel to the Sun's moving ecliptic and followed it, they would retain the same latitude: as it receded from the equator they would recede, and as it approached they would likewise approach. Since, then, the opposite is posited, it follows that the ecliptic the fixed stars have regard to of themselves is not the Sun's moving ecliptic.

[Margin: Kepler's corollaries from Tycho's hypothesis on the extrinsic change in the latitude of the fixed stars.]

Kepler, moreover, seems to have indicated these two distinct ecliptics in chapter 12 of the Rudolphine Tables, where he says: *Although Tycho did not entirely deny that the obliquity was greater under Ptolemy and Hipparchus, he nevertheless detected this: that the fixed stars do not undergo this variation together with it. For the ecliptic is not fixed beneath the fixed stars, so as to depart from and approach the equinoctial together with them; rather, the ecliptic alone nods away from or towards both the fixed stars and the equinoctial. If this is so, then that Prutenic variation of*

declinations and ascensions becomes altogether useless and superfluous, at least for the practical treatment of the fixed stars. For however great the declination and ascension of a fixed star comes out through the ancient obliquity of the ecliptic and the star's ancient latitude from it, exactly so great does each come out through both modern values as well. From this Tychonic hypothesis the same Kepler adds, in the last chapter of the Rudolphine Tables, precept 195: *For although the latitudes of the fixed stars perhaps change from the ecliptic, this nevertheless happens not by a real motion of the fixed stars, but by the departure of the ecliptic itself from the fixed stars and the equator: where the fixed stars and the equator, with respect to this change at least, do not wink at one another.*

In this hypothesis, however, it would be better to note down the latitudes that belong to the fixed stars in themselves and immutably with respect to their own proper ecliptic, whether that is the ecliptic midway between the least and the greatest solar ecliptic, which Kepler calls the Royal Road, or not, than to put only the current latitudes in the catalogue, provided there were a way of distinguishing it from the Sun's ecliptic.

[Margin: 3rd conclusion.]

Propoſitio 3. Probabilius eſt Fixarum ſtellarum Latitudinem non mutari: Poſita verò Eclipticæ obliquitatis mutatione, aut probabilior eſt Latitudinis Fixarum Immutabilitas aut incerta Mutabilitas.

Proposition 3. It is more probable that the latitude of the fixed stars does not change; but, given a change in the obliquity of the ecliptic, either the immutability of the latitude of the fixed stars is the more probable, or its mutability is uncertain.

First, because if any foundation exists, above all the Tychonic one discussed above, it rests on the change in the obliquity of the ecliptic; but it is more probable that the obliquity of the ecliptic is immutable, as we have sufficiently established in Book 3, chapter 27.

Second, because there are some fixed stars whose ancient latitude has been found the same as the one recently observed, however much our opponents assume the ancient obliquity in the time of Hipparchus and Ptolemy to have been greater by about 22′. Of this kind are not only the latitude of Capella, which is now 22° 50½′ and in Hipparchus's time was 22° 50′, and that of Aldebaran, which under Hipparchus was 5° 33′ and is now 5° 31′, and Regulus, whose latitude under Timocharis was 23′ and is now 26′, as Tycho himself deduces and admits, in the places cited above, from the ancient obliquity, from the declinations they observed and from the corrected longitude; but also far more other stars, as anyone running through Ptolemy's catalogue and comparing it with Tycho's will find on every side. From this a probable argument is also taken against the change in the obliquity of the ecliptic. Tycho, on p. 246 of the *Progymnasmata*, may think that, other things being equal, it is more incredible that the ancients erred in observing the obliquity of the ecliptic

than in the declinations of the fixed stars, since they could easily obtain the obliquity by the parallactic rulers. But Tycho does not notice that the obliquity of the ecliptic was observed by Ptolemy with a quadrant of no great size, as is clear from Book 1 of the *Almagest*, chapter 11, whereas the rules were devised by him later, when he began to observe the parallaxes of ☾, as is evident from Book 5 of the *Almagest*, chapter 12.

Third, there are many stars whose latitude at the time of the ancient observations is found to be greater than the recent latitude, when it should have been less, and some whose latitude is found to be less, when it should have been greater, if it had to change according to the variation in the obliquity of the ecliptic. Of this kind are not only Aldebaran, Sirius and the Northern Scale, as Tycho himself admits above, but far more others passed over in silence by Tycho, which meet anyone comparing Ptolemy's catalogue with Tycho's on every side. Such are the Bright star of the Vulture, Scheat of Pegasus, the Head of Andromeda and the Heart of Hydra.

Fourth, there are many stars whose latitude should have increased and did increase, or should have decreased and did indeed decrease, but neither exactly nor nearly by as much as the change in the obliquity admitted by our opponents required. Of this kind are not only some enumerated in the preceding catalogue, but very many others in Ptolemy's catalogue compared with Tycho's: such as the three in the tail of the Great Bear, the Bright star of Lyra, of Corona and of Aries, the Tail of Cygnus, the Side of Perseus, the Shoulder of Auriga, the Loins of Leo[54], the Shoulders of Orion, Fomahant [Fomalhaut], and very many others of lesser note.

Fifth, since in the places adduced Tycho sometimes accepts latitudes or declinations as they stand in Ptolemy, namely when they support a latitude of the fixed stars that changes in step with the change of the obliquity, and sometimes does not accept them, and calls them into suspicion of error in the ancient observations or in the transcription of the numbers, one may reason as follows. Either it is more probable that most of those noted by Ptolemy are false or erroneous, or that fewer are. If most, then from the ancient observations compared with more recent ones it either remains doubtful whether the latitude of the fixed stars changes or not, or else, in such a doubt, the pronouncement should rather be for immutability, because that agrees better with the immutable distance in longitude and with a motion parallel to the ecliptic itself known to us; nor should a new motion be charged to the heavens without sufficient foundation. But if it is more probable, as it certainly seems to me, that not most but fewer of those noted by Ptolemy suffer from faults or errors, then, since most of Ptolemy's do not support the mutability of latitude, it is more probable that latitude does not change.

[Margin: Boulliau's prudent judgement.]

[54]the page prints *Luni bi Leonis*, for *Lumbi Leonis*

This controversy can certainly never be settled evidently unless the numbers of the latitudes that Tycho, we and other more recent astronomers hold as ratified and evidently observed reach posterity uncorrupted, and posterity after many centuries observes the motion of the fixed stars with equal evidence. This is very nearly the opinion of Boulliau, Book 5, chapter 4, who, having acknowledged that the latitudes of few stars stand for Tycho and of many against him, said prudently: *From the contrariety of these observations we can certainly draw nothing. Nor are the earlier examples cited sufficient to establish that change of latitude. When, therefore, after some centuries there have arisen astronomers who will treat the heavenly matters with the same diligence and expense with which Tycho Brahe, a man never sufficiently praised, took them up in the past age, they will be able to pass a certain judgement on this variation of latitude.* In the same place he affirms that in a very old codex of Ptolemy, kept in the library of the Most Christian King, some numbers are noted in capital Greek letters otherwise than they commonly circulate, and he adduces four examples of this ambiguity. Yet expense on the Tychonic scale is not necessary for this or other astronomical work, as I shall show in the *Liber Organicus*.

SCHOLION.

Scholium.

[Margin: Two cautions for comparing the latitudes of Ptolemy and of Tycho.]

I. *If anyone wishes to weigh Ptolemy's latitudes and compare them with Tycho's, to see which they are that favour Tycho's opinion and which oppose it, he must note two things. First, that those near the equinoctial points must have undergone a small variation from the time of Ptolemy to Tycho, even if the obliquity of the ecliptic is taken to have varied by almost 20′. So if a latitude has varied markedly, as with Arcturus, whose north latitude is 31° 30′ for Ptolemy and 31° 3′ for Tycho, it opposes Tycho; for it ought to be a little greater or almost equal, as Boulliau too points out, Book 5, chapter 4. Second, a distinction must be made between stars whose longitude belongs to the northern semicircle and those whose longitude belongs to the southern. For among the northern stars, a north latitude should have increased and a south latitude decreased, if Tycho's opinion is true; among the southern stars, a south latitude should have increased and a north latitude decreased; and indeed, near the solstitial points, by about 20′. But when the difference should not exceed 5′, nothing can be made out of Ptolemy's table, because in it no minutes are set below multiples of five, and indeed in most entries only tens of minutes are noted, as the imperfection of the astrolabe dictated, which he admits he used, Book 7, chapter 2.*

CAPVT XVI.

Chapter 16.

Quantus ſit Motus Fixarum in Longitudinem, & Quanta illarum Periodus.

How great the motion of the fixed stars in longitude is, and how great their period.

[Margin: 1st opinion, of Hipparchus and Ptolemy.]

I. The first opinion was that of Hipparchus, in Ptolemy, Book 7 of the *Magna Constructio*, chapters 2 and 3, which Ptolemy confirms there from the places of three stars. For the Heart of Leo was observed at ♌ 29° 50′ by Hipparchus, in year 50 of the third Callippic period, that is, in the year 128 before Christ, but at ♌ 2° 30′ by Ptolemy, in year 2 of Antoninus, or the year 138 of Christ. So if it advanced 2° 40′ in 265 years, it seems to have completed one degree in 100 years: thus chapter 2. But from chapter 3 of Ptolemy: Timocharis, in year 36 of the first Callippic period, namely 294 before Christ, observed Spica at ♍ 22° 20′. Menelaus, in year 1 of Trajan, which Ptolemy says is year 845 of Nabonassar, that is, 97 of Christ, observed the same star, by its conjunction with the Moon, at ♍ 25° 45′, according to Ptolemy's reckonings. Therefore it advanced 3° 25′ in 391 years, and therefore 1° in 114 years, granted that Ptolemy says it advanced 3° 55′ in 391 years, so as to infer 100 years for one degree. Again, Timocharis, in year 36 of the first Callippic period, by contact with the Moon and Ptolemaic calculation, observed the northern star in the brow of Scorpius at ♏ 2°. Menelaus, likewise from the Moon's application, in year 1 of Trajan, observed the same star at ♏ 5° 55′, if you accept Ptolemy's calculations: so in 391 years it progressed 3° 55′, and thus in 100 years very nearly 1°.

[Margin: The annual motion and period of the fixed stars according to Hipparchus and Ptolemy.]

From this it follows further that, if the motion of the fixed stars is uniform, in the opinion of Hipparchus and Ptolemy they will complete the period of the zodiac only in 36000 years, and move 36″ in one year. Afterwards al-Farghānī subscribed to Ptolemy, *Differentia* 13, as did Proclus in the *Hypotyposes*.

[Margin: Al-Battānī's opinion.]

II. The second opinion was that of al-Battānī, chapter 51, where he asserts that the fixed stars advance in longitude one degree in 66 years. For he says that the northern star of the brow of Scorpius, found by Menelaus at 5° 55′ of Scorpius in year 845 of Nabonassar, was found by himself in year 1627 of Nabonassar at 17° 50′ of Scorpius, and so in 783 years it advanced 11° 50′ in round figures, or 11° 55′. On this basis he rightly derives that it advanced one degree in 66 years. If, however, you compare al-Battānī's observations with Ptolemy's, the years will be 64 1/6. For Ptolemy, in year 886 of Nabonassar, records that he observed Regulus at ♌ 2° 30′ and the northern star of the brow of Scorpius at ♏ 6° 20′. But al-Battānī, chapter 51, in year 1627 of Nabonassar, observed Regulus at ♌ 14°, as the common codices have it, granted that Copernicus, Book 3, chapter 2, reads ♌ 14° 5′, and the northern star of the brow of Scorpius at ♏ 17° 50′. Now the interval of years is 741, and the advance of each star 11° 30′, or 690′. So as 690′ is to 741 years, so 1°, or 60′, is to 64 12/69 years.

[Margin: The period and annual motion of the fixed stars.]

Further, if 66 years are supposed to be owed to one degree, the motion of the fixed stars comes out at 23760 years and the annual motion at $54'' 32''' 43''''$ 38^{v} 20^{vi}.

[Margin: Alfonso's earlier opinion.]

III. Most, however, subscribed to al-Battānī up to Copernicus, and above all King Alfonso, although he had earlier followed a different opinion, as Agostino Ricci testifies in his treatise on the motion of the eighth sphere, chapters 5, 38, 42 and 43, and, from him, Erasmus Reinhold in the Peuerbachian *Theorica* of the eighth sphere, pp. 235 and 244.

[Margin: Who is the author of the Alphonsine Tables?]

For when Moors and Jews skilled in astronomy had been summoned to Toledo by Alfonso, the chief among them was Isahac Hazan [Yitzchak ibn Sid], that is, Cantor: for he was Cantor of the synagogue of Toledo, and the Hebrews of Seville call him the author of the Alphonsine Tables.

[Margin: A fiction of the Cabalists on the motion of the fixed stars.]

Accustomed to cabalistic mysteries, then, he said that by the sabbatical year God signified the motion of the fixed stars that is called access and recess, and that its revolution is therefore completed in seven thousand years, because God, in Exodus 21, Deuteronomy 15 and Jeremiah 34, commands the Jews to rest every seventh year from agriculture and from exacting loans, and to release their slaves, etc.; and so this year was called *Scemita*, that is, the year of remission, and sabbatical, from the rest of the land. And since the same Lord commanded there that, when 7 weeks of sabbatical years had passed, that is, at the completion of every 49 years, a Jubilee year should be celebrated, so called from *Iobel*, that is, from the blast of the trumpet, a year in which everything sold returned to its former owners, Isahac therefore invented that these 49 years signify the restitution of the absolute motion of the fixed stars and of the auges of all the planets (since Ptolemy too, Book 9, chapter 5, thought that the fixed stars and the apogees of the five lesser planets move with equal motion), and that this revolution is therefore completed in forty-nine thousand years, and that all things then return to their former state, as in a universal Jubilee, as though a Great Year had run its course. Accordingly, on the Alphonsine view, the periodic time of the eighth sphere as it trepidates towards rising and setting is 7000 years; but the motion of the ninth sphere, which carries the fixed stars and the auges forward in the order of the signs, is of 49000 years, and so in one year by such a motion they complete about $26'' 26'''$[55] $54''''$: as much, that is, as the Sun advances in the time by which the solar year falls short of 365 days and six whole hours, which time for the Alphonsines is about 10^{m} 44^{s}, as Reinhold above, p. 235, Clavius in the *Sphere*, p. 56, and Maurolico, p. 88 of the *Cosmographia*. And this was the earlier opinion of the Alphonsines and of Alfonso himself.

[55] the page marks this figure with two primes

[Margin: Alfonso's later opinion, and his agreement with al-Battānī.]

IV. But Alfonso, 4 years after the Alphonsine planetary tables had been composed, namely in the year 1256 from the Incarnation, saw a book composed by Albuaſſim [?], translated from Arabic into the Sevillian tongue by Rabbi Iuda and presented to him by that same man, in which book the opinion of al-Battānī on the places and motion of the fixed stars was approved. So, *having recalled his former opinion, he embraced that of al-Battānī; and he placed the fixed stars, which are seen today set down in their places in Alfonso's tables, according to this same opinion, and wrote that the stars are carried in a continued course always towards the rising. The time of the roots of these same stars, moreover, is the year 1256, not 1252, as those note who have mixed the earlier Canons of Alfonso with the new roots of the stars. All this Abraham Zaguth [Avraham Zacuto] reports in his great composition.* So Ricci has it, chapter 46 on the motion of the eighth sphere. He himself there, and Reinhold, p. 244, both confirm that Alfonso adhered to al-Battānī, because Menelaus put the northern star of the brow of Scorpius at a distance of 35° 55′ from the autumnal equinox, while Alfonso has it at 53° 28′ from the same point. So if in the 1160 years that elapsed between Menelaus and Alfonso the star advanced 17° 33′, it certainly completed one degree in 66 years, granted that the earlier Alphonsine Canons put its advance at 15° 59′. Furthermore, al-Battānī observed and recorded the same star at ♏, 17° 50′, and Alfonso at ♏, 23° 28′. So according to Alfonso it advanced 5° 38′ in 381 years, and 1° in 66 years, granted that the same earlier Alphonsine Canons show it as having advanced only 4° 32′ in this time.

[Margin: Agreement of Pedro Nunes with al-Battānī.]

[Margin: And of Agostino Ricci.]

[Margin: And of Rabbi Levi.]

V. This same opinion of al-Battānī and the later one of Alfonso were followed by Pedro Nunes, Book 2 of *De observatione*, whose words I reported in chapter 14, near the end of number 1, and by Agostino Ricci, on the motion of the eighth sphere, chapters 5, 43, 46, 47, who affirms that both his own master Avraham Zacuto and that most diligent contemplator of the stars, Rabbi Leui [Gersonides], were of the same opinion. Rabbi Levi flourished 84 years after Alfonso, or in the year of the Incarnation 1336; for after many considerations on the stars, in the fifth treatise of the book *Milhamot heſcem* [*Milchamot HaShem*], that is, *of the Defences of God*, chapter 62, he affirms that the star Assimec, that is, Spica, as found by him, and the Heart of Leo, as observed, had advanced 6° 58′ since the time of al-Battānī, that is, in 460 years, and so had completed each degree in 66 years.

[Margin: And of Abraham Zaguth.]

Abraham, however, Zacuto, who taught astronomy at Salamanca, observed Spica, in the year of the Incarnation 1474, or about 223 years after Alfonso, by the application of the Moon to it, at ♎ 17° 10′. Alfonso in his own time put it at ♎ 13° 48′. So in 223 years it advanced 3° 22′, and therefore one degree in 66 years, although the earlier Alphonsine Canons assign only 2° 41′ to this interval.

Admittedly, for that figure of 66 to come out exactly, one must assume 219 years, which are those between Alfonso's later construction and the observation of Avraham Zacuto. Having reported these things, *Ricci* concludes that the fixed stars traverse one degree in any 66 solar years, and that their annual motion is 54″ 32‴ 43⁗ 38⁗⁗ 20⁗⁗.

[Margin: Annual motion of the fixed stars according to al-Battānī.]

VI. Before and after al-Battānī, however, there were not a few who, asserting a trepidation of the fixed stars, that is, an access and recess, now towards the east and now towards the west, brought in another, different opinion on the quantity of this motion, though on no sufficient foundations, as I have already shown in Book 3, chapter 28, where I reported those authors and their doctrines from number 6 and refuted them from number 11. So I will not repeat that opinion, just as I will not repeat that of *Fracastoro*, *Turrianus* [Giovanni Battista della Torre] and *Copernicus*, which *Reinhold*, *Magini*, *Longomontanus* and *Lansbergen* support, wholly or in part.

[Margin: The opinion of della Torre and Fracastoro.]

For *della Torre*, *Fracastoro* and *Copernicus*, in order to reconcile all the observations and opinions of the ancients, said that the fixed stars at times move most slowly, and then complete one degree in 100 years; at times most swiftly, and then one degree in 66 years; at times moderately, and then finish one degree in 72 years, which is very nearly the rate at which *Copernicus*, Book 3, chapter 2, affirms he found the fixed stars to have moved in his own century.

[Margin: The opinion of Copernicus.]

There, after surveying the observations of Ptolemy and al-Battānī, which we treated above, he adds that in the year 1525 he observed the meridian altitude of Spica at Frombork as very nearly 27°, under a pole altitude of 54° 19½′, and that Spica's south declination was therefore then 8° 40′. From this, by a most laborious calculation through rectilinear triangles, he derives Spica's place at ♎ 17° 21′. And from the declination of Spica of 30′ observed by Ptolemy, he derives that in Ptolemy's time Spica was at ♍ 26° 40′. So since it has advanced 20° 41′ in about 1390 years, he distributes those years so that from Ptolemy to al-Battānī, in 741 years, he gives 65 years to the completing of one degree, and from al-Battānī to his own time, or in 645 years, he assigns 71 years to one degree. But from the ancient observations of Spica, and also of Regulus and of the northern star of the brow of Scorpius, from Timocharis to Ptolemy, in 432 years, he attributes 100 years to one degree.

However, since the Tychonians found the pole altitude at Frombork to be 54° 22′ from the circumpolar stars, as we related in Book 3, chapter 27, number 2, the declination of Spica was 8° 38′. From this, with Spica's south latitude of 2° and the truer obliquity of the ecliptic, 23° 30′, there follows a place for Spica at that time of ♎ 17° 13′ by our Problem 7 of chapter 12, or ♎ 17° 14′ as *Tycho* has it, Volume 1 of the *Progymnasmata*, chapter 2. Granted that Lansbergen, in the *Treasury of Observations*, p. 156, using the uncorrected pole altitude of Frombork, 54° 19′, and diminishing Spica's altitude by 2′ 30″, brings

the Copernican declination to 8° 44′, and from it, with a latitude of Spica of 1° 58′ and an obliquity of the ecliptic of 23° 30′, derives a place for Spica of ♎ 17° 35′; but there is no need of a subtler correction, since Copernicus says he took the altitude of Spica approximately, not precisely.

[Margin: Copernicus's erroneous observation of Spica.]

VII. *Tycho Brahe*, Volume 1 of the *Progymnasmata*, p. 253, affirms that the fixed stars complete by their motion exactly 51″ every year. Therefore the tropical year, which is of $365^{d}\ 5^{h}\ 48^{m}\ 45^{s}$, is exceeded by the sidereal, which is of $365^{d}\ 6^{h}\ 9^{m}\ 26^{s}\ 43‴$, by a time of $20^{m}\ 41^{s}\ 43‴$, because in that much time the Sun completes 51″ in the zodiac and catches up with the fixed star with which it was in conjunction at the beginning of the year.

[Margin: Tycho's opinion.]

To establish this, *first*, he takes from Copernicus, Book 3, chapter 2, Spica's declination of 8° 36′, observed at Frombork in the year 1515, which, however, he corrects according to the truer pole altitude; and from it, with the obliquity of the ecliptic and the latitude of the star, he derives that Spica was at ♎ 17° 3′ 30″. So since he himself found the same star in the year 1585 at ♎ 18° 3′, and it advanced 1° 59′ 30″ [recte: 59′ 30″] in 70 years, it follows that it moved forward precisely 51″ each year.

[Margin: 1. Tycho's foundation.]

Second, Hipparchus, in *Ptolemy*, Book 7, chapter 3, in year 50 of the third Callippic period, which was the 196th from the death of Alexander and 128 before Christ, found Regulus at ♌ 29° 50′. *Tycho*, in the year of Christ 1585, that is, in the year 1713 after Hipparchus, found it at ♌ 24° 5′. So if it advanced 24° 15′ in 1713 years, the ratio of proportion requires that it advanced 50″ 9‴ 47⁗ in each year. And lest anyone suspect a large inequality in so great an interval of time, he takes from al-Battānī the place of Regulus at ♌ 14° 5′, observed about the year of the Lord 880. For if from Hipparchus to al-Battānī, namely in 1006 years, it advanced 14° 15′, and from al-Battānī to Tycho, in 705 years, it moved forward 10°, then certainly in one year it advanced 51″ or 50″ 56‴.

Nor does it stand against Tycho that Timocharis, in the year 454 of Nabonassar, found Spica at ♍ 22° 20′, Ptolemy, in the year of Christ 139, found it at 26° 40′ of ♍, and Tycho, in the year 1585, namely the year 2333 of Nabonassar, found it at ♎ 18° 3′, so that in the earlier interval, between Timocharis and Tycho, of 1879 years, it advanced 25° 43′, and 49″ 15‴ in each year, and in the later interval, of 1446 years, 21° 23′, and 53″ 15‴ in each year. For from this, rather, by bounding both and taking the mean, the annual motion of 51″ is confirmed.

[Margin: Tycho disposes of the objections.]

Tycho does not, however, claim that this answers to all ages, but at least to the nearest three or four centuries, without sensible difference. In these centuries, therefore, the fixed stars complete one degree in 70 years and seven months; and if they always moved so, their period would be of 25806 years.

Kepler carried this opinion into the Rudolphine Tables, p. 42, granted that he himself thinks the fixed stars do not move.

[Margin: The annual motion and period of the fixed stars.]

VIII. I come to *Longomontanus*, who in Book 1 of the *Theorica*, in the Commentary on the fixed stars, corrects, from his own hypothesis of the Moon's motion, the ancient observations of four stars taken from Ptolemy, Book 7, chapters 3 and 4, compares them with the Tychonic ones, and concludes that the mean annual motion of the fixed stars is 49″ 45‴, so that they complete their period in 26040 years and one degree in 72⅓ years. The stars, with their places and the times of the observations, are as set out below.

[Margin: The opinion and foundation of Longomontanus.]

[Margin: The mean annual motion and period of the fixed stars.]

Observers	Years of Nabonassar	Place in the zodiac
Timocharis	466	Spica ♍ 22° 30′
Hipparchus	630	Spica ♍ 24° 25′
Tycho	2350	Spica ♎ 18° 16′
Ptolemy	886	Regulus ♌ 3° 53′
al-Battānī	1626	Regulus ♌ 14° 27′
Tycho	2350	Regulus ♌ 24° 17′
Timocharis	454	Northern brow ♏ 1° 58′
Tycho	2350	of Scorpius ♏ 27° 36′
Timocharis	465	Of the Pleiades ♈ 29° 32′
Tycho	2350	the bright star ♉ 24° 24′

From these intervals of time and advances of the stars he gathers the annual motion of the fixed stars as below.

Annual motion of the fixed stars	″	‴
From Ptolemy to *al-Battānī*	51	0
From Hipparchus to *Tycho*	49	46
From Ptolemy to *Tycho*	49	37
From Timocharis to *Tycho*	49	10
From al-Battānī to *Tycho*	48	14
From Timocharis to *Ptolemy*	46	0
From Timocharis to *Hipparchus*	44	0

In this treatise, however, Longomontanus admits that the places of the fixed stars have been emended by means of the prosthaphaeresis of the equinoxes, as if this were better known and more certain than the unequal motion of the fixed stars which he is trying to establish, whereas the inequality of this motion ought rather to be set down first, as one of the chief foundations of that prosthaphaeresis. Moreover, this author could have gathered from the reckonings already mentioned a mean motion of a round 50″, with no less probability, as I shall show at number 11, argument 2.

IX. *Lansbergen* agrees with Longomontanus as regards the inequality of the motion of the fixed stars, which needs a prosthaphaeresis, but differs greatly in the measure of the mean motion. For in the

[Margin: The opinion of Lansbergen.]

Treasury of Observations, p. 160, he affirms that the fixed stars move 8‴ 25⁗ 12⁗′ 32⁗′′ every day and complete their period in 28000 years, and so 1° in 77 7/9 years. He does not, however, determine from which observations chiefly he derives this. But from some observations he himself set out beforehand a different motion of the fixed stars is not rarely gathered. For he puts Spica, observed by Ptolemy in the year of Christ 139, at ♍ 26° 28′ 4″, and by himself in the year 1599 at ♎ 18° 19′ 28″; the northern star in the brow of Scorpius, observed by Ptolemy in the same year 139, at ♏ 5° 51′ 4″, and by himself in the year 1601 at ♏ 27° 44′; and the Heart of Scorpius, by Ptolemy likewise in the year 139, at ♏ 12° 38′, and by himself in the year 1600 at ♐ 4° 30′. So from these intervals of years and advances of the stars it follows that they completed 53″ 52‴ or 54″ each year. But for Lansbergen it follows from the period of 28000 years that the fixed stars complete 46″ 2/7 each year, while from the daily motion he himself assigned they complete 51″ 15‴, as a careful calculator will find.

[Margin: Lansbergen's disagreement with himself.]

X. *Ismaël Boulliau*, Book 5 of the *Astronomia Philolaica*, chapter 3, rejects the observations of Timocharis, since Hipparchus too held them suspect as rather crude, on the testimony of Ptolemy, Book 7 of the *Almagest*, chapter 3, and selects the observations of Regulus and Spica made by Hipparchus, Ptolemy, al-Battānī and Tycho. The Ptolemaic one he corrects, because Ptolemy, Book 7, chapter 3, sets out the manner and circumstances of his observation, and so the star's place can be emended from a truer motion of the Moon. But he does not correct the observations of Hipparchus and al-Battānī, because it is not known by what methods and in what circumstances they observed the places of the stars. So the selected observations of Regulus are those set out below.

[Margin: Boulliau's opinion and foundation.]

Observers	Years of Nabonassar	Place of Regulus
Hipparchus	621	♊ [recte: ♋] 29° 50′
Ptolemy	886	♌ 3° 42′
al-Battānī	1627	♌ 14° 5′
Tycho	2350	♌ 24° 17′

Hence the annual motion of the stars:

From / to	″	‴	⁗
From *Hipparchus* to *Ptolemy*	52	31	42
From *Hipparchus* to *al-Battānī*	50	59	38
From *Hipparchus* to *Tycho*	50	54	29

From / to	″	‴	⁗
From *Ptolemy* to *al-Battānī*	50	26	27
From *Ptolemy* to *Tycho*	50	36	53
From *al-Battānī* to *Tycho*	50	47	18

Boulliau adds that from the given latitude of Spica of 2° south and the north declination of 36′, found by Hipparchus in the year of Nabonassar 621, its place follows at ♍ 23° 59′. From this, and from the place of Spica at ♎ 18° 16′ found by Tycho in the year of Christ 1601, which was of Nabonassar 2350, it comes about that in 1729 years Spica advanced 24° 17′, and that the annual motion was 50″ 33‴ 39⁗ 39⁗′ 52⁗′′ 22⁗′′′. But he concludes: *Nevertheless we shall retain the annual motion of the fixed stars from the motion of the Heart of Leo from Hipparchus to Tycho, in which we are little away from the limit of the motion of the fixed stars fixed by Tycho.* So in the *Philolaic Tables*, p. 10, he puts the annual motion of the fixed stars at 51″, following Tycho.

[Margin: Annual motion.]

In Book 5, chapter 3, however, for the sake of learning, he gives an observation of Regulus made by *Azophi*, or *Ebennen-Sophim*, in the year of the Arabs 325, or of Christ 936 November 18, the seventh day of the week, and reported by him in the book on the places of the stars, where Regulus is then put at ♌ 15° 12′. And he says that in the same volume is contained a catalogue of 47 fixed stars verified in the year of Christ 1364, in which Regulus is put at ♌ 20° 40′. Next he says that in the Persian Tables, which Georgios Chrysokokkes translated into Greek and which are kept in the library of the Most Christian King, there is found a catalogue of some fixed stars with this title: *This table [canonium] is adapted to the beginning of the Arab year 509, through 68 of whose years they advance one degree.* And there Regulus is put at ♌ 17° 30′. Now the Arab year 509, as computed by Hyginus, began in the year of Christ 1115 June 6, the fifth day of the week. So by comparing these years, and the place of Regulus observed by al-Battānī at ♌ 14° 5′ in the year of Christ 879, and at ♌ 24° 17′ by Tycho in the year 1601, Boulliau gathers the following motions of Regulus.

[Margin: Motion of the fixed stars from the Persian and Arabic tables.]

Annual motion of the fixed stars	″	‴	⁗
From *al-Battānī* to *Azophi*	69	18	37
From *al-Battānī* to the Persian Tables	52	7	7
From *al-Battānī* to the year 1364	48	51	57
From *Azophi* to the Persian Tables	46	31	0
From *Azophi* to the year 1364	45	5	20

Noſtra Opinio de Motu Fixarum.

Our opinion on the motion of the fixed stars.

XI. Having reckoned up all that has been said so far, and other observations, of which shortly, I have chosen an annual motion of the fixed stars of precisely 50″, and 72 years for completing one degree, and therefore a period of 25920 Julian years. Yet I do not deny that the Tychonic motion is almost equally as probable as ours; that you may use either of them; and that no certain and evident observation exists which could convict them of falsity. Indeed, since each motion has been gathered partly from evident and partly from far more probable observations, the places of the stars so far observed by others can rather be emended from it, especially with the addition of the difference of longitude, which is established with certainty for Tycho from his observations, as for us from ours. Further, I have been led to choose the motion already mentioned by the arguments set out below; before them, however, I set down the following observations.

[Margin: Our annual motion of the fixed stars, and period.]

First, Timocharis, as *Ptolemy* relates, Book 7 of the *Almagest*, chapter 3, in the year of Nabonassar 454, that is, 296 before Christ, observed Spica at ♍ 22° 20′, as Ptolemy gathers from the application to the Moon reported by him; and in the year of Nabonassar 466, or 284 before Christ, he observed it at ♍ 22° 30′. So if in 12 years it completed 10′, then certainly in 72 years it made 1°, and it moved forward 50″ each year. But since this interval is too short, let us compare his observation with ours. For at the end of the year of Christ 1644 we found Spica at ♎ 18° 54′ 20″. So the advance from the first observation of Timocharis was 26° 34′ 20″, and the interval is of 1940 years; from the second it is 26° 24′ 20″, and the interval of 1928 years. From the first there follows an annual motion of 49″ 26‴; from the second, 49″ 18‴. But since Ptolemy deduced the place of Spica from the place of the ☾ with no great certainty, and calls the observations of *Timocharis*, Book 7, chapter 1, *little explained and ambiguous*, and, together with Hipparchus, Book 7, chapter 3, *uncertain and too simple*, let us move on to others.

[Margin: 1. Observation.]

Second, Hipparchus, on the testimony of *Ptolemy*, Book 7, chapter 2, observed the Heart of Leo at ♌ 29° 50′ in year 50 of the third Callippic period, which was 128 before Christ. But since Ptolemy there relates that his own observations of the fixed stars were made with the astrolabe, by which he took the distance of the Moon from the Sun at sunset, and the distance of the fixed star from the Moon once the Sun had set, it is probable that he learned this from Hipparchus and that Hipparchus observed in a similar way. So since the refraction of the setting Sun, being nearly horizontal, was about 30′, and diminished the true longitude of the Moon by about as many minutes, it is probable also that the true longitude of Regulus was greater by about 30′, and thus that it was rather at ♌ 0° 20′. We, however, observed Regulus in the completed year 1644 at ♌

24° 55′ 20″. So in 1772 years it advanced 24° 35′ 20″, or 88520″. Dividing these by 1772 gives an annual advance of 49″ 1692/1772, or very nearly 50″.

[Margin: 2. Observation.]

Third, al-Battānī relates, chapter 51, that in the year of Nabonassar 1627, which was of Christ 879, Regulus was observed by him at ♌ 14°, as the common Latin codices have it. Add to these 30′ for refraction, on the reasoning by which we corrected observation 2 (since indeed, down to Tycho exclusively, the more common method of observing the places of the stars was by the distance of the ☾ from the setting Sun, and of the ☾ from the fixed stars on the following night), and the corrected place becomes ♌ 14° 30′, granted that *Longomontanus*, as I said at number 8, corrects it and brings it to 14° 27′. We, however, found Regulus in the completed year of Christ 1644 at ♌ 24° 55′ 20″. So in an interval of 766 years it advanced 10° 25′ 20″, that is, 37520″; dividing these by 766 gives an annual motion of very nearly 49″. But if we use al-Battānī's place, which Copernicus gives as 14° 5′ of ♌, the advance would be 10° 50′ 20″

[Margin: 3. Observation.]

and the annual motion 51″. So, holding to the mean, it will be 50″.

Fourth, comparing the observation of Hipparchus, of which we spoke in the second observation, and that of al-Battānī, of which we spoke in the third, whether you add 30′ to each for refraction or not, the advance of Regulus was 14° 10′ in 1006 completed years. So in one year it advanced 50″ 42‴.

[Margin: 4. Observation.]

Fifth, Hipparchus observed the north declination of Aldebaran, or the Eye of Taurus and brightest of the Hyades [succularum], at 9° 45′, as *Ptolemy* has it, Book 7 of the *Almagest*, chapter 3. But in chapter 2 he had said: *From the times of Hipparchus's observation to the reign of Antoninus, in which we chiefly observed very many advances of the non-wandering stars, about 265 years are gathered.* Now the first year of Antoninus was 137 of Christ, so the observation of Hipparchus was, not indeed certainly, but not improbably, in the year 128 before Christ. The south latitude of this star was found by us to be 5° 30′. From this, with the more probable obliquity of the ecliptic, 23° 30′, and the declination of 9° 45′, there follows by Problem 7, chapter 12, a place for Aldebaran at that time of ♉ 10° 27′. But we, in the completed year of Christ 1644, observed Aldebaran at ♊ 4° 48′. So in 1771 years this star advanced 24° 21′, and therefore in one year it advanced 49″ 30‴.

[Margin: 5. Observation.]

Sixth, in the first year of Antoninus, that is, 137 of Christ, *Ptolemy*, from Book 7 of the *Almagest*, chapter 3, observed the north declination of the same Aldebaran at 11°, and its south latitude is known to us as 5° 30′. From this and the constant obliquity of the ecliptic, 23° 30′, by Problem 7, chapter 12, the place of Aldebaran at that time comes to ♉ 14° 2′. So from Hipparchus to Ptolemy, from what is said here and in the preceding observation, it advanced 3° 35′ in 265 years, and very nearly 49″ in one year. But this interval is too small, and the observations are not so certainly known to us. Assuming, however, the

greater interval of 1506 years, which run to our observation of the year 1644, and the advance of Aldebaran, which was 20° 46′, the annual motion comes to 49″ 40‴.

[Margin: 6. Observation.]

Seventh, the north declination of the same Aldebaran was observed at 15° 37′ in the year of the Lord 1586, both by *Tycho* at Uraniborg, through a meridian altitude of 49° 42′, as found in his *Epistolae Astronomicae*, p. 52, since the altitude of the equator there is 34° 5′, and by *Lansbergen* in the *Treasury of Observations*, p. 151; and its south latitude is 5° 30′. From these and the obliquity of the ecliptic, 23° 30′, by Problem 7, chapter 10, the place of Aldebaran at that time is gathered as ♊ 4° 2′. But the Ptolemaic observation of the year of the Lord 137 gives its place at ♉ 14° 2′. So in an interval of 1449 years it crept forward 20°. Therefore, keeping the proportion, the annual motion is 49″ 40‴.

[Margin: 7. Observation.]

Eighth, the Persian mathematicians observed, in the year of the Lord 1115 June 6, Regulus at ♌ 17° 30′, and *Boulliau* holds that they are to be trusted on account of their diligence, as was related at number 10. We, however, in the completed year 1644 had Regulus at 24° 55′ 20″, and *Tycho* in the completed year 1600 at ♌ 24° 17′. So in the first interval, of 529½ years, it advanced 7° 25′ 20″, and in the second, of 485 years, from the Persians to Tycho, 6° 47′. Hence from the first there follows an annual motion of 50″ 28‴, and from the second 50″ 15‴. So, gathering the annual motion from the eight comparisons already mentioned, the result is as in the following table.

[Margin: 8. Observation.]

Annual motion of the fixed stars

Observations	″	‴
1	49	26
2	50	0
3	50	0
4	50	42
5	49	30
6	49	40
7	49	40
8	50	28
or	50	15

First, then, the argument for choosing a motion of 50″ rather than the Tychonic 51‴ [recte: 51″], which is otherwise very probable, was on account of the observations already mentioned, since it either answers to them or is a mean between the extreme ones, namely between 1 and 5 on one side and 8 on the other, and nearly between 4 and 6 or 7.

[Margin: 1. Argument.]

The *second* argument was that the round motion of 50″ is very nearly the mean between the extremes gathered from the reckonings of *Longomontanus* at

number 8 and the motion of 51″ of *Tycho* above at number 7 and of *Boulliau* at number 10. For, setting aside the uncertain observations of Timocharis, the extreme figures in *Longomontanus* are 51″ and 48″ 14‴. Their difference is 2″ 46‴ and its half 1″ 23‴; taking this from 51″ leaves 49″ 37‴. But by offsetting the uncertainty of Timocharis against the length of the interval from Timocharis to Tycho, he gathered 49″ 10‴, and from Ptolemy to al-Battānī 51″; the mean of these is 50″ 5‴. And the mean between 49″ 37‴ and 51″ is 50″ 18‴. So he could have chosen a round motion of 50″ no less probably than the 49″ 45‴ he did choose, since 50″ is the mean between 50″ 18‴ and 49″ 45‴, or between 49″ 10‴ and 51″, without sensible difference.

[Margin: 2. Argument.]

The *third* argument I drew from the data of *Lansbergen*, of which at number 9. For from his daily motion an annual motion of 51″ 15‴ is gathered; from the period of the fixed stars of 28000, an annual motion of 46″ 2/7; but from the places of the stars observed by him, and those of the ancients approved by him, 54″ is gathered; and the mean of these is 50″. So although this disagreement in him may displease, it is nevertheless permitted to show that he cannot by any right recoil from the motion of 50″.

[Margin: 3. Argument.]

The *fourth*, finally, was that an annual motion of 50″, or one degree in 72 years, is owed both to the times of Callippus, as *Reinhold* affirms in the *Theorica* of the eighth sphere, p. 241½, and before him *Regiomontanus*, Book 7 of the *Epitome*, proposition 5, and very nearly to the time from al-Battānī to us, as Copernicus admits, who gathers about 71 years to a degree in that interval, as I said at number 6. These two extreme intervals enclose the interval from Ptolemy to al-Battānī.

[Margin: 4. Argument.]

Not far from this are *Rabbi Iosue* [Rabbi Yehoshua] in the Talmud, book Horaioth, *Rabbi Moyses* [Maimonides] in the book Misnetora [Mishneh Torah], or of the repeated law, and *Rabbi Auenezra* [Avraham ibn Ezra] in the book Taamin, or of reasons, who, as *Agostino Ricci* reports in his treatise on the eighth sphere, chapter 4, said that the fixed stars complete one degree in 70 years; and Haly [ʿAlī ibn Riḍwān] too held this, Book 2 of the *Quadripartitum*. Granted that for other Moors and a few Jews, in Regiomontanus, the mean annual motion was 45″, and 1° of 80 years, and that for al-Zarqālī [Arzaëli] and Thābit they complete 1° in 75 years by mean motion, as the same *Ricci* has it.

[Margin: The opinion of the ancients and the rabbis.]

Finally, I see that this motion pleased our *Pétau*, Book 1 of the *Uranologion*, in the dissertations, chapter 3. Nor is there any danger that, if you use our motion rather than the Tychonic, you will be refuted by the risings and settings of the stars reported in Hesiod, who flourished 2400 years ago, as I shall say in the Scholia. But the fact that neither the Tychonic motion nor ours satisfies to the letter, whether with the less certain observations of the ancients, or with the more certain Tychonic ones and our own compared with each other, but

over too narrow an interval, ought to be no obstacle at all for those wise in astronomical matters. See the table with a synopsis of the opinions at the end of the Scholia.

SCHOLIA.

Scholia.

I. Johannes Kepler's *opinion I did not set down in the preceding chapter, both because he himself holds absolutely, with Copernicus, that the fixed stars do not move, but that their apparent motion is to be attributed to the equinoctial points creeping against the order of the signs, on account of the motion of the Earth; and because this same motion, which for Tycho and for us, with very many others, belongs to the fixed stars, he derives from no observation but follows Tycho, as is clear* first *from the Rudolphine table, p. 43, in which he puts the annual motion of the fixed stars at 51″.* Second *from the* Rudolphine Tables, *p. 115, where, speaking of the restitution of tropical and sidereal years, which he calls the great celestial year, he says that 25411 sidereal years equal 25412 tropical years of the Sun, and that the restitution of Julian and tropical years is nearly twice as slow. Granted that* Wendelen *in the* Idea of the Atlantic Tables, *p. 28, says that 25519 sidereal years equal 25520 tropical. For from this it follows that in one sidereal year the Sun completes the zodiac and 51″ besides, or 50″ 47‴, which is as much as the fixed stars are moved forward on the Tychonic reckoning.* Third *from the* Epitome of Copernican Astronomy, *p. 396, where he says that in the 2400 years from Hesiod to the year 1618 the fixed stars advanced about 34°, that is, 122400″, which, divided by 2400 years, give an annual motion of 51″.* Gassendi *too, in the* Institutio Astronomica, *by putting the fixed stars' completion of their period in 25000 years, gives them an annual motion of 51″ 19‴ 24⁗ and 70 1/3 years to one degree.*

[Margin: Kepler's opinion.]

[Margin: Wendelen's opinion.]

[Margin: Gassendi's opinion.]

II. *Let no one fear for our motion or the Tychonic from what the most ancient poet* Hesiod *sings of Arcturus in the books* Works and Days: *for he says that Arcturus in his age used to rise in the evening, 60 days after the winter solstice. Hesiod, moreover, flourished on Mount Helicon near Athens about the beginning of the Olympiads, that is, about the year 776 before Christ. So to the year of the Lord 1610 there are 2386 years, and to the year 1624, 2400 years. First, therefore, on this basis,* Longomontanus, *in the* Astronomia Danica, *Book 2 of the* Sphaerics, *chapter 4, Problem 2, gathers that the place of Arcturus at that time was at ♍ 12° 16′, taking the altitude of the pole on Mount Helicon as 37° 45′, according to Ptolemy, the apogee of the Sun at ♉ 20° 10′, and the place of the Sun, sixty days after the solstice of Capricorn, at ♓ 1° 10′. He then adds that in the year 1610, by a recent observation, Arcturus was at 18° 47′ ♎. So Arcturus would have advanced 36° 31′, or 131460″; dividing these by 2386 years, the annual motion would be 55″. But to draw this passage over to his own opinion on the precession of the equinoxes and the motion of the fixed stars, he says*

that about 2658 years are required, so that Hesiod is reporting the rising of Arcturus not of his own time, but of a time earlier by 272 years. He nevertheless has recourse to the refraction of Arcturus at the horizon, 30′, which cuts this interval by nearly half. But how easy it would be for us, with so much freedom to limit the small details of what is assumed, to defend Hesiod in such a way that the annual motion came out as 50″ or 51″! It is not worthwhile, however, to play at such labour on these matters, and the diversity among the authors who have examined this passage is quite enough to show this freedom, as will soon be clear.

III. *Now* Kepler, *in the* Epitome Astronomiæ, *at the end of Book 3, that is, p. 396, also quoting the verses of Hesiod, supposes 2400 years from Hesiod to the year of the Lord 1618, and an advance of the stars of 34°, from which, as I said in Scholion 1, an annual motion of 51″ follows. From this and from various assumptions he gathers that in Hesiod's time Arcturus used to rise in the evening on March 3 Julian, with the Sun placed at ♓ 5° 11′. But if anyone wants opinions on the rising of Canicula and of Arcturus in the times of Eudoxus or Pliny the Elder or others, let him consult* Kepler *in the already mentioned* Epitome, *from p. 378 to p. 398, and* Pétau *in the Dissertations on the* Uranologion, *Book 1, chapter 8, and Book 2, chapter 8.*

CAPVT XVII.

Chapter 17.

Qualis ſit Motus Fixarum & Quotuplex, Directuſne ſemper an Retrogradus cum Trepidatione, & Aequaliſne an Inæqualis.

What the motion of the fixed stars is like and of how many kinds; whether it is always direct, or retrograde with a trepidation; and whether it is equal or unequal.

I. We have already discussed the questions named in the title of this chapter, on the occasion of the precession of the equinoxes, in Book 3, chapters 28 and 30, setting out various opinions together with their authors and foundations. We showed that the fixed stars, besides the daily motion of the primum mobile, have a slow proper motion eastward on the poles of the ecliptic, as *Ptolemy* shows from the changed declinations of the fixed stars, Book 7 of the *Almagest*, chapter 3. This is true not only of the stars within the zodiac, as Hipparchus thought in his earlier hypothesis, but of all of them, because the unchangeableness of their distances has been found in them all; and in the end Hipparchus conceded it of all of them, on the testimony of Ptolemy, Book 7, chapter 1. Granted, *Joseph Justus Scaliger* invented the view that it takes place on the movable poles of the equator, and that the equinoctial points are moved westward on the equator with the motion of the equator; but we have reported and rejected his empty foundation in Book 3, chapter 28, number 10, and in this Book 6, chapter 4, at the passage on Ursa Minor and the changed declination of the Pole Star, a change that *Scaliger* quite ignorantly denied. We showed besides, in Book 3, chapters 28 and 30, that the motion of the fixed stars in longitude is always direct, without any trepidation or libration toward the east and west, and that it is uniform and equal. All of this should be reread at this

[Margin: 1. Argument for the equal [?] motion of the fixed stars.]

point, so that you may have the full doctrine of the motion of the fixed stars. Since, however, we adduced there chiefly two foundations for an inequality in the motion of the fixed stars, one from the inequality of the year, which we have now overthrown, and the other from an apparent variation in the motion of the fixed stars gathered from observations — observations by which, if you choose to abide by them as they stand in the ancient astronomers, the motion of the fixed stars appears to have been very slow from Timocharis and Hipparchus down to Menelaus and Ptolemy, so much so that they barely completed one degree in 100 years; to have begun to quicken from Ptolemy, and to have become so swift by the time of al-Battānī that they ran through one degree in *66* years; and from then on to have been slowed again, so that

in the century of Copernicus they completed one degree in nearly 71 years. We promised the overthrow of this foundation in those places, and deferred it to this one. Our pledge must therefore be redeemed, and it must be proved from the observations themselves that this foundation is not solid, and that the equality of the motion of the fixed stars is far more probable than its inequality, as will be made plain by the following arguments.

II. *First*, it is clear from what was said in chapter *16*, from number 7 to 11, that the annual motion of the fixed stars, gathered from numerous and more select observations, from Timocharis or Hipparchus to Ptolemy, from there to al-Battānī, and from al-Battānī to us, is always very nearly 50″ or 51″. These observations certainly outweigh those few on which *Copernicus* relied in establishing the inequality, both in number and in certainty, since they are either those of more recent astronomers, or those of the ancients, it is true, but corrected in places.

[Margin: 2. Argument from the false longitude of the ancients.]

III. *Second*, the motion of one degree in *66* years was gathered by al-Battānī from only one or two pairs of observations, and the motion in 100 years was deduced by Ptolemy from only three. But the ancient longitude of the fixed stars that was used is most certainly fallacious, since it does not agree with the difference of longitude which, by clear observations, we in this century and Tycho in the pre- ceding have found. Nor indeed do Ptolemy, al-Battānī or Copernicus deny that the fixed stars perpetually keep the same difference of longitude among themselves. The fallacy already mentioned cannot be shown more clearly than by setting out, in the small table below, the difference of longitude found by Tycho and by us between the stars used to establish the inequality of the motion, together with the difference between them when the longitude is placed as reported by *Ptolemy*, Book 7 of the *Almagest*, chapters 2 and 3, and by *al-Battānī*, chapter 51, from whom *Copernicus* copied them, Book 3, chapter 2.

[Margin: You have the Tychonic longitude and ours in the tables of the longitude of the fixed stars.]

Observers, with the years of Nabonassar	Pairs of stars observed	Longitude ✶ from the ancients	Difference of longitude: of the ancients	Ty- chonic	Ours
Timochares Year 465	Spica	♍ 22° 30′			
	Pleiades	♈ 29° 30′	143° 0′	143° 52′	143° 52′ 30″
Timochares Year 454	Spica	♍ 22° 20′			
	Northern brow of Scorpius	♏ 2° 0′	39° 40′	39° 20′	39° 20′ 50″
Hipparchus Year 620	Spica	♍ 24° 0′			
	Regulus	♌ 29° 50′	54° 10′	53° 59′	53° 59′ 0″
Menelaus Year 845	Spica	♍ 25° 45′			
	Northern brow of Scorpius	♏ 5° 55′	40° 10′	39° 20′	39° 20′ 50″

Observers, with the years of Nabonassar	Pairs of stars observed	Longitude ✶ from the ancients	Difference of longitude: of the ancients	Tychonic	Ours
Ptolemy Year 886	Spica	♍ 26° 30′			
	Regulus	♌ 2° 30′	54° 0′	53° 59′	53° 59′ 0″
al-Battānī Year 1627	Regulus	♌ 14° 0′			
	Northern brow of Scorpius	♏ 17° 50′	93° 50′	93° 19′	93° 19′ 50″

So whether the errors already mentioned in the difference of longitude flowed from the instruments, or from refraction being left out of account, or from an erroneous obliquity of the ecliptic, or from the motion of the luminaries, or from all of these together, it is certain that a motion of the fixed stars deduced from them cannot stand. The Ptolemaic observation does seem to bear the mark of truth in Spica and Regulus, because its difference of longitude departs by a single minute from Tycho's and ours; but the others taken with it for comparison exceed or fall short by a full 50′, 30′ or 20′. *Tycho* pointed out this disagreement, Volume 1 of the *Progymnasmata*, p. 255.

[Margin: 3. Argument from the same fallacy.]

IV. *Third*, neither the longitude given by Ptolemy for Spica, Regulus, the Pleiades and the northern star of the brow of Scorpius, which the authors already mentioned used in order to introduce an unequal motion of the fixed stars, nor the longitude of these or other stars deduced geometrically from their declination and latitude as observed by the same men and reported by Ptolemy, Book 7 of the *Almagest*, chapters 2 and 3, or in the table of chapter 5, supposing for the obliquity of the ecliptic in those times 23° 52′, which our opponents suppose along with Ptolemy — that longitude, I say, agrees neither with the true difference of longitude, which is certain to Tycho and to us, nor with the difference of longitude deduced from other observations of the ancients in the preceding argument. These longitudes are therefore fallacious, and Copernicus had no solid foundation on which to build upon them the anomaly of the precession of the equinoxes, or of the motion of the fixed stars. To make this clear at once, here in the following table [canone] is the longitude both of the four stars already mentioned and of the remaining stars of the first magnitude whose declination, observed by himself or by the ancients, Ptolemy gives with the latitude in the place already mentioned. It is deduced by the solution of triangles according to our problem 7 of chapter 12, assuming the obliquity of the ecliptic at 23° 52′, with the difference of longitude arising from this between the stars added, and compared with the Tychonic difference, which nearly equals ours. I shall compare stars nearer one another, and stars observed by Hipparchus and Ptolemy.

Observers	Stars	Observed declination	Observed latitude	Deduced longitude	Difference of longitude: ancient	Tychonic
Hipparchus	Bright star of the Pleiades	15° 10′ N	3° 40′ N	♉ 0° 12′		
	Aldebaran	9° 45′ N	5° 10′ S	♉ 8° 42′	8° 30′	9° 48 1/2′
Ptolemy	Bright star of the Pleiades	16° 15′ N	3° 40′ N	♉ 3° 11′		
	Aldebaran	11° 0′ N	5° 10′ S	♉ 12° 40′	9° 29′	9° 48 1/2′
Hipparchus	Aldebaran	9° 45′ N	5° 10′ S	♉ 8° 42′		
	Sirius	16° 0′ S	39° 10′ S	♊ 14° 16′	35° 34′	34° 23′
Ptolemy	Aldebaran	11° 0′ N	5° 10′ S	♉ 12° 40′		
	Sirius	15° 45′ S	39° 10′ S	♊ 17° 38′	34° 58′	34° 23′
Hipparchus	Arcturus	31° 0′ N	31° 30′ N	♍ 23° 48′		
	Capella	40° 24′ N	22° 30′ N	♉ 22° 54′	120° 54′	122° 23′
Ptolemy	Arcturus	29° 50′ N	31° 30′ N	♍ 25° 50′		
	Capella	41° 10′ N	22° 30′ N	♉ 25° 34′	120° 16′	122° 23′
Hipparchus	Regulus	20° 40′ N	0° 10′ N	♌ 0° 2′		
	Spica	0° 36′ N	2° 0′ S	♍ 23° 59′	53° 57′	53° 59′
Ptolemy	Regulus	19° 50′ N	0° 10′ N	♌ 3° 42′		
	Spica	0° 30′ S	2° 0′ S	♍ 26° 50′	53° 8′	53° 59′
Hipparchus	Antares	19° 0′ S	4° 0′ S	♏ 10° 26′		
	Spica	0° 36′ N	2° 0′ S	♍ 23° 59′	46° 27′	45° 57′
Ptolemy	Antares	20° 15′ S	4° 0′ S	♏ 14° 18′		
	Spica	0° 30′ S	2° 0′ S	♍ 26° 50′	47° 28′	45° 57′

Nor can one take refuge in uncertainty about the time of the observed declination, on the grounds that Ptolemy, Book 7, chapter 3, does not record the time but gives the bare declinations. For in chapter 2 he had said that his very many observations of the fixed stars were made in the reign of Antoninus, and in the same place he indicates about 265 years between his own and those of Hipparchus. Nor could there have been so much time between the observations of the same astronomer as to excuse so enormous a difference of longitude.

V. *Fourth*, if *Copernicus* and his followers want to accept the observations of longitudes exactly as they stand in Ptolemy and al-Battānī, even though *Ptolemy* deduced most of them from observed applications of the Moon to Spica, the bright star of the Pleiades and the northern brow of Scorpius, assuming his own hypotheses on the motion of the Sun and Moon, then with far greater right they ought to accept the longitudes deduced by trigonometry from the declinations and latitudes of the fixed stars given by the same astronomers, together with the obliquity of the ecliptic that the same men supposed. For this method is far more certain and simpler, and it rests on a spherical triangle in which all the sides are given, as is clear from our Problem 7 of chapter 12.

Now from the longitude of the ancients deduced in this way there does not follow, from Hipparchus to Ptolemy, a motion of the fixed stars of one degree in 100 years, but either one far slower, or a very swift one of 66 years, or a moderate one differing greatly from 100 years, provided you grant that very nearly 265 years passed between the declination observations of Hipparchus and those of Ptolemy, as *Ptolemy* indicates, Book 7, chapter 2. Or if you contend that as many years passed as are required to establish 100 years for one degree, you must necessarily interpose an improbable interval. So that this may appear at once, I shall repeat in the following table the longitudes of the fixed stars deduced from the declination, latitude and obliquity of the ecliptic that the preceding table treats, adding the years thereby required for 1°, and the years required between the observations for the advance of the stars to correspond in proportion to an advance of one degree made in 100 years.

Stars observed	Observers	Deduced longitude ✶	Advance of the stars	If there are 265 years between the observations: years to 1°	If 1° is made in 100 years: years between the observations
Bright star of the Pleiades	*Hipparchus*	♉ 0° 12′			
	Ptolemy	♉ 3° 11′	2° 59′	88 7/9	298
Aldebaran	*Hipparchus*	♉ 8° 42′			
	Ptolemy	♉ 12° 40′	3° 58′	66 19/24	397
Arcturus	*Hipparchus*	♍ 23° 48′			
	Ptolemy	♍ 25° 50′	2° 2′	130 1/3	204
Capella	*Hipparchus*	♉ 22° 54′			
	Ptolemy	♉ 25° 34′	2° 40′	99 3/8	266
Regulus	*Hipparchus*	♌ 0° 2′			
	Ptolemy	♌ 3° 42′	3° 40′	72 3/11	367
Spica	*Hipparchus*	♍ 23° 59′			
	Ptolemy	♍ 26° 50′	2° 51′	93	285
Sirius	*Hipparchus*	♊ 14° 16′			
	Ptolemy	♊ 17° 38′	3° 22′	78 7/10	337
Antares	*Hipparchus*	♏ 10° 26′			
	Ptolemy	♏ 14° 18′	3° 52′	69	387

So if the advance of Aldebaran is accepted, the motion from Hipparchus to Ptolemy would be very swift, one degree in *66* years, while over the same

interval it is elsewhere put at 100 years, and very slow. Nor, to excuse this, can one admit between the observations of Hipparchus and Ptolemy an interval of 397 years, as would be necessary, since *Ptolemy*, Book 7, chapter 2, indicates 265, and that his own were made in nearly the same year. In the others too there is a notable disagreement with 100 years, except for Capella and, nearly, Spica. Finally, a sufficient indication of rather crude observations is that in Ptolemy's catalogue the longitudes are noted only by degrees and decades of minutes, and the latitudes by pentads, that is, by fives; yet a neglected error of 10′ or 5′ can seriously corrupt the annual motion of the fixed stars.

[Margin: Authors asserting the equality of the motion of the fixed stars.]

VI. Let it stand, then, that from the observations of the ancients an inequality in the motion of the fixed stars cannot be gathered without contradiction between those observations themselves and the hypotheses of the same men. Therefore, so long as the inequality is not proved on other grounds, after observations over a very long time to be undertaken by future posterity, if the world lasts so long, or if there are people whom a passion for watching the stars has seized, it is rather the equality of this sidereal motion that is to be retained. So it was wisely held by *Hipparchus* and *Ptolemy*, Book 7 of the *Almagest*; *al-Battānī*, chapter 51; *al-Farghānī*, *differentia* 13; *Albuhassim* the Moor, in the book on the fixed stars; King *Alfonso*, in his later opinion, of the year 1256; *Haly* [ʿAlī ibn Riḍwān], on Book 2 of the *Quadripartitum*; *Rabbi Levi*, 84 years later than Alfonso, in his Milhamot hescem, that is, in the book of the defences of God, chapter *62*; *Rabbi Yehoshua* in the Talmud, book Horaioth; *Rabbi Moses* in the Mishneh Torah [Miſnetorà], or book of the repeated law; *Rabbi Auenezra* in the book Taàmin, or of reasons; *Abraham Zaguth* in his great composition, and his disciple *Agostino Ricci* in the treatise on the eighth sphere, chapters 5, 43, 46, 47; *Kepler* in the Rudolphine Tables, chapter 34; and *Boulliau*, Book 5 of the *Astronomia Philolaica*, chapter 2, along with the ancient Persian mathematicians.

[Margin: Tycho's opinion.]

Tycho, for his part, in Volume 1 of the *Progymnasmata*, chapter 2, p. 255, although he speaks timidly, favours us rather than the contrary opinion, since he says that the inequality of the motion of the fixed stars asserted by Copernicus is refuted by more recent observations, which show a much quicker motion of the fixed stars in this century than his hypothesis allows. And he adds:

[Margin: If you assert it, why do you say "hardly"?]

This, however, I do not hesitate to assert here for just reasons: that so enormous an anomaly as is detected from the observations of Timocharis and Ptolemy compared with Hipparchus and al-Battānī hardly underlies the motion of the fixed stars. For it is not likely that they sometimes traverse one degree in 100 years, as Ptolemy gathered, and at other times in 66, as al-Battānī wished. Rather, in the observations of the practitioners themselves some fault no doubt lay hidden. He confirms this from the errors indicated in the difference of longitudes, though not as we have demonstrated them above. Finally, on p. *256*, he says: *Nor yet would I think*

that the considerations of the ancients regarding the fixed stars were so far astray that it could not in truth be gathered from them that some inequality of motion underlies them; although I judge that this occurs from some external cause and by accident, and is not rightly to be imputed to them. On this matter, however, I am not yet pleased to pronounce an absolute judgement, thinking it more prudent to reserve it for a comprehensive treatment of astronomy and to hold it back for several more years. Nothing could have been said either more timidly or more cautiously; and I seem to myself to see in Tycho the cast of mind of Ptolemy, from Copernicus, as from his master Hipparchus, hanging again and again so closely that he does not dare abandon him entirely, and is fearful from time to time.

[Margin: Tycho's timidity.]

Now, I think that this external cause is the unequal motion of the equinoctial points, from which comes some inequality of the year, though a small one, and one that Tycho admitted.

[Margin: Authors in doubt about the inequality of this motion.]

But Simon Stevin too, in Hérigone, volume 5 of the *Cursus Mathematicus*, p. 579, and Pedro Nunes, Book 2 *De Observatione*, ch. 4, and Erasmus Reinhold at the opening of the *Theorica* on the eighth sphere, and Gassendi, *Institutio Astronomica*, Book 2, ch. 8, call into question the inequality of this motion and of the precession of the equinoctial points, as something that arose rather from error in the observations, or that remained undiscovered because of the slowness of the motion.

[Margin: Regiomontanus's suspension of judgement, and his advice.]

And before them that great man Johannes Regiomontanus had said, in the *Epitome of the Almagest*, Book 7, proposition 6: *Whether, then, the multitude of instruments has introduced this variation, or nature has implanted in the fixed stars some motion still hidden from us, it is and will be very difficult to work out the character of this motion, because of its slowness. For if our forebears were deceived by their instruments, we too shall necessarily be deceived, since our considerations, unless they are compared with the considerations of the ancients, can never teach anything. But if we judge that this hidden motion is present in the stars, it will be expedient to keep an eye constantly on the fixed stars, and for posterity likewise to weigh the considerations written down.* These are almost the very words of al-Battānī, ch. 52.

SCHOLION.

Scholion.

From what was said in the preceding chapter, that distribution and anomaly of the motion of the fixed stars which Fracastoro sets out in the *Homocentrica*, section 1, ch. 16, certainly collapses. *There he says that the whole period of the fixed stars is completed in 36000 years, but its anomaly in 3600 years; that the motion of the Aplanes, taken by itself, completes 1° in 100 years, and was of that size at the time of Christ; that it becomes faster and faster over 900 years, up to the fastest, as*

from Christ to al-Battānī; that from then on it began to diminish, and will return to the mean in the year of Christ 1800; that afterwards, over another 900 years, it will be slower and slower, until in the year 2700 it is at its slowest; and that from then, receding from its extreme slowness over another 900 years, it reaches the mean in the year of Christ 3600. So 900 years before Christ it was slow, but with its slowness diminishing. Those numbers of the anomalies treated in Book 3, chs 28 and 29, collapse as well; I did not set down this Fracastorian anomaly there, because it is not common to the precession of the equinoxes, but proper to the fixed stars. Look, then, at its measures in the following small table, that is, at how much of the four quadrants of this anomaly the fixed stars are said to complete in each century. To it I shall append the times before and after Christ to which such quadrants correspond.

Quadrants of the Fracastorian anomaly, with the motion above or below the mean, which is 1° in 100 years.

Order of the centuries	Quadrant 1	Quadrant 2	Quadrant 3	Quadrant 4
1	1° 5′ 20″	1° 48′ 0″	0° 54′ 40″	0° 17′ 20″
2	1° 10′ 40″	1° 42′ 40″	0° 49′ 20″	0° 22′ 40″
3	1° 16′ 0″	1° 32′ 0″	0° 44′ 0″	0° 28′ 0″
4	1° 21′ 20″	1° 26′ 40″	0° 38′ 40″	0° 33′ 0″
5	1° 26′ 40″	1° 21′ 20″	0° 33′ 20″	0° 38′ 20″
6	1° 32′ 0″	1° 16′ 0″	0° 28′ 0″	0° 44′ 0″
7	1° 42′ 40″	1° 10′ 40″	0° 22′ 40″	0° 49′ 20″
8	1° 48′ 0″	1° 5′ 20″	0° 17′ 20″	0° 54′ 40″
9	2° 0′ 0″	1° 0′ 0″	0° 12′ 0″	1° 0′ 0″
Years	**from year – to year**	**from year – to year**	**from year – to year**	**from year – to year**
Before Christ	3600 – 2700	2700 – 1800	1800 – 900	900 – 0
Before Christ	7200 – 6300	6300 – 5400	5400 – 4500	4500 – 3600
Of Christ	0 – 900	900 – 1800	1800 – 2700	2700 – 3600
Of Christ	3600 – 4500	4500 – 5400	5400 – 6300	6300 – 7200

CAPVT XVIII.

Chapter 18.

De Theorica motuum Octauæ Sphæræ, & Conciliandis eius apparentibus motibus in Oppoſitas Mundi plagas.

On the theory of the motions of the eighth sphere, and on reconciling its apparent motions in opposite quarters of the world.

I. We have dealt with this matter in Book 3, chs 28, 29 and 30, because of the connection that the motion of the fixed stars has seemed to many to have with the variation of the obliquity of the ecliptic, with the precession of the equinoxes and of the equinoctial points, and with the motion of the auges of the

five or six planets above the Moon. To explain these changes some introduced 10 spheres and others 11, the highest of which was to be the primum mobile, imparting the diurnal motion of 24 hours to all the lower spheres. We have already settled the controversy over the change in the obliquity of the ecliptic in Book 3, chs 27 and 29, and have likewise dispatched the question of the anomaly of the year and of the precession of the equinoxes in Book 3, chs 28, 29 and 30; and what is usually sought from the unequal motion of the fixed stars in order to establish that inequality we have sufficiently weakened in Book 3, ch. 28, no. 11, and in this Book, in the preceding chapter. It now remains for us to bring together and briefly set out the opinions on the number and kind of the motions that appear in the fixed stars, and to indicate by what hypothesis, and not a fictitious one, they can not only be drawn on paper but actually be performed in the heavens.

[Margin: 1. Opinion on the single motion of the fixed stars.]

II. The first opinion, then, was that of the Babylonians, the Egyptians and the Greeks, above all Eudoxus and Callippus, as is clear from Aristotle in the books *De caelo* and in Book 12 of the *Metaphysics*: that the fixed stars are carried to the west by a single diurnal motion. For that reason the Babylonians defined the year as *the revolution of the Sun to the same fixed star*, as to a fixed point of the sky, that is, one movable by no other motion than the diurnal and common motion of 24 hours. Yet some think that in those words of Cicero in the *Dream of Scipio*, taken from Plato's *Timaeus*, *when the eight heavens have completed their circuits*, the particle *their* indicates a proper motion of the eighth sphere in longitude, distinct from the common one. Granted, he recognised no more than eight orbs, as will be said below at no. 18. Scaliger, *De emendatione temporum*, Book 4, p. 283, judges that Thales of Miletus, in the two books that on the testimony of Diogenes Laertius he wrote on the solstices and equinoxes, and then Meton and Euctemon, and afterwards Aristarchus and Timocharis, suspected a difference between the tropical and the sidereal year, and so some proper motion, either of the fixed stars in the order of the signs, or of the equinoctial and solstitial points against the order of the signs. Ptolemy, however, attributes this suspicion rather to Hipparchus, Book 7, ch. 1.

[Margin: 2. Opinion of Hipparchus and Ptolemy.]

III. The second opinion, then, was that of Hipparchus and Ptolemy. For as Ptolemy relates in Book 7 of the *Almagest*, ch. 1, Hipparchus came to suspect a twofold motion of the fixed stars. These are Ptolemy's words: *Hipparchus too, from what he had at that time, had a suspicion of both of them, so that he conjectured about the longer time rather than affirmed; for he found very few observations of the fixed stars before his day, and virtually only those that Aristyllus and Timocharis had written down, which are little explained and ambiguous as well.* And in ch. 2 he adds about the same man: *For Hipparchus too, in the treatise on the displacement of the solstitial and equinoctial points, having set out lunar eclipses, partly observed in his own age and partly long before by Timocharis, gathers that the star Spica stood,*

in his own time, 6° from the autumnal section against the order of the signs, but in Timocharis's time very nearly 8°. For in concluding thus he says:

[Margin: Hipparchus's words.]

So Spica formerly preceded the autumnal point by 8° in longitude, but now it precedes it by only 6°. And he shows that the other fixed stars have moved by the same interval in the order of the signs. Ptolemy adds in the same place that Hipparchus at first recognised this motion only in those fixed stars that are in the zodiac, but that from the distances of all the other fixed stars from one another and from the zodiacal stars, the same motion is to be ascribed to all. For he says: *The same figures and lines of the fixed stars are seen quite unchanged even now as were observed at the time of Hipparchus, and not only of those in the zodiac among themselves, or of those outside the zodiac with respect to neighbouring stars (which would certainly happen if, according to Hipparchus's first hypothesis, only those in the zodiac advanced in the order of the signs), but of all without qualification, even of those in the zodiac when they are compared with those that lie far from it.* So what Hipparchus suspected because of the short interval and the fewness and uncertainty of the observations, Ptolemy affirmed outright, having obtained a longer interval and more observations, especially those of Hipparchus, which in ch. 1 he calls *most clearly set out*. Moreover Ptolemy, in ch. 3, discovered, not merely ambiguously as Hipparchus did, but with certainty, that the motion of the fixed stars in the order of the signs takes place on circles parallel to the ecliptic, and on the poles of the ecliptic, not of the equator. He shows this in Book 7, ch. 3, from the fact that the fixed stars, always keeping the same distance from one another, never changed their former latitude, or distance from the ecliptic, but did change their declination, or distance from the equator, so much that many that were in the southern hemisphere later crossed the equator and became northern, and conversely those in the northern hemisphere turned out southern; and that those near the equinoctial points underwent a greater and sudden change in declination, while those near the solstitial points underwent a smaller and slower one. He demonstrates this by adducing many observations of Hipparchus and of his own. This motion in longitude he thought to be always equal and direct.

Ptolemy was followed by al-Battānī, ch. 51; Haly [ʿAlī ibn Riḍwān], Book 2 of the *Quadripartitum*; al-Farghānī, *differentia* 13; Albuhassim; King Alfonso in his later hypothesis; and various rabbis, above all Moses, Levi, Yehoshua, ibn Ezra and Avraham Zacuto; likewise Agostino Ricci, Kepler and Boulliau, with the Persian mathematicians, in the places cited in the preceding chapter, no. 6.

[Margin: 3. Opinion on both the inequality and the trepidation of the motion of the fixed stars.]

IV. The third opinion was that of those who thought that the proper motion of the fixed stars in longitude is both unequal and not always direct, but for some years retrograde toward the west, and for some others direct again toward the east, with a slow trepidation or libration in longitude. Of this kind were, first, certain people before al-Battānī, as is clear from his ch. 52, above all

Hermes, as Isaach Israelita [Yitzchak Yisraeli] testifies in the book *Ieſſod holam*, or the foundation of the world, and Alpetragius [al-Biṭrūjī]; then Theon, on the testimony of al-Biṭrūjī in the *Theorica Physica*; then al-Zarqālī and Thābit, and al-Biṭrūjī himself, though he explains this access and recess differently, as I shall say at no. 9. For the rest see Book 3, ch. 28, no. 6, where we rejected this fiction, because no fixed star from Hipparchus down to us has so far been seen to go back and have a smaller longitude from the beginning of Aries than it had before.

[Margin: 4. Opinion on the inequality of the motion and on a certain other trepidation.]

V. The fourth opinion was that of Alfonso in his earlier hypothesis, and of the Alphonsines, who thought that the mean motion of the fixed stars is always direct, but the true motion unequal, now slow, now fast, so that because of its speed they appeared direct, and because of its slowness stationary or retrograde; but not to such a degree, nor in the way that the third opinion holds. They therefore admitted a motion of trepidation or libration in another sense. Very many followed the Alphonsines, especially Gherardus Cremonensis [Gherardo da Cremona] and Georg von Peuerbach with his commentators; Maurolico in dialogue 3 of the *Cosmographia*; and Clavius on ch. 1 of the *Sphere*, from pp. 56 and 63. Magini seems to have agreed with them in Book 1 of the *Theoricae Planetarum*, but in reality he belongs rather to the following opinion.

[Margin: 5. Opinion on the inequality of a motion always direct, without trepidation.]

VI. The fifth opinion was that the motion of the fixed stars in longitude is always direct, with no trepidation that would make it retrograde, but that it is nevertheless unequal. This at length was the view, above all, of Giovanni Battista della Torre, and with him of Fracastoro in the *Homocentrica*, section 2, from ch. 9 to ch. 17; of Copernicus, Book 3 of the *De revolutionibus*, and with him of Reinhold in the Prutenic Tables, precepts 10 and 11; and of Rheticus in his *Narratio*, of Mästlin in his notes on that *Narratio*, of Magini, who in Book 1 of the *Theoricae Planetarum* sets out a libration of the spheres without retrogradation, of Longomontanus, Book 1 of the *Theorica*, chs 2 and 4, and of Lansbergen in his *Theoricae*, chs 1, 7 and 8, with precept 4 joined to 11. For although not all of these attribute this motion to the fixed stars in reality, as Fracastoro, Magini and Lansbergen do, but some grant it to them only as apparent and in reality attribute it to the Earth, as Copernicus, Mästlin, Rheticus and in part Longomontanus do, nevertheless all posit this apparent motion as always direct but unequal. For the remaining matters bearing on the measure and periods of this anomaly, see Book 3, ch. 28, no. 8, and ch. 29.

Since, however, the inequality of this motion, let alone its retrogradation, has been rejected by us in Book 3, chs 28 and 30, and in this Book, in the preceding chapter, there remain only three motions of the fixed stars that are true, either in reality or as to true appearance: namely the diurnal motion to the west, the proper motion to the east, and the variation of declination. The

various hypotheses that have been devised, or could be devised, to reconcile these without contradiction or violence I shall now review.

Hypotheſes Motus Fixarum.

Hypotheses of the motion of the fixed stars.

[Margin: 1. Hypothesis.]

VII. The first hypothesis was that of very many who admit solid orbs. It places above the eighth sphere another, distinct sphere, called the primum mobile, which mediately or immediately carries the eighth along with it from east to west, by a motion described around the poles of the equator, while meanwhile the eighth sphere of the fixed stars, or Aplane, moves eastward on the poles of the ecliptic, gradually striving against the motion of rapture [raptus] and of the primum mobile. But some have said that the primum mobile is the ninth sphere, others the tenth, others the eleventh.

[Margin: Sphere 9, the primum mobile for some.]

For some of the older astronomers thought that the ninth sphere performs the office of the primum mobile, especially those who thought that the motion of the fixed stars is uniform and perpetually direct and that the obliquity of the ecliptic does not vary. So Johannes de Sacrobosco, ch. 1 of the *Sphere*, and many Jews and Arabs, chiefly Rabbi Moshe, Rabbi Yehoshua, al-Farghānī, ibn Ezra and Haly, in Agostino Ricci. Yet Ptolemy, whatever Scheiner says in the *Disquisitiones Mathematicae*, p. 50, never mentions a ninth sphere, as I shall show below. But later more people assigned the tenth sphere to the primum mobile; and the ninth to the motion toward the east imparted by it to all the lower spheres: to the eighth with respect to the motion of the fixed stars, and to the rest, the Moon excepted, with respect to the motion of the auges, each to be completed in 49000 years. The eighth, or firmament, they assigned to the motion of access and recess, or trepidation, to the east and west, to be completed in 7000 years. So, indeed, the Alphonsines, Georg von Peuerbach and Johannes Regiomontanus, to whom Maurolico subscribed in the *Cosmographia*, dialogue 1, p. 24, and dialogue 3, p. 89, and Clavius on ch. 1 of the *Sphere*, pp. 44 and 72, in the first edition.

[Margin: Sphere 11, but motionless.]

To these must be added those who posited an eleventh sphere, but one wholly motionless, in order to save the differences of the influences that dominate in particular regions and produce different plants and animals in different places. In this way Pierre d'Ailly, questions 2 and 9 on the *Sphere*, posits an eleventh, resting sphere, and a tenth for the motion of the primum mobile, and a ninth for the motion to the east, but one to be completed in 36000 years, and an eighth for the motion of access and recess.

[Margin: Sphere 11, but movable.]

Indeed Clavius himself, with Bede, Strabo and other theologians, admits an eleventh heaven, motionless, whether watery or empyrean. Others, however,

added an eleventh sphere that is movable and destined for the office of the primum mobile; the tenth they assigned to the motion of the first libration and trepidation, in latitude, by force of which they said the obliquity of the ecliptic is changed; the ninth they assigned to the motion of the second libration or trepidation, to the east and west, to preserve the anomaly both of the motion of the fixed stars and of the year and of the precession of the equinoxes; and the eighth to the proper motion of the fixed stars in longitude toward the east. So Johannes Werner, in Osualdus [?] on the theory of the eighth sphere, and Magini, Book 1 of the *Theoricae Planetarum* and in the *Secunda Mobilia*, canon 18, though using the measures of the Copernican motion. Leupoldus Austriacus [Leopold of Austria] adhered to this view in his compilation published in the year 1489, and Clavius in the second edition of the *Sphere*, p. 36, as Scheiner has it in the *Disquisitiones Mathematicae*, p. 49. In line with this opinion, the theory of the eighth sphere is set out by Deusingius [Anton Deusing] and by Gassendi in the *Institutio Astronomica*. But we have said enough on the tenets of these authors concerning the quantity and period of the motion of trepidation in Book 3, the whole of ch. 29, above all at nos 12 and 13, where we also treat the opinion of Thābit and al-Zarqālī and of others who have written on the trepidations of the eighth sphere. All the authors already mentioned therefore require at least two distinct total spheres, one of which sweeps the fixed stars and the other lower orbs from east to west, by a motion performed around the axis of the equator, while the other pushes the fixed stars eastward on the axis and poles of the ecliptic.

[Margin: 2. Hypothesis.]

VIII. The second hypothesis is that of Giovanni Battista della Torre and of Girolamo Fracastoro in the *Homocentrica*, section 1, chs 15, 16 and 17. There, having said that it is more probable that the Aplanes is always carried direct beneath the ecliptic of the highest heaven, though with a motion now slow, now fast, now moderate, he places 6 orbs above the Aplanes, namely the primum mobile, then the *Circumducens*, which carries all the lower orbs around in breadth from north to south and conversely; beneath this the *Circitor*, by force of which the Aplanes is moved eastward, but unequally; and the *Controvectus* and the *Anticircitor*, so that the latitude of the fixed stars should not change, or should change only insensibly. He says that the anomaly of the motion, from fastest back to fastest, is completed in 3600 years, but the whole period of the motion of the fixed stars in 36000 years. You have a specimen of this anomaly in the scholion of the preceding chapter.

[Margin: 3. Hypothesis of Alpetragius and Achillini.]

IX. The third hypothesis was that of al-Biṭrūjī in the *Theorica Physica* and of Alessandro Achillini in the book *De orbibus*: that there are not two motions in any stars, one eastward and the other to the west, but a single motion, westward and diurnal. It is fastest in the primum mobile, as in the idea of motions, which the other spheres are to emulate, but in the rest it is slower and slower the further they are from the primum mobile. Because of this slowness they do not

match the speed of the primum mobile, nor do they reach the same meridian at the moment the primum mobile does, and they therefore seem to recede toward the east, because they do not reach the meridian so quickly in moving west. From this, they say, it has come about that as the shortfalls multiply, the distance from the meridian becomes perceptible and grows greater and greater from day to day, and gives occasion for feigning a second motion toward the east; but that motions are not to be multiplied without necessity, especially ones that conflict with one another or are violent. This hypothesis is refuted by Agostino Ricci in the treatise on the eighth sphere, ch. 10, and by Clavius on the *Sphere*, p. 48, because they think that this retardation takes place on the same poles and along the same line, and so the declinations of the stars would not vary, though it is agreed that they do vary.

[Margin: Alpetragius defended against the objections of Clavius and Ricci.]

But it appears that neither examined the text of al-Biṭrūjī. For al-Biṭrūjī was not so unskilled as not to know of the change of the declinations; indeed, to explain them, he said that this motion takes place on different poles surrounding the pole of the world. So al-Biṭrūjī says, on p. 9 of the *Theorica Physica*, that the primum mobile moves the lower orbs, not by sweeping them along through identity, continuity or the immediate conjunction of contact, but by imprinting on them a power and impetus that is separated from it, just as one who throws a stone or arrow is separated from the stone or arrow; and this power in the lower orbs is more and more relaxed and fails, so that they cannot keep up with the speed of the primum mobile. He then says that the poles of the eighth sphere are different from the poles of the primum mobile, that they move on their own small circles around the poles of the equator toward the east, and that they are as far from the poles of the primum mobile as the greatest declination of the Sun. So from the motion of the poles of the eighth sphere arises the variety of the declinations, and a motion mixed of a motion in longitude, but a slower one to the west, and one in latitude toward the poles of the equator. Since the motion of the poles of the eighth sphere is not uniform, it follows that the fixed stars always move to the west, but sometimes faster, a motion that Hermes, Theon and al-Zarqālī call recess against the order of the signs; and sometimes more slowly, a motion they call access in the order of the signs; whereas in this hypothesis the former should rather be called access and the latter recess. So al-Biṭrūjī has it, though in a longer discussion, from p. 10 to p. 15. This hypothesis retains the motion toward the east only in the poles, for this does not conflict so much with the motion of the primum mobile, since it is the motion of only two points, and the whole eighth sphere revolves with a single motion, following and imitating the motion of the primum mobile.

[Margin: Hypothesis of Alpetragius rejected in part.]

In the planets, to be sure, the apparent motion to the east does seem explicable by the retardation already mentioned, because we can compare their diurnal motion with the faster motion of a higher planet, and the diurnal motion of Saturn with the diurnal motion of the fixed stars, which return to the same

meridian sooner than Saturn and the other planets. But we cannot perceive the slowness of the fixed stars themselves, because we have no visible sign in the heavens above the fixed stars that moves faster than they do toward the west and with which we might compare their motion; and below them all the planets are posited as moving more slowly than the fixed stars. Moreover, if the motion of the primum mobile is continuous, as is fitting, and if it imprints the diurnal impetus on the eighth sphere contiguous to it continually and not once only, it does not seem that the impetus can ever be relaxed, and so this is not the physical cause of the slower motion of the eighth sphere. Finally, both the sphere of the primum mobile and its motion are multiplied in vain, since the eighth sphere itself can be the primum mobile and the first measure of all times, at least of those perceptible to us, as we shall say below, given, however, the other things that al-Biṭrūjī posited, or their equivalents.

[Margin: 4. Hypothesis of Agostino Ricci.]

X. The fourth hypothesis is that of Agostino Ricci in the treatise on the motion of the eighth sphere, chs 1, 13 and several others following. In these he teaches that there are only eight movable spheres, and that each is moved by a twofold motion, one to the west and the other to the east; and that primum mobile can be taken in two senses. In one it means some celestial body that is moved per se and first by the first mover, and in this sense there is no other primum mobile than the aggregate of all eight spheres, in which the parts are not moved per se, while the whole is moved per se, according to the doctrine of *Physics* 6, text 86. The other is that in which primum mobile is said of what is first in nobility and order in such a kind of motion, and in this sense the eighth sphere is the primum mobile; whereas the ninth, tenth or eleventh, feigned by others for the common diurnal motion, is a being of reason [ens rationis]. He goes on to confirm this opinion of his with great erudition and subtlety, and answers the arguments brought against it. Orontius [Oronce Finé] subscribes to Ricci, in Clavius on the *Sphere*, ch. 1, p. 50. Clavius, however, says that Ricci's hypothesis cannot be grasped even in thought, since it is impossible for a whole, an animal for example, and each and all of its parts to be moved by two contrary motions, if there is no other body by which it is moved. Unless, then, it is explained how the same sphere can be moved by two contrary motions without physical conflict, this hypothesis cannot be sustained.

[Margin: 5. Hypothesis of Joseph Scaliger.]

XI. The fifth hypothesis is that of Joseph Justus Scaliger in the *Diatriba de Aequinoctiis*, and *De emendatione temporum*, Book 4, p. 284. He relates that the Basilas at Olympia and the hierophants at Athens defined the year as 365 1/4 days; but that Hipparchus recognised that the tropical year is shorter than the hierophantic or Julian, and the astric or sidereal year longer than either, and that the solstitial and equinoctial points had receded from the fixed stars to the west. He asserts that this motion must be attributed to those points, and to the whole equator with its parallels, creeping toward the west, on movable and different poles from those of the world.

He confirms this from the immobility of the Pole Star, for he says: *That star which is in the tail of Cynosura was believed by the ancients to be the arctic pole of the world, and not without reason: for it never seems to us to move, not even in the least.* And he contends, on the testimony of Hyginus and Germanicus, that this star was once, otherwise than now, the most northerly among the stars of Cynosura. This star once stood 12° 24′ from the pole of the equinoctial, as *Ptolemy* reports in Book 1 of the *Geography*; it was not believed to be the pole of the world by Pytheas of Massalia and by Hipparchus, as it was believed by Eudoxus; and it now stands 3° 24′ from the pole of the equinoctial circle. All this, he says, came about not through a motion of the star itself approaching the pole of the world, but through a motion of the poles of the equator approaching the star itself; and because these poles have come nearer to that star through the ecliptic's [Greek: λόξωσιν (loxōsin, "obliquity")], which is now small, in former times, when the obliquity of the ecliptic was greater, the pole of the equator stood farther from that star; yet that distance will go on decreasing until the pole of the equator meets the pole of the world. He confirms the same from the star Canopus, which even now grazes the horizon of Rhodes, just as it once skimmed it on the testimony of Pliny the Elder, Book 2, chapter 70; and this is a sign that the declination has not changed and that the motion of the stars does not take place on the poles of the ecliptic. Finally, Scaliger holds that the fixed stars are not carried round and do not move in the order of the signs. He calls the motion of the eighth sphere a monstrosity, and the opinion about the motion of the fixed stars an old wives' tale and a trifle; the fixed stars, he insists more than once, retain the same distance from the poles of the world. Instead, he holds, the equinoctial and solstitial points are carried round by a proper and inexplicable motion, and it is they that bring about the [Greek: μετάπτωσιν (metaptōsin, "shift")].

But Scaliger's fabrication has already been refuted, besides Boulliau in Book 5, chapter 4, by four most learned men of our Society: *Clavius* on the *Sphere*, p. 62; *Paulus Guldinus* [Paul Guldin] in his refutation of the *Elenchus* written by Seth Calvisius against the Gregorian Calendar, Book 2, chapters 9 and 10; *Georgius Furnerius* [Georges Fournier], *Hydrography*, Book 10, chapter 26; and, most eruditely, *Pétau* in his dissertations on the *Uranologion*, the whole of Book 3. For the present, what we said in Book 3, chapter 28, no. 10, and in this Book, chapter 4 — where we treated Ursa Minor and the approach of the Pole Star to the pole of the world, observed through its greatest and least meridian altitudes — is quite enough to confute Scaliger. For it is all too evident from observations that the fixed stars describe now larger, now smaller circles about the poles of the world and of the equator. Whether a certain third motion, distinct from the daily motion and from the motion of declination, follows from this can be disputed, even if Pétau in chapter 4 asserts that it is demonstrated from this with the greatest certainty *that the eighth heaven moves in the order of the signs, whereas the equinoctial points are in no way carried against the order of the signs.* On this, see below.

[Margin: 6. Hypothesis of Copernicus.]

XII. The *sixth* hypothesis is that of Copernicus, Book 1, chapters 10 and 11, and Book 3, chapter 1, where he says that the sphere of the fixed stars, as the place containing all things, is motionless, although it seems to us to move because of the motion of the Earth. For he attributes to the Earth the threefold motion that appears in the fixed stars. The daily motion he attributes to the daily revolution of the Earth about its own centre toward the east. The motion of declination he attributes to the deflection of the axis of the terrestrial equator, which is oblique to the celestial ecliptic; through the varying inclination of this axis, he says, the obliquity of the ecliptic varies, and so do the declinations of the fixed stars from the equator, or rather of the terrestrial equator from the fixed stars. Finally, he ascribes the apparent motion of the fixed stars in the order of the signs to a motion of the equinoctial points against the order of the signs. So the fixed stars seem to us to advance toward the east, receding from the equinoctial points, when in fact and physically the fixed stars stand still; it is rather the equinoctial points themselves, which lie in the terrestrial equator, that little by little recede from the fixed stars against the order of the signs, toward the west, because of the libration of the terrestrial axis. This third motion, he says, is the Precession of the Equinoxes, and it is anomalous; about its anomaly we said much in Book 3, chapter 28, no. 9, and chapter 29. This hypothesis was followed by *Reinhold*, *Rheticus*, *Mästlin*, and many others of the Copernican sect, against whom we must argue at greater length in Book 9.

[Margin: 7. Hypothesis of Longomontanus.]

XIII. The *seventh* hypothesis, akin to the Copernican, is that of *Longomontanus* in the *Astronomia Danica*, Book 1 of the *Theorica*, chapters 2 and 4. He fears that, if any motion of conveyance is granted to the fixed stars, they may be torn apart and may alter the distance between them, which is agreed to be unchanging, or at least that they may be forced to suffer, if not a conflict of motions, at any rate some violence. He therefore attributes the annual motion to the Sun, not to the Earth, and in this he departs from Copernicus. But with Copernicus he nevertheless attributes the daily motion not to the stars but to the Earth, turning about its own axis toward the east in the space of 24 hours; and he likewise attributes to the Earth their apparent motion in the order of the signs, which he ascribes to a precession of the equinoxes that takes place in the motion of the Earth, though otherwise than Copernicus did. For Copernicus places on the surface of the Earth an equator oblique to the celestial ecliptic, and holds that the axis of this equator librates in such a way that the sections of the equinoxes shift little by little against the order of the signs. Longomontanus, however, places on the terrestrial surface not only an equator but also an ecliptic, lying beneath the celestial ecliptic; and he represents the precession of the equinoxes and the apparent motion of the fixed stars in the order of the signs by means of the poles of the Earth going back gradually, with a very slow motion, about the axis of the terrestrial ecliptic.

[Margin: 8. Hypothesis of Lansbergen and Boulliau.]

XIV. The *eighth* hypothesis is that of *Lansbergen* in the Tables, precept 11, and of *Boulliau* in the *Astronomia Philolaica*, Book 5, chapter 2. They attribute the annual motion of the Sun to an annual motion of the Earth about the Sun through the great orb, and the daily motion of all the stars to a daily rotation of the Earth toward the east about its own centre, and in this they agree with Copernicus. But they attribute the motion of the fixed stars in the order of the signs to the fixed stars themselves, and to their sphere, carried round gradually toward the east on the poles of the ecliptic. For *Lansbergen* thinks it fitting that, just as in the microcosm the brain, which is in the highest part, moves with a slow and barely perceptible motion, so the eighth sphere, the highest part of the macrocosm, should not be motionless but should move with a slow motion, which it communicates to the lower spheres. Nor does he think it likely that the sections of the ecliptic and the terrestrial equator gradually move against the order of the signs; otherwise the quarters of the world at each place on Earth would by now be other than they were at the beginning of the world, which he considers absurd. In the *Theoricae* of the celestial motions, chapter 7, however, he refers the inequality of the motion of the fixed stars to an unequal motion of the vernal equinox, from which the longitude of the fixed stars is counted; and so he counts the mean motion of the fixed stars from the mean equinox, in which he agrees with Longomontanus. It is in this sense that I said in Book 3, chapter 28, no. 9, that both attribute to the fixed stars a motion reckoned from the mean equinox. Otherwise they differ from each other, because Lansbergen attributes a real motion to the fixed stars, and attributes the inequality of the motion of the fixed stars to the inequality of a point that is not terrestrial but celestial.

Boulliau, on the other hand, grants the fixed stars a real but uniform motion, so that that body, which is farthest from the centre of the world, that is, from the place of rest, should not be without motion. He judges that every body set about the centre of the world is owed some motion about that centre by nature, which preserves all things in motion and never lets them grow torpid. He also gives the reason why the motion of the fixed stars does not in fact come about through a slow motion of the terrestrial poles, carried round like a spinning top about the poles of the zodiac against the order of the signs. Granted, he says, this could be admitted if no planet existed other than the Sun; but once the other planets are posited, as they exist in nature, it cannot. Otherwise, through that spinning of the Earth, the remaining planets would appear to approach the zenith and to recede from it by some peculiar motion, which nevertheless does not appear in them. In the fixed stars, however, because of their slowness, he grants that in that fictitious hypothesis this approach and recession would go unperceived, especially since there is no other body above them moved in a different manner with which the motions of the fixed stars could be compared. These, then, are the many and so diverse hypotheses we have so far had devised for reconciling the motions of the fixed stars with one another.

Noſtra Opinio & Hypotheſis de Motu Fixarum.

Our Opinion and Hypothesis on the Motion of the Fixed Stars.

[Margin: 1. Assertion.]

XV. *First* I assert that if the solid sphere of the fixed stars is posited as moving toward the east on the poles of its ecliptic, and meanwhile, turned round by another, higher sphere about the poles of the world and of the equator, as moving toward the west — whether by mere carrying-round and the sweep of a contiguous orb, or by an impressed impetus — no conflict, or violence, or other absurdity follows. For there is no danger that those two bodies will be worn away by long friction, or catch fire and melt, or give out a sound perceptible to us at so great a distance, or a sound perceptible indeed, but to which our dulled ears went deaf immediately after our first cries, as is imagined in the *Dream of Scipio*.

Nor can it be violent for a part to be moved in one direction for the good of the universe while, tending meanwhile in the other direction because of a particular function assigned to it by nature and by God, it experiences a certain mixed motion.

[Margin: Various comparisons for motions in contrary directions.]

The conflict, however, that some perceive in these two motions, or in this one motion mixed from two, is commonly removed by various comparisons: that of an ant crawling in the contrary direction on a wheel turned round the other way; or of fish making their way up a river against the current, which nevertheless carries them down, though not in so headlong a rush as if they strove with no effort in the contrary direction; or of a sailor walking back from prow to stern while the prow of the ship is being borne toward the opposite quarter; or of the ship itself, which, carried to the west by the course of the ocean or a river, yet driven back to the east by the force of oars or winds, either overcomes or retards its being swept to the west; or of a glass sphere full of water, which, turned round in one direction, communicates the same impetus to the water enclosed in it, while the sphere itself, after that impression, is turned back by a reciprocal rotation in the opposite direction, the former motion of the water still persisting toward the earlier quarter; or finally by the comparison of a basin, likewise full of water, which you turn to the right with one hand, gripping its handle, about a pole fixed beneath it, while the water, driven round meanwhile by a finger of your other hand thrust into it, is carried with its eddies in the contrary direction, to the left, and a cork or something else floating on top rolls the same way.

[Margin: Correction of the imagining of two motions in contrary directions.]

In these and similar cases, however, we must not, from the false imagination of the vulgar, conceive of two real continuous motions of the same movable point, really or even formally distinct, one of which is an approach toward a given fixed quarter of the world and the other a recession from that same quarter

of the world. That manifestly conflicts with the essence and definition of local motion, and *Clavius*, on the *Sphere*, p. 52, rightly said that there is no instant in which the fixed stars do not move toward the west, or in which they approach farther toward the east. We must therefore conceive of one motion made from two that are distinct only equivalently, or extrinsically, by reference to the different quarters of the world and by dependence on two efficient principles. One of these prevails absolutely, moves toward one side, and really brings into act the motion it intends. The other, striving against it in the opposite direction, does not actually move the movable body toward the side it strives for, but resists, so that the body is not swept along by the first principle with as great an impetus as it otherwise would be; and, if that resistance is oblique, so that the body is not swept along exactly the same line along which it would otherwise be swept. Therefore, if the impetus of the primum mobile to the west on the one hand were equal to that of the eighth sphere resisting to the east on the other, the eighth sphere would move in neither direction but would remain in the same state. But if the impetus of the eighth sphere, striving obliquely toward the east on the poles of the ecliptic, were greater than the impetus of the primum mobile, the fixed stars would move continually toward the east, but obliquely. So a star placed at the beginning of Capricorn and on the ecliptic itself — such as Præregulus nearly is, that is, the little star preceding the Heart of Leo — seen at the setting-point of the winter solstice, would gradually rise from the horizon, and in 6480 years, according to my motion, would arrive through the ecliptic at the meridian of the horizon already mentioned and at the equator itself. Then, descending step by step, after another 6480 years, having completed a semicircle of the ecliptic, it would set for those people at the point of the summer rising. Yet because of the resistance of the primum mobile, striving in the opposite direction on the poles of the equator, it would not be carried through the ecliptic at the same speed, nor along exactly the same path, as it would go without such resistance.

Now, however, the impetus of the primum mobile (in this hypothesis, at any rate, which we are setting out) is far greater than that of the eighth sphere, and the latter's effort aims at a motion otherwise feasible on the poles of the ecliptic. It does not actually obtain this motion, but it does bring about that no fixed star is swept along by the primum mobile with so great an impetus, and that none describes the same and perfect daily circle parallel to the equator, but that each is twisted rather into a spiral or helicoidal line, ever looser and looser over some centuries and tighter and tighter over others, according as the declination from the equator turns out at one time smaller, at another larger. But *Clavius*, on chapter 1 of the *Sphere*, p. 53, accustomed to the ten spheres of the Alphonsines, tries to explain the very thing we have said in another way, but by a motion physically unintelligible: by a motion in a qualified sense [secundum quid] and an approach to the eastern signs of the zodiac of the ninth sphere.

[Margin: What if there are two motions, divided and interrupted.]

XVI. But if anyone were to say that the two motions already mentioned are really distinct, yet not continuous but discrete — so that through imperceptible brief pauses the primum mobile rests, and meanwhile allows the eighth sphere to be advanced ever so little on the poles of the ecliptic in the order of the signs, whether that pause were single in one natural day or multiple, so that between any two perceptible parts of the day there came an imperceptible pause — he, in my judgement at least, would be saying nothing absurd, nor could he be refuted by any observations, since he would be positing the motion of the primum mobile as physically continuous to the senses, or at any rate interrupted by those intermissions, to some of which he might perhaps ascribe the twinkling of the fixed stars. Yet he too would have no argument from observations by which he could prove this motion to be interrupted and composed of two really distinct motions, rather than mathematically continuous and only virtually double. He would, however, have to concede that those brief pauses, taken together, produce a perceptible change over the course of time.

On my reckoning, moreover, the fixed stars advance daily by 8‴ 13⁗ 9⁗′ 3/73. But let us suppose, for ease of calculation, that it is only 8‴, so that to each hour of one day there fall 20⁗, to each minute 20⁗′, and to each second 20⁗′, that is, sixths. Therefore, if anyone were to say that these spheres complete their motion in alternate seconds, and that the natural day is so distributed that of the 86400^{s} in it half falls to the primum mobile and half to the eighth sphere, so that in one second of time the eighth sphere would accomplish 40⁗′ toward the east, and in the next second the primum mobile would accomplish 30″ of the equator — no one could discern, from observed altitudes or courses of the stars, the 40⁗′ made toward the east, nor whether an interruption of the motion of the primum mobile occurred through alternate seconds. How much less, if it were through alternate thirds or fourths of time, which are already not perceptible to us?

[Margin: 2. Assertion.]

XVII. *Secondly*, however, I say that a primum mobile distinct from the whole sphere of the fixed stars is not necessary, but that their apparent motions can really be carried out through that very sphere of the fixed stars or beneath it, and indeed in three ways above all, which I have recently devised and now propose.

[Margin: 1. Way of the motion of the fixed stars within one heaven.]

The *first way* is if the heaven of the fixed stars is either penetrable by the fixed stars, or rather fluid, and this heaven itself moves toward the west on the poles of the equator, carrying round with it the fixed stars as if swimming in that huge ocean, while the stars themselves, meanwhile, by their own effort on the poles of the ecliptic, resisting against that aetherial torrent, retard their being swept along. They do not allow themselves to be carried off through circles strictly parallel to the equator, but let themselves be carried round in daily gyres through spiral semi-helices. Each star may undertake this resistance by its own internal force; or the resistance may proceed from God, or from

individual Intelligences, or from a single Intelligence that governs all the stars, bound together by a bond hidden from us, like lamps or carbuncles fastened on a spheroidal lattice. For make or imagine for yourself a little net of iron wires, shaped into a spherical surface, with little balls turned from cork inserted at its knots or at certain parts of the wires, by whose lightness the net floats within water enclosed in a spherical glass vessel. Let the water, turned round to the right, carry the net round, yet in such a way that, with someone resisting toward the left and obliquely, those balls are carried to the right indeed, but more slowly and through one whorl after another. What you would see in that motion can be transferred exactly to the appearance of the motion of the fixed stars, if it takes place in a similar way.

[Margin: Whether the fluidity of the heavens is probable.]

For the perpetual constancy of the fixed stars in the same latitude and difference of longitude, and in their distance from one another, is indeed a probable argument that they are fixed like golden nails or fire-spewing gems in solid adamant; and the solidity of the heavens in general is favoured by that saying — not indeed of God, or of the canonical writer himself, but of Elihu in Job, chapter 37: *Perhaps you have fashioned the heavens, which are most solid, as if cast in bronze.* Even so, fluidity is not improbable; indeed in the planetary heaven, as will be said in Book 9, it is more probable; and that saying could be understood metaphorically of the constancy in distances already mentioned, or of incorruptibility, or of the perenniality of the motion.

[Margin: 2. Way.]

The *second way* is if, admitting likewise the fluidity of the Aplanes rather than mutual penetrability, the heaven itself of the fixed stars is not primarily moved of itself so as to sweep the fixed stars to the west, but, so far as lies in it, is motionless, like water in a pool, its parts being moved only accidentally, upon the motion of the fixed stars by which they are pushed forward; while the fixed stars themselves, each turned round either by an intrinsic force or by an Intelligence, undergo a single daily motion through spiral helices about the equator, as is required by the variety of declinations that appears in them and by the immutability of their latitude with respect to the ecliptic alone. But the Sun itself too, of itself or by an Intelligence assisting it, traces with its centre its helicoidal spirals in its own heaven, intersecting the equator twice a year at points ever different and ever farther west, and returning each day more slowly to the same meridian in which it was on the previous day with or beneath one of the fixed stars. With these things posited together, through one daily motion, single in kind and quasi-spiral, in each of the stars and in the Sun, the fixed stars will appear ever farther to the east of the equinoctial points, and the variety of declinations and the other phenomena we observe in them will be saved. Nor will a motion be posited from two principles, one moving and prevailing, the other resisting and retarding, but from a single principle without any resistance, and therefore worthier of the heaven.

[Margin: The objection of Clavius is dissolved.]

As for *Clavius*, on the *Sphere*, p. 47, who denies that the stars can move of themselves like birds in the air or fish in the sea, so far as to pronounce: *It is impossible that the stars should move of themselves, if the things that appear in their motions are true; rather, they must be carried round only at the motion of the orb in which they are* — this ought to have been demonstrated, if it could be demonstrated; and it must be forgiven in a man steeped in the ancient opinion of the Alphonsines and the followers of Peuerbach, and long accustomed to picturing solid orbs. The examples, however, that he himself supplies on p. 54 — of the motion of a ship's master on a ship, or an ant on a wheel, or water enclosed in a glass sphere or a basin, toward the east, while the ship, wheel, sphere or basin is carried toward the west — presuppose the fluidity of air and water, which do not resist.

[Margin: 3. Way.]

The *third way* is if, in keeping with the commoner understanding of astronomers and physicists, we wish to retain the solidity of the eighth sphere, with the fixed stars set in it like gems in crystal, and we conceive of some Mover moving any one of the fixed stars on the spherical surface through helices and, as it were, daily spirals toward the west, not on the poles either of the equator or of the ecliptic, but about the centre of the world; yet in such a way that it has regard to the equator in varying the declinations of that star, to the ecliptic in preserving its latitude, and to the equinoctial points in increasing the star's distance from them. For it is certain that if it moves even one star so as to reproduce its apparent motions, all the others fixed in the same sphere will equally be moved, with the appearances to be preserved being preserved, because of the perpetual distance they keep among themselves. What is difficult for our apprehension, however, we must not judge [Greek: ἀδύνατον (adynaton, "impossible")], or difficult for the moving Intelligences; especially since we can move a globe half-enclosed in a bowl with such ease that, by carrying one point of its convex surface round the same centre, we can trace lines so varied and admirable and exhibit the motions of the fixed stars already mentioned by a single motion. We could do the same with a free sphere, enclosed in no orb or bowl, if its centre, taken mathematically, were supposed motionless and fixed. The poles of the world, however, and the equator and the ecliptic will have to be conceived as outside the eighth sphere.

[Margin: A notable corollary on the primacy of the sphere of the fixed stars.]

XVIII. It is evident, therefore, that the motions of the fixed stars can be explained without a motion of the Earth, and indeed not by multiplying spheres, but in and through the single sphere of the fixed stars; and so there is no necessity to posit another moving heaven beyond the sphere that they call the Eighth, from the excess of its number over the path and place of the seven planets. Hence it comes about that the eighth sphere itself can be called the primum mobile, by priority of speed and by eminence over all the movable spheres; the first mover of the other celestial bodies, not efficiently but exemplarily, in

that the other planets or their movers strive to imitate it in their daily spirals or helices; and, finally, the first measure of all times.

[Margin: Eight heavens in Plato, Nembroth and Ptolemy.]

Finally, it is not necessary to multiply motions in this sphere. Plato said this, though in another sense, in Book 10 of the *Republic*, where he introduces the Pamphylian [Pamphilium], killed in war and returning from the underworld, and asserting *that he saw eight tracks, of which the eighth was driven in the swiftest course.* And in the *Epinomis* he says: *The philosopher must not be ignorant of how the seven circuits revolve beneath the first.* Nembroth the Chaldaean too, in his astronomical work, ascribes only a single motion to the signs of the heaven. Nor does Ptolemy describe the equator and the zodiac in different spheres, in Book 1 of the *Almagest* or elsewhere, nor does he anywhere mention a ninth or tenth sphere, even if *Averroes* on *De caelo* 2, commentary 67, imposes on Ptolemy a number of nine heavens, and *Albertus Magnus* in the same place, treatise 3, chapter 11, a number of ten. *Abraham Abenezra* [Avraham ibn Ezra], moreover, at the opening of the little book entitled *Miſpate hamazaloth*, that is, *On the Judgements of the Signs*, says: *The great and glorious orb, where the glorious hosts of God are, is called the heaven of heavens, because beneath it are the orbs of the seven planets, etc.* But a number of theologians hold that the heaven of heaven is another, motionless heaven.

SCHÓLIA.

Scholia.

[Margin: A new question about the fixed stars, if the planets did not exist.]

I. It could be asked what would happen if there were no planets, and the fixed stars alone moved with the motion with which they now move: that is, whether a double motion in longitude could still appear in them and be established for us. For it is certain that it would then be possible, from two greatest digressions, or from two equal altitudes of the same star on either side toward east and west, to obtain an arc of the horizon, by bisecting which a meridian line could be drawn; that on this line, from two meridian altitudes of the same never-setting star, the altitude of the pole, and so of the equator, could be obtained; and lastly that from meridian altitudes of the same fixed star, observed in different centuries and preserved in writing or by tradition, a change of declination in the fixed stars could be recognised, with the approach of some to the visible pole and the recession of others. On these premises I shall answer the question briefly in the following scholia.

[Margin: 1. Response. On the ecliptic of the fixed stars.]

II. *First* I say that in such a case there would be neither the ecliptic that now exists, nor equinoctial points, nor right ascensions or longitudes that could be counted from them. If, however, some one or more of the fixed stars lacks all latitude — as perhaps does the little star immediately preceding Regulus, although in the Rudolphine table it has a southern latitude of ½′ —

that star would mark out for us the circle along which the centre of the Sun now goes, a circle that in such a case we may call the ecliptic of the fixed stars. Its greatest declination would be as great as the obliquity of the ecliptic, which for me is always 23° 30′. And such a star would arrive from its greatest southern declination at no declination in 6480 years, in my opinion; from its greatest southern at its greatest northern in 12960 years; and finally from its greatest southern back to its greatest southern in 25920 years. From that point of the equator which such a star would reach, then, just as from the equinoctial intersections, the right ascensions and longitudes of the other fixed stars could not unfittingly be counted, and the latitudes could be counted from the same.

[Margin: 2. Response. On the oblique circles of the others.]

III. *Secondly* I say that all stars whose latitude, reckoned now from the ecliptic of the Sun and then from the ecliptic of the fixed stars, is 23° 30′ will, in changing declination, come to touch the equator, but will not cross it; indeed they will return from there again to their greatest declination toward the same pole. Such is a certain little star following in the hand of Ophiuchus. Those whose latitude is less than 23° 30′ will cut the equator; and all will describe circles parallel to the ecliptic of the fixed stars, that is, to the circle described by any star without latitude, smaller and smaller for greater and greater latitude. The remaining stars, whose latitude is greater than 23° 30′, will reach neither contact with the equator nor its section; and any that have a latitude of 66° 30′, as nearly does the little star following in the bend of Draco, will reach the pole of the world at their greatest declination.

CAPVT XIX.

Chapter 19.

In quo Selecta & identidem noua Problemata ſpectantia potiſſimùm ad Declinationes & Aſcenſiones Fixarum tum Rectas tum Obliquas.

In which are selected and, now and again, new problems, concerning chiefly the declinations and ascensions of the fixed stars, both right and oblique.

In chapters 11 and 12 we set out in advance certain problems, and in chapter 13 certain rules, which concern the declinations and ascensions of the fixed stars, and indeed their longitudes and latitudes, because the order of the teaching so required. The other matters of longitude or latitude present scarcely any difficulty, since the latitude of the fixed stars, at least of itself, does not change, any more than does the difference of longitude; and it is very easy, by adding to or subtracting from the root according to their annual progress, to find the longitude of the fixed stars for any future or past time. Certain other matters that remain, however, seem to me to belong partly to this place, and partly, as being more general, to Book 10, of Problems of the primum mobile; although in this sorting it is very hard to satisfy everyone.

Problema 1. An & quando ſtella datæ Longitudinis & Latitudinis peruentura ſit ad Aequatorem, aut Tropicum ſuum, vel etiam illum tranſitura.

Problem 1. Whether and when a star of given longitude and latitude will reach the equator or its tropic, or will even cross it.

I. *First*, a star without latitude reaches the equator when it reaches the beginning of Aries or Libra. So seek the arc of longitude remaining to the equinoctial points, and convert it into the time that corresponds to it. For example, the star immediately preceding Regulus either lacks all latitude or has a latitude of scarcely half a minute, and in the year 1644 it stood at ♌ 22° 21′ 50″. To the beginning of Libra these fall short by 37° 38′ 10″; and if one degree requires 72 years, these in every case require 2710 years.

[Margin: Example of case 1.]

Second, if the latitude of a star is greater than the obliquity of the ecliptic, it will never reach the equator; and if it is greater than double the obliquity, it will not reach the tropic.

Third, if the latitude of a star is equal to the obliquity of the ecliptic, it will reach the equator when it reaches the beginning of Cancer, if the latitude is south, or when it reaches the beginning of Capricorn, if the latitude is north; and from there it will go on receding from the equator. So from the distance of such a star from the beginning of ♋ or ♑, seek the time corresponding to that distance.

Fourth, if a star's latitude is less than the obliquity of the ecliptic, it will at some time cross the equator, and will change south declination into north, or north into south, etc.

Problema 2. An & quæ Stella capax ſit tranſitus per Verticem habitantis extra Zonam Torridam.

Problem 2. Whether a star, and which, is capable of passing through the zenith of someone living outside the Torrid Zone.

[Margin: 1. Rule.]

II. *First*, a star without latitude never passes through the zenith of the inhabitant already mentioned; just as a star having south latitude does not pass through the zenith of northerners, nor a star having north latitude through the zenith of southerners.

[Margin: 2. Rule.]

Second, a star whose north latitude is less than the distance of the zenith from the tropic of ♋ does not pass through the zenith of northerners, and always remains south. Likewise, a star whose south latitude is less than the distance of the zenith from the tropic of ♑ does not pass through the zenith of southerners, and always remains north.

[Margin: 3. Rule.]

Third, a star whose north latitude is equal to the distance of the tropic of ♋ from the zenith passes through the zenith of northerners when it is at the beginning of ♋; otherwise it is always south. Similarly, a star whose south latitude equals the distance of the tropic of ♑ from the zenith passes through the zenith of southerners when it is at the beginning of ♑; otherwise it is always north.

[Margin: 4. Rule.]

Fourth, a star whose north latitude is greater than the sum of the distance of the equator from the zenith and the declination of the tropic does not come to the zenith of northerners, but is always north for them. Similarly, a star whose south latitude is greater than the sum already mentioned does not come to the zenith of southerners, but is always south for them.

[Margin: 5. Rule.]

Fifth, a star whose north latitude is equal to the sum of the distance of the equator from the zenith and the declination of the tropic passes through the northern zenith when it is at the beginning of ♑. Similarly, a star whose south latitude equals the sum already mentioned passes through the southern zenith when it is at the beginning of ♋.

[Margin: 6. Rule.]

Sixth, therefore, every star whose latitude is neither less than the distance of the zenith from the nearer tropic nor greater than the distance of the farther tropic from the zenith is capable of passing through the zenith of northerners, if the latitude is north, and of southerners, if south, who live outside the Torrid Zone.

Problema 3. An & quæ Stella capax ſit tranſitus per verticem habitantis in Zona Torrida.

Problem 3. Whether a star, and which, is capable of passing through the zenith of someone living in the Torrid Zone.

[Margin: 1. Rule.]

III. *First*, a star without latitude passes at some time through the zenith: through that of those living under the equator when it is at the beginning of ♈ and ♎, and through that of those living under the tropics when it comes to their tropic.

[Margin: 2. Rule.]

Second, a star whose latitude does not exceed the distance of the zenith from the farther tropic is capable of passing through the zenith, that of northerners if the latitude is north, that of southerners if south. But if it exceeds the distance already mentioned, it is not capable of such a passage, but is always north for northerners, if the latitude is north, and south for southerners, if the latitude is south.

[Margin: 3. Rule.]

Third, a star whose north latitude is equal to the distance of the zenith from the farther tropic comes to the zenith of a northern inhabitant when it is at the beginning of ♎. Similarly, a star whose south latitude equals the distance of the zenith from the farther tropic comes to the zenith of a southern inhabitant when it is at the beginning of ♋.

[Margin: 4. Rule.]

Fourth, a star whose latitude toward the opposite quarter does not exceed the distance of the zenith from the nearer tropic is capable of passing through the zenith; but if it exceeds it, it is not capable.

[Margin: 5. Rule.]

Fifth, a star whose south latitude equals the distance of the zenith from the nearer tropic passes through the zenith of northerners when it is at the beginning of ♋; just as a star whose north latitude equals the distance of the zenith from the nearer tropic passes through the zenith of southerners when it is at the beginning of ♎.

Problema 4. Inuenire Tempus, quo ſtella Fixa capax tranſitus per verticem loci dati, tranſijt, aut tranſitura eſt per illum; ſi detur ſtellæ Latitudo & Longitudo.

Problem 4. To find the time at which a fixed star capable of passing through the zenith of a given place has passed, or will pass, through it, if the star's latitude and longitude are given.

IV. Let a star capable of passing through the given zenith be found by Probl. 2 or 3. We must then seek the longitude, or place on the ecliptic, that the star must reach in order to pass through that zenith; for from the given present longitude the time will easily be gathered. So let ABCD be the meridian and solstitial colure, and AC the equator, whose pole is B; let EL be the ecliptic, whose pole is K; and let the zenith be V, through which let VG be drawn parallel to the equator. For it is certain that whenever the star reaches that parallel, it will pass through the zenith V at its culmination, as if it is at F or at H. So we must seek the longitude of the star corresponding to such a position. Now suppose that the star must be at F, and through its centre let there be drawn both the circle of declination BFM and the circle of latitude KFI. Then in

Diagram. A circle set into the right column at the foot of the text, the meridian and solstitial colure of Problem 4, crossed by straight and curved lines representing the equator, the ecliptic, the parallel through the zenith, and circles of declination and latitude through the star's place.

- A (top left, on the circle): point of the meridian
- E, V (top, side by side, on the circle): the end of the ecliptic and the zenith
- B (right, on the circle): pole of the equator
- I (inside, upper left): on the circle of latitude

- F (inside, upper centre): the star's position
- M (left, inside the circle): on the circle of declination
- D (left, on the circle): point of the meridian
- ♎ and ♈ (centre, side by side): the equinoctial points
- K (right, on the circle): pole of the ecliptic
- H (inside, lower right): a second position of the star
- G (lower right, on the circle): end of the parallel through V
- P (inside, lower left): not named in the text on this page
- N (lower centre, inside the circle): not named in the text on this page
- C (lower right of centre, on the circle): point of the meridian
- L (bottom, on the circle): end of the ecliptic triangle FBK find the angle at the pole of the ecliptic, namely FKB; for it will be the argument of the longitude sought. All the triangle's sides are given: BK, the distance of the poles; KF, the complement of the star's latitude; and FB, the complement of the distance of the parallel from the equator, which is always equal to the complement of the altitude of the pole. So the angle FKB will not remain hidden, which measures the ecliptic arc EI, namely the star's distance in longitude from the beginning of ♋, E, both on this side in the first quadrant and beyond it in the second. From this the desired longitude will at once be known. When it is compared with the present longitude, the difference of longitudes will be established, and from that, according to the motion of the fixed stars, the time required for the star to have come or to come to the parallel VG, and so to have passed or to be about to pass through the zenith V. But if the star is supposed at H, draw the arcs of declination BHN and of latitude KHP; and in triangle BHK, in which are given the distance of the poles BK, the complement of the star's latitude KH, and the complement of the altitude of the pole, which is BH, find the angle BKH, which measures the arc EP of the ecliptic. By adding 90° to it you will have the desired longitude of a star of the third quadrant; by subtracting it from 450° the desired longitude of the star will be known, but in the fourth quadrant of the ecliptic. Do likewise in the other cases.

[Margin: Corollary.]

From what has been said you will gather that it is possible for a fixed star, in the whole period of its longitude, if the world lasts so long, to pass twice through a given zenith, according to two of the four quadrants of the ecliptic in which it can come to the given parallel.

EXEMPLVM.

Example.

V. *At Bologna the arc AV, the distance of the equator from the zenith, is 44° 29′ 30″, and its complement VB, that is FB, 45° 30′ 30″; BK, the distance of the poles, is 23° 30′; and the north latitude of the bright star of Lyra, namely the arc FI, 61° 46′*

30″; therefore the arc FK is 28° 13′ 30″. So by the analysis of triangles the angle FKB, and hence the arc EI, is 55° 22′ 45″. Therefore when Fidicula [the Lyre] has been, or will be, at ♉ 4° 37′ 15″ or at ♌ 25° 22′ 45″, it has passed or will pass through the zenith of Bologna. But since in the year 1644 it stood at ♒ 10° 25′ 40″, the difference of longitude to ♉ 4° 37′ 15″ is 114° 11′ 35″, for which there are required, in my opinion, 8222 years; going backward, however, to ♌ 25° 22′ 45″, it is 135° 2′ 55″, for which there are required about 9721 years. So on the true chronology Fidicula has never yet passed through the zenith of Bologna, nor will it pass except 6062 years from now.

Problema 5. An ſtella Polaris, aut alia fuerit aut futura ſit vnquam in ipſo Mundi Polo.

Problem 5. Whether the Pole Star, or another, has been or will ever be at the very pole of the world.

VI. Two conditions are required for a star to be at the very pole of the world. The *first* is that its latitude be precisely as great as the complement of the distance of the poles; the *second*, that if the latitude is north, the star be at the beginning of Cancer, and if south, at the beginning of Capricorn. In our view, then, the star's latitude ought to be 66° 30′, and I find none such in the corrected catalogues. According to Copernicus and his followers, however, the greatest distance of the poles is 23° 52′ and the least 23° 28′; so the star would have to have a latitude not greater than 66° 32′ nor less than 66° 8′. Such is the star of the 4th magnitude in Cygnus, the leading one of the two toward Lyra, whose latitude is 66° 15′. But when will these conditions coincide, so that this star is at the beginning of Cancer at the very time when, as the variation of the obliquity of the ecliptic brings it about, the star's latitude is precisely equal to the complement of the obliquity, or of the distance of the poles? The latitude of the star now the Pole Star, that is, of the last one in the tail of Ursa Minor, is 66° 2′. So it has never been, nor will be, at the very north pole of the world, even though it is going to approach it as closely as it ever will, and to reach the beginning of Cancer in the year of Our Lord 2092 according to Tycho, 2103 according to us; and it will then be about 7′ from the pole of the world, after which it will begin to recede from it. We, however, once misled by the authority of Regiomontanus, used to think that this star would reach the very pole of the world.

[Margin: The Pole Star never at the pole of the world.]

[Margin: Regiomontanus's deception.]

Problema 6. Data ſtellæ Declinatione, & Altitudine Poli, ſcire vtrum ſtella Oriatur & Occidat, necne.

Problem 6. Given a star's declination and the altitude of the pole, to know whether the star rises and sets or not.

VII. *First*, if the complement of a south declination is less than the altitude of the north pole, or the complement of a north declination is less than the altitude of the south pole, the star will always lie hidden below the horizon.

Second, if the complement of a south declination is equal to the altitude of the north pole, or the complement of a north declination is equal to the altitude of the south pole, the star will graze the horizon, and will never appear of itself, but only by the aid of refraction.

Third, if the complement of a south declination is less than the altitude of the south pole, or that of a north declination less than the altitude of the north pole, or equal to it, the star will always appear above the horizon; for although, when they are equal, it should graze the horizon, refraction will nevertheless lift it up.

Fourth, if the complement of a north declination is greater than the altitude of the north pole, or the complement of a south declination is greater than the altitude of the south pole, and likewise if a south declination is less than the complement of the altitude of the north pole, or a north declination less than the complement of the altitude of the south pole, the star will rise and set.

Problema 7. Data Poli altitudine, & ſtellæ latitudine versùs illum Polum, ſcire an & quando ſtella quæ Oritur & Occidit, euaſura ſit Semper Apparens, & è conuersò.

Problem 7. Given the altitude of the pole and a star's latitude toward that pole, to know whether and when a star that rises and sets will become always visible, and conversely.

VIII. *First*, we must find the declination of the always-visible circle that grazes the horizon, which is done by subtracting the altitude of the pole from 90°. So for a star that rises and sets to become always visible, its latitude toward your pole must be so great that the sum of the latitude and of the distance of your tropic from the equator equals or exceeds the declination of the always-visible circle. For if it equals it, the star will reach contact with the circle of always-visible stars; if it exceeds it, the star will pass inside that circle.

Second, if a star is to turn from always visible to rising and setting, its latitude must be less than the sum of the declination of the circle of always-visible stars and the distance of the opposite tropic from the equator.

[Margin: Finding the desired time.]

Third, from what has just been said, ask whether the star is capable of such a change. Then use the figure of Problem 4, but take the parallel VG for the circle of always-visible stars; and in triangle BFK, with BK, the distance of the poles, with KF, the complement of the star's latitude, and with BF, an arc that always equals the altitude of the pole, or the complement of the declination of the circle of always-visible stars, seek the angle at the pole of the ecliptic, namely BKF. For it will be the argument of the longitude, as we said there. When the star reaches that longitude (which will become known from the

present longitude and the difference from the longitude found, and from the motion in longitude, or the time owed to that difference), it will also reach the circle of always-visible stars, etc.

Problema 8. Mediationem Cæli ſeu Punctum Eclipticæ Culminans cum Stella Fixa Inuenire.

Problem 8. To find the mediation of the heaven, or the point of the ecliptic culminating with a fixed star.

IX. Seek the star's right ascension in the usual tables of right ascensions corresponding to the points of the ecliptic, but in the body of the tables. For opposite it, in the left margin, you will find the degrees, and under the head of the table the sign of the ecliptic with which the star mediates heaven, or crosses the meridian. Or, from the given right ascension and the obliquity of the ecliptic, seek that point by the analysis of a right-angled spherical triangle. For let AIL be the equator and A♋LV♑ the ecliptic, and let the right ascension given in the first quadrant of the equator be AD. When the arc of declination GD is drawn, the triangle ADG is formed, right-angled at D, in which, with the side AD given, and the angle GAD of the obliquity of the ecliptic, find the base AG, and you will have at G the point of the ecliptic culminating with the star, reckoned from the beginning of Aries. *Second*, let the right ascension be AH, in the second quadrant; for its complement to 180° will be the side HL, in triangle HLV, right-angled at H. So with the angle at L seek the base VL, and subtract it from 180°; for the arc of the ecliptic AV will remain, and the point of the ecliptic, reckoned from the beginning of Aries, with which the star mediates heaven will be known. *Third*, let the right ascension be in the third quadrant; for when 180° is taken from it, HL will remain. With that side and the angle HLS, namely with the obliquity of the ecliptic, find the base SL; for when it is added to 180° it will give the longitude from Aries of the point of the ecliptic culminating with the star. *Fourth* and last, let the right ascension be in the fourth quadrant of the equator; for its complement to 360° will be the arc AD. With this, in triangle ADP, right-angled at D, and with the angle of obliquity DAP, seek the base AP; subtract it from 360°, and there will remain the longitude of the point of the ecliptic crossing the meridian with the star.

Diagram. A lens-shaped figure set into the head of the left column, text wrapped on its left: two arcs of the ecliptic meeting at the ends of a straight line, the equator, with three perpendiculars dropped to that line from the upper and lower arcs.

- G (upper arc, left): the culminating point of the first quadrant
- ♋ (upper arc, centre): beginning of Cancer
- V (upper arc, right): the culminating point of the second quadrant
- A with ♈ below it (left end): beginning of Aries
- D (on the line, left): foot of the perpendicular from G and to P
- I (on the line, centre): midpoint of AIL

- H (on the line, right): foot of the perpendicular from V and to S
- L with ♎ beside it (right end): beginning of Libra
- P (lower arc, left): the culminating point of the fourth quadrant
- ♑ (lower arc, centre): beginning of Capricorn
- S (lower arc, right): the culminating point of the third quadrant

Problema 9. Diem inquirere quo Stella cum Sole tranſibit meridianum.

Problem 9. To find the day on which a star will cross the meridian with the Sun.

X. Seek by Probl. 8 the point of the ecliptic culminating with the star, and, from ephemerides or other astronomical tables, the day on which the Sun will reach that point of the ecliptic; and you will have the desired day.

Problema 10. An & cuius ſtellæ Fixæ Aſcenſio Recta poſſit decreſcere etiam ſi creſcat Longitudo eius.

Problem 10. Whether a fixed star's right ascension, and which star's, can decrease even if its longitude increases.

XI. In most stars the right ascension also increases as the longitude increases; in a few, however, it decreases although the longitude increases. Capable of this retrogradation is every star, and that star only, whose complement of latitude is less than the distance of the poles of the ecliptic and the equator. Now the rules for the increase and decrease of the right ascension of the fixed stars, which we of necessity indicated in advance in chap. 13, no. 3, so that no one should err in using the table of right ascensions assigned to the fixed stars by thinking that they always increase: those rules, gathered from here and from the following problem, you have more conveniently at the end of the chapter, in the Corollaries.

Problema 11. Tempus Inuenire Quo ſtellæ Fixæ Aſcenſio recta incipiet decreſcere, durabitq. in tali decremento donec iterum creſcere incipiat; ſi ſit Capax talis decrementi: & Quanta ſit Maxima Aſcentio eius recta. Datis Longitudine ac Latitudine Stellæ vnà cum Diſtantia Polorum.

Problem 11. To find the time at which the right ascension of a fixed star will begin to decrease, and will continue in that decrease until it begins to increase again, if it is capable of such a decrease; and how great its maximum right ascension is. Given the longitude and latitude of the star together with the distance of the poles.

XII. If the star's longitude is in the 1st or 4th quadrant of the ecliptic, use the former of the diagrams that follow; but if in the second and third quadrant, use the latter. In both, let AT be the solstitial colure, and on it let A be the pole of the equator and B that of the ecliptic; let the equator CE and the ecliptic DF be

described from them; and from the pole of the ecliptic B, as centre, with an interval smaller than the distance of the poles BA, describe a small semicircle parallel to the ecliptic, HMOP, which we shall call the semicircle of division [ſemicirculum diſcriminis].

[Margin: 1. Case.]

First, let the star's longitude be in the first quadrant of the ecliptic, ♈F, or in the fourth, D♈; and from the pole of the equator A draw a quadrant of a circle of declination to the equator so that it touches the semicircle of division, namely AMI, touching it at M. For as long as the star proceeds along the arc PM of the semicircle, that is, from the beginning of Capricorn as far as Aries and beyond, short of the point of contact M, its right ascension will increase as the longitude increases. This will be clear to anyone who describes through the star the quadrants of the circles of latitude and declination of the star, and who gathers its two right ascensions from two given longitudes by Probl. 3 of Chapter 12. Thus if the star is at O, draw the quadrant of latitude BS and of declination AL, so that the triangle BOA results. In it, from the given longitude, the angle OBA will be known, and BA, the distance of the poles, and BO, the complement of the star's latitude. So the angle BAO will not remain hidden, which measures the arc CL, the star's equatorial distance reckoned from the beginning of ♎. Next let the star be at M, or at a point between O and M; and when the quadrants of latitude BR and of declination AI are drawn, in triangle BMA you will gather from the given longitude the angle MBA, with which, and with BA, the distance of the poles, and BM, the complement of latitude, you will gather the angle MAB, which measures the arc of the equator CI, to be reckoned from the beginning of ♎. For the arc CI will be greater than CL, and so on for the others, as long as the star is within POM.

Diagram. A large circle occupying the upper part of the right column, the solstitial colure AT of Problem ii, with the equator CE and the ecliptic DF as chords-like curves, the small semicircle of division about B, and quadrants of latitude and declination, some dotted, drawn from B and from A.

- P (top left, outside the small semicircle's end): end of the semicircle of division
- B (top, on the circle): pole of the ecliptic
- H (top right, on the circle's rim): end of the semicircle of division
- O (upper left inside): a position of the star on the semicircle
- N (upper right inside): a further position of the star on the semicircle
- A (upper right, on the circle): pole of the equator
- M (centre, upper): point of contact on the semicircle
- C (left, on the circle): end of the equator
- L (left, on the equator): foot of the quadrant of declination from A through O and N
- I (left of centre, on the equator): foot of the quadrant of declination AMI
- D with ♎ below it (far left, on the circle): end of the ecliptic, beginning of Capricorn

- S (on the ecliptic, left of centre): foot of the quadrant of latitude BS
- ♈ (on the ecliptic, centre): beginning of Aries
- R (on the ecliptic, right of centre): foot of the quadrant of latitude BR
- ♋ with F beside it (far right, on the circle): end of the ecliptic, beginning of Cancer
- a letter-like sign at the foot of the dotted quadrant through N, on the ecliptic just inside F: probably the Q of the quadrant BNQ cited in the prose [?]
- E (lower right, on the circle): end of the equator
- T (bottom, on the circle): end of the colure AT

But on the contrary, when the star has passed the point of contact M, along the whole arc MH, and so in the whole remainder of the first quadrant of the ecliptic, the right ascension will decrease as the longitude increases. This will be clear to anyone who gathers from two given longitudes the right ascensions corresponding to them. Thus suppose in triangle BMA you gather, as above, the angle MAB, measuring the arc of the equator CI, and next, with the star advancing to N, the quadrant of latitude BNQ and that of declination ANL are drawn through it: you will always find the angle at the pole of the equator less than the preceding one, and so the arc CL less than the arc CI; and therefore the right ascension will decrease although the longitude increases.

We must now find the point R of the ecliptic, in the first quadrant, on reaching which the star already mentioned will be at the contact M. So in the spherical triangle MAB, right-angled at the contact M, by 5 of the second and 15 of the first of the *Sphaerics* of Theodosius, since AB, the distance of the poles, and BM, the complement of the star's latitude, are given, you will find the angle MBA, which measures the arc RF of the ecliptic. When it is subtracted from 90° there will remain the arc ♈R, that is, the longitude on reaching which the star already mentioned will be at the contact M; and thereafter, in the whole remainder of the first quadrant, its right ascensions will decrease.

[Margin: Maximum right ascension of a star.]

Again, you will find the angle MAB, which measures the arc of the equator CI; this, added to 270°, will give the maximum right ascension that the star already mentioned can have.

[Margin: Time at which it will happen.]

Moreover, since its present longitude is given, you will easily gather, from the difference of longitudes and the time corresponding to it, when the star came or will come to the contact M, and whether it is on the arc PM of the semicircle, which is the arc of increase, or on the arc MH, which is the arc of decrease of the right ascension. I will give an example when I have explained the use of the second diagram.

[Margin: 2. Case.]

XIII. *Second*, let the star be in the second or third of the ecliptic's

quadrants, as in the semicircle FD of the diagram that follows. For when a quadrant AMI of a circle of declination is drawn from A, the pole of the

equator, touching the semicircle of division [ſemicirculum diſcriminis] at M, then so long as the star already mentioned is on the arc HM, its right ascension will decrease while its longitude increases. After that contact, however, it will begin to increase, as will become clear to anyone who works out the right ascensions as above. For if the star is at N, and the quadrants BNQ of latitude and ANL of declination are drawn, then in the triangle ANB you will find the angle NAB, that is, the arc LC. But when the star has advanced to M, and BMR and AMI are drawn, you will find the angle MAB, that is, the arc IC, a larger one to be subtracted from 270°; and so the right ascension of the star placed at M will be smaller than of the star placed at N. Once the contact M has been passed, however, as when the star is at O, the arc LC to be subtracted will be smaller than the arc IC; and so the right ascension will now increase.

Diagram. A large circle set into the left column, breaking the sentence at `arcum | LC`: the second diagram of Problem ii, with the equator EC and the ecliptic FD crossing inside it, the small semicircle of division through N, M and O, and straight and curved quadrants of latitude and declination, some dotted, drawn from B and from A.

- A (top, on the rim, left of centre): the pole of the equator
- H (top, on the rim): end of the semicircle of division
- N (just inside H): a position of the star
- B (top right, on the rim): a pole, the other end of the distance of the poles AB
- P (upper right, on the rim): end of the semicircle of division
- M (upper centre, inside): the contact of the quadrant AMI with the semicircle
- O (upper right, inside): a further position of the star on the semicircle
- F (left, outside the rim), with the sign ♋ beside it: end of the ecliptic
- Q (left, on the ecliptic just inside F, set turned): foot of the quadrant of latitude BNQ
- E (left, outside the rim): end of the equator
- R (left of centre, inside, on the ecliptic): the point sought in the second quadrant
- ♎ (centre, at the crossing of equator and ecliptic, set slanted): the beginning of Libra
- I (right of centre, on the equator): foot of the quadrant AMI
- L (right, on the equator): foot of the quadrant ANL
- C (right, outside the rim): end of the equator
- S (lower right, on the ecliptic): foot of the dotted line through O
- a turned sign on the ecliptic just inside D, resembling ♑: [?]
- D (lower right, on the rim): end of the ecliptic
- T (foot of the circle, outside the rim)

[Margin: Beginning of the increase of right ascension.]

Here too we must find the point R of the ecliptic, belonging to its second quadrant, on reaching which the star will see the decreases cease, and from

which the increases of the right ascensions will begin again. So in the triangle AMB, right-angled at the contact M, given the distance of the poles AB and the complement of the star's latitude BM, seek the angle MBA, which measures the arc FR. Add it to 90°, and you will have the longitude sought, and from it the time, as above.

[Margin: Duration of the already mentioned increase or decrease.]

Finally, by joining the arcs RF of the earlier diagram and FR of the later one, or by doubling either of them (for they are equal), you will have the arc of the ecliptic, and from it the time, through which the decrease of the right ascension will persist, even though the longitude is increasing. The remainder to the whole circle will be the arc in which it increases.

EXEMPLVM.

Example.

[Margin: The hesitation or omission of the Tychonians.]

XIV. While examining the bright star in the shoulder of Ursa Minor, we came upon this very beautiful and new problem, and from it we conjectured why either Tycho or the Tychonians left this star out of their catalogue of right ascensions, although it is of the second rank [fecundi honoris]: because, namely, its right ascension, appearing to them to decrease from the year 1600 to 1700, raised a scruple in them, since they did not know the cause. I should like to give an example in this star, and indeed from the data supplied by Tycho. Now the northern latitude of the bright star in the shoulder of Ursa Minor is 72° 51′ 30″. So in the diagrams above, the arc BM is 17° 8′ 30″, and AB, according to Tycho, is 23° 31′ 30″. So in the spherical triangle AMB, right-angled at M, the angle MAB, that is, the arc CI reckoned from the beginning of ♎, is 47° 25′ 49″. Adding 270°, then, gives the greatest of the right ascensions this star can have, 317° 25′ 49″. Next, in the same triangle the angle MBA, that is, the arc of the ecliptic RF, is found to be 44° 53′ 14″, and accordingly ♈R is 25° 6′ 46″. On reaching this point of Aries the star was at the contact M, and from there its right ascension began to go back and diminish. Now in the year 1600 this star was at ♌ 7° 16′ 30″. So the difference of longitude between this place and the ♈ 25° 6′ 46″ just found is 102° 9′ 44″, for which more than 7150 years are required, and it is certain that the world has not existed for that many years. So this star was never on the arc of increase of the ascensions; rather, its right ascension has always been retrograde and has continually decreased while its longitude increased. For the arc RF, doubled, makes 89° 47′ 28″, which is the arc of decrease. And when 44° 53′ 14″ are added to the beginning of ♋ in the second diagram, one arrives at ♌ 14° 53′ 14″. When this star comes to that point it will be at the second contact M, and its right ascensions will then begin to increase. Now from 7° 16′ 30″ of ♌, where it stood in the year 1600, to 14° 53′ 14″ there are 7° 36′ 44″, for the completion of which Tycho requires 537⅓ years. Therefore the right ascension of this star has always been

decreasing since the beginning of the world, while its longitude increases, and it will go on decreasing until the year of the Lord 2137⅓. This has until now been unknown to astronomers, or, so far as I know, published by no one. The arc of decrease, moreover, is of nearly 6465 years.

COROLLARIA & PROPOSITIONES insignes ex Problemate 11.

Notable corollaries and propositions from Problem 11.

1. Prop. *Those stars whose complement of latitude is less than the distance of the poles of the ecliptic and the equator do not always increase in right ascension, even though their longitude increases.*
2. Prop. *The right ascension of those of the stars already mentioned that are northern increases continually throughout the whole southern semicircle of the ecliptic and in some part of the northern semicircle, while in some other part they decrease.*
3. Prop. *The right ascension of the stars already mentioned, but the southern ones, increases continually in the northern semicircle of the ecliptic; in a part of the southern semicircle they increase and in a part they decrease.* This is clear to anyone who draws, from the southern poles of the ecliptic and the equator, the arcs of latitudes and declinations and the small semicircle touching the circle of declination, on the model of the two diagrams given above in Problem 11.
4. Prop. *The right ascension of the northern stars already mentioned begins to decrease in the first quadrant of the ecliptic and stops decreasing in the second; that of the southern ones begins to decrease in the 3rd quadrant and stops in the 4th, when they come to the mutual contact of their circle of declination and the parallel of the ecliptic along which they travel.*
5. Prop. *The right ascension of the bright star in the shoulder of Ursa Minor has continually decreased since the beginning of the world, and will go on decreasing until about the year of the Lord 2137.*
6. Prop. *The stars whose right ascension decreases, or can decrease, while the longitude increases, number in the Rudolphine catalogue 59 northern and 35 southern*, because their latitude is greater than the complement of the distance of the poles. They lie in the asterisms of the table below.

Northern asterisms [Aſtra Boreal.]	Number of stars [Numerus Stellarum]	Southern asterisms [Aſtra Auſtral.]	Number of stars [Numerus Stellarum]
Ursa Minor	14	Argo Navis	4
Draco	29	Chamaeleon	8
Cepheus	5	Piscis Volans	7
Hercules	4	Doradus	7
Cygnus	7	Hydrus	9
Total [Summa]	59	Total [Summa]	35

CAPVT XX.

Chapter 20.

In Quo Problemata ſpectantia ad Fixarum Ortus Occaſuſq. Aſcenſiones ac Deſcenſ. Obliq. Amplitud. Ortiuas, Puncta Eclipticæ coorientia aut cooccidentia &c.

In which are problems concerning the risings and settings of the fixed stars, their oblique ascensions and descensions, their ortive amplitudes, the points of the ecliptic rising or setting with them, etc.

Problema 1. Differentiam Aſcenſionalem aut Deſcenſionalem ſtellæ aut Puncti cuiuſuis reperire, Data eius declinatione, & altitudine Poli.

Problem 1. To find the ascensional or descensional difference of any star or point, given its declination and the altitude of the pole.

[Margin: What the ascensional and descensional difference is.]

I. The ascensional and descensional difference [DIFFERENTIA Aſcenſionalis & Deſcẽſionalis] is the arc of the equator intercepted between the horizon and the circle of declination of a star standing on an oblique horizon. So in the figure that follows, let APQ be the meridian, on which P is the north pole of the equator, HMR the horizon, and AMQ the equator. Now let the star be at B, the rising point on the horizon, with BI its southern declination. The ascensional difference will then be the arc MI, which becomes known in the spherical triangle BMI, right-angled at I, since the declination BI is given, and the angle BMI, which measures the altitude HA of the equator, or the complement of the altitude of the pole. But if the star is at D, with the northern declination DL, the ascensional difference will be the arc LM, which becomes known by analysis of the triangle MLD, right-angled at L, since in it are given the declination DL and the angle LMD, which equals the angle HMA, the measure of the complement of the altitude of the pole. If, however, the points D or B were on the western semicircle of the horizon, the differences would be descensional. By the same device the ascensional differences are sought for points of the ecliptic whose declination is given. In brief, add the 2nd mesologarithm of the declination to the mesologarithm of the complement of the altitude of the pole, and the logarithm of the ascensional difference will result. Or say: as the radius is to the 2nd tangent of the complement of the altitude of the pole, so is the tangent of the declination to the sine of the ascensional difference.

Diagram. A circle set into the right side of the left column beside the opening of paragraph I, the figure of Problem 1 and of Problems 3 and 4, which refer back to it: the meridian as the rim, the horizon HMR across it, the equator AMQ, and straight and curved arcs through B and D.

- C (top, on the rim)
- A (upper left, on the rim): end of the equator
- K (left, on the rim): end of the parallel KN
- P (upper right, on the rim): the north pole of the equator
- H (left, on the rim): end of the horizon
- I (inside, above the horizon, on AMQ): foot of the declination BI
- M (centre, on the horizon): intersection of horizon and equator
- B (left of centre, just below the horizon line): the star on the rising side, with southern declination
- D (right of centre, on the horizon): the star with northern declination
- R (right, on the rim): end of the horizon
- L (below D, on AMQ): foot of the declination DL
- T (lower right, on the rim): end of the parallel CT
- Q (lower right, at the foot of the rim): end of the equator
- N (foot of the rim, left of Q): end of the parallel KN

Aliter per Tabulas.

Another way, by tables.

II. In the *Tables of Directions* [Tabulis Directionum] of Regiomontanus and of Reinhold there are tables headed "Of Ascensional Differences", and in Magini's *Directions of the Primum Mobile* there is such a table, that of the Fourth Analogy, from page 30. In these, entering with the altitude of the pole at the head or the foot and with the declination at the sides of the table, you will find the ascensional difference in the common cell. But the table of Regiomontanus, which Clavius copied out in his *Sphere*, p. 340, does not go beyond 32° of declination, because he constructed it for the planets, which never have a greater declination; nor does it extend beyond 60° of altitude of the pole.

[Margin: Example.]

I will give an example at number VIII.

Problema 2. Aſcenſionem ac Deſcenſionem Obliquam ſtellæ aut puncti Eclipticæ, cuius data ſit Declinatio, & Aſcenſio Recta, data Poli Altitudine reperire.

Problem 2. To find the oblique ascension and descension of a star or of a point of the ecliptic whose declination and right ascension are given, the altitude of the pole being given.

III. Find the ascensional difference by Problem 1, and subtract it from the right ascension if the declination is northern, or add it if southern, and the oblique ascension will result. Conversely, if the declination is northern, add the ascensional difference to the right ascension; if southern, subtract it, and the oblique descension will result. The table of oblique ascensions was constructed by this technique, but for points of the ecliptic, and it also serves stars with no greater declination than the ecliptic has. There is one such table in Clavius's

Sphere, from p. 349, which begins at 36° of altitude of the pole and goes up to 60°, assuming an obliquity of the ecliptic of 23° 30′. Another is in Magini, in the tables of the *Primum Mobile* or of directions, from 1° to 66° of altitude of the pole, for a least obliquity of 23° 28′ and a greatest of 23° 52′. It is followed by a table from 1° to 79° of altitude of the pole, but for the Tychonic obliquity of 23° 31′ 30″, which Renieri cut down to an altitude of 62° in his most recent *Tabulae Mediceae*, p. 316.

[Margin: Example.]

In these tables you will find the oblique descension if you look up the oblique ascension of the opposite point and take 180° away from it, borrowing a whole circle if need be. An example will come below at number VIII.

Problema 3. Amplitudinem Ortiuam Stellæ aut Puncti inquirere Datis eius Declinatione & Altitudine Poli.

Problem 3. To find the ortive amplitude of a star or point, given its declination and the altitude of the pole.

IV. The ortive amplitude [Amplitudo Ortiua] is the arc of the horizon intercepted between the rising star or point and the equator: in the diagram of Problem 1 it is the arc BM, and MD. It is found by analysis of the spherical triangle right-angled at I or at L, since in these are given the angle at M, which is the measure of the complement of the altitude of the pole, and the declination, BI if southern or DL if northern.

[Margin: A shortened form of the rule.]

In brief, join the logarithm of the declination to the residual of the logarithm of the complement of the polar altitude, and the logarithm of the ortive amplitude will result. Or say: as the radius is to the second secant of the complement of the altitude of the pole, so is the sine of the declination to the sine of the ortive amplitude. I will give an example at number VIII.

Problema 4. Arcum Semidiurnum ac Seminocturnum ſtellæ aut puncti Eclipticæ reperire; & inde Tempus, quod ſtella aut punctum conſumit ab ortu ad occaſum ſui, aut quo latet ſub Horizonte, Data Aſcenſionali Differentia.

Problem 4. To find the semidiurnal and seminocturnal arc of a star or of a point of the ecliptic, and from it the time the star or point takes from its rising to its setting, or during which it lies hidden below the horizon, given the ascensional difference.

V. Here the star is supposed to be one of those that neither always appear nor always lie hidden, which is known by Problem 6 of Chapter 19. With this laid down, recall the diagram of the first problem of this chapter, and let the star or point be at B, with southern declination. Its semidiurnal arc [arcus ſemidiurnus] on the parallel of the equator KN will be the arc BK, which is similar to the arc of the equator AI. So when the ascensional difference IM is

taken from the 90° that the arc AM encloses, the semidiurnal arc will remain. But if the star is at D, with northern declination, add the ascensional difference ML to 90°, and the arc AL will result, to which the semidiurnal arc CD on the parallel CT is similar. The complement of these to a semicircle will be the seminocturnal arc, and by doubling the arcs already mentioned the diurnal or nocturnal arc will result. By converting them into times of the equator you will have the time the star takes from its true morning rising to the meridian, and from there to its setting. When, however, a star rises in the evening with a true rising, the arc is called diurnal improperly, since it is the arc the star runs through by night above the horizon. I will give an example at number VIII. For points of the ecliptic, and for the Sun standing at them, tables of semidiurnal arcs and the like are to be had everywhere.

Problema 5. Punctum Eclipticæ, cum quo ſtella Oritur aut Occidit, ſeu cum quo eleuatur ſupra aut deprimitur infra Horizontem, Data eius Aſcenſione aut Deſcenſione obliqua, & Obliquitate Eclipticæ, cum Altitudine Aequatoris, Inueſtigare.

Problem 5. To find the point of the ecliptic with which a star rises or sets, that is, with which it is raised above or depressed below the horizon, given its oblique ascension or descension and the obliquity of the ecliptic, together with the altitude of the equator.

VI. Let HVR be the meridian, HGR the horizon, AGQ the equator, and ELCPE the ecliptic, whose intersection with the equator is K or M. So in the oblique-angled triangle KGL, given the star's oblique ascension KG, the angle of the obliquity at K, and the angle KGL, which is the complement to 180° of the angle AGH that measures the altitude of the equator, you will find by the analysis of triangles the arc of the ecliptic KL, counted from the vernal section

Diagram. A circle set into the right side of the right column beside the opening of paragraph VI, with the meridian as the rim, the horizon HGR, the equator through G, and the ecliptic through L and M; a dotted line runs from G to D.

- V (top, on the rim)
- A (upper left, on the rim): end of the equator
- E (left, on the rim, below A): where the ecliptic meets the rim
- K (inside, just below E): an intersection named in the prose
- D (inside, right of centre): end of the dotted line from G
- L (right of D, on the horizon's right part): end of the arc KL
- R (right, on the rim): end of the horizon
- H (left, on the rim): end of the horizon
- P (left of centre, below the horizon)
- G (centre, on the horizon)
- M (below G, inside): the other intersection of ecliptic and equator
- C (lower right, on the rim): a point of the ecliptic ELCPE

• Q (lower right, at the foot of the rim): end of the equator

K; and so the point of the ecliptic with which the star rises will be known. But if KG were the oblique descension, the point L would be the one with which the star sets. Similarly in the triangle PMG, when the oblique ascension is greater than 270°, if it is subtracted from 360°, the arc GM will remain. With this, the angle of the obliquity M, and the angle PGM, which is the complement to 180° of the angle HGA subtending the altitude of the equator, you will find the arc of the ecliptic PM. Subtracted from 360°, it will give the arc of the ecliptic counted from the beginning of Aries, with whose terminal point the star rises, etc. You have an example at number 8.

Aliter per Tabulas.

Another way, by tables.

VII. Look up the oblique ascension of the star in the tables named in Problem 2, but in the body of the table [arealiter]; for at the head of the tables you will find the sign of the ecliptic, and in the left margin the degree of the sign, that rises with the star. But if you look up in them, in the body of the table, the oblique descension first increased by 180°, you will find the point of the ecliptic diametrically opposite the point with which the star sets.

EXEMPLVM Problematum Præcedentium in Sirio & in Procyone ad Annum Domini 1644. in Bononienſi Horizonte.

Example of the preceding problems in Sirius and in Procyon, for the year of the Lord 1644, on the horizon of Bologna.

[Margin: Example of Problem 1.]

VIII. In the year already mentioned the southern declination of Sirius is 16° 17′ 30″, and its right ascension 97° 27′ 40″. This, looked up in Magini's table (on which see number 2) under an altitude of the pole of 44° 29′ 30″, gives an ascensional difference of 16° 41′.

[Margin: Example of Problem 2.]

Since the declination is southern, this difference added to the star's right ascension makes the oblique ascension 114° 8′ 40″; subtracted from it, the oblique descension 80° 46′ 40″.

[Margin: Example of Problem 5.]

The oblique ascension already mentioned, looked up in the body of Clavius's table under the altitude of the pole already mentioned, shows the point of the ecliptic with which Sirius rises, ♌ 9° 37′. The oblique descension, increased by 180°, gives ♐ 1° 24′ 30″ of the ecliptic; opposite it is ♊ 1° 24′ 30″, with which Sirius sets.

[Margin: Example of Problem 4.]

Again, since the star's declination is southern, when the ascensional difference of 16° 41′ is taken from 90°, there remains a semidiurnal arc of 73° 19′. To this

correspond 4^h 53^m 16^s, namely the amount of time the star takes from its rising to its culmination.

[Margin: Example of Problem 3.]

Finally, for the southern ortive amplitude, from the said complement of the altitude of the pole, 45° 30′ 30″, and the declination of Sirius, 16° 17′ 30″, the arc of the horizon, or ortive amplitude, is found to be 23° 9′ 27″.

Keeping to the same method: since the northern declination of Procyon in that year is 6° 6′ 40″ and its right ascension 110° 11′ 38″, its oblique ascension is found to be 104° 10′, and the point of the ecliptic rising with it ♌ 2° 27′. Its oblique descension is 116° 14′, and the point of the ecliptic setting with it ♋ 0° 52′. And so for the rest.

Problema 6. Ortum & Occaſum verum Stellæ tam matutinum quàm veſpertinum, ſeu Coſmicum & Acronyctum reperire, ſi Stella ſit ex orientibus & occidentibus.

Problem 6. To find the true rising and setting of a star, morning as well as evening, that is, cosmic and acronychal, if the star is one of those that rise and set.

[Margin: Cosmic rising.]

IX. You will find the true morning rising, or cosmical rising [Ortum Coſmicum], of a star if by Problem 5 you find the point of the ecliptic with which the star rises, and from an ephemeris the day on which the Sun reaches that point.

[Margin: Cosmic setting.]

You will find the true morning setting, or cosmical setting, if by Problem 5 you find the point of the ecliptic with which the star goes down, and from an ephemeris the day on which the Sun reaches the point of the ecliptic diametrically opposite it.

[Margin: Acronychal rising.]

You will find the true evening rising, or acronychal rising [Ortum Acronyctum], if by Problem 5 you find the point of the ecliptic with which the star rises, and from an ephemeris the day on which the Sun reaches the point diametrically opposite that point.

[Margin: Acronychal setting.]

You will find the true evening setting, or acronychal setting, if by Problem 5 you find the point of the ecliptic with which the star goes down, and from an ephemeris the day on which the Sun reaches that point.

I am assuming, moreover, the definitions of the risings and settings already mentioned, given in Book 1, Chapter 32, with their diagrams.

EXEMPLVM IN SIRIO. Ad Annum 1644. Bononiæ.

Example in Sirius, for the year 1644, at Bologna.

X. Since at number eight the points of the ecliptic were found with which Sirius and Procyon ascend above the horizon of Bologna in the year 1644, and

with which they descend, and since from Montebruni's ephemeris, constructed for the meridian of Bologna, the day is established on which the Sun reaches these points and the points diametrically opposite them, I have easily gathered the points of the ecliptic and the days of the risings and settings already mentioned into this little table.

Year 1644, Bologna [Anno 1644. / Bononiæ]	Sirius: place of ☉	Sirius: month	Sirius: day	Procyon: place of ☉	Procyon: month	Procyon: day
Cosmic rising	♌ 9° 37′	Aug.	2	♌ 2° 27′	July	25
Cosmic setting	♐ 1° 25′	Nov.	23	♍ 0° 52′	Dec.	22
Acronychal rising	♒ 9° 37′	Jan.	29	♒ 2° 27′	Jan.	23
Acronychal setting	♊ 1° 25′	May	22	♋ 0° 52′	June	22

Problema 7. Horam diei vel noctis inuenire, qua Stella qualibet earum quæ Oriuntur & Occidunt, emergat ab Horizonte, vel infra illum deſcendat.

Problem 7. To find the hour of the day or night at which any star among those that rise and set emerges from the horizon or goes down below it.

XI. First weigh whether on the given day the star precedes the Sun, that is, reaches the horizon first, or follows it, which will be established from an ephemeris and by inspecting a globe. Next, by Problem 2, seek the oblique ascension and descension of both the Sun and the star, and convert the difference of both into time of the equator. Finally, by Problem 4, seek the diurnal and nocturnal arc of the Sun. With these prepared, keep to the following rules.

[Margin: Rising of a star preceding the Sun.]

First. If the star precedes the Sun, subtract the time of the difference of the oblique ascensions from the nocturnal arc (taking in, if need be, the diurnal arc reckoned from the rising of the preceding day). For the remainder will be the hour from the beginning of the night at which the star emerges, if the subtraction was made from the nocturnal arc alone; but it will be the hour from the rising of the preceding day, or Babylonian hour, if the diurnal arc was taken in.

[Margin: Rising of a star following the Sun.]

Second. If the Sun precedes the star, add the time of the difference of the ascensions to the time of the Sun's rising, and the result will be the time at which the star will emerge from the horizon on that day, or on the following night.

[Margin: Setting of a star preceding the Sun.]

Third, for the setting. If the star precedes the Sun, subtract the time of the difference of the oblique descensions from the time of the Sun's setting reckoned from noon, if this is possible, or from the same time counted from the preceding midnight, and you will have the time at which the star goes

down below the horizon, reckoned either from noon or from the preceding midnight.

[Margin: Setting of a star following the Sun.]

Fourth. If the Sun precedes the star, add the time of the difference of the oblique descensions to the time of the Sun's setting, and the result will be the time at which the star sets on the following night, or after the rising of the day.

When, however, the star's rising or setting precedes or follows the Sun's rising or setting by several hours, gather the oblique ascension of the Sun corresponding to one degree, multiply it by those several hours, divide the sum by 24, and add the quotient to the difference of the oblique ascensions if the star rises or sets later than the Sun, but subtract it if earlier.

Another way, from Magini in the *Directions*, Canon 17. Subtract the oblique ascension of the Sun from the oblique ascension of the star; for if the remainder is less than the Sun's diurnal arc, the star will rise by day; if greater, by night. When this has been done, sub- tract the Sun's semidiurnal arc (for so it should have been, although there it is wrongly *diurnum*, "diurnal") from the difference of the oblique ascensions of the Sun and the star. For if nothing remains, the star will rise at noon; but if 180° remain, it will rise at midnight. But if the remainder is greater or less than a semicircle, convert it into hours, and you will have the time of the star's rising from noon; and if you take away the diurnal arc, it will be the time from the Sun's setting.

For the star's setting, subtract the oblique descension of the Sun from the oblique descension of the star, taking in a whole circle if the subtraction cannot be made; and the remainder, converted into hours, will be the time from the Sun's setting at which the star sets. If it exceeds the Sun's nocturnal arc, the star will set during the following day; but if it is less, it will set by night.

EXEMPLVM IN SIRIO. Anno 1644. Septembris 22. Bononiæ.

Example in Sirius, 1644 September 22, at Bologna.

XII. The longitude of Sirius in the year 1644 is ♋ 9° 19′. The place of the ☉ on September 22, at Bologna, at noon, I have as ♍ 29° 45′; the star therefore precedes the Sun. The oblique ascension of Sirius, from what was said at number 8, is 114° 9′, and its descension 80° 47′. The Sun's oblique ascension at that time is 179° 42′, and its oblique descension 179° 53′. The difference of the ascensions is therefore 65° 33′, to which correspond $4^h\ 22^m\ 12^s$; and the difference of the descensions is 99° 6′, whose time is $6^h\ 36^m\ 24^s$. The Sun's diurnal arc, like its nocturnal arc, is 12 hours. From these I subtract $4^h\ 22^m\ 12^s$, and there remains the time from the Sun's setting at which Sirius emerges from the horizon, namely $7^h\ 37^m\ 48^s$ Italian.

Again, since the star's setting precedes the Sun's setting, and I cannot subtract the time of the difference of the oblique descensions from the time of the Sun's setting reckoned from noon, which is 6^h, I take the time of the Sun's setting

from midnight, and this makes 18 hours. From these I subtract $6^h\ 36^m\ 24^s$, and there remain $11^h\ 23^m\ 36^s$ from midnight, at which Sirius goes down below the horizon.

If one wishes to work more precisely: since the Sun's oblique ascension corresponding to one degree is 78′ on that day, this multiplied by 7⅔ hours gives about 598, and when this is divided by 24 it makes 25′, whose time is $1^m\ 40^s$. I subtract this from the time of the difference of the oblique ascensions, and there remain $4^h\ 20^m\ 32^s$. When these are subtracted from the Sun's nocturnal arc, or from 12^h, there remains the time of the emergence of Sirius, $7^h\ 39^m\ 20^s$ from the Sun's setting.

Problema 8. Dato Puncto Eclipticæ, cum quo Stella Fixa oritur, aut occidit Coſmicè, vel Acronycè, & Latitudine Stellæ Poliq. altitudine; Inquirere locum ſtellæ, & inde Sæculum quo ſubijt ortum illum occaſumq.

Problem 8. Given the point of the ecliptic with which a fixed star rises or sets cosmically or acronychally, and the latitude of the star and the altitude of the pole, to find the star's place, and from it the century in which it underwent that rising and setting.

XIII. This problem, certainly an ingenious one and not useless for examining ancient observations of the fixed stars, is given by Longomontanus, Book 2 of the *Sphaerics*, Chapter 4, Problem 2, and by our own Pétau in the dissertations of the *Uranologion*, Book 1, Canon 19.

Let the evening rising of Arcturus be examined. For this, in the following diagram, let ABZ be the meridian, B the pole of the world, C that of the zodiac, and GHL the horizon, on which let Arcturus, rising for the sake of example, be D. Let FHI be the equator and EKO, etc., the ecliptic, with its equinoctial section at P. When an arc of latitude CDM has been drawn through the star D, the star's latitude will be the arc MD, and the star's place with respect to the ecliptic will be at M; and the point of the ecliptic with which the star rises will be K, whose declination from the equator is KS. First

Diagram. A large circle (the meridian ABZ of the text), set into the lower part of the left column with the text running in a narrow measure to its left. A small circle is centred at B on the upper right of the great circle and another at the Z-shaped label on its lower left; these are joined by straight and curved arcs crossing the interior, which meet at D, K, H, the point labelled Q and the point labelled R.

- A (top of the circle, outside): point on the meridian
- B (upper right, inside the small circle): pole of the world, per the text
- C (right of the upper small circle, on its rim): pole of the zodiac, per the text
- E (upper left on the rim): end of the ecliptic EKO, per the text
- F (left on the rim, above G): end of the equator FHI, per the text
- G (left on the rim): end of the horizon GHL, per the text

- T (upper interior): not cited on this page
- R (left interior, below T): not cited on this page
- Q (left interior, on the line from G): not cited on this page
- H (centre left, on the horizon line): intersection of horizon and equator, per the text
- S (below H): foot of the declination KS, per the text
- K (centre, above S): co-rising point of the ecliptic, per the text
- D (right of centre, on the horizon line): Arcturus, per the text
- L (right on the rim): end of the horizon, per the text
- P (lower right interior): equinoctial section, per the text
- N (lower right interior, right of P): not cited on this page
- M (lower right interior, below P): the star's place on the ecliptic, per the text
- I (right, outside the rim, below L): end of the equator, per the text
- O (lower right, outside the rim): end of the ecliptic, per the text
- V (lower left on the rim): not cited on this page
- Z (lower left, inside the small circle; a looped, tailed sort): end of the meridian ABZ, per the text

it is necessary to seek the arc KM, that is, the difference between the star's place on the ecliptic and the co-rising point of the ecliptic, which will be done as follows. In triangle KPH are given KP, the distance of the co-rising point from the nearer equinox; the angle KHP, equal to the altitude of the equator; and HPK, the obliquity of the ecliptic. The angle HKP will therefore not be hidden, and its complement to 180° will be the angle MKD, in triangle MKD, right-angled at M, in which the star's latitude MD is given. Hence by the analysis of this triangle the arc of the ecliptic KM will not be hidden, namely the difference between the known co-rising point of the ecliptic, K, and the point of the ecliptic M, which is the star's required place. And from the place of the same star taken from a star catalogue for the time of the epoch, you will gather the difference of the two longitudes, and from it the interval of time.

EXEMPLVM IN ARCTVRI. Ortu veſpertino, ex Heſiodo.

Example in the evening rising of Arcturus, from Hesiod.

Hesiod, who flourished on Mount Helicon near Athens at about the beginning of the Olympiads, or about the year 775 before Christ, sings thus of Arcturus in Book 2 of the *Works and Days*:

> When sixty days after the turnings of the Sun, Days of winter,
> Jupiter has completed, then indeed the star Arcturus, leaving the immense flood of Ocean, First appearing whole, rises in the evening.

Here he clearly describes the true evening rising of Arcturus 60 days after the winter solstice, as Longomontanus rightly has it above, and Kepler in the *Epitome of Copernican Astronomy*, p. 398. At that time (for one needs to know that century roughly for a more precise working) the Sun's apogee was at

about ♉ 20°, and therefore the Sun's corrected motion in 60 days is 61⅙°, as Longomontanus says. When this is added to the place of the winter solstice, that is, the beginning of Capricorn, the Sun's place comes to ♓ 1⅙°, which is the place opposite the place with which Arcturus rose in its true evening rising. Therefore point K, co-rising with Arcturus, was ♍ 1⅙°. Hence its distance from the nearer equinox, or arc KP, is 28° 50′; the altitude of the equator at Athens, that is, angle PHK, is 52° 15′, from Ptolemy's *Geography*; and the obliquity of the ecliptic, HPK, which Longomontanus uses, is 23° 32′. Therefore angle PKH is 107° 43′ and MKD 72° 17′.

The latitude of Arcturus, or side MD, is 31° 3′ north; therefore arc KM is 11° 5′, which, added to point K, that is, to ♍ 1° 10′, gives the place M of Arcturus, ♍ 12° 15′. But at the completed year 1644 the place of Arcturus has been found by us to be ♎ 18° 19′. Arcturus has therefore advanced from Hesiod's time to ours by 36° 4′, and to traverse these, according to our motion of the fixed stars, 2597 years are required. From these I subtract the 1644 years of Christ, and there remain 953 years before Christ. Hesiod therefore seems to speak of the rising of Arcturus not of his own time but of the second century preceding him. This working, however, is rendered uncertain both by the refraction of Arcturus, which hastens its rising, and by that of the Sun, which delays the Sun's setting, and by the day of the winter solstice having been computed in a civil and rather coarse way. So this practice is not to be trusted much, unless you have more certain indications from ancient observations.

EXEMPLA ALIA INDICATA.

Other examples pointed out.

XIV. In Chapter 16 of the *Elements of Astronomy*, Geminus says that, according to Euctemon, Arcturus used to rise on days 10 and 19 of Parthenon; hence the first rising was the cosmic, the second the heliacal. And Pliny the Elder, Book 18, Chapter 25, relates that Thales set the morning setting of the Pleiades on the 25th day after the autumnal equinox, which Pétau says is to be understood of the cosmical setting, Book 1 of the *Dissertations* of the *Uranologion*, Canon 19. There, by the preceding problem, he gathers that in the century of Euctemon Arcturus was in ♍ 19° 7′, and the bright star of the Pleiades in the time of Thales in ♈ 23° 53′, and thus that Euctemon flourished about the year 4188 of the Julian Period, and Thales in 4116; that is, Euctemon in the year 526 before Christ, and Thales in 598.

Problema 9. Ortum & Occaſum Heliacum Stellæ inueſtigare In Data Altitudine Poli.

Problem 9. To investigate the heliacal rising and setting of a star at a given altitude of the pole.

XV. On this problem, carefully, Regiomontanus, Book 8 of the *Epitome of the Almagest*, Proposition 14; Magini

[Margin: Authors of this problem.]

in the *Tables of the Primum Mobile*, or of Directions, Canons 20, 21 and 22, and in Book 8 of the *Primum Mobile*, Problem 22; Longomontanus, Book 2 of the *Sphaerics*, Chapter 4, Problem 3; Kepler in the *Epitome of Copernican Astronomy*, from p. 371; and Pétau, Book 1 of the *Dissertations* of the *Uranologion*, Canon 14; and before these, Ptolemy, Book 8, Chapter 6; Regiomontanus in the *Epitome*, Book 8, Proposition 11. From these, keep to the following method.

First, find the arc of vision, that is, of a vertical circle, by which the Sun must be depressed below the horizon so that the Sun's nearness and the twilight do not hinder the star's appearance. This arc varies with the varying apparent magnitude and brilliance of the stars, and with the varying depth of the Sun required for the first twilight, which for some is 18° and for others 19°, according to what was said in Book 1, Chapter 31; we shall establish this depth in the Book on Optics, once the refractions have been settled. For now let it suffice to present this arc from what is commonly observed, as the authors already mentioned use it, in the following little table, in line with the view of Ptolemy, Book 8, Chapter 6, and Book 13, Chapter 7.

[Margin: Arc of vision.]

Arc of vision for the stars [ARCVS VISIONIS PRO STELLIS]

Planets	Arc	Fixed stars, magnitude	Arc
♄	11° 0′	First	12°
♃	10° 0′	Second	13°
♂	11° 30′	Third	14°
♀	5° 0′	Fourth	15°
☿	10° 0′	Fifth	16°
		Sixth	17°
		Least	18°

Second, find the point of the ecliptic with which the star truly rises or sets, by Problem 5, and by the common problems of the primum mobile seek the angle that the ecliptic makes with the horizon at that point co-rising or co-setting with the star; or else by tables made for that purpose, which Magini gives in the Tables of Directions from p. 200, from 30° to 51° of altitude of the pole, but for all altitudes of the pole Kepler in the Rudolphine Tables, p. 26, and from him Boulliau in the tables, p. 158; or else hunt it down by the analysis of triangles in the following scheme.

Diagram. A large circle (the meridian ABC of the text), set into the lower part of the left column with the text running in a narrow measure to its left. A small circle centred at B stands on its upper right. The horizon HFR crosses the great circle from left to right, and the ecliptic EFC crosses it from upper left to lower right, the two meeting at F; further arcs descend from A and from the small circle to the region of F, G, I, L, M, S and N.

- A (top, outside the rim): vertex, per the text
- P (top, above the small circle): a pole of the ecliptic, per the text

- B (upper right, inside the small circle): a point of the meridian ABC, per the text
- Q (right of the small circle): a pole of the ecliptic, per the text
- E (upper left, on the rim): end of the ecliptic EFC, per the text
- H (left, on the rim): end of the horizon HFR, per the text
- R (right, on the rim): end of the horizon, per the text
- G (centre, on the horizon line): foot of the vertical arc on the horizon, per the text
- I (centre, immediately right of G): star on the horizon, per the text
- L (right of I): star on the horizon, per the text
- F (centre, below G): intersection of horizon and ecliptic, per the text
- M (below F): foot of the latitude MI on the ecliptic, per the text
- S (below M): the Sun, per the text
- N (below and right of S): foot of the latitude LN on the ecliptic, per the text
- C (lower right, on the rim): end of the ecliptic and of the meridian ABC, per the text

In it let ABC be the meridian, HFR the horizon, and EFC the ecliptic, whose poles are either at P or at Q, as the star's position requires. Let the star be at point I or L of the horizon, rising or setting, and through it let a circle of latitude QIM or PLN be drawn to the ecliptic; for the latitude of the star I will be MI, and of the star L, LN. Since, therefore, in triangle FMI, right-angled at M, if the star is at I, the latitude MI is given, and point F of the ecliptic, co-rising or co-setting with the star, when compared with the point of the star's longitude, which is M, shows the arc of the ecliptic FM, the angle MFI, which the ecliptic makes with the horizon at the point co-rising or co-setting with the star, will not be hidden from a trigonometer. Likewise in triangle FNL, right-angled at N, from the star's latitude NL and from the difference of point F, co-rising or co-setting, from point N, the star's place, that is, from arc FN, you will gather the angle NFL, which the ecliptic makes with the horizon, etc.

Third, from the vertex A draw the arc of a vertical circle AS down to the Sun S, placed below the horizon, so that the arc of vision given above is GS. For in triangle FGS, right-angled at G, with the angle at F now found and the arc of vision GS, you will find by the solution of triangles the arc of the ecliptic FS. This is, and is called, the interval of the ecliptic for the star's appearance or occultation [Interuallum Eclipticæ Apparitionis vel Occultationis], which serves to determine the star's heliacal rising and setting; for from an ephemeris one can learn the day on which the Sun reaches the degree of the ecliptic distant from the point F of the ecliptic, co-rising or co-setting with the star, by just as much as the interval FS.

[Margin: Shortcut of the operation.]

But if the altitude of the pole is 43°, 44° or 45°, use Magini's table in the *Directions of the Primum Mobile*, p. 195. In it, under the arc of vision noted at the head of the table, and with the sign and point of the ecliptic with which

the star rises or sets looked up in the left or right margin of the table, you will find in the common area the interval of appearance suited both to the planets and to fixed stars of any magnitude.

Fourth, since the star rises with the Sun in its true morning rising, or cosmical rising, before it rises out of the Sun in its heliacal morning rising; and conversely sets heliacally in the evening before it sets truly, or acronychally, it will be easy, from the interval of appearance and the days in which the Sun traverses it on the ecliptic, to know by how much time the heliacal morning rising follows the cosmical rising, or the heliacal setting precedes the true evening setting.

EXEMPLVM IN SIRIO ET PROCYONE Per Tabulam Maginii, pro Anno 1644. Bononiæ.

Example in Sirius and Procyon, by Magini's table, for the year 1644, at Bologna.

XVI. Sirius, from what was said at number VIII, in the year 1644 at Bologna, where the altitude of the pole is 44° 29′ 30″, rises cosmically with ♌ 9° 37′ and sets acronychally with ♊ 1° 24′ 30″. To the former point, under the altitude of the pole already mentioned and under a star of the first magnitude, such as Sirius is, or under an arc of vision of 12°, corresponds an arc of appearance of 13° 55′; when these are joined with ♌ 9° 37′, the result is ♌ 23° 32′. In that year the Sun reached this degree on August 16. To the latter point, of the setting, or 1° 25′ of ♊, corresponds an arc of occultation of 23° 27′; when these are subtracted from ♊ 1° 25′, there remains ♉ 7° 58′, which the Sun reached in that year on April 27, on which day Sirius sets heliacally in the evening, whereas before it was appearing on the horizon.

Next, the point co-rising with Procyon is ♌ 2° 27′, and the arc of appearance 15° 56′; therefore the heliacal rising occurs with the Sun placed in ♌ 18° 23′. The co-setting point, however, is ♋ 0° 52′, and the arc of occultation 20° 16′; therefore the heliacal setting will be with the Sun in ♊ 10° 36′. For Procyon is of the second magnitude. You will find nothing different if you seek these risings or settings by the analysis of triangles. So, combining all the risings and settings of Sirius and Procyon from what has been said here and at number X, let there be a second little table, fuller than the one placed there.

Year 1644, Bologna [ANNO 1644. / Bononiæ]	Sirius: ☉ in	Sirius: month	Sirius: day	Procyon: ☉ in	Procyon: month	Procyon: day
Cosmic rising	♌ 9° 37′	Aug.	2	♌ 2° 27′	July	25
Heliacal rising	♌ 23° 32′	Aug.	16	♌ 18° 23′	Aug.	11
Cosmic setting	♐ 1° 25′	Nov.	23	♑ 0° 52′	Dec.	22
Acronychal rising	♒ 9° 37′	Jan.	29	♒ 2° 27′	Jan.	23
Heliacal setting	♉ 7° 58′	Apr.	27	♊ 10° 36′	June	1
Acronychal setting	♊ 1° 25′	May	22	♋ 0° 52′	June	22

CAPVT XXI. In Quo Definitiones ac Regulæ Ortuum & Occaſuum Explicantur ampliori Notione quàm anteà.

Chapter 21. In which the definitions and rules of risings and settings are explained in a fuller sense than before.

I. In Book 1, Chapter 32, indeed, when instructing the beginner, I preferred to explain only four species of the rising of stars, and as many of setting, along with most of the recent writers of little books on the sphere. Now, however, it has seemed right to set them out a little more fully for a better-instructed reader, whom I nonetheless refer to that chapter for the diagrams representing rising and setting. Not all the ancients, moreover, use either the same names or the same distribution and number.

[Margin: Opinion of Theophrastus.]

For Theophrastus, in the book *On the Signs of Rain*, mentions only two settings and two risings. The former setting he calls [Greek: ἀφανισμὸς δύσις (aphanismos dysis)], namely a setting that does not appear, which, he says, occurs when [Greek: σονδύνῃ τῷ ἡλίῳ τὸ ἄστρον (sondynēi tōi hēliōi to astron)], that is, when the star sets together with the Sun.

[Margin: Pétau corrected.]

Pétau, Book 1 of the *Dissertations* of the *Uranologion*, Chapter 1, interprets this of a heliacal setting occurring a little after the Sun's setting, but not correctly, since at that time the star and its setting appear, and the setting does not occur with the Sun; whereas Theophrastus says that it occurs with the Sun and does not appear. The latter setting is [Greek: ὅταν ἀνατέλλοντι τῷ ἡλίῳ δύνῃ (hotan anatellonti tōi hēliōi dynēi)], *when it sets as the Sun rises*, which the more recent writers call the cosmical setting. The former rising is [Greek: ἀνατολὴ ἑῴα (anatolē heōia)], *morning rising*; but he shows that he is speaking of the heliacal rising when he adds [Greek: ὅταν πρωανατέλλῃ τοῦ ἡλίου τὸ ἄστρον (hotan prōanatellēi tou hēliou to astron)], *when the star rises before the Sun*. The latter rising he calls [Greek: ἀνατολὴ ἀκρόνυχος (anatolē akronychos)], *evening rising*, which he teaches occurs [Greek: ὅταν ἀμαδυομένῳ τῷ ἡλίῳ ἀνατέλλῃ (hotan amadyomenōi tōi hēliōi anatellēi)], when the star rises together with the setting Sun; and this is the acronychal evening rising.

[Margin: Opinion of Achilles Tatius.]

Achilles Tatius, in the *Isagoge* to the *Phaenomena* of Aratus, touches on just as many risings and settings, but only true ones: namely the morning rising with the Sun and the evening rising at the Sun's setting, and the evening setting with the Sun and the morning setting at the Sun's rising. But this rising, which has reference to the Sun, he calls [Greek: ἐπιτολὴ (epitolē, "rising with reference to the Sun")], while the absolute one, which occurs without reference to the Sun, he calls [Greek: ἀνατολὴ (anatolē, "absolute rising")], a distinction that Geminus also uses, as below.

[Margin: Opinion of Ioannes Tzetzes.]

Ioannes Tzetzes, on Book 2 of Hesiod, agrees on nearly the same number, but not on the species. For he says that a star preceding the Sun by 15° makes [Greek: ἑῴαν ἀνατολὴν (heōian anatolēn)], that is, a morning rising; but when it is less than 15° from it, [Greek: ἑῴαν δύσιν (heōian dysin)], a morning setting. When, however, it follows the preceding Sun by fifteen degrees, it makes [Greek: ἀνατολὴν ἑσπερίαν (anatolēn hesperian)], namely an evening rising; and when it is less than 15° distant, [Greek: ἑσπερίαν δύσιν (hesperian dysin)], or an evening setting. He adds, however, that when a star goes down below the earth diametrically opposite the Sun, it is called [Greek: ἀκρονυχίαν (akronychian, "acronychal")]. So the first four species are heliacal emergences from the Sun's rays, or immersions, while the fifth is the true morning setting [recte: *verus*; the page prints *verſus*]. On this Pétau notes that the heliacal evening rising suits only Mercury and Venus, but the Moon should have been added.

Julius Firmicus, Book 2, Chapter 8, also offers us a fourfold division, saying: *The five stars, namely* ♄, ♃, ♂, ♀ *and* ☿, *become morning or evening, or western, or hidden, which by the Greeks are called* [Greek: ἀφανῆται καὶ συνοδικαὶ (aphanētai kai synodikai)]*, or* [Greek: ἀκρονύκται (akronyktai)]. He then explains: *Morning stars in rising are those that rise preceding the orb of the* ☉*; evening stars in rising are those that follow the rising Sun; hidden stars are those that the orb of the* ☉ *covers;* [Greek: ἀκρονύκται] *are those that rise when the Sun sets.* Thus the first is the heliacal morning rising and the second the heliacal evening rising; in the others he indicates risings and settings with the Sun that do not appear, and in the last place the true evening rising.

[Margin: Distribution of Geminus and, nearly, of Proclus.]

II. Geminus, however, has distinguished more species for us, in the *Elements of Astronomy*, Chapter 11, and Proclus, expounding Book 2 of Hesiod, nearly follows him. Geminus says that [Greek: ἀνατολὴν (anatolēn)] is the daily rising of a star without reference to the Sun, but [Greek: ἐπιτολὴν (epitolēn)] with reference to the Sun. Next, according to him there are four species of rising and as many of setting, namely:

1. [Greek: ἐπιτολὴ ἑῴα ἀληθινὴ (epitolē heōia alēthinē)], *true morning rising*.
2. [Greek: ἐπιτολὴ ἑῴα φαινομένη (epitolē heōia phainomenē)], *apparent morning rising*.
3. [Greek: ἐπιτολὴ ἑσπερία ἀληθινὴ (epitolē hesperia alēthinē)], *true evening rising*.
4. [Greek: ἐπιτολὴ ἑσπερία φαινομένη (epitolē hesperia phainomenē)], *apparent evening rising*.
5. [Greek: δύσις ἑῴα ἀληθινὴ (dysis heōia alēthinē)], *true morning setting*.
6. [Greek: δύσις ἑῴα φαινομένη (dysis heōia phainomenē)], *apparent morning setting*.
7. [Greek: δύσις ἑσπερία ἀληθινὴ (dysis hesperia alēthinē)], *true evening setting*.

8. [Greek: δύσις ἑσπερία φαινομένη (dysis hesperia phainomenē)], *apparent evening setting*.

Here the epithet *apparent* is not taken to mean feigned or false, nor is it thus distinguished from *true*; rather, it is so called because the star then appears in its rising or setting, and the nearby rays of the Sun do not obstruct the sight of it.

[Margin: Pliny the Elder's view on this.]

Pliny the Elder, Book 18, Chapter 25, does not depart far from this when he says: *Risings and settings are understood in two ways. For either the stars are hidden by the Sun's approach and cease to be seen, or they show themselves at its departure. Custom would better have called this an emergence than a rising, and that an occultation rather than a setting. In another way, the day on which they begin to appear, or cease to, at the rising or setting of the Sun, named morning and evening according as either of these happens to them in the morning or at twilight.* He restricts himself, however, to the fixed stars, saying: *And the whole discussion concerns those stars which we have said adhere to the heaven.*

Kepler subscribes to Pliny the Elder in the *Epitome of Copernican Astronomy*, p. 366, saying that the heliacal rising is more correctly called an appearance or emergence than a rising, and the heliacal setting more correctly an occultation than a setting. He confirms this from the Greeks, who call the former [Greek: φάσιν (phasin)], that is, appearance, and the latter [Greek: κρύφιν (kryphin)] or [Greek: κρίψιν (kripsin)], that is, occultation or hiding.

But if, at the same moment at which they emerge from the Sun's rays, stars ascend above the horizon, and at the moment they begin to be immersed within its brilliance they descend, it seems to me that for a double reason the former deserves the name of rising, and the latter that of setting; so far is it from being the case that those names do not fit. So in this I subscribe neither to Pliny the Elder nor to Kepler.

[Margin: Pliny the Elder and Kepler corrected.]

When, however, a star begins to emerge from the rays of the Sun under which it previously lay hidden, yet at that time does not ascend from the horizon but rather descends, as happens in the first phase of the Moon and sometimes in Mercury and Venus as evening stars; or when it begins to be submerged under them and yet ascends from the horizon, then it seems doubtful whether that appearance should be called a rising and this occultation a setting. Geminus certainly calls the former an apparent evening setting, while the latter he passes over; more on this below, when we have heard Ptolemy.

[Margin: Ptolemy's teaching on these.]

III. For Ptolemy seems to have been more generous and more careful than the others, since in Book 8 of the *Magna Constructio*, Chapter 4, after listing the aspects of the stars (on these, our Book 1, Chapter 33), he considers not only more risings and settings than the others but also mediations of the heaven. I believe this is because he was contemplating the astrological powers of the stars at the four cardines of the day and of the heaven, according as on these they

are opposed to or joined with the Sun, exactly or [Greek: πλατικῶς (platikōs, "broadly")].

[Margin: 9 Ptolemaic schematisms.]

He therefore brings these comparisons back to nine schematisms [Schematifmos], or configurations with the Sun, from whose subdivision 24 species spring, and they are those written below. Regiomontanus also points them out in the *Epitome of the Almagest*, Book 8, Proposition 5; Reinhold on Peuerbach's *Theoricae*, p. 149; and Pétau, Book 1 of the *Dissertations* of the *Uranologion*, Chapter 2.

[Margin: 1. Rising of a star with the Sun, before the Sun and after the Sun.]

The first [Greek: σχηματισμὸς (schēmatismos, "configuration")] is called [Greek: πρωινὸς ἀπηλιώτης (prōinos apēliōtēs)], that is, the morning east wind [Subfolanus], and it is threefold. Either the star climbs the horizon at the same moment as the Sun, and this is called [Greek: ἑῴα συνανατολὴ ἀληθὴ (heōia synanatolē alēthē)], *true morning co-rising*; or it rises at dawn before the Sun and begins to appear in the east, when previously it did not appear in the morning because of the Sun's nearness, and this is called [Greek: ἑῴα προανατολὴ φαινομένη (heōia proanatolē phainomenē)], *apparent morning pre-rising*; or, the Sun having risen a little before, it ascends from the horizon but is not seen, and Ptolemy calls this [Greek: ἑῴα ἐπανατολὴ μὴ φαινομένη (heōia epanatolē mē phainomenē)], namely *non-apparent morning sub-rising*. For a rising of this kind to have a definite distance from the Sun, however, the star seems to have to be at so great an interval that it begins to be immersed in its rays, or as great as it stands from the Sun at its first morning appearance.

[Margin: [?] Mediation of the heaven by a star, with the Sun rising, risen, or about to rise soon.]

The second schematism is [Greek: πρωινὸν μεσουράνημα (prōinon mesouranēma)], *morning mediation of the heaven*, or midheaven [medicælium], or occupation of the meridian, both above and below the earth. This is threefold, according as the star holds the meridian either at the Sun's rising, and this is called [Greek: ἑῷον συμμεσουράνημα ἀληθινὸν (heōion symmesouranēma alēthinon)], *true morning mediation of the heaven*; or with the Sun having risen a little before, and therefore it ceases to appear, and it is called [Greek: ἑῶον μεσουράνημα μὴ φαινόμενον (heōon mesouranēma mē phainomenon)], *non-apparent morning mediation of the heaven*; or with the Sun not yet risen but about to rise shortly, and it is called [Greek: ἑῶον προμεσουράνημα (heōon promesouranēma)], *morning pre-mediation of the heaven*.

[Margin: Setting of a star with the Sun rising, or risen, or about to rise shortly.]

The third schematism is called [Greek: πρωινὸς λὶψ (prōinos lips)], *morning setting*, and it is threefold. Either the star descends below the horizon as the Sun rises, and this is called [Greek: ἑῴα συγκατάδυσις ἀληθὴ (heōia synkatadysis alēthē)], *true morning setting*; or it plunges down with the Sun now risen, and

this is called [Greek: ἑῴα ἐπικατάδυσις μή φαινομένη (heōia epikatadysis mē phainomenē)], *non-apparent morning sub-setting*; or with the Sun about to rise a little later, and this is called [Greek: ἑῴα πρόδυσις φαινομένη (heōia prodysis phainomenē)], *apparent morning pre-setting*.

[Margin: Rising of a star at noon or at midnight.]

The fourth schematism is called [Greek: μεσημβρινὸς ἀπηλιώτης (mesēmbrinos apēliōtēs)], *noon eastern rising*, and it is twofold. Either the star climbs the horizon at noon and therefore does not appear, and this rising is called [Greek: ἡμερινὸς μὴ φαινόμενος (hēmerinos mē phainomenos)], *non-apparent diurnal*; or it does so at midnight and appears, and is called [Greek: νυκτερινὸς φαινόμενος (nykterinos phainomenos)], *apparent nocturnal*.

[Margin: Culmination or lowest transit [imatio] of a star, at noon or at midnight.]

The fifth schematism is called [Greek: μεσηβρινὸν μεσουράνημα (mesēbrinon mesouranēma)], *noon mediation of the heaven*, and it is twofold: either diurnal, when the star culminates at noon with the Sun or is opposed to it at the bottom of the heaven; or nocturnal, when at midnight it either holds the bottom of the heaven or culminates. This configuration could have been divided in four ways.

[Margin: Setting of a star at noon or at midnight.]

The sixth schematism is called [Greek: μεσημβρινὸς λὶψ (mesēmbrinos lips)], *noon setting*, and it is twofold, according as the star slips below the horizon either at noon or in the middle of the night.

[Margin: Rising of a star with the Sun setting, or set, or about to set shortly.]

The seventh schematism is called [Greek: ὀψινὸς ἀπηλιώτης (opsinos apēliōtēs)], *evening rising*, and it is threefold. Either the star climbs the horizon as the Sun sets, and this is called [Greek: ἑσπερία συνανατολὴ ἀληθινὴ (hesperia synanatolē alēthinē)], *true evening rising*; or it climbs the horizon with the Sun not yet set but about to set shortly, and therefore does not appear, and this is called [Greek: ἑσπερὶα προανατολὴ μὴ φαινομένη (hesperia proanatolē mē phainomenē)], *non-apparent evening pre-rising*; or it climbs the horizon with the Sun having slipped below the horizon a little before, and this is called [Greek: ἑσπερία ἐπανατολὴ φαινομένη (hesperia epanatolē phainomenē)], *apparent evening sub-rising*.

[Margin: Mediation of the heaven by a star, with the Sun setting or set, or about to set shortly.]

The eighth schematism is called [Greek: ὀψινὸν μεσουράνημα (opsinon mesouranēma)], *evening mediation of the heaven*, and it is threefold, according as the star holds the meridian as the Sun sets, and this is called [Greek: ἑσπερινὸν συμμεσουράνημα ἀληθινὸν (hesperinon symmesouranēma alēthinon)], *true evening mediation of the heaven*; or with the Sun now having set a little before, and this is called [Greek: ἑσπερινὸν ἐπιμεσουράνημα φαινόμενον (hesperinon epimesouranēma phainomenon)], *apparent evening post-mediation of the heaven*; or with the Sun about to set shortly, and this is called [Greek:

ἑσπέριον προμεσουράνημα μὴ φαινόμενον (hesperion promesouranēma mē phainomenon)], *non-apparent evening pre-mediation of the heaven*.

[Margin: Setting of a star with the Sun setting, or set, or about to set shortly.]

The ninth schematism is called [Greek: ὀψινὸς λὶψ (opsinos lips)], *evening setting*, and it is threefold, inasmuch as the star descends below the horizon either together with the Sun, and this is called [Greek: ἑσπερία συγκατάδυσις ἀληθινὴ (hesperia synkatadysis alēthinē)], *true evening co-setting*; or with the Sun having slipped below the horizon a little before, and this is called [Greek: ἑσπερία ἐπικατάδυσις φαινομένη (hesperia epikatadysis phainomenē)], *apparent evening sub-setting*; or finally it occurs with the Sun not yet setting but about to set a little later, and this is called [Greek: ἑσπερὶα πρόδυσις μὴ φαινομένη (hesperia prodysis mē phainomenē)], *non-apparent evening pre-setting*. So far Ptolemy. Let us come to the authors of the middle period.

[Margin: Opinion of Alkindus, Campanus, Sacrobosco, Stöffler, Clavius and Biancani.]

IV. Alkindus [al-Kindī] in the book *me motu diurno* [recte: *de motu diurno*, *On Daily Motion*]; Campanus in Maurolico, Dialogue 3; Johannes de Sacrobosco in Chapter 3 of the *Sphere*, and there his commentators, especially Clavius, p. 314; on Proclus's *Sphere*, Johannes Stöffler, pp. 33 and 36; Biancani on the *Sphere*, Book 17, Chapter 10. These writers divide the rising and setting, both of signs and of stars, into astronomical and poetic. They further subdivide the astronomical into apotelesmatic [Apotelesmaticum], that is, judicial, and inapotelesmatic [Inapotelesmaticum]; and this last they again split in two, into the horizontal, or absolute from the Sun, and the solar, or that which has reference to the Sun. The poetic, so called because poets almost always use it, is in fact the same as the astronomical solar. They subdivide it into the cosmic or mundane [Mundanum], that is, the morning one, because in the morning the world and its adornment seem to be renewed; 2. into the chronic or temporal, that is, the evening one (for so Martianus Capella, at the end of Book 8, and others called chronic what they should have called [Greek: ἀκρονύκτον (akronykton)] or [Greek: ἀκρόνυχον (akronychon)], that is, at the very first edge of the night, as is plain from what was said in number 2); 3. into the heliacal, which they finally subdivide into morning and evening. From the poetic, therefore, there spring eight species, just as in Geminus too. These are also used by Fernel, p. 40 of the *Cosmotheoria*; Magini in the *Theoricae*, Book 2, Chapter 14; Origanus in Part 2 of the *Ephemerides*, Chapter 8; Reinhold on Peuerbach's *Theoricae*, p. 149; and Magini in the *Secundum Mobile*, Canon 98.

The eight are: 1. Cosmic rising [Ortus Coſmicus], that is, the true morning rising. 2. Cosmic setting [Occaſus Coſmicus], that is, the true morning setting. 3. Chronic rising [Ortus Chronicus], that is, the true evening rising. 4. Chronic setting [Occaſus Chronicus], that is, the true evening setting. 5. Morning heliacal rising [Ortus Heliacus matutinus], that is, the morning emergence from the Sun's rays. 6. Evening heliacal rising [Ortus Heliacus veſpertinus],

that is, the evening emergence from the Sun's rays. 7. Morning heliacal setting [Occaſus Heliacus matutinus], namely the morning immersion in the rays of the Sun. 8. Evening heliacal setting [Occaſus Heliacus veſpertinus], namely the evening immersion beneath the rays of the Sun.

V. To us, however, it seems that the mediations of the heaven should be omitted, since they do not bear on the rising of stars, but that all the other species should be retained, so that nothing may be left out in this matter that could serve agriculture, medicine, navigation, and the illustrating or understanding of writers, whether they were poets or not. I shall therefore not be reluctant to go over again, from the authors named above, the arrangement of risings and settings with its Greek nomenclature, adding rules that establish to which wandering or fixed stars each applies. The risings and settings of the stars (though they can be extended to the signs as well) are thus divided into absolute, or purely horizontal, and those having reference to the rising or setting of the Sun. For although in the absolute ones one considers the ascension and descension, right if they occur in a right sphere and oblique if in an oblique sphere, and there is reference to the parts of the equator with which they co-ascend or co-descend, so that the time of these risings and settings can be known, or even reference to the point of noon or of midnight, no account is taken of the Sun rising or setting at that time or very near it. This is the sense in which we take the name "having reference to the Sun" [Reſpectiui ad Solem]. First, then, the 8 species of the absolute, and next the 12 of those having reference.

[Margin: Of the absolute.]

Ortus & Occaſus Abſolutus, Quid & Quotuplex, Quibuſq. conueniat.

Absolute rising and setting: what it is, of how many kinds, and to which stars it applies.

[Margin: 1. Species.]

The absolute noon rising [Ortus abſolutus Meridianus] is the ascension of a star above the horizon at noon, which therefore does not appear; Ptolemy calls it [Greek: ἀνατολὴ μεσημβρινὸς ἡμερινὸς μὴ φαινομένη (anatolē mesēmbrinos hēmerinos mē phainomenē)]. It applies to all stars except Mercury and Venus on those horizons where, with the point of the winter solstice rising, the arc of the ecliptic between the east and the meridian is greater than their greatest digression from the Sun, unless a latitude toward the hidden pole helps a little.

[Margin: 2. Species.]

The absolute midnight rising [Ortus abſolutus Medinocturnus] is the ascension of a star above the horizon at midnight, and hence apparent; Ptolemy calls it [Greek: ἀνατολὴ μεσημβρινὸς νυκτερινὸς φαινομένη (anatolē mesēmbrinos nykterinos phainomenē)]. It applies to all stars except ♀ and ☿, on the horizons mentioned above.

[Margin: 3. Species.]

The absolute noon setting [Occaſus abſolutus Meridianus] is the descension of a star from the horizon at noon; Ptolemy calls it [Greek: μεσημβρινὸς λὶψ ἡμερινὸς μὴ φαινομένη (mesēmbrinos lips hēmerinos mē phainomenē)]. It applies to all stars except ♀ and ☿ on the horizons already mentioned.

[Margin: 4. Species.]

The absolute midnight setting [Occaſus abſolutus Medinocturnus] is the descension of a star from the horizon at midnight; in Ptolemy's terms, [Greek: μεσημβρινὸς λὶψ νυκτερινὸς φαινομένη (mesēmbrinos lips nykterinos phainomenē)]. It applies to all stars except ♀ and ☿ on the horizons already mentioned.

[Margin: 5. Species.]

The absolute diurnal rising [Ortus abſolutus Diurnus] is the ascension of a star from the horizon made in the daytime, without reference to the four cardines of the day; in Greek, [Greek: ἀνατολὴ ἡμερινὸς μὴ φαινομένη (anatolē hēmerinos mē phainomenē)]. It applies to all stars.

[Margin: 6. Species.]

The absolute nocturnal rising [Ortus abſolutus Nocturnus] is the ascension of a star from the horizon made at night, and hence apparent, without reference to the four cardines of the day; in Greek, [Greek: ἀνατολὴ νυκτερινὸς φαινομένη (anatolē nykterinos phainomenē)]. It applies to all stars.

[Margin: 7. Species.]

The absolute diurnal setting [Occaſus abſolutus Diurnus] is the descension of a star from the horizon made in the daytime, without reference to the four cardines of the day; in Greek, [Greek: δύσις ἡμερινὸς μὴ φαινομένη (dysis hēmerinos mē phainomenē)]. It applies to all stars.

[Margin: 8. Species.]

The absolute nocturnal setting [Occaſus abſolutus Nocturnus] is the descension of a star from the horizon made at night, without reference to the four cardinal points of the day; in Greek, [Greek: δύσις νυκτερινὸς φαινομένη (dysis nykterinos phainomenē)]. It applies to all stars.

So much for the first 8 species of risings and settings, namely the absolute. Now to be explained are those risings and settings of stars that concern the rising or setting of the Sun.

Quotuplex ſit Ortus & Occaſus Reſpectiuus ad Solis ortum occaſumue, & Quibus conueniat.

Of how many kinds is the rising and setting having reference to the Sun's rising or setting, and to which stars each applies.

[Margin: 1. Species.]

The cosmical rising [Ortus Coſmicus] is the true morning rising, but not apparent because of the Sun's presence; that is, it is the ascension of a star from the horizon as the Sun rises. For Geminus and Tatius it is [Greek: ἐπιτολὴ ἑῴα

ἀληθινὴ (epitolē heōia alēthinē)], but for Ptolemy [Greek: ἑῴα συνανατολὴ ἀληθὴ (heōia synanatolē alēthē)]. It applies to all stars.

[Margin: 2. Species.]

The morning heliacal rising [Ortus Matutinus Heliacus], or apparent morning rising, is the ascension of a star from the horizon a little before the Sun's rising, with its first appearance, that is, its emersion from the rays of the Sun, under which it previously lay hidden. For Geminus and Achilles Tatius it is [Greek: ἐπιτολὴ ἑῴα φαινομένη (epitolē heōia phainomenē)], but for Ptolemy [Greek: ἑῴα προανατολὴ φαινομένη (heōia proanatolē phainomenē)]. It applies to all stars except the Moon, because the Moon is faster than the Sun and cannot be left behind by the Sun, as the Sun advances eastward, in such a way that it begins to appear in the morning on the eastern horizon when previously it lay hidden under the Sun's rays. Yet before the Sun's rising the Moon can be in its last phase and at its first immersion, and thus it is rather setting heliacally. In the others, however, it earns the name of rising on two counts.

[Margin: 3. Species.]

The subsolar morning rising [Ortus Matutinus ſubſolaris], or the morning rising that is neither true nor apparent, occurs a little after the Sun's rising, at about as great an interval of the ecliptic as there is from the cosmical rising to the heliacal morning rising. It applies to all stars faster than the Sun. For if they are slower than the Sun, as are the fixed stars and the three superior planets, it is the first morning immersion beneath its rays; but if they are faster than the Sun, as are the Moon and sometimes Mercury and Venus, it comes with the first morning emersion from the rays of the Sun, and so it does not forfeit the name of rising. Ptolemy calls it [Greek: ἑῴα ἐπανατολὴ μὴ φαινομένη (heōia epanatolē mē phainomenē)].

[Margin: 4. Species.]

The acronychal rising [Ortus Acronychus], called by others, half-barbarously, the chronic rising [Ortus Chronicus], is the true evening rising, but not apparent because of the presence of the Sun standing opposite; that is, it is the ascension of a star from the horizon as the Sun sets. For Geminus it is [Greek: ἐπιτολὴ ἑσπερία ἀληθινὴ (epitolē hesperia alēthinē)]; for Ptolemy [Greek: ἑσπερία συνανατολὴ ἀληθὴ (hesperia synanatolē alēthē)]; for Theophrastus [Greek: ἀνατολὴ ἀκρόνυχος (anatolē akronychos)]; for Firmicus the [Greek: ἀκρόνυκτος (akronyktos)] rising. It applies to all stars, usually except ♀ and ☿; I shall give the reason in the Scholium.

[Margin: 5. Species.]

The evening rising that is apparent but not true [Ortus Veſpertinus apparens ſed non verus] is the ascension of a star from the horizon a little after the Sun's setting, at as great an interval as is required for it, in spite of the twilight, to be able to appear for the first time on the eastern horizon, when on the preceding days it lay hidden; and for Geminus it is [Greek: ἐπιτολὴ ἑσπερία φαινομένη (epitolē hesperia phainomenē)], but for Ptolemy [Greek: ἑ[?]περία ἐπανατολὴ φαινομένη (he[?]peria epanatolē phainomenē)]. This, moreover, is one of the

more notable and commonly observable risings. I know, however, that most people understand in its place that heliacal evening rising in which the star descends from the horizon yet emerges for the first time from the rays of the Sun, as sometimes happens to the Moon, Venus and Mercury alone. But this we now relegate to the evening setting, on which see species 11. The evening rising in the first sense, moreover, applies to all stars, usually except ♀ and ☿, according to what will be said in the Scholium.

[Margin: 6. Species.]

The evening rising that is neither true nor apparent [Ortus Veſpertinus nec verus nec apparens] is the ascension of a star from the horizon a little before the Sun's setting, at as great an interval as the acronychal evening rising stands from the apparent evening rising. For Ptolemy it is [Greek: ἑσπερία προανατολὴ μὴ φαινομένη (hesperia proanatolē mē phainomenē)]. It applies to all stars, usually except ♀ and ☿, etc.

[Margin: 7. Species.]

The cosmical setting [Occaſus Coſmicus], or true morning setting, is the descension of a star from the horizon as the Sun rises, and therefore it does not appear. Geminus and Tatius call it [Greek: δύσις ἑῴα ἀληθινή (dysis heōia alēthinē)], but Ptolemy [Greek: ἑῴα συγκατάδυσις ἀληθὴ (heōia synkatadysis alēthē)]. It applies to all stars, usually except ♀ and ☿, etc.

[Margin: 8. Species.]

The morning setting that is apparent but not true [Occaſus Matutinus apparens ſed non verus] is the descension of a star from the horizon a little before the Sun's rising, with its first appearance in this descent, when on the preceding days it did not appear because of the Sun's presence or the excessive light of the morning twilight. For Geminus it is [Greek: δύσις ἑῴα φαινομένη (dysis heōia phainomenē)], but for Ptolemy [Greek: ἑῴα πρόδυσις φαινομένη (heōia prodysis phainomenē)]. This species applies to stars slower than the Sun, that is, the fixed stars and ♄, ♃ and ♂, but to ☾ never, and to ♀ and ☿ almost never. For although Mercury and Venus are sometimes slower than the Sun, they nevertheless do not digress from the Sun in such a way that, with the Sun rising or a little later about to rise, they set, except on very few horizons, as below in the Scholium. For this species, however, not a few substitute the heliacal morning setting, which is nevertheless rather a rising, according to what was said in species 3.

[Margin: 9. Species.]

The morning setting that is neither true nor apparent [Occaſus Matutinus nec verus nec apparens] is the descension of a star from the horizon a little after the Sun's rising, at as great an interval as there is from the acronychal setting to the apparent morning setting. For Ptolemy it is [Greek: ἑῴα ἐπικατάδυσις μὴ φαινομένη (heōia epikatadysis mē phainomenē)]. It applies to all, usually except ♀ and ☿, etc.

[Margin: 10. Species.]

The acronychal setting [Occaſus Acronychus], half-barbarously the chronic setting [Occaſus Chronychus], is the true evening setting, that is, the descension of a star from the horizon with the Sun likewise setting. For Geminus and Tatius it is [Greek: δύσις ἑσπερία ἀληθινὴ (dysis hesperia alēthinē)], but for Ptolemy [Greek: ἑσπερία συγκατάδυσις ἀληθὴ (hesperia synkatadysis alēthē)], and for Theophrastus [Greek: ἀφανισμὸς δύσις (aphanismos dysis)].

[Margin: 11. Species.]

The apparent evening setting [Occaſus veſpertinus apparens] is the descension of a star from the horizon after the Sun's setting, with its first appearance if the star is faster than the Sun, as ☾ is and sometimes ♀ and ☿; or with its last evening appearance, and the first evening occultation following soon after, if it is a star slower than the Sun, as are the fixed stars and the three superior planets. In the former case, therefore, not a few more recent writers call it the heliacal evening rising because of the first emersion from the rays of the Sun, but it is simply a setting. For that reason Geminus and Tatius call it [Greek: δύσις ἑσπερία φαινομένη (dysis hesperia phainomenē)], and Ptolemy [Greek: ἐπικατάδυσις φαινομένη (epikatadysis phainomenē)]. In the second case, however, it earns the name of setting on two counts.

[Margin: 12. Species.]

The evening setting that is neither true nor apparent [Occaſus veſpertinus nec verus nec apparens] is the descension of a star from the horizon a little before the Sun's setting, at as great an interval as there is between the acronychal setting and the apparent evening setting. For Ptolemy it is [Greek: ἑσπερία πρόδυσις μὴ φαινομένη (hesperia prodysis mē phainomenē)]. It applies to all stars.

[Margin: Corollary.]

So we have 10 species of rising and as many of setting, 20 in all, of which 8 are absolute and 12 have reference to the Sun's exact or nearest rising or setting.

Regulæ aliæ de Ordine ac Interuallis Ortuum & Occaſuum Reſpectiuorum.

Further rules on the order and intervals of risings and settings having reference to the Sun.

Rule 1. Among morning risings, the one that is neither true nor apparent comes first, the cosmic follows, and the apparent or heliacal comes after that, if the stars are slower than the Sun.

Rule 2. Among evening risings, the apparent comes first, the true or acronychal follows, and then the one that is neither true nor apparent, if the stars are slower than the Sun.

Rule 3. Among morning settings, the one that is neither true nor apparent comes first, the true or cosmic follows, and then the one that is apparent but not true, if the stars are slower than the Sun.

Rule 4. Among evening settings, the apparent comes first, the true or acronychal setting follows, and then the one that is neither true nor apparent, if the stars are slower than the Sun.

In the Moon, however, the order of the phases is already known; in ♀ and ☿ it is too varied, so much so that general rules can hardly be committed to memory.

On the order among the six principal risings and settings, see a specimen in the example of Sirius and Procyon below in Chapter 22, on the rising and setting of Canicula. But beware of that looser rule of Pliny the Elder, who says in Book 18, Chapter 25: *Those intervals require at the least three-quarters of an hour before the Sun's rising or after its setting, so that the stars can be seen.*

Rule 5. In fixed stars having no latitude or a very small one, the true risings and settings stand about six months apart in time.

Rule 6. In all fixed stars, the acronychal rising stands from the morning heliacal rising that follows it by an interval greater than 6 months, whatever Geminus may say to the contrary in the *Elements of Astronomy*, Chapter 11, and however Pétau may hesitate in the *Uranologion*, Book 1 of the *Dissertations*, Chapter 2.

Rule 7. In fixed stars having a great northern latitude, the cosmical rising stands from the following cosmical setting, and the cosmical setting from the acronychal rising, by a greater span than six months; but if the latitude is southern, by a smaller span than six months. In these, however, the span from the cosmical setting to the cosmical rising is greater than six months, in those smaller.

Rule 8. Stars endowed with latitude, in an oblique sphere, do not rise or set with that point of the ecliptic in which they lie according to longitude. If the latitude is northern, they rise with an antecedent degree; with a following degree they set. They do so in roughly this order: first they rise cosmically, then heliacally; next they set heliacally, afterwards acronychally; then they rise acronychally, and finally they set cosmically, as can be seen in Arcturus, Capella and the other northern stars. But if their latitude is southern, they rise with a following degree of the ecliptic and set with an antecedent one. First they set heliacally, then acronychally; next they rise cosmically, afterwards heliacally; after that they set cosmically; afterwards they rise acronychally. These things are to be understood [Greek: πλατικῶς (platikōs)].

Rule 9. Not all stars that rise together also set together, nor do all that rise first also set first. For the rest, see Autolycus, Book 2.

SCHOLION.

Scholium.

[Margin: ♀ and ☿: where the acronychal rising and the cosmic setting can apply.]

I said in species 4 that on some horizon Venus and Mercury can at times rise acronychally as the Sun sets: namely on that horizon where the north pole of the ecliptic coincides with the zenith. For the Sun in the southern signs can set so close to noon that, in spite of the small digression of these planets (which can nevertheless reach about 50° in ♀ and 30° in ☿), either of these planets, placed on the ecliptic, rises. This can also occur on a horizon whose zenith declines little from the pole of the ecliptic on one side or the other, provided these planets have a sufficient latitude to one side or the other. Say the same when the south pole of the ecliptic is at the zenith or near it, provided Venus and Mercury are either on the ecliptic or have some sufficient latitude, as will be plain to anyone who turns a sphere. From this you will understand that these planets too can at times set cosmically, or rise a little after the Sun's setting with their first appearance, the species of rising I spoke of in species 5. Since, however, these things do not happen in the whole of the Torrid Zone or in the greatest part of either temperate zone, and since within these zones the smallness of the digressions does not allow them to set cosmically or rise acronychally, astronomers therefore commonly deny this rising and setting to Venus and Mercury, and we too have followed them in the instruction of beginners, Book 1, Chapter 32.

CAPVT XXII. De Ortu & Occaſu Siderum apud Poetas & Hiſtoricos inſigni tum ad Annum primum Iulianum, tum ad alios expenſis, cum Auctoribus qui Fixarum Ortus & Occaſus in Tabulas digeſſere aut in Faſtos.

Chapter 22. On the risings and settings of stars notable in the poets and historians, weighed both for the first Julian year and for others, with the authors who have set out the risings and settings of the fixed stars in tables or in calendars.

I. We have chosen first, with Pétau, this Julian year because Ovid and Virgil flourished around it, and because from that time a judgement can easily be passed on that whole century and indeed on the nearest ones as well. For within one century the fixed stars do not move from their place a full degree and a half, and it is enough for us to know, more or less, the day on which they rose or set. But if the poets or historians seem to depart markedly from that year, it will have to be said either that they copied the risings and settings from a century or an altitude of the pole very different from the century in which Christ was born, and [?] from the Roman altitude of the pole; or that they had regard to the common appearance, which, because of the clouds and vapours of the horizon, differs greatly from the rising and setting of stars considered in itself; or that, because of the dislocation of the calendar and the inconsistency of intercalations, the days of the old year do not agree with the days of the Julian year; or that for some other reason an error of one or more days crept in from calendars [Faſtis] composed for civil use only; or that they confused the rising of the signs with the rising of the stars.

For ease of finding, we shall proceed in alphabetical order in reviewing the stars rather than in the order of days and months, so that whenever a

controversy arises about the ancient rising or setting of some star it can be discussed at once from what is to be said, although a calendar is to be drawn up for these afterwards. We assume that the motion of the fixed stars is 50″ annually, and one degree in 72 years. On this assumption, our own Pétau computed the following risings and settings, for an obliquity of the ecliptic of 23° 32′ and the Roman altitude of the pole, for the first Julian year, that is, the year 45 before the first year of Christ. He prudently set first the true ingress of the Sun into the twelve signs for the same year, computing the hours from midnight, which was as follows.

The true ingress of the Sun into the signs at Rome in Julian year 1, that is, 45 before the birth of Christ.

Signs	Months	Days	Hours and minutes
♒ Aquarius	January	22	7^h 52^m
♓ Pisces	February	21	9^h 13^m
♈ Aries	March	22	23^h 47^m
♉ Taurus	April	23	12^h 10^m
♊ Gemini	May	24	12^h 22^m
♋ Cancer	June	24	23^h 3^m
♌ Leo	July	26	5^h 39^m
♍ Virgo	August	26	2^h 37^m
♎ Libra	September	25	11^h 11^m
♏ Scorpius	October	25	5^h 54^m
♐ Sagittarius	November	23	15^h 54^m
♑ Capricornus	December	22	23^h 54^m

From the day of the Sun's ingress into any sign you will easily infer the day on which the Sun in that year was at the other degrees of the same sign, since the Sun completes very nearly one degree in the zodiac each day. For example, the bright star of Aquila set heliacally in that year with the Sun placed at 10° 29′ ♑, while the Sun's ingress into ♑ occurred on December 22 at 23^h 54^m. If you add ten and a half days to this, you will arrive at January 2 and a half. Therefore Aquila sets heliacally there between January 2 and 3; and so with the others.

Here now is Pétau's table, to which we have only added the day and month. As for the synonyms of the stars: in place of Canis Major look for Sirius; in place of Canis Minor, Procyon; in place of Antares [Antare], the heart of Scorpius; in place of Aldebaran [Aldebara] or Palilicium [Palilicio], see the bright star of the Hyades or Suculae, or the southern eye of Taurus; in place of the bright star of the Pleiades, the bright star of the Vergiliae.

Table of the risings and settings of the stars at Rome in the year 45 before the first of Christ.

Names of the stars	Place	Rising: cosmic	Rising: heliacal	Rising: acronychal	Setting: cosmic	Setting: heliacal	Setting: acronychal
Bright star of Aquila [Aquilæ lucida]	♒ 3° 39′	♐ 8° 45′; Dec. 2	♐ 27° 8′; Dec. 20	♊ 8° 45′; June 2	♋ 26° 20′; July 21	♒ 10° 29′; Jan. 2	♒ 26° 20′; Jan. 18, o
Arcturus	♍ 25° 48′	♍ 13° 32′; Sept. 9	♍ 26° 16′; Sept. 21, o	♓ 13° 32′; Mar. 6	♊ 3° 16′; June 28	♏ 10° 48′; Nov. 5	♐ 3° 16′; Nov. 27
Bright star of Aries above the head [Arietis lucida ſupra Caput]	♈ 9° 15′	♓ 17° 0′; Mar. 9	♈ 22° 8′; Apr. 18	♍ 17° 0′; Sept. 12, o	♎ 12° 45′; Oct. 8	♓ 27° 45′; Mar. 20	♈ 12° 45′; Apr. 3

Hiſtoria Selecta Ortus & Occaſus Siderum ex Plinio lib. 18. à cap. 26. ad 30. Varrone, Columella lib. 11. cap. 2. Ouidij Faſtis, Virgilij Georgicis, & Alijs multis Scriptoribus.

A selected history of the rising and setting of the stars, from Pliny the Elder, Book 18, Chapters 26 to 30; Varro; Columella, Book 11, Chapter 2; Ovid's Fasti*; Virgil's* Georgics*; and many other writers.*

II. Some things about these are reported by Stöffler on the *Sphere* of Proclus, from p. 35; Clavius on the *Sphere* of Sacrobosco, p. 314; Kepler in the *Epitome of Copernican Astronomy*, from p. 378; and Pétau in the books of dissertations of the *Uranologion*.

[Margin: Aquila.]

AQUILA. Varro, *De re rustica* Book 2, Chapter 2, and Pliny the Elder, Book 8, Chapter 47, say that the time for admitting the male to breed young runs from the setting of Arcturus to the setting of Aquila, that is, as the same authors say, from May 13 [tertio Idus Maias] to July 20 [13. Kal. Auguſti]. They are speaking of the cosmical setting, or true morning setting. Ovid, however, in *Fasti* 5, sings of the acronychal or evening rising at the end of May, saying:

You will see the beak of the tawny bird, welcome to Jove.

[Margin: Arcturus.]

ARCTURUS. Theophrastus, *Historia plantarum* Book 4, Chapter 12, indicates the heliacal rising of Arcturus in the month of Boedromion, that is, in September. Ptolemy, however, reports its rising on September 26 and October 3. Pliny the Elder assigns its evening rising to February 23 [7. Kal. Martij], Columella to February 21 [9. Kal. Mart.]. Firmicus, on the other hand, is far astray when, in Book 8, Chapter 14, he puts its rising in the 5th degree of ♐:

see Pétau in the *Uranologion*, Book 2 of the dissertations, Chapter 8. Ovid, for his part, in *Fasti* 3, sang thus of the apparent evening setting on March 5:

When the wife of Tithonus begins to shed dew from her saffron cheeks and brings on the time of the fifth day, whether it is Arctophylax, or whether that sluggish Bootes, it will sink and escape your sight.

But in *Fasti* 5 he speaks of the cosmical setting about May 26, though from faulty calendars, or very ancient ones:

Aurora, as she comes, will take Bootes from your eyes.

On the evening rising, see what was said from Hesiod in Chapter 20, Problem 8. Kepler, in the *Epitome of Copernican Astronomy*, p. 178, from data given by Tycho about the beginning of this century and from the calculation of Mästlin, sets out the risings and settings of Arcturus as you see in the following small table, in which we give the days in the Gregorian style.

Arcturus		Sun in
Rises in the evening [Oritur veſpere]	March 23	♈ 2° 24′
Sets in the morning [Occidit manè]	June 16	♊ 25° 18′
Rises with the Sun [Oritur cum Sole]	Sept. 25	♎ 2° 24′
Emerges from the rays of ☉ [Emergit è radijs ☉]	Oct. 9	♎ 15° 40′
Culminates with ☉ [Culminat cum ☉]	Oct. 25	♏ 1° 34′
Is hidden in the evening [Occultatur veſperi]	Nov. 25	♐ 3° 2′
Sets with the Sun [Occidit cum Sole]	Dec. 17	♐ 25° 18′

[Margin: Aquarius.]

AQUARIUS. That verse of Ovid, *Fasti* 2,

Now light Aquarius sinks with his tilted urn; you who are next, Fish, receive the horses of the ether,

is interpreted by Stöffler, Clavius and Biancani as referring to the heliacal rising, on the ground that the Sun, entering Pisces, leaves behind Aquarius, which it was overwhelming with its brightness, so that Aquarius can now appear in the morning; and for that reason Pisces begins to set heliacally. But the poet is to be understood of the sign rather than of the stars, although at that time the visible stars [Aſtra viſibilia] were not very far from the invisible signs of the zodiac of the same name. On the heliacal setting about January 16, however, this verse of the same Ovid in *Fasti* 1 holds good:

When these have passed, Phoebus, with Capricorn left behind, you will run through the signs of the youth who rules the waters.

ALDEBARAN. See the Hyades.

[Margin: Delphin.]

DELPHIN. Ovid, in *Fasti* 1, sings of the heliacal rising of the whole Dolphin about January 13 [circa Idus Ianuarij]:

Meanwhile the Dolphin, a bright star, rises above the ether and thrusts out its face from its native shallows.

But of the acronychal rising on June 10 or 11 he sings thus in *Fasti* 6:

The sailor, sitting on the stern, says: we shall see the Dolphin when damp night has risen and the day has been driven off.

And a little later, on the rising of the whole constellation:

The Dolphin will be visible through the whole night.

[Margin: Cancer.]

CANCER. On this, Ovid, *Fasti* 1:

So when the third night is at hand before the coming Nones, and the ground is wet, sprinkled with heavenly dew, the arms of eight-footed Cancer will be sought in vain; headlong he will go down under the western waters.

He is speaking of the cosmical setting on January 2, although for Pétau, strictly, it fell on December 28. Of the heliacal setting you will form a conjecture from *Fasti* 6, where the Sun's ingress into ♋ is placed on June 17, for he says:

Now six and as many days of the month remain; yet add one day to this number. The Sun departs from Gemini, and the signs of Cancer redden.

Here you will note an error of six days, since in fact the Sun entered ♋ about June 24: unless you refer that *Now six* to months, as if he had meant to say that six months remain, and of the month of June six days, for in that way he would rightly have said that the Sun enters ♋ on June 24 or 25. But in fact the former interpretation must be retained, because the ancients thought that the ingresses of the signs take place in the eighth degree before the visible signs.

[Margin: Canicula.]

III. CANICULA. Whether this is Sirius or Canis Major, or rather Procyon or Canis Minor, is disputed, both because of the nearness of their risings and settings and because of the similarity of their effects. And what is to be said, if you look to authority, is no less doubtful, since almost as many authors in number, and of equal authority, stand for Procyon as for Sirius, as I showed in Chapter 5, number 6, where I also touched on the effects of the dog days. Now we must deal with the rising and setting of each. And since the ancient writers speak of this confusedly and variously, we shall set the certain before the uncertain, and we shall choose three centuries above all: namely the century of Hippocrates the physician, who presses the observation of the dog days, and who flourished not long before Meton and Eudoxus, whom Aratus followed in his *Phaenomena*, especially since the Eudoxan calendars are repeatedly drawn on by Varro, Columella and Pliny the Elder; the second century will be that of Caesar and Augustus, and in particular the first

Julian year; the third century will be our own, or the one immediately preceding.

[Margin: Risings etc. of Canicula in the time of Hippocrates and Eudoxus.]

In the time of Hippocrates, therefore, and almost of Eudoxus, that is, about 400 years before Christ, the fixed stars stood about 28 degrees further back [anteriores] than now. On this basis Kepler, in the *Epitome of Copernican Astronomy*, Book 3, p. 388, taking Sirius at that time in ♊ 10° 36′ with southern latitude 39° 30′, and Procyon in ♊ 12° 19′ with southern latitude 15° 57′, for climate 4, whose parallel runs through Rhodes, that is, at an altitude of the pole

of 36°, derives for each star the risings etc. written below, by the Problems on which we treated in Chapter 20, with the months and days of the Julian year projected back, but with the addition of the days on which the Sun is now at those points of the zodiac.

About 400 years before Christ: order	Sirius, old style: months of the Julian year	Sirius: ☉ in	Sirius, old style: where the Sun is today, on the day	Procyon, old style: months of the Julian year	Procyon: ☉ in	Procyon, old style: where the Sun is today, on the day
Heliacal setting [Occaſus Heliacus]	May 2	♉ 7° 24′	April 17	May 22	♉ 25° 40′	May 6
Acronychal setting [Occaſus Acronychus]	May 16	♉ 20° 25′	May 1	June 7	♊ 11° 39′	May 23
Culmination with ☉ [Culminatio cum ☉]	June 11	♊ 15° 38′	May 27	June 19	♊ 22° 41′	June 4
Cosmical rising [Ortus Coſmicus]	July 11	♋ 13° 49′	June 26	July 1	♋ 4° 37′	June 16
Heliacal rising [Ortus Heliacus]	July 26	♋ 28° 17′	July 11	July 18	♋ 21° 49′	July 4
Cosmical setting [Occaſus Coſmicus]	Nov. 18	♏ 20° 25′	Nov. 3	Dec. 9	♐ 11° 39′	Nov. 24
Acronychal rising [Ortus Acronychus]	Jan. 9	♑ 13° 49′	Dec. 25	Dec. 31	♑ 4° 37′	Dec. 16

[Margin: Risings etc. of Canicula in the time of Julius Caesar.]

In Julian year 1, however, that is, 45 before Christ, at Rome, from the calculation of Denis Pétau, as is plain from his table [Canone] already set out at the end of number 1, the risings and settings of each Dog were as follows, in the old style.

Year 45 before Christ: order	Sirius: months, days	Sirius: ☉ in	Procyon: months, days	Procyon: ☉ in
Heliacal setting [Occaſus Heliacus]	April 29	♉ 5° 31′	May 22	♉ 29° 2′
Acronychal setting [Occaſus Acronychus]	May 11	♉ 19° 14′	June 6	♊ 13° 24′

Year 45 before Christ: order	Sirius: months, days	Sirius: ☉ in	Procyon: months, days	Procyon: ☉ in
Acronychal rising [Ortus Acronychus]	Jan. 15	♒ 22° 48′	Jan. 3	♒ 11° 0′

[Margin: Risings etc. of Canicula at the beginning of this century.]

For the year of Christ 1600, further, Kepler in the *Epitome of Copernican Astronomy*, p. 387, from data given by Tycho, for an altitude of the pole of 48° 30′, that is, for climate 7, derives the following risings of each Dog; here the days are given in the old style, so that the difference between the ancient and the recent risings may be more readily apparent.

Year of Christ 1600: order	Sirius: month, days	Sirius: ☉ in	Procyon: month, days	Procyon: ☉ in
Heliacal setting [Occaſus Heliacus]	April 21	♉ 11° 7′	May 16	♊ 4° 16′
Acronychal setting [Occaſus Acronychus]	May 7	♉ 26° 40′	June 9	♊ 17° 36′

Acronychal rising [Ortus Acronychus]	Jan. 23	♒ 13° 32′	Jan. 13	♒ 3° 40′

[Margin: Risings of Canicula for the year 1644.]

Lastly, for the year 1644, we have already in Chapter 20, number 16, derived the risings and settings of each Dog from our own observations at Bologna, at an altitude of the pole of 44° 29′ 30″. It is good to repeat them here, but with the days given in the old style, so that a comparison can be made with the ancients, even though there, at that number 16, we followed the days of the Gregorian calendar: for they are easily reduced to Gregorian days by adding 10 days.

Year of Christ 1644: order	Sirius: months, days	Sirius: ☉ in	Procyon: month, days	Procyon: ☉ in
Heliacal setting [Occaſus Heliacus]	April 17	♉ 7° 58′	May 22	♊ 10° 36′
Acronychal setting [Occaſus Acronychus]	May 12	♊ 1° 25′	June 12	♋ 0° 52′
Cosmical rising [Ortus Coſmicus]	July 23	♌ 9° 37′	July 15	♌ 2° 27′
Heliacal rising [Ortus Heliacus]	Aug. 6	♌ 23° 32′	Aug. 1	♌ 18° 23′
Cosmical setting [Occaſus Coſmicus]	Nov. 13	♐ 1° 25′	Dec. 12	♒ 0° 52′
Acronychal rising [Ortus Acronychus]	Jan. 19	♒ 9° 37′	Jan. 13	♒ 2° 27′

From what has been said it is plain that the places and positions of the risings etc. have changed; and from the days given above it will be possible to form

a judgement on the statements of the poets or of other writers. For if they disagree by several days, the blame will have to be laid either on the uncertainty of the days of the ancient calendar, which was dislocated; or on a different altitude of the pole; or on corrupted calendars, expressed in too popular a fashion, or confusing the old risings with more recent ones; or on ignorance of the motion of the fixed stars; or finally on the carelessness of the writers.

First, then, Virgil presents himself, singing in *Georgics* Book 1:

When the white Bull opens the year with his gilded horns [carnibus; recte: cornibus], and the Dog, yielding to the star opposite, sets.

And indeed aptly, for about that time, around the end of April, the Sun, entering Taurus, opened the year, and

with its warmth it roused the earth to gladder sprouting. Then, however, Sirius was setting heliacally at the coming of the Sun opposed to it: not hostile on the ground that the Sun drives dogs to madness, as Kepler interprets it, but because the Dog is turned, in its celestial figure, towards the west, and so appears opposed to the Sun coming to meet it, as if barking at it; and yet, overwhelmed by the Sun's rays as it set, it seemed to give way. Or else the reading should be *auerſo* [turned away], which Servius allows, so that the Dog gives way to the Argo following at its back. The inexperience of Salmasius [Claude Saumaise], who takes Virgil to mean the cosmical setting, Pétau has amply refuted in the *Uranologion*, Book 7, Chapter 3. But what are we to do with Ovid? In *Fasti* Book 4 he says plainly, of April 24 or 25:

When you have six days of April remaining, the season of spring will be at the middle of its course. And you will look in vain for the beast of Athamantian Helle; the signs give rains, and the Dog rises.

And in *Fasti* Book 5, of May 21, where he sings:

On the night following the day, the Erigonian Dog comes out.

For neither Dog, on any of those days, rose even approximately by a rising reckoned relative to the Sun; rather, it was setting around the middle of spring. Homer, in Book 10 of the *Iliad*, places the rising of the Dog at the close of summer, meaning the heliacal rising, which most of the ancients kept to, foretelling the changes of the weather from the first morning sighting of the Dog. Granted that Theon on Aratus seems to start the dog days from the cosmical rising of Sirius, this rather suits later centuries, in which, the fixed stars having advanced [Greek: ἐις τὰ ἑπόμενα (eis ta hepomena, "towards the following signs")], the effects and indications of the dog days drifted away from the heliacal rising of the Dog to the cosmical, as Pétau observes in the *Uranologion*, Book 2, Chapter 10. Manilius, whom some contend flourished under Augustus, others under Constantine or a little after, says in Book 5 of the *Astronomica* that Sirius rises in a part of Leo. Scaliger, correcting him in his notes, says: *He would have done better to say that the Dog rises at the beginning of Cancer on the barbarian horizon. In Manilius's age it was rising in the 7th degree of Cancer,* meaning the age of Augustus, as Scaliger supposes. But Pétau, cited above, rebukes Scaliger, because the true rising of Canicula at Alexandria then

took place at ♋ 12° 27′, and the heliacal at 26° 9′. Many of the ancients, however, placed the heliacal rising of Canicula at the beginning of ♌, which agrees with the age of Hipparchus and Geminus, as they themselves testify; but later it moved away from that first degree. And yet, since the Sun's entries into the cardinal points were commonly thought to occur in the eighth degrees of the signs, they also put its entries into ♋ and ♌ forward by the same number of days. The solstice had been fixed by Julius Caesar at June 24; so they reckoned that the Sun enters ♋ 8 days before, namely on June 17, and ♌ on July 18. This way of counting carried over into the start of the dog days, as Pétau notes in the place cited, and Kepler in the *Epitome of Copernican Astronomy*, p. 392. For Varro indeed, Book 1, Chapter 28, and Columella, Book 9, Chapter 14, count 29 or 30 days from the solstice to the rising of Canicula; reckoned from the Julian solstice, these would fall on July 23 or 24. Palladius, however, in Book 7, Title 9, records that Canicula rises on July 19, and Pliny the Elder, Book 2, Chapter 47, says: *In the hottest season of summer the star of Canicula rises, as the Sun enters the first degree of Leo, which is July 18 [XV. ante Auguſti Kalendas].* And in Book 18, Chapter 28, he records that Canicula rises on the 23rd day after the solstice, that is, July 18 or 19, the day to which Hephaestion of Thebes also assigns its rising. Censorinus, in Chapter 21, or as I have it from the Manutian emendation, Chapter 8, says: *The 13th day before the Kalends of August [Ante XIII. Kal. Auguſti], at which time Canicula usually makes its rising in Egypt*, that is, July 20. So too Firmicus, Book 8, says it rises in the first degree of ♌ (at any rate not in his own age), and Manilius, Book 5, at ♋ 27°. So great is the variety among those writers about this rising, whether for the reason just given, or because of the difference of the climates from which they transferred their calendars to others; or because they confused the cosmical rising with the heliacal; or followed the Eudoxan or other older calendars.

[Margin: On the setting of the Dog according to the ancients.]

IV. Nor is there less variety about the setting of Canicula, which Columella (Book 11, Chapter 2), Manilius (Book 1) and Pliny the Elder (Book 18, Chapter 29) believed stirs up cold and frosts. Columella indeed says: *On April 30 [Pridie Kalendas Maias] the Dog hides itself in the evening; this signals a storm.* Yet on April 29 it was setting heliacally in the first Julian year, that is, on the third day before the Kalends of May [3. Kal. Maij]. Pliny the Elder, in the place just cited, reports as follows: *Numa instituted the Robigalia in the 11th year of his reign, which are now held on April 25 [ad VII. Kal. Maij], since that is about when rust takes hold of the crops. Varro fixes this time as when the Sun holds the tenth degree of Taurus, as the reckoning then required. But the true reason is that nineteen days after the spring equinox, across that four-day period, by the varying observation of the peoples, on April 28 [in IV. Kal. Maij], the Dog sets, a star both vehement in itself and one before which Canicula must set.* He seems to be speaking of the heliacal setting, yet with a looser use of a day or two: for a century before Pliny the Elder it fell on April 29. He errs, however, in thinking that Canicula must set before the Dog: for by the very fact that Procyon precedes the Dog in heliacal rising and has a

northern declination, it must follow Canis Major, which declines to the south, in heliacal setting. So Kepler rightly rebukes him in the *Epitome of Copernican Astronomy*, p. 392. Pétau, in the *Uranologion*, Book 7, Chapter 2, does indeed rebuke Salmasius for building Canicula's earlier setting on Pliny the Elder's testimony, but he interprets Pliny the Elder as speaking of the canine sacrifice to be offered beforehand to appease the star Canicula, red dogs being killed at the Catularian Gate. Further, Geminus states that in Euctemon's calendar the Dog sets in the 2nd degree of ♉, but in Eudoxus's table in the 4th degree.

[Margin: Philander's error.]

Philotheus [?], on Section 4 of the *Aphorisms* of Hippocrates, says that the Dog rises on July 19. But Philander [?], on Book 9, Chapter 7, says: *It is established that for them the Dog rose on July 27 [ſexto Kal. Auguſti]; for us it rises on July 1 [calendis Iulijs]*; which is utterly false. So much for the more ancient writers.

[Margin: The opinion of more recent writers on the rising of the Dog.]

After them, Stöffler, on the *Sphere* of Proclus, says that the rising of Canicula in the time of Hippocrates, that is, about 400 years before CHRIST, in climate 4, was around July 14; but in the time of Avicenna of Seville, that is, in the year of CHRIST 1100, in the same climate, around July 17; and that around the year of Our Lord 1500, in climate 7, Canicula rises around St James's day. Stadius, in the *Canones*, p. 199, says that at Bergis in Flanders Sirius rises with the Sun at 16° ♌, but heliacally on August 25 [8. Kal. Septembris]. Magini, in his *Directions of the primum mobile*, Canon 22, for a polar elevation of 45° in the year 1600, gathers from data given by Tycho the evening occultation of Canis Major on May 6; the morning one on June 6; the cosmical rising on August 2; the heliacal rising on August 17; the evening emersion on January 16.

[Margin: Length of the dog days.]

Argoli, in the *Pandosion Sphaericum*, Chapter 23, states that at Rome the dog days now begin on July 23 and end on August 18. Kepler, however, in the *Epitome of Copernican Astronomy*, p. 395, notes that the dog days were formerly held to be at the least 30 but usually 45, because the Etesian winds blew for the same number of days after the rising of the Dog; but he adds, as his own opinion, that they last until the rising of Arcturus, which brings on contrary and evident weather. What if they begin from the morning pre-rising with the first immersion into the rays of the Sun, with which the Dog begins to be conjoined platically [platicè], and last only until the morning heliacal rising; or rather from the cosmical rising of Canis Minor until the heliacal rising of Canis Major, that is, in the new style, from July 25 to August 16?

[Margin: Capella.]

V. CAPELLA rose on May 1 [Kalendis Maij], according to Columella, and to Ovid, singing in *Fasti* 5:

Let the work rise from Jove: on the first night I am to see the star that served in the cradle of Jove. The rainy constellation of the Olenian She-goat rises.

But Pliny the Elder says it rises on the eighth day of May, which was true of the heliacal rising in Egypt, not at Rome.

[Margin: Centaurus.]

CENTAURUS rises on the third day of May, according to Ovid, saying in *Fasti* 5:

On the night short of the fourth, Chiron will bring out his stars.

[Margin: Corona.]

The heliacal rising of CORONA Borealis is indicated by Virgil, *Georgics* 1, in that verse:

And let the Gnosian star of the blazing Crown withdraw.

It took place on October 5. But its acronychal rising, which then occurred around March 18, is set by Ovid, *Fasti* 3, on the eighth day of March, in this line:

At once, on the night that comes, you will see the Gnosian Crown.

[Margin: Corvus.]

CORVUS, Crater and Anguis rise on February 14 [16. calendas Martij], according to Ovid, *Fasti* 2:

Three stars continuous in place, the Raven and the Snake, and the Bowl lies hidden in the middle between the two: on the Ides they lie hidden; they rise on the following night.

This was taken from excessively old calendars, for in Ovid's age they rose acronychally around the 8th day of March, and cosmically and heliacally in the month of November.

[Margin: Hyades.]

HYADES, or Suculae, of which the brightest is the southern Eye of Taurus, called Palilicium and in Arabic Aldebaran: it set cosmically on November 2 according to Columella and Geminus. Pliny the Elder, Book 18, Chapter 31, said that the Suculae rise with the Sun on October 31 [pridie Kal. Nouembris], but he should have added *with the setting Sun.* Ovid places the heliacal setting of the Hyades around April 18, in *Fasti* 4, and rightly, but describes it in a phrase too ambiguous, saying:

But when the fourth Morning Star looks back on the Ides now past, on this night the Hyades hold Doris.

But in Book 6 he records the heliacal rising on June 2, thus:

The next day calls forth the Hyades, the horns of the Bull's brow, and the earth grows wet with much water.

[Margin: Lyra.]

LYRA. What Ovid sings for January 5 [Nonis Ianuarij], in *Fasti* 1, about its rising is most uncertain:

The Nones will give signs as Lyra rises.

And in the same place, around January 23 [10. Kal. Febr.], he places the setting of Lyra, namely the heliacal:

When the seventh rising from now has let itself down into the waves, no Lyre will any longer shine in all the sky.

Columella puts the same setting on January 22. Ovid thought it rises on May 12, saying in *Fasti* 5:

The ninth day was at hand, when you, most just Chiron, had your body girt with twice seven stars. The curved Lyre would wish to follow him, but the way is not yet fit; the third night will be the proper time.

[Margin: Orion.]

ORION. Polybius, Book 1, writes that the Romans crossed from Sicily into Africa between the rising of Sirius and that of Orion, in unfavourable weather. He seems to be meant of the heliacal rising of each, for Orion rose a little after the solstice, and Sirius at the start of August, and so the voyage was made in the month of July: thus Pétau, above, Book 2, Chapter 8. But what unfavourable weather was there then? Is he then rather to be understood of the acronychal rising of each, since the middle star of Orion's belt rose by such a rising around the middle of December, and Sirius around the middle of January, and the time between was truly unfavourable? Ovid places the setting of Orion around the middle of April, saying in *Fasti* 4:

Sword-bearing Orion will be sunk in the sea.

So this was the heliacal setting, as is clear from Pétau's table. But the acronychal setting is meant when, around May 10, he says in *Fasti* 5:

If in the midst of these you look for Boeotian Orion, you will be deceived.

Pliny the Elder and Ovid rightly said that the Belt of Orion rises heliacally on June 28 [4. Kal. Iulij], if we take the older times, and the first star in the belt; for the middle one rose heliacally on July 11 at Rome in the age of Ovid, whose words in *Fasti* 6 are:

Your Belt is hidden now, and perhaps will be hidden tomorrow; after that, Orion, it is to be seen by me.

[Margin: Pegasus.]

The acronychal rising of PEGASUS Ovid, *Fasti* 3, places a little after the start of March, saying:

And when the stars dapple the dark-blue sky, look up: you will see the neck of the Gorgonian Horse.

[Margin: Pisces.]

The acronychal setting of PISCES the same Ovid assigns to March 3, in these words, *Fasti* 3:

When the third night, sent down, has set its risings moving, one of the twin Fishes will be hidden.

[Margin: Pleiades.]

The PLEIADES, or Vergiliae, daughters of Atlas, set cosmically about the start of the sowing; and to this belongs that passage of Virgil, *Georgics* 1, where he calls them *Eoas* [of the dawn], because the setting was in the morning:

Let the Eoan daughters of Atlas be hidden from you before you commit the owed seed to the furrows.

Pliny the Elder also, Book 18, Chapter 25, says that Thales fixed the morning setting of the Pleiades on the 25th day from the autumnal equinox. Virgil,

moreover, took the precept from Hesiod, *Works and Days*, Book 2, where it says:

When the Pleiades, born of Atlas, are rising, begin the harvest, and the ploughing when they are setting; they indeed are hidden for forty nights and days, etc.

But the bright star of the Pleiades in Hesiod's time rose heliacally at 11° ♉ on May 11, and set heliacally in the 4th degree of ♈ on April 4: for in that age the Sun entered Aries on March 31. It is astonishing, however, how they place the rising of the Vergiliae either 44 days after the spring equinox (Varro, Book 1) or 48 (Columella, Book 9, Chapter 14, and Pliny the Elder, Book 18, Chapter 25), which at Rome and in the ages of these writers was utterly false, but true in the age of Meton and at Athens: for the bright star of the Pleiades then rose heliacally at ♉ 18° 46′, or about May 15, and the equinox was on March 27, so that 48 days intervened. You see how ill-advisedly that Metonic reckoning, brought into Latium after so many years, has upset farming, and has deceived the common people, indeed the most eminent of the poets. Ovid, *Fasti* 5, puts the rising of the Pleiades on May 13 [3. Idus Maij]:

You will see all the Pleiades, and the whole troop of sisters, when one night remains before the Ides.

That is, on the 57th day from the spring equinox, although it occurred there around May 20. Manilius, Book 5, Firmicus, Book 8, Chapter 7, and Pliny the Elder, Book 2, Chapter 47, put their rising in the 6th degree of Taurus.

Varro, Book 1, Chapter 28, puts the setting of the Pleiades at a distance of 32 days from the autumnal equinox; but Columella, Book 9, Chapter 14, at 40 days; and Pliny the Elder, Book 2, Chapter 47, at 44 days. And in Book 18, Chapter 25, he puts their setting in Hesiod's time at the equinox, but in Thales's time on the 25th day, in Anaximander's the 29th, in Euctemon's the 48th. But Anaximander is to be taken of the heliacal setting and Thales of the true setting, as Pétau learnedly shows, Book 2, Chapter 9. In Hesiod's case no reckoning stands firm, and perhaps Pliny the Elder took the morning setting for the heliacal. Geminus, from Callippus, says that the Pleiades set at ♏ 16°; for Eudoxus at 19°; for Euctemon at 15°; he is speaking of the apparent setting. Their evening setting, according to Geminus, was for Euctemon at 10° ♈, for Eudoxus at 13°. Ovid put it on April 2, saying in *Fasti* 4:

The Pleiades will begin to lighten their father's shoulders, who are called seven, yet are usually six.

The same poet is to be understood of the evening rising in *De Ponto*, Book 1, Elegy 9:

The risen Pleiad makes four autumns.

Finally, Virgil is to be understood of the morning rising and the evening setting, when, in accordance with Aristotle, *History* Book 9, Chapter 40, he prescribes two times for gathering honey, *Georgics* 4:

Twice they gather the heavy yield; there are two seasons of honey: as soon as Taygete the Pleiad shows the earth her comely face, and with her foot has spurned the scorned streams of Ocean.

[Margin: Regulus. Heart of the Lion.]

REGULUS, or Basiliscus, the Heart of the Lion, set cosmically on January 24 in the first Julian year. Ovid has the same thing in *Fasti* 1, saying:

From this star, on the coming night, the fire that flashes in the middle of the Lion's breast will be sunk.

Columella, however, puts it on the 27th; Geminus, at ♒ 2°, that is, January 23; but Ptolemy on January 27. Its rising Pliny the Elder, Book 18, Chapter 28, assigns to July 30 [tertio Kal. Auguſti], if *emergit* [emerges] is read there for *immergitur* [is immersed], as Pétau wishes, above, Chapter 8.

[Margin: Scorpius.]

SCORPIUS began to set on March 16 [17. Kal. Aprilis], and set whole on April 1 [Kalendis Aprilis], cosmically; and so Ovid, marking also the acronychal rising, says in *Fasti* 3:

When the next Dawn has refreshed the tender grasses, Scorpius will be visible from its first part. The third day after the Ides is, etc.

And in *Fasti* 4:

While I speak, Scorpius, to be feared for the sting of its raised tail, plunges into the green waters.

In *Fasti* 5 the same poet rightly sings, in May, of the Heart of Scorpius rising acronychally around May 7 [circa Nonas Maij]:

Scorpius in the sky, when we say that tomorrow the Nones dawn, will be visible from its middle part.

[Margin: Taurus.]

TAURUS, according to Ovid, rises cosmically on May 15 [Idibus Maij], for so in *Fasti* 5:

On the Ides the earlier one indicates that Taurus lifts his starry face.

[Margin: Vindemitor.]

VINDEMITOR rises acronychally on March 6, according to Ovid, *Fasti* 3, where after March 5 he has this:

When Tithonus's wife begins to wet her saffron cheeks with dew, and brings on the hours of the fifth day, whether it is Arctophylax, or that sluggish Bootes, it will sink, and will escape your sight. But Vindemitor will not escape, etc.

Auctores qui Catalogos Ortuum & Occaſuum Siderum condiderunt.

Authors who have compiled catalogues of the risings and settings of the stars.

VI. One may consult: Geminus, in the *Elements of Astronomy*, Chapter 16, where he gathers a patchwork from the calendars of Callippus, Eudoxus, Meton, Euctemon, Dositheus and Democritus; Ptolemy, *On the Appearances of the Fixed Stars and Their Indications*, edited from a Greek codex by Pétau, far more accurately than the version that circulates under Ptolemy's name in the translation of Niccolò Leonico Tomeo; the old calendar of Julius Caesar, which survives in Johannes Rosinus, in the book of *Roman Antiquities*, and in

Gyraldus [Lilio Gregorio Giraldi], at the end of the short work *On Years and Months*; the old Roman calendar of Denis Pétau, collected from Ovid's *Fasti*, Columella, Book 11, Chapter 11, and Pliny the Elder, Book 18, from Chapter 18 to 30, which he has in the *Uranologion*, p. 102; the Roman calendar drawn up in the time of Constantine the Great, which the same man publishes from the collection of Johann Georg Herwart von Hohenburg; Aratus's *Phaenomena*, with its interpreters; Stadius, in the *Canones* of motions, in the commentary on the fixed stars, Chapter 10, where he has a catalogue of the risings and settings of 27 fixed stars for the year of Our Lord 1558, from 16° to 63° of polar altitude, with a table of the rising and setting of the fixed stars at Alexandria and Rome for the ancient age; Origanus, *Ephemerides*, Volume 1, Part 2, Chapter 8, where he gives the rising and setting, both morning and evening, of very many fixed stars for the year 1620, from both Tycho and Copernicus, but at a polar altitude of 52° 20′; Magini, in the *Introduction to the Ephemerides*, Part 4, where from Copernicus's data he gives two tables, one of 170 fixed stars, with rising and setting, from 6° to 56° of polar altitude, the other of 34 fixed stars from 1° to 56° of polar altitude; Longomontanus, *Sphaerics*, Book 2, Chapter 4, where he has a table of the rising and setting of 100 fixed stars for the year 1630 and a polar altitude of 56°; and finally Francesco Montebruni, at the end of the *Ephemerides*, where he gives the rising and setting of 245 stars for the year 1650 and the polar altitude of Bologna, or 44° etc., and indeed from data given by Tycho and sometimes by Lansbergen.

CAPVT XXIII.

Chapter 23.

De Galaxia feu Lacteo Circulo.

On the Galaxy, or Milky Circle.

[Margin: Authors on the Milky Circle.]

I. So far we have dealt with the fixed stars or asterisms, for the most part separately, or as belonging to distinct figures. It remains, in imitation of Ptolemy, to treat of the mass of innumerable stars that make up the Milky Circle. Many have written on it, but above all: Aristotle, *Meteorologica* Book 1, text 43, and his interpreters there; Plutarch, *De placitis philosophorum* Book 3, Chapter 1; Ptolemy, *Almagest* Book 8, Chapter 2; Ruffus Festus; Ovid, *Metamorphoses* 1, fable 6; Hyginus, *Poetica Astronomica* Books 2 and 4; Marcus Manilius, *Astronomica* Book 1, Chapter 9; Macrobius, on the *Dream of Scipio*, Book 1, Chapters 4, 12 and 15; Proclus, at the end of the *Sphere*, and Stöffler there, from p. 69; Albertus Magnus, *Meteorologica* Book 2, Tractate 2, from Chapter 3 to 6; Giorgio Valla, *Astronomy* Book 16, Chapter 1; Clavius, on the *Sphere*, p. 306; the Coimbra commentators on the *Meteorologica*, Tractate 4, Chapter 2; Io. Cottunius [Ioannis Kottounios] on *Meteorologica* Book 1, Lecture 34; Libertus Fromondus [Libert Froidmont], *Meteorologica* Book 2, Chapter 5,

Article 2; Bartholomæus Mastrius [Bartolomeo Mastri], on the *Meteorologica*, Disputation 2, Question 2, Article 3, from number 79; Aversa, Question 32, Section 3; and Nicolaus Cabæus [Niccolò Cabeo], on *Meteorologica* Book 1, text 43, sole question; Antonio Rocco, Antonius Polus [?], Cremoninus [Cesare Cremonini], Licetus [Fortunio Liceti] and Amicus, in the places to be cited at number 5.

De Nomine ac Notione Viæ Lacteæ.

On the name and notion of the Milky Way.

[Margin: Names of the Milky Way.]

II. By the Greeks it is called [Greek: Γαλαξίας (galaxias, "the milky one")], or [Greek: κύκλος γαλακτίος (kyklos galaktios, "milky circle")], or [Greek: γαλακτικὸς (galaktikos, "milky")], that is, the Milky Circle, or, as Cicero puts it in the *Dream of Scipio*, the Milky Orb, from the whiteness of milk, which it imitates; for in Greek milk is called [Greek: γάλα (gala, "milk")], and in the oblique case [Greek: γάλακτος (galaktos, "of milk")], which is also why the gem galactites, of this colour, has its name. In Arabic, if we believe Albertus Magnus and Stöffler, and indeed the old interpreter of Ptolemy, it is called *Maiarati*, that is, a movable area. But Father Athanasius Kircher, in his letter to me, states that among the Arabs and almost all the Orientals it is called *Almegiret*, which means a track of scattered chaff, or a course in the sky, called the way of straw; and he confirms this by the authority of Aben-Ragel [Ibn Abī al-Rijāl] in his *Astronomy*. He adds that the Hebrews call it *Nedibath theben*, the Chaldeans *Schabil tabno*, the Ethiopians *Chasara tsamangadu*, and finally the Egyptians [Greek letters: πινωιτεν τέπιτοχ], or the way of straw; for they feign that Typhon scattered in the sky the bundle of ears of grain thrown in his way by Isis as she fled. Others call it the Way of Rome or the Way of St James. This is a great circle, as Proclus notes, since it is described from the centre of the world; or rather a Zone conspicuous in the sky, of varying breadth and density, running obliquely across the equator and the tropics. For it is narrower around Cassiopeia and Centaurus; broader at Heniochus, Gemini and Sagittarius; but nowhere is it broader than 10°. It is usually held within about 7° or 6°, in some places within 8° or 9°, where, however, it does not divide into a fork.

Situs Viæ Lacteæ in Cælo.

The position of the Milky Way in the sky.

III. No one has been more careful in this than Ptolemy, Book 8, Chapter 2, in describing it word by word; but it is better to contemplate it on more recent globes or maps or hemispheres, and better still to note its position carefully with the eyes, as Ptolemy did, and as we once did at Parma.

[Margin: The asterisms through which the Milky Way passes.]

Beginning, then, from the segment of the colure that passes through the vernal intersection, the course of the Milky Way runs through Cassiopeia,

Perseus, Erichthon, the feet of Gemini, the Club of Orion, the Tail of Canis Major, the Argo, and the feet of Centaurus. Beyond these, over against Ara, like a river embracing an island, it divides into two branches, or a fork. Its more easterly part passes through Ara, the end of the Tail of Scorpius, the more easterly foot of Ophiuchus, and the bow of Sagittarius; its more westerly part through the fore part of the tail of Scorpius and the knee of Ophiuchus, beyond which it is joined to the eastern branch by a crosswise path. But the division continues by a straight path towards the Poles, and its more easterly part runs through the feet of Antinous, through Aquila, and the following wing of Cygnus; its more westerly part through the bend of the Serpent, the right hand of Ophiuchus, and the Neck of Cygnus, at whose shoulders and breast it is joined to the eastern branch. Then in one single track it passes through the tail of Cygnus and the Chain and right hand of Andromeda, and completes its circuit in Cassiopeia, where we began it; although Ptolemy starts it from the feet of Centaurus. The more notable stars that shine in the Milky Way are the Breast of Cassiopeia; the bright side of Perseus; Capella, on the eastern border; the Northern Horn of Taurus, on the western border; Propus of Gemini; the bright stars on the thwarts and at the foot of the mast of the Argo; the Southern Cross, or the four bright stars at the feet of Centaurus; the sting of Scorpius; the knee and right hand of Ophiuchus; the Bright Star of Aquila; the Breast and Tail of Cygnus. So it runs from Graecus towards Notolybicus.

[Margin: Manilius's description of the Milky Way.]

Not inelegantly, Manilius, Book 1, Chapter 9, after the zodiacal circle, describes this other, the Milky one, in these verses:

The other moves up towards the Bears set opposite, and with its circuit draws its threads back a little from the north, and passes through the stars of inverted Cassiopeia. From there, descending obliquely, it touches the Swan, and cuts the summer bounds, and supine Aquila, and the circle that equals the seasons, and the Zone that bears the Sun's horses, within the tail where Scorpius burns and the furthest left hand and arrow of Sagittarius. From there it winds its bends through the legs and feet of the other Centaur, and again begins to climb the sky, and cuts the Argive ship through the top of its stern-ornaments, and the middle circle of the world, and the signs at lowest Gemini; it enters under Heniochus, and, making for Cassiopeia, from where it set out, passes over Perseus himself, and closes in her the orb begun from her.

Fabellę de Via Lactea.

Little fables about the Milky Way.

IV. The little fable of the straw and the bundle of ears of grain I have already indicated at number 2. Another fiction concerns the milk from the breasts of Juno, which Manilius, Book 1, Chapter 9, hints at, saying:

[Margin: Fable of Juno's milk.]

nor must I conceal the gentler tale of ancient rumour, spread abroad, that from the snowy breast of the queen of the gods a liquid of milk flowed and stained the sky with

its liquid; for which reason it is called the Milky Circle, and the name descends from that very cause.

And Rufius Festus Avienus:

Look up at the stars: the appearance of gleaming milk is stretched out across the sky; the colour established its name for it, from its first origin, etc.

[Margin: Fable of Phaëthon.]

The third fable concerns Phaëthon and the horses of the Sun, which strayed from the zodiac and, driven accordingly crosswise, burned up the whole of that part of the sky in which the Milky Circle is seen. So Ovid sings, *Metamorphoses* Book 1, Fable 6, from those verses:

There is a high road, manifest in a clear sky (it bears the name Milky), notable for its very whiteness. By this way [inter] [recte: iter] the gods go to the roof of the great Thunderer and his royal house, etc.

And Manilius, above:

Or does that belief better endure through the ancient ages, that the horses of the Sun went that way on a different course and wore another road, and that through long ages the scorched seats, and the stars baked by the flames, changed their blue appearance, the colour turned, and that ash was poured over the place, and the world buried?

[Margin: Fable of the road to the gods above.]

The fourth fable comes from the springs of Plato. It tells of a footpath worn by the gods and by heroes and brave and just men going back and forth that way; or of souls that have slipped down along it into bodies and return again along the same path to their former seats, placed in the Milky Circle. Hence that passage in the Dream of Scipio in Cicero: *That life is the way to heaven, and to this assembly of those who have already lived and, released from the body, inhabit that place which you see. It was a circle shining out among the flames with the most splendid whiteness, which you, as you have received it from the Greeks, call the Milky Circle.* On these words Macrobius, Book 1, Chapter 4, says: *For it must be understood that the place in which Scipio seemed to himself to be during his sleep is the Milky Circle, which is called* γαλαξίας [Greek: galaxias, "the milky one"]. This he confirms from those words of Cicero: *Moreover he was pointing out Carthage from a certain high place, full of stars, bright and clear.* On the gate of Cancer, through which the Platonists imagined that souls go out, and that of Capricorn, through which they return to the gods above, see what we said in Chapter 3, number 6. Following these, Manilius, Book 1, Chapter 9, sings:

Or do brave souls, and names deemed worthy of heaven, released from their bodies and given back by the earth, migrate here from the world, and dwelling in a heaven of their own live ethereal years and enjoy the Universe?

Then, having listed many Greek and Latin men distinguished for wisdom and uprightness, he adds:

Higher, where the circle of the ethereal orb gleams white, is that seat of the gods; this one, nearest to them, is of the divine ones who by their virtue touch on footsteps like theirs.

[Margin: Stöffler's pious allegory.]

Stöffler indeed, piously to be sure, turned this fiction into an allegory worthy of a Christian man, teaching that this is that way to Heaven of which Psalm 14 speaks: *Lord, who shall dwell, etc. He who walks without stain and works justice*; and again Psalm 23: *Who shall ascend the mountain of the Lord, or who shall stand in his holy place? The innocent in hands and clean of heart, etc.* This way is indeed steep and narrow, but, as Ovid sings, *manifest in a clear sky*; that is, to an intellect directed by prudence and, I add, divinely illuminated and free from disturbances.

[Margin: Fable of the scar and of the joint of two hemispheres.]

The last fable (for such it seems, rather than a philosophical opinion) is that of Theophrastus, of which Macrobius, Book 1 on the *Dream of Scipio*, Chapter 15, says: *Theophrastus said that the Milky Circle is the joint by which the sphere of the heaven is made solid out of two hemispheres; and that therefore, where the edges meet from either side, a notable brightness is seen.* Manilius too, above, did not neglect this, saying:

Or does the Universe come together, and do the extremities of its double hollow meet, and touch the edges of the sky and the stars; and does a manifest scar, through those very bonds, join them, making the cleft of the world, while the crowded orb, turned by its bright seam into airy mist, forces into wedges the foundations of the lofty sky?

As if God, in the way our craftsmen do, had glued two hemispheres together with gypsum or some other white cement!

Opiniones Phyſicorum aut Aſtronomorum de Lacteo circulo.

Opinions of the natural philosophers or astronomers on the Milky Circle.

V. Plutarch, *De Placitis Philosophorum* Book 3, Chapter 1, and Macrobius, Book 1 on the *Dream of Scipio*, Chapter 15, report these opinions of the ancients. Some of the Pythagoreans, and Metrodorus, said that this was once the path of the Sun, retaining traces of its former burning; as if the zodiac now glowed like that from the Sun! Others of the Pythagoreans said it is the light of the Sun reflected from the sky as from a mirror, like the light in the rainbow; if that were so, it would change position with the motion of the Sun. Anaxagoras said it is the shadow of the Earth when the Sun is below the Earth; as if either a shadow were white, or the Earth were not smaller than the Sun and its shadow rose beyond 300 semidiameters of the Earth. Parmenides said it is a mixture of dense and rare, from which a whitish colour arises; Posidonius, a fabric of Fire brighter than a star, denser than splendour; Aristotle, a continuous mass of exhalations kindled in the highest air, from the matter out of which he thinks comets are made.

[Margin: Aristotle's opinion is rejected.]

But first, it seems incredible that so great a mass of exhalations should exist only under that tract of the sky, should last perpetually with so constant a figure, and should move with the motion of the primum mobile. Next, since

on Aristotle's own view exhalations do not pass beyond the elementary sphere, the Milky Way, seen in different regions, would undergo a most manifest variation of view [aſpectûs diuerſitatem], or parallax, and would be seen under widely different fixed stars; whereas in fact all people everywhere on earth see it under the same ones. For that reason Averroes here deserted his Aristotle, because both at Córdoba in Spain and at Marrakesh [Marochi] in Africa he saw the bright star of Aquila in precisely the same position in the Milky Way. Moreover, if it were a sublunary meteor, it would darken the planets moving above it, which it does not do. Notwithstanding all this, Aristotle is defended by Cremoninus [Cesare Cremonini] in his *Apology on the Milky Way*; Antonio Rocco on *Meteorologica* 1, question 4; Antonius Polus [?] in his *Digression on the Milky Circle*; Amicus [Giovanni Battista Amico], Treatise 4, question 7, doubt 4; Cottunius [Ioannis Kottounios] on *Meteorologica* 1, lecture 34; and Fortunius Licetus [Fortunio Liceti], *De novis astris* Book 2, Chapter 56. And to escape the argument from parallax, and that from the telescope, which shows a mass of stars in the Milky Way, Kottounios and Licetus in particular say that in Aristotle there are two Galaxies: one celestial, set in the firmament, spread with very many little stars and shining, which Aristotle called *Sporades*, or scattered stars [ſparſiles]; the other elementary, made of vapours and breaths perpetually drawn upwards by the celestial Galaxy and set on fire, and therefore keeping the same position and figure beneath it. But how can stars so far removed have so great a power of preserving beneath them, in such a figure, a fluid matter, when the nearer Sun has no such power of preserving the clouds and mists raised by its own force? Besides, if there are two Galaxies wholly alike in colour and figure, we would certainly see one of them without parallax and the other with a manifest and large parallax. For although it is true that halos, rainbows and the like, which appear by refraction, are not seen with parallax, because each eye sees its own rainbow (a comparison by which Cremonini thinks he triumphs over parallax), yet, as Father Cabæus [Niccolò Cabeo] rightly presses him, at the time when we see a rainbow, say at Bologna, those who are in Africa or Germany do not see a rainbow. Nor is that vapour, which hangs under certain fixed stars with respect to one city or region, also hanging under them with respect to all other places, in which the Milky Circle is nevertheless seen perpetually under the same fixed stars. Finally, the two Galaxies are multiplied to no purpose, and for no other reason than that Aristotle may be granted never to have erred. On that reasoning one would have to invent two Torrid Zones: one that Aristotle denied to be habitable, the other that evident experience has shown to be habitable. Many other things I leave to the natural philosophers; for us the ocular and astronomical foundation from the Dutch tube, or telescope, is enough, of which shortly.

VI. The true view, then, is the one that Democritus reached, before the use of the telescope, by conjectures and merely probable reasons, when he asserted, in Plutarch, *De Placitis* Book 3, Chapter 1, *that the Milky Circle is a collection and*

condensation of splendour proceeding from many stars, small and contiguous, shining together; and Manilius, Book 1, Chapter 9, indicated it in those verses:

Or does a greater crowd of stars, in a dense crown, weave together its flames, and glow white with thick light, and does the circle shine out brighter with their gathered brilliance?

So too Ptolemy, Book 8, Chapter 2, placing this circle in the sphere of the non-wandering stars and saying that it varies in the density of its stars; and Albertus Magnus, Chapter 5, and Stöffler, above. After the use of the telescope, moreover: Galileo in the *Sidereus Nuncius*, p. 16; Kepler in the dissertation with that *Nuncius*; Fromondus [Libert Froidmont], Cabeo, Aversa and Mastrius [Bartolomeo Mastri], in the places cited at the beginning. Nor would Clavius have denied it, if he had come by the telescope before the earlier editions of his *Sphere*, for he would not then have said that these are denser parts of the sky, apt to receive the light of the Sun. The true view, I say, is that the Milky Way is a mass of very many small stars, which on account of their enormous distance cannot be seen individually, distinct from the others, but only together with others; just as white grains of sand viewed from afar cannot be seen separately, although their heap may be seen. For the telescope shows us the Galaxy as just such a thing, and likewise the nebulous stars, which the naked eye judges to be whitish clouds, but which the spyglass reveals to be a mass of stars.

[Margin: The Milky Way near the Antarctic Pole.]

That part of the Milky Circle around the southern pole which, as the eye-witness Josephus Acosta [José de Acosta] relates in his *History of the New World*, Book 1, Chapter 2, shines wonderfully, and in places glows red with rust-coloured patches like the redness of the eclipsed Moon, consists of very many little stars of a somewhat reddish colour, imitating Mars in their light.

[Margin: A new star in the Milky Way.]

Finally, it is worth noting that all the new stars that appeared in this and the preceding century appeared in the Milky Way. For in the year 1572, about the beginning of November, a new star appeared on the northern border of the Milky Way, among the stars in the chair of Cassiopeia; and it lasted there until March of the year 1574. Then in the year 1600 there came forth that star which still shines today at the boundary of the neck and breast of Cygnus. Lastly, on 1604 October 9 there first shone out in Serpentarius that flame-spewing star which imitated the colours of the rainbow, namely on the left knee of Ophiuchus and at the edge of the Galaxy; and it persisted there until the year 1606 and the beginning of February of that year, when it was extinguished. It is just as if the Galaxy were a storehouse from which God, when he wishes, sends these bright portents to the lower parts of this world.

CAPVT XXIV.

Chapter 24.

Tabula Fixarum 70. à nobis verificatarum ad Annum CHRISTI 1644. completum, cum eius vſu & extenſione ad alia tempora.

Table of 70 fixed stars verified by us, for the completed year of Christ 1644, with its use and its extension to other times.

I. There follows at last the table promised at the end of Chapter 14. So that it can be extended to all ages as regards longitude, it has attached a small table of the motion of the fixed stars in longitude. We made this motion most probable in Chapter 16, from number 11; and its perpetual uniformity we showed to be much more probable in Chapter 17. We also taught in Chapter 15 that the latitude is the same and unchangeable. Further, so that the right ascension and declination of these fixed stars can be extended to other times, we give two methods. The first and principal, serving all ages and stars, is by Problem 3 of Chapter 12, given of course the longitude, the latitude and the obliquity of the ecliptic. The other is by the annual equation that we have added to the fixed stars listed below. This equation serves for only one and a half centuries, or at most for two; that is, from the year of Christ 1644 up to the year 1800 going forward, and back to 1500 going backward. The equation of right ascension is always to be added, going forward, to the right ascension of the year 1644, and subtracted going backward, except for the bright star in the shoulder of Ursa Minor [humero lucido Vrſę minoris], according to what was said in Chapters 13 and 19. But the equation of declination is to be applied, according to the letters A and S, which indicate addition or subtraction, in the forward progress of the years; in going backward the contrary is to be done, subtracting where A is set and adding where S is set.

II. The longitude and latitude of the remaining stars, however, will be set out in the catalogue at the end of the second part, preserving nevertheless the difference of longitude from the stars we observed, and in other respects imitating Kepler and Boulliau in their catalogue of fixed stars.

TABVLA LXX. FIXARVM, A NOBIS OBSERVATARVM Ad Annum CHRISTI MDC XLIV. Completum.

Table of 70 fixed stars observed by us, for the completed year of Christ 1644.

Stars observed: Latin names [STELLÆ Obſeruatæ / Nomina Latina]	Arabic names corrected, from Athanasius Kircher or Bayer [Nomina Arabica Correcta Ex Athanaſio Kircher, vel Bayero]	Declination	Right ascension	Longitude	Latitude
Northern star of the tail of Cetus [Ceti caudæ Borealior]	*Denneb Elkaitus Schemah*, that is, northern tail of Cetus	10° 47′ ♒	23′ 19″ ♓ A	26° 0′ 10″ ♓	10° 1′ 40″
Bright star of the breast of Cassiopeia [Caſſiopeæ lucida pectoris]	*Scheder*, that is, breast	54° 36′ ♑ B	12′ 0″ ♉	2° 54′ 0″ ♉	46° 36′ 0″

Stars observed: Latin names [STELLÆ Obſeruatæ / Nomina Latina]	Arabic names corrected, from Athanasius Kircher or Bayer [Nomina Arabica Correcta Ex Athanaſio Kircher, vel Bayero]	Declination	Right ascension	Longitude	Latitude
Southern star of the tail of Cetus [Ceti caudæ Auſtralior]	*Denneb Elkaitus genubi*, that is, southern tail of Cetus	19° 57′ 0″ A	25° 0′ 0″	27° 34′ 0″	20° 46′ 50″
Polaris, last star of the tail of Ursa Minor [Polaris, vltima caudæ Vrſę min.]	*Ruccabah*	87° 24′ 30″ B	32° 10′ 0″	23° 38′ 0″	66° 2′ 0″
Bright star of the belt of Andromeda [Andromedæ cinguli lucida]	*Mizar* or *Mirach*	33° 47′ 0″ B	26° 26′ 30″	25° 26′ 0″	26° 0′ 37″
Leading star on the horn of Aries, Head of Aries [Arietis in cornu præcedens, Caput Arietis]	*Ras Hammel*	17° 32′ 0″ B	33° 32′ 30″	28° 12′ 5″	7° 8′ 13″
Southern foot of Andromeda [Andromedæ pes Auſtralis]	*Allamak*	40° 35′ 30″ B	34° 10″	9° 16′ 0″	27° 47′ 0″
Knot of the Line of Pisces [Nodus Lini Piſcium]		1° 3′ 0″ B	25° 56′ 0″	24° 27′ 0″	9° 4′ 30″
Bright star above the Head of Aries [Lucida ſupra Caput Arietis]		21° 46′ 0″ B	26° 50′ 10″	2° 43′ 20″	9° 58′ 0″
Brighter star of the jaw of Cetus [Ceti mandibulæ lucidior]	*Mēkar Elkeitus*, that is, beak of Cetus	2° 40′ 0″ B	40° 58′ 0″	9° 21′ 16″	12° 36′ 42″
Head of Medusa [Meduſæ Caput]	*Ras Algol*, that is, head of the demon	39° 33′ 0″ B	41° 11′ 54″	21° 12′ 0″	22° 25′ 15″
Bright star of the side of Perseus [Perſei lucidum latus]	*Elgenab*, that is, side	48° 31′ 10″ B	45° 0′ 43″	26° 51′ 0″	30° 2′ 0″
Middle and brighter star of the Pleiades [Pleiadum media & lucidior]	*Altorieh*, not *Athoraie*	22° 59′ 30″ B	36′ 18″	25° 2′ 0″	4° 2′ 35″
Southern eye of Taurus, Palilicium [Tauri oculus Auſtr. Palilicium]	*Aldebaran*, that is, the ruling star	15° 44′ 30″ B	73° 54′ 47″	4° 48′ 0″	5° 29′ 45″
Capella, or Hircus, on the left shoulder of Auriga [Capella, ſeu Hircus, in humero ſiniſtro Aurigæ]	*Alhaioth*, that is, Beast of Auriga	45° 34′ 0″ B	72° 36′ 38″	16° 54′ 0″	22° 51′ 18″

Stars observed: Latin names [STELLÆ Obſeruatæ / Nomina Latina]	Arabic names corrected, from Athanasius Kircher or Bayer [Nomina Arabica Correcta Ex Athanaſio Kircher, vel Bayero]	Declination	Right ascension	Longitude	Latitude
Leading foot of Orion [Orionis pes præcedens]	*Regel Elgebar*, that is, foot of the giant	8° 39′ 40″ A	74° 23′ 31″	11° 55′ 0″ B[56]	31° 11′ 0″
Northern horn of Taurus [Tauri cornu Boreale]		28° 15′ 30″ B	75° 58′ 41″	17° 38′ 0″	5° 21′ 30″
Leading shoulder of Orion [Orionis humerus præcedens]		5° 58′ 30″ B	76° 32′ 46″	15° 59′ 2″	16° 52′ 16″
First star of the belt of Orion [Orionis balthei prima]		0° 36′ 0″ A	78° 31′ 54″	17° 26′ 5″	23° 36′ 0″

[56] on this copy the printed B is struck through in pen, with A written beside it by hand

Stars observed: Latin names [STELLÆ Obſeruatæ / Nomina Latina]	Arabic names corrected, from Athanasius Kircher or Bayer [Nomina Arabica Correcta Ex Athanaſio Kircher, vel Bayero]	Declination	Right ascension	Longitude	Latitude
Second of the belt [Balthei ſecunda]		1° 27′ 24″ A	79° 34′ 30″	18° 30′ 54″	24° 32′ 0″
Third star of the belt of Orion [Orionis balthei tertia]		2° 9′ 50″ A	80° 43′ 16″	19° 42′ 56″	25° 20′ 0″
Right shoulder of Auriga [Aurigæ humerus dexter]		44° 51′ 48″ B	83° 30′ 30″	26° 30′ 0″	21° 28′ 30″
Following shoulder of Orion [Orionis humerus ſequens]	*Bectelgeuze*, that is, house of the giant	7° 17′ 54″ B	84° 2′ 7″	23° 52′ 0″	16° 4′ 30″
Bright foot of Gemini, Propus [Geminorum lucidus pes, Propus]		16° 39′ 30″ B	91° 16′ 45″	4° 10′ 0″	6° 46′ 40″
Sirius, splendid star of the mouth of Canis Major [Sirius, Splendida oris Canis maioris]	*Alhabor*, or *Scheer Eliemini*	16° 17′ 39″ A	97° 27′ 20″	9° 19′ 0″	39° 32′ 58″
Castor, northern or leading Head of Gemini, Apollo [Caſtor, Geminor. Caput Bor. ſeu præcedens, Apollo]	*Ras Elgiautze*, that is, Head of Gemini	32° 37′ α″ B	107° 53′ 25″	15° 15′ 0″	10° 3′ 40″
Procyon, bright star of Canis Minor [Procyon, Canis minoris lucida,]	*Algomeiza*, or *Kelbelazguar*	6° 6′ 40″ B	110° 11′ 38″	20° 57′ 20″	15° 55′ 51″
Pollux, southern or following Head of Gemini, Hercules [Pollux, Geminorum Caput Auſtr. ſeu ſequens, Hercules]	*Ketpholtsuman*, that is, shoulder of Gemini	28° 51′ α″ B	110° 54′ 22″	18° 22′ 0″	6° 40′ 36″
Heart of Hydra [Hydræ cor]	*Kalb Elhauich*, heart of Hydrus	7° 8′ 0″ A	137° 33′ 40″	22° 26′ 18″	22° 22′ 0″
Heart of Leo, or Regulus, Basiliscus, etc. [Leonis Cor, ſeu Regulus, Baſiliſcus &c.]	*Kalb Ellessed*, that is, Heart of Leo	13° 41′ 12″ B	147° 21′ 30″	24° 55′ 20″	0° 27′ 0″
Bright star of the mane of Leo [Lucida iubæ Leonis]		21° 38′ α″ B	150° 3′ 7″	24° 34′ 0″	8° 47′ 37″
Leading lower star of Ursa Major in the □ [Vrſæ maioris in □ præcedens inferior,]	*Dubhe*	58° 17′ α″ B	159° 54′ 41″	14° 15′ 0″	45° 6′ 30″
Leading upper star of Ursa Major in the □ [Vrſæ maioris in □ præced. ſuperior]		63° 40′ α″ B	160° 21′ 6″	10° 15′ 0″	49° 40′ 32″
Bright star in the loins of Leo [Lucida in lumbis Leonis]		22° 28′ α″ B	163° 48′ 11″	6° 22′ 0″	14° 21′ 9″
Tail of Leo [Leonis Cauda]	*Denneb Ellessed*	16° 32′ α″ B	172° 43′ 13″	16° 44′ 0″	12° 17′ 10″
Following lower star of Ursa Major in the □ [Vrſę maioris in □ Sequēs inferior]		55° 38′ α″ B	173° 39′ 40″	25° 27′ 0″	47° 4′ 20″
Following upper star of the same [Sequēs ſuperior]		59° 0′ 0″ B	179° 25′ 42″	26° 4′ 0″	51° 37′ 48″
First star of the tail of Ursa Major [Vrſæ maioris prima caudæ]	*Alhaiath*, life-giving	57° 56′ α″ B	189° 31′ 11″	3° 49′ 30″	54° 18′ 30″
Vindemiatrix, Protrigetis	*Alaraph*	12° 55′ α″ B	191° 9′ 54″	5° 6′ 0″ B	16° 16′ 30″

Stars observed: Latin names [STELLÆ Obſeruatæ / Nomina Latina]	Arabic names corrected, from Athanasius Kircher or Bayer [Nomina Arabica Correcta Ex Athanaſio Kircher, vel Bayero]	Declination	Right ascension	Longitude	Latitude

End of the Sixth Book. [LIBRI SEXTI FINIS.]

LIBER SEPTIMVS DE QVINQVE PLANETIS MINORIBVS.

Book Seven: On the five lesser planets.

SECTIO PRIMA DE PLANETIS MINORIBVS IN COMMVNI.

Section One: On the lesser planets in general.

CAPVT I.

Chapter 1.

De Nominibus, Characteribus, Attributionibus, & Analogijs Planetarum cum alijs rebus Septenario præſertim inſignibus.

On the names, signs, attributions and analogies of the planets with other things especially marked by the number seven.

I. In this Book 7 we are going to treat only of the five lesser wandering stars, which the Greeks call [Greek: πλανήτας (planētas, "wanderers")] or [Greek: πλανόντας (planontas, "wandering")], or, with Ptolemy, [Greek: πλανώμενα ἄστρα (planōmena astra, "wandering stars")], that is, wanderers or roamers. Even so, in this chapter it has pleased us to take in the names and characteristic signs of all seven planets, together with the properties they have or that are attributed to them, and their manifold analogies.

[Margin: Names of Saturn.]

Saturn, then, is called in Hebrew *Schabtai*, that is, satiety or rest; in Greek [Greek: κρόνος (kronos, Saturn's Greek name)], from the slowness of time with which it completes its period beneath the zodiac, a period that requires nearly 30 years. But by Plato in the *Timaeus* and by Martianus Capella, Book 8, it is called [Greek: φαίνων (phainōn, "appearing")], that is, appearing; for of all the planets it lies hidden least beneath the rays of the Sun, and because of the slowness of its motion it is left behind by the Sun and emerges sooner. By the Egyptians it is called *Rephan*, that is, god of time; by the Chaldeans *Caun*; by the Arabs *Tzogel*; by astrologers the Greater Infortune [Infortuna maior]. Its astronomical sign is ♄, namely a sickle, with which time mows down all things; and in Plutarch, in the opuscule *On the Face in the Orb of the Moon* [de facie

Lunæ], it is called [Greek: Νυκτιούρος (Nyktiouros, "guardian of the night")], or guardian of the night.

[Margin: Names of Jupiter.]

Jupiter is called in Hebrew *Tzedek*, that is, justice or equity, by which it is believed to govern lower things; in Greek [Greek: Ζεύσ (Zeus)]; but by Plato in the *Timaeus* and by Capella, Book 8, [Greek: φαέθων (phaethōn, "shining")], from its splendour; by the Egyptians *Picheus*, that is, god of life; by the Chaldeans *Taus*; by the Arabs *Elmesteri*; by astrologers the Greater Fortune [Fortuna maior]. Its sign is the first letter of the Greek name, intersected thus: ♃.

[Margin: Names of Mars.]

Mars, or Gradivus, is called in Hebrew *Maadìm*, that is, red like blood; in Greek [Greek: Ἄρης (Arēs)]; by Plato and Capella [Greek: Πυρόεις (Pyroeis, "fiery")], from fire; by the Egyptians *Meloch*, that is, god of destruction; in Chaldean *Aris*; in Arabic *Elmarigh*; by astrologers the Lesser Infortune [Infortuna minor]. Its sign is ♂, that is, an arrow with a shield. Pliny the Elder, Book 2, Chapter 8, writes that some call it the star of Hercules.

[Margin: Names of the Sun.]

The Sun is called in Hebrew *Chammah* or *Schemasch*, from its heat; in Greek [Greek: Ηλιος (Hēlios, "Sun")], or [Greek: φοίβος (phoibos, "bright")], as if [Greek: φῶς τοῦ βίου (phōs tou biou, "light of life")], that is, light of life; by the Egyptians *Potiris*, that is, holy god; in Chaldean *Schemso*; in Arabic *Elschems*; and its mark is ☉.

[Margin: Names of Venus.]

Venus is called in Hebrew *Nogah*, that is, light; in Greek [Greek: Αφροδίτη (Aphroditē)], from the foam of the sea. But by Plato in the *Timaeus* and by Capella, when in the morning it goes before the Sun, it is called [Greek: φώσφορος (phōsphoros, "light-bearer")], that is, Lucifer, and [Greek: ἑώσφορος (heōsphoros, "dawn-bearer")], as if east-bearing [orientifer]; when, however, in the evening it shines after the Sun, it is [Greek: ἕσπερος (hesperos, "of the evening")], that is, Hesperus or Vesper or Vesperugo, as Pliny the Elder has it, Book 2, Chapter 8, and Vitruvius, Book 9, Chapter 4. By the Egyptians it is called *Suroth*, that is, mistress of love; by the Chaldeans *Astaroth*; by the Arabs *Elzahareh*; by astrologers the Lesser Fortune [Fortuna minor]. Its sign is ♀, namely a round mirror with a handle.

[Margin: Names of Mercury.]

Mercury, or Hermes, is called in Hebrew *Cochau* or *Cochab*, that is, shining star, or *Choteb*, that is, scribe and man of letters; in Greek [Greek: Ερμῆς (Hermēs)], as if interpreter; but by Plato in the *Timaeus* and by Capella [Greek: Στίλβων (Stilbōn, "glittering")], from the flashing, quivering light with which it gleams red; by the Egyptians *Hermanibis*, that is, god of speech; by the Chaldeans *Nobu*; by the Arabs *Adared*; by astrologers Fortune by aspect [Fortuna per aſpectum], because on account of its versatile nature it is reckoned malefic with the malefics and benefic with the benefics. Its sign is the caduceus, or ☿,

namely a rod entwined by two serpents gazing at each other. For, as Hyginus says in Book 2, Mercury was presented with this rod by Apollo in return for the seven-stringed lyre, tuned to the number of the Pleiades or Atlantides; and coming upon two dragons fighting in Arcadia, he restrained them and at once bound them to each other by a mutual bond of alliance. Pliny the Elder, Book 2, Chapter 8, says that some call it the star of Apollo.

[Margin: Names of the Moon.]

The Moon, finally, is called in Hebrew *Lebanah*, from its whiteness, or *Ianeah*; in Greek [Greek: Σελήνη (Selēnē)], or [Greek: Σελαναία (Selanaia)], from the new splendour with which it is renewed after the interlunium; by the Egyptians *Isis Pcochos Actephcom*, that is, mistress of the sea and of moist things; by the Chaldeans *Schaoro*; in Arabic *Elkamer*. Its sign is ☾. But we have said more about the other names of the Moon and the Sun in Book 3, Chapter 1, and Book 4, Chapter 1. The more elegant astronomers, however, following Plato, have not infrequently named Saturn *Phænona*, Jupiter *Phætonta*, Mars *Pyroënta*, Venus *Phosphoron* and *Hesperon*, and Mercury *Stilbonta*, with a half-Greek inflection of the word.

[Margin: Seven angels presiding over the 7 planets.]

II. Further, it is the view of many Rabbis and Christian philosophers and theologians that seven Intelligences or angels were divinely set over the seven planets from the beginning of the world, to move and direct them, as the Scholastics teach on Book 2, Distinction 2 [in 2. diſt. 2.]. St Thomas Aquinas, *De potentia*, Question 6, Article 3, in the body of the article, says: *But it is the teaching of the faith that the angels by their command move locally not only the heavenly bodies, but also other bodies, as God ordains, etc.* And in Opuscule 10, Article 3: *But I remember reading that none of the Saints or philosophers denied that the heavenly bodies are moved by a spiritual creature.* And in Opuscule 11, Article 2, he affirms that this has been demonstrated by physical reasons. Trithemius concurs. Near the beginning of his book on the 7 Intelligences that move the orb, addressed to the Emperor Maximilian I, he says: *It is the view of the ancients that this lower world is governed, by the ordinance of the First Intellect, who is GOD, through secondary Intelligences. Assenting to their opinion, the Conciliator of physicians says that seven Spirits have been set over the seven planets from the beginning of heaven and earth.* Some refer to this the words of Apocalypse 1, *And from the seven Spirits who are in the sight of his throne*, as can be seen in Cornelius à Lapide on that passage. St Jerome notes that the seven-lamped candlestick [cādelabrum illud heptalychnon] of Exodus 25 was a figure of these angels, with their planets as its lamps.

[Margin: Names of the 7 angels.]

The names of these 7 Spirits, as our own Serarius notes on Chapter 12 of Tobit, are gathered by some: Michael, Gabriel, Raphael and Uriel from Books 3 and 4 of Esdras, Schaltiel from Genesis 16, Jehudiel from

Exodus 23, and Barachiel from Genesis 18. These names, divinely revealed in the year of the Lord 1460 to Blessed Amedæus, Cornelius relates in the place

cited above, adding their interpretations: Michael, that is, *Who is like God?*; then Gabriel, that is, *Strength of God*; next Raphael, that is, *Medicine of God*; there follows Uriel, namely *Light* or *Fire of God*; after him Scaltiel, or *Prayer of God*; then Jehudiel, namely *Praise* or *Confession of God*; and finally Barachiel, that is, *Blessing of God*.

[Margin: The epithets and emblems of the 7 Angels.]

Lastly, these names were found in their church at Palermo, with their images, epithets and emblems, in the year 1516, as Father Cornelius à Lapide reports, in the passage cited, from the public records of Palermo. They were as follows. 1. *Michael the Victorious*, treading Lucifer underfoot, carrying a green palm in his left hand and in his right a lance, at whose tip a white banner, with a red cross woven into it, wound itself around the shaft. 2. *Gabriel the Messenger*, carrying in his right hand a small torch enclosed in a lantern, and in his left a mirror of green jasper dotted with red spots. 3. *Raphael the Physician*, leading by the right hand the boy Tobias, who carries a fish seized by the mouth, while in his raised left hand he bears a box. 4. *Uriel, Companion of the Strong*, who in his right hand gripped a drawn sword held crosswise before his breast, while on his left, near his feet, a flame shone upon him. 5. *Jehudiel the Rewarder*, holding out a crown of gold in his right hand and in his left a scourge set off with three black cords. 6. *Barachiel the Helper*, carrying white roses in the fold of his cloak. 7. *Scaltiel the Intercessor*, who, with face and eyes lowered and palms joined at the breast, presented the appearance of one praying. On the church erected at Palermo to the seven princes of the Angels, and on the other church at Rome, at the Baths of Diocletian, dedicated by Pius IV in honour of St Mary of the Angels, see the same Cornelius.

[Margin: 7 dukes of the Persians.]

[Margin: 7 Deacons of the Church.]

[Margin: 7 Cardinal Deacons.]

Therefore, just as Ahasuerus, following the custom of the Kings of the Persians, had *Seven dukes of the Persians and Medes, who saw the King's face and were accustomed to sit first after him*, as is told in Esther 1; and just as it is established from the book *On the Roman Pontiffs* that, ever since Evaristus, as many Cardinal Deacons were substituted for the Seven Deacons of the primitive Church, and used to attend the supreme Pontiff; so the Seven Angelic Spirits, whether they are those who preside over the 7 Planets or are distinct from them, appear to hold the chief place before GOD in administering the affairs of this World. And as Clement of Alexandria says in Book 6 of the *Stromata*: *There are seven, whose power is greatest, the first-born princes of the Angels.* This has been said on the occasion of the name of the Planets, and of their first and noblest analogy with the seven Spirits of God.

III. [Margin: Praises of the number seven.] Among the many things that Macrobius brings forward, in Chapter 6 of Book 1 on the *Dream of Scipio*, to show that the number seven, composed of even and odd, is full, and to illuminate that saying of Cicero's about the number seven in the same Dream,

a number which is virtually the knot of all things, he first adduces the judgement of Hippocrates, who says that what has been conceived in the womb moves from the seventieth or the ninetieth day, and that this day, multiplied by three, points to a birth in the seventh or in the ninth month. He then adds that the Ocean wanes for 7 days from the interlunium and waxes again on the eighth day. Next, from the same Hippocrates, *who knows neither how to deceive nor how to be deceived*, he marks out the seven weeks by which the human foetus is formed and the newborn is strengthened, explaining what is brought to completion in each of them, as I shall say at no. 6. But in Chapter 12, closer to our subject, he teaches from the Platonic fables that the soul descends from the upper part of the World and from the Milky Circle through the gate of Cancer, and that in passing through the seven spheres of the Planets it is imbued by them with a particular faculty and acquires:

[Margin: Platonic fictions about the descent of souls through the 7 spheres.]

in the sphere of Saturn, reasoning and understanding, which they call λογιστικὸν θεωρητικὸν [Greek: logistikon theōrētikon, "the reasoning, contemplative [faculty]"]; *in Jupiter's, the power of acting, which is called* πρακτικὸν [Greek: praktikon, "the active [faculty]"]; *in Mars's, the ardour of spirit, which is named* θυμιτικὸν [Greek: as printed, "the spirited [faculty]"]; *in the Sun's, the nature of sensing and of forming opinion, which they call* ἀισθητικὸν [Greek: aisthētikon, "the sensitive [faculty]"] *and* φανταστικὸν [Greek: phantastikon, "the imaginative [faculty]"]; *and the motion of desire, which is called* ἐπιθυμητικὸν [Greek: epithymētikon, "the desiring [faculty]"], *in Venus's; that of pronouncing and interpreting what it senses, which is called* ἑρμηνευτικὸν [Greek: hermēneutikon, "the interpretive [faculty]"], *in the orb of Mercury;* φυτικὸν [Greek: phytikon, "the vegetative [faculty]"], *that is, the nature of planting and increasing bodies, on entering the globe of the Moon, etc.*

IV. [Margin: The Harmony of the World in the spheres of the 7 Planets.] But nothing in praise of the seven Planets sounds more pleasant to the ears of not a few than that celebrated harmony of divine Providence through the heptachord of the seven spheres. For Dorylaus, in Censorinus, Chapter 11, shrewdly declared that *the World is the Organ of God*. With this Plutarch agrees, near the end of his little work on Music, saying: *Pythagoras, Archytas, Plato and the other ancient Philosophers proclaimed that the motions of all things and the revolutions of the stars can neither come about nor persist without Music: for they maintain that the Demiurge and maker, God, fashioned all things with harmony.*

[Margin: 8 Muses or Sirens.]

Indeed the ancient theologians of the Gentiles, as is found in Macrobius on the *Dream*, Book 2, Chapter 3, assigned to eight or 9 spheres as many Muses, and Plato as many Sirens, or Songstresses of God. They also attributed to them musical intervals, and to each its own tones, which Cicero carried over from Platonic sources into what is his own dream more than Scipio's, and which Macrobius expounded in Book 2, Chapter 4. And before them Pythagoras did so, as is clear from Pliny the Elder, Book 2, Chapter 22, from Censorinus,

Chapter 11, and from Macrobius on the *Dream*, Book 2, Chapter 3. Granted that Pliny the Elder says this was done *with a charm more agreeable than necessary* [iucunda magis quàm necessaria vtilitate]; that Macrobius says that to treat harmonics at greater length on this occasion *is the mark of one showing off, not teaching*; and that Glareanus [Heinrich Glarean], in Book 1 of the *Dodecachordon*, p. 11, says that these things have seemed to many *frivolous dreams*. Even so, I ought not to pass over in this place that distribution, both of those who assigned the Muses to the seven Planets and of those who assigned the strings or tones. Of these, some, holding that the highest sphere moves most swiftly and the lowest most slowly, considering, that is, the daily motion to the west, gave to the fixed stars Nete, the sharpest of the strings, and to the Moon Hypate, the deepest. Conversely, others, who considered the proper motion to the east, and recognised that the slowest is in the highest sphere and the swiftest in the lowest, gave Hypate to the highest and Nete to the lowest.

[Margin: Authors from whom the following little tables are drawn.]

Besides the authors already reviewed, those who write on these matters are, in the first place, Nicomachus in the *Enchiridion of Harmonics*; Boethius, *On Music*, Book 1, Chapter 20, and Book 4, Chapter 10; Servius and the other commentators on that line of Virgil, *Eclogue* 2:

I have a pipe made of seven unequal hemlock stalks [Est mihi disparibus septem compacta cicutis Fistula]

and on that line of *Aeneid* 6:

He accompanies in measure the seven distinctions of notes [Obloquitur numeris septem discrimina vocum].

For the seven-stringed lyre, invented by Apollo in imitation of the seven Planets, or devised by Mercury in imitation of the seven-star group of the Pleiades, is recorded by Hyginus, Book 2 [recte: Book 1, per the book's errata]; by Vitruvius, Book 5, Chapter 4, and there by Daniel Barbarus [Daniele Barbaro] and Gulielmus Philander [Guillaume Philandrier]; also by Ficinus [Marsilio Ficino] on Plato, on poetic frenzy; by Glareanus in Book 2 of the *Dodecachordon*, Chapters 8 and 13; by Guido Aretinus [Guido of Arezzo] in his *Scala Musica*; by Petrus Valla [?] on Pliny the Elder, Book 2, Chapter 22; by Zarlinus [Gioseffo Zarlino], Part 2 of the *Institutiones Harmonicae*, Chapters 6 and 29; and by Bettini in the *Apiarium* 10, Progymnasma 1, Proposition 3. From these, let the distribution of the Muses, Strings, Tones and Notes that are attributed to the Planets according to the differing opinions be set out in the following tables.

MVSÆ (Muses): Ficinus & Zarlinus, after the mind of Plato	MVSÆ (Muses): Glareanus, after the mind of Hesiod	Strings, Notes and Tones, or Phthongi: Cicero & Macrobius in Valla	Strings, Notes and Tones, or Phthongi: Cicero in Glareanus & Zarlinus	[Margin: The ancient order of the spheres]
Calliope	Calliope			Ninth
Vranie	Vranie		Μέση, sharpest [acutissima]	✶

MVSÆ (Muses): Ficinus & Zarlinus, after the mind of Plato	MVSÆ (Muses): Glareanus, after the mind of Hesiod	Strings, Notes and Tones, or Phthongi: Cicero & Macrobius in Valla	Strings, Notes and Tones, or Phthongi: Cicero in Glareanus & Zarlinus	[Margin: The ancient order of the spheres]
Polhymnia	Polhymnia	Nete	λιχανὸς ὑπατῶν	♄
Terpsichore	Erato	Paranete	παρυπάτη μεσῶν	♃
Clio	Terpsichore	Paramese	ὑπάτη μεσῶν	♂
Melpomene	Melpomene	Mese	λιχανὸς ὑπατῶν	☉
Erato	Thalia	Hyphypate	παρυπάτη ὑπατῶν	♀
Euterpe	Euterpe	Parhypate	ὑπάτη ὑπατῶν	☿
Thalia	Clio	Hypate	προσλαμβανόμενος	☾

CHORDÆ VOCES TONI &c.
Strings, Notes, Tones, etc.

Nicomachus and, for the most part, Boethius	Boethius in Glareanus & Zarlinus	[Margin: The ancient order of the spheres]
	λιχανὸς ὑπατῶν — A, rè	✶
Hypate	ὑπάτη μεσῶν — B, mi	♄
Parhypate	παρυπάτη μεσῶν — C, fà, vt	♃
Hyperhypate	λιχανὸς μεσῶν — D, sol, rè	♂
Mese	μέση — E, là, mì	☉
Paramese	τρίτη συνεμμένων — E, fà, vt	♀
Paranete	παρανέτη συνεμμένων — G, sol, rè, vt	☿
Nete	νέτη συνεμμένων — E, là, mì, rè	☾

57

[Margin: The ancient order of the spheres]	VOCES &c. (Notes, etc.): Father Mario Bettini	INTERVALLA (Intervals): Pythagoras in Pliny the Elder, Censorinus, Macrobius, Zarlinus
✶	Hypate — Vt	Lesser semitone [Hemitonium minus]
♄	Parhypate — Rè	Greater semitone [Hemitonium maius]
♃	Lichanos — Mì	Lesser semitone [Hemitonium minus]
♂	Mese — Fà	Tone [Tonus]
☉	Paramese — Sol	Tone with a lesser semitone [Tonus cū hemitonio minori]
♀	Paranete — Mi mì	Lesser semitone [Hemitonium minus]
☿	Trite — Rè rè	Greater semitone [Hemitonium maius]

[57]The Greek string names are given as printed. They mean: ὑπάτη, the "highest" string, which is the deepest in pitch; παρυπάτη, the string next to it; λιχανὸς, the "forefinger" string; μέση, "middle"; τρίτη, "third"; νέτη with παρανέτη, the "last" string and the one next to it; προσλαμβανόμενος, the "added" note; ὑπατῶν, μεσῶν, συνεμμένων, "of the highest", "of the middle", "of the conjunct" tetrachord. In the first table the third column has no entry in its first two rows, and the fourth none in its first; in the second table the first column has no entry in its first row. The planetary signs stand in the margin outside the ruled frame, level with the rows. ✶ is a printed star sign for the fixed stars.

[Margin: The ancient order of the spheres]	VOCES &c. (Notes, etc.): Father Mario Bettini	INTERVALLA (Intervals): Pythagoras in Pliny the Elder, Censorinus, Macrobius, Zarlinus
☾	Nete — Fà fà	Tone to the Earth [Tonus ad Terram]

But note that Bettini uses the Moon at apogee, the Sun and Mars at a mean distance, and the rest at perigee.

V. [Margin: Planetary hours.] As one passes from the heptachord to the hebdomad, one meets a varied economy of times, arranging hours, days, months and years by the number seven. As regards the Planetary hours, from which the lordship of the days of the week is then believed to arise, see what we said in Book 1, Chapter 30.

[Margin: The days of the week distributed to the Planets.]

Cassius Dio, in Book 37, says: *That the days were arranged according to the seven stars which the Greeks call Planets and the Latins Wanderers was first established by the Egyptians, and then spread to the other nations. There is a twofold reason for this, and it is not difficult. For if someone refers that harmony called* διατέσσαρον [Greek: diatessaron, "the fourth"]*, in which the ancients believed the foundation of all music to be contained, to those stars by which the whole ornament of the heaven is varied and divided, and to the order in which each of them moves;*

[Margin: 1. Reason for this distribution.]

and then, taking his beginning from the outermost orb, that of Saturn, and leaving out the next two, counts the ruler of the fourth orb; then, passing over two others, reaches the seventh; and, running through the same stars and their ruling Gods in the same manner, applies them to the days: he will find that they all agree in a kind of musical way with the ornament of the heaven. This, then, is how this reason stands. Now the ancient order of the Planets is the one I reported above, and it is shown by that well-worn line:

Cynthia, Mercury, Venus, and Sun, Mars, Jove, Saturn [Cynthia, Mercurius, Venus, & Sol, Mars, Ioue, Saturn.]

with these figures printed beneath the names in the same order: 3, 5, 7, 2, 4, 6, 1.

So, entering on the week from the Sabbath and setting Saturn over it, go down, always leaving out the two in between, and you will find that the Sun presides over the following day, that is, the second after the Sabbath, and the Moon over the third. Then go back to Saturn and, leaving him out along with Jupiter, you will find that Mars presides over the fourth day and, by the same jump, Mercury over the fifth. Finally, going down through the Moon and going up again through Saturn, you will find Jupiter set over the sixth day after the Sabbath and Venus over the seventh.

[Margin: 2. Reason for this distribution.]

Cassius Dio goes on to the second reason, saying: *The other reason is of this kind. Review all the hours of the day and night, in such a way, however, that Saturn holds the first place, Jupiter the second, Mars the third, the Sun the fourth, Venus the fifth, Mercury the sixth, the Moon the seventh. For the Egyptians judge this to be the*

order of the orbs. If you do this with the twenty-four hours reckoned up, you will find the first hour of the following day assigned to the Sun; again, if you go on through the same 24 hours in the manner stated above, you will assign to the Moon the first hour of the third day; lastly, if you pursue the rest in this way, each day will have its own Gods, suited to it; namely, that Planet which has obtained the first hour of the day. We followed this order, represented in a little table, in Book 1, Chapter 30.

[Margin: 3. Reason from the aspects.]

In the same place we set out the third reason for this distribution, drawn from the aspects. You come back to the same thing if, beginning from the Sun, as Bettini does, with Scheiner, in the *Apiarium* 10, Progymnasma 1, Proposition 4, you assign to it the first hour of the first day, going down through ♀ ☿ ☾, and then going up from there to ♄, etc.

[Margin: The emptiness of this distribution.]

But these reasons assume that that old system stands, which Io. Picus [Giovanni Pico della Mirandola] rejects in Book 10 *Against the Astrologers*, Chapter 4. Certainly Mercury is in reality nearer the Sun than Venus is, and both, for a great part of the time in which they run through their epicycle, are above the Sun. That foundation is therefore empty; and much emptier is the superstition of those who hold that those days are ruled by the Planets as by divinities. St Isidore rightly detests them in Book 5 of the *Origines*, Chapter 30, mocking the folly of the Gentiles, *who from these seven stars gave names to the days, saying that the spirit is had from the Sun, the body from the Moon, wit and speech from Mercury, pleasure from Venus, blood from Mars, temperance from Jupiter, and humour from Saturn.* And he adds that the days of the week are better begun from the Lord's Day, and the rest called, according to the order of the feriae, the second, third, fourth feria, etc., up to the Sabbath. Philastrius too held this, in his book *On Heresies*. The Emperor Constantine introduced this custom into the Church at the urging of Sylvester, the Supreme Pontiff, as Bede reports in his book *On the Nature of Things*, Chapter 8.

VI. [Margin: The order of the Planets in forming the foetus.] Nor was it believed that the Planets preside only over the hours and the days of the weeks, but also over the months in which the infant is formed in the womb and, once born, is strengthened and made firm, and finally over the gradatory or climacteric years, which the common people call scalar. So indeed Macrobius, partly from the sources of Hippocrates, in Book 1 on the *Dream of Scipio*, Chapter 6, and partly from those of Plato Marsilio Ficino, in the book *De vita longa*, Chapter 19. Ficino says that Saturn presides over the first month of the forming foetus, Jupiter over the second, Mars over the third, the Sun over the fourth, Venus over the fifth, Mercury over the sixth, and the Moon over the last.

[Margin: The order of the Planets in the years of our life, and on the climacterics.]

In the contrary order, the Moon presides over the first year after the boy is born, Mercury over the 2nd, Venus over the 3rd, the Sun over the 4th, Mars over the 5th, Jupiter over the 6th, and Saturn over the 7th; so that every seventh year, which is climacteric and decisive and in which the greatest change of the body occurs, namely the year 7, 14, 21, 28, 35, 42, 49, 56, 63, 70, 77, 84, 91, 98, 105, etc., is under Saturn.

But Macrobius, speaking of the number seven, says: *This, finally, is the number that causes a human being to be conceived, formed, brought forth, to live, to be nourished, to be handed on through all the stages of the ages to old age, and altogether to subsist.* Then, from Hippocrates, Strato and Diocles, he teaches that in the first week a little sac covered with a thin membrane is formed; in the second, blood begins on the outside; in the third, it is filled with blood within; in the fourth, it curdles, and the distinctions of flesh and blood appear; in the fifth, if the birth is to be in the seventh month, the limbs are shaped, and the outlines of all the limbs are moulded, though within the size of a bee. Otherwise, if the birth is to be in the ninth month, and female, this happens in the sixth week; if male, in the seventh. The born child, if it endures the breath of the air for 7 hours, is viable; at the end of the first week it casts off the remains of the navel; at the end of the second it moves to see the light; at the end of the seventh it freely turns its whole face and its pupils to look at each thing. Again, after 7 months the teeth come through; after 14 the child sits without fear of falling; after 21 its sound breaks out into words; after 28 it stands firmly and walks; after 35 it turns from the nurse's milk. As for years, in year 7 it puts in more solid teeth and speaks readily; at 14 it reaches puberty; at 21 it becomes a young man and stops growing in length; at 28 it stops growing in breadth; at 35 it gains strength for the last time, without hope of acquiring greater strength any further; in year 42 a decrease of strength begins, though an imperceptible one, while judgement is brought to completion, up to year 49, in which age is perfected in every way, and a man is fit for counsel and no stranger to the exercise of his strength. But in year 63 or 70 one comes to the goal of living, or the perfected span of human life: *Whoever has passed it, free of every duty, gives himself to the exercise of wisdom alone, and has his whole use in giving counsel, venerable for his release from other offices*, says Macrobius, who judges that all these things flow from the seven spheres of the heaven.

VII. There are many other things that the astrologers, and in part the Spagyrists and Chemists, attribute to the Planets, collected from the sewage of Arabic books, or from the masters of the Pyronomic sect, namely Hermes, Geber, Ruperissa [?], Arnoldus de Villanoua [Arnau de Vilanova], Raymundus Lullus [Ramon Llull], Rogerius Bacho [Roger Bacon], Albertus Magnus, Isaacius Hollandus [Isaac Hollandus] and Theophrastus Paracelsus; they are to be read with a grain of salt and with antidotes against superstition. Besides these, what concerns metals and gems is touched on by Ficino in the book *De vita coelitus comparanda*; by Cardano in Book 5 of *De subtilitate*; by Tycho in the letter to Rothmann of 1588 August 17, where he calls spagyric art terrestrial

Astronomy on account of its analogy with the Planets; and by Kepler in the *Epitome of Copernican Astronomy*, p. 488. These things, and others besides, are covered by Redemptus Baranzanus [Redento Baranzano] in Part 2 of the *Uranoscopia*. The rest, which concerns the Houses, Exaltations, Detriments and Falls of the Planets, is found throughout the Introductions to the Ephemerides. From these I have selected, for the sake of learning rather than from my own judgement and opinion, the little tables set out below.

[Margin: Table 1.]

True order [Ordo verus]	Tycho and most others	Baran-zano and others	Ficino, for the most part Baranzano, and others	Colours	Humours and Spirits
♄	Lead [Plumbum] — Spleen [Splen]	Lead [Plumbum]	Onyx, jasper, topaz [Onyx, Iaspis, Topacius]	Black [Niger]	Black bile [Atra bilis]
♃	Tin [Stannum] — Liver [Iecur]	Bronze [Æs]	Sapphire, emerald, Pracius [?] [Sapphirus, Smaragdus, Pracius]	Yellow [Flauus]	Radical moisture [Humidū radicale]
♂	Iron [Ferrum] — Gall [Fel]	Steel [Chalybs]	Amethyst, jacinth, garnet [Amethystus, Iacinthus, Granatus]	Red [Rubeus]	Yellow bile [Flaua bilis]
☉	Gold [Aurum] — Heart [Cor]	Gold [Aurum]	Diamond, carbuncle, balas [Adamas, Carbūculus, Ballacius]	Saffron [Cro-ceus]	Vital spirit [Spiritus vital.]
☿	Quicksilver [Argentū viuum] — Lung [Pulmo]	Copper [Cuprum]	Agate, chrysolite, beryl [Acathes, Chrysolithus, Berillus]	Blue [Cæruleus]	Animal spirit [Spiritus animal.]
♀	Copper, bronze [Cuprum Æs] — Kidneys [Renes]	Tin [Stan-num]	Pearl, turquoise, chrysoprase [Margarita, Turquesia, Chrysoprasus]	Green [Viridis]	Blood [Sanguis]
☾	Silver [Argentum] — Brain [Cerebrum]	Silver [Argen-tum]	Coral, chalcedony, selenite [Corallus, Chalcedonius, Selenites]	White [Albus]	Phlegm [Pituita]

But Kepler differently, as follows: ♄ *a very hard, dense gem, as 324;* ♃ *a magnet, as 438;* ♂ *iron, as 810; the Earth silver, as 1000;* ♀ *lead, 1175;* ☿ *quicksilver, 1605; the Sun gold, 1800.* And in the *Astronomia Optica*, p. 261, he says that *if a black surface is strongly lit, it gives the colour of Mars; if a bright red, of* ♃; *if leaden or white, of* ♄; *if blue, of* ☿; *if yellow, of* ♀. Then he compares the light of Mars, Jupiter, Venus, Mercury and Saturn to the light of a burning coal, of a very transparent ruby, of a yellow but very bright body, of sapphire, and of coarser crystal: for if the crystal is fine, the light is Mercury's.

[Margin: Table 2.]

Order [Ordo]	Houses of the Planets: Diurnal [Domus Planetarum: Diurna]	Houses of the Planets: Nocturnal [Nocturna]	Detriment of the Planets [Detrimentum Planetarum]	Exaltation of the Planets [Exaltatio Planetarum]	Depression or Fall [Depressio seu Casus]	Joy or Throne [Gaudium seu Thronus]	Sex of the Planets [Sexus Planetarum]
♄	♒	♑	♌ ♋	♎ 19	♈ 19	♒	Male [Masculus]
♃	♐	♓	♊ ♍	♋ 15	♑ 15	♐	Male [Masculus]
♂	♈	♏	♎ ♉	♑ 28	♋ 28	♏	Male [Masculus]
☉	♌		♒ —	♈ 19	♎ 19	♌	Male [Masculus]
☿	♊	♍	♐ ♓	♍ 15	♓ 15	♍	Hermaphrodite [Hermaphroditus]
♀	♎	♉	♈ ♏	♓ 27	♍ 27	♉	Female [Fœmina]
☾		♋	— ♑	♉ 3	♏ 3	♋	Female [Fœmina]

CAPVT II.

Chapter 2.

De Figura Quinque Planetarum, Maculisq. ac Zonis aliquorum Telescopio detectis.

On the Figure of the Five Planets, and the Spots and Belts of Some, Detected with the Telescope.

[Margin: New phenomena indicated.]

I. By a plainly secret design, that supreme maker of the stars, *who shuts up the stars as under a seal*, at the end of the preceding century and the start of the present one, gave so many and such new phenomena in the heaven to be viewed, partly by naked eyes, partly by eyes armed with the telescope. Redoubling in the heavens the spectacles of a New World, as he had most recently done on earth, he admitted into the vast theatre of wonder and contemplation the latest Argonauts there, and Prometheuses here. So at about the same time, and at no very long interval of years, there came forward on the stage of heaven: besides the hosts of almost infinite small stars, ancient but once undistinguished, in the nebulous stars and along the whole tract of the Galaxy, the outstanding splendours of three new stars, in Cassiopeia, in Serpentarius and in Cygnus; then the face of the Moon, and the Sun himself, gleaming all round with innumerable shadows of spots and lights of faculae; and at once Venus, with

her horned brow, and perhaps unlovely with caverns or spots; and half-flashing Hermes, with his sickle-shaped radiance; then the fire of Mars, with a humped and blunted boss, not quite round, yet grim and dreadful still with its rust-coloured spot; then the tetrastric star of Jupiter, surrounded by the splendours of four petty kings rather than satellites, and girt crosswise with a belt that is seldom single, more often double, and more rarely triple; and then, finally, Saturn, the Geryon of the Planets, marvellous for the portent and astonishment of a three-bodied star. So true is it that neither the choir of the unwandering stars nor any of the Planets has appeared without new array and new insignia. Since these matters belong above all to this place, they must be set out from what we have partly observed ourselves with our own eyes and spyglasses, and have partly received from the books of others or from letters written to us.

Mercurij ac Veneris Figura.

The Figure of Mercury and Venus.

II. All stars, whatever their figure may be, appear round when viewed from afar, just as a flame does, which is established to be pyramidal: for their angles are optically compressed into the narrowness of the visual angle, so that they do not appear. But viewed with the spyglass, once Belgian and later, by the craftsmanship of Galileo, of Fontana [Francesco Fontana], of Torricelli [Evangelista Torricelli] and of Eustachio [Eustachio Divini], now Italian, they appear otherwise. Thus Mercury and Venus, after their morning emersion from the rays of the Sun, appear sickle-shaped a little before the second station, as at position I of the following figure; then, around their greatest digression from the Sun, split in two, imitating the look of the Moon at dichotomy, as at G; afterwards, approaching with direct motion their heliacal morning immersion, they appear gibbous and gradually brought round to the roundness of a disc, as at E. From this an argument is drawn that, if the brightness of the Sun S did not stand in the way, they would be seen by us from the Earth T as perfectly round, when viewed at the conjunction in apogee C.

Diagram. Set into the right column, with the text running down its left side. A large circle with the Sun S at its centre carries eight small planet-discs along its circumference, each showing a phase by a dark part and a light part. From S a vertical line runs down through K to T, the Earth, at the foot of the figure; a curved line joins F and G through the region of S; two further straight lines run up from T to the dark discs at H and I.

- C (top of the circle): open disc, wholly light; the conjunction in apogee.
- D (upper left): disc largely light, dark on its outer side; nearly round.
- E (upper right): disc largely light, dark on its outer side; gibbous.
- S (centre): the Sun.
- F (left): disc half dark; bisected.
- G (right): disc half dark; bisected.
- H (lower left): disc mostly dark, the light part sickle-shaped; horned.

- I (lower right): disc mostly dark, the light part sickle-shaped; sickle-shaped.
- K (bottom of the circle): wholly dark disc; the conjunction at perigee.
- T (foot of the figure): the Earth.

When they have come down from the summit of their Pericycles and, having become evening stars, have emerged from the rays of the Sun, they again appear nearly round, as at D; and around the greatest evening digression bisected, as at F; and near the next station horned again, as at H.

In conjunction with the Sun occurring at perigee K, and on the days nearest on either side, they lie hidden under the splendours of the Sun and are not seen except very rarely: either covering, because of their small latitude, a little part of the Sun like a very black spot,

[Margin: Mercury seen under the Sun.]

in which way we have already told of Mercury seen under the Sun in Book 3, Chapter 3, Scholium 3, and Scaliger testifies the same of himself in Exercitation 72, and after him the Coimbra College, on Book 2 of *De caelo*, Chapter 2, Question 4, Article 2; or else, because of its enormous latitude, Venus, which is visible in some measure.

[Margin: Venus seen under the Sun but outside the Sun.]

For, by the testimony of Longomontanus in Book 2 of the *Theorica*, Chapter 18, and of Kepler in the *Optics*, p. 261, Tycho saw Venus near the perigee conjunction on the Danish horizon, when she had a northern latitude of almost 9°. These things being so, a very strong argument is made that these Planets circle the Sun S, and that by it they are illu- minated. For if they always trailed along below the Sun, never departing from it beyond 29 or 30 degrees in the case of ☿ and beyond 50 in the case of ♀, they would always appear in the telescope sickle-shaped, or at most dichotomous; but if they always moved above the Sun, they would always appear round, or as good as round, as will be plain from inspecting the figure itself and from drawing the lines of illumination and of reflection from there to our eyes according to the rules of optics. And if they shone of themselves on all sides, they would be seen as always round. But now each of them must be treated individually.

De Mercurij Figura seorsim.

On the Figure of Mercury Individually.

[Margin: Scheiner's opinion.]

III. Our colleague Scheiner, in the *Disquisitiones Mathematicae*, no. 38, has this: *Of Mercury it is established that it often shines out spherical, so that it is as good as certain that it moves above the Sun*; and shortly after: *But some also assert that Mercury becomes crescent; since we have not yet experienced this, we leave the matter undecided.* And in fact, because of its small digression from the Sun and the vapours of the horizon, the opportunity of seeing it sickle-shaped rarely arises, especially since the quivering of its intensely twinkling light, on account of which the Greeks called it [Greek: στίλβων (stilbōn, "the glitterer")], hinders

that phase unless the eyes are strong and the glass [specillum] outstanding. Yet from that liveliness of brightness, communicated from nearer the Sun, by which it surpasses Venus herself and Jupiter,

[Margin: And Galileo's.]

Galileo, in Dialogue 3 of *De Mundi systemate*, thinks a very firm argument is drawn that Mercury is closer to the Sun than Venus and runs around it in a tighter circuit; whereas in the *Sidereus Nuncius*, p. 16, he had said that the Planets appear exactly round, without scintillation.

[Margin: The testimony of Hortensius.]

Martinus Hortensius, in the Dissertation with Gassendi on Mercury seen under the Sun, where he dealt with certain matters concerning the telescope, affirms that Mercury, no differently from Venus, when it lowers itself beneath the Sun, was observed by him to pass into horns, but when ascending towards the apogee to become gibbous, and finally round.

Diagram. Three discs of Mercury stacked one above another, inset in the left column, the text narrowed beside them and a printed rule dividing the first two. Each disc is a circle with its dark part solidly stippled and its lit part left white.

- Upper disc, sign at upper left: ☿. Label at upper right: `Vespr- / tinus` (evening star). The dark part fills the upper left and centre; the lit part is at the lower right. Dates beneath it: 1639 May 23; 1646 January 26 (`1646. Ian26.`, the `I` not separated from an `L`); 1647 April 30 (printed `Apru`).
- Middle disc, sign at upper left: ☿. Label at upper right: `Mattuti / nus` (morning star). The dark part fills the upper right and centre; the lit part is at the lower left. Dates beneath it: 1643 August 25; 1644 August 6.
- Lower disc, sign at upper left: ☿. Label at upper right: `Vesper / tinus` (evening star). The dark part is a cap across the top; the lit part fills the lower portion (gibbous). Date beneath it: 1643 March 5.

[Margin: Kepler's and Simon Marius's.]

Kepler testifies to the very same in the *Epitome of Copernican Astronomy*, p. 762, also adducing the testimony of Simon Marius; and so does Biancani in Book II of the *Sphere*, Chapters 3 and 4, who however holds Mercury, like all the planets alike, to be rough, lest, if it were turned to a polished roundness, it should reflect to us a single ray of the Sun or very few.

[Margin: Father Giovanni Battista Zupi's observations.]

From the letters, too, that Father Niccolò Zucchi of the Society of Jesus wrote to me, and from the observations of Francesco Fontana, Tract 5, Mercury was observed by Father Giovanni Battista Zupi, mathematician of our Society, at Naples in the year 1639 May 23, three quarters of an hour after sunset, and indeed with a tube of Fontana's, which inverts objects by means of a small glass globe near the eye; but I show it to you upright in the figure above, as the same man later saw it in the year 1646 January 26, one quarter of an hour after sunset. In the earlier observation it stood about 22° from the Sun, and in the later 18°.

[Margin: And ours.]

We too saw it like this, only very slightly smaller, as an evening star in the year 1647 April 30, when it was 20½° east of the Sun. And we saw the same planet as a morning star in the year 1643 August 25, when it was 19° from the Sun, and in the year 1644 August 6, when it was 20° from it, in the shape and position that you see in the second of the preceding figures; and in the last of them as an evening star and gibbous, in the year 1643 March 5, since it was no more than 15° from the Sun and still in the upper part of the Epicycle. Nor is there any need to add other observations; for among recent writers skilled in the telescope and in observing it is now beyond dispute that Mercury is illuminated by the Sun in the same way as the Moon would be, if the Moon went around the Sun rather than the Earth in its circuit.

De Veneris Figura seorsim.

On the Figure of Venus Individually.

IV. Venus, however, appears now round or gibbous, now bisected, now sickle-shaped, so frequently and so plainly that it would be pointless to pile up witnesses here. The same ones adduced for Mercury in the preceding number are as good as enough: among them Galileo in Dialogue 3 and in *De maculis Solis*, p. 15; Biancani in Book 12 of the *Sphere*, Chapter 2; and Scheiner in the *Disquisitiones*, no. 38, and in the second letter to Markus Welser. They testify that in various cities of Italy she was seen gibbous at one and the same time, bisected at another such time, and horned at another. And they add that she is seen smallest but rounder when, moving direct, she is heading for her morning conjunction with the Sun, and largest in length but narrower in breadth, departing most from the roundness of the disc, when, retrograde, she is heading for her evening conjunction; and that she then appears forty times larger (understand Galileo as speaking of the area).

[Margin: The varying size of Venus.]

Scheiner adds, and from him Hortensius in the Dissertation with Gassendi, that after her second quadrature (understand: when she appears bisected and imitates the Moon in □; otherwise she is never 90° from the Sun) her horns appear very blunt, but then gradually taper to points until they become very sharp; yet that when she is two-horned [bifida] she lights up the lands with a very strong radiance, so that she then serves very well for reading letters and casts a more evident shadow, because she has grown in apparent bulk and in light. For although her luminous sickle is a portion of a large circle, it is nevertheless slenderer, and falls far short in vigour of light of the light with which she shines when dichotomous. And indeed we too have very often observed Venus sickle-shaped, and more than once two-horned or gibbous, but always flame-spewing: especially in the year 1643 January 9, with Fontana's tube lent to me, in the position and shape that can be seen in the present diagram.

Diagram. One large disc of Venus set in the right column between the lines of text. The circle has its dark part solidly stippled, occupying the upper

left and centre, and its lit part left white as a sickle along the right and lower right.

- Upper left: ♀ (sign).
- Upper right: `Vesper.` (evening star).
- Left of the circle, set vertically: `Oriens.` (east).
- Right of the circle, set vertically: `Occid.` (west).
- Beneath: `1643 Ianuarij 9.` (1643 January 9).

Toward the Sun she was ruddy, in the middle yellowing, and in the part turned away from the Sun blue-green; but that variety probably came from the glass of the tube. The bright half-ring by which she was crowned from behind perhaps came from Jupiter and Saturn illuminating her, since they were more easterly. She was observed both at other times and most frequently in the year 1644, when, having already slipped down in the evening from the Apogee of her Epicycle, she had appeared after her evening heliacal rising. From May 7 she was clearly gibbous, as seen through larger tubes, until June 20; around the beginning of July she was [Greek: διχότομος (dichotomos, "cut in two")], or very like the Moon at quadrature, but strongly flame-spewing towards the Sun and the lands; then, until August 4, when we stopped observing her, she grew from day to day more sickle-shaped and narrower in breadth, but more drawn out in length,

Diagram. A very large and very thin sickle of Venus filling the width of the left column, its convex edge to the right and its two needle-sharp horns reaching back to the left at the top and foot. The inscription stands inside the concavity.

- At the upper horn: `Occidens` (west).
- At the lower horn: `Occidens.` (west).
- Inside the concavity, above the inscription: ♀ (sign).
- Inside the concavity, below the inscription: ♀ (sign).
- Inscription: *VENERIS Vltima Phasis vespertina, cùm esset proxima Occasui Heliaco, & in Apogeo Eccentrici. Anno CHRISTI 1649. Iunij die 29. Post quem Soli coniuncta fuit Die 7. Iulij.* (The last evening phase of Venus, when she was very near her Heliacal Setting and in the Apogee of the Eccentric. In the year of Christ 1649, June 29. After which she was conjoined with the Sun on July 7.)

so that she rivalled the Moon in its first phase, just as she rivals the last phase of that same Moon when she rises heliacally in the morning. This was above all most splendidly evident in the year of the Lord 1649 June 29, on the evening of which Vesperugo was last seen through the tube, very close to the evening heliacal setting that soon followed; seen, I say, exactly as you see in the figure above, with very sharp horns and both edges very clean, without any filaments of rays, let alone that head of hair mentioned above. The telescope, moreover, was one familiar to us, though not ours but belonging to the Most Illustrious Lord Giuseppe Maria Grimaldi, of whom more elsewhere. Venus was very near the Apogee of the Eccentric and was rushing headlong to the Perigee of

the Epicycle, in which she was due to be conjoined with the Sun on July 7. In exactly the same phase, though in the opposite position, ♀ was observed by us after her ♂ with ☉: not immediately, because the clouds did not allow it, but on July 18 of the same year 1649, when she was already appearing in the morning in the East, sickle-shaped, her very cleanly sharpened horns turned to the West, with a weak and diminished light, although already Lucifer or Phosphoros. So much from our own observations.

But in the observations of Francesco Fontana, Tract 5, Chapter 2, I read that ♀ was seen through his tube as an evening star, oblong and nearly half a foot long, and as large as the Moon is seen without the telescope, half-rough on its concave side and darting rays, especially when she imitates a parabolic figure; and (something unheard of until now) with one or another blackish little globe, now outside, now inside the body of Venus, who is certainly unlovely on that account, as can be seen in the following figures, though on a reduced scale. If these things are true (far be it from us to call into suspicion the good faith of those who so affirm), it seems we must say either that it was some meteor, for example a wisp or a small cloud lying between or set around Hesperus; or that they are spots like the Solar ones, blown out from the body of Venus and as it were bubbling up; or spots like the Lunar ones, of caverns and mountains, more or less illuminated according to Venus's varying position with respect to the Sun, or perhaps her rotation or libration. For I would not dare to say that they are planets accompanying Venus, until time teaches something more certain on this matter. Certainly I have never been able, nor has Father Grimaldi ever been able, nor Gassendi, as is plain from Book 3 of the *Institutio Astronomica*, to view those little globes on Venus or near Venus with any telescope whatever.

Diagram. A ruled box in the right column holding four sickles of Venus in two rows of two, each with its convex edge to the right drawn with a fringe of short rays and its concave edge jagged and irregular. Dark oval globes stand beside or within them.

- Head of the box: ♀ Vesprtine 4. Phases (the four evening phases of Venus).
- Upper left sickle, `1645 Nou. 11.` (1645 November 11): one dark oval within the concavity.
- Upper right sickle, `1645.Nou / 15.` (1645 November 15): one dark oval above the upper horn, and one dark oval beside the lower horn, standing next to the figure `25.` of the next label.
- Lower left sickle, `1645. Dec. 25.` (1645 December 25): one dark oval beyond the lower horn.
- Lower right sickle, `1646. Ian 22.` (1646 January 22): one dark oval within the concavity.

The last thing is to set forth that most ancient portent which St Augustine reports from Varro; for in Book 21 of *De Civitate Dei*, Chapter 8, he has this: *It is in the books of Marcus Varro entitled* De Gente populi Romani*, and I shall set it down here in the very words in which it is read there: In the heaven, he says,

there appeared a marvellous portent; for in the most noble star of Venus, which Plautus calls Vesperugo and Homer Hesperos, calling it most beautiful, Castor writes that so great a portent appeared that it changed its colour, size, shape and course; which neither before nor after has happened in this way. Adrastus of Cyzicus and Dion of Naples, noble mathematicians, said that this happened in the reign of Ogyges. This* *certainly Varro, so great an authority, would not call it a portent unless he saw that it was against nature.* What sort of portent this was cannot be judged from the position of the Stars, since neither the year nor the season of the year has been noted. What if there was nothing extraordinary in Venus herself? What if it was rather a Comet or a New Star near a place which at that time was thought least to suit Venus, yet within the limits of the digression of ♀ from the Sun? Or surely some chasm, or a Meteorological apparition?

De Martis Figura.

On the Figure of Mars.

V. Kepler, in Book 6 of the *Epitome of Copernican Astronomy*, affirms that Mars, on approaching its quadrature aspect with the Sun and having come nearer the Earth, appears almost [Greek: διχότομον (dichotomon, "cut in two")] or gibbous; and he thinks this also happens with Jupiter and Saturn, inasmuch as they are illuminated by the Sun. But whether he draws this about Mars from his own experience or from that of others is uncertain. Gassendi, in Book 3 of the *Institutio Astronomica*, denies that he saw Mars with a red spot, although he used Galileo's glass. Francesco Fontana, on the other hand, in his observations, Tract 6, Chapter 1, says that Mars appeared to him by means of the telescope as large as the full Moon appears to the naked eyes, but with a black spot in the middle, which others think a boss and he himself a cavity; that is, in the year 1636; and shining more dimly around the limb,

[Margin: Mars gibbous and perhaps spotted.]

as can be seen in figure A, which we have reduced from three inches to one.

Diagram. A circular disc of Mars inset in the left column. A broad ring of short radial strokes runs inside the outer circle, around a clear field holding a small round hatched spot at the centre.

- A (above the central spot): the figure's letter.
- Beneath: `Anno 1636.` (in the year 1636).

And in the year 1638 August 24 he saw it gibbous with a spot, which appeared narrower from day to day in step with the decrease of the Martian disc, from which he and Father Zupi infer the gyration of Mars around its own centre. You have a specimen of it in figure B, but reduced, with the portion CEDF of the disc illuminated by the Sun.

Diagram. A gibbous disc of Mars inset in the left column, beneath the previous figure. The circle is cut off at the top by a shallower arc running from C through E to D. A band of radial strokes follows the curved edge from C

down round to D, inside the lower circle, and an almond-shaped hatched spot lies in the middle.

- C (upper left, at the end of the top arc).
- E (above the top arc).
- D (right, at the other end of the top arc).
- B (below the almond-shaped spot).
- F (beneath the circle).
- Beneath: `Anno 1638. Aug. 24.` (in the year 1638, August 24).

At that time Mars was at about 19° ♐ and the Sun at the beginning of ♍, and so, having just passed the first □, it was heading for △. Father Niccolò Zucchi of our Society testifies to me in his letters that it was observed by him at Rome in exactly the same figure in the year 1640 May 23, but without a spot of any kind, either black or red. The Sun was then at 2° ♊, and ♂ at 14° ♒; and so, the trine aspect being passed, it was heading for the second quadrature with the Sun.

[Margin: The retinue of Mars doubtful.]

Finally, Antonín Maria Šírek, in the preface to Book 4 of the *Radius Sidereomysticus*, has these words: *Mars perhaps, as we have often observed, at a certain time stealthily attended as it were by its companions.* He said "perhaps" because he was perhaps doubtful whether they were Fixed stars nearer to Mars; and in Chapter 4 he repeats that it is uncertain whether it is attended by satellites and whether it shines with its own light. Yet it often appeared to him maned, no differently from the Greater Dog; but he depicts this mane as though really distinct from its edge. Therefore, of everything reported so far, the more certain things are the gibbous figure between the quadrature and trine aspects, and, from that, the light communicated by the Sun; the rest is less certain, especially the satellites.

[Margin: Mars seen with a double spot.]

Father Daniello Bartoli of our Society, now most celebrated throughout all Italy for his talent, his eloquence, and his manifold and uncommon erudition, wrote to me from Naples in the year 1644 December 24 that he had seen Mars, with the outstanding telescope of Father Sersale, not with a spot in the middle but with two spots in the lower part of the disc. Many things therefore remain to be observed, which God, their Storekeeper or rather their Founder, will one day, as their Dispenser, grant to us, or to you, O posterity.

De Iouis Figura.

On the Figure of Jupiter.

[Margin: The atmosphere of Jupiter doubtful.]

VI. Let us leave aside the vaporous sphere [vapidâ sphærâ] which Šírek, on p. 177 of his *Radius Sidereomysticus*, asserts he saw around Jupiter with a large spyglass. Pierre Gassendi, in Book 3 of the *Institutio Astronomica*, denies that he could see the bands of Jupiter, although he was using Galileo's tube. But they were seen first, as far as I know, by Father Giovanni Battista Zupi of our Society, and by Francesco Fontana and Father Bartoli, all at Naples. I have

seen them very often, and more often still has Father Francesco Maria Grimaldi, who with his usual sharpness of sight and wonderful circumspection observed not only their number but also their situation with respect to the Ecliptic and the Equator. We have here many full sheets of figures, but lest we burden the book and the reader with superfluities, we display in the attached small table six figures containing nearly all the variety of this phenomenon. In this table, however, the size of Jupiter's disc is not that which our larger tubes represent.

Diagram. A heavy ruled box across the full width of the page holding six circular discs of Jupiter in two rows of three, each numbered above in Roman, crossed by hatched bands.

- I (upper left): three hatched bands, the topmost narrower than the two below.
- II (upper centre): two hatched bands, the upper narrower than the lower.
- III (upper right): one hatched band near the top, with a thin line under it.
- IV (lower left): one hatched band, with a thin line above and a thin line below.
- V (lower centre): one broad hatched band, with a thin line above and a thin line below.
- VI (lower right): two parallel hatched bands running obliquely from lower left to upper right.

[Margin: Explanation of Figure 1.]

The first figure shows Jupiter with three Zones, the topmost however narrower. It was seen so in the year 1639 May 22, one day before its Opposition with the Sun. Three bands, too, seen at Naples, are reported in Fontana's observations, Tract 6, in the year 1643 and in 1646 January 28, of which the third was on the eastern edge; and there had been an Opposition of ♃ with ☉ in the year 1645 December 21; but at that time it was seen with only two zones, as I shall say shortly.

[Margin: Figure 2.] The second figure has Jupiter with two bands set very far apart from each other, their convexity turned downward and their concavity upward. Jupiter was seen in this form at Naples by Father Zupi in the year 1644 January 20, 21, 22, when it was more easterly than the Sun by nearly 80°. But the figure of Jupiter that he sent me at once, with great generosity, is far larger, and equals five inches of the Roman foot given in Book 2, Chapter 7. From a drawing by Father Niccolò Zucchi communicated to me, I gather that it was seen in the same form at Rome in the year 1630 May 17, around its □ aspect with the Sun. It was seen so at Bologna in the year 1647 January 23, on which night it was opposite the Sun. At Naples too it is reported as seen in the same form, in Fontana's observations, in the year 1645 January 21, at $2\frac{1}{2}^{h}$ of the night, on which night its opposition with the Sun took place; and again in that form at the same place it was observed on December 31, and once more in the year 1646 on January 1 and 22. On January 28, however, a third zone emerged on the eastern edge of Jupiter, the one I spoke of under the first figure.

[Margin: Figure 3.] The third figure of Jupiter is with two bands, but closer to each other, and the lower one very slender, seen by us at Bologna in the year 1643 from the beginning of October, over several nights, up to the opposition of ♃ with ☉, which fell on the 13th.

[Margin: Figure 4.] The fourth figure offers Jupiter with a broader zone, lying a little lower than before, enclosed on either side by two very slender, parallel zonelets. It was seen so at Bologna a little after the opposition with the Sun, namely in the year 1643, from the 15th to the 20th of October, always near the Meridian. So much for the curved zones.

[Margin: Figure 5.] The fifth figure shows us a more level Jupiter, now girt with straight belts, these lying nearer the middle, and the middle one of the zones wider, with two thinner, parallel ones on either side. In this configuration it appeared to Father Grimaldi at Bologna in the year 1643 from the beginning of November to December 22, but especially on November 10 at 4^h of the night, and on the 12th at 4^h, and on the 13th at 5^h, and on the 14th, 15th, 23rd and 30th, not far from the Meridian.

[Margin: Figure 6.] The sixth figure gives Jupiter as observed by Father Grimaldi in the year 1648 from February 24 to March 16, but most evidently on the 11th at $2½^h$ after sunset, when Jupiter, in the eastern quadrant and moderately distant from the Meridian, appeared with two entirely straight bands. The upper of these, turned toward Arctapeliotes [the north-east wind], that is, the more easterly, was narrower and darker; the more westerly, turned toward Libycus [the south-west wind], was seen as more spread out and less dark, while the part of Jupiter's disc enclosed between them shone far more brightly than all the rest of the disc. The opposition of ♃ with ☉, moreover, was on February 22.

[Margin: Parallelism of Jupiter's zones with the ecliptic.] As for the parallelism of the bands, and very nearly of the satellites, with the ecliptic, I read these very words in the notes and drawings of the same Father Francesco Maria Grimaldi: *"At Bologna we have often observed the satellites, very nearly, and the bands of Jupiter keeping along the length of the ecliptic; but especially on February 24 of the year 1648, at 3^h after the setting of ☉. For at that time, if a line parallel to the bands and to the path of the satellites had been drawn from the bright star of the Lion's tail, it would have had to be drawn a little above the bright star of the neck of the same Lion. This observation was repeated on the 26th of the same month and on March 11."* And on the next page: *"The length of the bands was parallel to the ecliptic, as was gathered from an imaginary line drawn from the tail to the mane of the Lion, which was nearly parallel to the bands themselves."*

[Margin: Rotation or libration of Jupiter.] Now from this phenomenon it is gathered plainly enough that Jupiter moves, by either rotation or libration about its own centre, nodding roughly toward the north and south; and that for this reason its zones appear sometimes as three, sometimes as only two, now close together and slight, now farther apart and wider, and finally now curved,

now straight — whether they are cavities or valleys shadowed by higher parts and not enjoying the light of the Sun, or rows of spots, or something else.

[Margin: Roughness of Jupiter.] That Jupiter is rough, however, and indeed even around its edges, with mountains and swellings standing out most evidently, appears from a drawing sent to Italy from Flanders, where it is stated to have been seen in that form through the excellent telescope of Dom Leander Bandtius [?], Abbot *Disbergensis* [?], in the year 1643 November 2 at $8\frac{1}{2}^{h}$ after noon, the opposition with the Sun having come before it, on October 12. In this drawing, too, two satellites were seen below Jupiter, darkening it like spots, of which the more northerly occupied a sixteenth part of Jupiter's diameter; and in the same drawing two great spots or cavities, one round, the other oval, equalling in length a seventh part of the same diameter.

De Saturni Figura.

On the Figure of Saturn.

VII. At last the keen sight of the optical tube stretched as far as Saturn. With Galileo the first to observe it, as one finds in his first letter to M. Velser [Markus Welser], pp. 25 and 148, then Scheiner (*Disquisitiones Mathematicae*, no. 44), and afterwards a great many others at Rome, Venice and Naples, and we ourselves at Parma and Bologna, that sight revealed Saturn as either three-bodied, or enormously oblong, or very closely propped on either side by two companions or attendants [lateronibus]. These at times seem to form one and the same body with it, but an oblong one, the intervals on each side having contracted toward the extreme tips; at other times, with arms stretched out and an interval left in the middle, they cling to Saturn like little handles; at other times they are entirely separate from it, either like round and smaller planets, as in the first of the following figures, or like pears, as in the second, or like Moons, gripping it with their horns as if with pincers, as in figures 3 and 4. For although Galileo formerly ascribed changes and alternations of this kind to an imperfection of the eye or of the telescope, which could not distinguish the companions and represented them as if they were a single thing, the case is otherwise. For Scheiner at Ingolstadt in 1614 February 12, 13 and 14 and often at other times, and our colleagues at Rome and Parma, at Ingolstadt, and at Naples with Francesco Fontana, as is clear from his observations, Tract 7, and we at Bologna with excellent spyglasses, have very often observed it as the five figures below display it, and that with the glass lenses exchanged, so that no one should dare to ascribe it to bubbles in the glass.

Diagram. A heavy rectangular frame across both columns at the foot of the page, holding four numbered figures of Saturn in two rows of two.

- I (top left): a large plain disc with a smaller round disc standing clear of it on each side.
- II (top right): a large plain disc with an oval body touching or nearly touching it on each side.

- III (bottom left): a large disc with a plain outlined circle overlapping it on each side; within each side circle, against the disc, a hatched crescent whose horns run toward the disc's top and bottom.
- IV (bottom right): the same arrangement, with the crescents narrower.
- Or (between III and IV): the East.
- Occ. (right of IV, inside the frame): the West.

[Margin: Figure 1.] The first figure is of Saturn separated from entirely round companions, as we saw him at Bologna in the year 1643, three days after his opposition with the Sun, that is, from the beginning of October for some days, with the tube of Galileo and also with that of Fontana. But earlier Fontana had seen him so in the year 1630 June 20.

[Margin: Figure 2.] The second figure gives Saturn separated indeed from his companions, but with these now having taken on the shape of a gourd or of a rather large pear. Father Niccolò Zucchi wrote to me from Rome that Saturn was seen in this form in the year 1640 May 23, near his □ aspect with ☉; and we ourselves saw it in the year 1643 from October 29.

[Margin: Figures 3 and 4.] The third and fourth figures embrace Saturn closely joined with companions that are now crescent-shaped and, because of their nearness, shadowed by him and half-hidden behind his back. Fontana observed him in this way in the years 1633, 1634 and 1636, and nearly so did Father Bartoli at Naples in the year 1644, in December, and we in the year 1646 October 10, when he was five signs, or 150°, from the Sun and near the Meridian; but at that time the more easterly companion was smaller than the other and nearer the body of Saturn. [Margin: Parallelism of Saturn's companions with the equator.] Both lay on a line parallel to the equator, which was evident because a line drawn through their centres was parallel to a line drawn from the bright star of Aries to the southern eye of Taurus. *"This too was observed rather often by us,"* adds Father Francesco Maria Grimaldi in his autograph. And in the year 1647 on February 3 and 4, at which time, with the same man observing, the line of the companions appeared parallel to a line drawn from the bright star of Aries to the Pleiades, and thus parallel to the equator rather than to the ecliptic. So too Galileo had once observed. Father Bartoli adds that they appeared curved into a rather parabolic figure, and the upper one smaller.

Diagram. Figure V of Saturn, set in the left column: an oval outline, longer from side to side, within which stand two large solid black crescents, horns inward toward top and bottom, one on each side of a plain centre.

- V (above the oval, at centre): the figure's number.

[Margin: Figure 5.] The fifth figure shows the companions now united behind Saturn and touching each other, or as it were intersecting, so that, with him nearly round in the middle, they seem shaped into a kind of ellipse. For we saw him so in the year 1648 October 15, around the trine aspect with ☉, and in the year 1649 toward the end of March, and then very often, both as western up to his heliacal setting and as eastern after his heliacal rising, namely on July 20.

A line drawn through the greater diameter of this ellipse was parallel to a line drawn through the Pleiades and through the centre of Saturn himself, placed at ♊ 32[58], with south latitude 1° 32′, as the same Father Grimaldi noted. [Margin: Parallelism to the equator confirmed.] Thus in the year 1647 October 15 a line extended through the extreme points of the companions passed through the southern horn of Taurus and through the most southerly of the Pleiades; and from these observations the parallelism of these companions to the equator was confirmed. Giuseppe Biancani, in the *Sphaera*, Book 15, Chapter 7, testifies that he saw him in this form in the year 1616, in October, and in 1619, in November.

From this some gather that these planets do not move around Saturn. For then at some time they would, by their size, cast their shadow onto his middle, since from Saturn's shadow cast upon them when they are nearer it is very nearly established both that they lack light of their own as much as Saturn does, and that they shine only from the Sun. Rather, they hold, behind and at the back of Saturn, by alternate approaches to him and recessions from him, they present such phases to us, especially if they are egg-shaped; and this too seemed more probable to Scheiner than that they are generated anew or perish. [Margin: Saturn's solitude without companions.] For at times they are hidden, and then the attendants truly lie wholly concealed behind Saturn's back, and then he himself appears round and solitary (the fables would repeat "devourer of his children"). Galileo first observed this, not without astonishment, in the year 1612 toward the end of autumn. From this, because the winter solstice was near, he timidly ventured to conjecture and predict that Saturn's companions would reappear around the summer solstice of the year 1613, and afterwards be hidden until the winter solstice of the year 1614; that once this had passed they would show themselves again for some months, and hide once more around the following winter solstice; that afterwards, on emerging, they would not withdraw in part before the solstice, and that the summer solstice, of the year 1615; and that when these turns were completed they would grow larger and appear continually for many years. But by no observation, that I know of, was that prediction confirmed.

Pierre Gassendi, however, in his *Iudicium* on the 9 stars seen around Jupiter, no. 6, affirms that he always saw Saturn with handles in the year 1633 in the month of June, and in 1634 in April, and in 1636 in November, and in 1637 in February, July and November, and in 1638 in December; but that in the year 1642, around the beginning of August, Saturn, soon to be acronychal, was found with Galileo's telescope to be without handles, and that from then on he began, on as many nights as he could, to watch whether and when they would be restored; and that this had still not happened in the whole of the time that elapsed up to Saturn's heliacal setting, which took place in the year 1643, in February, near the conjunction of ♄ with ☌. What then became of the handles, and of their observation, he does not record. He only advises shrewdly, in

[58] so printed; a degree above 30 within one sign cannot stand, and the intended figure is not recoverable from the page

Book 3 of the *Institutio Astronomica*, that we must wait until the whole diversity of appearances and periods has been observed, which is to be hoped for from the Providence of the Divine Power gradually instructing mortals.

For although Seneca, when speaking of comets, said in his *Natural Questions*: *"How many things besides these go their way in secret, never rising for human eyes! For neither has God made all things known to human eyes. How small a part of so great a work is entrusted to our eyes?"*, [Margin: Seneca's twofold prophecy, as it were.] the same author nevertheless declares as follows: *"How many things have we come to know for the first time in this age? And indeed the people of the coming era will know many things unknown to us. Many things are reserved for ages yet to come, when the memory of us will have faded. The universe is a paltry thing, unless the whole universe has in it something to seek."* And in Book 7 of the same *Questions*, speaking of the eclipse of the Moon: *"THE TIME WILL COME when the day, and the diligence of a longer age, will draw into the light those things that now lie hidden; THE TIME WILL COME when our descendants will wonder that we did not know things so plain."* To this oracle of his, if it is permitted to speak so, what we have said in this whole chapter lends marvellous support; just as the discovery of the New World confirmed another prophecy of the same Seneca, *Medea*, Act 2, Chorus:

> *... In late years there will come an age when Ocean will loosen the bonds of things, and the vast earth will lie open, and Tiphys will uncover new worlds, and Thule will not be the last of lands.*

Meanwhile two things are very hard to reconcile. For the shadow of Saturn to produce the phase we see, it seems that it must be calathoid [calathoides] and that the companions ought to lie very far from ♄, if indeed those black Moons, or crescent-shaped shadows, are segments of Saturn's shadow. But for that shadow to be calathoid, and its segments perceptible, Saturn must be larger than the Sun; and this is not allowed by its distance, ten times the Sun's distance from the Earth, unless you increase its apparent diameter beyond 3′. It is in fact smaller, as will be shown below in the last section, even granting that on a hypothesis and a certain probable observation I conceded it 3′ in Book 6, Chapter 7, No. 14.

CAPVT III.

Chapter 3.

De Satellitibus Iouis, seu Stellis Mediceis, eaq. occasione de Numero Planetarum.

On the Satellites of Jupiter, or the Medicean Stars, and on that occasion on the Number of the Planets.

I. Since the very treatment of the figure of the planets has led us to Saturn's companions, and we have explained them sufficiently at the end of the preceding chapter, it remains for us to deal separately with the satellites of Jupiter. Galileo

of Florence, their first discoverer, named them the MEDICEAN STARS, so as to consecrate in a family heaven the surname and house arms of Cosimo, truly Grand Duke of Tuscany. [Margin: Authors who treat of Jupiter's companions.] He discusses them both in the *Sidereus Nuncius*, from p. 17 to the end, reporting 65 observations, and in the letters to Markus Welser on the Sun's spots, at the end of which he sets an ephemeris of their motions; and in dialogue

3 *De systemate Mundi*; Simon Marius in his *Mundus Iovialis*; Christophorus Scheinerus [Christoph Scheiner] in the *Disquisitiones Mathematicae*, no. 39; Biancani in the *Sphaera*, Book 14, Chapters 1 and 7; Kepler in the *Dissertatio cum Nuncio Sidereo* from p. 10, in the notes to Chapter 16 of his *Mysterium Cosmographicum*, and in the *Epitome of Copernican Astronomy*, pp. 538 and 553; Pierre Hérigone in volume 5 of the *Cursus Mathematicus*, pp. 580, 663 and 857; Pierre Gassendi in his *Iudicium* on the nine stars seen around Jupiter; Antonín Maria Šírek of Rheita, Capuchin, in the *Oculus Enoch et Eliae*, or *Radius Sidereomysticus*, Book 4; Francesco Fontana in his observations, Tract 6, Chapter 2; and finally Govaert Wendelen and Father Giovanni Battista Zupi in their very recent letters to me; and in the same letters Dom Vincenzo Renieri, an Olivetan, Galileo's pupil and chief mathematician of the University of Pisa. Renieri, diligently devoting himself to observing these for ten whole years, had composed most complete ephemerides and tables and had sent me a specimen of them. [Margin: Vincenzo Renieri's work on the motion of Jupiter and of its companions, and its loss.] But alas, while he was preparing the publication of the book *De motu stellae Iovis et quatuor Comitum ac recentioribus caeli phaenomenis* [On the motion of the star of Jupiter and of its four companions, and on the more recent phenomena of the sky], which he had promised me, in his letter of the year 1647 September 11, would be begun after one month, I learned in the month of November that he had died. And because he was then living outside the monastery on account of his affairs, those who seized his effects either lost his writings or did not find them, lost or stolen as they were; so that they could not be recovered by any search of ours, nor indeed even of the Grand Duke of Tuscany. A truly lamentable loss, both of these writings and of three most distinguished men of Galileo's school, who departed from the living within two months in the same year: namely Fathers Vincenzo Renieri and Bonaventura Cavalieri, whose astronomical friendship I enjoyed and profited from, and Evangelista Torricelli. But let us return to our own subject and gather in a few words what we know has so far been published on the number, position, motions, periods, eclipses, etc., of these stars. And let us not trouble ourselves at all about Martinus Horckius [Martin Horký], barking with futile effort at Galileo's discovery and at the whole *Sidereus Nuncius*, as at a fiction or a trick of the eyes.

De Numero Iouialium Comitum.

On the Number of Jupiter's Companions.

II. Galileo, the first to do so, discovered near Jupiter first three stars, in the year 1610 January 7, at the first hour of the night, and thereafter never more than four, on the same line parallel to the ecliptic, now closer to each other and to Jupiter, now farther off, yet never departing from it beyond 14′ or 17′, and at times nowhere to be seen. From this he found that they were not fixed stars but certain little planets, companions of Jupiter. With him Kepler, Biancani, Hérigone, Gassendi, Renieri, Scheiner and Wendelen affirm this set of four. For although Scheiner, in his first letter to Welser, suspects that there are more than four, yet in the *Disquisitiones* he acknowledges four.

[Margin: Antonín Maria Šírek, asserter of five other companions of Jupiter.] But Šírek asserts that in the year 1642 December 29, and afterwards on other occasions, besides the four Galilean and inner attendants of Jupiter, another five, outer or more remote and much larger, were observed with a new telescope that takes in a larger space of the sky at a single look; for with other, narrower tubes, he says, this phenomenon cannot be seen. These five he named the Urbanoctavian stars, after Urban VIII, the Supreme Pontiff then reigning, and he wrote of this novelty to Erik van der Putte. A copy of that letter, sent from Belgium to Gabrielem Naudæum [Gabriel Naudé], roused Gassendi to call into dispute this addition of five circum-Jovial planets.

[Margin: Gassendi's judgement on the 5 new companions of Jupiter, and his first reason for doubting.] First, because on the same night of December 29 of that same year 1642 he observed Jupiter's four companions all more easterly than Jupiter, which Šírek's drawing nevertheless represented as western; either because Šírek used a glass that inverts objects, or because, as he was using both eyes at once, the sections of the glasses produced an exchange of vision similar to that by which, when we look with each eye alternately at our nose or at a finger held close to the eye, we see that it covers the left part of a more distant object for the right eye, and the right part for the left. And the drawing represented them not only as western, but also the outermost of the Medicean Stars as more southerly than it had appeared to him.

[Margin: Gassendi's second reason.] Second, because he noticed that those five Urbanoctavian stars are non-wandering, namely of those that in Tycho are in the Effusion of Aquarius, nos. 24, 25, 26, 27, 28 in the catalogue, or others nearer Jupiter from the constellation of Aquarius.

[Margin: Gassendi's third reason.] Third, because it seems improbable, and against the analogy of motions, that those five stars should move around Jupiter in an entirely contrary direction, as Šírek says: namely, above, from east to west, whereas the four Medicean planets, Saturn, Jupiter, Mars, Venus and Mercury around the Sun, and the solar spots themselves, by what is now common opinion, are carried in the upper part of their pericycle from west to east.

[Margin: Gassendi's fourth reason.] Fourth, because it is easy, unless you are very circumspect, to take fixed stars near Jupiter, whether visible to the naked

eye or only with the telescope, for new satellites on account of their nearness. He confirms this by the example of Propus in Gemini and of certain small stars on the brow of Scorpius, which he saw occulted by Jupiter. Yet at the end of this *Iudicium* he withholds assent, until Šírek either seeks fuller credit for his observations, or, once the error about these new wanderers has been exposed, sings a palinode.

III. But indeed Šírek, in Book 4 of the *Radius Sidereomysticus*, Chapter 1, Member 2, replies to Gassendi, as before him Io. Caramuel [Juan Caramuel], Suffragan of the see of Mainz, had replied: that those Urbanoctavian stars changed their distance from one another, and therefore could not have been fixed stars; and that it is no wonder they later vanished, since just as they had been newly generated, so they could perish. For he says he observed around Jupiter a vaporous atmosphere, an indication of changes such as occur in our air when meteoric chasms are kindled and afterwards extinguished. He also cites Io. Stampion [Johan Stampioen], mathematician to the Prince of Orange, who with Prince Willem of Nassau observed around Jupiter for two months two new planets, which he thought were breathed out and generated by Jupiter from itself, just as spots are from the Sun; since Jupiter, viewed through larger tubes, appears like the Sun.

[Margin: Francesco Fontana's opinion on this number, and his observations.] I find, moreover, in Francesco Fontana's observations, Tract 6, Chapter 2, that he saw Jupiter in the year 1630 with 9 stars never distant from Jupiter more than 10 Jovian diameters; and in the years 1636 and 1643 with 8; and in the year 1645, December 21 and 31, at $2\frac{1}{2}^{h}$, with 7; and in the year 1646, January 1, at 2^{h} of the night, with 7; and in the year 1646, January 22, at 1^{h}, and January 28, with 6 satellites, which did not keep the same distance from one another and are not seen around Mars or Saturn; and that to see these stars it was necessary to extend the tube, whereas to see the fixed stars perfectly one must contract the tube.

[Margin: Father Giovanni Battista Zupi's observation on these.] But it is worth reporting what Father Giovanni Battista Zupi, S.J., in two letters to me dated at Naples in the year 1644 January 23 and February 4, wrote that he had observed with an excellent tube made by Fontana, adding a drawing of the stars observed around Jupiter. His words, put into Latin, are these: *"As regards the five satellites that, as I learned a few months ago, are written from France to have been seen around Jupiter besides the usual four, we saw one or another besides the 4; and because there was as yet no suspicion of novelty, we thought them to be fixed stars, either known ones or of those scattered over the whole sky and invisible without the telescope, such as those in the Milky Way; especially since from the telescope they acquired neither enlargement nor steadiness, which is a sign that they were very high."* And a little later: *"On January 22, returning to the observation of Jupiter, I saw six stars near Jupiter, of which the two new ones, or fifth and sixth, had not changed position relative to each other but had, however, approached Jupiter; I think they are in the heaven of Jupiter."* This is in the letter written the following day, that is,

January 23. But in the letter of February 4 he writes as follows: *"I owe Your Reverence much for the occasion first given to me of observing, in these regions, many more than 4 satellites around Jupiter, just as I was the first to note bands on it. I say, therefore, to Your Reverence that it is established for me that not only 6 but many more satellites wander around Jupiter, since I have counted not only 9 but 12, whose figure I send to Your Reverence, though drawn with a rather coarse hand, because, since they could not be seen by me at a single look, it was necessary to beg their intervals and proportion from estimation itself. It is true indeed that among the latest observed I do not dare to list all among the wanderers; yet four of those new ones, because they did not twinkle and acquired some change from the telescope, seem to me to be wandering."* When I had told Dom Vincenzo Renieri about these, he flatly denied to me that in the whole ten years of his most frequent observations he had ever seen more Jovian little stars than 4.

Therefore, since the truth, which should outweigh friendship, is not yet clear to me, I do not wish to settle a dispute between friends or to pronounce any judgement on this matter. Rather, with the Roman praetors, I would bring myself back to that ancient formula: *Amplius* ("further hearing"), because *Non liquet* ("it is not clear").

De Situ Satellitum Iouis.

On the Position of the Satellites of Jupiter.

[Margin: Whether their path is parallel to the ecliptic?]

IV. First, the path of these satellites, by which they move from west to east, does seem to be parallel to the ecliptic itself, as it seemed earlier to Galileo and to Biancani, and to others, who drew a line through them and through Jupiter and two, or at least one, of the fixed stars. Yet at times, as the latitude of Jupiter or of the satellites themselves requires, they depart somewhat from it on an oblique track. Scheiner admits this slight inclination to the ecliptic in the *Disquisitiones Mathematicae*, p. 87, and so does Gassendi, above, p. 15; and the drawings of the observations themselves prove it.

[Margin: Whether in different circles?]

Second, it is certain among all the authors already mentioned that they do not move in one circle, or on the circumference of one circle, but in different ones, which this diagram of Scheiner and Biancani represents.

Diagram. Set in the left column, with the text running in a narrow measure down its left side. Four concentric circles stand around a small central disc, Jupiter, with a horizontal diameter through the centre and a vertical line from the top of the outer circle down to the Earth's centre below; small six-pointed stars mark the satellite positions where lines cross the circles. A hatched band, the shadow of Jupiter, runs obliquely from the central disc up and to the left, beyond the outer circle, to its cut-off end at R. Below, an arc passes through M to a small circle, the Sun, at lower right; lines run from B to the top of the figure and from the Sun's circle up to the Jupiter system.

- Top of the shadow band: R
- Along the left edge of the shadow band, top to bottom: a, b, c, d
- Above the outer circle, left to right: C, D, E
- Upper interior, right of the band: e; f below it
- Upper right, on the three inner circles' upper parts: g, h, m
- Horizontal diameter, left to right: F, H, P, Q, A (at the central disc), L, K, I, G
- Lower left interior, top to bottom: n, o, p
- Lower right interior, top to bottom: b, z, q
- Foot of the outer circle: r at left; u at right
- On the arc below the circles: M
- Foot of the figure: B; N; S (in the small circle); T (right of the small circle)

In it A is Jupiter and B as the centre of the Earth, around which lies the heaven of the Sun, MS, with the Sun at S, illuminating Jupiter and touching it with the rays NR and TR. AR is the shadow of Jupiter, which, though cut short here, in fact ends in a conical apex. Around Jupiter's centre A four circles are described. The largest is DFG, in which the outermost of the satellites, G, revolves in the upper part of its pericycle in the order of the signs, namely from G to D. Next is the circle gHI, in which the next-to-outermost satellite, I, turns from I to g; then the circle hPK, in which the next-to-innermost satellite, K, turns from K to h; and lastly the circle LmQ, in which the satellite innermost to Jupiter, or nearest it, L, turns from L to m. This difference is inferred both from their different periods, since the innermost completes its period far faster than the outermost, and because at their greater digressions from Jupiter they are never seen joined but well separated, as at F, H, P, Q, or at G, I, K, L; whereas near Jupiter they appear crowded together, as at E, g, h, m.

[Margin: Whether in the same plane?]

Third, they are indeed thought all to lie in one plane, because when Jupiter has no latitude, or an imperceptible one, they appear without any declination from the ecliptic. Otherwise, however, the outermost undergoes a greater deviation from the plane of the ecliptic than the next-to-outermost, this one a greater than the next-to-innermost, and this one a greater than the innermost. It is probable that they have this deviation from Jupiter's latitude: "for just as they accompany it in its motion in longitude, so it is likely that they accompany it in latitude," says Scheiner. But because we are not in the plane of these small circles, the digressions do not occur in their lower part but on the diameter itself, FG or HI, etc.

[Margin: In which position they decline to the south and in which to the north.]

Fourth, Galileo and Scheiner agree that when they are above, as at E, g, h, m, they appear to us southerly with respect to Jupiter and in the antarctic quarter, because there they approach or tend towards their own eclipse; but when they are below, as at b, z, q, u, they decline to the north and, at an equal

digression from Jupiter, appear larger. Here, however, one must be very much on guard against a delusion of the imagination. For when they are really in the upper part of the pericycle (which is inferred from their motion towards the east), they then appear depressed below Jupiter towards the south, and are so represented in the drawings of the observations, as being below the line FG. Conversely, when they are really below Jupiter and nearer the Earth than it is, they nevertheless appear to us higher and carried up to the north, as the rules of optics require. We, however, in the preceding figure represent them according to the position they actually have, so that the outermost satellite at C is above Jupiter, and at r below it. Hence it comes about that when several or all of the Jovian stars converge with Jupiter on one straight line in longitude, and towards one quarter of longitude, as when they are on the line AG, to the west, or on AF, to the east, then, with Jupiter placed on the meridian or in the nonagesimal, they appear to us hardly perceptibly above it or below it; and at that time they are close to the moments of their stations. But when they appear on one straight line in latitude, which cuts the line of longitude at right angles, as on the line BD, or nearly BE, then if all appear in the northern quarter, the outermost appears most northerly and the innermost northerly by the least possible amount; if they are seen depressed to the south, the outermost appears most southerly and the innermost southerly by the least possible amount. And in either case, that is, when they are on one line in latitude, they are seen to be less distant from one another and from Jupiter, and can more easily be taken in together with Jupiter at a single glance of the astronomical eye, that is, the telescope, and their apparent diameters compared with Jupiter's diameter.

De Iouialium Satellitum Motibus, Digressionibus à Ioue, Coniunctionibus, & Periodis.

On the Motions of the Jovian Satellites, Their Digressions from Jupiter, Conjunctions and Periods.

[Margin: Motion in circles or near-circles; where it takes place in the order of the signs.]

V. First, that they move around Jupiter describing small circles or ellipses, in whose upper part they are carried from west to east and in the lower part from east towards west, is inferred from this: from their greatest western digression from Jupiter, such as, for example, that of the outermost at G, at which they seem stationary, they next approach Jupiter towards the east and then appear to us lower towards the south, until they join it and are hidden. From there, emerging again towards the eastern quarter and heading for their greatest eastern digression, say at F, they appear less and less depressed towards the south; and having completed there a stay, or second station, they go back towards Jupiter to the west, and then, as far as appearance goes, they seem to us more and more carried up to the north, and they join Jupiter again. Hence, once the rules of optics and astronomy are considered, it follows that they

move in the way already described. For if they only approached and receded from Jupiter along one line of longitude, that motion could be accounted for by a mere libration on the diameter FG. But since in approach and recession they apparently change position towards the arctic and antarctic quarters, they must describe either circles or ellipses or figures very like these. And since, when at an equal digression from Jupiter they appear larger than themselves and carried up to the north, they then approach Jupiter towards the west, and when smaller and depressed to the south they approach it heading east, they must be carried in the upper part of their pericycle in the order of the signs and in the lower part against the order of the signs. We are speaking, however, of the four ordinary and certain companions of Jupiter; for the five remaining Urbanoctavian ones, if we believe Šírek, appear to move with the contrary motion, namely in the upper part against the order of the signs and in the lower part in the order of the signs, in the way the Moon is imagined to move on its epicycle. And when they appear carried further up to the north, or, as far as appearance goes, higher than Jupiter, they appear smaller, but when depressed to the south, larger: *"which would indeed be astonishing,"* says Šírek in his letter to Erik van der Putte; by these words he indicates that he doubts this alternation. On account of their anomalous motion, the same author holds (Book 4, ch. 4) that all the satellites move in circles eccentric to Jupiter.

Second, the greatest digressions of the satellites, in various ways, [Margin: The greatest digression from Jupiter.]

are determined. For most authors use the apparent diameters of Jupiter as the measure here. But Šírek (Book 4, ch. 4), after first giving the distance of Jupiter from the Earth as, on the Copernican reckoning, 10798 semidiameters of the Earth and, on the Tychonic, 12798, also measures the greatest digressions in semidiameters of the Earth, and adds that the apparent diameter of Jupiter, from his own observation, is 3′. So look at the table set out below, in which Kepler and Hérigone follow Simon Marius, and Wendelen follows Galileo. If you want these intervals in minutes and seconds, work them out from what is to be said below in Section 6 on the apparent diameter of Jupiter, which we shall show there does not reach 2′.

Greatest Digression of the Satellites of Jupiter from Jupiter [Digressio Maxima Satellitum ♃ à Ioue.]

Satellites	Diameters of Jupiter: Galileo	Diameters of Jupiter: Marius	Diameters of Jupiter: Šírek	Semidiameters of the Earth
1	3	3	3	21
2	5	5	4	27
3	8	8	6	41
4	14	13	10	69

[Margin: The period of the satellites of Jupiter.]

Third, the period of the motions is not so certainly obtained from the stations, or greatest digressions, and the satellite's return to them, as Simon Marius did it, because the satellites linger in these for several hours. It is better, therefore, as Scheiner advises in the *Disquisitiones Mathematicae*, p. 82, to observe the time at which the satellite is joined to Jupiter, or begins to be hidden, and again the time at which it emerges, and to take half as the time of central conjunction; and so to observe the times that elapse between one conjunction and another of the same kind, that is, both upper or both lower. For these, let there be a second table, in which Biancani, Scheiner, Kepler, Hérigone and Šírek either follow or report the opinion of Simon Marius, although some, such as Kepler and Šírek, use rounder numbers. In these tables we use "first" for the innermost, the one nearest to Jupiter.

Periods of Revolution of the Satellites of Jupiter around Jupiter [Periodi Reuolutionum Satellitum ♃ circa Iouem.]

Satellites	Period	Or
1	$1^d\ 18^h\ 28^m\ 30^s$	$1^d\ 18^h\ 30^m$
2	$3^d\ 13^h\ 18^m\ 0^s$	$3^d\ 13^h\ 20^m$
3	$7^d\ 3^h\ 56^m\ 34^s$	$7^d\ 4^h\ 0^m$
4	$16^d\ 19^h\ 9^m\ 15^s$	$16^d\ 19^h\ 9^m$
Next-to-outermost of the new ones, according to Šírek		$67^d\ 0^h\ 0^m$
Third-from-outermost, according to the same		$33^d\ 12^h\ 0^m$

[Margin: The diurnal and hourly motion of the satellites.]

On these suppositions Hérigone, dividing 360° by the periodic motions, obtains their diurnal motion in their own circles or pericycles; and, dividing the diurnal motion by 24, he obtains the hourly motion, as in the following table.

Motion of the Satellites of Jupiter in Their Own Pericycles [Motus Satellitum ♃ in proprijs Pericyclis.]

Satellites	Diurnal	Hourly
1	203° 25′ 0″	8° 28′ 0″
2	101° 17′ 22″	4° 11′ 0″
3	50° 14′ 57″	2° 5′ 37″
4	21° 29′ 4″	0° 53′ 43″

[Margin: The irregularity of this motion.]

Fourth, the motion of these satellites is judged irregular, whether because it takes place on a circle eccentric to Jupiter, as Šírek thinks; or because they are ordered not primarily to Jupiter but to the Sun, by which they are illuminated, and the motion is not equal with respect to lines drawn from the centre of the Earth through Jupiter, but through the Sun, as Kepler thinks with Simon Marius; or because, as Hérigone holds, this apparent inequality arises from the

parallax, or angle at Jupiter, which changes somewhat each day, owing to the excess by which the Sun's motion exceeds Jupiter's. From this it would follow that to know the moment of conjunction of the Jovian stars with Jupiter, one must first know the mean motion of the Sun and of Jupiter.

De Illuminatione, Diminutione luminis, & Eclipſibus Satellitum Iouis

On the Illumination, Diminution of Light, and Eclipses of the Satellites of Jupiter.

[Margin: Occultations and eclipses of the satellites.]

First, it is now the common opinion, introduced by Galileo in his last letter to M. Velser [Markus Welser] on the sunspots, p. 161, and confirmed by Scheiner in the *Disquisitiones Mathematicae*, p. 83, and by others and by frequent experiments, that the satellites of Jupiter, when they come very close to conjunction with it, whether lower, which occurs when they are carried westward in the lower part of their pericycle, or upper, when they approach it towards the east, are not seen because of Jupiter's brilliance, and set, so to speak, *Zeusiacally*. Indeed, outside conjunctions they sometimes suffer eclipse and lie hidden in it for a longer or shorter stay, according to the different inclinations of the cone of Jupiter's shadow and its different latitude, and the different nearness of the satellites to Jupiter: for those nearer fall into a denser shadow, as does satellite m at d, but with its faster motion it gets clear of the shadow.

[Margin: The evidence for these eclipses.]

The evidence for these eclipses is that, for example, after the opposition of Jupiter with the Sun, at an equal distance from Jupiter along the line of longitude, when they are carried towards Jupiter lying further to the west they appear, whereas when receding from it towards the east they do not appear until they have gained a greater distance, evidently because they were lying hidden in Jupiter's shadow. For example, satellite a does not emerge or first shine out except at a great distance from Jupiter, whereas on its way back to the west it usually appears at a much smaller distance from Jupiter; and likewise with the others. Moreover, those further from Jupiter are hidden when, depressed to the south, they approach Jupiter, yet they appear when they approach it carried up to the north; and this has been observed only before the opposition of Jupiter with the Sun. Finally, when the hours and moments of the occultations that occur in these satellites heading east, and the position of the Sun relative to Jupiter, are considered, it is established that these occultations occur when the satellites are in that part of the sky towards which the shadow of Jupiter, illuminated by the Sun, is directed.

[Margin: Corollaries on the light of Jupiter and of the satellites.]

From this it is rightly inferred that Jupiter lacks light of its own, and therefore cannot impart light to its satellites hidden behind its back; and that they likewise shine from no other source than the Sun. Granted that, against the common

opinion, Šírek says that the first and third scintillate so much that this is sufficient proof that they shine with their own light: but if that were so, they would shine even in Jupiter's shadow, at least the third and more remote one, as at e and b, where nevertheless it is hidden.

[Margin: Why they are larger than themselves at an equal distance from Jupiter.]

Second, since the Medicean Stars, although they complete very narrow rotations around Jupiter, nevertheless sometimes appear twice as large as themselves at nearly equal distance from Jupiter, Galileo, at the end of the *Sidereus Nuncius*, holds that there is a vaporous atmosphere and a denser aether, because of which the satellites appear smaller near apogee, owing to the greater thickness of that denser body interposed between them and our eyes, but larger towards perigee, owing to its lesser thickness. Simon Marius, however, holds that this comes from the light of Jupiter, which is increased in them when they are near perigee. Scheiner, however, both regards that vaporous sphere as an arbitrary fiction and holds that the increase of the light communicated from Jupiter is imperceptible to us across so great an interval. He adds, however, that the light of twilight helps the pupil, and that therefore both the satellites and Venus are then better seen; just as they are better discerned when they are indeed far from Jupiter but are nevertheless seen together with Jupiter at one glance, because Jupiter illuminates the eye and the air; for a moderately illuminated medium assists vision.

Problema. Iouis Diſtantiam à Terra ope Satellitum obſeruare.

Problem. To observe Jupiter's distance from the Earth by means of the satellites.

[Margin: First method of the problem.]

VII. Let the figure of no. 4 be repeated here. In it Biancani (Book 14, ch. 1) wants observed the time between the first occultation under Jupiter's rays above (which he thinks occurs on the line BD, as if the outermost of the Jovian stars were at D) and the first emersion from Jupiter's shadow, say at a, so that the arc Da may be known. For if we make: as the time of the whole period, which we suppose known, to the 360° of the whole circle DFuG, so the time already mentioned to another quantity, the arc Da will be known, which subtends at Jupiter's centre A an angle similar to itself. When this angle is known, together with the angle ABS, known from the distance of the Sun and Jupiter in the zodiac, and with the distance SB of the Sun S from the Earth B also known, you will have the triangle ABS, with three data sufficient for finding the side AB, that is, the distance of Jupiter from the Earth.

Diagram. The figure of p. 490 is printed again here, set in the left column with the text running in a narrow measure down its left side, as the text says it is to be repeated. Four concentric circles stand around a small central disc, Jupiter, with a horizontal diameter through the centre; small six-pointed stars mark the satellite positions. A hatched band, Jupiter's shadow, runs obliquely

up and to the left beyond the outer circle to its cut-off end at R. Below, an arc passes through M to a small circle, the Sun, at lower right; lines run from B up to the circles and from the Sun's circle up to the Jupiter system.

- Top of the shadow band: R
- Along the left edge of the shadow band, top to bottom: a, b, c, d
- Above the outer circle, left to right: C, D, E
- Upper interior, right of the band: e; f below it
- Upper right, on the upper parts of the circles: g, h, m
- Horizontal diameter, left to right: F, H, P, Q, A (at the central disc), L, K, I, G
- Lower left interior, top to bottom: n, o, p
- Lower right interior, top to bottom: b, z, q
- Foot of the outer circle: r at left; u at right
- On the arc below the circles: M
- Foot of the figure: B; N; S (in the small circle); T (right of the small circle)

Yet the first occultation does not occur on the line BD but on the line BE, tangent to Jupiter, or even a little short of it; nor does the first emersion occur on the axis of the shadow (which my engraver omitted here) but on the Sun's ray Na, likewise tangent to Jupiter; nor does the arc Ea exactly measure that angle made at Jupiter's centre.

[Margin: Second method of the problem.]

Second, Scheiner, in the *Disquisitiones Mathematicae*, p. 82, directs that one observe the first lower occultation of the satellite, say at p, and the first emersion from Jupiter's rays, say at q, so that from the proportion of the whole periodic time to the whole circle HpI, the arc pq may be known. For since the rays Be and Bg, touching Jupiter, are sensibly parallel because of the enormous distance of the eye at B, just as the Sun's rays TR and NR are too, or else have sensibly equal convergences, it follows that, once the arc pq is known, the arc eg is sensibly equal to it, as is also the shadowed arc eb. On these assumptions, from the time between the first occultation at p, or emersion at q, and the first emersion from the shadow at b, you will be able to find the arc pqb, or qeb, and from this be helped towards knowing the angle at Jupiter's centre made by the axis of the shadow and the straight line BD. For if from the whole known pqb you subtract pg, which is supposed here to be of 180°, and half of both the arc ge and the shadowed arc eb, the remainder will be the arc intercepted between the axis of the shadow AR and the line AD, which measures the angle made by the lines already mentioned at the centre A. Equal to this will be the angle vertical to it, made at the centre A by the axis SA (to be supplied here in imagination) and the straight line AB. With this angle, therefore, and with the distance of the Sun BS, and with the angle ABS, the distance of Jupiter from the Sun in the zodiac, AB, the distance of Jupiter from the Earth, will become known in the rectilinear triangle ABS. In this truly excellent and ingenious

inquiry you see that geometrical rigour is not kept throughout, as being by no means necessary for what is intended.

SCHOLIA.

Scholia.

[Margin: The number of the planets according to Kepler.]

I. On one side the telescope, by detecting new wanderers around Saturn and Jupiter, has called the number of the planets into doubt; on the other, Kepler has done so in the *Mysterium Cosmographicum*, contending that there are six primary planets and seeking the cause of this number from the five regular, or Platonic, solids. He assumes, however, that the Sun is not a planet but is immobile at the centre of the universe as regards motion of translation, and that the Earth is a planet, carried along the annual orb with the Moon, its secondary planet. On these suppositions he says in the preface to the reader: "The Earth is the circle that measures all the others. Around it circumscribe a dodecahedron; the circle enclosing this will be Mars" (that is, the orb of Mars). "Around Mars circumscribe a tetrahedron; the circle enclosing this will be Jupiter. Around Jupiter circumscribe a cube; the circle enclosing this will be Saturn. Now inscribe an icosahedron in the Earth; the circle inscribed in it will be Venus. Inscribe an octahedron in Venus; the circle inscribed in it will be Mercury." But because the intervals of some planets favour this opinion more closely and others do not, he tries to correct the latter so that they may be drawn to the desired measure, one fitting this mystery. And when he had heard of the four satellites of Jupiter detected by Galileo, he makes use of these very satellites both in the *Dissertatio cum Nuncio Sidereo*, on the last page, and in the notes to ch. 16 of the *Mysterium Cosmographicum*; and he increases the semidiameter of the Jovian orb by as much as the greatest digression of the outermost satellite from Jupiter comes to, which is very nearly 14′. In the same way he includes the Moon within the Earth's annual orb, and adds to the semidiameter of the great orb the distance of the Moon at apogee. If satellites should be discovered around Mars, he says, a more just interval arises from this for the commensuration of the planetary system, fitted to the number of the five regular solids. But more on these in Book 9, where the system of the world is treated. Meanwhile you see, reader, that Kepler has struck from the roll of the primary planets the two great luminaries: the Sun, which he will not have to be a planet, and the Moon, which he will have to be a secondary planet and the Earth's companion, or circumterrestrial planet.

[Margin: A skirmish against Kepler.]

II. But from this there at once arises the question of the notion or class of planets: which are to be counted primary, and which not. Kepler, however, will answer immediately that only those are primary that are not companions of another. If you say that Venus and Mercury are companions of the Sun and yet primary, he will deny that they are companions of the Sun as of a planet,

because he will not have the Sun to be a planet, but substitutes the Earth in its place, so as to make the Moon its companion. And that is why he embraced the hypothesis of Copernicus, because otherwise, with this removed, the whole foundation of the *Mysterium Cosmographicum* is undermined. For if the Earth stands still, the Moon turns out to be a primary planet, but its interval from the Earth fits none of the regular solids inscribed in or circumscribed about the lunar orb. Yet in this way he increases the improbability of the Copernican system. For Copernicus does not make the Sun a planet, but this man makes neither the Sun nor the Moon a planet, and makes the Moon only a periplanet, or secondary. Then, what has the number of the regular solids to do with the number of the planets, when the determination of that number arises not from the diameter of an inscribed or circumscribed circle, but from the solid bodies themselves, in so far as they are such bodies, and from the equality of the surfaces bounding them? Certainly these things have nothing to do with the bare intervals of orbs, or rather of circles, or, as Kepler prefers, of ellipses, in which they move irregularly. But of this elsewhere. Meanwhile, however, it is established that on the hypothesis of a stationary Earth there are seven primary planets, namely those which are not companions of another; or, if they are, as Venus and Mercury are of the Sun, they are nevertheless visible to the naked eye without the aid of the telescope, they move away from it by a notable interval, and they have very distinct effects on sublunary things.

[Margin: Whether the satellites of Jupiter are a hindrance to the ancient astrology.]

The companions of Saturn and Jupiter do not have such effects, because of their excessive nearness to Saturn or Jupiter: they do not stand more than 14′ from the latter, and so the diameter of the circle they complete does not equal in the sky so great an apparent space as the Sun does, which subtends more than 28′. Therefore, as Kepler rightly thought on this point in the *Dissertatio cum Nuncio Sidereo*, p. 11, although they concur with Jupiter by aspect in stirring the sublunary faculties, the difference of their effect from the effects of Jupiter is imperceptible, nor does any danger not to be despised threaten the ancient astrology from that quarter.

[Margin: Wendelen's ingenious speculation on the motions and intervals of the satellites of Jupiter.]

III. No less ingenious than Kepler's is the observation of that most sagacious astronomer Wendelen on the proportion of the periods and intervals of the Jovian satellites, which he communicated to me with the greatest generosity in a very long and very learned letter. For just as in the major planets the mean distances of the planets from the Sun are to one another in the sesquialteral ratio of their periodic times, so the distances of these little Jovian planets from Jupiter, which are 3′, 5′, 8′, 14′, are to one another in the sesquialteral ratio of the periods, which are 1 769/1000 days for the innermost, 3 554/1000 days for the next-to-innermost, 7 164/1000 days for the next-to-outermost, and 16 756/1000 days for the outermost. But of these in the harmonic system. Meanwhile he

adds cleverly that, given this proportion, if there were a fifth little Jovian planet whose period was 29 531/1000 days, or $12^{h}\ 44^{m}\ 3^{s}\ 12'''$, its interval from Jupiter at acronychal position would be 20′ for us who live on the Earth. He further adds that if the Sun were to look upon the Earth in central conjunction with Jupiter, it would come about that the Sun looks upon the four or five orbs of Jupiter's satellites under angles proportional to the periodic times: that is, the orb of the innermost under an angle of 2′ 20″, of the next-to-innermost under 3′ 40″, of the next-to-outermost under 5′ 50″, of the outermost under 10′ 10″, of the fifth under 15′ 0″; and that it impresses on them a motion and time proportioned to those angles.

[Margin: The rotation of Jupiter about the centre of its own body.]

IV. Vuackerius [Johann Matthäus Wacker von Wackenfels] maintained, according to Kepler in the *Dissertatio cum Nuncio Sidereo*, p. 12, that Jupiter has a rotation about the centre of its own body, by which it carries its four Companions around eastward. Kepler himself holds the same, both there and in the *Epitome of Copernican Astronomy*, p. 549, where he assigns this motion to all the planets: to the Earth, as it carries the Moon around; to Venus, which seems to unfold different spots one after another in its daily scintillation; and even to the Sun, which by a rotation of about 27 days leads all the planets around. But Jupiter's eastward rotation seems to conflict with its rotation toward the poles, by which it changes the appearance of its bands, according to what was said in chapter 2, near the end of no. 6, unless you would rather call that a libration than a rotation.

[Margin: The distance between meridians can be corrected by means of the eclipses of the Jovian satellites.]

V. Not content with discovering the four satellites around Jupiter, Galileo's sagacity scented out from this, above all, the following: if the moment of one and the same eclipse of one of the Jovian satellites (for instance, the moment at which the outermost begins to emerge from Jupiter's shadow) is observed with an excellent telescope by two observers in different places, the difference of longitude between those two places on the Earth can be derived from it. When this reached our ears at Parma, Biancani noted it in the margin of his manuscript *Sphere*. Galileo himself proposed it to the Catholic King in the year 1631, as Michael Florent van Langren testifies in his *Selenographia*, and also to the States of Holland through D. Deodatus of Lucca [Élie Diodati], as Father Bonaventura Cavalieri, Galileo's pupil, assured me. Yet Pierre Hérigone, in volume 5 of the *Cursus Mathematicus*, p. 872, affirms that it had occurred to him two years before Galileo made this discovery public. That is neither incredible nor surprising, for it has not rarely happened to me too that I thought out certain things which I later learned had been thought of by others at almost the same time. He adds that nothing in Morinus's [Jean-Baptiste Morin's] objection stands in the way of this discovery, namely that Jupiter is absent for almost three months on account of the Sun's rays: for if all the intervals in each month during which the Moon does not appear on account of the

Sun's presence are added together, they will amount in a whole year to a little less than three months. But he would have answered better by saying that lunar eclipses, which cosmographers have so far used to measure the distances between meridians, occur far more rarely than eclipses of Jupiter's satellites. For an eclipse of the Moon happens once or twice, and very rarely three times, in the same year; whereas the eclipses of Jupiter's four satellites that can happen in one year, taken together, are almost as many as the sums of their periods, namely about 480: for the innermost has 180, the next-to-innermost 130, the next-to-outermost 50, the outermost 20.

[Margin: The number of eclipses of the Jovian stars.]

CAPVT IV.

Chapter 4.

De Ordine ac Syſtemate Planetarum.

On the Order and System of the Planets.

I. What we said in Book 3, chapter 6, and Book 4, chapter 10, together with the diagrams, should be reread here. The rest, which concerns the universal constitution of the World, we reserve for Book 9. As for the ancient arguments by which the order of the planets is usually confirmed (namely the length of the shadow, parallax, the speed of the periods, and the eclipse of one planet hidden by a lower planet), we have set them out sufficiently in Book 4, chapter 10, which you should likewise go over again. Now in Book 3, chapter 6, we said that in the more recent system (which nevertheless stems as far back as Plato), both according to Copernicus and Tycho and according to all recent astronomers, the Sun is encircled by Venus and Mercury, so that they are now above it, now below; and we pointed out the ancient authors on this matter. We now wish to report their words, and those of others.

[Margin: Plato's opinion on the place of the planets.]

Plutarch, then, in *De placitis philosophorum*, Book 2, chapter 15, which is entitled "On the order of the stars", has this: "Xenocrates holds that the stars move on one surface. The rest of the Stoics hold that some are lower and higher than others. Democritus arranges them in this order: first the fixed stars, then the wanderers, among which the Sun, Lucifer and the Moon. Plato, after leaving the non-wandering stars, made the nearest the star of Saturn, which he calls Phaenon, and which we could, I think, call 'the brilliant one'; then Phaëton, unless you prefer 'the flashing one', which is Jupiter; next to this Pyroeis, that is, 'the fiery one', the star of Mars; then Lucifer, which is assigned to Venus; fifth the star of Mercury, which he calls Stilbon, as if to say 'the gleaming one'; and certain of the mathematicians subscribe to Plato. Others put the Sun back in the middle. Anaximander, Metrodorus of Chios and Crates assign the highest place to the Sun and set the Moon next below it, and below these they place the rest of the stars, fixed and wandering." So crude

and stammering, or so hot-headed and lawless, was the philosophy of certain of the ancients in astronomical matters. Yet when what Plato teaches in the *Timaeus*, in the *Epinomis* and in Book 10 of the *Republic* is compared, it appears that for him Venus and Mercury move now above, now below the Sun.

[Margin: Aristotle's opinion.]

Some have been in doubt about Aristotle's opinion on this. For in *De caelo*, Book 2, chapter 10, or text 60, after saying it is reasonable that the bodies nearer to the primum mobile, which is carried by a single motion, should be moved by fewer motions, he adds: "But as it is, the opposite occurs: for the Sun and the Moon are moved by fewer motions than some of the wandering stars, although these are farther from the centre and nearer to the first body than the Sun and the Moon." And to confirm that the Moon is lower than those stars he says: "For we have seen the Moon, at dichotomy, pass under Mars, which was hidden by its dark part and emerged from its bright part. And in like manner, concerning the other stars too, the Egyptians and Babylonians tell, who long ago observed them over very many years, and in whom we place much trust concerning each of the stars."

[Margin: Mars occulted by the Moon, with Aristotle observing; Kepler says, in his *Commentaries on Mars*, last chapter, that this happened on the evening of 357 BC April 4.]

So although he does not expressly say that Venus and Mercury are farther from the centre of the Universe than the Sun, he nevertheless says it implicitly, since he subscribes to the Egyptians, who, as is agreed, placed the Sun below these planets. This is confirmed from *Meteorologica* 1, chapter 4, where he says: "Moreover, if, as is shown in the astrological theorems, the size of the Sun is greater than that of the Earth, and the distance of the stars from the Earth is much greater than that of the Sun, just as that of the Sun from the Earth is greater than that of the Moon, then the cone which the Earth casts from the Sun's rays does not rise very far from the Earth, nor will the shadow of the Earth, which is called night, reach the stars; rather, the Sun must look around all the stars, and the Earth must obstruct none of them." Having considered these things, Clavius nevertheless says in the last edition of the *Sphere*, p. 42: "Aristotle alone, in the little book *De Mundo* to Alexander (if indeed it is his), places Venus immediately above the Sun and below Mercury."

[Margin: Apuleius's opinion.]

Scheiner, in the *Disquisitiones Mathematicae*, no. 38, asserts that Apuleius in his book *De Mundo* is in accord with this. Yet it seems to not a few interpreters that Aristotle, in *Metaphysics* 12, chapter 7, followed the system of Eudoxus and Callippus and with them placed Venus and Mercury below the Sun. For that reason we cited him for the Ptolemaic system in Book 3, chapter 6, no. 4, especially since he holds that these planets move not around the Sun but around the Earth; granted that he can be cited for the Copernican and Tychonic system, in that he seems elsewhere to have placed Mercury and Venus above the Sun.

[Margin: Vitruvius's opinion on the place of ♀ and ☿.]

Most explicitly, however, Vitruvius says in Book 9, chapter 4: "The stars of Mercury and Venus, about the Sun's rays, crowning the Sun itself with their paths as with a centre, make their regressions backward and their retardations; and through that circling they also linger at stations in the spaces of the signs. That this is so is known above all from the star of Venus: when it follows the Sun, appearing in the sky after the Sun has set and shining very brightly, it is called Vesperugo; at other times, running ahead and rising before daylight, it is called Lucifer." Here Daniel Barbarus [Daniele Barbaro], with little expertise and long accustomed to the Ptolemaic or the Plinian system, suspects an error in the manuscript of Vitruvius, because in his view it does not agree with the others. If only he had read Plato and Plutarch on this order, all that suspicion would have vanished.

[Margin: Martianus Capella's opinion on the place of ☿ and ♀.]

Next comes Martianus Capella, who in Book 8 of *De Nuptiis Philologiae et Mercurii*, that is, the book on astronomy, in the chapter on the orbs of the planets, says: "But Venus and Mercury do not go around the Earth." And in the next chapter, whose title is "That the Earth is not the centre for all the planets", he goes on: "For Venus and Mercury, although they show daily risings and settings, nevertheless their circles do not go around the Earth at all, but they circle around the Sun in a looser compass. In short, they set the centre of their circles in the Sun, so that they are carried sometimes above it and, more often, inside it, nearer to the Earth; and from it Venus stands apart by one sign and a half (that is, by 45°). But when they are above the Sun, Mercury is nearer to the Earth; when inside the Sun, Venus, since it curves in a purer and more extended orbit."

II. But we must consult Macrobius, on the *Dream of Scipio*, Book 1, chapter 19, where he gives the reason why

[Margin: Macrobius's view on the place of ♀ and ☿.]

Cicero, with the Chaldeans and with Archimedes, gave the Sun a different place among the wandering stars, namely the fourth and middle one, whereas Plato gave it the sixth place and the Moon the seventh; and he reconciles the two opinions. For he says: "Plato followed the Egyptians, the parents of all the branches of philosophy, who hold that the Sun is placed between the Moon and Mercury, yet in such a way that they discovered by reason, and declared, why the Sun is believed by some to be above Mercury and above Venus." And shortly after: "So there was no dissension among the ancients either about the order of the three upper planets, which their immense distance marks off plainly and clearly, or about the region of the Moon, which has withdrawn far from them all. But the order of these three that are close to one another, Venus, Mercury and the Sun, their proximity has confused, though among others. For the reason did not escape the ingenuity of the Egyptians, and it is this. The circle through which the Sun runs is surrounded by the circle of Mercury, as the lower one; and the higher circle of Venus encloses that one too. So it comes about that when these two stars run through the upper summits of their circles,

they are understood to be placed above the Sun; but when they travel through the lower part of the circle, the Sun is thought to be above them. So those who said that their spheres are below the Sun took this view from that course of the stars which sometimes, as we have said, appears lower, and which is also truly the more noticeable, because they then appear more freely: for when they hold the upper part, they are more hidden by the rays. Hence that conviction grew strong, and this order was accepted into use by almost everyone. A more penetrating observation, however, detected a better order, which, besides the investigation of sight, this reasoning also recommends, and so on."

So keen, without a spyglass, was the eye of some that from the faint light of Venus and Mercury they inferred that the planets' distance from the Earth is greater than the Sun's, while from their abundant light and the more frequent phases of both they inferred that it is less. What if they had seen with the telescope what has been so clearly revealed to the eyes of our age: namely, that Venus and Mercury are illuminated by the Sun in such a way that they look like other Moons, and moreover with the alternation that the circuit of both around the Sun toward the East requires, as we said in chapter 2, nos. 2, 3 and 4? Thus no one may any longer doubt the order of these planets, provided the place in the universe of the Sun, which is the centre of the circles of Mercury and Venus, is established.

[Margin: This order is confirmed by the illumination of ♀ and ☿.]

Granted, Macrobius thinks that the five minor planets shine with their own light, and from this confirms that they are above the Sun, and the Moon below it because it shines by the Sun's light. Yet there is no manifest disagreement between Cicero and Plato, for Cicero's words in that *Dream* are: "Of these, one globe is held by that star which on Earth they call Saturn's. Next comes that radiance, propitious and healthful to the human race, which is called Jupiter's; then the red one, dreadful to the lands, which you call Mars; then, below, almost the middle region is held by the Sun, leader, prince and ruler of the other lights, mind and regulator of the world, of such size that it illuminates and fills all things with its light. Him, like companions, the courses of Venus on the one hand and of Mercury on the other follow; and in the lowest orb the Moon turns, kindled by the rays of the Sun." He said "companions", not "lower ones"; and when he said that the Sun holds "almost the middle region", he perhaps added that particle to indicate that it usually is or appears to be in the middle, but sometimes is not. So in the same way the Greeks call them [Greek: σύνδρομοι (syndromoi, "running together"), ἰσόδρομοι (isodromoi, "running at an equal pace"), καὶ ὁμόδρομοι (kai homodromoi, "and running on the same course") τῷ ἡλίῳ (tōi hēliōi, "with the Sun")], that is, the Sun's fellow runners, or equal runners.

[Margin: Bede's view on the place of ♀ and ☿.]

III. There is also, in the first volume of the works of Bede, a book *De Mundi caelestis terrestrisque constitutione*, and in it a chapter on epicycles and intersecting circles, p. 383 in my copy, in which it is said: "Mercury, when it has come to

the 12th degree, is seen, as is the Moon too. Venus, when it has withdrawn from the Sun to the 7th degree of a sign, is seen as if already larger. The Moon too would be seen there, if it had its own light. That they are carried above and below the Sun is shown by conjecture in three ways: either through the intersection of the circles; or because they are epicycles, that is, supercircular, and, not having the Earth as centre, make the Sun as it were the centre of their course; or they measure out the height of the Sun with obtuse circles, or with acute windings"; that is, with either circles or ellipses, unless I am mistaken.

[Margin: Ptolemy's opinion on the position of ♀ and ☿.]

Before we hear al-Biṭrūjī, however, we must first give Ptolemy's opinion, which al-Biṭrūjī refuted. For Ptolemy says in the *Magna Syntaxis*, Book 9, chapter 1: "The spheres of Venus and Mercury were placed below the solar sphere by the ancients; but by some of the more recent they are also placed above it, because the Sun has never been seen to suffer an eclipse from these planets. But this reasoning seems weak to us: for some planets can be below the Sun and yet not be on the line that runs through them, the Sun and our sight, but on another, and for that reason not be interposed between us and the Sun, as happens in most new Moons. However, since knowledge of this matter cannot be had from any other source, because none of these stars produces a sensible parallax, the one phenomenon by which distances are taken, the system of the ancients seems to me more probable and more natural, in which the Sun, in the middle, separates the planets that can recede from it by any distance whatever from those that do not behave so, but are always led around it."

[Margin: Alpetragius's opinion.]

With this set out first, al-Biṭrūjī, in his *Physical Theory of the Planets*, chapter 9, first rebuts Ptolemy's answer, saying: "Both these planets, Venus and Mercury, necessarily run along lines that sometimes pass through our sight and the Sun, as the roots and motions he himself has laid down concede; and Mahumedes Geber son of Afflah [Jābir ibn Aflaḥ] has already brought forward a demonstration on this matter, criticising Ptolemy's order." That Mercury has certainly been seen below the Sun we have already shown in Book 3, chapter 3, Scholium 3. al-Biṭrūjī then adds his own view, which is that Venus is above the Sun and Mercury below it, because in the daily motion toward the West Venus is faster, reaches the meridian sooner and falls short of the first motion of the highest orb less than the Sun does; whereas Mercury, on the contrary, is slower in this than the Sun and falls short more. To those who put Mercury too above the Sun, because they have never seen or read that it has brought an eclipse on the Sun, he replies that this has happened because Mercury shines of itself on all sides, and so, although interposed between the Sun and us, it does not bring on an eclipse.

[Margin: Geber's opinion on the place of ♀ and ☿, and his refutation of Ptolemy.]

But I ought to have reported first the view of Geber son of Afflah, of Seville. In Book 7 of his *Astronomy*, chapter 1, he convicts Ptolemy of a threefold

contradiction. First, that he said Mercury and Venus have no sensible parallax and yet placed them below the Sun, to which he gave a parallax of 2′ 51″, and relied on it in constructing his tables and in solar eclipses. Second, from the commensurations of the orbs given by Ptolemy, he shows that a parallax of about 3′ belongs to Venus at perigee and of 7′ to Mercury. Third, from what Ptolemy gives in Book 13 on the latitude and motion of Venus and Mercury, he demonstrates that each can be interposed between the Sun and our sight if they are lower than the Sun, because they are sometimes found on the same line that passes from our eyes through the centres of the Sun and of the planets themselves. Finally, he concludes that it is more probable that Venus and Mercury are above the Sun and closer to the three upper planets, because of the likeness in the composition of their orbs and of their motions of double anomaly, and in retrogradation and station. For if Ptolemy's reasoning held, which places above the Sun the planets that digress from it by a whole semicircle, the Moon would have to be placed above the Sun. In Book 3, chapter 6, no. 1, however, I cited Jābir ibn Aflaḥ for the Ptolemaic system, with regard to the centre of the planetary system: for although Jābir ibn Aflaḥ places Venus and Mercury above the Sun, he thinks they move not around the Sun but around the Earth.

[Margin: The opinion of Theon, and of Summarius and Aristotle, on the same planets.]

Of the same opinion as Jābir ibn Aflaḥ was Ptolemy's interpreter Theon, on Book 9 of the *Almagest*, chapter 1, who teaches that the Sun is to be placed immediately above the Moon, and Mercury and Venus above the Sun. For this opinion stands also Summarius [?], and even Aristotle, according to Io. Picus Mirandulanus [Giovanni Pico della Mirandola], Book 10 *Against the Astrologers*, chapter 4, where he contends that the order of the planets is uncertain.

[Margin: Pico's opinion.]

He adds, however, that Venus and Mercury, interposed between the Sun and us, can fail to bring on an eclipse because of the smallness of their bodies, or their nearness to the Sun, by whose rays they are overwhelmed, or because they are endowed with their own light and with it make up for what they intercept of the Sun's, or because they are diaphanous. At last he concludes: "Averroes, in his paraphrase of Ptolemy's *Great Composition*, says that he once noted in the Sun two blackish spots, as it were, and that when he had worked through the numbers, Mercury was found at that time to be opposite the Sun's rays. Rightly, then, did Moses the Egyptian [Maimonides], also on the testimony of Abubachesis [?], pronounce the position and order of the planets uncertain."

[Margin: Averroes sees Mercury below the Sun.]

[Margin: Regiomontanus's opinion on the place of Venus and Mercury.]

IV. Regiomontanus saw and reported the view of al-Biṭrūjī in the *Epitome of the Almagest*, Book 9, proposition 1. But he rejected it, and retained with Ptolemy Venus and Mercury below the Sun, lest the space between the Sun at

perigee and the Moon at apogee, namely, as he himself sets it, 1006 semidiameters of the Earth, should be empty of every star. He denies, however, that what Venus can withdraw from the surface of the Sun from our sight is sensible, because if its visual diameter is one-tenth of the Sun's diameter, as the ancients supposed, it follows that its apparent disc is one-hundredth of the Sun's disc in surface. For let the Sun's diameter be 30′. Then, by what was said in Book 1, chapter 4, the circumference will be 94′, and a fourth part of these 23½′, which, multiplied by 30′, gives the area of the solar disc, 705. Likewise, if the diameter of Venus is 3, the circumference will be 9⅖, and a fourth part of this 2⅖, which, multiplied by 3, makes the area of the disc of Venus 7⅕, which is to the area of the solar disc, 705, very nearly as 1 to 100. He says it is uncertain which of these planets is the lower, because the greatest parallax of Mercury, when it is at the perigee of its epicycle, cannot be observed on account of the Sun's glare, and because we do not have full precision in reckoning its motions, any more than those of Venus.

[Margin: Refutation of Regiomontanus's arguments.]

But if these two planets are supposed to go around the Sun, they will fill now the space between the Sun and the Moon, now the space between the Sun and Mars at apogee; and from the digressions of each from the Sun, together with the Sun's distance, the distance of each from the Sun and from the Earth can be derived, from which, finally, the parallax is obtained, as we shall show below. Nor would the portion of the Sun covered by Venus be wholly insensible, if its diameter were 3′ and the Sun's 30′: for there would be an eclipse of 1 digit 12′, which is sensible; especially since Averroes saw Mercury below the Sun, as did others, of whom in Book 3, chapter 3, in the Scholia.

[Margin: The opinion of Clavius and the Coimbra commentators.]

So I cannot assent to Clavius in the *Sphere*, and to the Coimbra commentators on *De caelo*, Book 2, chapter 7, question 4, article 2, who say that this eclipse cannot be perceived by the natural sharpness of the eye, if they exclude the telescope. It must be judged, however, that they were speaking of vision effected with the naked eye alone.

[Margin: The opinion of Copernicus, Tycho and the more recent astronomers.]

V. At last Copernicus, in Book 1, chapter 10, having brought forward the opinions of Plato, Ptolemy, al-Biṭrūjī and, though he withholds the name, Regiomontanus, and having rejected the reasons of those who place Venus and Mercury always below the Sun, concludes with Martianus Capella and certain unnamed Latin writers that they go around the Sun as the centre of their motion. This has since been endorsed by Tycho, *Progymnasmata* volume 1, p. 477, and volume 2, chapter 8, p. 189; Longomontanus, *Theorica*, Book 1, chapter 1; Kepler in the *Epitome of Copernican Astronomy*, p. 535, who cites Campanus for this view and confirms it from the use of the telescope, with which Galileo observed Venus, and Simon Marius Mercury, to be sickle-shaped and illuminated by the Sun in the manner that a circuit around the Sun requires; Galileo, in Dialogue

3 of *De Mundi systemate*; Biancani in the *Sphere*, Book 2, chapter 1, Book 11, chapter 1, and Book 12, chapter 1; Argoli in the *Pandosion*, chapter 3; Gassendi in the *Institutio Astronomica*; Scheiner in the *Disquisitiones Mathematicae*, nos. 22, 23 and 38; Hérigone in volume 5 of the *Cursus Mathematicus*, p. 546; and the rest of the more recent astronomers.

[Margin: Four classes of opinion on the place of ♀ and ☿.]

It is clear, then, from what has been said that there have been principally four opinions on the place of Mercury and Venus. The first was that of the Chaldeans, Archimedes, Ptolemy, Regiomontanus and probably Cicero: that Mercury and Venus are always below the Sun. The second, that of Jābir ibn Aflaḥ, Theon, Summarius, Apuleius and perhaps Aristotle, who place them above the Sun. The third, that of al-Biṭrūjī, who placed Venus above the Sun and Mercury below it. The fourth, that of the Egyptians, Plato, Vitruvius, Martianus Capella, Macrobius, Bede, Copernicus, Tycho and all the more recent astronomers, who affirm that they move around the Sun and are carried now above it, now below it; and rightly so. For that reason we were right to call a system of this kind Platonic in Book 3, chapter 6. For if Venus and Mercury were always above the Sun, they would always appear round in the telescope; and if always below, they would be seen sickle-shaped around both conjunctions with the Sun. But around the upper or apogee conjunction they are seen round and small, and around the perigee conjunction sickle-shaped, from what was said in chapter 2, nos. 2 and 3. The reason why Venus is said never to have been seen below the Sun, however, is the great latitude that Venus mostly has at its perigee conjunction with the Sun, or the forgetfulness or carelessness of observers at the time. So Hortensius, in the *Dissertatio cum Gassendo de Mercurio sub Sole viso et Venere invisa*, said "unseen", not "invisible". Yet Scheiner, in *Apelles post tabulam*, Letter 1, relates that ♀ was seen below the Sun by someone, in the form of a certain spot; and in Letter 2 he reports that he himself lay in wait in vain for such a phenomenon, which Magini's calculation promised.

CAPVT V.

Chapter 5.

De Lumine Planetarum Minorum.

On the Light of the Minor Planets.

I. Above, in Book 6, chapter 2, no. 4, when I was asking whether the fixed stars shine of themselves or from the Sun, the need for comparison forced me to touch on the planets as well. Now that question must be taken up separately for the planets. On it there are principally four views.

[Margin: First view: that all the stars shine of themselves. Macrobius.]

The first is that of those who think that all the stars shine of themselves, though most of them except the Moon. So Macrobius, Book 1 on the *Dream*

of Scipio, chapter 19, confirms that Mercury and Venus are carried not only below but also above the Sun, because they do not shine from the Sun as the Moon does, saying: "A more penetrating observation, however, detected a better order, which, besides the investigation of sight, this reasoning also recommends: that the Moon, which lacks light of its own and borrows it from the Sun, must be below the source of its light. For this reasoning makes the Moon have no light of its own and all the other stars shine with theirs: because those, being placed above the Sun, are in the purest aether itself, in which everything, whatever it is, is natural light and its own."

[Margin: Aguilonius.]

And Aguilonius [François d'Aguilon], *Optics*, Book 5, proposition 81: "Picture in your mind the globes of the stars, which I, for my part, judge to shine of their own."

[Margin: Cardano.]

And before him Cardano, *De subtilitate*, Book 3, p. 138, after saying of the Moon: "Whose light does not, as some think, depend wholly on the Sun, and much less does that of the other stars", adds: "Therefore above the aether all things shine and flash to such a degree, etc."

[Margin: Kepler's earlier view.]

Before the use of the telescope, Kepler defended this view in his theses published in the year 1602, and in the *Astronomia Optica*, p. 261. There, having supposed from the view of Copernicus and Tycho the circuit of Venus around the Sun, carried now above and now below it, he says: "It would therefore be fitting that the light of Venus, like that of the Moon, should be extinguished when she comes between the Sun and us, and appear fullest when Venus flees to the upper conjunction", if, that is, she shone from the Sun, as al-Battānī and Vitellio [Witelo] would have it, whom Kepler attacks there. And he adds: "But this is not so: for she lies hidden for a long time at the upper conjunction, and when she is very high she spreads a feeble light and casts a scant shadow from bodies. Then, the lower she descends, the brighter she becomes, and she darts a light that rivals the Moon's; and finally she is of such brightness that at times, at the very moment of conjunction, she can be seen like a great star, as I find noted in the Brahean observations, and she is not obliterated by the almost immense brightness of the air diffused all around, she herself occupying a single point. By that solitude she moves the sight and turns it toward herself, and so she certainly has a very strong light. She must therefore have this exceptional light as her own." He confirms this thesis both from twinkling, which indicates light of its own, and from those sublunary things in which there is some little light of their own; how much more in superlunary things. He changed his view, however, as I said in Book 6, chapter 2, and shall shortly report in no. 3.

[Margin: Alpetragius and Longomontanus.]

Finally, al-Biṭrūjī, in his *Physical Theory*, chapter 9, denies that Mercury and Venus receive light from the Sun, and so does Longomontanus, *Theorica*, Book 2, chapter 18, on account of Venus seen by Tycho in conjunction with the Sun.

[Margin: Second view: that all the stars shine from the Sun. Metrodorus, Plato.]

II. The second view declares that all the stars, wandering and non-wandering, shine wholly or primarily from the Sun. So Metrodorus of Chios seems to have held, according to Plutarch, *De placitis*, Book 2, chapter 19, and Plato in the *Timaeus*, on whom Copernicus, Book 1, chapter 10, reports as follows: "So those who follow Plato, since they think that all the stars, otherwise dark bodies, shine with light received from the Sun, etc."

[Margin: Al-Battānī, Vitellio.]

Of the same view were al-Battānī, chapter 30, and Vitellio, Book 4, proposition 77, whose words I reported in Book 6, chapter 2, no. 4, where he attributes the reason why the planets do not sensibly change shape and phase, even though they are illuminated by the Sun, to their immense distance, on account of which any flame, which is truly pyramidal, nevertheless appears round.

[Margin: Reinhold, the Coimbra commentators, Biancani, Scheiner.]

Finally, the same is held by Reinhold on Peuerbach's *Theoricae*, p. 163; the Coimbra commentators on *De caelo* 2, chapter 7, question 4; Biancani, *Sphere*, Book 17, chapter 12; and Scheiner, *Disquisitiones Mathematicae*, no. 35, who says: "If we admit that light flows to the wanderers from the Sun, why we should deny the same to the fixed stars, there is no cause." And in no. 38, where he proves from this that Venus and Mercury sometimes move above the Sun, because they sometimes appear spherically illuminated over the whole roundness of their disc, and small. This would not happen, he says, if they moved below it, for they would always appear halved, because they are opaque. When they are below the Sun, however, he says they shine sickle-shaped or crescent, and he testifies that he himself observed this, not indeed in Mercury as others have, but in Venus. And in no. 41 he drew this thesis from the eclipses of the Jovian satellites: "From these we have, first, that Jupiter lacks light of itself; next, that it is a body opaque like the Moon. Moreover, that all its light redounds upon it from the Sun. Further, that the condition of the Jovian satellites is the same, for otherwise they would shine in Jupiter's shadow."

[Margin: Third opinion: that all the stars shine partly of themselves, partly from the Sun. Boulliau's opinion.]

III. The third opinion is that of Ismaël Boulliau, *Astronomia Philolaica*, Book 1, chapter 11. He asserts there that all the stars, and especially the planets, are indeed lit by the Sun as regards that more intense light which strikes our eyes, and more so those that are nearer to it, of which kind are Mercury, Venus and the Earth in his hypothesis; but that they nevertheless have something of their own native light, which is greater in the more remote planets, namely Saturn, Jupiter and Mars, because on account of their greater distance they would have more need of a light of their own.

Boulliau's ground is twofold.

[Margin: Boulliau's first ground.]

The first is the differing colour of the planets. "For Saturn looks somewhat pale, Jupiter most splendid, Mars suffused with red, the Moon silvery, Venus yellowish, Mercury somewhat reddish." He denies that these colours can come from the Sun's rays; and since colour can nowhere exist without light, if they have a colour of their own rooted in their bodies, they also have some light. But the answer to this argument is that it is enough for them to have a differing opacity, and differing colours in first act [in actu primo] as regards visibility, which become visible only when they are illuminated, as in gems, plants and so on. We do not see these on a cloudy night, and yet we do not judge that they lose their colour. But we have argued these matters more fully in the *Physics*, in the treatise *On the Soul*, where the object of the eye is dealt with.

[Margin: Boulliau's second ground.]

The second ground is the huge distance, especially of Jupiter and Saturn, from the Sun. He says it is so great that the Sun, seen from Saturn, appears no greater than 3′ 24″, and from Jupiter no greater than 6′ 10″. "It cannot be, therefore," he says, "that so tiny a light, appearing to them like a shining point, should communicate to them as much light as they transmit to us, and much less so if it is called not direct but reflected." Granted that Venus is very strongly illuminated by the Sun, because it sees the Sun under a diameter of 42′ 28″. Since, therefore, the Sun appears to Jupiter seven times smaller than to Venus in diameter, and forty-eight times smaller in the area of its disc, Jupiter, he says, ought to be lit forty-eight times less than Venus, whereas they are illuminated almost equally; it is therefore a sign that there is native light in Jupiter, Saturn and the rest. But because Venus appears through the tube like the Moon, he admits that it, and Mercury too, do not have so much native light that they could strike the pupil effectively by themselves; the three superior planets, however, he contends are endowed with a native and remarkable light.

But the conclusion first laid down does not seem to cohere with this second ground. For if that primary light which strikes our eyes comes from the Sun to them, and is reflected from them to us, then the Sun's distance, or the smallness of the diameter it presents to them, does not stand in the way of that intensity and of so strong an illumination. But if the Sun's excessive distance stands in the way of sufficient illumination, it will also stand in the way of sufficient intensity (sufficient, I mean, to move our sense), and they will have from themselves that primary light which strikes our eyes. But if this is so, how then do Jupiter and Saturn overshadow their satellites with the shadows of their bodies? Does Boulliau doubt this? Or will he say that they lack their own light in the part of the globe turned away from us? Moreover, by what reasoning does Mars, near quadrature (☐) with the Sun (☉), appear gibbous like the Moon?

[Margin: Fourth opinion: that the fixed stars shine of themselves, the planets from the Sun. Of Giordano Bruno. Of Kepler.]

IV. The fourth opinion is that the fixed stars indeed shine of themselves, as we said in Book 6, chapter 2, no. 4, whereas the planets are opaque of themselves but are illuminated by the Sun. So held Giordano Bruno in the book *De Infinito*

& innumerabilibus, saying that the fixed stars are Suns and the planets Moons illuminated by the Sun; and Kepler in the *Dissertatio cum Nuncio Sidereo*, p. 15. There, having considered the observations Galileo made with the spyglass, and his words in the *Nuncius*, p. 16, which are: "The difference between the appearances of the planets and of the fixed stars also seems worth noting. For the planets present their globes exactly round and as if drawn with compasses, and appear orbicular, like little Moons flooded with light on every side; whereas the fixed stars are by no means seen bounded by a circular periphery, but as flashes darting rays all around and twinkling strongly." Having considered these, I say, he says: "Another most delightful observation of yours is the rayed shape of the fixed stars, differing from the circular shapes of the planets. What else shall we gather from this, Galileo, than that the fixed stars emit their lights from within, while the planets, being opaque, are painted from without; that is, to use Bruno's words, that the former are Suns, the latter Moons or Earths?"

Yet in the *Epitome of Copernican Astronomy* he suspends judgement as regards the fixed stars, and confirms it for the planets in these words: "The distance of the fixed stars is so great that the Sun appears to them 18000 times smaller than to us, or appears to them under the six-hundredth part of one minute, which is 6‴. It is doubtful, therefore, to Galileo and to me, whether from so great a distance they can receive so much light from the Sun as to reflect it to us. Nor do I affirm anything; but they can have it, just as certain animals, and gems by a chemical force, receive a constant light. Of ☾ and ♀ it is certain that they are illuminated by the Sun. Jupiter casts shadows, with which it darkens the satellites when it is interposed between them and the Sun. Mars, Jupiter and Saturn always appear brighter on the side from which they look more nearly at the Sun, and darker and coloured on the opposite side. Mercury appears brighter when it is higher than the Sun, and shows that same part of its body which is also bounded by the Sun's light; and Simon Marius says he saw it sickle-shaped."

[Margin: Galileo's opinion.]

Galileo stands for this opinion in Dialogue 3 of *De Mundi systemate*, where, however, he says that Mercury is indeed seen sickle-shaped, but not so easily as Venus, namely because of the smallness of its disc, its nearness to the Sun, and the liveliness of its darting light; the result is that the telescope is not enough to strip off its curls so that it appears shorn all round.

[Margin: And of René Descartes.]

Renatus Cartes [René Descartes] subscribes to it in the principles of the new philosophy, part 2, nos. 9, 20 and 23. For the planets, because they are near the Sun and shine with a duller light, are illuminated by the Sun; but the fixed stars shine of themselves, because they flash with a very vivid light and, set at a vast interval from the Sun, cannot be illuminated by it.

[Margin: And of Šírek.]

The same in Antonín Maria Šírek in his *Radius Sidereomysticus*, p. 177: namely, that with respect to the fixed stars the Sun is like a point, so that it cannot impart light to them as it does to the planets.

[Margin: Our opinion.]

V. Our opinion, therefore, is that all the planets receive light from the Sun. For it stand all the authors of the second and third opinions, and the very many reasons they have pointed out: namely, that they shine with a duller light than the fixed stars, although they are nearer to us, and are bounded all round; and that not only do we see Venus and Mercury sickle-shaped and diminished in light, as their illumination by the Sun requires, but with larger and clearer telescopes Mars too, around the quadrate aspect with the Sun, has appeared like the Moon, ἀμφίκυρτος [Greek: amphikyrtos, "gibbous", curved on both sides]; and Jupiter eclipsing its satellites with the shadow of its body; and between Saturn and its companions, blackish shadows of differing shape according to its differing situation relative to the Sun, as we showed above, with figures set before the eye, in the individual expositions of each planet, chapter 2.

I judge, however, that the planets are not opaque as the Earth is, which is what Kepler thought, but that in their opacity they resemble metals, or rather gems steeped in some colour and very dense: Saturn, say, onyx; Jupiter, sapphire; Mars, pyrope or amethyst; Venus, chrysoprase; Mercury, beryl or agate; the Moon, the larger pearl-shells or large pearls themselves; and that they are something intermediate between mirrors and the merely opaque. For tracts of land illuminated by the Sun, although far nearer to our eyes, by no means shine so as the planets do. The planets, therefore, are not like earths, nor overlaid with so foul an opacity, but are better suited to drink in light and to send it back more vividly and more ruddily.

[Margin: A threefold objection is put forward to be answered.]

VI. We must, however, answer a threefold objection, partly against the second opinion, partly against the fourth and our own. For if Mercury and Venus do not shine of themselves, and turn now below, now above the Sun, three things follow, which experience nevertheless seems to oppose. First, as they approach the Sun in the upper part of the epicycle, they must appear with round and whole light but a smaller disc, while at their greatest digressions they must shine with only half of themselves, namely on the part that inclines toward the Sun itself; further down, however, they must appear sickle-shaped or curved into horns, like the Moon at its third or fourth day, but greater in the length of the visual diameter, so much so that Venus would appear nearly forty times greater in the lower than in the upper part of its epicycle; and in the lowest part of its cycle they must shine for us either not at all or with a very thin light. Second, in their lower conjunction with the Sun, when latitude does not prevent it, some part of the Sun would be covered as the opaque body of Mercury or Venus ran beneath it. Third, Tycho would not have seen Venus joined to the Sun below it on 1587 February 24, as Longomontanus testifies in Book 2 of the *Theorica*, chapter 18.

Yet the contrary of these things occurs, since they seem neither to change their shape or apparent magnitude, nor to hide any particle of the Sun. For this reason al-Biṭrūjī, who puts Mercury below the Sun, admits that if it did not shine with its own light it would sometimes be seen by us as oblong and arched and falling short of roundness, and would take up a particle of the Sun; but that because it shines with its own light, it shines in the same way near to and far from the Sun, and with its own light makes good as much of the Sun as it covers from us; or else, certainly, that it is diaphanous and transmits the Sun's rays. Copernicus, moreover, in Book 1, chapter 10, although he seems to lean toward al-Biṭrūjī's answer, in fact shows himself undecided, when he says that these planets "shine either with their own light or with the Sun's, with which their whole bodies are steeped, and that for this reason the Sun is not obstructed; or that, because of their smallness, so tiny a spot is not easily seen under a most excellent light. Although Averroes too, in his paraphrase of Ptolemy, recalls that he saw something blackish when he found by the numbers that a conjunction of the Sun and Mercury had been set out."

The answer, briefly, is that all those things do occur and appear, but to one who views these planets with the telescope at suitable times. Venus, however, because of its latitude, has not yet been seen in this or the previous century to run beneath between us and the Sun and darken it; but it has been seen sickle-shaped, though very large in length; without the telescope, however, it appears round, just as flames viewed by us from afar appear.

[Margin: Longomontanus's objection answered.]

That Tycho saw Venus in perigee almost joined to the Sun was the work of the obliquity of the Danish horizon and of ♀'s northern latitude of nearly 9°, as Longomontanus himself states in the passage cited; so he tries in vain on this ground to claim a light of their own for Venus and the other planets, though condensed from the Sun's light. The Moon, on the other hand, at 9° from the Sun can seldom be seen, because it is not as near to the Sun as Venus, nor so apt to drink in and reflect light. But it is clear from what was said in Book 4, chapter 3, no. 5 that the Moon, although near the Sun, has sometimes been seen; and so Longomontanus's objection, taken from the Moon's being invisible near the Sun, is answered.

[Margin: Whether the planets twinkle, and from what source.]

The remaining points on the twinkling of the planets were dealt with sufficiently in Book 6, chapter 2, no. 6.

[Margin: What the argument from the distance of the Sun is worth.]

VII. There remains the argument by which, as we said here in no. 5 and in Book 6, chapter 2, no. 4, Galileo, Kepler, Renatus [Descartes] and Antonín Maria Šírek deny that the fixed stars are illuminated by the Sun, and grant it of the planets: namely, their great distance from the Sun. But for this distinction to hold, the difference between the distance of the fixed stars from the Sun and that of the planets must be as remarkable as the followers of the Copernican hypothesis make it. But because that empty interval between Saturn and the

fixed stars does not seem so vast to us, that argument does not seem so effective. It must therefore be helped in another way, from truer distances, if it is to be worth anything, taking into account, however, also the quantity, and indeed the quality, of the light drawn from the Sun into another star. If, therefore, as we said in Book 6, chapter 7, no. 14, Saturn very probably stands at 73000 semidiameters of the Earth at its mean remoteness from the Earth, and at about 80000 at its greatest, and the fixed stars stand at 100000, it follows that the Sun, viewed according to its visible diameter, appears to Saturn as nearly 3′, and to the fixed stars as 2′ 20″. So if it communicates so leaden and languid a light to Saturn, it will not be able to communicate to the fixed stars a light as vivid and intense as that which comes from them to us; and so the argument from distance holds not of light absolutely, but of light of such a kind and such a quantity. Unless perhaps someone should try to attribute this distinction to a difference of substance or of accidents, by which the fixed stars, although more remote, are nevertheless better suited to drink in the Sun's light and spew it back upon us.

CAPVT VI.

Chapter 6.

De Modo & Difficultate obſeruandi exactè loca quinque Minorum Planetarum, Vnde in ipſorum calculo enormes antiquiorum Tabularum errores.

On the method and difficulty of observing exactly the places of the five minor planets, the source of the enormous errors of the older tables in calculating them.

I. Ptolemy was unwilling to enter the labyrinth of these planets without a preface and a protestation of the difficulty, which he sets out in Book 9, throughout the second chapter. Tycho professes the same difficulty in the preface to the *Epistolae*; Kepler in the *Mysterium Cosmographicum*, chapters 18 and 19, and in the foundation of the *Ephemerides*, p. 15. That difficulty arises from many causes, which pertain either to the objects to be observed themselves, or to the observers themselves and their instruments, places or times; among them Ptolemy expressly names "the error of instruments, the variation of the air, and the difference of the observers' eyes."

The first difficulty, then, lies in the motions of these planets themselves, which are entangled not in one but at least in two inequalities, and in a varied and manifold maze of stations and retrogradations, latitudes, inclinations and deviations, through unimaginable windings and bends. Moreover, the three superior planets can indeed be observed conveniently at their acronychal shinings, when, namely, being opposite the Sun, they rise in the evening, because then they both shine all night and wander with only the single, first inequality of motion; and so through three such observations their motions can be investigated after a fashion. But because they are slow-paced, especially

Saturn, which needs nearly 30 years, and Jupiter, which needs nearly 12, to run through the zodiac once, a small error in observation brings about a large error in their place; and a shortfall or excess of a few minutes in longitude delays or hastens their conjunctions and other aspects by a difference of several days, let alone hours. A much greater occasion of going astray lies in observing the moments of the stations, both because of the double anomaly and because of the longer stay during which they seem to stick in the same places.

[Margin: Mars, an unobservable star.]

Mars, moreover, seems so lawless and exorbitant that with coils scarcely to be untangled it has wearied the wits of all astronomers; so much so that Pliny the Elder, Book 2, chapter 17, said: "In the star of Mars, whose course is most unobservable."

[Margin: Rheticus's despair over the motion of Mars.]

And there is a report, related by Kepler in the dedicatory letter of the *Commentaries on Mars*, that Georg Joachim Rheticus, the pupil of Copernicus, while he was stuck in wonder at the motion of Mars, importunately questioned his familiar spirit about these matters; but that, seized by the hair by the spirit and dashed head first by turns against the overhanging ceiling, he was at once let go and hurled to the floor, with this answer added: "This is the motion of Mars." Unless perhaps, says Kepler, he himself, frustrated of success in his speculations, in a raging and disordered state of spirit struck his head against the wall, as Augustus once did when five legions were lost through Quintilius Varus, and the report then spread among the people grew as it went, all the way to that fiction. Kepler himself, for his part, although like another Vulcan he bound this Gradivus in chains and did not let him roam as freely as before, nevertheless says in the Introduction to the already mentioned commentaries: "I myself, who am called a mathematician, on rereading this work of mine grow faint in the powers of my brain, while I recall from the figures to my mind the meanings of the demonstrations, which I had first brought from my mind into the figures and the text."

[Margin: The difficulty of observing Venus and Mercury.]

II. As for Venus and Mercury: although some, with Copernicus, Book 5, chapter 20, think that they can measure their orbs more easily from their greatest digressions from the Sun than those of the superior planets from observation at ἀκρονυχία [Greek: akronychia, the acronychal rising, at nightfall], a more precise observation of them is hindered both by a parallax greater than in the three superior planets, and especially by the lack of suitable fixed stars from which their distance could be taken, and by the vapours of the horizon and the refractions arising from them, on account of which

Bernhard Walther in his observations, and Michael Mästlin, thesis 58, were surprised that Venus appeared to them much higher than it should.

[Margin: The peculiar difficulty of Mercury.]

Mercury, moreover, mostly lies hidden under the rays of the Sun, because of its small digressions from the Sun, and is almost always exposed to great

refractions of the horizon; and, as Regiomontanus notes in Book 9 of the *Epitome of the Almagest*, proposition 1, it cannot be observed in most climates, because even at its greatest elongations from the Sun it is overwhelmed by the light of morning or evening twilight, as the obliquity of the horizon demands. Copernicus, in Book 5, chapter 30, laments and admits that this happened to him, because of the vapours of the Vistula and the slope of the horizon at Frombork, so much so that he could never observe it there and was forced to take refuge in the observations of Bernhard Walther. And he adds: "For this reason this star has tormented us with many windings and much labour, as we searched out its errors." For with no lesser wrappings of coils than his caduceus has in the twisting bends of its snakes, this Hermes, the craftiest of the planets, steals himself away from the efforts of astronomers. As for Tycho's observations of this planet, hear what Kepler testifies before the *Ephemerides*, p. 15: "In Mercury the difficulty is greater, although the occasions for detecting an error are very rare. All its observations recorded by Brahe over 20 years (those, that is, which are reliable and undoubted) fall within a single third of Mercury's eccentric; the other two thirds remain unobserved, in this century at any rate, and in our hemisphere."

III. Now if a small number of observations is exposed to these difficulties one by one, how much more so is the great number needed to finish the business of these five wanderers, when the opportunities of observing are so rare, and either life is so short, or one's manner and way of life does not allow as many years as would be needed for observations of this kind.

[Margin: The time required for these observations.]

Tycho, in the preface to his *Epistolae Astronomicae*, lays it down thus: "At least 4 or 5 lustra are therefore required before the appearances of all the planets can be sufficiently observed, in so many and such different places as may be needed, with suitable instruments." And a little later: "Therefore, for the places and motions both of the wandering and of the unwandering stars to be conveniently brought from celestial observations into the knowledge of numbers, and fitted to common use, and finished so far as one man can accomplish at his age, about three decades of years, if not more, seem to be required." For, as is said in the same place, for the motion of the three superior planets to be corrected from acronychal observations in each sign of the zodiac, 30 years are required for Saturn, 12 for Jupiter, and for other reasons 24 for Mars. We can, however, by trusting and using the observations of others carefully made, and by comparing them with our own, make up for the small number of ours.

IV. No one, then, should be surprised if, on the testimony of Ptolemy, Book 9, chapter 2, Hipparchus, lacking suitable observations from his predecessors, did not attempt to treat these five planets. For hear Ptolemy:

[Margin: Hipparchus φιλαληθέστατος [Greek: philalēthestatos, "most truth-loving"].]

"On account of these difficulties I judge that Hipparchus proved a very great friend of truth. Because of them, and because he did not have from the ancients

as many exact observations as he himself has furnished to us, he did indeed investigate the business of the Sun and the Moon, and demonstrated, so far as could be done, that it takes place through equal and circular motions; but the business of the five planets, so far as is shown from his commentaries, he did not even take up, but only collected their observations into a better order and showed by means of them that the phenomena do not agree with the hypotheses of the mathematicians of that time." And after a few intervening words he continues: "But some demonstrated nothing at all, others did not reach the end. He therefore judged that it did not befit him, who had advanced all the mathematical disciplines exactly and honestly, to begin, as the rest had done, things that seemed by no means able to be brought to a conclusion." And finally he adds: "I think, therefore, that this seemed most difficult to him also; which we have said not for the sake of display."

[Margin: Ptolemy's excuse.]

So it comes about that Ptolemy himself too, in the same place, more than once fortifies himself with an excuse before posterity, when he says: "We should make much of whatever we attain in this matter. This business is most difficult for many reasons: first, because it has not yet been rightly considered by earlier writers; next, because in considering the periods of the individual motions, a minute error can arise in observations made by instruments, which produces a sensible difference afterward all the sooner when the later observation has been made at a shorter interval after the earlier. And now the time from which we have recorded observations of the planets is so short, compared with the magnitude of the things, that it makes a prediction for a long time weak." Lastly, he admits that, under the compulsion of the things themselves, he has used some devices contrary to reason, and fictitious circles in the plane of the ecliptic, as if they did not decline from it at all, for convenience; and certain hypotheses as first principles, not plainly evident but supported by a certain congruence; and that he has sometimes used right-angled triangles for oblique-angled ones, and did not think that an error needing attention could arise from this; and finally that he used that astrolabe of his in taking the distances of the planets from the Moon or from the fixed stars. Kepler will give us a similar excuse for Copernicus below.

[Margin: On the errors of the tables in the 5 planets.]

V. Nor is it to be wondered at if, down to Tycho, the calculation of any astronomers whatever, especially in these planets, has gone so enormously astray from the heaven and the manifest phenomena. So that no one may think we say this from a lust to accuse, let us call together some witnesses to be questioned.

[Margin: Errors of the Alphonsine Tables in these planets.]

Johannes Stöffler had predicted from the Alphonsine Tables that the great conjunction of Saturn and Mars would take place in the year of the Lord 1536, on May 25; but Pietro Pitati observed that it took place on the 20th. Gemma Frisius the younger, in chapters 19 and 20 of the *Radius Astronomicus*, affirms that he observed Mars on 1544 October 31 at 7^h at $16^\circ\ 22' \approx$, with a southern

latitude of 1° 39′, and that the Alphonsine Tables nevertheless showed it then at 18° 38′, and at other times went astray from the truth by three degrees and more. Franciscus Iunctinus [Francesco Giuntini], in the preface to his astronomical tables, giving the reason why he preferred the Prutenic Canons to the Alphonsine Tables, says that the former differ from the latter at times by 11° in Mercury indeed, and by nearly 4° in Mars; and that Giuliano Ristori of Prato, a Carmelite, doctor of sacred theology, a most excellent mathematician and his teacher, observed in 1536, on May 19, about the second hour of the night, the meeting of Saturn and Mars, with Saturn almost covered by Mars, whereas according to Stöffler and the Alphonsine Tables it should have occurred on May 25; and that in 1542, on the night following January 29, at 9^{h}, Saturn and Mars were in conjunction; and that on 1563 August 24 at Orange [Aurangæ] he himself observed the conjunction of Saturn and Jupiter at 14^{h} 30^{m} after noon, the more northerly Jupiter covering almost the whole of the more southerly Saturn, at the end of degree 28 of ♋; whereas the Alphonsine table put that conjunction on September 25, at 4° 12′ of Leo. And he adds: "There are many others, indeed innumerable and intolerable, errors in the motion of Mercury."

Tycho, moreover, in the *Mechanica Astronomica*, p. 39 in my copy, speaking of the Alphonsine and Prutenic tables, says: "I was led to the point of detecting most manifestly the intolerable errors of both calculations, which that great conjunction of the year 1563, of which I spoke at the beginning, also betrayed more than enough in the motion of Saturn and Jupiter: since it deceived the Alphonsine numbers by a whole month; those of Copernicus also by some days, though only a few." He had said that he observed it in the 16th year of his age, at Leipzig, at the end of Cancer.

[Margin: Alfonso's error of a whole month in ♄.]

With Giuntini and Tycho joined as witnesses, then, an error of a whole month, owing to the slowness of the motion of ♄ and ♃, was detected in the numbers of Alfonso. The same Tycho, in the same work, p. 43, says of the Alphonsine and Prutenic tables: "The result is that the planets are sometimes southern in the heavens when their numbers show them northern, and the reverse." In the *Epistolae Astronomicae*, p. 56, comparing his observations made in January of the year 1587 with the Alphonsine and Copernican calculation, he gathers an error at times of 2° in ♄, 2° ½ in ♂, and nearly 3° in ☿. And in Volume 1 of the *Progymnasmata*, p. 648, against Apian, who trusted the Alphonsine calculation too much, he says: "Since the motion of ♂ especially, to say nothing now of ♄, has not so far been so well explored that their conjunction could safely be made known to within three or four days from the calculation, especially the Alphonsine, which he used, no, not even the Copernican, which is a little more exact."

[Margin: And of 7° in ☿.]

His follower and assistant Longomontanus, in the *Astronomia Danica*, Book 2 of the *Theorica*, chapter 20, says that he has detected between the Alphonsine and Copernican calculations an immense discrepancy in ☿, so great that it sometimes

rises beyond 7°; and in chapter 13 he adduces the following disagreement of the Alphonsine and Prutenic tables from his observations made at Uraniborg.

[Margin: Disagreement of the Alphonsine and Prutenic tables from the observed places in ♄ ♃ ♂.]

Planets observed	Year, month, day (old style)	After noon at Uraniborg	Longitude: observed	Longitude: Alphonsine	Longitude: Copernican	Latitude: observed	Latitude: Alphonsine	Latitude: Copernican
♂	1587 January 18	$15^h\ 56^m$	♎ 4° 1′	1° 32′	5° 5′	North 3° 13′	2° 58′	3° 1′
♄	1591 March 17	$7^h\ 30^m$	♊ 22° 43′	25° 7′	22° 23′	South 0° 56½′	0° 56′	1° 35′
♃	1591 April 14	$11^h\ 0^m$	♏ 14° 16′	12° 32′	14° 40′	North 1° 23′	1° 51′	1° 58′

Giovanni Antonio Magini too, in a letter to Richard Fasterus of London [?] [Rchardum Fasterum] [recte: Richardum] of 1601 December 15, which is found in Magini's *Directions*, p. 95, prefers Tycho's observations to the Prutenic calculation and to the Alphonsine, which, except for the Sun, he affirms errs more than the Copernican.

[Margin: Copernicus accused and excused.]

And Kepler, in the *Mysterium Cosmographicum*, chapter 18, accuses Copernicus in such a way as to excuse him for neglecting hours and quarters of a degree in computing the places of Mars, Venus and the others of the 5 planets. For he says: "And so he would seem justly to incur censure, had he not done it deliberately, because it was better to have an astronomy that was in some way imperfect than none at all. For difficulties of this kind will indeed arise as long as the stars run their course; and to overcome them, and to aspire unhindered to the establishment of the science with the least loss, as Copernicus dared to do, is the mark of a brave man; to evade them is the mark of the idle; to despair and to cast aside all this care, that of the timid. Thus he neither hides about himself these errors [Greek: σφάλματα (sphalmata, "errors")] just listed, nor confesses them with shame. He arms himself with the example of Ptolemy and the ancients, he excuses himself by the difficulty of observing, etc."

[Margin: Error of the Prutenic tables: 12 days in ♄, 2° in ♂.]

And in chapter 19 he relates that in the year 1594 on November 12, new style, Saturn was seen by him exactly between the Neck and the Heart of the Lion, where according to the Prutenic calculation it should have been on October 31, the difference in longitude being about 37′. Mästlin, however, in the preface to the Ephemeris for the year 1577, testifies that "the errors of Mars from the calculation cannot be forced within the narrow bounds of two degrees."

[Margin: The difficulty of observing Mercury, and the errors of the Ephemerides.]

And speaking of Mercury he adds: "This one, certainly, is the planet that most brings the astrologers' reputation into disrepute and upsets all reckoning

of meteorological phenomena; and in predicting winds (which it most certainly stirs up, whenever it stands in suitable places) it is often off by so constant a number of days that I can very nearly correct its circle as then faultily given in the Ephemeris. And so, if I saw any astronomer applying himself too anxiously to searching out the errors of this planet, I would warn him to spend that time more properly." And a little later: "Meanwhile, if errors concerning the motions of the Earth and the Moon deserve indulgence, the errors in Mercury will deserve it much more, since it is both more remote from us and almost always hides under the Sun."

[Margin: Error of the Prutenic tables: 4° in ♂.]

Kepler likewise, in the introduction to the *Commentaries on Mars*, says that in the year 1608, in the month of August, the Prutenic place of Mars fell short of the true one by almost 4°; that in the year 1593, in August and September, it fell short by nearly 5°; and again that it fell short throughout the year 1625, but in October by almost 5°, owing to a wrong prosthaphaeresis.

[Margin: Errors of the various tables in ☿ ♂ with ☉.]

Moreover, in the year 1631 on November 7, Mercury was observed under the Sun and joined to the Sun at 7^{h} 58^{m} by Pierre Gassendi, as I reported in Book 3, chapter 3, scholium 3. From that moment and place the Ptolemaic tables departed by 4° 25′, the Copernican by 5°, the Danish by 7° 13′, those of Lansbergen by 1° 21′, the Rudolphine by 14′ 24″. And so Natalis Duret [Noël Duret], a follower of Lansbergen in his Ephemerides, here deserted to the Rudolphine camp.

Martinus Hortensius, for his part, in the dissertation with Gassendi on Mercury seen under the Sun, testifies that in the year 1632 on July 31 he observed the conjunction of ♀ and ☿ at about the hour 11½ of the night, whereas according to Longomontanus's canon these planets ought then to have been 2° 53′ apart from each other in longitude. Finally Antonín Maria Šírek [Anton. Maria de Rheita], in Book 2 of the *Radius Sidereomysticus*, chapter 2, notes an error in Tycho's hypotheses in ♄ ♃ ♂ and ☿ of 5, 6, 7 degrees, and in ♀ of 3, about which I shall see elsewhere. But let there now be an end of these errors and mistakes [Greek: σφαλμάτων, καὶ ἁμαρτημάτων (sphalmatōn, kai hamartēmatōn, "of errors and of mistakes")].

VI. Everything said so far tends to this: that the indulgence others ask of us, they should grant to us in the same way, if even in Tome 3, where we shall offer more observations, and ones brought back under a finer file, we shall not have attained as much as the avidity of astronomers demands; mindful of that saying of Horace in the *Ars Poetica*:

We know this, and this indulgence we both desire and grant in turn.

And:

For no one is born without faults; the best is he
who is burdened by the least.

Next, so as not to hold anyone back through despair, but rather to sharpen those eager to observe, so that they may not be content with ordinary diligence: I think we must here say farewell to astrolabes and armillary spheres and torqueta, to astronomical radii and to such instruments of the roughest observations [Greek: ὁλοσχεροτάτων τηρίσεων [recte: τηρήσεων] (holoscherotatōn tērēseōn, "of the roughest observations")], for reasons to be set out in the *Liber Organicus*.

[Margin: A method of observing the places of the 5 planets exactly.]

The places of the five planets, however, are to be investigated only with large quadrants, or geometric or astronomical squares, or parallactic rulers that do not wobble at all, or larger sextants, by taking their meridian altitude and by counting most exactly the seconds of time between their transit through midheaven and that of an accurately known fixed star, so that from the declination of the planets and the right ascension their longitude and latitude may be found trigonometrically, according to Problem 1, which we gave in Book 6, chapter 12.

But if the planet cannot be observed on the meridian, take with the instruments already mentioned their altitude, as far from the horizon as you can, and the azimuth, but wait for the star to reach a determined degree, and use the thread triangle, on which see Book 6, chapter 11, no. 3. Or else, with skilfully built sextants divided into minutes and tens of seconds, take the distances of the planets not from the Moon, so as not to run into the entanglements of parallaxes, but from two fixed stars placed far from the horizon, avoiding, however, those that form too acute-angled a triangle with the planet, and choosing a time when the planet is as high as possible.

So that the swift setting of Venus or Mercury hastening to the horizon may not slip away, the instruments must be ready beforehand, and several observers at the same moment, so that as soon as the twilight allows them to be seen, two may take the distance of the planet from one of the fixed stars, and two others the distance of the same planet from the other of those fixed stars that have already been assigned and chosen for this; and finally two others may take, one the altitude of the planet, the other the altitude of that fixed star, so that, the refraction being known from this, the apparent distance may be converted into the true one, and at the same time the moment of time may be known through the problems of the *Primum Mobile* to be given in Book 10.

If, however, the good fortune of an opportunity should occur that the planet covers some fixed star of known longitude and latitude, the determination of the planet's place will be most exact and most ready; whereas, on the contrary, it will not be so exact if the planet is covered by the horns or limbs of the Moon, on account of the parallaxes and the manifold motions of the Moon.

An observation will also be exact if you direct the thread triangle mentioned above at the planet, and, as the planet passes through the plane of the triangle, take the planet's altitude; then let someone else count the times of the pendulum until a fixed star passes through that same plane, and at that moment take the

star's altitude. For from these you will learn the planet's place, if the declination and right ascension of the fixed star are known, as I shall teach in the problems of the *Primum Mobile*.

CAPVT VII.

Chapter 7.

De Motuum ſpeciebus ac varietatibus obſeruatis in quinq. minoribus Planetis.

On the kinds and varieties of motion observed in the five minor planets.

I. Since from the beginnings of astronomy, the first observations being cruder and made almost without instruments, there was a gradual advance to observations of the motions carried out with one instrument after another, so too must the novice be led by the hand by us, in the same order, to the knowledge of these motions.

[Margin: Proper motion in longitude.]

First, then, there was observed, besides the diurnal motion from east to west that is common to all the stars, a proper motion in longitude, owing to the withdrawal of these planets from the fixed stars towards the east, greater and greater on most nights; and so a slower daily return from the east to the same meridian than in the fixed stars. In this motion, of the three superior planets, Saturn appeared slower than Jupiter, and Jupiter than Mars, because each day Saturn moves away from the same fixed star towards the east less than Jupiter, and Jupiter less than Mars.

[Margin: Order of risings and settings in ♄ ♃ ♂: cosmical rising; morning heliacal rising; cosmic setting; acronychal rising; evening heliacal setting; acronychal setting.]

II. Second, it was noted that risings and settings occur in this order. In the three superior planets, after the cosmical rising comes the morning heliacal rising; then (as the Sun withdraws from them up to a full semicircle of the zodiac) they become eastern and morning planets from ♂ with the Sun up to ♌, in which the cosmical setting occurs, and presently the acronychal rising, after which they shine all night; and they are western and evening planets from ♌ to ♂ with the Sun. Next, as the Sun approaches them, the evening heliacal setting occurs, which the acronychal setting must necessarily follow. You see this order noted in the margin.

From this and from the earlier motion it became clear that these planets do indeed move in the order of the signs, but more slowly than the Sun, since they cannot catch up with the Sun once it has been joined to them and is then withdrawing; on the contrary, the Sun catches up with them, overwhelms them with its rays, and leaves them behind overwhelmed. And from this, again, was confirmed the greater slowness of Saturn than of Jupiter, and of Jupiter than of Mars, since Saturn hides under the rays of the Sun less than Jupiter, and

Jupiter less than Mavors, the Sun withdrawing more quickly from the former than from the latter.

[Margin: Why is Mars Gradivus? Why is Saturn Phaenon?]

Mars is rightly called Gradivus, because, marching with longer strides, it follows the Sun, which is indeed swifter than it, yet more swiftly than ♄ and ♃ do. Saturn is called Phaenon, that is, "appearing", because its stay under the Sun, from the evening heliacal setting to the morning heliacal rising, is shorter.

[Margin: Order of risings and settings in ♀ in ☿: morning heliacal rising; last morning heliacal setting; cosmical rising; evening heliacal emersion; evening heliacal setting; acronychal setting.]

Venus and Mercury, moreover, have been observed never to move so far from the Sun as to set cosmically or rise acronychally, since they are never set opposite the Sun across the diameter of the world. But after they have risen heliacally in the morning, they digress further from the Sun each day, and at its rising appear higher and higher above the horizon, up to certain limits of greatest digression, which in Venus does not exceed about 50°, nor in Mercury 30°. Then, approaching the Sun again, they are hidden heliacally in the morning, and lie concealed under the Sun's brilliance, until they emerge heliacally in the evening; and on the following nights, at sunset, having become higher and higher above the horizon, they digress from it up to the limits of greatest elongation already mentioned. When this is completed, having come to meet the Sun, they set in the evening with a heliacal setting. From this is gathered both the order of these phases, which you see in the margin, and that these planets are sometimes faster than the Sun, namely when after the morning digression they approach it, or in the evening after the heliacal rising withdraw from it; and sometimes slower, namely when after the evening digression they fall back towards it, or in the morning after the heliacal rising withdraw from it.

[Margin: Motion in altitude.]

III. Third, there was observed a marked decrease of light and of apparent size when they approach superior conjunction with the Sun and the heliacal setting, evening if they are the three superior planets, or morning if the two inferior.

[Margin: Planets *Hipaugi*, diminished and increased in light.]

Hence they are then said to be *Diminished in light*, until, hidden under the Sun, they are called in Greek [Greek: ὑπάυγοι (hypaugoi, "under the rays")], in Latin *Combusti* or *subradiati*. Conversely, when either the three superior planets approach opposition with the Sun and the acronychal rising, or the two inferior planets, through greatest digression, approach evening conjunction with it, they become noticeably *Increased in light*. This, then, is judged to happen, if not necessarily, yet far more probably, from withdrawal from the Earth when they decrease and from approach when they increase.

[Margin: Planet apogee, perigee, aphelion, perihelion.]

From this a planet is called [Greek: ἀπόγειος (apogeios)], that is, standing off from the Earth, and sometimes [Greek: ἀπογειότατος (apogeiotatos)], that is, most remote from it; and [Greek: ἀφήλιος (aphēlios)] or [Greek: ἀφηλιότατος (aphēliotatos)], that is, remote or most remote from the Sun; and conversely [Greek: περίγειος (perigeios)] or [Greek: περιγειότατος (perigeiotatos)], namely around or near the Earth, or nearest to it; and [Greek: περιήλιος (periēlios)] or [Greek: περιηλιότατος (periēliotatos)], that is, near or very near the Sun.

[Margin: Revolution of ♄ ♃ ♂ to the Sun, and its time.]

IV. Fourth, by counting the intervals of time in which the Sun returns to opposition with the superior planets, from which a conjecture was drawn about the return to conjunction, it was observed that in the same planet this revolution is not equal in the number of days and hours, but is sometimes shorter, sometimes longer. Yet, taking the mean revolution of the planet to the Sun, or rather of the Sun, as being the swifter, to the planet, it is established that this is about 378 days in ♄, 399 in ♃, 780 in ♂. From this, again, it became clear that Saturn is slower than Jupiter and Jupiter slower than Mars, since the Sun catches Saturn more quickly than Jupiter, and Jupiter more quickly than Mars.

[Margin: Revolution of ♀ and ☿ to ☉, and its time.]

Venus too was not seen to return equally from one greatest digression from the Sun to another of the same kind, for instance from morning to morning, and neither was Mercury. Yet, considering the mean revolution, Venus returns in about 580 or 583 days; and Mercury in about 115 days, or returning three times within one year to the same syzygies with the Sun.

[Margin: Why Mercury is winged and the messenger of those above.]

On account of this speed the mythographers not inappropriately added wings to his shoulders and soles, and made him up, above the others, as the messenger of those above and those below, that is, the interpreter of changing weather.

[Margin: Inequality of the revolution to the Sun.]

V. Fifth, as astronomy advanced, in this very revolution of the Sun to the planet, commonly called the revolution of the planet to the Sun, besides the inequality of one whole revolution compared with another, a marked inequality was detected within the same revolution, by comparing its parts with its parts, even if the Sun is in the same sign of the zodiac.

[Margin: Direct planet.]

For sometimes they appear faster than themselves from day to day, and indeed fastest at conjunction with the Sun (understand apogee conjunction in ♀ and ☿). From this a planet was called Direct, or going forward directly, and in Greek [Greek: ὑπολειπτικὸς (hypoleiptikos)], that is, following, or proceeding in the order of the signs; and that succession [Greek: ὑπόλειψις (hypoleipsis)].

[Margin: And retrograde.]

Sometimes, however, with a crab-like regress they seem to fall back further towards the west each day, namely when they approach opposition with the Sun, or, if the planet is an inferior one, the evening perigee conjunction with it. Then, as regards the motion in the order of the signs, they are slow, and at the very moments of opposition or of evening perigee conjunction [copulæ] slowest, although fast in retrogression, yet not as much as at conjunctions, etc. For example, Mars on the days nearest conjunction on either side completes directly 47′ a day in the zodiac, but in opposition retrogresses 24′ a day. From this a planet was called in Latin *Retrogradus*; in Greek [Greek: προηγούμενος (proēgoumenos)] or [Greek: προηγητικὸς (proēgētikos)], that is, going before, or withdrawing against the order of the signs; and that motion [Greek: προηγήσις (proēgēsis)], namely precession.

[Margin: Stationary planet.]

Sometimes, namely just at the beginning of and after the end of retrogradation, they seem to stick for some days or hours in the same place of the zodiac, neither going forward nor going back. From this a planet was called Stational or Stationary, in Greek [Greek: στηρήζων [recte: στηρίζων] (stērizōn)], and that stay a Station, or, as in Cicero in the *Tusculans*, *Institio*; and the first station [Greek: πρώτος στήριγμος (prōtos stērigmos)], the second [Greek: δεύτερος στήριγμος (deuteros stērigmos)].

[Margin: The time that the station, direction and retrogradation of the 5 planets lasts.]

When the intervals of time they spend in the arc of direction, in the arc of retrogression and in the stay of the stations were observed, it became clear that these are not equal but sometimes shorter, sometimes longer, and that in them a sometimes shorter, sometimes longer arc of the zodiac is completed. Yet, taking a mean time, the station of ♄ is of nearly 8 days, of ♃ 4, of ♂ 2, of ♀ 1, of ☿ ½. Direct progress of ♄ is of about 244 days, of ♃ 284, of ♂ 705, of ♀ 542, of ☿ 93. Retrogradation, lastly, of ♄ is of almost 136 days, of ♃ 119, of ♂ 75, of ♀ 42, of ☿ 22. A far greater inequality, however, appears in Mars, then in Venus and Mercury. And ♄ becomes stationary [Sationarius] [recte: Stationarius] between the □ and △ aspects with ☉, but ♃ in △ exactly, and ♂ between eighths and two-fifths of its distance from the Sun; and the higher each planet is, the longer it remains retrograde.

[Margin: Revolution of the planets to the fixed stars and to the same point of the zodiac.]

VI. Sixth, as the patience of astronomers extended to observations over a longer time, begun by themselves or by their elders, and when the revolutions of these planets were compared both to the same fixed star with which they had once been joined, or with which they had climbed the meridian, and to the same point of the zodiac, it became clear that these are not indeed equal in the number of days and hours, even in the same planet. Yet, taking a mean restitution, Saturn passes through the zodiac in 29 simple or Egyptian years

and about 174 days, but it does not return to the same fixed star except in 29 years and nearly 184 days.

[Margin: The time of these revolutions.]

Jupiter completes the zodiac in 11 Egyptian years and almost 315 days, and reaches the same fixed star in 11 years and about 318 days. Mars, however, flies through the zodiac in one Egyptian year and almost 321 days, and reaches the same fixed star on the following day or night. This could not be so readily determined for Mercury and Venus, because they always accompany the Sun. When the daily or frequent motions and the parts of this revolution were also compared, and the longitudes of the planets were taken from time to time with instruments, it became plain that they move unequally, and in equal times complete unequal arcs of the zodiac, even if they were at the same distance from conjunction with the Sun.

[Margin: Twofold inequality.]

VII. Seventh, therefore, from the observations indicated in nos. 4, 5 and 6, there was at last recognized in these five planets, besides the common motion, a twofold motion in longitude, each irregular with its own inequality, and a twofold inequality or anomaly, which, merged into one, had formerly appeared undifferentiated. For the revolution to the Sun is shorter in those planets in which the revolution to the fixed stars and to the same point of the zodiac is longer; and, on the contrary, longer to the Sun in those in which it is shorter to the zodiac. Moreover, revolutions of the same planet to the Sun compared with each other, and its parts compared with parts, for instance retrogradations with retrogradations, appear unequal. So too revolutions to a point of the zodiac in the same planet compared with each other, and its parts with parts, for instance the time spent in completing one sign compared with the time in another sign, have shown their own separate inequality.

[Margin: First inequality.]

The first inequality, then, is free of any respect to the Sun, especially in the three superior planets, and is restored with the planet's return to the same point of the zodiac. It was called first, not indeed by origin of observation, for perhaps it came later; but because of itself it first belongs to the planet, even if there were no Sun, or if neither the Sun itself nor the Earth in its place were moving, or, speaking of the inferior planets, even if they moved only with mean motion; and because it appears plainly in conjunctions and oppositions with the Sun, whether true or mean, in which, however, the anomaly of motion relative to the Sun is extinguished, or appears barely perceptibly.

This inequality, as will be explained later, Ptolemy, either by his own invention or in imitation of the ancients, attributed to an eccentric circle enclosing the Earth: both because he saw that more time passes from the slowest motion of this anomaly to the mean than from the mean to the fastest, and because the places of this slowest and fastest motion lie diametrically opposite in the zodiac, two properties that suit an eccentric more than an epicycle. And so he laid down that the greatest slowness of the planet's motion in the zodiac occurs

at the apogee of the eccentric, and the greatest speed at the perigee. This was discussed in no. 6.

[Margin: Second inequality.]

The second inequality and anomaly is tied to the respect to the Sun, and this was discussed in nos. 4 and 5. For according to it the planet so adjusts its motion to the Sun's proximity that as the Sun approaches it becomes faster than usual, and as the Sun goes off to opposition, or, in the inferior planets, to evening conjunction, it becomes slower, and in the intermediate times stationary. This anomaly is restored with the return of the Sun to the planet. It was called second because of itself it belongs second to the planet, or even accidentally and from the extrinsic motion of the Sun or the Earth. Indeed, if one posits with the Copernicans the Earth's annual motion, which we nevertheless reject, stations and retrogradations are in reality nothing, but mere changes and accidents of our sight, as we shall set out later.

This anomaly, further, was attributed to an epicycle carried by the eccentric, because in it more time passes from the fastest motion to the mean than from the mean to the slowest, which is proper to an epicycle; and because this alone seemed suitable to represent the stations and retrogradations of the planets. So, in the contrary fashion from the Moon, the first and free anomaly could in the Ptolemaic manner be called eccentric, and the second, which is tied to the Sun, epicyclic. Thus Ptolemy decreed that the greatest speed of this anomaly occurs at the apogee of the epicycle and the greatest slowness at its perigee. But in the inferior planets the mean motion is the same as the mean motion of the Sun, and in this respect their first motion is connected with the Sun.

[Margin: The opportunity of separating the first inequality from the second is pointed out.]

From this I would now like novices to scent out why astronomers, in order to know more exactly both the mean motion of the first anomaly and its equations separately from the second, have studiously chosen in the three superior planets oppositions with the Sun, or acronychal shinings, and in the inferior planets the greatest digressions. For in conjunctions, no differently from oppositions, the second inequality ceases; but conjunctions cannot be observed, the planet being hidden at those times for some days under the rays of the Sun. Therefore oppositions of the three superior planets with the Sun had to be chosen, and in the inferior planets, from the pairs of greatest digressions from the Sun on either side, as close a conjecture as possible had to be drawn about the time of the conjunctions. But more fully on these matters below.

[Margin: Motion of the apogee, and its quantity.]

VIII. Eighth, when the study of observations was carried back further into more ancient times, it was decided to inquire into the places of the zodiac in which, formerly and later, these planets had held the apogeism [apogeismū] of their eccentric, or the greatest slowness of their first motion in longitude. And at last, after an interval of very long time, it was established that this does not occur at the same point of the zodiac, but at different points according to

the sequence of the signs, and that this apogee therefore moves in the order of the signs, but with so slight a motion that the astronomers up to Copernicus, with Ptolemy, Book 9, chapter 5, thought it equal to the motion of the fixed stars. And thus the auges of the five planets, according to the motion of the eighth sphere, complete 1° in 100 years, as the Ptolemaists hold, and complete the period in 36000 years; or, as the Alphonsines and Peuerbach's followers hold, in 49000 years. Copernicus, however, thinks that the apogee of ♄ by a peculiar motion of its own moves uniformly under the fixed stars by 36″ 40‴ 48⁗ a year, and completes its period in 35333 Egyptian years; the apogee of ♃ by 10″ 49‴ 26⁗ a year, completing its period in 119734 years; that of ♂ by 28″ 44‴ 37⁗ a year, and revolves to the fixed stars in 45088 years; the apogee of ☿ by 57″ 50‴ 38⁗ a year, but under the signifer, completing its period in 22700 years; but that the apogee of ♀ does not change under the fixed stars. Others hold otherwise, on whom see below.

[Margin: Motion in latitude?]

IX. Ninth, in the latitudes of these planets, taken from time to time with instruments, a remarkable diversity appeared. For their path was detected to be inclined to the ecliptic, with its nodes, as in the Moon, which they call in Greek [Greek: συνδέσμους (syndesmous, "bonds")], and limits, which they call [Greek: πέρατα (perata, "limits")] or umbilici or bellies. Further, as became clear when observations were compared with each other, the three superior planets, whenever they are around the apogee of the eccentric, have northern latitude, and around the perigee, southern. Mars has its greatest in the very apogee and perigee, or nearly; Saturn on this side of the apogee and Jupiter beyond the apogee have their greatest northern, just as the former on this side of the perigee and the latter beyond it have their greatest southern. The three superior planets stay longer in northern latitude than in southern; conversely ♀ and ☿ stay more in southern than in northern. And in ♀ the greatest latitudes are greater in the north, the contrary in ☿.

But in this too a twofold inequality appeared. For on comparing the greatest latitudes of several revolutions with each other, it became clear that they become greater still when the planet is placed in the perigee of the epicycle, and smaller in the apogee.

[Margin: Inclination of ♄ ♃ ♂: what it is and how great.]

Accordingly the ancient astronomers attributed the first cause of the greatest latitude to the inclination of the eccentric from the plane of the ecliptic, which was called [Greek: ἔγκλισις ἐκκέντρου (enklisis ekkentrou, "inclination of the eccentric")], that is, inclination of the eccentric, and by the Latins *Deviation*. It is measured by the angle made at the centre of the world by straight lines drawn from there, one through the plane of the ecliptic, the other through the plane of the eccentric; and its greatest, among the ancients, is in ♄ 2° 26′, in ♃ 2° 24′, in ♂ 1° 0′.

[Margin: Deviation of ♄ ♃ ♂: what it is and how great?]

The second cause of the varied latitude they attributed to the inclination of the epicycle, turning about the diameter of the mean longitudes, or about the diameter cutting the line of apsides orthogonally at the centre of the epicycle. By force of this libration its apogee is inclined towards the ecliptic when the centre of the epicycle is in the northern segment of the eccentric, and therefore it diminishes the northern latitude of a planet placed at the apogee of the epicycle, whereas, on the contrary, at the perigee of the epicycle it is increased; just as in the southern segment the southern latitude is diminished at the apogee and increased at the perigee of the epicycle. This, then, was called by the Greeks [Greek: ἔγκλισις ἐπικύκλου (enklisis epikyklou, "inclination of the epicycle")], that is, inclination of the epicycle, and by the Latins simply *Inclination*, understood of the epicycle to the plane of the eccentric. It is measured by the angle made at the centre of the epicycle by the diameter of the apsides of that epicycle and by a straight line drawn from the centre of the epicycle to the centre of the eccentric; and the greatest inclination reckoned by the ancients is in ♄ 4° 30′, in ♃ 2° 26′, in ♂ 2° and 15′.

Meanwhile, so that you may not be without any specimen of the observations of the ancients, the greatest latitude of the three superior planets is among them as you see in this little table, from which, however, recent observations differ not a little.

GREATEST LATITUDE

Planets	Northern in the epicycle: Apogee	Northern in the epicycle: Perigee	Southern in the epicycle: Apogee	Southern in the epicycle: Perigee
♄	2° 3′	3° 3′	2° 1′	3° 5′
♃	1° 6′	2° 5′	1° 4′	2° 8′
♂	0° 5′	4° 20′	0° 2′	7° 30′

[Margin: On the latitude of ♀ and ☿.]

X. Tenth, however, in Venus and Mercury, beyond the deviation of the eccentric circle from the plane of the ecliptic and the inclination of the epicycle from the plane of the eccentric towards north or south, a certain twisting [detorsio] of the plane of the epicycle from the plane of the eccentric has been observed, crosswise, to the right here and to the left there. This obliquity is called by the Greeks [Greek: λόξωσις ἐπικύκλου (loxōsis epikyklou, "obliquity of the epicycle")] and by the Latins reflexion [Reflexio] or reflection [Reflectio]. From these three causes and differences is believed to have arisen that far more remarkable variety of latitudes in these two planets which the observations have indicated. For once the places under the zodiac and the times of the latitudes, especially of the greatest, had been observed, three varieties were found.

[Margin: Deviation of ♀ and ☿.]

The greatest *deviation* of the eccentric, then, is reckoned at 10′ in ♀ and 45′ in ☿, approximately, and it occurs always when the centre of the epicycle is in the apogee of the eccentric or in the perigee. But it is not invariable, as it is in the three superior planets; on the contrary, it decreases from greatest to none

as the plane of the eccentric comes to coincide with the plane of the ecliptic, which happens when the centre of the epicycle is at the node. As the centre of the epicycle moves away towards the apogee of the eccentric's equant, the deviation grows, until at the apogee it becomes greatest, that of ♀ towards the north by about 10′, that of ☿ towards the south by about 45′. From there it decreases again until at the other node it comes to nothing; and from there it grows again, until at the perigee of the eccentric it becomes greatest, ♀ always to the north, about 10′, and ♀ [recte: ☿] always to the south, about 45′.

[Margin: Inclination of ♀ and ☿.]

The *inclination* of the epicycle to the plane of the eccentric, by which the diameter through the apogee and perigee of the epicycle is inclined to the north or to the south upon the diameter of the epicycle's mean longitudes, is at its greatest nearly 2° 30′ in ♀ and nearly 6° 15′ in ☿. This inclination is adjusted to the motion of the eccentric and of the longitude by this rule: when the centre of the epicycle occupies the apogee of the equant and the deviation becomes greatest, the inclination of the epicycle is none, and its plane lies in the plane of the eccentric. But when the centre of the epicycle recedes from the apogee of the equant, the inclination grows continuously, so that the apogee of the epicycle declines to the north in ♀ and to the south in ☿; and at the descending [deuehente] node of the eccentric with the ecliptic, where the deviation ceases, the inclination becomes greatest. As the centre of the epicycle recedes from the southern node, however, the inclination begins to diminish continuously, until, with the centre of the epicycle carried to the perigee of the equant, the inclination becomes none. As the centre recedes from there towards the northern node of the eccentric, the inclination of the epicycle's apogee is to the south in ♀ and to the north in ☿, and it grows continuously until it reaches its greatest at the northern node of the eccentric; and at last it decreases from there, until at the northern limit of the eccentric and at the apogee of the equant it is none. Therefore, when the deviation of the eccentric is none, the inclination of the epicycle is greatest, and when the deviation of the eccentric is greatest, the inclination of the epicycle is none. And although the deviation is always towards the same quarter, namely that of ♀ to the north and that of ☿ to the south, yet the inclination of the epicycle of ♀ is not to the north except in the northern semicircle of the eccentric, nor that of ☿ to the south except in the southern semicircle. The greatest latitude, which is derived trigonometrically from the greatest inclination, is in ♀ at apogee nearly 1° 3′ and at perigee nearly 7° 12′; in ☿ at apogee nearly 1° 46′ and at perigee nearly 4° 5′, according to the older authorities. But these are corrected by the reflexion, of which presently.

[Margin: Reflexion of ♀ and ☿.]

The *reflexion*, by which the diameter of the mean longitudes of the epicycle is moved about the diameter through the apogee and perigee of the same epicycle, and is thus bent crosswise so that the plane of the epicycle cuts the plane of the eccentric, is at its greatest close to 2° 30′ in ♀; in ☿ it is 2° 15′ at the apogee

of the eccentric and 2° 45′ at the perigee. The libration of this motion is so adjusted to the motion of the centre of the epicycle that it is none at the nodes of the eccentric and the ecliptic, that is, when the deviation is none. But as the centre of the epicycle ascends towards the apogee of the eccentric and the northern limit, the reflexion of the left or eastern semicircle of the epicycle is to the north in ♀ and to the south in ☿; and it grows until at the apogee of the eccentric it becomes greatest. From there it diminishes as far as the other node, where it dies out; and as the centre of the epicycle descends from there towards the perigee of the eccentric and the southern limit, the left portion of the epicycle is bent to the south in ♀ and to the north in ☿, and so on.

[Margin: Greatest latitude of ♀ and ☿.]

Once all the differences of deviation, inclination and reflexion that can concur to increase the latitude have been computed, the greatest latitude according to the older authorities is what you see in this little table, with the planets placed in the apogee or the perigee of the epicycle.

Planet	At the node of the eccentric	Or in the equated anomaly of the eccentric	Greatest latitude in the epicycle: Apogee	Greatest latitude in the epicycle: Perigee
♀	Northern	9ˢ	South 1° 3′	North 6° 22′
♀	Southern	3ˢ	North 1° 3′	South 6° 22′
☿	Northern	9ˢ	North 1° 46′	South 4° 5′
☿	Southern	3ˢ	South 1° 46′	North 4° 5′

[Margin: Motion of the nodes and limits.]

XI. Eleventh, it has been observed that the nodes and limits of greatest latitude of the five planets do not stay fixed under the same point of the zodiac, but advance with a slow motion in the sequence of the signs, if their motion is reckoned from the vernal equinox. If it is reckoned from the first star of Aries, however, they seem to move in the antecedents, because they are so slow that the apparent motion of the fixed stars in the sequence is faster than theirs; with the exception, however, of the motion of Mercury's node, which appears faster than the fixed stars, if what Ptolemy reported in his day about the place of that node is true. Copernicus, moreover, thinks the node of Venus stationary under the fixed stars. From Ptolemy down to our own time the node of ♄ has advanced 22°, of ♃ 5°, of ♂ 17°, of ♀ 18°, of ☿ 35½°. The Alphonsines, however, trusting in the slowness of this motion, thought that both the nodes and the apogees of these planets move with the motion of the eighth sphere.

[Margin: Motion of rotation.]

XII. Twelfth, a motion of rotation about the centre of its own body is attributed to all the planets by Hérigone, tome 5, p. 566; by Kepler, *Dissertatio cum Nuncio Sidereo*, p. 12, and in the *Epitome of Copernican Astronomy*, p. 549; and by Antonín Maria Šírek in his *Radius Sidereomysticus*, Book 4, chapter 2, member 3, on account of the conjecture I reported in Book 3, chapter 4, number 3. See also what we touched on here, chapter 3, Scholium 3.

[Margin: Variation of the eccentricity and the epicycle.]

XIII. Thirteenth, not only in Mercury formerly and later in Mars but, as it has seemed to us, in all these five planets, a variation of the eccentricity has been noticed, and indeed also a variation in the size of the semidiameter of the epicycle, on which more in chapter 6 of Section 2.

[Margin: Epiphonema.]

So many motions, then, and so wonderful, has the Best and Greatest implanted in these planets, and so great a knowledge of them has he granted to mortals, that by inquiring further they may advance in the worship of him and in veneration of his most certain Providence.

[Margin: Summing-up of the motions.]

Seven of them, to be exact. They are: the common motion of 24 hours; the proper motion in longitude, with a twofold anomaly and restitution, one free and referred to the zodiac, the other tied to the Sun; the motion in altitude; the motion of the apogees; the motion of the nodes; the motion of latitude, with a twofold anomaly in ♄ ♃ ♂, namely deviation and inclination, but a threefold one in the inferior planets, namely deviation, inclination and reflexion; and perhaps the motion of rotation and the change of the eccentricity and the epicycle.

SCHOLIA.

Scholia.

I. In reviewing the motions of the planets and their measure, we know that opinions vary; we shall give these below, in their proper places, in a single view. For now, let us hear what Vitruvius, Pliny the Elder and Martianus Capella, drawing from I know not what sources, have reported about them.

[Margin: Opinion of Vitruvius on the motions of the planets.]

So then Vitruvius, Book 9, chapter 4, after mentioning the circuits of Venus and Mercury around the Sun, their regressions backwards, their retardations and their stations, added that Mercury returns in 360 days to the place of the same sign from which it had begun its course, and that Venus stays about 40 days in any given sign, and after 485 days returns to the same place from which it began its journey; that Mars completes its revolution in about 683 days, and after its first station is swifter; that Jupiter, climbing with a gentler step against the daily motion, stays nearly one year in each sign, and accomplishes its period in 11 years and 363 days; further, that Saturn stays in one sign for 29 months and a few days more, and completes its restitution in 29 years and 160 days.

[Margin: Cause of station and retrogradation, from Vitruvius.]

He next adds that the three superior planets make a station when they have come to the trine aspect of the Sun with that degree of the zodiac in which they were joined to the Sun, and from there make their regressions, until the same Sun has crossed from that trine into another sign. He denies that the cause of this is that the Sun, by its distance, does not make the paths of the wandering

stars bright; for the Sun, even when the planets stand or retrogress, lights the whole world with open and evident splendour, so that it is seen by us, who are nonetheless less near to it. Instead, he brings forward another cause, saying: "Rather, therefore, this reasoning stands firm with us: just as heat calls out all things and draws them to itself (as we also see it raise fruits rising from the earth to a height through warmth, no less than the vapours of water from springs to the clouds through arcs), by the same reasoning the vehement impetus of the Sun, with its rays stretched out in the form of a trigon, draws to itself the stars that follow, and those running ahead it does not allow to advance, as if by reining them in and holding them back, but compels them to go back towards it and to be in the sign of another trigon." And he says that so great a force resides in the trigonism of the rays because of the equality of the sides, and so on. The Copernicans, however, assign the cause of stations and retrogressions to the annual motion of the Earth, through which it comes about that the planets appear to go back although in reality they are always advancing, as will be explained below.

[Margin: Opinion of Pliny the Elder on the motions of the 5 planets.]

II. Pliny the Elder, Book 2, chapter 8, first thinks that all the wandering stars are driven with a contrary and leftward motion against the headlong motion of the world to the right, "so that the air, rolled round in the same direction by the eternal rotation of the world, may not grow torpid as an inert mass, but may be split by the opposing blow of the stars, separated and spread out." He adds that Saturn is carried round in about 30 years, Jupiter in 12, Mars in 2; and that Jupiter is wholesome for this reason, that it is tempered on the one side by the rigour of Saturn and on the other by the heat of Mars, which is fiery from the neighbouring Sun and is called by some the star of Hercules. He next subjoins: "The star of Venus, wandering in alternating course and by its very surnames a rival of the Sun and the Moon: for, going before and rising ahead of the morning, it receives the name of Lucifer, as a second Sun, hastening the day; by contrast, shining out from the west, it is called Vesper, as prolonging the light and taking the Moon's turn.

[Margin: The time of Pythagoras, and V. C.]

Pythagoras of Samos first detected this nature of it, about the 42nd Olympiad, which was the 142nd year of the city of Rome." Before that, some indeed had thought Lucifer and Hesperus to be two distinct stars. He adds that its brightness is so great "that shadows are cast by the rays of this one star." Kepler, however, affirms in the *Optics*, p. 263, that distinct lights on a wall were seen by him, not only of Venus but of Jupiter and Spica, which we too have seen more than once with ♃ and ♀. Nonetheless the surrounding light of twilight, bounding the shadow, helps the distinct seeing of Venus's shadow. Pliny the Elder goes on and says that, according to a tenet of Timaeus, Venus never stands off from the Sun by more than 46°; and that the star of Mercury, called by some the star of Apollo, in a lower circle shines for 9 days on the one hand before the rising of the Sun and as many on the other after its setting, and is not distant from the

Sun beyond 23°, in the opinion of Sosigenes. This he repeats also in chapter 17, where he wraps up rather than unfolds many things about these five planets, I believe from the opinion of Sosigenes.

[Margin: Things worth noting about the planets, from Pliny the Elder.]

These are the clearer points: that Mars never makes a station with Jupiter in trine, and rarely in sextile with ♃, and does not rise except in ♋ and ♌; that Mercury has its evening risings rarely in ♓ and most frequently in ♍, its morning risings frequently in ♊ and in ♒ and most rarely in ♌; that it does not become retrograde in ♉ and ♊, nor in ♋ on this side of the 25th degree; that Saturn and Mars lie hidden, at the most, for 170 days; Jupiter 36, but at the least 10; Venus 69, or at the least 52; Mercury 13, or at the most 17. In these passages he is not always speaking of heliacal occultation, as Jacob Milich thought, who nonetheless rightly adds that Pliny the Elder here speaks in a loose manner. I think he had regard to the rather crude observations of his own or of the preceding age.

[Margin: Opinion of Martianus Capella.]

III. Finally, Martianus Capella, *De Nuptiis Philologiae et Mercurii*, Book 8, towards the end, hammers out on these matters many things that call for the file. The more notable are these: that Mercury cannot stand off from the Sun beyond 32 degrees, nor be away from the Sun's light within 20 moments [momenta], and completes its period every fourth month; that Venus has a latitude of 12°, at fifty moments from the orb of the Sun, but does not depart beyond 46°; that it goes direct for eleven months; that it alone among the five planets casts a shadow and is seen by day; that at its morning rising it generally stays for four months, at its evening rising never more than twenty days; that its revolution is renewed in 19 months. That Mars runs out to a latitude of 5°, has its apogee at 29° ♑, and makes both stations in quadrate aspect with the Sun. That Jupiter ranges to a latitude of 5° and has its apsis at ♋ 15°. Lastly, that Saturn has its apsis at the 20th degree of ♎, that it makes its morning station at a digression of 120° from the Sun, and its evening station when it is the same number of degrees from the Sun. Finally he too, with Vitruvius, refers the causes of these diversities to the Sun; for he concludes Book 8 with these words:

[Margin: Physical cause of the retrogradation, etc., of the planets, from Capella.]

"But the diversities of course and the causes of altitude, of standing, of going back and of advancing are brought to all the above by the shining ray of the Sun, which, striking them, either lifts them on high, or presses them down into the depth, or makes them decline in latitude or go retrograde."

[Margin: Opinion of Kepler, Wendelen and Šírek on the physical cause of the slow and swift motion of the planets is indicated.]

IV. These things, to be sure, partly favour the opinion of Kepler, who refers them to the magnetic tractions of the Sun, by which it seizes the planets and leads them round, in the *Commentaries on Mars*, chapter 57, and in the *Epitome of Copernican Astronomy*, from p. 571. Not to mention the opinion of Wendelen,

who, as Antonín Maria Šírek reports in Book 4 of the *Radius Sidereomysticus*, chapter 2, held that the Sun once ejaculated the remaining planets, as Vesuvius and Etna or Mount Hekla eject fiery stones. He himself, however, thinks that the planets are carried round by the Sun, and that those nearer to it are therefore carried round faster: the spots, for instance (which he calls solar stars), in 27 or 30 days, Mercury in 87, and so on. I said "partly", because on other points Kepler dissents; indeed, in the *Commentaries on Mars*, chapter 6, he convicts of falsity the opinion of the Latins, who attribute the speed and slowness of the planets to the aspects and rays of the Sun, because Saturn begins to retrocede in quadrate of the Sun or beyond, Jupiter in trine, Mars in biquintile or before the sesquiquadrate [ſeſquadrum], all at an inconstant interval.

CAPVT VIII.

Chapter 8.

Indicantur Hypotheſes quibus Planetarum quinque Minorum motus Explicari, ac de Machinis quibus repræſentari ſolent.

The hypotheses are indicated by which the motions of the five minor planets are usually explained, and the machines by which they are usually represented are discussed.

I. I find among the authors eight species of hypotheses, by which astronomers have until now been accustomed to draw and set forth, in the astronomical dust, the variety and anomaly of the motions indicated in the preceding chapter.

[Margin: 1st species of hypotheses.]

The first is by means of solid but homocentric orbs, that is, concentric with the world, accelerated and retarded by various circitors [circitoribus] and anti-circitors [anticircitoribus]. These were employed by Callippus, Eudoxus and Aristotle, *Metaphysics* 12, with very many Peripatetics; and Girolamo Fracastoro in his *Homocentrica*, Giovanni Battista Amico in his opuscule *De motibus corporum caelestium*, and a few others have tried to revive them. But they have been rejected by the better astronomers, because they do not maintain the motion up and down from apogee to perigee, which is contrary to the evident difference of the parallaxes, at least in the Moon; and because solid orbs conflict with the passages of comets through the aether.

[Margin: 2nd species.]

The second is that of Hipparchus and Ptolemy, which most of the Arabs, Greeks and Latins embraced down to Copernicus. They use a double eccentric circle, by which they set forth the first motion, free from the syzygies with the Sun and from relation to it, and its first anomaly. One eccentric indeed carries the centre of the epicycle, but it does not move uniformly in the arc of its own circumference, that is, with respect to its own centre, but with respect to the centre of the other eccentric; and this other eccentric is called the equant for this reason, that its equal arcs are the measure of the mean motion with which the former eccentric carries the centre of the epicycle. The epicycle

carries the planet, and by its own motion the second motion of the planet, and its second inequality, and the revolutions of the planet to the Sun, it brings to completion. Some Arabs, Sacrobosco, Peuerbach, and Magini in their *Theoricae* have stuffed this hypothesis with matter and solid orbs. In this hypothesis, one thing indeed is praiseworthy: that it makes the planet's motion perfectly circular over a completed period. But this has seemed unpraiseworthy: that the planet's uniformity of motion is begged from another's eccentric, in which it is not itself and by which it is in no way carried, while meanwhile it moves with a true and physical inequality in its own proper eccentric. This seemed unworthy to Copernicus and unbefitting the simplest bodies, which require uniform motion. Moreover, for this hypothesis the second inequality ceases at the mean ♂ and ♌ with the ☉, which ♂ and ♌ are something fictitious and scarcely ever really occur.

[Margin: 3rd species.]

The third species, therefore, devised by Copernicus, Book 5, chapter 4, explained by Mästlin in the appendix to Kepler's *Prodromus*, and indicated by Kepler in the *Commentaries on Mars*, chapter 4, uses a single eccentric and a single epicycle, with the orbs so proportioned and the motions so ordered that the motion of each is uniform with respect to its own centre. But although this preserves uniformity of motion, it nevertheless twists the planet's path into various bends and drives it out of a perfectly circular way. Further, it measures the 2nd inequality of the planet from the mean ♂ and ♌ with the ☉, as from termini, when the true ones should rather have been considered; and finally it supposes an annual motion of the Earth.

[Margin: 4th species.]

The fourth species, also of Copernicus, and indicated by the same authors as the third, contains only two eccentrics with one small circle varying the eccentricity. By this, likewise, the uniformity of motions in the proper circle is indeed saved, but the circular path is not saved with respect to the line which the planet describes by its motion; and here too the second inequality is ascribed to the mean rather than the true motion of the ☉, and to the annual revolution of the Earth.

[Margin: 5th species.]

The fifth species, discovered by the same Copernicus, explained more fully above by Kepler, and selected by Tycho and Longomontanus and adopted as their own, is by means of one concentric with two epicycles, with their motions and the symmetries of their semidiameters so ordered that it is as nearly as possible equivalent to the Ptolemaic, but retains uniformity of motion about its proper circle; granted that it departs from a perfectly circular path of the planet and multiplies circles excessively, and so on.

[Margin: 6th species.]

The sixth species is that of Lansbergen in the *Theoricae*, who uses a single eccentric whose centre is carried round by a small circle placed near the centre of the universe. This too keeps uniformity of motion with respect to its proper

centre safe and sound, but it draws the planet's path away from the course of a perfect circle; and it ties the second anomaly of the planets to the annual motion of the Earth rather than of the Sun, and to the mean motion rather than the true. Hérigone, for his part, transferred it to the hypothesis of a stationary Earth.

[Margin: 7th species.]

The seventh species is that of Kepler in the *Commentaries on Mars* and in the *Epitome of Copernican Astronomy*, and also of Boulliau in his *Astronomia Philolaica*, towards which Hérigone also inclines. This species both rests on the annual motion of the Earth and makes neither a physical uniformity nor a perfectly circular path of the planet. Instead, it supposes that the planet moves in an ellipse, with the Sun standing in one of the umbilici or foci; moves about it, I say, with a physical inequality, so that in equal times it completes unequal arcs of the elliptical circumference on this side of the centre of the ellipse, and is retarded or accelerated in its motions according to the ratio of greater or lesser distance. Yet because of the simplicity of the planetary path, which accomplishes everything with a single circle or a single ellipse, and because it has regard to the true motions of the Sun, this hypothesis has pleased many.

[Margin: 8th species.]

The eighth species is our own. In it the uniformity of the first motion about its proper centre is preserved, and the eccentricity is not bisected, but varied by a libration of the eccentric's centre up and down according to second sines corresponding to the mean anomaly of the eccentric. The motion of the second inequality is accomplished in an epicycle, but in one that is different from time to time, made through a spiral and varying its semidiameter, according to ratios similar to the variation of the eccentricity.

[Margin: 9th species.]

The ninth species, indicated long ago by al-Biṭrūjī in his *Theorica Physica Planetarum*, but accepted not only by Franciscus Patritius [Francesco Patrizi], by Io. Antonius Delphinus [Giovanni Antonio Delfino] in his book *De caelestibus globis et motibus*, by Biancani in the *Sphaera* throughout, and by not a few more recent authors, gathers all the motions of a planet into one bundle and reduces them to a single spiral motion made from east towards west, but slower in the inferior and faster in the superior planets, so that another motion into the east, contrary to the first, only appears to exist and does not. This spire, since it takes place up and down and to the sides of the world, nevertheless embraces in itself all the motions of the planet. This hypothesis, though perhaps it is the truer, and the one which the Intelligences actually use in moving the planets, as we shall say in Book 9, and may therefore be called Angelic, cannot, so to speak, be called Human; that is, accommodated to human capacity and to demonstrating geometrically the motions of the planets and their equations, so that from uniform motions the apparent inequality at any given time can be shown by linear descriptions and diagrams, explained by numbers and extended to future times. For it perpetually disagrees with itself, so much so that no spire

answers to another as regards the interval of time, and none passes into the neighbouring one by a bend of the same size.

[Margin: Kepler's opinion on the spires of the planets.]

On this spire Kepler, *Commentaries on Mars*, chapter 1, speaks thus: "If anyone should put all these together in one bundle, and at the same time believe that the Sun really moves through the zodiac in the space of a year, as Ptolemy and Tycho Brahe believed, then it is necessary to concede that the circuits of the three superior planets through the aethereal space, composite as they are of several motions, are really spiral; not, as before, in the manner of wound thread, with the spires ordered next to one another, but more truly in the figure of a Lenten loaf [panis quadrageſimalis], in about this manner." The same author sets out this figure in

Diagram. A woodcut filling the width of the right column, without a printed title: a single continuous spiral line winding round a small central circle, forming a dense interlaced rosette within an outer boundary formed by its own widest turns. Around the central circle the line makes small inward loops. Labels read:

- centre of the small circle: `a`, with a dot beside it
- within the small circle, left of `a`: a sort that reads as `6` on the block; the text below cites this circle as `a b`, and this sort is not otherwise labelled [?]
- inner loops, right of the small circle: `d`, `e`, `f`
- star on the line, right of the centre: `c`
- star on the line at the outer left: `h`
- lower left, cut in the block: in h est / finis 1596. (at h is the end, 1596)
- lower right, cut in the block: in c / initium 1580. (at c is the beginning, 1580)

Labels not read: none known. No label `b` is separately identifiable on the block unless it is the sort listed above.

notes in the margin, in these words: "This is an accurate delineation of the motions of the star of Mars, which it runs through the aethereal air from the year 1580 to the year 1596, if it is true that the Earth stands still, as Ptolemy and Brahe hold. To continue those motions further would have been tangled, for the connection is infinite, never returning into itself." And after saying that the small circle a b encloses around the Earth a the sphere of Venus, of Mercury and of the elements, he added: "We are forced to ascribe similar spires also to the remaining four, and to Venus indeed much more tangled ones, if the Earth stands still, etc. Copernicus, by attributing one annual motion to the Earth, altogether strips all the planets of these most tangled spires, leading all the planets into single, quite bare orbits, as nearly as possible circular. This one and the same orbit it runs through, in the time just mentioned, as many times as you see here little crowns twisted towards the centre, with one subtracted, namely nine times, while meanwhile the Earth runs through its circle sixteen times." The spire of Mars began in the year 1580 at c and ended in the year 1596

at h. It has been our pleasure to indicate these hypotheses, which we are going to set out one by one in the following Sections.

[Margin: Planetary automata.]

II. From the hypotheses already mentioned, and especially from the ancient or Ptolemaic and Alphonsine one, many have tried to construct machines and automata by which to put the motions of the planets before the eyes, through various armillaries and circles, for any moment of time, and to rival the glass sphere of Archimedes. Especially Ioannulus

[Margin: Automaton of Iannellus of Cremona.]

Torrianus, commonly known as Iannellus of Cremona [Giovanni Torriani], the most ingenious craftsman of Charles V, who built an automaton consisting of fifteen hundred copper circles, gilded all over, with such subtlety that it represented all the celestial motions exactly.

[Margin: Automaton of Christian, King of Norway.]

No less celebrated is that silver automaton [Greek: αὐτόματον (automaton, "self-moving")] of the celestial motions, containing a noble synopsis of them, which Christian, King of Norway and Denmark and founder of the Academy of Copenhagen, sent among other gifts to the Caesar, Duke of the Muscovites, to obtain peace from him. But the barbarous Muscovite, boasting that he could arm two hundred thousand horsemen, kept the other gifts and sent the automaton back to the Dane, declaring that it was useless for him to concern himself about heaven when the two of them had to fight it out with arms over the earth.

[Margin: Automaton of Maximilian and Ferdinand.]

Of a more civilized temper, certainly, Suleiman, Emperor of the Turks, most gladly accepted a very similar instrument from the Emperor Ferdinand, though one built from the design of the Emperor Maximilian.

[Margin: The *Astronomicum Caesareum* of Peter Apian.]

[Margin: The *Aequator Planetarum* of Schöner and Sarzosus.]

[Margin: The *Monalosphaerium* of Fernel.]

III. At less expense, however, though with no less ingenuity, others tried to display the same motions on planispheres by means of paper wheels, and to lessen the labour of astronomical calculation: Petrus Apianus [Peter Apian], in that most artful work which he named the *Astronomicum Caesareum* and dedicated to the Emperor Charles V and his brother Ferdinand, King of the Romans, besides the instrument of the primum mobile; Franciscus Sarzosus [Francisco Sarzosa] of Cella, an Aragonese, in his *Aequator Planetarum*, and Johannes Schöner in his *Aequatorium Astronomicum*; and Ioannes Fernelius [Jean Fernel] of Amiens in his *Monalosphaerium*. All of these, however, rest on Ptolemy's theorics and the Alphonsine Tables. Reinhold attempted something similar in his work on Peuerbach's *Theoricae*, p. 95, and, more successfully and most recently,

[Margin: The *Rota Planetaria* of Cavalieri.]

[Margin: Hypothesis of Šírek.]

Father Bonaventura Cavalieri in his *Rota Planetaria*, which rests on the tables and hypotheses of Lansbergen. Nor does the hypothesis of Širek [Schyrlæi], which uses a transferred ecliptic, serve the heavens; it serves those charts of his, and the calculation to be completed by means of them.

[Margin: Kepler's censure of Apian and the automaton-makers.]

[Margin: Eulogy of Apian.]

IV. But Kepler, having concluded in his *Commentaries on Mars* [Commentario de ſtella Martis], chapter 14, that the planes of the planetary eccentrics are *Atalanta* — that is, that they do not librate or nod this way and that toward north and south but remain in perfect equilibrium, that their inclination to the ecliptic does not vary at all, and that the plane of the Ptolemaic epicycle keeps a perpetual parallelism to the ecliptic — attacked Apian and his imitators, the instrument-makers [organopœios], with a censure perhaps too severe, in these words:

Who now will give me a fountain of tears with which to bewail, as it deserves, the pitiable industry of Apian, who in his Caesarean work, following the authority of Ptolemy, spent so many good hours and squandered so many most ingenious meditations, in order to express with spirals, little crowns, helices and volutes, and that whole labyrinth of most intricate windings, figments of men which nature plainly does not recognize as her own? But that man shows us that with the divine gifts of a most penetrating intellect he could easily have been nature's equal. For the rest, he delighted his own mind with these juggleries (in which he had challenged nature herself), most bravely overcome and cast into diagrams, and from them won the palm of lasting fame, whatever damage that fortune may have done to the works themselves. But what shall we say of the empty art [Greek: κενοτεχνίᾳ (kenotechnia, "empty artifice")] *of the automaton-makers, who fabricate six hundred, indeed twelve hundred wheels, so that they may triumph over latitudes (that is, over human figments) expressed in their works, and raise the price of them?*

So he writes.

SECTIO SECVNDA DE MOTV LONGITVDINIS SATVRNI IOVIS ET MARTIS Eiuſque Theorica, & Hypotheſeos Fundamentis.

Section Two: on the motion in longitude of Saturn, Jupiter and Mars, and its theory, and the foundations of the hypothesis.

CAPVT I. De Antiqua ſeu Ptolemaica Hypotheſi vſq. ad Copernicum vſitata.

Chapter 1: on the ancient or Ptolemaic hypothesis, in use up to Copernicus.

[Margin: Followers of the Ptolemaic hypothesis.]

I. This hypothesis of which we are speaking, begun by Hipparchus, was completed and perfected by Ptolemy, who set it out in Book 9 of [Greek:

περὶ τῆς μαθηματικῆς συντάξεως (peri tēs mathēmatikēs syntaxeōs, "On the Mathematical Composition")], from chapter 5. The Arabs received and developed it, first among them al-Battānī, chapter 45; al-Farghānī, Differentia 12; Jābir ibn Aflaḥ, Book 7 of his *Astronomy*; then, among the Greeks, Proclus, chapter 4 of the *Hypotyposes*; and very many of the Latins, foremost among them Johannes de Sacrobosco and his commentators, listed at the start of Book 1; Georg Peuerbach in his *Theoricae*, with his scholiasts Nonius, Osualdus [Erasmus Oswald Schreckenfuchs], Reinhold and Wurstisen. Likewise Regiomontanus in the *Epitome of the Almagest*, Book 9; Luca Gaurico in his notes on the *Almagest*; Fernel, *Cosmotheoria*, Book 1 from chapter 5, and Book 2, chapter 2; Francesco Maurolico, *Cosmographia*, Dialogue 3, from p. 93; Alexander Piccolomineus [Alessandro Piccolomini] in the *Theorica Planetarum*, from p. 36 to p. 45; Johannes Schöner in the *Aequatorium Astronomicum*; Egnatius Dantes [Egnazio Danti] in the *Tabulae Mathematicae*; Giovanni Antonio Magini in the *Theoricae Planetarum* and in Canon 31 of the *Secunda Mobilia*, though he transferred the numbers of the motions from Copernicus into Ptolemaic form. Besides these, some who are not committed to this hypothesis nevertheless explain it, such as Antonius Deusingus [Anton Deusing]; Kepler, *On Mars*, chapters 2 and 4; Longomontanus, *Theorica*, Book 1, chapter 2, and Book 2 throughout; Petrus Herigonus [Pierre Hérigone], *Cursus Mathematicus*, volume 5, *Theorica*, Book 1, proposition 8; and Pierre Gassendi, *Institutio Astronomica*, Book 2, from chapter 6.

Schema Ptolemaicæ Hypotheſis.

Diagram of the Ptolemaic hypothesis.

[Margin: Deferent.]

II. In the following figure let A be the centre of the world and AB the semidiameter of the ecliptic, and with that interval describe the ecliptic BHCPB; and let the whole CAB be the line of apsides. On it take a centre D, a little distant from the world's centre A, and with the eccentric's semidiameter DF describe the eccentric FKMLF, which is called the deferent [Deferens], because it carries [defert] the epicycle.

[Margin: Epicycle.]

[Margin: Equant.]

Then at the points F and M of its circumference, where it is cut by the line of apsides, make centres, and with the interval of the semidiameter FG on the one side and MV on the other describe the epicycle GQ and, equal to it, OV. After that, above D on the line of apsides, take another centre E, as far from the deferent's centre D precisely as the centre D is from the world's centre A; and with the semidiameter ER, equal to the deferent's semidiameter DF, describe another circle eccentric to the centre of the world, and let it be KOLR. This eccentric is called the equant [Æquans], because the centre F of the epicycle,

carried in the order of the signs by the deferent, moves uniformly about E, the centre of this eccentric, or traverses

Diagram. Woodcut set in the left column: the Ptolemaic hypothesis of the three superior planets. A large outer circle (the ecliptic) has its centre at A. A vertical line of apsides runs from B at the top through G, R, F, E, D, A, O, M and V to C at the foot, with a horizontal diameter through A. Inside are two overlapping eccentrics about D and E. Three epicycles are drawn: one at the top on the line of apsides, with centre F; one at the foot, with centre M; and one displaced to the upper left, with centre I. Straight lines run from A and E to the left-hand side of the outer circle, with a dashed line among them.

- B (top of the outer circle), with a zodiac sign beside it read as ♋
- G (top of the upper epicycle)
- R, F (on the vertical line, inside the upper epicycle)
- b, d (left and right of F, on the upper epicycle)
- Q (foot of the upper epicycle)
- T, u, S, X, Z (upper left, at or near the outer circle, in that order downward)
- I (centre of the displaced epicycle)
- n (lower edge of the displaced epicycle)
- K, N, a (left, one below another, at the inner circles)
- E, D (on the vertical line above A)
- L, Y, m (right, one below another, at the inner circles)
- A (centre)
- H (left end of the horizontal diameter), with a zodiac sign beside it read as ♎
- P (right end of the horizontal diameter), with a zodiac sign beside it read as ♈
- O (top of the lower epicycle)
- M (centre of the lower epicycle)
- V (foot of the lower epicycle)
- C (foot of the outer circle), with a zodiac sign beside it read as ♑

Labels cited in the text but not found on the block: none.

in equal times equal arcs, not of the deferent but of this eccentric, intercepted by lines drawn from the centre E through the centre of the epicycle to the circumference of this second eccentric; such is the arc IR.

[Margin: Why it is called the equant.]

We explained this with another diagram in Book 3, chapter 22, on the occasion of the equant introduced by some into the theory of the Sun. For this reason Ptolemy calls the centre E the point of equality, and the circle described from it [Greek: ἔκκεντρος ὁμαλῆς κινήσεως (ekkentros homalēs kinēseōs, "eccentric of even motion")], that is, the eccentric of regular motion.

De Excentricitatibus & Apogeis.

On the eccentricities and apogees.

[Margin: What the eccentricity is, and how many kinds there are.]

III. With these things laid down, the eccentricity, that is, the distance from the world's centre A, will be, for the centre of the deferent, the line AD; and for the centre of the equant, the line AE, which is always double the eccentricity AD, except in the hypothesis of Mercury. The apogee, or highest apsis, or aux, is considered threefold in this theory.

[Margin: The apogee of the eccentric and its line.]

1. The apogee of the deferent eccentric, which is the point F. Its longer longitude, or greatest distance from the world's centre, is the line AF; opposite it stand the perigee M and the nearer longitude AM.

[Margin: What the mean apogee is, and what its line is.]

2. The mean apogee of the epicycle, which is the point G. Its longer longitude is the line EG; opposite it stands the mean perigee of the epicycle, which is the point O, and its nearer longitude, the line EO. The mean apogee of the epicycle is the point on the epicycle's circumference on which there falls a straight line produced from the equant's centre through the epicycle's centre, as is not only the line EG drawn through F but also E g drawn through I; for it is considered outside the line of apsides as well, in whatever position the epicycle's centre may be, and it is not unique, as the apogee of the eccentric is, but multiple in number.

[Margin: What the true apogee of the epicycle is, and what its line is.]

3. The true apogee of the epicycle, which is the point on the epicycle's circumference on which there falls a straight line produced from the world's centre through the epicycle's centre, such as the line AFG and A I u. So in the first example the same point G is both the mean and the true apogee of the epicycle, just as the point O is both the mean and the true perigee of the epicycle; for they coincide whenever the epicycle's centre is in the apogee or the perigee of the eccentric. But in the second example the true apogee of the epicycle is the point u; hence this too is multiple, and as many in number as the mean apogee is. The point B, however, under which the apogee of the eccentric lies, is not the apogee but the place of the apogee in the ecliptic. For Mercury's eccentricity, however, a small circle must be conceived that carries the equant's centre on its circumference, and whose semidiameter is as large as the least eccentricity.

De Duodecim Lineis in hac Hypotheſi Memorabilibus.

On the twelve lines worth noting in this hypothesis.

[Margin: 1. Line of apsides.]

IV. The line of apsides is the straight line through the centres of the world and of the eccentrics, and through the apogee and perigee of the eccentrics,

produced on both sides as far as the ecliptic; such is the line BC, drawn through the centres A, D, E and the points F, M.

[Margin: Diameter of apsides of the eccentric.]

This line, restricted to the eccentrics, is called the diameter of apsides of the eccentric, as FDM is.

[Margin: 2. Line of the mean apogee.]

The line of the mean apogee is the straight line from the equant's centre, produced through the epicycle's centre as far as the epicycle's circumference; such are both EFG and E I g.

[Margin: 3. Line of the true apogee.]

The line of the true apogee is the straight line from the world's centre, produced through the epicycle's centre as far as the epicycle's circumference, as is both the line AFG and the line A I u.

[Margin: 4. Line of mean motion in the equant.]

The line of the mean motion of the epicycle's centre, considered in the equant, is the straight line from the equant's centre, produced through the epicycle's centre as far as the equant's circumference; such is the straight line EFR, and EI, if you consider the letter I as on the equant's circumference.

[Margin: 5. Line of mean motion in the zodiac.]

The line of the mean motion, or mean place, of the epicycle's centre in the zodiac is the straight line from the world's centre to the zodiac, produced so as to be parallel to the line of mean motion considered in the equant, that is, to the straight line produced from the equant's centre through the epicycle's centre, as far as the zodiac if you please; such is the straight line AZ, which is to be parallel to the line EIS. For in order to have in the zodiac an arc similar to the arc of the equant, it must be measured by an equal angle, and therefore one made at the centre of the zodiac or of the world. So if the epicycle's centre has come from F to I and has completed the equant's arc RI, measured by the angle IER, of 45° for example, then if you produce the straight line EI to S, the arc SB is not of 45°, because the angle BES does not measure it, since it is not made at the centre from which the arc BSZ etc. has been described. But if you draw the already mentioned parallel from A, the angle BAZ measures the arc BZ and is equal to the angle BES on account of the parallelism, by 29 of Book 1 of the *Elements*. The use of this arc will become clear later.

[Margin: 6. Line of the true place of the epicycle's centre.]

The line of the true place of the epicycle's centre, or of the true longitude of the epicycle's centre, is the straight line from the world's centre, produced through the epicycle's centre as far as the zodiac; such is the line AFB, if the epicycle's centre is at F, and AIT, if it is at I.

[Margin: 7. Line of the true place of the planet.]

The line of the true place of the planet is the straight line from the world's centre, produced through the centre of the planet's body as far as the zodiac; such is the line A n X, if the planet is at the point n of the epicycle's circumference.

[Margin: Corollary.]

It is clear, then, that when the epicycle's centre is in the apogee of the eccentric, all of the first six lines run together into one and the same line, though not taken at its full extent; indeed the seventh does too, if the planet is then in the apogee or perigee of the epicycle. And say the same, proportionally, if the epicycle's centre is in the perigee of the eccentric.

[Margin: 8. Line: diameter of apsides of the epicycle.]

The diameter of apsides of the epicycle is the straight line drawn from the true apogee of the epicycle to its true perigee through its centre, in the plane of the circle around whose circumference the planet moves; such is G F Q. This line does not always coincide with the diameter of apsides of the eccentric; indeed, it is not always in the plane of the eccentric that carries the epicycle, but is mostly inclined to it, as we said in Section 1, chapter 7, numbers 9 and 10.

[Margin: 9. Line: diameter of mean longitudes of the epicycle.]

The diameter of mean longitudes of the epicycle is the straight line drawn to opposite points of the circumference through the epicycle's centre, in the plane in which the epicycle's diameter of apsides lies, and at right angles to that same diameter; such is the straight line b F d. It is called "of mean longitudes" because its end-points b and d lie at the middle of the elongation from the true apogee, and divide in two the semicircle of the whole elongation, G b Q or G d Q.

[Margin: 10. Line: diameter of mean longitudes of the eccentric.]

The diameter of mean longitudes of the eccentric is the straight line drawn to opposite points of the circumference through the deferent's centre, in the plane of the deferent, at right angles to the line of apsides; such is the straight line NDY. It is so called both because at its ends the epicycle's centre stands midway between the apogee and perigee of the eccentric, and because at these points occurs the [Greek: πάροδος μέσος (parodos mesos, "mean passage")], that is, the mean transit from the greatest of the equations of the centre or toward the greatest; for Reinhold shows in his work on Peuerbach's *Theoricae*, p. 100, that this reaches its greatest at these points.

[Margin: 11. Line of mean longitude, or distance.]

The line of mean longitude, taken for the average distance of the epicycle's centre from the world's centre, is the straight line drawn from the world's centre to the epicycle's centre and equal to the eccentric's semidiameter; such is the line A a or A m, if the epicycle's centre is at a or at m. These points are determined by a straight line drawn at right angles through the line of apsides and bisecting the eccentricity of the deferent; such is the straight line a m, which some therefore take for the line of mean longitudes.

[Margin: 12. Line: the radius.]

Finally, the radius is the semidiameter of the eccentric, and it too is equal to the average distance of the epicycle's centre from the world's centre: as are DF, DN and DY.

The remaining definitions, concerning the arcs of the motions and of the equations, we shall give more suitably below.

Eadem Hypotheſis per Orbes Solidos explicata.

The same hypothesis explained through solid orbs.

V. Here we shall set out solid orbs: not those concentric with the world which Aristotle with Eudoxus assumed, or those which Fracastoro assumed in his *Homocentrica*, but those which the Arabs and their principal imitator Peuerbach introduced into Ptolemy's bare hypothesis, abstracted from this solidity. In the following diagram, then, let there be

Diagram. Woodcut set in the left column: the same hypothesis in solid orbs. A heavy black crescent lies between the outer circle and an inner eccentric circle, thin at the top and broad at the foot. Inside it is a white ring holding the two epicycles, at the top and at the foot on the vertical line. Inside that is a second black crescent, broad at the top and thin at the foot, around a white central circle. A horizontal line runs across the figure through A, a shorter one through D from N to Y, and a vertical line through the centres. Two thin circles run through the white ring.

- B (top, above the black ring)
- G (top of the upper epicycle)
- R, F (on the vertical line, inside the upper epicycle)
- Q (foot of the upper epicycle, at the edge of the inner black crescent)
- K, N (left, one below the other, in the white ring)
- Z (left, at the outer edge of the inner black crescent)
- E, D (on the vertical line, E at the edge of the central circle, D below it)
- T (right, at the outer edge of the inner black crescent)
- L, Y (right, one below the other, in the white ring)
- H (left end of the horizontal line, outside the black ring)
- A (centre)
- P (right end of the horizontal line, outside the black ring)
- X (foot of the central circle)
- O (top of the lower epicycle)
- M (centre of the lower epicycle)
- V (foot of the lower epicycle)
- C (foot, below the black ring)

Labels cited in the text but not found on the block: none.

the line of apsides BAC, on which lie the centres of the world A, of the deferent D, and of the equant E; and let the straight line HP cut it in two at right angles at the centre A. From the centre A describe the circumference BHCP, and from the centres D and E the eccentrics as above, namely the deferent FKML and the equant RKOL; then from the points F and M the equal epicycles GQ and OV. After that, from the centre D, with the interval DG, describe the circumference GV, passing through G and V, the apogees of the epicycles, and colour the space between it and the circumference BHCP black. From the same centre D describe another circumference QZOT through Q and O, the perigees of the epicycles; and from the centre A describe the circumference EX,

which encloses the three centres within its circle, in such a way that the upper part EQ is wider than the lower XO; and fill the space enclosed between it and the circumference QZOT with black. Finally, through the centre D draw NDY, the diameter of mean longitudes of the eccentric. When this has been done, 5 solid orbs are to be conceived in this plane figure, belonging to the theory of Saturn, Jupiter, Mars and Venus; for Mercury requires several more.

[Margin: 1. Orb.]

The first orb is the innermost and white, EX, which consists of the lower spheres enclosed in the sphere of these planets, namely the elementary sphere, that of the Moon, etc.

[Margin: 2. Orb carrying the apogee.]

The second orb is the outermost and black, concentric with the world in its convex surface BHCP but eccentric in its concave surface GV. This orb carries the apogee of the eccentric in the order of the signs from B to H, about the centre A of the ecliptic and of the world, and it moves in the plane of the ecliptic, granted that F, the apogee of the eccentric, is not in this plane but in the plane of the deferent, which, as I said in Section 1, chapter 7, numbers 9 and 10, is inclined to the plane of the ecliptic. And although the plane of the ecliptic is cut by the plane of the deferent at the centre of the world, a common section indicated by the line HAP, yet because the centre D of the deferent is outside the centre of the ecliptic, it follows by Euclid's definitions in Book 3 of the *Elements* that the upper segment of the deferent is the larger — the one, that is, in which the centre D lies, and whose height is AF — and the lower segment, from A to M, the smaller.

[Margin: Path of the apogee.]

And because the apogees of the three superior planets are perpetually toward the north, it comes about that the centre of the deferent is toward the north, and the greater part of the deferent's axis likewise toward the north. Finally, it follows from this that the apogee of the eccentric, under the motion of the orb BHCP, describes a circle parallel to the ecliptic, and never passes through the ecliptic.

[Margin: 3. Orb carrying the perigee.]

The third orb is the innermost of the black ones, concentric with the world in its concave surface EX but eccentric in its convex surface QZOT. It carries the perigee M of the eccentric in the order of the signs; indeed, by supporting the orb of the eccentric, it helps the second orb to move the apogee at an equal pace. Moreover, the perigee of the three superior planets is always to the south, and describes a circle parallel to the ecliptic, and never crosses the ecliptic. And the thicker part of this orb always lies beneath the narrower part of the outermost orb, and the reverse.

[Margin: 4. Eccentric orb carrying the epicycle.]

The fourth orb is white, and simply eccentric to the world, in both its convex surface GV and its concave surface QZOT. In its thickness, through the middle, is described the eccentrepicycle, or [Greek: ἐπικυκλόφορος (epikyklophoros,

"epicycle-carrier")], or deferent, carrying the epicycle in the order of the signs from F to K; and in the same thickness the equant RKOL is imagined as drawn. The equant, however, requires no really distinct orb, because no motion is performed through it; only the arcs are marked out in it which are the measure of the uniform motion made by the deferent through the force of the fourth orb.

[Margin: 5. Orb: the epicycle.]

The fifth orb is the epicycle GQ or OV, wholly solid and hollowed out by nothing except the globe of the planet, whose centre, fixed in its circumference, it carries in the order of the signs, performing its motion about the centre of the epicycle itself; and with the motion of the eccentric there moves in it also the mean and true apogee of the epicycle. And this too is eccentric to the world.

De Motu Apogeorum eorumq. Aequatione.

On the motion of the apogees and their equation.

[Margin: Motion of the apogee of the eccentric.]

VI. The motion of the apogee of the eccentric is uniform and needs no equation. It is the motion of which I spoke in Section 1, chapter 7, number 8, and of whose path and instruments, through solid orbs 2 and 3, I spoke a little earlier in number 5. This motion is counted from the beginning of Aries, P, in the order of the signs, that is, from the vernal equinox.

[Margin: Motion of the mean apogee of the epicycle.]

The motion of the mean apogee of the epicycle, by contrast, is irregular and needs an equation; and this motion is counted from the true apogee of the same epicycle in the order of the signs. Here I assume the definitions of these apogees given at the end of number II, and those of lines 2 and 3 given in number III. Now, so that this motion and its equation may be grasped, in the following figure let BAG be the line of apsides, on which lie three centres: of the world A, of the deferent D, and of the equant E. From the world's centre describe the circumference GHBK, and from the centre D the deferent FTLN. Taking as centres the four cardinal points of its circumference, that is, the apogee F, the perigee L, and the points of mean longitudes T and N, describe four equal epicycles GQ, CR, PO and CS; and, choosing four centres I around the middles of the eccentric's four quadrants, describe four other epicycles equal to the first. Then from the centre D draw two circumferences, one through the apogees or apices of the epicycles, which is to be GCPCG, the other through the perigees or lowest curvatures, which is to be QRO SQ. Next draw the diameter of mean longitudes, but as far as the circumferences of two epicycles, which is to be C TDNC; and from the centre D, through the centres I of the other epicycles, draw the straight lines D I C. Finally, through the centres of all the epicycles, as far as their circumferences, draw pairs of straight lines: one from the world's centre, namely the line of the true apogee of the epicycle, which are to be AIV,

AT V, ANV; and the other from the equant's centre, namely the line of the mean apogee of the epicycle, which are to be EIM, ETM, ENM.

[Margin: What the point of contact or of concavity is.]

When this has been done, the point on the epicycle's circumference on which there falls a straight line drawn from the deferent's centre through the epicycle's centre is called the point of contact and of concavity; such are the points G, P and the six points C. It is called the point of contact because this point alone of the epicycle's circumference always touches the concave surface of the outermost solid orb, nor is that surface touched by the mean apogee or the true apogee, or other points, except when they come together at this point, as at G and P. It is also called the point of concavity,

Diagram. Woodcut set in the left column: the eight-epicycle figure of the motion of the mean apogee. A heavy black crescent lies between an outer circle and an inner eccentric circle, thin at the top and broad at the foot. The vertical line of apsides runs from G at the top to B at the foot, and a horizontal line of mean longitudes runs through D. Inside the black crescent stands a ring of eight small circles, the epicycles: one at the top around F, one at the foot around L, one each at left and right around T and N, and four on the diagonals, each around a centre I. Each of the six epicycles other than the top and foot carries the three letters V, C, M in a group on its outer edge. Straight lines cross the central circle from the epicycles' centres to the two points E and A on the vertical line. Two thin circles pass through the epicycles.

- G (top, on the vertical line, above the black ring)
- F (on the vertical line, inside the upper epicycle)
- Q (on the vertical line, at the foot of the upper epicycle)
- E (on the vertical line, directly below Q)
- D (centre of the figure, on the vertical line, at the crossing of the horizontal line)
- A (on the vertical line, below D)
- O (on the vertical line, at the head of the lower epicycle)
- L (on the vertical line, inside the lower epicycle)
- P (on the vertical line, at the foot of the lower epicycle)
- B (foot, on the vertical line, below the black ring)
- H (far left, outside the black ring)
- K (far right, outside the black ring)
- T (left epicycle, its centre)
- N (right epicycle, its centre)
- R (inner edge of the left epicycle)
- S (inner edge of the right epicycle)
- I (four times: the centres of the diagonal epicycles, upper left, upper right, lower left, lower right)
- V, C, M (a group on the outer edge of each of the six epicycles other than the top and foot)

because with this point, as with a tip, the semidiameter of the eccentric seems to hollow out or mark out the outermost solid orb, or because it travels along that orb's concave surface GCPCG. With these things laid down, the rules for the motion of the mean apogee are to be given.

[Margin: 1. Rule on the motion of the mean apogee.]

First: when the epicycle's centre is placed at the deferent's apogee F or perigee L, the mean apogee and the true apogee and the point of contact come together in one point, G or P. No equation is needed, and they stand in the same place under the zodiac, under which the apogee or perigee of the eccentric stands.

[Margin: 2. Rule.]

Second: when the epicycle's centre is placed at the points of mean longitudes, T or N, the point of contact C stands off by an equal arc of the epicycle from the mean apogee M on one side and from the true apogee V on the other, and by the greatest arc by which it can stand off. Therefore the mean apogee is at its greatest distance from the epicycle's true apogee, and needs the greatest equation to be reduced to the true one.

[Margin: 3. Rule.]

Third: when the epicycle's centre is placed in the eccentric's first quadrant, which is FT, the mean apogee recedes further in the order of the signs from the point of contact than the point of contact does from the true apogee. In the second quadrant, TL, the mean apogee approaches the point of contact, and is carried against the order of the signs until it joins it at L. In the third quadrant, LN, the mean apogee M recedes from the point of contact C, likewise against the order of the signs. In the fourth, finally, NF, it again approaches the point of contact, going in the order of the signs, until it joins it at F.

[Margin: 4. Rule and 2 corollaries.]

Fourth, therefore: in the upper part of the eccentric, NFT, the mean apogee moves along the epicycle's circumference in the succession of the signs; in the lower part, TLN, against the series of the signs.

[Margin: Why and where the planet's motion on the epicycle is faster or slower.]

Moreover, it follows from this that the planet's motion on the epicycle, which is uniform with respect to the mean apogee, from which it recedes through equal arcs of the epicycle in equal time, nevertheless becomes irregular because of the irregular motion of the mean apogee. It becomes faster in the upper part of the eccentric and slower in the lower, because there the mean apogee goes along with the motion of the epicycle's centre, whereas here it resists that motion and is carried in the opposite direction. Wurstisen explains this with an excellent comparison: "For if we must walk," he says, "on the condition that you always keep a thousand paces ahead of me, then surely, if I follow you quickly, you must run on ahead faster, so as to keep an equal interval." The same is therefore necessary for the planet when the mean apogee, from which it recedes uniformly, pursues it faster in the upper hemisphere of the eccentric,

the motion being made in the same direction in which the epicycle's centre moves. But when the mean apogee draws back in the opposite direction, as happens in the lower hemisphere, the planet must move more slowly, so as to preserve the uniformity of the motion by which it stands off from the mean apogee. Although these points also concern the planet's own motion, of which below, they had to be touched on here beforehand because of their affinity.

[Margin: Equation of the centre on the epicycle.]

VII. The equation of the mean apogee [Aequatio Apogei medij], or the prosthaphaeresis of the motion of the mean apogee, is called the equation of the centre on the epicycle [Æquatio Centri in Epicyclo]. It is the smaller arc of the epicycle's periphery between the mean and the true apogee, or the difference of these two apogees counted in the already mentioned arc, such as the arc MCV; or it is the reduction of the mean apogee to the true one, made by adding or subtracting the already mentioned arc.

[Margin: Rule for this equation.]

When the epicycle's centre is placed at the eccentric's apogee F or at its perigee L, no equation of this kind is needed; but at the points of mean longitudes, T and N, it is at its greatest. Next, in the first semicircle of the eccentric, counted in the order of the signs, that is, in the semicircle FTL, this equation is to be subtracted from the mean apogee, so that it may be reduced to the true one; in the second, LNF, it is to be added.

[Margin: The angle that measures this equation.]

The immediate measure of this equation is the angle formed at the epicycle's centre by straight lines drawn out from it, one to the mean apogee and the other to the true apogee, namely the angle MIV, or MTV, or MNV. Its mediate measure is the angle vertically opposite and equal to that one, which is formed at the epicycle's centre by straight lines drawn from it, one to the centre of the equant and the other to the centre of the world, such as the angles AIE, ATE and ANE. But since the equation of the centre outside the epicycle also consists in these angles, and is of the same quantity as the equation of the centre on the epicycle, we shall more conveniently teach below the way of finding these angles, after the motion of the epicycle's centre has been explained.

De Motu Centri Epicycli, ſeu Anomaliæ Excentrici, ſeu Longitudinis eiuſdem, Et ipſius Aequatione.

On the motion of the epicycle's centre, or the anomaly of the eccentric, or its longitude, and on its equation.

VIII. The motion of the epicycle's centre, carried by the deferent in the order of the signs, in Greek [Greek: περιδρομὴ κατὰ μῆκος (peridromē kata mēkos, "circuit along the length")], has various names and senses, according to whether it is considered as mean and uniform or as apparent to us and non-uniform; and either in the equant or in the zodiac; and finally according to the different terms from which the start of the count is taken. So the first figure set out in

number 2 is repeated here, with most of the definitions explained in numbers 3 and 4; go on to the following definitions.

Diagram. Woodcut set in the right column: the Ptolemaic hypothesis repeated, with an outer circle bearing signs of the zodiac at its four cardinal points, an eccentric circle, an equant circle, and three epicycles: one at the top around F, one at the foot around M, and one at upper left around I. A vertical line of apsides runs from the top to the foot through E, D and A. Straight lines run from A, D and E up and to the left through or beside the epicycle at I to the outer circle, one of them dashed, and horizontal or nearly horizontal lines run from the vertical line to the left and right of the figure.

- B, with the sign ♋ (top, outside the outer circle)
- G (top of the upper epicycle)
- R, F (on the vertical line, inside the upper epicycle)
- b, d (left and right edges of the upper epicycle)
- Q (on the vertical line, below the upper epicycle)
- T, u, S, X, Z (upper left, at or outside the outer circle, going downward)
- g (at the left edge of the upper-left epicycle, beside X and S)
- n, beside a small star marking the planet (left, at the foot of the upper-left epicycle, beside Z)
- I (centre of the upper-left epicycle)
- K, N, a (left, one below the other, at the ends of the horizontal lines)
- E, D, A (on the vertical line, going downward)
- L, Y, m (right, one below the other, at the ends of the horizontal lines)
- H, with the sign ♎ (left, outside the outer circle)
- the sign ♈, with P (right, outside the outer circle)
- O, M, V (on the vertical line, in the lower epicycle, going downward)
- the sign ♑, with C (foot, outside the outer circle)

[Margin: Mean anomaly of the eccentric, or mean centre.]

The mean anomaly of the eccentric [Anomalia media Excentrici], or, as the Alphonsine astronomers say, the mean centre [Centrum Medium] (understand this of the epicycle's centre), is the mean motion of the epicycle's centre counted from the eccentric's apogee in the order of the signs. If it is viewed in the circle of the equant, it is the arc of the equant counted from the equant's apogee as far as the line of mean motion of the epicycle's centre, such as the arc RI, contained between the lines ER and EI. The same motion viewed in the zodiac is the arc of the zodiac counted from the line of apsides in the order of the signs as far as the line of mean motion in the zodiac, that is, as far as the parallel to the line drawn from the equant's centre through the epicycle's centre, this parallel being produced from the world's centre as far as the zodiac: such is the arc BZ, between the lines AB and AZ, AZ being parallel to EIS. Why this parallel is used I said in number 4, definition 5.

The true anomaly of the eccentric [Anomalia vera Excentrici], or, with the Alphonsine astronomers, the true centre [Centrum verum], or coequated centre [centrum coæquatum], is the true motion of the epicycle's centre, counted in

the order of the signs from the eccentric's apogee; or it is the arc of the zodiac counted in the order of the signs from the line of apsides as far as the line of true motion of this centre, that is, as far as the line produced from the world's centre through the epicycle's centre to the zodiac, such as the arc BT, between the line AB and AIT.

[Margin: True anomaly of the eccentric, or true centre.]

[Margin: Mean longitude of the eccentric, and its mean place.]

The mean longitude of the epicycle's centre [Longitudo Media centri Epicycli], or mean longitude of the eccentric [Longitudo media Excentrici], which is also called the planet's mean longitude, is the mean motion of the epicycle's centre counted in the order of the signs from the beginning of longitude, that is, either from the vernal equinox or, with Copernicus, from the first star of Aries; or the sum of the longitude of the eccentric's apogee and the mean anomaly of the eccentric; or it is the arc of the zodiac counted in the order of the signs from the beginning of longitude as far as the line of mean motion, such as the arc PBZ, if P is the beginning of longitude and the point Z is the mean place of the epicycle's centre.

[Margin: True longitude of the eccentric.]

The true longitude of the epicycle's centre [Longitudo vera centri Epicycli], or true centric longitude [longitudo vera centrica], or coequated longitude of the centre [longitudo centri coæquata], is the true motion of the epicycle's centre counted in the order of the signs from the beginning of Aries as far as the line of the true place of the same centre; or the sum of the true longitude of the eccentric's apogee and the true anomaly of the same eccentric; or it is the arc of the zodiac counted in the order of the signs from the beginning of Aries as far as the line of true motion of the epicycle's centre, such as the arc PBT.

[Margin: True place of the epicycle's centre.]

And the point T is the true place of the epicycle's centre under the zodiac, or the planet's true eccentric place.

[Margin: Corollary.]

Hence it happens that if the mean longitude of the eccentric is known, then when the motion of the apogee, or the arc PB, which is found in the tables, is taken away from it, the mean anomaly of the eccentric, or the arc BZ, becomes known. Or, if this is known, adding the motion of the eccentric's apogee to it composes the mean longitude of the eccentric. Likewise, if the motion of the apogee is taken away from its true longitude, its true anomaly becomes known; and conversely, if the motion of the eccentric's apogee is added to the true anomaly, the true longitude of the eccentric becomes known.

[Margin: What the equation of the centre in the zodiac is.]

The equation of the centre in the zodiac [Aequatio centri in Zodiaco], or equation of the anomaly of the eccentric [Aequatio Anomaliæ Excentrici], which when applied to the eccentric's mean longitude is called the equation of the longitude of the eccentric, in Greek [Greek: προσθαφαίρεσης μήκους (prosthaphairesis mēkous, "prosthaphaeresis of longitude")] [recte:

προσθαφαίρεσις], is the difference between the mean and the true anomaly of the epicycle's centre, or between the mean and the true centre. Referred to longitude, it is the difference between the mean and the true longitude; or it is the arc of the zodiac between the mean and the true place, or between the lines of the mean and the true place of the epicycle's centre, such as the arc TZ, between the lines AZ and AT.

[Margin: The angle that measures this equation.]

Its measure is the angle formed at the world's centre by the lines of the mean and the true place, etc., such as the angle TAZ; and to this the angle AIE is equal, because of the parallelism of the lines EIS and AZ.

[Margin: Rule for this equation.]

The equation of the centre in the zodiac is to be subtracted from the mean anomaly in the first semicircle of this anomaly, that is, in the semicircle BHC, because T, the true place of the epicycle's centre, precedes the mean place Z, or stands off from it against the order of the signs. So, when the arc ZT is subtracted from the arc ZB, the true anomaly TB remains. But in the second semicircle it is to be added, because the true place follows after the mean, or stands off from it in the order of the signs.

[Margin: 2. Rule.]

The equation of the centre in the zodiac is nil when the epicycle's centre is at F, the eccentric's apogee, or at M, the perigee. It grows from the eccentric's apogee until the epicycle's centre is at the first point of mean longitude, namely at the point N, where it becomes greatest, as Reinhold has demonstrated on Peuerbach's *Theoricae*, p. 100. From there, once it has passed that point, it decreases until at M it again becomes nil; and from there, taking increase again, it grows as far as the point Y, of the second mean longitude, where it becomes greatest, and from there it decreases continuously until it vanishes at F.

[Margin: 3. Rule.]

Finally, at points of the eccentric diametrically opposite it is equal; as also at points equally distant either on both sides from the apogee or on both sides from the perigee of the eccentric.

Yet the true motion of the epicycle's centre is slowest at the apogee and fastest at the perigee of the eccentric. This will be clear even from the following: if, having divided the equant into equal arcs (since the uniformity of this motion is viewed in it), you draw through the points of division the lines of true motion, that is, straight lines through the epicycle's centre to the zodiac, you will see that the arcs of the zodiac nearer the apogee are smaller, and larger near the perigee.

De Motu Planetæ in Epicyclo, ſeu de Anomalia Orbis, eiuſque Aequationibus.

On the planet's motion on the epicycle, or on the anomaly of the orb, and its equations.

[Margin: Mean anomaly of the orb, or mean argument.]

IX. The mean anomaly of the orb [Anomalia Orbis media], or the anomaly of commutation [Anomalia Commutationis] as Copernicus says, or, as the Alphonsine astronomers say, the mean argument [Argumentum Medium], in Greek [Greek: κίνημα τῆς ἀνωμαλίας (kinēma tēs anōmalias, "motion of the anomaly")], is the planet's mean motion on the epicycle about the epicycle's centre, counted in the order of the signs from the epicycle's mean apogee; or it is the arc on the epicycle's periphery, counted in the order of the signs from its mean apogee as far as the centre of the planet's body. In the preceding figure, such is the arc Gb, if the epicycle's centre is at F and the planet at b; or the arc gn, if the epicycle's centre is at I and the planet at n.

[Margin: What the true argument is.]

The true anomaly of the orb [Anomalia orbis vera], or true argument [Argumentum verum], or coequated argument [Argumentum coæquatum], is the planet's true motion on the epicycle, counted in the order of the signs from the true apogee; or it is the arc of the epicycle's periphery counted in the order of the signs from the epicycle's true apogee as far as the planet, such as the arc Gb, when the epicycle's centre is at F, the eccentric's apogee, for then the mean and the true apogee of the epicycle are the same, at G; or the arc ugn, if the epicycle's centre is at I and the planet at n.

[Margin: The harmony between the planet's motion on the epicycle and the motion of the Sun.]

Further, the planet's motion on the epicycle, although when counted from the true apogee it is irregular, and quicker so long as the epicycle's centre is in the upper semicircle of the eccentric, the one containing the equant's centre, and slower in the lower, for[59] the reason already set out at the end of number 6, is nevertheless uniform when counted from the epicycle's mean apogee, and is tempered in admirable harmony to the Sun's mean motion, by which the Sun is elongated from the mean conjunction with the planet. For the planet's mean motion on its epicycle is as great as the Sun's elongation, according to its mean motion, from the mean conjunction with the planet. From this there follow notable corollaries and 6 rules.

[Margin: 1. Rule.]

1. At every mean conjunction of the planet with the Sun, that is, one viewed according to the Sun's mean motions, the planet is at the true apogee of the epicycle; and at every mean opposition with the Sun, the planet is at the true perigee of the epicycle. So Ptolemy, Book 10, chapter 6, and there Regiomontanus, propositions 9 and 11; granted that Peuerbach, and following him Reinhold, Wurstisen, Magini and others, have said that this happens at the mean perigee. I shall refute them in Scholium 5.

[Margin: 2. Rule.]

[59] *ob* is printed twice here, at a line end and at the start of the next line

2. One whole revolution of the planet on the epicycle takes as much time as passes from one of its mean conjunctions to the next mean conjunction with the Sun, or from one mean opposition to the other opposition.

[Margin: 3. Rule.]

3. The planet's two mean motions, namely of longitude and of argument, or of the epicycle's centre on the eccentric and of the planet's centre on the epicycle, taken together, equal the Sun's mean motion made in the same time.

[Margin: 4. Rule.]

4. When the planet's mean motion in longitude, or the mean longitude of the epicycle's centre, is subtracted from the Sun's mean motion made in the same time, there remains and becomes known the planet's mean motion on the epicycle, or mean argument, or mean anomaly of the orb. Therefore no special tables are needed for it; the tables of the mean motions of the Sun and of the epicycle's centre in longitude suffice. Conversely (which serves as a check of the calculation), if you subtract the planet's mean argument from the Sun's mean motion, there remains the planet's mean motion in longitude, or the mean motion of the longitude of the eccentric; and if to the planet's mean motion in longitude you add the mean argument, the result is precisely the Sun's mean motion in longitude.

[Margin: 5. Rule.]

5. From these things, and from what was said at the end of number 8 about the slower motion of the epicycle's centre in the upper part of the eccentric and the faster in the lower, and from what was said about the quicker motion of the planet on the epicycle in the upper and the slower in the lower semicircle of the epicycle, it follows that when and by how much the motion of the epicycle's centre on the eccentric is slower, then and by so much the planet's motion on the epicycle becomes faster, because the Sun then joins the planet sooner. Conversely, when and by how much the motion of the epicycle's centre is faster, then and by so much the planet's motion on the epicycle becomes slower, and the Sun overtakes the planet more slowly.

[Margin: 6. Rule.]

6. The line drawn from the epicycle's centre to the planet at every mean conjunction or opposition [☌, ☍] with the Sun coincides with the line of mean motion of the Sun; but outside conjunction and opposition [☌, ☍] it is parallel to that line. So Ptolemy, Book 10, chapter 6, and Regiomontanus there, in the *Epitome*, proposition 10. An example, in the diagram to be set in Scholium 5, is the line IR, compared with the line AH of the Sun's mean motion.

[Margin: What the equation of the argument is.]

The equation of the argument [Aequatio Argumenti] is not the equation of the epicycle's centre, although it partly depends on it. It is the equation by

which the planet's mean motion in longitude is finally equated, so that its true place in the zodiac may be known. This equation is the difference between the true place of the epicycle's centre and the true place of the planet in the zodiac; or it is the arc of the zodiac between the true place, or the line of the true place, of the epicycle's centre and the true place, or the line of the true place, of the planet, such as the arc XT, between the lines AIT and AnX.

[Margin: The angle that measures this equation.]

Its measure is the angle formed at the world's centre by two straight lines produced as far as the zodiac, one through the epicycle's centre and the other through the centre of the planet's body: such an angle is TAX. The rules for this equation are written below.

[Margin: 1. Rule for the equations of the argument.]

1. When the epicycle's centre is at F, the eccentric's apogee, and the centre of the planet's body at G, the apogee, or at Q, the mean perigee of the epicycle, it is also at the true one, and no equation of the centre or of the argument is needed. The mean place of the epicycle's centre is the true place both of that centre and of the planet, and the same as the place in the zodiac under which the eccentric's apogee stands. Say the same if the epicycle's centre is at M, the eccentric's perigee, and the planet at V, the apogee, or at O, the mean and then also true perigee of the epicycle; but then the planet's true place is the one under which the eccentric's perigee stands.

[Margin: 2. Rule.]

2. When the epicycle's centre is at F, the eccentric's apogee, or at M, the perigee, but the planet is away from the epicycle's mean apogee, as if it is at b or at d, no equation of the centre is needed, only the equation of the argument. But this is then obtained more easily by solving one triangle, in which there are given: the distance of the epicycle's centre from the world's centre, namely either AF, consisting of the radius DF and the deferent's eccentricity AD, or AM, the remainder of the radius DM after the eccentricity AD has been taken from it; the epicycle's semidiameter, as the other side; and the angle contained by these, which is the complement to a semicircle of the argument, true and mean at that time, if the argument does not exceed 6^s, or its excess above a semicircle, if the argument exceeds 6^s. From these data the angle opposite the epicycle's semidiameter is gathered, and this is the equation of the argument; for it, consult rule 4, to be given in number 10.

[Margin: 3. Rule.]

3. When the epicycle's centre is away from the eccentric's apogee and perigee, and the planet away from the epicycle's true apogee or perigee, an equation is needed both of the centre and of the argument, or orb: as if the centre is at I and the planet at g or at n.

[Margin: 4. Rule.]

4. The equation of the argument is greatest when the epicycle's centre is at M, the eccentric's perigee, and the planet is at the point of the epicycle's periphery at which a line drawn from the world's centre to the centre of the planet's body touches the epicycle, as we shall say in chapter 11, where there will be a diagram for this matter.

[Margin: 5. Rule.]

5. The equation of the argument is to be added to the true place of the centre in the first semicircle of the anomaly of the orb, or of the epicycle; but in the second it is to be subtracted, so that the planet's true place under the zodiac, as seen by a terrestrial observer, may be had. For instance, if the planet is at n, add to the arc PBT the arc XT, so that the arc PBX results, which is the planet's true longitude, counted from the beginning of Aries, P. Nothing else, therefore, is required, except that we give the whole series of the geometrical calculation for finding the planet's true motion in longitude, assuming the mean motions and the commensurations of the orbs, which are to be set out at the end of the chapter.

Methodus Calculi Geometrici Pro Vero Motu Planetæ in Longitudinem.

Method of the geometrical calculation for the planet's true motion in longitude.

X. Let the explanation of the diagram given in number 2 of this chapter be repeated here; and with this assumed, let the planet be placed at n and the epicycle's centre at I. Then follow this method.

[Margin: 1. Step of the calculation.]

First, for the given time, find from the Ptolemaic or Alphonsine roots, and from the tables of mean motions, the mean or uniform motion both of the eccentric's apogee, namely the arc BP, and of the longitude or centre, namely the arc PBZ. Subtract the apogee's motion from the centre's mean motion, and there will remain the mean anomaly of the centre, that is, the arc BZ, and so also the angle BAZ, to which the angle REI is equal; and the complement of this to two right angles, or to 180°, is the angle IED.

[Margin: 2. Step.]

Second, in the triangle IED there are given: the angle IED, from the first step; and, from the measures of the hypothesis to be given at the end of the chapter, both the eccentricity DE, which is as great as AD, and the radius DI, in the same kind of parts. So by the rules of rectilinear triangles find the angle DIE, which is the physical part of the equation of the centre; keep it in reserve.

[Margin: Physical equation.]

The sum of this and the angle IED is equal to the external angle ADI, by proposition 32 of Euclid's first book.

[Margin: 3. Step.]

Third, in the triangle ADI there are given the angle ADI, the eccentricity AD and the radius DI. So by the rules of triangles find both the base AI, that

is, the distance of the epicycle's centre from the centre of the universe, which keep in reserve, and the angle AID, which is the optical part of the equation.

[Margin: Optical equation.]

Join this to the physical equation, and there will result the whole equation of the centre in the zodiac, that is, the angle AIE, to which, because of the parallelism, the angle TAZ is equal by proposition 29 of Euclid's first book, measuring the arc TZ of the zodiac. Since, then, the mean anomaly was in the first semicircle BHC, or less than 6^s, subtract the equation of the centre, that is, the arc TZ, from the mean anomaly, and you will have the true or equated anomaly of the centre, namely the arc BT. Again subtract the same equation from the mean longitude of the centre, and you will have the true longitude of the centre, or the true centre, that is, the arc PBT. But if the anomaly had been in the second arc CPB, the equation would have had to be added.

[Margin: 4. Step.]

Fourth, having drawn from the world's centre A the straight line AnX through the centre of the planet's body, and to that centre the epicycle's semidiameter In, find in the proper tables the mean motion of the anomaly of the orb, which Ptolemy calls the motion of the inequality; or, if the tables lack this motion, as the Alphonsine do, find for the given time the Sun's mean motion, and from it take away the true motion of the centre, and there will remain the true argument, that is, the arc ugn of the epicycle, counted from the true apogee u to the planet. Or (which comes to the same thing, but by a longer way) take away from the Sun's mean motion the mean motion of the centre, and there will remain the mean argument, that is, the arc gn, counted from the mean apogee g. To this add the equation of the centre, that is, the arc gu, which the angle gIu measures, as great as the angle AIE vertically opposite to it, which we said is the equation of the centre in the zodiac; and there will result the true or coequated argument, namely the arc ugn, as above. But if the epicycle's centre were in the second arc CPB, then the equation of the centre on the epicycle would have to be subtracted from the mean argument, so as to have the true argument.

[Margin: 5. Step.]

Fifth, subtract the true argument from 180°, and you will have the angle AIn in the triangle AIn, by proposition 13 of Euclid's first book. With this, and with the epicycle's semidiameter In, which is given from what was said in number 9, and with the distance AI found above in step 3, find by the analysis of triangles both the planet's distance from the Earth, that is, the side An, which serves for finding parallaxes, and the angle IAn, that is, TAX, measuring the zodiac's arc TX, that is, the equation of the argument. Since we are dealing with the first semicircle of the anomaly, add this to the true longitude of the centre, or the true centre PBT, and there will result the planet's true longitude in the zodiac, that is, the arc PBX. But if the epicycle's centre were in the second arc of the anomaly, the equation of the centre in the zodiac would have to be added,

while the equation of the centre on the epicycle, just like the equation of the argument, would have to be subtracted.

The reduction of the planet's place in the zodiac from its orbit to the ecliptic depends on the planet's latitude, of which below.

Menſuræ & Numeri ad Ptolemaicam & Alphonſinam Hypotheſim ſpectantes.

Measures and numbers pertaining to the Ptolemaic and Alphonsine hypothesis.

XI. In reporting these measures from the tables of Ptolemy and Alfonso, the variety among writers is incredible as regards the semidiameters of the Earth, since different writers pursue different distances of the Sun from the Earth, which become mixed up in this business:

for in parts of which the radius of the planet's orb is 60, nearly all agree with Ptolemy. Ptolemy gives the numbers of the motions in Book 9, chapters 3 and 5, and those of the equations in Book 11, chapter 10, as the Alphonsines do in their tables. He gives the measures of the epicycles and eccentricities in Book 10, chapters 7 and 8, for ♂; in Book 11, chapters 1 and 2, for ♃; and in chapters 5 and 6 for ♄. This is so although he sets the eccentricity of ♂ now at 12°, now at 13° 7′, and although the former number is kept by al-Battānī, chapter 50; al-Farghānī, differentiae 16 and 21; Regiomontanus in the *Epitome of the Almagest*, Book 10, proposition 18, and Book 11, propositions 7 and 16; Reinhold on Peuerbach, p. 139, and in the same place Wurstisen, pp. 132, 145, 149; Maurolico at the end of the *Cosmographia*; Clavius at the end of the *Sphere*, who at times carries the planet's distances from the Earth over from Maurolico to the semidiameters of the heavens, neglecting the addition of the semidiameter of the planet's body; and Barozzi, *Cosmographia*, Book 1, p. 48. These authors report these and other measures. But the latter opinion, of 13° 7′, is held by Thābit and Campanus in their *Theoricae*, by Fernel in Book 1 of the *Cosmotheoria*, and by Danti in part 2 of the *Astrolabium* and in his tables. Besides these, the present measures and distances are adduced by Mauro Fiorentino, by Giuntini in his own *Sphere* and from him Baranzano in part 1 of the *Uranoscopia*, by Schöner in the *Aequatorium Astronomicum* from p. 10, by Osualdus on Peuerbach, p. 425, by Tycho in volume 1 of the *Progymnasmata*, p. 468, following al-Battānī, and by Kepler in the *Epitome of Copernican Astronomy*, p. 494, who however follows the Copernican correction of the Ptolemaic intervals. And Mästlin, in Kepler's *Prodromus*, p. 92, gathers from Reinhold's data that Saturn's greatest distance is 24718 semidiameters of the Earth. So take first the measures in which all agree with Ptolemy, then the distances from the Earth in which they do not agree. On the distances from the Sun, which are to be determined one way in Ptolemy's time and another way at other times, consult Scholia 7 and 8 below; and to picture the lines, look at the figure set out at nos. 2 and 8.

[Margin: Authors who deal with these numbers and measures.]

Measures pertaining to the Ptolemaic and Alphonsine hypothesis

[Margin: See the figure set out at no. 2 and 8.]

In parts of which the radius DF is	Planet	60° 0′	or 100000
Eccentricity of the deferent AD	♄	3° 25′	5694
	♃	2° 45′	4583 ½
	♂	6° 0′	10000

The Ptolemaic roots are fixed to Alexandria in Egypt, at noon of the first day of Thoth in the first year of Nabonassar; the Alphonsine roots to Toledo, at noon of the last day of December in the year 1252. Just as the mean motion of the anomaly of the orb, or of the planet in the epicycle, is obtained by subtracting the mean motion of the centre from the mean motion of the Sun, so too its root is obtained by subtracting the root of the centre from the root of the Sun, that is, from the mean motion of the Sun placed at the root.

[Margin: For the places of the apogees in Ptolemy's time, see below, chapter 9.]

SCHOLIA.

Scholia.

I. In the figure of the preceding chapter, set at nos. 2 and 8, the centre of the epicycle revolves on the circumference of the deferent from F to I, but it does not move uniformly on it, for the measure of the uniform motion of the eccentric is taken from the arcs of the equant, counted from R towards I. So if we imagine, for example, that the centre I of Mars's epicycle has in 86 days completed the arc RI on the equant (for in this diagram, because of their closeness, the letter I serves both eccentrics) of 45°, and in another 86 days another 45°, and thus a quadrant of the equant in 172 days, it will nevertheless not have completed equal arcs on the circumference of the deferent. For the angle IER, which measures the arc IR of the equant, is not equal to the arc IDF, which measures the arc IF of the deferent, since it is greater than this by propositions 16 and 32 of Euclid's Book 1. The Ptolemaic hypothesis therefore seems to have two imperfections. The first is that the uniformity of the motion is begged from a foreign and external centre, namely the centre E of the equant, which has nothing to do with the subject in which it is, nor with the instrument by which the centre of the epicycle is carried, but is assumed by a fiction, so that equal arcs are held to be traversed in equal times with respect to it. The second is a physical and real irregularity or inequality in the motion of the celestial body, viewed not indeed as a whole, but in part and as half of itself. For even if no eye is placed at A, or anywhere else, still

[Margin: Objections to Ptolemy's hypothesis.]

[Margin: Physical inequality.]

the centre of the epicycle in this hypothesis really does move non-uniformly with respect to the centre D, and on the circumference of the deferent it traverses unequal arcs in equal times. Accordingly the equation of this anomaly, that is the angle DIE, is called the physical equation, as was also said in Book 3, chapter 22. Let the other part of the inequality, with respect to the centre of the world A, where the eye is, be called the optical inequality because of its appearance, and its equation, that is the angle AID, the optical equation. So if the eye were at the centre D of the deferent, there would be one and the same inequality, at once physical and optical, and an eye placed at the centre of the deferent would see the planet move uniformly, since the motion of the planet in the epicycle is computed from the true apogee of the epicycle, which is irregular because of the irregularity of the motion of the centre of the epicycle, according to what was said at no. 5.

[Margin: Optical inequality.]

II. What then was the reason why Ptolemy, knowing the imperfections already mentioned, admitted them? For it was not, as Kepler had said in the *Mysterium Cosmographicum*, chapter 22, and Mästlin in the Appendix in the same place, that he introduced the equant led by a blind conjecture; he did it deliberately, as Kepler later admits in the *Commentaries on Mars*, chapter 16. First, so that the planet's motion in longitude would be perfectly circular with respect to some centre. This perfection in the hypothesis is acknowledged by Mästlin in the Appendix to Kepler's *Prodromus*, by Kepler in the *Commentaries*

on Mars, chapter 4, and by Hérigone in volume 5 of the *Cursus Mathematicus*, p. 507. Second, because Ptolemy saw that the equations of the eccentric's motion require an eccentricity as large as, or not much smaller than, the one the equant has, that is, the circle that is the measure of the uniform motions; but that if all of it were used for the difference between the greatest and least longitude, it would be too much, and, when applied to the centre of the epicycle, would yield incorrect equations of the argument. He therefore bisected the eccentricity, so that the greatest longitude would not turn out too great or the least longitude too short, and so that the centre of the epicycle would come nearer to the Earth at apogee and recede at perigee than a simple eccentric would otherwise require, and so that the centre of the deferent would stand midway between the centre of uniform motion and the centre of sight. Kepler touches on this reason, in other words and fitted to his own mysteries, in the *Mysterium Cosmographicum*, chapter 22, and in the *Commentaries on Mars*, chapters 16 and 32. But Regiomontanus, in the *Epitome*, Book 10, proposition 8, speaking of the bisected eccentricity in ♄ ♃ ♂ ♀, says: "But what reason drove him to this is not sufficiently clear, unless that experience agrees with the position." In the perigee of Mars, however, the Ptolemaic hypothesis is more deceptive, as we shall say in chapter 3, scholium 4.

[Margin: The reason for the equant introduced by Ptolemy.]

[Margin: 1. Reason for the equant.]

[Margin: 2. Reason for the equant.]

III. Giovanni Antonio Magini in his *Theoricae Planetarum* presents the Ptolemaic form to us, but by means of solid orbs, and he borrowed the measures of the epicycles and eccentricities from Ptolemy, although he also indicated the Copernican eccentricity of Mars and followed Copernicus for the numbers of the motions. So there is no need for us to set out Magini's hypothesis separately. In the *Supplement to the Ephemerides*, however, he follows Tycho in the motion of the Sun, which is connected with the planets' second inequality, Kepler in the motions of Mars, and in the rest the numbers of Copernicus; and he bisects the eccentricity with Kepler.

[Margin: Magini's hypothesis.]

IV. Ptolemy and all who followed him, even Copernicus and Lansbergen, take the measure of the second inequality from the mean conjunction of the planet with the Sun, or its mean opposition, and require the mean motion of the Sun to be used in finding it. This does serve ease of calculation, but it is something fictitious, since the mean and true motions of the Sun very rarely coincide; nor is it consonant with nature that the movers of the planets should in their revolutions look to a position and motion of the Sun that is for the most part fictitious, rather than the true one. Moreover, it seems improbable that these same movers should look to the centre of the orbs, which is an empty point in the world, lacking any prerogative; for it seems that what is set as the centre of the planetary orb ought rather to be either the Earth itself, or the Sun itself, or something else of the kind. But of these things below, chapter

5, nos. 5 and 6, where we shall teach that the celestial motions are not exactly represented unless we use the true place of the Sun.

[Margin: Other objections to Ptolemy's hypothesis.]

V. In the preceding chapter, no. 8, in Rule 1, I said that many, with Peuerbach, erred in assigning to the mean apogee of the epicycle what should be assigned in the Ptolemaic hypothesis to the true one. For Peuerbach, in the *Theorica* of the superior planets, part 2, p. 49, says this: "So that at every mean conjunction such a centre of the planet's body is in the mean aux of the epicycle; hence also at every such mean opposition it will be in the opposite of the aux of the epicycle." Reinhold teaches the same with him, in that place, p. 91,

[Margin: Slip of Peuerbach, Reinhold, Wurstisen, Magini and Langius.]

and Wurstisen, p. 142, and Magini in his *Theoricae*, p. 20, and our Langius, p. 375. But Ptolemy, *Almagest* Book 10, chapter 6, and Regiomontanus in the *Epitome of the Almagest*, Book 10, propositions 9 and 11, expressly teach that the superior planets, when they are in mean conjunction with the Sun, are in the true apogee of the epicycle; when they are in mean opposition with the Sun, in the true perigee of the epicycle; and conversely, when they are in the true apogee or perigee of the epicycle, they are on the line of the Sun's mean motion. And rightly so, because according to the opinion of the whole of old astronomy down to the last days of Tycho, or down to Kepler's speculations, whenever these planets fall on the line of the Sun's mean motion, that is in mean ☌ or ☍ with the Sun, they are stripped of the second inequality, and the planet's place under the zodiac is the same as that of the centre of the epicycle, also under the zodiac. So the centre of the planet's body and that of the epicycle are on the same line drawn from the centre of the world to the zodiac, by which line the true apogee and perigee of the epicycle are determined, as Peuerbach's own definitions teach. Therefore, when the centre of the epicycle is placed away from the apogee and perigee of the eccentric, the planet never occupies the line of the Sun's mean motion while set in the mean apogee or perigee of the epicycle, but only in the true one. That this is so the very diagram of Ptolemy and Regiomontanus will teach, which is as follows.

Diagram. The Ptolemaic scheme of the deferent and epicycle, set into the right column with the text running down its left side. A large circle (the deferent) carries a vertical diameter through the points B, F, E, D and A down to C. A small circle centred at F stands at the top, reaching up to B. A second small circle, the epicycle, is drawn on the deferent's left side with its centre at I. Solid lines run from E through I to M, from A through I to V, and from A down to H and to G on the lower arc of the large circle. Dotted lines run from A towards M and towards K. A further solid line runs from I down to R, and the circumference of the large circle passes through I, the centre of the epicycle.

- B (top of the vertical diameter, on the small circle): point labelled B
- F (centre of the small circle at the top of the deferent): point labelled F
- E (on the vertical diameter): point labelled E
- D (on the vertical diameter, below E): point labelled D

- A (on the vertical diameter, below D, where the lines converge): point labelled A
- C (foot of the vertical diameter, on the large circle): point labelled C
- G (lower right on the large circle): point labelled G
- H (lower left on the large circle): point labelled H
- I (centre of the epicycle): point labelled I
- V (upper left on the epicycle): point labelled V
- M (far left on the epicycle): point labelled M
- R (lower left on the epicycle): point labelled R
- L (bottom of the epicycle): point labelled L
- P (lower right on the epicycle): point labelled P
- K (right on the epicycle, on the line from E): point labelled K

Let FC be the diameter of the deferent and the line of apsides, in which the centre of the deferent is D, and A the centre of the world, and E the centre of the equant. If the centre of the epicycle is at F, the apogee of the eccentric, and the planet at B, the apogee of the epicycle, and a mean conjunction with the Sun then occurs, the same line BC will be the line of the Sun's mean motion, and B will be the true and at the same time the mean apogee. Now let the centre of the planet be at I, through which let the line EIM be drawn from the centre of the equant; then the mean apogee of the epicycle will be M, and the mean perigee K. But when the straight line AIV is drawn from the centre of the world, the true apogee of the epicycle will be V, and the true perigee P, from the definitions of Peuerbach and our own, indeed those of all astronomers. Then if a mean conjunction of the planet with the Sun occurs, the planet is at V; but if a mean opposition, it is at P; and the line of the Sun's mean motion is VAG, which at the same place of the zodiac indicates the true place of the centre of the epicycle and at the same time that of the planet. So there is then no need of any other equation than the equation of the centre, that is the angle AIE, which is equal to the angle MIV, by which the true apogee is distant from the mean. Hence Regiomontanus aptly teaches, Book 10, proposition 12, that if at the extreme shinings the planet's place observed by instruments is opposite the place of the zodiac where the mean place of the Sun is then found, the place of the epicycle, or of its centre, has been found. But if, as Peuerbach's followers teach, the planet in mean ♂ with the ☉ were at M, the mean apogee, the line AM would show a different place from the place of the centre I and would be different from the line AI, nor would the planet be free of the second inequality, but the equation of the angle MAI would have to be added to the place of the centre; and likewise, if in mean ♌ it were at K, the mean perigee, the angle IAK would have to be subtracted. The occasion for the error, moreover, was that they thought that the conjunction and opposition with the Sun had to be regarded as mean according to the mean motions of both the planet and the Sun, whereas the mean motion of the planet in the epicycle is counted from the mean apogee.

VI. The greatest and least distances of ♄♃♂ from the centre of the Earth do not vary in Ptolemy, but the distances from the Sun do vary, both because of the Sun's eccentricity, if its variation is admitted, and because of the Sun's unequal annual distance from the Earth, and the motion of the apogee of the Sun and of the planets. The planet's greatest distance from the Sun occurs when it is in conjunction with the Sun and the centre of the epicycle is at the apogee of the eccentric, for then the planet is at the apogee of the epicycle, since it is then most apogean, in Greek [Greek: ἀπογειότατος (apogeiotatos, "farthest from the Earth")]. But the least distance occurs when the planet is opposed to the Sun and the centre of the epicycle is at the perigee of the eccentric, for then the planet is at the perigee of the epicycle and is most perigean, in Greek [Greek: περιγειότατος (perigeiotatos, "nearest the Earth")]. Therefore, when the distance of the Sun from the Earth that belongs to that time of conjunction is taken from the planet's greatest distance from the Earth, what remains is the planet's greatest distance from the Sun. Conversely, the distance of the Sun from the Earth at the time of the already mentioned opposition, added to the planet's least distance from the Earth, makes up the planet's least distance from the Sun. Yet at least for the distances of ♄ and ♃, one could without perceptible inconvenience always use the mean distance of the Sun from the Earth, which in Ptolemy is 1168 semidiameters of the Earth, subtracting it at the already mentioned ☌ and adding it at the already mentioned ☍.

[Margin: On the greatest and least distances of the planets from the Sun.]

If anyone should wish to represent these distances for the time at which the line of apsides of the Sun coincided or will coincide with the line of apsides of the superior planets, a hypothetical time would have to be sought, long before the creation of the world or after it. For since the world was made those two lines have not yet coincided, nor is it probable that it will last so long that they should coincide. For only in the year of Christ 4000 will the apogee of the Sun be joined to the perigee of Saturn, at about 17° ♌, and the perigee of ☉ to the apogee of ♄, at 17° ♒. And not until about the year of Christ 76300 will the perigee of ♂ reach the apogee of ☉, at 14° ♒, and the apogee of the former the perigee of the latter, at 14° ♌. Finally, the apogees of ☉ and ♃ will not be joined until the year of Christ 24000, and that at the beginning of ♌. But for the apogee of ☉ to coincide with the apogee of ♄ or ♂, many more myriads of years are required; and more still, if the apogees of ☉ and of these three planets were all to run together at the same point of the zodiac.

VII. From what has been said, a twofold way can be gathered of setting out the greatest and least distances of the planets from the Sun. One is for a hypothetical time, in which, to obtain the greatest possible distance of the planet from the Sun under this hypothesis, the Sun at the time of its conjunction with the planet would be at the perigee of its eccentric, and the planet at the apogee of its eccentric and epicycle; and to obtain the least, at the time of opposition ☉ would likewise be at the perigee of its eccentric, but the planet at the perigee of its eccentric and epicycle. The other way is for the time of Ptolemy, when

the apogee of ☉ was at 5° ♊, that of ♄ at 23° ♏, that of ♃ at 11° ♍, and that of ♂ at 25½° ♌. Accordingly, with the Sun's anomaly taken into account, the distance of ☉ from the Earth to be used for ♄ was 1147, for ♃ 1166, and for ♂ 1181. Therefore, if we choose the planetary distances of Maurolico and Clavius, the greatest and least distances at that time were as you see in the following small table.

Distance of ♄ ♃ ♂ in semidiameters of the Earth, from Ptolemy, in Ptolemy's time

Planet	Greatest, from the Earth	Greatest, from ☉	Least, from the Earth	Least, from ☉
♄	20072	18925	14378	15525
♃	14370	13204	8854	10020
♂	8848	7667	1216	2397

VIII. To put the size of the epicycle of ♂ before your eyes in the old hypothesis, here is a diagram from Fernel, Book 1 of the *Cosmotheoria*, chapter 8. In it C is the centre of the deferent AB; E the centre of the equant OP; and D the centre of the world. The centre of the Martian epicycle is sometimes at A, the apogee of the eccentric, sometimes at B, its perigee, and the epicycle's semidiameter is BG or AQ. Therefore the outermost orb enclosing the heaven of Mars is FH, KM, and so on, the whole thickness of the globe of Mars itself being counted in, even though it is not shown in the diagram.

Diagram. Fernel's scheme of the Martian orb, set into the lower right of the left column with the text of paragraph VIII running beside it. A single vertical line runs down the middle of the figure. Two large circles overlap on it, and two equal smaller circles sit at its upper and lower ends, the upper around A and the lower around B. An arc from F to H passes over the top of the upper small circle, and an arc from K to M passes under the bottom of the lower small circle.

- Q (top of the vertical line, just inside the upper small circle): epicycle's far point, as cited in the text (AQ)
- F (upper left, at the end of the upper arc): end of the arc FH
- H (upper right, at the end of the upper arc): end of the arc FH
- O (on the vertical line, at the top of one large circle): cited in the text with P as the equant OP
- A (on the vertical line, at the top of the other large circle): apogee of the eccentric; one position of the epicycle's centre
- E (on the vertical line): centre of the equant
- C (on the vertical line, below E): centre of the deferent
- D (on the vertical line, below C): centre of the world
- L (on the vertical line, below D, near the top of the lower small circle): not cited on this page
- P (on the vertical line, below L): cited in the text with O as the equant OP

- B (on the vertical line, below P): perigee of the eccentric; the other position of the epicycle's centre
- G (foot of the vertical line): end of the semidiameter BG
- K (lower left, at the end of the lower arc): end of the arc KM
- M (lower right, at the end of the lower arc): end of the arc KM

CAPVT II.

Chapter 2.

De Triplici Hypothesi Copernici ac Sectatorum eius.

On the threefold hypothesis of Copernicus and his followers.

I. Up to this point all astronomers, along with Ptolemy, except the very few who have dug up the ancient homocentrics (who, not even admitting motion in height, are refuted by the parallaxes of the Moon, which regularly vary most plainly, and are forced into silence), all of them, I say, by admitting the equant had admitted a physical inequality into the motion of the planets, something that ears accustomed to Peripatetic axioms judged especially discordant. For this reason Copernicus, in Book 4, chapter 2, and Book 5, chapter 2, thought it unworthy to ascribe to a heavenly body any real inequality in its own motion, and unbecoming for the mover of the planet itself, whoever that might be, to beg uniformity from another's circle and centre; that is, to borrow the rule of uniformity of motion not in the circle in which the planet moves, nor from the centre of the circle that carries it, but from another, extraneous circle and centre. And he burst out, whether in wonder or in indignation, into this question: "What kind of uniformity, then, will that be, in an alien circle in which its motion does not exist, but in its own eccentric? Thus indeed we marvel," etc. And after a few intervening words: "If now we should wish to establish the inequality of the appearance from unequal motions, it is permissible to observe what kind of argument it will be. For what else shall we do but give a handle to those who disparage this art?"

[Margin: From Copernicus, Book 4, chapter 2.]

"For someone could rise up against the astronomers in this way: Either your observations, by which the motion of the planets appears unequal to you, are fallacious; or, if they are not fallacious, either that inequality is not only apparent to you but real in the world, and this is absurd, since it is proclaimed in the schools and accepted by the wise that a simple and uniform motion befits a heavenly and simple body; or else it appears to you, viewing it from an alien centre, but is not real, and to what end, then, do you pour part of this inequality back into the heavens? It would surely have been better to attach to a heavenly body one single and simple inequality than two, and those mixed with uniformity."

[Margin: Argument against the inequality of the Ptolemaic deferent.]

Fearing these or similar weapons, Copernicus began to think how, from two or more uniform motions in the heavens, and with respect to the circles and centres of such motions, he might demonstrate the inequality that appears to us, or even refer it to a mere accident of sight. He indicated to us three hypotheses for the five minor planets in Book 5, chapter 4. These are set out by Rheticus in his *Narratio*; by Mästlin in the appendix to Kepler's *Prodromus*, that is, to the *Mysterium Cosmographicum*; by Kepler himself, in the same place, chapters 1, 14 and 15, and in the *Commentaries on Mars*, chapters 4, 5 and 6; and by Longomontanus in the *Astronomia Danica*, Book 1 of the *Theorica*, chapter 1, and throughout Book 2. But none of them did so fully or in order, with everything brought together that is necessary for equivalence with the Ptolemaic hypothesis, or for avoiding fallacies or ambiguities in understanding these hypotheses.

[Margin: Authors explaining these hypotheses of Copernicus.]

The first is by a single eccentric with an epicycle, that is, by an eccentrepicycle. The second is by two eccentrics with no epicycle at all. The third is by two epicycles carried on a concentric, that is, by a homocentrepicepicycle [Homocentrepicepicyclum]. Before we set them out, four foundations, as it were, must be laid first, so that you do not keep stumbling on account of less perfect diagrams.

II. The first is that for Copernicus the Sun, at the centre of the world and exempt from all translatory motion, is the centre of the orbs both of the five minor planets and also of the great orb of the Earth, which circles the Sun with an annual motion, as was indicated in Book 3, chapter 6, number 3. It is, I say, a centre not from which the orbs themselves are to be described, but from which the eccentricities, in the hypothesis of eccentrics, are to be measured, as from a starting point, if you examine Copernicus's first idea and intention; whereas Ptolemy reckoned them from the centre of the Earth.

[Margin: Four foundations laid down first for understanding the Copernican hypothesis.]

The second is that Copernicus nonetheless, so as not to seem too fastidious to those accustomed to Ptolemy and to the eccentricity of the Sun, eccentricities of the planets he reckoned not from the very centre of the Sun's body but from that point of the universe around which he posited that the Earth moves uniformly. This point is as far from the Sun as, in the hypothesis of a resting Earth, the centre of the Sun's orb is distant from the centre of the Earth, that is, as great as the eccentricity of the Sun's orb. This distance is indeed so small in respect of the distance of the Sun from the Earth that for this reason some say everywhere that for Copernicus the Sun is the centre of the orbs, and so on. This point, then, around which the Earth is imagined to be turned uniformly each year, is what Copernicus, in reforming the Ptolemaic hypothesis, uses as the centre of the universe. He takes it as the centre of the concentrepicepicycle [Concentrepicepicycli], or as the starting point from which he measures

the eccentricities of the eccentrepicycle, or of the eccentrhypocycle [Eccentrhypocycli], that is, of the biseccentric [Bifeccentrici], as Kepler notes in the *Epitome of Copernican Astronomy*, page 449.

[Margin: Second foundation.]

[Margin: Some call this centre the centre of vision.]

The third is that Copernicus first tried to represent the Ptolemaic hypothesis as to its measures while avoiding a physical inequality of motions, and therefore divided the whole of Ptolemy's eccentricity into 8 parts. He assigned 6 of these to the eccentricity of the eccentrepicycle and the remaining 2 to the semidiameter of the epicycle. So too in the form of the biseccentric he assigned 6 of them to the mean eccentricity of the true eccentric, and the remaining 2 to the semidiameter of the small circle that varies the eccentricity from greatest to least. And finally, in the form of the homocentrepicepicycle, he assigned those 6 to the semidiameter of the greater epicycle and the remaining 2 to the semidiameter of the lesser epicycle. In this way he represented for us the equivalence of his hypothesis with the Ptolemaic. Later, however, weighing the observations of his own time, he took for himself some liberty of correcting the Ptolemaic eccentricity somewhat.

[Margin: Third foundation.]

The fourth is that the annual, or great, orb of the Earth does for Copernicus whatever the epicycles do for Ptolemy. So in this respect Copernicus has no need of those epicycles by which Ptolemy displays the stations and retrogradations, granted that he has converted part of the Ptolemaic eccentricity into other epicycles.

[Margin: Fourth foundation.]

Prima Forma Copernicanæ Hypotheſeos.

The first form of the Copernican hypothesis.

III. In the following figure let E be the Sun, or rather that centre of the universe around which the Earth is to move through the great orb OPQR toward the east. (For since the apogees of the superior planets always tend toward the north, Mästlin not inappropriately turns the eye toward the north in this diagram, and has the east on the right.) Let the eccentricity EA be 6 parts, of which the whole eccentricity of the Ptolemaic equant is 8. From A, at the interval AB, as great as the semidiameter of the Ptolemaic eccentric, describe the eccentric BCD. From the points B, C, D on its circumference as centres, with the semidiameter BG, of 2 parts of which the eccentricity AE was 6, describe three epicycles, one at each of these three places;

[Margin: First form of the Copernican hypothesis.]

Diagram. Mästlin's scheme, set across the left column between two lines of paragraph III. A vertical line runs from F at the top to H at the bottom. Small circles (epicycles) stand at B on top, at C on the right and at D at the bottom. Several large overlapping circles and arcs surround the figure. Within them is

a middle-sized circle around E, and a small circle around A. Horizontal lines run from N and from A to the right, reaching L and C. Straight lines radiate from E to the left and right, and straight lines join G and H to points on the left and right of the middle circle.

- F (top, above the upper epicycle)
- B (centre of the upper epicycle)
- G (below B, at the foot of the upper epicycle)
- O (on the vertical line, above N)
- N (on the vertical line, at the top of the small circle)
- A (left of the vertical line, inside the small circle)
- M (on the vertical line, below A)
- E (on the vertical line, below M; lines radiate from this point)
- V (left, on the middle circle, above R)
- R (left, on the middle circle, level with E)
- T (left, below R)
- X [?] (lower left, below T; the sort is not a clear X: a single diagonal with a foot serif and a short heavy stroke at its base, nearer an italic A in form; the text on the next page cites a point X here)
- S (right, above P)
- P (right, on the middle circle, level with E)
- L (right, above the right epicycle)
- C (centre of the right epicycle)
- K (right, below the right epicycle)
- Q (on the vertical line, at the foot of the middle circle)
- I (on the vertical line, below Q)
- D (centre of the lower epicycle)
- H (bottom, below the lower epicycle)

[Margin: Scheme of Mästlin and in part of Copernicus.]

and let the line of apsides be BAD. Let the eccentric move in the order of the signs toward the east from B to C, and meanwhile let the epicycle, carrying the planet on its circumference, move around its own centre with equal speed and in an equal revolution, in the order of the signs as to its upper part, but against the order of the signs as to its lower part. And let this be on the condition that when the centre of the epicycle is at the apogee B, the planet is at the perigee of the epicycle, G, and when the centre is at D, the planet is at the apogee of the epicycle, H; but there, with the Earth placed at O, B will be the perigee of the eccentric and D the apogee.

With this motion maintained, when the eccentric, having completed the quadrant BC, which the right angle BAC measures, has carried the centre of the epicycle to C, the planet, having completed a quadrant of the epicycle, will be at L. So when NL is drawn parallel to AC, AN will be equal to the epicycle's semidiameter CL. Moreover, the path that the planet describes by its motion is GLH, which is not a perfect circle but a quasi-circle. For if a perfect circle were to be had, the circle GCH would have to be described from the point

M, as far from A as N is from A, that is, a third of the whole eccentricity AE; but the planet does not proceed along this circle. And Copernicus himself, who proposes this form in Book 5, chapter 4, with a very similar and single diagram, demonstrates that the planet goes not along a perfect circle but along a quasi-circle.

The same form is set out by Longomontanus, in Book 1 of the *Theorica*, chapter 1, with this other diagram, in which A is the centre of the eccentric, B the centre of the universe, the eccentricity AB is 6 parts of the 8 that the eccentricity of the Ptolemaic equant has, and CG, a third part of the eccentricity AB, serves as the semidiameter of the epicycle. But the left-hand side is the east, and while the eccentric moves from C to D, the epicycle with equal motion puts the planet from G at H; when the centre of the epicycle is at E, the planet is at I; and then at K, and finally at G. Therefore the path of the planet is GHIKG, departing somewhat from a perfect circle. Yet he adds that in ♂ and ☿ GC is not a third part of the eccentricity.

[Margin: Longomontanus's scheme for Copernicus.]

Diagram. Longomontanus's scheme, set into the right column with the text of the same paragraph running down its left side. A solid circle around A carries four small epicycles at its top, left, bottom and right, with C, D, E and F inside them. A dotted circle stands just inside or crossing the epicycles, through G, H, I and K. A vertical line runs from C through G, A, L and B into the lower epicycle; a horizontal line joins D, A and F; straight lines run from B up to the left and right epicycles.

- C (top, in the upper epicycle)
- G (on the vertical line, below C)
- H (upper left, at the left epicycle)
- D (left, in the left epicycle)
- K (upper right, at the right epicycle)
- F (right, in the right epicycle)
- A (centre, right of the vertical line, above the horizontal line)
- L (on the vertical line, below A; not cited on this page)
- B (on the vertical line, below L)
- E (bottom, in the lower epicycle)
- I (bottom, below the lower epicycle, on the dotted circle)

Secunda Forma Copernicææ Hypotheſis.

The second form of the Copernican hypothesis.

IV. Now, in Mästlin's earlier diagram, for the second form, which Copernicus indicated but did not illustrate with a diagram, let there be the point A, distant from the centre of the universe E by 6 parts, of which the eccentricity of the Ptolemaic equant is 8. From it describe the small circle MN, whose semidiameter AM is to be 2 parts. Let there be a single eccentric BCD, described from A, which is to move the true eccentric that carries the planet, along the small

circle of the eccentricity, in the order of the signs; so that this small circle is understood to move in the order of the signs at N, but against the order of the signs at M. Whenever the planet is at the apogee or perigee of its eccentric, the centre of the true eccentric is to be at M, and the position of the true eccentric GCH; but when the planet is a quadrant from the apogee or perigee, as at L, the centre of the true eccentric is to be at N, and the position of the eccentric along the path FCI.

[Margin: Second form of the Copernican hypothesis, and its first part, for the first inequality.]

For from this too it follows that the planet's path is GLH, very like a circle but not entirely so; and that N is a point which is indeed movable, but a point of uniformity, around which the planet moves uniformly. For with the planet placed at H or G, a straight line is drawn to the planet from M, the centre of the true eccentric, through N, because it lies on the same straight line; outside G and H, if it is at L, then the centre of the true eccentric is united with N; and with the planet and the centre of the true eccentric placed elsewhere, a straight line is nevertheless always drawn from the planet through N. It is necessary, then, that as the planet's motion around the centre of the true eccentric is uniform, so it should be around N; and that this point should be equivalent to the centre of the Ptolemaic equant, as regards accounting for the first inequality, the eccentric one, that is, the one not tied to the Sun.

As for the second inequality and anomaly, which to the motion of the Sun, or in Copernicus's opinion to the motion of the Earth, is attuned, it is the great orb OPQR that exhibits it, because the Earth, viewing the planet from different sides by its annual motion, produces various angles of apparent motion. This variation Copernicus calls the commutation [commutationem] and parallax of the great orb toward the planet. For if the planet is at G or H, and the Earth at O or Q, the same straight line GEH is the line of the true and of the apparent place: of the true place with respect to the centre of the world E, and of the apparent place with respect to the Earth at O or Q. But if the Earth is in the semicircle QRO, say at R, and the planet at G or F, then, when the straight line RG is drawn, the straight line EG will indicate the true place and the straight line RG the apparent place, and the planet will be seen farther on, in the order of the signs. And with the Earth in the semicircle OPQ, it will be seen farther ahead, against the order of the signs, than the line EG requires.

[Margin: Second part, for the second inequality.]

Moreover, the motion of the Earth from the point P, or a little before it, through Q as far as R or a little beyond, makes the planet appear to move faster in the order of the signs than the line EG demands. But when the Earth has revolved from R, approximately through O, to P, the planet appears slower than the line EG requires, because the Earth, being swifter than the planet, comes to meet it when moving through ROP, and draws away from it through PQR. Hence the planet appears to us not only slow but even retrograde, although in reality it always proceeds directly. And so this one motion of the Earth does

what the Ptolemaic epicycles do, and frees the heavenly body from that second inequality, transferring it to mere appearance.

The greatest equation of the centre, or of the eccentric, is the angle ELN, based on the greatest eccentricity, from which, together with the radius NL, it is gathered. The greatest equation of the parallax of the annual orb, if the planet is at apogee, is the angle EGV, which is obtained from the radius of the annual orb EV and the planet's greatest distance EG; but if it is at perigee, it is EHX, which the radius EX and the least distance EH give. But GV and HX ought to have been tangents to the annual orb at the points V and X.

[Margin: Note on the Copernican hypothesis.]

Tertia Forma Copernicææ Hypotheſeos.

The third form of the Copernican hypothesis.

V. The third form, which Copernicus indicates without a diagram in Book 5, chapter 4, and which alone among the Copernican forms Kepler sets out with a diagram, in the *Commentaries on Mars*, chapter 4, works by a circle concentric with the centre of the universe, though eccentric to the Earth, with two epicycles. For this form let A be the Sun, or near the Sun, that is, the centre of the universe. From it describe the concentric BCDI, and let the line of apsides be DF, on which, from the centres B and M, describe one greater epicycle each, whose semidiameter BF is to be 6 parts, of which the whole eccentricity of the Ptolemaic equant has 8. With these parts draw from C and E the two other equal epicycles, that is, positions of the greater epicycle.

[Margin: Third form of the Copernican hypothesis.]

Diagram. The third form, set into the lower part of the left column with the text of paragraph V running down its left side. A circle around A carries four larger circles, on its top, left, bottom and right, with B, C, D and E in them. A smaller circle stands on each of these: above the top one around F, on the upper left around G, inside the bottom one around H, and on the upper right around I. A vertical line runs from the top circle through A to the foot of the bottom circle; a horizontal line runs through C, A and E; straight lines run up from A toward L on the left and N on the right.

- F (top, in the uppermost small circle)
- K (on the vertical line, below F)
- B (on the vertical line, below K, in the upper larger circle)
- L (upper left, outside the small circle around G)
- G (upper left, in a small circle)
- C (left, on the horizontal line, in the left larger circle)
- N (upper right, by the small circle around I)
- I (upper right, in a small circle)
- E (right, on the horizontal line, in the right larger circle)
- A (centre, just below the horizontal line)
- T (below and to the right of A; not cited on this page)

- H (on the vertical line, in the lower small circle)
- M (on the vertical line, below H)
- D (on the vertical line, in the lower larger circle)

Then, with the centre placed at F, a point on the circumference of the greater epicycle, describe the lesser epicycle, whose semidiameter FK is to be 2 parts, of which BF is 6, that is, about a third of it. Let the centre of the greater epicycle B move around the centre A, with the motion of the concentric, in the order of the signs from B to C; and meanwhile let F, the centre of the lesser epicycle, move with an equal revolution against the order of the signs above and in the order of the signs below, striving against the motion of the concentric. But let the planet, beginning its motion from K, move with a doubled revolution against the order of the signs below and in the order of the signs above, resisting the motion of the centre F but following the motion of the eccentric.

For so it will come about that, with the centre F placed at the apogee, the planet holds K, the perigee of its epicycle; and at D, the perigee of the orb, it holds M, the apogee of the epicycle. And when B has completed a quadrant and has been carried to C, the planet, having completed a semicircle of its epicycle, is at L, as far as possible from the centre C. Therefore the arc CL, and its measure the angle CAL, will be the greatest equation to be subtracted from the mean place indicated by the line AC, so that the true place, indicated by the line AL, may be had. But when B, having completed the semicircle BCD, is at D, then the planet, having completed a semicircle of its epicycle, will be at M; and when B has come through CD to E, three quadrants now being finished, the planet, having completed a semicircle and a half, will be at N, and the greatest additive equation will be the arc EN, or the angle EAN.

On these assumptions, as Kepler demonstrates and Copernicus does not deny, and as will be evident to anyone tracing the planet's path mechanically, the planet does not describe a perfect circle in the heavens, but one departing from a perfect circle outward from K to L, and inward from L to M. For another diagram see below, chapter 3, number 4.

Indicatur Methodus Calculi Geometrici.

The method of geometrical calculation is indicated.

VI. The method of the first form is similar to the Ptolemaic method as regards representing the place with respect to the centre of the universe, provided that Copernican measures are used and that the motions are numbered from the first star of Aries, to which the precession of the equinoxes, when added, produces the motion from the equinox. To obtain the place seen from the Earth, imagine the Earth at P, as in the figure of number 3, and the planet at G. For when the centric place of the planet is subtracted from the mean motion of the Sun, or the latter from the former, you will have the anomaly of the orb, or the angle at the Sun, which is GEP. With this, and with the radius of the annual orb EP, or rather with the true distance of the Sun from the Earth, and with EG, the

distance of the planet from the Sun found by the earlier procedure, you will have the equation of the orb EGP, and its elongation from the Sun, or the angle EPG. But in the hypothesis of the moved Earth this method will occur more often; see, therefore, what is to be said in chapter 3, number 5, in the second procedure. The method of the second form, because it is Lansbergen's, is given in chapter 4. The procedure for the third form, but transferred to a standing Earth, will be indicated in chapter 3, numbers 4 and 5.

De Numeris ac Menſuris ad Copernici Hypotheſim ſpectantibus.

On the numbers and measures pertaining to the hypothesis of Copernicus.

VII. The numbers of the motions are found in Copernicus, Book 5, and in the Prutenic Tables, from which Giuntini, Stadius and Magini took their canons. Copernicus indeed gives only the motion of the commutation, or anomaly of the orb, and wants the mean motion of longitude to be gathered by subtracting the motion of commutation from the mean motion of the Sun, and to be numbered from the first star of Aries. But the Alphonsines, omitting the motion of anomaly, give the mean motion of the planet in longitude, numbered from the equinox, and want the motion of the anomaly of the orb, or, as they themselves call it, the motion of the argument, to be gathered by subtracting the planet's mean motion in the zodiac from the mean motion of the Sun. But Reinhold, imitating Ptolemy, arranged three motions in the Prutenic Tables: those of longitude, of the apogee, and of the anomaly or commutation.

[Margin: Difference between the Alphonsine and Prutenic Tables.]

As for the measures of the orbs, Copernicus exhibits or indicates them in one way, in Book 5, chapters 5, 6 and 9 for ♄, chapters 9, 10 and 11 for ♃, and chapters 14, 15 and 16 for ♂. Reinhold gives them in another, since, as is clear from the preface to the Prutenic Tables, he considered that they had to be corrected before he built the edifice of his tables on them. Therefore Mästlin tracked those measures down from the Prutenic prosthaphaereses, and reported them partly in the notes to Kepler's *Prodromus*, or *Mysterium Cosmographicum*, after chapter 15, and partly in the appendix to the same *Prodromus*.

[Margin: Diversity of the measures in Copernicus, Reinhold and Mästlin.]

For in the figure of number 3 consider the triangle ELN, right-angled at N, and look up in the Prutenic Tables the angle L of the equation of the centre, at an anomaly of 90°. For the tangent of that angle will be the quantity of the whole eccentricity EN, in parts of which the radius NL of the planet's orb has been taken, whether as 10000 with Copernicus or as 100000 with Mästlin. The half, EM, will be the least eccentricity, and a fourth part of the whole EN will be AM or GB. Therefore by adding the line EM to the radius one gets EG, the planet's greatest distance from E, the centre of the universe; and by subtracting, EH, the least. Then in the triangle EGP, right-angled at E, there is given from the Prutenic Tables, at an anomaly of the orb of 90°, the angle EGP of the

annual parallax, or commutation, or prosthaphaeresis of the orb, and from it GPE, which is the complement of the other to a right angle, whose tangent EG is the apogee distance of the planet from the centre of the world, but in parts

[Margin: Method of fishing out these measures from the tables.]

of which the radius EP of the Earth's annual orb shall have been 10000 or 100000. But by adding to the angle EGP the whole and greatest excess set down in the tables of the prosthaphaereses of the orb, one gets the angle EHP, whose complement to a right angle is the angle EPH. Its tangent, or what is equal to the tangent, is the line EH, that is, the perigee distance, in parts of which the radius EP of the annual orb has been taken. Half of the whole GH will be the radius AC of the planet's orb in the same parts. The difference between EG and EH will be the whole eccentricity EN; a fourth part of it will be AM or BG; and ME will be half of the whole eccentricity. Mars, however, is an exception: in it Copernicus in his own time found EM smaller than MN, and the whole EN smaller than Ptolemy did, so that as the Sun's eccentricity decreased Mars seemed to Copernicus to have diminished its own eccentricity as well. He thought the same about the eccentricity of Venus.

[Margin: Exception for the eccentricity of ♂.]

In the first place we shall give the measures derived by Mästlin from the Prutenic Tables, and from them we shall append the others he omitted, adding the same measures in semidiameters of the Earth, which he passed over, setting only the mean distance of the Sun from the Earth at 1160 semidiameters of the Earth; by this we shall determine the others. Then we shall set out the measures deduced from Copernicus himself, and we shall use a distance of the Sun from the Earth of 1142 at the mean, but of 1190 at its greatest, at the greatest eccentricity, according to what was said in Book 3, chapters 7 and 24. By these we shall increase or diminish the distances of the planets from the Earth, supposing that the line of apsides of the Sun or Earth and of each individual planet is the same, so that it may appear how far these measures can possibly be extended; granted that such a meeting will never occur, as I said in chapter 1, scholium 6. And because Mars has varied its eccentricity, we shall distinguish its eccentricities and distances at the greatest eccentricity by the letter M, and at the least by the letter m. How the greatest distances from the Earth are to be established for another time will be clear from what is to be said in chapter 5, number 20, § *Tertiò* [Thirdly].

Measures from Mästlin and the Prutenic Tables for the time of Copernicus, the same mean distance of the Sun from the Earth being assumed and applied. Then from Copernicus himself, but for the time of the meeting of the line of apsides with the Sun's line of apsides, and with the greatest of its possible distances applied.

Because Mästlin takes the radius of the annual orb as 1160 semidiameters of the Earth, larger than Copernicus, who takes it as 1142, the measures of the distances in semidiameters of the Earth therefore come out larger from the former than from the latter. Copernicus, Book 5, chapters 5, 6, 10, 11, 15 and 16, sets EN at 1139 parts in Saturn, 917 in Jupiter and 2000 in Mars, of which AC is 10000. But EA he sets at 854 in Saturn, 687 in Jupiter and 1460 in Mars, and

BG at 285 in Saturn and 229 in Jupiter, always in parts of which AC is 10000. We, however, have reduced them to a radius of 100000.

Copernicus reckons his motions from the first star of Aries. Therefore, when the motion of the fixed stars is added to the motion of the apogee or of longitude, one gets the motion of the same, but computed from the mean equinox. The motion of longitude reckoned from the apogee of the planet is called the anomaly of the eccentric, and is had by subtracting the motion of the apogee from the motion of longitude. The motion of the planet on the Ptolemaic epicycle, or of the anomaly of the orb, is transferred by Copernicus to the annual motion of the Earth, which produces this parallax, and it is therefore called the motion of commutation, or of the annual parallax. This motion is had by subtracting the motion of longitude under the fixed stars from the mean motion of the Sun, likewise under the fixed stars.

SCHOLIA.

Scholia.

I. I see that six objections especially can be raised against the hypotheses of Copernicus. The first is that in none of his forms does a planet trace a perfect

circle, and that in this he is outdone by Ptolemy. For it seems as absurd to attribute to a heavenly body a path of irregular figure, as Copernicus does, as to attribute to it an irregular motion, which Copernicus detests in Ptolemy. Further, as Boulliau notes in Book 1, chapter 14, the planet does not move in the very circle that is the index of the mean motion but on epicycles, as far as forms 1 and 3 are concerned.

[Margin: Objection 1 against Copernicus.]

II. The second is the disagreement with Ptolemy in the calculation, especially of Mars, by almost one degree, as Kepler shows by examples in his *Mars*, chapter 4; and that the calculation of the first inequality is easier in the Ptolemaic form than in the Copernican, as Kepler shows in the same place, chapter 5. But that disagreement is perhaps no fault, if it agrees with the heavens rather than with Ptolemy.

[Margin: Objection 2.]

III. The third is that if Copernicus admits solid orbs, he too multiplies the movers, as many as the circles he employs. But if, as Tycho establishes from the trajections of comets and from other arguments, there are no solid orbs, something almost impossible is imposed on either one mover or several: namely, that they should look to centres that have no stable or known seat in any body. And in forms 2 and 3 there is a conflict of motions, since while one small circle advances another goes back. Kepler noted this in Copernicus in part above, and Boulliau in part in Book 1, chapter 14.

[Margin: Objection 3.]

IV. The fourth is that he uses the mean motion of the Sun rather than the true in separating the second inequality from the first and in investigating the anomaly of commutation. We shall show in chapter 5, numbers 5 and 6, that this is neither probable a priori nor in agreement with observations.

[Margin: Objection 4.]

V. The fifth is that the variety of effects in sublunary things, evident from the stations and retrogradations of the planets, is attributed to the Earth itself, which receives their rays in one position after another, going to meet them or receding from them. Yet it seems more consonant with reason that this cause should lie in the heaven itself and in the motion of the planets; although the Copernicans will easily make light of this objection.

[Margin: Objection 5.]

VI. The sixth is the absurdity of the Earth's motion and the rest of the Sun, against the senses and against the authority of Holy Scripture, without any evident reason to the contrary. For his chief reason for devising new hypotheses was so as not to admit a motion of a heavenly body that is unequal about its own centre and equal about another's, as is clear from his own words in Book 5, chapter 2, where he says of the ancients: “They grant, therefore, here too that the equality of circular motion can occur about a centre that is another's and not its own, and likewise that this happens all the more in Mercury. But this has already been sufficiently refuted in connection with the Moon” (namely

in Book 4, chapter 2). "These and similar things gave us the occasion for thinking about the mobility of the Earth and about other ways by which the equality and the principles of the art might remain, and the reason of the apparent inequality might be rendered more constant." And so immediately in chapter 3 he explains away, by the annual motion of the Earth, the stations and retrogradations apparent in the planets. But that very equality of motion about its own centre

[Margin: Objection 6.]

[Margin: The occasion for introducing the motion of the Earth.]

is upheld by Tycho, Longomontanus and ourselves, below, without the motion of the Earth; and, on the contrary, Kepler and Boulliau admit the motion of the Earth, but in such a way that they nonetheless admit a physical inequality of motion, and for this reason they bisect the eccentricity, as will be clear below. The motion of the Earth was therefore not necessary, nor, once it is posited, is an inequality of motion about its own centre necessarily excluded. But more against Copernicus in Book 9.

VII. Although Copernicus, out of all three forms, finally chose the eccentrepicycle for the three superior planets, as is clear from his statement in Book 5, chapter 4, where he says: "But we have here chosen the eccentrepicycle", nonetheless for the two inferior planets, Mercury and Venus, he chose the eccentric of the eccentric [Eccentri Eccentrum]; for he says of them in Book 5, chapter 22: "and this will be demonstrated more easily and conveniently by means of the eccentric of the eccentric." I wonder, therefore, why for the three superior planets Mästlin proposes the eccentric of the eccentric [Eccentri Eccentricum], and Kepler epicepicycles, as Copernicus's view, with the other forms set aside, as if that were the chief one in Copernicus's judgement.

[Margin: Which of the three forms is to be chosen according to Copernicus's mind.]

CAPVT III.

Chapter 3.

De Tychonis & Longomontani Hypotheſibus.

On the hypotheses of Tycho and Longomontanus.

I. Tycho himself too, in volume 1 of the *Progymnasmata*, p. 479, and in volume 2, p. 188, detesting "an incongruous coherence with mathematical regularity", to use his words, that is, the physical inequality of motion admitted by Ptolemy in introducing the circle of the equant, treated in the scholia of chapter 1, chose the third form of Copernicus, sufficiently explained in chapter 2, number 5, and to be repeated below in number 6, which has a concentric with two epicycles. He kept their measures and the kind of their motions, and indeed their quantity too, until he might correct them, should he survive. Since God did not grant him this, on his deathbed he asked Kepler to demonstrate

everything in this form of his as well, as Kepler himself attests in his *Mars*, chapter 6. For although it is equivalent to the Copernican and the Ptolemaic, it nonetheless differs from them in certain respects and has its own characteristic features.

It agrees with the Ptolemaic hypothesis both because it keeps the same measures, though transferred to the semidiameters of two epicycles, and because it lays down that not the Earth but the Sun moves about the centre of the universe in an annual revolution. Again, it agrees with the Copernican both because, having rejected real inequality, it recognises in all the circles it employs an equal motion with respect to their own centres, and transfers the whole inequality to our sight, which is outside those centres, so that it is all apparent or optical, not physical; and because it would have the planets move about the Sun as about the centre of their orbs. In these two conditions it differs from Ptolemy, who both attributes half of the inequality to a physical irregularity and measures the eccentricity of the planetary orbs from the centre of the Earth, not from the Sun or from a point near the Sun.

[Margin: Agreement of the Tychonic hypothesis with the Ptolemaic and the Copernican.]

It differs from Copernicus both as regards the annual motion of the Earth, which it denies, as I have already said in Book 3, chapter 6, number 4, where I indicated the Tychonic system; and as regards the cause of the second inequality, which it attributes to the motion of the planet about the Sun and of the Sun about the Earth, so that the orb of the Sun serves Tycho as a great epicycle, just as the annual orb of the Earth serves Copernicus in the manner of the Ptolemaic epicycle. And so in volume 2, p. 188, he says: "From this an evident cause is given why the simple motion of the Sun is necessarily mixed with the motions of all five planets in a particular and fixed tenor, so that all the celestial appearances direct themselves by the norm of the Sun, and it governs the whole harmony of the choir of the planets like Apollo in the midst of the Muses." In volume 1, p. 478, he had said from his own observations that the Copernican symmetries of the orbs are somewhat different, but with a very small discrepancy, which he could not explain to us. We shall therefore turn to Longomontanus.

[Margin: Difference of the Tychonic hypothesis from the Ptolemaic and the Copernican.]

[Margin: Why the Sun is Apollo.]

II. Now then, Longomontanus, in the *Astronomia Danica*, Book 1 of the *Theorica*, chapter 2, towards the end, and throughout Book 2, prefers the Tychonic form to the others, although he also presents the Copernican of the third form, and the Ptolemaic, but reformed. We shall briefly indicate these here from him.

Ptolemaica Hypotheſis à Longomontano Reformata.

The Ptolemaic hypothesis as reformed by Longomontanus.

This form, applied to Saturn, Longomontanus proposes in Book 2 of the *Theorica*, chapters 2, 3 and 4, for the three superior planets, and indeed for the other two planets in chapters 17 and 20. On that occasion he also indicates a method of geometrical calculation.

[Margin: First form of the Longomontanic hypothesis.]

Diagram. A figure set into the right column, with the text running in a narrow measure to its left. A straight vertical line runs from B at the top through A to P at the bottom. A large arc runs from B up and to the left and down around to P. On the upper left of this arc stand three circles of different sizes, overlapping. The largest passes near I and K at the upper left and near L at the right. A middle-sized circle lies below it, with E on its left. A small circle stands between them, with D inside it, G above it and H to its right. F and C stand side by side below the small circle, with M to the right of them. Straight lines run from A up and to the left into the group of circles, and a dotted line runs from A towards L. Within the arc, below the circles, stand the planetary signs ♄ ☉ ♂, and below them the word *Ptolem*.

- I (upper left of the largest circle)
- K (just below I)
- G (top of the small circle)
- H (right of G)
- D (inside the small circle)
- E (left of the middle-sized circle)
- F (below the small circle)
- C (right of F)
- L (right of the largest circle)
- M (below L)
- A (on the vertical line, right of the circles)
- B (top of the vertical line)
- P (foot of the vertical line)
- ♄ ☉ ♂ (inside the arc)
- *Ptolem* (inside the arc, below the signs)

In the accompanying figure, then, let A be the centre of the Earth, about which is the concentric BCP etc., on which the simple revolution of the planet through the whole zodiac is completed by a motion in the order of the signs from B to C. At some point on its circumference, say C, let there be a centre about which you are to describe the larger epicycle DE etc., whose semidiameter in Saturn is to be 8721 parts, of which the radius AB of the orb is 100000. Let this epicycle move against the order of the signs in its upper part and in the order of the signs in its lower part, with a motion commensurable with the motion of the concentric itself, so that if the centre of this epicycle has been carried by the concentric from B to C through an arc of 60°, the point E, that

is, the centre of the smaller epicycle, of which more shortly, has come to D, an arc ED of 60° having been completed. Therefore from the point D, on the circumference of the epicycle, describe the smaller epicycle GHF, whose semidiameter DG is to be a third part of the semidiameter CD, that is, 2907 parts (this epicycle Longomontanus calls the equant). Let this move with a double revolution, or twice as fast as the larger epicycle, but at the top in the order of the signs from F, its perigee, through H to G; and let the point that was at F when the centre C was at B be, in the case of the present figure, at H, an arc FH of 120° having been completed.

Although by these epicycles alone the anomaly of the three superior planets can be saved in most respects, yet so that their acronychal position may be better saved, because they then come closer to the Earth, from the point H on the circumference of the small epicycle describe the largest epicycle IEL, which Longomontanus calls the annual. Its semidiameter HI Longomontanus, Book 2, chapters 3 and 4, finds from acronychal observations of Saturn to be now 10398½ parts, now 10453½ parts; and he therefore chooses the mean, of 10426 or 10425 parts, of which the radius AB is 100000. For he says that this satisfies the observations, namely those Tycho has in the *Epistolae Astronomicae*, p. 56, in such a way that no sensible difference, that is, one reaching a whole minute, is detected; and that on account of the varied eccentricity of the Sun, with whose increase the semidiameter HI ought to decrease and with whose decrease it ought to increase, no sensible difference is however found in the place of Saturn and Jupiter, which nevertheless, if the proportion of increase and decrease were kept, should have reached a fifth part of a degree.

[Margin: The variation of the Sun's eccentricity does not sensibly vary the place of ♄ and ♃.]

Accordingly in the acronychal position, when the planet is opposed to the Sun in true ☍, if the centre of this largest epicycle is at H, the planet will be at M; but outside it, elsewhere, say at L or K; and in true conjunctions with the Sun it will be at the apogee I. The motion of the planet on this annual epicycle is to be in the order of the signs from I to K, and as great as the elongation of the Sun from the planet, or as great as the motion of the anomaly of the orb in the tables.

Methodus calculi Geometrici in hac Forma.

The method of geometrical calculation in this form.

III. First, let us suppose, as above, that the centre of the first epicycle has been carried from B to C by the planet's mean motion in longitude, and that the centre of the smaller or second epicycle is at H by a double and contrary motion; and let the straight line CH be drawn. For in triangle CDH the sides CD and DH are given from the semidiameters of the epicycles, and so is the angle CDH, which measures the arc FH, double the arc ED or CB, and in our case of 120°. Therefore by trigonometry the side CH will be given, and the

angle DCH, which in this figure and case is to be added to the angle ECD, or the arc ED, to make the angle ECH. With the straight line AHI then drawn through H, the triangle ACH arises, in which the angle ACH is given, since it is the complement to two right angles of the angle ECH just found; the side CH is given too, in parts of which the given or assumed side AC, or radius, is 100000. Therefore, by a further solution of this triangle, the angle CAH will be given, which is the equation of the centre [Æquatio Centrica], or of the first inequality. In the first semicircle BCP, as you see, it is to be subtracted from the mean motion in longitude, and the true motion results at H, as shown by the line AHI, which is the line of the true place of the centre. Indeed, if an acronychal opposition occurs, it will be the line of the true place of the planet, and the planet will be at M. Outside the acronychal position, however, the prosthaphaeresis of the second inequality has to be sought.

[Margin: 1. Step.]

Second, therefore, in the triangle ACH, from the data above, find the side AH, which is the distance of the centre H from the centre of the Earth. And let the planet be at L (to which draw the straight lines AL and HL), where it has completed the arc of anomaly IKEL from the apogee I, which in this figure exceeds the semicircle IEM by the arc ML. The angle MHL, that is, the angle AHL, will therefore be known. But the side HL is given, which is the semidiameter of the annual epicycle; so the angle HAL, that is, the equation of the second inequality, will not remain unknown. Subtracted here from the true place of the centre, it will show the true place of the planet in the zodiac. But if the planet were at K, one would have to draw to it the straight line HK, and from A the straight line AK (which is missing from the figure); and the arc of anomaly IK would give the angle IHK, whose complement to a semicircle, measuring the arc KEM, would have to be used as the angle contained by the sides HK and HA. From these the equation KAH would be gathered, to be added to the true place of the centre so as to have the true place of the planet in the zodiac. Longomontanus says that this form also suits Jupiter and Mars, if the semidiameters of the epicycles and the radius of the annual orb suited to each are applied, according to the measures to be given below after number 8.

[Margin: 2. Step.]

Copernicæa Hypotheſis à Longomontano Propoſita.

The Copernican hypothesis as proposed by Longomontanus.

IV. This is the third form of Copernicus, already set out in chapter 2, number 5, where we indicated the motions and measures of the epicycles. As regards the first two epicycles, these agree with the motions and measures of the preceding form set out in number 2. We shall therefore be briefer here, as Longomontanus too is in Book 2 of the *Theorica*, chapters 2, 5, 6 and 7, where he proposes it. Let A, then, be the Sun, for Copernicus the centre of the universe, about which is the orb of the planet BCP, in which the mean motion under the zodiac

is performed from B to C. And from C describe the larger epicycle (for we suppose that centre to have come from B to C by the arc BC, which let be, for example, 60°). Meanwhile, on the circumference of that epicycle, let the centre of the smaller epicycle have come from E to D, by a motion equally swift but contrary, the arc ED having been completed; and let the planet, on the circumference of the smaller epicycle, by a doubled motion but in the order of the signs, have come from its perigee F to H, an arc FH of 120° in our figure having been completed.

Diagram. A figure set into the foot of the left column, with the text running in a narrow measure to its left. A straight vertical line runs from B at the top, past A, to P at the bottom. A large arc runs from B up and to the left and down around to P. On the upper left of this arc stand two overlapping circles: a smaller one with G above it, D inside it, F inside it below D and H on its right, and a larger one with E on its left and C at its lower part. Short straight lines join the points inside these circles. From the group of circles a solid line and a dotted line run down and to the right to a small circle about A, whose circumference carries M at the upper left, L at the left and K and I at the lower right; a line runs on through A to the lower right. Within the arc, below the circles, stand the planetary signs ♄ ♃ ♂, and below them the word *Coper*.

- G (above the smallest circle)
- D (inside the smallest circle)
- H (right of the smallest circle)
- E (left, where the two circles overlap)
- F (below D)
- C (lower part of the larger circle)
- B (top of the vertical line)
- M (upper left of the circle about A)
- L (left of the circle about A)
- A (centre of the small circle, beside the vertical line)
- K (lower right of the circle about A)
- I (below K)
- P (foot of the vertical line)
- ♄ ♃ ♂ (inside the arc)
- *Coper* (inside the arc, below the signs)

And let two straight lines be drawn from A, one to the centre of the larger epicycle, which is to be AC, the other to the planet, which is to be AH. For AC will be the line of the true place of the centre as seen from the Sun, and AH the line of the true place of the planet, likewise as seen from the Sun. Then, about A, or about a point distant from the Sun by just as much as the Sun's eccentricity at the given time, describe the Earth's Annual or great orb MLIK. For if a true opposition of the planet H with the Sun occurs, the Earth will be at M; but if a true conjunction, the Earth will be at I; at other times it will be in other places, say at K or at L. The semidiameter AM of the annual orb, however, must be equal to the semidiameter of the annual epicycle discussed

in the preceding form, namely, in Saturn, 10425 parts of which AB is 100000, so that this hypothesis may be equivalent to that reformed Ptolemaic one. From this you see that, given the mean distance of the Sun from the Earth in semidiameters of the Earth, AB is given too, and also the semidiameters of the epicycles, CE and FD, in semidiameters of the Earth, together with the distances of the planet from the Earth and from the Sun, if they are given in parts of which AB is 100000, as they will be given below in a table.

[Margin: Foundation of the measures by semidiameters of the Earth.]

Indicatur Calculus Geometricus in hac Forma.

The geometrical calculation in this form is indicated.

V. First, let there be a true opposition or conjunction of the planet H with the Sun A, so that the whole second inequality ceases and only the equation of the centre, or of the first inequality, is needed; and let the line IAMH be the line of the true place, and of the place seen both from the Sun A and from the Earth at M, in ☍, or at I, in ☌ of the planet with the Sun. For then, with the straight line AH drawn, and from C to the planet H the straight line CH, and from D to the same planet the straight line DH, one must first solve the triangle CDH. In it are given the semidiameters of the epicycles, CD and DH, and the angle they contain, CDH, as great as the arc FH, which is known from the planet's mean motion in longitude, but doubled: thus, if BC was 60°, let FH, that is, the angle CDH, be 120°. So, with trigonometry as your guide, find the side CH and the angle DCH; add this to the angle ECD, that is, to the planet's mean motion, and the angle ECH results, whose complement to two right angles is the angle ACH. With this angle, in the triangle HCA, and with the side CH just found, and the radius AC, seek both the angle of the equation CAH, which here is to be subtracted from the mean motion to make the true place both of the centre and, in this first case, of the planet; and the side AH, which is the distance of the planet from the Sun. If, in acronychal ☍, you subtract from this AM, the distance of the Sun from the Earth, MH will be known, the distance of the planet from the Earth at M; and in ☌, when the distance IA of the Earth at I from the Sun is added, HI will become known, the distance of the planet from the Earth.

[Margin: 1. Step in true ☍ and ☌ of a planet with the ☉.]

Second: if there is not a true opposition or conjunction of the planet with the Sun, but the Earth is, for example, at L, count the anomaly of the orb from the apogee of the annual orb, which is I, in the order of the signs through K and M, so as to have the arc IKML. And if, as in this figure, it exceeds 180°, when these have been cast off there will remain the arc ML, which measures the angle HAL. Therefore, when LH is drawn, the triangle LAH will arise, in which are given the angle at A, as I said, and the side AH, found by the previous step, and AL, the semidiameter of the annual orb. So the angle LHA will not remain unknown, which is the prosthaphaeresis of the parallax, or of

the commutation, or of the second inequality. In this case it would have to be subtracted from the true place of the centre H found above, so that the true place of the planet H in the zodiac, but as seen from the Earth, might become known. But if the Earth were at K, the arc of anomaly IK would give the angle IAK, whose complement to a semicircle would have to be used as the angle contained by the semidiameter AK of the annual orb and the distance HA of the planet from the Sun, so that from these data the angle at H might be gathered, which would have to be added to the true place of the centre so as to have the true place of the planet in the zodiac.

[Margin: 2. Step outside ☍ and ☌.]

Tychonica Hypotheſis à Longomontano Propoſita.

The Tychonic hypothesis as proposed by Longomontanus.

VI. This third form, finally, which is plainly Tychonic (for the first is Tycho-Ptolemaic, the second Tycho-Copernican, or altogether Copernican), Longomontanus proposes in Book 1 of the *Theorica*, towards the end of chapter 1, and in Book 2, chapter 2, at the end, and chapter 9. In it let A be the centre of the body of the Sun, M the centre of the Earth, and ARL the annual orb of the Sun; and about A describe the orb of the planet BCP etc., concentric with the Sun, in which its mean motion in longitude is performed under the zodiac; and from C describe the larger epicycle, and from D the smaller, whose revolutions and measures are to be altogether of the same quantity and kind as in the two preceding forms. For when the planet H is truly opposed to the Sun at A, or truly conjoined with the Sun at L, the second inequality will cease, and nothing will be needed but the equation of the centre.

Diagram. A figure set into the head of the left column, with the text running in a narrow measure to its left. A straight vertical line runs from B at the top, past R and A, to P at the bottom. A large arc runs from B up and to the left and down around to P. On the upper left of this arc stand two overlapping circles: a smaller one with G above it, D and F inside it and H on its right, and a larger one with E on its left and C at its centre. Straight lines run from C towards E and towards H, and from the region of the circles down and to the right to a circle about M, which passes through A at its foot and has L at its upper left and R at its upper right. A dotted line runs from H to R, and a short dotted line from R towards M. Within the arc, below the circles, stand the planetary signs ♄ ♃ ♂, and below them the word *Tycho*.

- G (above the smaller circle)
- D (inside the smaller circle)
- H (right of the smaller circle)
- E (left, at the larger circle)
- F (inside the smaller circle, below D)
- C (centre of the larger circle)
- B (top of the vertical line)

- L (upper left of the circle about M)
- R (on the vertical line, upper right of the circle about M)
- M (inside the circle)
- A (foot of the circle, on the vertical line)
- P (foot of the vertical line)
- ♄ ♃ ♂ (inside the arc)
- *Tycho* (inside the arc, below the signs)

Indicatur Methodus Calculi Geometrici in hac Forma.

The method of geometrical calculation in this form is indicated.

VII. When the planet H is in true opposition with the Sun at A, or in conjunction with the Sun at L, the line AMLH of the place seen from the Sun and from the Earth is the same; and then, with CH drawn, the side CH is sought in the triangle CDH. For in it are given the sides CD and DH, which are the semidiameters of the epicycles, and the angle CDH, which is as great as the arc FH, that is, double the planet's mean motion. Further, the angle DCH is sought, which, added here to the angle ECD, that is, to the planet's mean motion, makes up the angle ECH, whose complement to two right angles is the angle HCA. Therefore, in the triangle CAH, with the angle at C, and the side CH found, and the radius of the orb AC, the angle CAH is found, that is, the equation of the centre, or of the first inequality, to be subtracted, in this semicircle BCP, from the mean motion of the centre C; and the true place both of the centre and of the planet in the zodiac results. Further, the side AH is to be sought, so as to have the distance from the Sun at A, in opposition; or, with the diameter of the Sun's orb AL subtracted, the distance from the Sun at L, in conjunction. From these, by subtracting the distance of the Sun from the Earth in the first case and adding it in the second, the distance of the planet from the Earth will be known.

[Margin: 1. Step, for a planet in ☌ or ☍ with the ☉.]

But if a true ☌ or ☍ does not take place, and the Sun is, for example, at R, and the motion of the anomaly counted from the apogee L in the order of the signs is the arc LAR, its complement to a circle will be the arc RL, measuring the angle LMR. So, with RH and MR drawn, the triangle HRM will be formed, in which the angle at M is known from the anomaly or its complement; the side MH was already found in the first step; and MR is the semidiameter of the Sun's orb, or rather the distance of the Sun from the Earth. So the angle at H will not remain unknown, to be added in this case to the true place of the centre, so as to make the true place of the planet in the zodiac.

[Margin: 2. Step outside ☌ and ☍.]

De Menſuris & Numeris ad Tychonis aut Longomontani Hypotheſim ſpectantibus.

On the measures and numbers pertaining to the hypothesis of Tycho or of Longomontanus.

VIII. We have derived the Tychonic measures, as many as we could, from the data given by Tycho in volume 1 of the *Progymnasmata*, pp. 476 and 480. The Longomontanic measures, on the other hand, we have derived from the data given by Longomontanus in Book 2 of the *Theorica*, chapters 2 and 3, where he assesses the semidiameters of the epicycles of Saturn; chapters 5 and 6, those of Jupiter; and chapters 8 and 9, those of Mars, together with the semidiameters of the annual orb, in parts of which the radius of the orb of each planet is 100000. Since, moreover, in Book 1 of the *Theorica*, chapters 6 and 8, he has defined the semidiameter of the annual orb, that is, the Sun's mean distance from the Earth, as 1288 semidiameters of the Earth, the greatest as 1334 and the least as 1242, the semidiameters of the Earth corresponding to the semidiameters of the epicycles and to the radius of the planetary orb will easily be gathered by the golden rule of proportions, and from these the distances from the Earth and from the Sun.

[Margin: Method of gathering the distances of the planets from the Sun and from the Earth.]

In Mars, however, two things are to be noted specially from Longomontanus, Book 2 of the *Theorica*. The first is from chapter 8, where he says that the semidiameter of the equating small circle [circelli æquatorei], or smaller epicycle, is not to be given a third part of the semidiameter of the larger epicycle (as was done in Saturn and Jupiter), but only a fourth, as is gathered from the prosthaphaereses of Mars that agree with Tycho's observations. The second is from chapters 9 and 12, where he affirms, from observations treated geometrically, that the semidiameter of the annual orb, in proportion to the radius of the orb of Mars, comes out much greater when the Sun and Mars are at the apogee of their eccentric than when both are at perigee, so much so that in the former case it is 67962½, in the latter 63028½, of which the radius of the orb of Mars is 100000; the mean, therefore, is 65497. But if we always used this mean, an error of nearly two degrees could be committed at the apogees and perigees of both bodies; and so it is not permissible to use it in the prosthaphaereses of Mars, but a more exact value, suited to each place, must be used. This variation, moreover, he attributes not to the orb of Mars itself but to a certain libration, either of the eccentric or of the annual orb, by which it would imitate the distances of the Sun from the Earth.

[Margin: The smaller epicycle of Mars is unlike the others.]

[Margin: The Annual Orb of Mars is one at apogee, another at perigee.]

IX. For an easier grasp of the measures written below, from the hypothesis of Longomontanus according to Tycho's mind, we shall add three diagrams, one for Saturn and Jupiter, the second and third for Mars.

Diagram. A tall, narrow figure set into the right column, with the text running in a narrow measure to its left. A single straight vertical line runs through all its parts. At the top a small circle with F overlaps a larger circle carrying K and B; an arc of the planet's orb crosses at B, ending in G at left and G at right. Below on the line stand the planetary signs ♄ ♃, then A at the top of a circle with T inside it and C at its foot. At the bottom a small circle with H overlaps a larger circle carrying M and D; a second arc crosses here, ending in G at left and G at right.

- F (inside the top small circle)
- K (below F)
- B (on the upper arc)
- G, G (ends of the upper arc)
- ♄ ♃ (on the vertical line)
- A (top of the middle circle)
- T (inside the middle circle)
- C (foot of the middle circle)
- H (inside the lower small circle)
- M (below H)
- G, G (ends of the lower arc)
- D (lower part of the bottom circle)

In these diagrams A is the centre of the body of the Sun and of the planets' orbs, and T the centre of the Earth, or at least of the solar or annual orb, namely the orb AC. Let the orb of Saturn and Jupiter be understood as described from A through the arcs BGGD, even though here they are not continued; let the orb of Mars BGDG, which cuts the annual orb at the points R and S, be continued. So when the centre of the smaller epicycle is at F, the apogee of the larger, the planet is at K, the perigee of the smaller, and then the planet's distance from the Sun is greatest, namely AK; and if a conjunction with the Sun is supposed then to occur, the distance KT from the Earth will be greatest. Conversely, when the centre of the smaller epicycle is at H, the perigee of the larger, the planet is at M, the apogee of the smaller, and the distance from the Sun, AM, is least; indeed, in acronychal oppositions the least distance from the Earth is TM. Therefore Mars then approaches the Earth most of all, and descends to the heaven of the Sun, below the Sun, as the parallax of Mars at perigee requires, which has been found greater than the parallax of the Sun, as will be said in Scholium 4.

[Margin: Parallax of Mars at perigee.]

Diagram. A figure filling the lower part of the right column. A straight vertical line runs down the whole figure. At the top a small circle with F overlaps a larger circle carrying K and B. A large circle, the orb of Mars, runs from B down both sides, with G at left and G at right, and ♂ on the vertical line within it, above A. From A a second large circle, the annual orb, runs down around T, with C at its foot. The two large circles cross at R on the left

and S on the right. Near the foot a small circle with H overlaps a larger circle carrying M and D.

- F (inside the top small circle)
- K (below F)
- B (at the top of the large circle)
- ♂ (on the vertical line)
- G (left of the large circle)
- G (right of the large circle)
- A (top of the second large circle)
- T (on the vertical line, inside the second large circle)
- R (left crossing of the two large circles)
- S (right crossing of the two large circles)
- H (inside the lower small circle)
- M (below H)
- D (below M)
- C (foot of the second large circle)

Finally, so that another position of Mars in the acronychal place, according to the

Tychonic hypothesis may be drawn, from Longomontanus, Book 2 of the *Theorica*, chapter 8: let A be the Sun, the centre of the orb of Mars BCP, which carries the larger epicycle, or its centre C; and let this carry the centre D of the smaller; and let M be the Earth, about which describe the annual orb of the Sun passing through A. And let Mars be at H, close to the opposition with the Sun that occurred on the line AH when that line passed through M; and let the equation of the centre be the angle CAH, and the equation of the orb MHA. The rest is clear from what was said above.

Diagram. A figure set into the head of the left column, with the text running in a narrow measure to its left. A straight vertical line runs from B at the top, through A, to P at the bottom. A large circle about M runs from the upper left past B and down to A, and round below M. A large arc runs from B to the left and down to P, crossing that circle. In the upper left stand a small circle about D, with G above it and H on its right, and a larger circle with F in its upper part and C at its centre. Straight lines run from C to the points on these circles and down to the right towards M and A, and lines run from H towards M and A. Within the arc, near its foot, stand the sign ♂ and the word *Tycho*.

- G (above the small circle)
- D (inside the small circle)
- H (right of the small circle)
- B (top of the vertical line)
- F (inside the larger circle, upper part)
- C (centre of the larger circle)
- M (below C, right of the larger circle)
- A (on the vertical line, at the large circle)

- P (foot of the vertical line)
- ♂ (inside the arc)
- *Tycho* (inside the arc, right of the sign)

Measures from Tycho, volume 1 of the Progymnasmata*, pp. 476 and 480.*

See number 9, figure 1 or 2		Parts of which the radius of the planet's orb is 100000	Semidiameters of the Earth
Semidiameters KF	♄	2849	300
Semidiameters BF	♄	8537	900
Mean distance, or radius AB	♄	100000	10550
	♃	100000	3990
	♂	100000	1745
Radius AT of the annual orb	♄	10900	1150
	♃	28140	1150
	♂	65903	1150
Distance from ☉, AK [Margin: Greatest.]	♄	105688	11150
Distance from ☉, AM [Margin: Least.]	♄	94312	9950
Distance from the Earth, TK [Margin: Greatest.]	♄	116588	12300
Distance from the Earth, TM [Margin: Least.]	♄	83412	8800
Distance of the centre B from the Earth, BT [Margin: Greatest.]	♄	110900	11700
	♃	128140	5140
	♂	165903	2895
Distance of the centre D from the Earth, DT [Margin: Least.]	♄	89100	9400
	♃	61860	2840
	♂	34097	595

From this it is clear that the least distance of Jupiter and of Mars from the Earth is less than the distance of the centre D. But Tycho determined for us neither these nor the epicycles.

Measures pertaining to the hypothesis of Longomontanus.

See number 9, figure 1 or 2, for these lines	Planets	Parts of which the radius of the planet's orb is 100000	Semidiameters of the Earth

	Planet	Root
Of longitude	♄	$2^{s}\ 12^{\circ}\ 32'\ 51''$
	♃	$5^{s}\ 29^{\circ}\ 56'\ 46''$
	♂	$1^{s}\ 9^{\circ}\ 39'\ 14''$

These motions, like the places of the apogees, are reckoned from the mean equinox. The motion of the anomaly of the eccentric, which Longomontanus sets down in his tables contrary to the custom of others, is obtained by subtracting the motion of the apogee from the mean motion of longitude. The anomaly of the orb, however, is not set down, because in this hypothesis it is obtained by subtracting the planet's coequated eccentric place from the true motion of the Sun; both of these are irregular, and it is therefore excluded from tables of mean and regular motions.

SCHOLIA.

Scholia.

[Margin: Censure of the Danish hypothesis.]

I. This Danish hypothesis has the following advantage: it preserves the uniformity of motion in each of the circles about their own proper centres; it does not fall back on an annual motion of the Earth; it uses the true motion of the Sun; and for the centre of the planets it has a definite and conspicuous point in the world, namely the centre of the Sun. But it does not carry the planet round along a perfect circle, and, by in fact employing an orb eccentric to the centre of the world, though concentric with the Sun, it seems to multiply circles, namely an eccentric with two epicycles, and these indeed having no definite centre in the world but one perpetually uncertain and unstable, with motions that conflict with one another.

II. It is one thing to determine the highest altitude of a planet, and another to determine the highest elevation of the heaven assigned to it. In the first way Tycho, tome 1, p. 480, sets Saturn's greatest distance from the Earth at 12300 terrestrial semidiameters; in the second way at 12900 semidiameters, that is, with the diameter of the lesser epicycle added, granted that in his scheme the planet is never at the apogee of the lesser epicycle when the centre of that epicycle is at the apogee of the greater.

[Margin: Baranzanus's error in the Tychonic distances.]

But Baranzanus, part 1 of the *Uranoscopia*, p. 121, ascribes to the planet itself the Tychonic greatest distance of 12900. He errs far more intolerably when he attributes to Tycho a least distance of Mars from the Earth of 1176 semidiameters, for it is much smaller. Since the mean distance of Mars, as he himself agrees, is 1745, and this same figure is the semidiameter of Mars's orb, then when Mars is opposite the Sun one must subtract the Sun's distance from the Earth, which at its mean is 1150. And so the centre D of Mars's greater epicycle, as in the figure placed above at no. 9, is then distant from the Earth by the quantity of the line TD, that is, by only 595 terrestrial semidiameters. From this distance two-thirds of the semidiameter of the greater epicycle have still to be subtracted, so that the least distance of Mars itself remains, which is certainly less than 595. We must therefore beware of mere collectors of this sort, who copy out figures without examining the hypotheses.

[Margin: Athanasius Kircher's Tychonic measure.]

Nor do I find correct the Tychonic measures of Father Athanasius Kircher, which he sets out at the end of the *Ars Magna Lucis et Umbrae*, from p. 762, where he gives the mean distance from the Earth, in semidiameters of the Earth, as ♄ 10550, ♃ 3990, ♂ 1745. But for their distances from the Sun, the Sun however at apogee, and in oppositions, in order to calculate their shadows, he gives ♄ 10588, ♃ 3652, ♂ 1628, and the Sun's apogeal distance from the Earth as 1181. These figures cannot hang together. For in oppositions the planet is at M, and the distance TM of ♄ from the Earth is then, in Tycho's terms, 8800;

if you add AT, 1181, it will make 9981, not 10588. And so with the rest, which need correcting.

III. Although Longomontanus, with the Sun and Mars at perigee, had set the semidiameter of the annual orb at 63028 parts, of which the radius of Mars's orb is 100000, nevertheless in Book 2 of the *Theorica*, at the end of chapter 12, he concludes that it is more correct and better suited to the phenomena of Mars if a radius of 63100 parts is always used for the least semidiameter of the annual orb. Students of this hypothesis should bear this in mind.

[Margin: The parallaxes of Mars.]

IV. Kepler reports in his work on Mars, chapter 11, that in 1582, when Mars was opposite the Sun in ♋, Tycho, with incredible diligence and by observation over several nights, morning and evening, hunted for the parallax of Mars through its distance from stars near the ecliptic but remote from Mars, so that their refraction should not interfere, and that he ordered his assistants to seek out the parallax by comparing the morning and evening observations. But they, Kepler says, fitted the observed places to the Copernican scheme, using a concentric and a double epicycle, and by an immense labour of triangles worked out how much parallax the Copernican scheme would produce; and perhaps it came about from this that Tycho stated that the parallax of Mars when acronychal is notably greater than the Sun's.

[Margin: Kepler's opinion on the parallax of Mars.]

But Kepler, examining these passages most diligently and reading through the volume of Tycho's observations, affirms that the parallax of Mars, even at perigee, is very small, yet somewhat greater than the Sun's, and that both are scarcely perceptible; and that solar eclipses require the parallax of the Moon from the Sun to be almost nil, because the Sun's is almost nil. Kepler teaches this in the *Ephemerides*, p. 2, in the *Epitome of Copernican Astronomy*, p. 479, and in the already mentioned work on Mars, chapters 11 and 64. There he proves it, first, because in that volume of Tycho's it is noted in Tycho's own hand that the matter sometimes turned out the opposite way, that is, that the effect found from the observations was at times the contrary of what a parallax of Mars greater than the Sun's would require.

[Margin: The method of observing the parallaxes of Mars, etc.]

Next, because parallax must throw retrograde Mars toward the east in the evening, and in the morning, when it is setting, throw it toward the west, and so accelerate its daily retrograde motion. Therefore, if its parallax is perceived near the acronychal position, that is, when it is retrograde, the retrograde motion must be perceived as excessively increased. But when the daily motions after the first station and during the time of retrogradation were examined from Brahe's observations of 1582, from 1582 November 23 and 24, on which days the distances from the fixed stars, found the same at different hours, showed the station, up to 1583 January 17, the retrograde motion was found either not increased at all, or scarcely perceptibly, or even at times diminished. Therefore the parallax of Mars, even at perigee, is either nil or scarcely perceptible. Lastly,

from the observation of the 17th he demonstrates that it is much less than 4′, and scarcely 2′, and therefore that the Sun's parallax is about 1′.

[Margin: Tycho's opinion on the parallaxes of Mars.]

Granted, Tycho, in a letter to Rothmann [Christoph Rothmann] of 1587 January 20, affirms from observations of 1582 that the parallax of acronychal Mars, and indeed of Jupiter too, is perceptible. And in a letter of 1588 to Peucer [Caspar Peucer], which Mästlin reports in his notes to the *Narratio* of Rheticus, p. 135, he says, again from observations of 1582, when Mars, up all night, was opposite the Sun in Cancer and had north latitude, that he found the daily motion of retrograde Mars against the order of the signs to be faster than the Alphonsine and Ptolemaic calculation allows, and almost as the Copernican calculation requires; that this acceleration arose from no other cause than a distance from the Earth smaller than the Sun's distance; that therefore in that position the parallax of Mars is greater than the Sun's; and that in this the Ptolemaic hypothesis gives way to the Copernican.

[Margin: Mästlin's opinion on the parallax of Mars.]

In that place, however, Mästlin, moved by Kepler's authority, does concede to Copernicus, Rheticus and Tycho that the parallax of acronychal Mars is greater than the Sun's, yet he affirms that it is very small and scarcely observable.

[Margin: Other authors for the nearness of acronychal Mars.]

After these men, the doctrine that Mars at perigee is nearer the Earth than the Sun is was taught by Longomontanus, Book 2 of the *Theorica*, chapter 9; Biancani in his *Sphaera*, book 13, chapter 1; Argoli in the *Pandosion Sphaericum*, chapter 3; Lansbergen, precept 14; Boulliau in his hypotheses; Galileo in Dialogue 3 *On the Cosmic System*, where he adds that Mars at perigee comes eight times nearer to the Earth, and appears six times larger, than when it is at apogee; and Antonín Maria Šírek, book 4, chapter 4, who adds that in ♌, when the Sun is in ♒ [recte: in ♒, when the Sun is in ♌, per the book's errata, which exchange the two signs; the corrected order is also written by hand in the margin of this copy], it sinks below the Sun. But it does this also in ♓ and in the opposite signs, as Lansbergen notes; and then, because of the nearness, the Sun's eccentricity bears a perceptible ratio to the radius of Mars's orb and cannot be neglected without error in the places of Mars.

[Margin: ♒ ♌, handwritten]

CAPVT IV.

Chapter 4.

De Hypotheſi Philippi Lansbergij.

On the hypothesis of Philips van Lansbergen.

[Margin: The source from which Lansbergen drew his hypothesis.]

I. This hypothesis, which by means of an eccentric with a small circle varying the eccentricity, together with the annual orb of the Earth, Copernicus

indicated and Mästlin expounded, as I reported in chapter 2, no. 4, Lansbergen offers us as if it were new, and expounds all too briefly in his

Theoricae of the heavenly motions, chapter 9, where he calls it "new and true and in agreement with all ages". But let the same judgement hold for it as for the second Copernican form, according to what was said in the scholia of chapter 2.

Let A, then, be the centre of the universe, about which the Earth revolves through the annual or great orb TRN, in the order of the signs, from R to N; and let the greatest eccentricity of the planet's orb be AD, the least AB, and the mean AC, so that AB is as large as BD, although the engraver has made BD somewhat larger.

Diagram. Lansbergen's scheme, set in the left column. A large circle, the eccentric orb, carries O at the top, K at the upper right, P at the foot, and Q at the left. Inside it are the signs ♄ ♃ ♂ (upper left). A vertical diameter runs from O down through G and E to P. A horizontal line runs from G through H to K. A second vertical runs from H down through the small circle's letters to A and on to I. A smaller circle about A, the annual orb, carries T at the upper right, R with a rayed disc at the lower left, N at the lower right, and I near its foot. A small circle stands above A, passing through a small letter at its top, through E with a rayed disc at its left, and through B at its foot, with F and C on its vertical diameter. Straight lines join E to K, A to K, E to F and E to C, and straight lines pass through A from R to T and from N to E. A line joins N to K, and a dashed line runs from T to K.

- O (top of the large circle): O
- G (on the vertical diameter, upper): G
- H (on the horizontal line): H
- K (right end of the horizontal line): K
- T (upper right of the annual orb): T
- D (top of the small circle): D
- E (left of the small circle, with a rayed disc): E
- F (on the small circle's vertical): F
- C (below F): C
- B (foot of the small circle): B
- A (centre of the annual orb): A
- N (lower right of the annual orb): N
- R (lower left of the annual orb, with a rayed disc): R
- I (foot of the second vertical): I
- P (foot of the large circle): P
- Q (left edge of the large circle): Q, drawn with a long tail turning right
- Inside the large circle, upper left: ♄ ♃ ♂

Then, having bisected BD at C, with semidiameter BC describe the small circle of the eccentricity DEB, on whose circumference let the centre of the planet's orb lie. This centre is to revolve on it in the order of the signs from B, through D, toward E, beginning from B, but with a double motion, that is,

twice as fast as the motion by which the planet, fixed on the circumference of the eccentric OQPK, moves with the motion of longitude in the order of the signs from the apogee O to Q. For in this way, when the planet is at apogee and at perigee, the centre of the orb will be at B.

Further, let the diameter of the great orb AD be the line of apsides, or of the mean apogee, to which a straight line drawn through the centre of the planet's orb is always parallel. Thus in our scheme, because the centre of the orb is at E, the straight line PEO is parallel to AD. Let this parallel be called the line of the true apogee, and let the planet's apogee be understood to move with the very slow motion of the line AD in the order of the signs. For so it will come about that when the centre of the planet's orb is at D the eccentricity is then greatest, and when at B least; and that if the planet is on the line of apsides it is at apogee, or below at perigee.

In the scheme, with the planet supposed at K, its apogee is at O, and the semidiameter of the planet's orb is EO. The line drawn from the centre of the orb through the planet, as here the line EK, is called the line of the mean place of the centre; but the line drawn from the centre of the universe through the planet is the line of the true place of the centre, as the line AK. Finally, the line drawn from the Earth to the planet is the line of the true place of the planet in the zodiac as seen from the Earth: if the Earth is at T, the line TK will be the line of the true or apparent place of the planet.

Therefore the equation of the centre is the angle AKE, to be subtracted from the mean motion of longitude in the first semicircle of the anomaly, OQP, and added in the second, PKO, so as to obtain the true centre. But the equation of the planet's orb, or of the second inequality, which arises from the annual motion of the Earth, is the angle AKT. In the first semicircle of the anomaly it is added to the true place of the centre, and in the second subtracted from it, so as to obtain the planet's true place in the zodiac with respect to the Earth, but reckoned from the mean equinox. If the true precession of the equinoxes is added to this, the result is the planet's true place reckoned from the true equinox.

[Margin: Why Mars needs a special correction.]

II. Since Mars, in travelling through the signs of Aquarius, Pisces, Aries and Taurus, comes very close to the Earth and at the same time to its acronychal opposition with the Sun, and in that position the Sun's eccentricity has a very perceptible proportion to the radius of Mars's orb, it follows that Mars then needs a special equation. Lansbergen has not yet set out the theory of this equation, but only a practical precept, which is number 14 among the precepts of his tables; we deal with it in the precepts of the tables. He supposes that the centric longitude of Mars must be corrected by a second equation: but what if this variation arises from the equations of the orb?

Methodus Calculi Geometrici in Hypotheſi Lansbergij.

Method of geometrical calculation in Lansbergen's hypothesis.

[Margin: 1. Step of the calculation.]

III. First, from Lansbergen's tables gather the planet's mean motion of longitude and the motion of its apogee, and subtract the latter from the mean motion of longitude; the result is the mean anomaly of the centre. For example, if Saturn's mean motion of longitude is 153° and that of its apogee 226°, then take 360° and join them to the 153°, which makes 513°, so that the subtraction can be made; and when 226° are taken away, there remains a mean anomaly of the centre of 287°. Double this anomaly and count it from the perigee of the small circle of the eccentricity in the order of the signs, and you will obtain the point on its circumference at which the centre of the eccentric lies. So in our case, when 287 has been doubled and made 574, a whole circle of 360 must be subtracted, and there remain 214°. Counted from B through D, these show the place of the eccentric at E, from which describe the eccentric orb OQPK. Through E draw a straight line parallel to the diameter AD of the great orb, so that the planet's apogee is at O. Counting from O in the order of the signs toward Q the anomaly of the centre, that is, in our case 287°, you will have the planet's place on the eccentric, which in our scheme is K. To it draw the straight line EK from the centre of the orb, and from the planet to OEP, the diameter of the orb, draw the perpendicular GK, and extend to it the diameter AD of the annual orb as far as H. Since, then, the arc KO is given, which is the complement of OQPK, that is, of the anomaly of the centre, to the full circle, and which in our case is 73°, its right sine GK is also given, 9563 in parts of which the semidiameter or radius of the orb EO is 10000; and the second sine GE will be 2924. Keep this in reserve.

[Margin: 2. Step.]

Second, in the small circle of the eccentricity the arc DE is given, which in our case is the excess over a semicircle, of 34°, and its sine EF, 5592, and its second sine CF, 8290, in parts of which the radius CE is 10000. CE is likewise given, because it is a third part of the supposed mean eccentricity, as in Saturn BC or CE is 285 of the parts of which EO is 10000, and AC is 855. Let it be done, then, as CE, 10000, to 285, so the sine FC, 8290, to another, and FC will come out at 236 of the parts of which EO is 10000. Therefore the whole AF will be 1091; and when FH, equal to the sine GE, 2924, is added, the whole AH becomes 4015 parts. Let it be done again as CE, 10000, to 285, so the sine EF, 5592, to another, and EF, that is GH, will come out at 159 of the parts of which EO is 10000. When this is taken from GK, 9563, there remains KH, 9404. And so in the triangle AKH, right-angled at H, the sides about the right angle are given, namely HK, 9404, and AH, 4015, from which by the analysis of triangles you will gather the angle HAK, 66° 58′, and the base AK, 9448. But the angle OEK was 73°. To it, because of the parallelism of the lines OE and HA, the angle HDK is equal, by 29 of the First Book; and this angle, by

32, is equal to the two interior and opposite angles DAK and AKD. Therefore, when DAK, 66° 58′, is taken from HDK, 73°, there remains AKD, 6° 2′, which is the equation of the eccentric. Here it is to be added to the planet's mean longitude, which was 153°, and so its centric longitude will be 159° 2′.

[Margin: 3. Step.]

Third, count from D, the planet's apogee, toward R, the distance of the planet's mean apogee from the mean motion of the Sun, and suppose it to be 117° 15′, that is, if the mean motion of the Sun is 117° 15′. For the remaining arc to the semicircle, RI, will be 62° 45′, equal to the arc DT, that is, to the distance of the Earth T from the planet's mean apogee D, and so the angle DAT will be known. Subtracted from the angle HAK found above, 66° 58′, it leaves the angle TAK, 4° 13′, in the triangle TAK, in which the side AK was found to be 9448, and the semidiameter of the annual orb AT is supposed known, in parts of which EO is 10000; in Saturn it is 1007. Therefore the angle AKT will not be hidden. This is the equation of the orb, to be taken away here from the longitude of the centre, so that the planet's true longitude from the mean equinox results; and when the prosthaphaeresis of the equinoxes is applied, the planet's true longitude from the true equinox will be obtained.

[Margin: 4. Step, for ♂.]

Fourth, if the place of Mars is to be computed, Lansbergen's precept 14 must be consulted, which we hold over for the precepts of the tables, because it concerns a merely logistic calculation and does not teach a way of hunting out this equation geometrically for the place of Mars.

Menſuræ ac Numeri ad Hypotheſim Lansbergij ſpectantes.

Measures and numbers concerning Lansbergen's hypothesis.

IV. Lansbergen has given the measures of the eccentricities and of the radius of the planets' orb, but only in parts of which the radius of their orb is 10000, in the *Theoricae* of the heavenly motions, chapter 9, and at the end of the *Treasury of Observations*. From these, and from the Sun's distance from the Earth, which is the same as the semidiameter of the annual orb, and which he gives in the *Uranometria*, book 2, Element 9, as 1498 35/60 terrestrial semidiameters, we have gathered the distances of the three planets from the Sun and from the Earth, the greatest, the mean and the least, which, however, he himself indicates in book 3 of the *Uranometria*, Elements 4, 5 and 6.

Recall that the centre of the planet's orb is at B, with the planet both at apogee and at perigee; and therefore that when the least eccentricity AB and the radius of the orb EO are joined, the planet's greatest distance from the Sun A results, and when AB is subtracted from the same radius, the least distance from the Sun is left. Therefore, if to the former you add, and from the latter subtract, the radius of the great or annual orb, the result will be, in the former case, the greatest, in the latter, the least distance of the planet from the Earth. For Lansbergen uses the Sun's mean distance from the Earth, because the radius

of the great orb is equal to it. These distances are, moreover, those that are possible in this hypothesis, if the lines of apsides of any planet and of the Sun were to coincide, and the planet at apogee were to be joined with the Sun at apogee, or the planet at perigee opposed to the Sun at apogee: for in the former case the distance of the planet from the Earth would be the greatest among those possible in this hypothesis, and in the latter the least; though [?] we rightly said in chapter 1, scholium 6, that these have never coincided and never will.

[Margin: Phocylides's opinion on the eccentricity of Saturn.]

Furthermore, Johannes Phocylides Holwarda, in his *Examination of Lansbergen's Astronomy*, contends from acronychal observations of Saturn that the greatest eccentricity of ♄ is 1140 and the mean 860. Everyone sees that the other objections that can be brought against the second form of Copernicus can also be brought against this one.

	♂	$7^{s}\ 29^{\circ}\ 20'\ 7''$

SCHOLIA.

Scholia.

[Margin: Objections against this hypothesis.]

I. Lansbergen's hypothesis, which is in fact that of Copernicus, does keep the motions equal in the circles about their own proper centres. But the centres of the eccentric or of the small circle of the eccentricity are not a definite point in the world, or one worthy of the planet's mover having regard to it; the planet's path in the world is not perfectly circular; and it is bound to the annual motion of the Earth. These are the things I see can be objected to it. It does, however, contain the equivalent of the Ptolemaic equant, since it has bisected the whole eccentricity into two equal parts.

[Margin: Hérigone's semi-Lansbergian hypothesis.]

II. Further, Pierre Hérigone, in tome 5 of the *Cursus Mathematicus*, in the *Theoricae*, p. 536, transferred this hypothesis to the hypothesis of a stationary Earth, which I shall not be reluctant to set out here. Let A be the centre of the motionless Earth, about which let there be the circle CT, carrying the apogee in the order of the signs from C toward T; and let the line of apsides be FAY; and from the point C, where that line cuts the circumference of the circle CT, describe the small circle

BDE, which is to be called that of the anomaly of the eccentric; and on its own circumference let it carry the centre E of the eccentric PGYH, with a double motion, that is, one twice as fast as the motion of the centre G from the mean apogee I, the motion beginning at D toward E, and from there to B, etc. Next, from G describe the circle of the anomaly of the orb, or epicycle, NML, on whose circumference let the planet be, as at L, and let it move in the order of the signs from the true apogee of the epicycle, N, by as much as the mean motion of the Sun exceeds the mean motion of the centre G. Let the line FY, drawn through the centres of the Earth and of the small circle of the anomaly of the centre, be the line of the true apogee; and let IE, parallel to it and drawn through the centre E of the eccentric, be the line of the mean apogee I, from which the anomaly of the centre is counted. So when the centre of the epicycle is at the apogee F or the perigee Y, the centre of the eccentric will be at D; the lines of the mean and the true apogee will coincide, there will be no need

of any equation of the centre, and its true place in the zodiac will be the same as that of the apogee or the perigee. Now, however, since the centre of the eccentric is supposed to have completed the arc DE at E, say of 100°, while the centre G, departing from the apogee I, has completed the arc IG toward G, of 50°, let the straight line EM be drawn from the centre E through the centre G of the epicycle; for it will be the line of the mean motion of the centre. Parallel to it let AK be drawn from the centre of the Earth, and through the centres of the Earth and of the eccentric the straight line VAEP, so that the angle IEC [recte: IEG] is equal to the angle FAK. And from A let the straight line AGN be drawn through the centre of the epicycle, to be the line of the true place of the centre G; for the angle AGE will be the equation of the centre, to be subtracted, in the first semicircle of the anomaly, from the mean motion of the centre G, so that the true motion may be had. Finally, since we have supposed the planet at L, let the straight line AL be drawn to it, and the semidiameter of the epicycle GL; for the angle GAL will be the equation of the anomaly of the orb, to be added, in the first semicircle of the anomaly, to the true place of the centre G, so that the true place of the planet may result, counted from H, which is the point of the mean equinox, or from R, that of the true equinox.

Diagram. A figure set into the left column, for the construction just described. A large circle (the eccentric) has a vertical line running from F at its top down through the small circle and A to Y at its foot. A smaller circle stands inside it about A, and a small circle bearing B, C, D and E lies just above A. An epicycle centred on G sits on the upper left of the large circle, with N, M and L on its circumference. Straight lines run from the region of A and E to the points on the circumference.

- N, M (upper left, on the epicycle): epicycle points
- G (centre of the epicycle)
- L (left side of the epicycle)
- F (top of the vertical line)
- I (immediately right of F): mean apogee
- P (upper right of the large circle)
- K (left, outside the large circle)
- B, C, D, E (small circle above A)
- H (right, on the large circle)
- R (right, below H)
- T (left of A, by the inner circle)
- A (centre of the Earth)
- V (lower left)
- Y (foot of the vertical line)

Labels read: N, M, G, L, F, I, P, K, B, C, D, E, H, R, T, A, V, Y. Labels not read: none known. T is on the figure and is not cited in the text on this page.

[Margin: Method of geometrical calculation for the equation of the centre.]

III. With these things laid down, if the mean motions are given from the tables, and the measures of the semidiameter of each of the circles, the

prosthaphaereses will be gathered by this method. Subtracting the motion of the apogee from the mean motion of longitude gives the anomaly of the eccentric, or of the centre, that is, the angle IEG, to which FAK is equal. Twice this is the arc DE, that is, the angle ACE in the triangle ACE, in which the semidiameters AC and CE are given (CE is missing in the figure). So the eccentricity AE will not be hidden, nor the angle CAE, to which the angle IEP is equal; added to the angle IEG, it makes up the angle PEG, whose complement to two right angles is the angle AEG. Therefore, in the triangle AEG, with the angle just mentioned, the eccentricity AE and the semidiameter of the eccentric EG, you will find the angle AGE, to which, because of the parallelism, the angle GAK is equal, that is, the equation of the centre. Subtract this from the mean motion of longitude in the first semicircle of the anomaly and add it in the second, and the true place of the centre G in the zodiac will result, counted from the mean equinox; and, with the prosthaphaeresis of the equinoxes, from the true equinox.

[Margin: Method of calculation for the equation of the orb and the distance of the planet from the Earth.]

IV. Then, in the triangle AGE, from the data already mentioned, seek the side AG, that is, the distance of the centre of the epicycle from the Earth; and by subtracting the mean motion of the centre G, or of longitude, from the mean motion of the Sun, obtain the anomaly of the orb, or the motion of the planet L on the epicycle from the aux M. For when MGN is added, the arc NML will be known, whose complement to a semicircle in this case will make known the angle AGL. So, this being given, with the side AG and the semidiameter of the epicycle GL, you will hunt out in the triangle AGL the angle GAL, which is the equation of the anomaly of the orb, to be added to the true place of the centre G in the first semicircle of this anomaly and subtracted in the second, so that the true place of the planet may be established. And, if you wish, you can find in the same triangle the planet's distance from the Earth, AL.

[Margin: The measures pertaining to this hypothesis.]

V. As for the measures of the circles or semidiameters, consult the first table of the preceding page, placed after number 4. For, as Hérigone would have it, the semidiameter of the small circle CD is as great as the semidiameter of the small circle of the eccentricity in Lansbergen, namely in ♄ 285, of which the radius of the eccentric EG is 10000, etc.; and the semidiameter of the deferent of the apogee, or AC, is as great as the eccentricity midway between the greatest and the least, for example in ♄ 855 parts. Finally, the semidiameter of the epicycle GM is as great as the radius of the great orb in Lansbergen's hypothesis, that is, in ♄ 1007.

[Margin: A mistake in Hérigone.]

But Hérigone's numbers in ♂, as regards the semidiameter of the small circle CD, are corrupt: he has 247 ½, when 485 ought to be put in its place, for CD in Lansbergen is a quarter of the greatest eccentricity, which is 1940. Unless perhaps Hérigone, led by some reason of his own, thought Lansbergen needed

correcting on this point; but in that case he ought at least to have said so. The numbers of the motions and the greatest equations, however, are exactly as in Lansbergen.

[Margin: The same hypothesis fitted to ♀.]

Finally, he adds that this same theory suits Venus, assigning for ♀ 102 to CD itself, likewise 102 to AC, and 7193 to GM, of which EG is 10000; the greatest equation of the centre 2° 32′; and the orb 45° 10′ at the apogee and 46° 51′ at the perigee.

CAPVT V.

Chapter 5.

De Hypotheſi Kepleri, & Bullialdi.

On the hypothesis of Kepler and Boulliau.

[Margin: Summing-up of the preceding hypotheses.]

I. Until now astronomers had remained divided, as it were, into two classes. The older of these, from Ptolemy down to Peuerbach and beyond, affirmed that the inequality which appears in the motion of the planets is partly physical and real, partly apparent; and it held that half of it, namely the apparent part, rests on half the eccentricity of the circle that carries the planet or its epicycle. But it used nothing but circles; indeed, it led the planet around a perfect circle. Finally, it measured the second inequality from the mean conjunctions of the planet with the Sun and by the mean motion of the Sun. The other class, from Copernicus onward, together with the earlier opinion of Tycho and Longomontanus and together with Lansbergen, rejected the physical inequality and maintained that the motions of the planets about the centres of their orbs are equal. It said that the whole inequality appearing in their motion is optical, or appears such to us, because we view these motions from a position outside the centre of the celestial orbs; and so it kept the entire eccentricity as the foundation of this irregularity. For that reason, although it used perfect circles, it nevertheless carried the planet around along the path of an imperfect circle. Of these, some used the mean motions of the Sun and others the true motions in measuring the second anomaly.

[Margin: The new hypothesis of Kepler, and his followers.]

II. Both were succeeded by Johannes Kepler, who broke away from both, agreed with both on certain points, and introduced an entirely new hypothesis. He pursues it at length in the *Commentaries on the Motion of Mars* and in the *Epitome of Copernican Astronomy*, Books 5 and 6. Hérigone leans toward it in tome 5 of the *Cursus Mathematicus*, from p. 550 to p. 588; Ismaël Boulliau embraced the same hypothesis wholeheartedly (if you except the planet's motive force) in his *Astronomia Philolaica*; and so did Magini, as regards the motions of Mars, in the *Supplement to the Ephemerides*. Kepler, then, emboldened by the authority of the former class, granted that the second inequality is optical

and arises from the motion of the Earth, but he asserted that the first is wholly physical and real, even though, if the eye is transferred to the Sun, he may have called part of it optical; so that the planet, about the centre of its orbit and indeed about the Sun as well, completes unequal arcs in equal times. And yet he taught that the eccentricity must be bisected. From the second class he drew the imperfection of the planetary path, or its deviation from a perfect circle; and, daring to break up perfect circles and the whole structure of eccentrics and epicycles, he carried each planet around along the simple circumference of a single ellipse, in one of whose foci, or umbilici, is the Sun. About the Sun, likewise motionless as regards motion of translation, he revolved the Earth in an annual motion as one of the planets. The second inequality, however, from the true or apparent conjunction and motion of the Sun, he measured. Although we have already given a foretaste of this hypothesis in connection with the Sun and the Moon in Book 3, chapter 23, no. 3, and more fully in Book 4, chapter 27, up to no. 17, and in the scholia of the same chapter from 1 to 10, and I have touched on many things that belong here and are to be reread here, it must nevertheless be set out in this place, with its properties and, as it were, its characteristic marks distinctly added, by which it is distinguished from the other hypotheses. I shall do this more clearly if I first provide a diagram suited to representing it.

III. In the following figure let the Sun be A, at the centre of the universe, from which let the ecliptic BDCE be described, whose diameter BC is to be the line of apsides of the Sun and the Earth; and on it the centre G, from which describe the Earth's ellipse PNQT. Along it let the Earth move toward the east, from the aphelion P to N, with an annual motion; let the Earth's perihelion be Q, and let the eccentricity of this ellipse from the Sun be AG. Now let us imagine the aphelion or apogee of one of the three superior planets to be under the same point of the zodiac B as the aphelion of the Earth, say under the beginning of ♈, and therefore the line of apsides of the planet and of the Earth to be the same, with the centre on it at F. From F describe the planet's ellipse XHZY, on whose circumference let the planet move in the order of the signs from the aphelion X to H. Let the eccentricity of this ellipse from the Sun be AF, and the greater semidiameter, or semiaxis, FX; the lesser, or conjugate, semidiameter FH, which is to be perpendicular to the axis XZ; and let the Sun A be at one of the foci, or umbilici, of the ellipse. Let the centre of the Sun be joined to the end H of the lesser semidiameter by the straight line AH. For by the properties of the ellipse demonstrated by Apollonius, AH will be equal to the greater semidiameter FX, and therefore the planet at H, as also at the opposite point, will be at its middle distance from the Sun, while its greatest distance from the Sun will be AX and its least AZ. The planet's greatest distance from the Earth will be QX, if, with the planet placed at X, the Earth is at Q; yet it would come out greater if, with the planet at the apogee X, the Earth, at Q, were at aphelion, and AQ were as great as AP, that is, as great as the greatest distance of the Earth from the Sun. The planet's least distance from

the Earth will be ZQ, which would come out smaller still if, with the planet placed at perihelion Z, the Earth at Q were at aphelion and, receding from the Sun, were approaching the planet. But on this meeting see what was said in chapter 1, Scholium 6.

[Margin: Four situations of the Earth, the planet and the Sun.]

With these things laid down, four possible situations of the Sun, the Earth and the planet taken together must be considered. The first is if, at the same moment at which the planet appears to the Earth conjoined with or opposite the Sun, it is at aphelion or at perihelion. Then both inequalities cease and no equation is needed; the place in the zodiac of the centre F and of the planet is the same, and the mean and the true motion coincide: as when, with the Earth placed at P or at Q, the planet is at X or at Z.

[Margin: 2. The situation in which the first inequality ceases.]

The second is if the planet is at its aphelion X or at its perihelion Z, but the Earth is outside the planet's line of apsides, which is always passed through the centre of the Sun. Then the planet's first inequality ceases and there is no need of the equation of the centre, but the second inequality comes in, as when the Earth is at T; and the equation of the second anomaly, or prosthaphaeresis of the orb, is needed. For the true place of the centre F will be under B or C, but the apparent place of the planet X will be the point V in the zodiac, which is marked by the line of true motion TXV, drawn, that is, from the Earth through the planet.

[Margin: 3. The situation in which the second inequality ceases.]

The third situation is if the planet, away from its aphelion and perihelion, is conjoined with or opposed to the Sun in true ☌ or ☍. Then the first inequality will come in and the equation of the centre will be needed, but the second anomaly will cease: as when, to the Earth at T, the planet appears either conjoined with the Sun at S or opposite it at Y.

[Margin: 4. The situation in which both inequalities show themselves.]

The fourth situation is if the planet is away from its aphelion and perihelion and neither joined to nor opposite the Sun. In this case a twofold irregularity comes in, and an equation is needed both of the centre, or of the eccentric place, and of the anomaly of the orb, or of commutation: as when it is at H and the Earth at T.

[Margin: Correction of an imagining, and a sketch of a truer diagram.]

IV. But so that no one, misusing the present diagram, may carry over the most perfect idea of this hypothesis from mere possibility to actual use, it must be understood that it has never happened, nor, granted the end of the world (which by probable conjecture is expected after a few centuries), will it ever happen, that the aphelion of the Earth and that of any of the three superior planets are under the same point of the zodiac; and we judge it impossible for the aphelia of all of them together to meet at the same point, because of the incommensurability in their motion. For the apogee of the Sun at the beginning of the world was under the beginning of ♈ and is now a little after

the beginning of ♋; the Earth's aphelion was then in ♎ and is now in ♍; Saturn's aphelion was then about the end of ♏, and is now about the end of ♐.

Diagram. A figure set into the right column, for the hypothesis of the planetary ellipse. A large outer circle, the ecliptic, is ringed outside by the twelve zodiac signs. At the centre stands a rayed Sun at A. Inside the outer circle are a smaller and a larger closed curve (the Earth's and the planet's ellipses) and a vertical diameter from B at the top to C at the foot. Straight and dotted lines run through A across the figure to the signs and the planet symbols.

- ♍ with V and K (top, outside the circle)
- ♒ (upper left), ♓ (left), ♈ (left), ♉ (lower left), ♊ with D (lower left), ♋ with R and C (foot), ♌ (lower right), ♍ (right, lower), ♎ (far right), ♏ (upper right), ♐ with E (upper right)
- B (top of the vertical diameter)
- X with ♄ (below B)
- P, F, G (descending on the vertical above A)
- A (centre, in the rayed Sun)
- Y (upper right, inside the outer circle)
- T (right of the vertical)
- H (left, end of a horizontal line from F)
- M (left, below H)
- N (left of A)
- L (right of A)
- ♃ with γ (right, on a dotted line through A)
- δ (left, at the outer end of the same dotted line, below ♈; cut with a descending tail)
- I with ♂ (lower right of A)
- Q, Z (below A on the vertical)
- S (lower left of A)

Labels read: all those listed. Labels not read: none known.

Jupiter's aphelion was then near the end of ♋, and is now a little after the beginning of ♎. Finally, Mars's aphelion was then at the middle degrees of ♉, and is now at the end of ♌ or the beginning of ♍. As for a future meeting, if the world were to last, I have already spoken of it in chapter 1, Scholium 6. So, that you may be able to draw a diagram fitting any time, once the planet's aphelion is given, a straight line must be passed through the centre of the Sun A to the places of the zodiac in which the aphelion lies on the one side and the perihelion on the other, and the eccentricity from the Sun must be taken on it, so that you obtain the centre of the ellipse to be drawn. Accordingly, to give an example fitted to this time of ours, the line of apsides of Saturn will be KAR, its aphelion under K and its perihelion under R, and its eccentricity approximately AF. So from the centre F Saturn's elliptical orbit must be described, so that Saturn at aphelion is at ♄ and at perihelion almost at Z. The line of apsides of Jupiter, on the other hand, will be γ A δ, its aphelion under γ, its perihelion under δ, and its eccentricity from the Sun AL. Therefore from the centre L you

will describe Jupiter's ellipse, so that Jupiter at aphelion is at ♃ and at perihelion at N. Finally, the line of apsides of Mars will be ♍ A ♓, its aphelion nearly under ♍ and its perihelion nearly under ♓, and its eccentricity from the Sun AI. So from the centre I you will draw the ellipse of Mars, in such a way that Mars at aphelion is at ♂ and at perihelion approximately at M. But such will be the proportion between the Earth's annual orb and the ellipse of Mars that Mars in opposition to the Sun, especially at perihelion, is much nearer to the Earth than the Earth is to the Sun. Now we must come down to the more notable properties of this new theory.

De Proprietatibus & Characteribus huius Hypotheſeos.

On the properties and characteristics of this hypothesis.

Propoſitio 1. Apſidum Linea Quinque minorum Planetarum tranſit per Centrum Corporis Planetæ, & Solis.

Proposition 1. The line of apsides of the five minor planets passes through the centre of the body of the planet and of the Sun.

[Margin: 1st property.]

V. So Kepler teaches in the *Mars*, chapters 5, 6, 33 and 52, and in the *Epitome of Copernican Astronomy*, pp. 539 and 763; Boulliau, in Book II, theorems 2, 6, 11, 12. For in the ancient hypothesis the line of apsides of these planets passed either through the centre of the Earth or through the centre of the annual orb of the Sun, and the centre of the planetary system was the point about which the Sun was supposed to move uniformly. But Copernicus put that centre at the point about which he thought the Earth moves uniformly, and therefore near the Sun, distant from the Sun only by the amount of the eccentricity attributed to the Sun; and from that limit he computed the eccentricities of the planets. Ty- cho, however, placed the same centre near the Sun, because they wished to represent in their hypotheses the equivalence of the Ptolemaic hypothesis. But Kepler and Boulliau placed the centre of the planetary system in the very centre of the body of the Sun, on a twofold argument.

[Margin: 1st argument, a posteriori.]

The first is a posteriori, from observations, especially of Mars in its acronychal shinings. These observations, properly handled, testify that the line of apsides, that is, the line that cuts the planet's orbit into two semicircles equal in the quantity and speed of motion, or that passes through the two points at which the slowness on one side and the speed on the other are greatest, passes through the body of the Sun. The observations by which this is urged are presented and weighed, for Mars, by Kepler, chapters 51 and 52 of the *Mars*, and by Boulliau, Book II, theorem 2; for Saturn, theorem 6; and for Mercury, theorem 12. For when two observations are chosen at which the planet is equally distant from the aphelion on either side, that is, before and after, or from the point of greatest slowness, the lines drawn from them to the centre of the Sun are found to be

equal, as they must be, while those drawn to any other point are unequal. And the angles of the equations of both inequalities are never correctly found, that is, they never agree exactly with the observations, unless the line of apsides is drawn through the centre of the Sun itself.

[Margin: 2nd argument, a priori.]

The second argument is a priori: it is not likely that the planet's moving power, in dispensing its motions, looks to a point in the world that is empty, of no account and unstable, especially for Copernicus, who set the Earth's eccentricity as different in different centuries, and finally a point inhering in no body of the world and resting on imagination alone (for Tycho destroyed solid orbs from the trajectories of comets). Indeed, it is more probable that, if the centre is near the Sun, it is rather the Sun itself, whether the Sun is the centre of the universe, as in Copernicus, or as it were the centre of the planetary system, as in Tycho; for it is the worthiest centre and the fountain of light. And so these planets move around it in order to be lit by it; for we have already all but proved, in Section 1, chapter 5, that they are lit by the Sun. So if you remove the body of the Sun from the centre of the planetary system, you do just as if you took the heart out of its body. Let it stand, then, that the line of apsides, that is, the line that bisects the planet's course into two semicircles equal in the quantity and speed of motion, is passed through the centre of the Sun's body, and that the planet's orbit is cut by the ecliptic at places that appear opposite from the centre of the Sun and not from any other point. Granted that Longomontanus, Book 2, chapter 9, Mars excepted, doubts about the others and seems to persist in the opposite opinion: let it stand, I say, in the hypothesis of a motionless Sun; for in Ptolemy's hypothesis that line must be passed through the centre of the Earth.

Propoſitio 2. In ſecunda Inæqualitate, ſeu in Anomaliæ Commutationis menſura, non Media Planetarum cum Sole oppoſitio vel coniunctio, nec Medius motus, ſed Vera Veruſque ſeu apparens Solis motus adhibendus eſt.

Proposition 2. In the second inequality, that is, in measuring the anomaly of commutation, it is not the mean opposition or conjunction of the planets with the Sun, nor the Sun's mean motion, but the true opposition or conjunction and the true or apparent motion of the Sun that must be used.

VI. This proposition is akin to the first and connected with it, yet different from it, because that one concerns the first inequality and this one the second. This proposition is shown, both a posteriori and a priori, by Kepler in the *Mars*, chapters 6, 7, 9, 18, 52, in the letter to Magini that Magini reports in the *Supplement to the Ephemerides*, from p. 242, and in the *Epitome of Copernican Astronomy*, p. 535; and by Boulliau, Book 11, theorems 3, 7, 8 and 11. For their arguments to be understood, the procedure of the ancients must be gone over again here.

[Margin: Two reasons for which the ancients chose the mean motions of the Sun here.]

So Ptolemy, from Book 9 of the *Almagest*, and with him Regiomontanus in the *Epitome of the Almagest*, Book 10, propositions 9 and 10, and Copernicus, Book 5, chapters 5, 6, 10, 11, 15 and 16, and Lansbergen in his *Theoricae*, thought that these planets are stripped of the second inequality, which is tied to the motion of the Sun, whenever they fall at the points of mean conjunction or opposition with the Sun, because the difference of the planet's place from its centric place then appears either nil or barely perceptible; and it was customary for Ptolemy to disregard slight differences of this kind, or to refer them to the fault of the instruments and observations. On the other hand, the calculation came out far easier if the mean motion of the Sun was used.

[Margin: The procedure of the ancients in separating and establishing the first inequality.]

Confident in this persuasion, then, they observed the superior planets in their acronychal shinings, when it is established that they are close to opposition to the Sun. If, at the moment of the observation, the planet's place had been opposite the place that the tables of mean motions then assigned to the Sun, they concluded that at that very point the mean opposition with the Sun took place, and that at the same point the planet was under the same place as the centre of the epicycle, at the very middle of its retrogradation, that is, of that greatest slowness which appears in the motion of the second inequality. But if the planet was not then at the point of mean opposition with the Sun, they compared other observations made on other nights, and the daily motions of the planet and the Sun, and hunted out the point of mean opposition and the moment at which it had taken place, or was to take place, a little before or after. When they had done this in various places of the zodiac, and had compared the acronychal observations and the equations needed to make the planet's place derived from the tables of mean motions agree, at the points of mean opposition, with the place observed by instruments, they began to investigate, on the one hand, in which places of the zodiac it needed no equation, and at these they said the apogee and perigee of the eccentric lay; and, on the other, in which places equations had to be subtracted or added. Throughout the time in which they had to be subtracted, they said the planet was receding from the apogee of the eccentric toward the perigee; and throughout the time in which they had to be added, that it was receding from the perigee and climbing toward the apogee. Finally, from the angles of the equation and of the mean motion, and from the radius of the eccentric, they worked out the eccentricity, and thus established the hypothesis of the first inequality. Passing from here to the second inequality, they took its measure from the planet's elongation from the mean place of the Sun. For when they saw that, outside the conjunctions and oppositions with the Sun, the usual equations of the eccentric were not enough to make the planet's place drawn from the tables agree with the place observed in the sky, they distributed the increase and decrease of those equations into

tables, according to the greater or lesser elongation of the planet from the mean place of the Sun. And so, to find the anomaly of the orb, or of the epicycle, some ordered the planet's mean motion in longitude to be subtracted from the mean motion of the Sun, and others the true motion of the centre, that is, the motion of longitude coequated by the first equation. Finally, they affirmed that the line drawn from the centre of the epicycle to the centre of the planet's body, when the planet is at the apogee or perigee of the epicycle, coincides with the line of the Sun's mean motion; but that outside those two points it is a different line, though always parallel to the line of the Sun's mean motion.

VII. But Kepler and Boulliau, in the places indicated above, show that the second inequality ceases exactly when the planet is at the points of true, or apparent, conjunction or opposition with the Sun; and that therefore, to find the anomaly of the orb, or of commutation, that is, of the second inequality, the coequated centre of the planet, or the planet's eccentric place, must be subtracted from the motion of the Sun, not the mean but the true, as Tycho did in the case of the Moon. After reading the work on Mars, Longomontanus subscribed to Kepler's view, Book 2 of the *Theorica*, chapter 9.

[Margin: 1st argument, a posteriori, for the true place of the Sun.]

This, I say, they show first a posteriori, from observations. For although near the conjunctions or oppositions with the Sun the difference between the planet's observed place and the place derived from the tables is very slight, for those who use the Sun's mean motion in finding the anomaly of the orb or of commutation, yet outside these points a quite perceptible difference is found, especially with the Sun at perigee, as it now is at about 6° ♑, and greater still if the line of the mean longitudes of the annual orb coincides with the line of apsides of Saturn, Jupiter and Mars.

[Margin: The difference between those who use the true and those who use the mean place of the Sun.]

So much so that the difference between those who refer the places of the planets to the true place of the Sun and those who refer them to the mean can then run up to about 5° 19′ in Mars, to 15′ in Saturn and to 30′ in Jupiter, that is, to an error of several days, because of the slowness of the motion. Boulliau shows this difference in Book 11, theorem 8, with a diagram of this kind, in which the Sun is at P, the eccentricity of the annual orb is PR, the annual orb MKI is described from the centre R, the Earth's line of apsides is MI, with its aphelion in ♑ when the Sun appears to the Earth in ♋, and the line of the mean longitudes of the annual orb is LPN, because it cuts the line of apsides perpendicularly at the centre of the Sun. The orb

of ♄, ♃ or ♂, now, is to be ACFH, and let their line of apsides be BPE, drawn through the Sun. Parallel to it let ARF be drawn through the centre of the Earth's mean motion, representing the apsides of the planets as they pass through the mean motion of the Earth, or rather of the Sun. Let the planet move from A to B, that is, from ♌ to ♋, and the Earth from L to M (for the viewer of this diagram is supposed to be facing north, toward which the apogees

of the three superior planets tend), and let the planet be supposed at D, and let the line PD mark its eccentric place. On this line the Earth will be at L if the planet is truly opposite the Sun, or at N if it is in conjunction with it; just as, if the planet is at G, it will appear truly opposite the Sun P to the Earth at N, but in conjunction with the Sun P to the Earth at L.

Diagram. A figure set into the left column, for the comparison of true and mean opposition. A large outer circle (the planet's orb) carries zodiac signs at its rim. A smaller circle (the annual orb) stands inside it. A vertical line runs from the top of the large circle down to its foot, and a second, nearly parallel vertical line beside it. Oblique lines cross the small circle through its centre region and run out to the large circle, from D and C at the upper left to G and H at the lower right, and from M at the upper right to I at the lower left.

- Top of the large circle: sign ♌, with A and B just below it.
- Upper right, outside the circle: sign ♋.
- Upper left, on the large circle: C and D, with a zodiac sign beside D [?].
- On or near the small circle: L, K and T at the upper left, S and M at the upper right, I at the lower left with a zodiac sign below it [?], N and O at the lower right.
- Centre: R and P.
- Lower right: G, with the sign ♈ beside it.
- Foot of the large circle: F, E and H.

Labels read: A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, R, S, T, ♌, ♋. Labels not read: the three signs marked above. T stands on the figure but is not cited in the text on this page.

Next draw CRH parallel to the line DPG, passing through R, the centre of the Earth's mean motion; for according to the old astronomy the acronychal point [Acronychium], that is, the mean opposition of the Sun and planet, will occur when the planet is at C and the Earth at K, or when the planet is at H and the Earth at O. The question now is how far the places of the planet among the fixed stars, as seen from the Earth at L and at K, or from the Earth at N and at O, differ: that is, the angle KDL if the planet is at D, or OGN if it is at G. This angle is found in the triangle KLD, by the following method. Given the planet's place at D, its distance from the aphelion B is given, that is, the angle BPD, to which the angle ARC is equal because of the parallelism. The planet's distance from the Sun, PD, is then derived, in parts of the radius of the annual orb, from the given eccentricity of the planet, PS, and the radius SD, which is here to be supplied in the figure in imagination. Next the distance of the Earth at L from the Sun, that is, PL, is assumed as given in the tables or as found; and when it is subtracted from DP, the side DL remains known. Moreover, the difference between the true and the mean place of the Sun, or rather of the Earth, is given, that is, the arc KL, and its sine, to be understood here in parts of which the radius of the annual orb, RK, is known; for the arc KL is taken here for a straight line making a right angle at L, since it differs imperceptibly from one. Therefore in the triangle KLD, right-angled at L, the

angle KDL will become known, which was to be done. Since, therefore, the celestial motions cannot be represented with rigour, nor observations exactly reproduced by calculation, unless they are referred to the true place of the Sun, it is clear that the ancient astronomers, as many as used the mean, strayed from the heaven and from the truth. Remember, however, that at true ☌ and ☍ the planet's place must be reduced from the ecliptic to the orbit, as Kepler teaches and does in the *Mars*, chapter 9; otherwise an error of 9′ can be committed.

[Margin: 2. Reason a priori.]

VIII. The second reason is a priori, from the causes of the planet's motive force. Whether this is the Sun, as Kepler holds, or an intrinsic force and the planet's own form, as Boulliau holds, no probable reason persuades us that the planets, which circle the Sun so as to be illuminated by it, and which with wonderful harmony quicken or slacken their motion about it, so much so that in ☌ they are direct and swiftest and in ☍ retrograde and slowest, look to a point near the Sun, empty and unstable, rather than to the very centre of the Sun's body, which is the heart and source of the planetary light; and that they regulate their courses by a fictitious line and by the Sun's mean motion, which is true in only two cases and in all the others is false and fictitious, not really existing in the heaven but only drawn, from our imagination, in our tablets and papers. Kepler adds, in the *Mars*, p. 53, that this hypothesis fits better with the intervals he had determined in his *Mysterium*.

[Margin: Tycho's last opinion, and Longomontanus's.]

Finally, just as Copernicus and Tycho placed the centre of the planetary system not at the centre of the Earth or at a point near the Earth, but at a point near the Sun, so as to represent the motions of the planets more exactly and more elegantly, so it was more in keeping with their view that they should set it in the very Sun itself. Tycho finally acknowledged this in his last days, as Kepler testifies in the *Mars*, chapter 6, p. 47, and Longomontanus in Book 2 of the *Theorica*, chapter 3, at the end of chapter 11, and chapter 13; granted that Boulliau, in Book 11, theorem 11, lumps him in with the ancient astronomers who use the Sun's mean motion.

[Margin: To whom Boulliau attributes the opposite.]

Propoſitio 3. Planetæ iter eſt per lineam Ooidem ideſt Ouiformem, ſeu Ellipticam; ſeu Orbis illum deferens non eſt perfectus circulus, ſed Ellipſis.

Proposition 3. The planet's path runs along an ooid line, that is, an egg-shaped or elliptical line; that is, the orb that carries it is not a perfect circle but an ellipse.

IX. Kepler urges this proposition in the *Mars*, chapters 22, 23, 39 and from chapter 40 to 50, in the *Epitome of Copernican Astronomy*, Book 5, from p. 658, and in the Rudolphine Tables, chapter 20. So does Boulliau, in Book 11 of his *Astronomia*, Book 10, chapter 1, where he says: *I held it a matter of religious scruple to depart from the circular hypothesis, and it had not occurred to me that the*

path of the planets could be elliptical; apart from which, if anyone tries to twist the planets' progress into other orbits, he will waste his oil and his labour by doing violence to them, and will roll the stone of Sisyphus. And in Book II, theorems 7 and 13, he admits that, because the difference from a circle of the ellipse attributed to them is scarcely perceptible, it cannot readily be shown from particular observations of Saturn, Jupiter and Venus that their path is elliptical, but that no one will be left in doubt about this if he reads his arguments set out in Book I, chapter 15; and in Book II, theorem 13, he tries to show it in the case of Mercury.

[Margin: 1. Reason a posteriori.]

The sum of the a posteriori arguments is this. If, by geometrical calculation from the given eccentric anomaly, eccentricity and radius of the eccentric, the eccentric place of the planet and its distance from the Sun are found, and from these, with the anomaly of the orb or of commutation, the planet's place, using a perfect circle and lines drawn from the centre of the circle to the circumference; and if this is compared with the place given by the more exact observations of more recent astronomers, for instance Tycho, Gassendi, etc., a perceptible difference is found, which almost wholly vanishes if we use an ellipse, in such a way that the planet at aphelion or perihelion is at the ends of the axis of the ellipse, while around the mean longitudes it is at the ends of the conjugate diameter.

Thus Boulliau, in that theorem 13, reports that he observed Mercury at Loudun [Iulioduni] in 1630 December 12, in the morning, at $6^h\ 50^m$ after midnight, by means of its distance from Spica, and with the place corrected for refraction, at 29° 13′ of Scorpio; whereas its place, sought geometrically on a perfect eccentric circle, came out at 28° 41′ 39″, but on the ellipse at 29° 8′ ♏, and, applying the curtation on account of latitude, at 29° 12′ 59″ ♏. Again, in 1635 December 1, at $5^h\ 30^m$ after noon, at Digne, Mercury by distances from the stars of Ophiuchus stood at 0° 26′ ♐, with the refraction computed, for it was 1⅔° above the horizon. The geometrical calculation resting on the circle gives the place of ☿ as 0° 47′ 35″ ♐, but resting on the ellipse it comes very close to the observed place, that is, it puts ☿ at 0° 23′ ♐. Since, then, Mercury was observed around its morning and evening digressions, in nearly opposite places, and since, with the radius of the eccentric, the eccentricity and the anomaly otherwise equal, the planet's place comes out far more exactly from the ellipse than from the circle, Boulliau concludes that Mercury is carried round not along the circumference of a circle but along that of an ellipse. By the same argument, Kepler, in the *Mars*, from chapter 40, tries to show from the observed places of the Sun and Mars that the planet's path, as it approaches the mean longitudes, does not stray outward from the circle, as it does in the epicycles of Copernicus and Tycho, but inward, approaching the centre of the eccentric; and that it is therefore ooid or oval, since otherwise the equations do not answer to the observed places.

[Margin: This a posteriori reason is not evident.]

X. Notwithstanding all this, Boulliau himself, in Book 1, chapter 13, and in Book 11, at the end of theorems 7 and 13, frankly admits what Kepler had confessed about the Sun's orbit in the *Mars*, chapter 40: namely, that it cannot be discerned from calculation alone and the comparison of observations whether these planets move in an ellipse rather than in a circle: the Sun and Venus because of their slight eccentricity, which makes the minor diameter of the ellipse to be attributed to them by hypothesis scarcely perceptibly smaller than the axis, or major diameter, so that their ellipse departs imperceptibly from the circle; Saturn and Jupiter because of the slowness of their motion, which makes a very slight error in observation give rise to a larger error than in the others,

and therefore it cannot be evidently established whether the discrepancy between the geometrical calculation and observation arises from the figure used in the calculation being circular rather than elliptical, or else from the fallibility of observations, which easily creeps up on any observer, however careful. For Mars it is indeed inferred with greater conjecture, and in a way demonstrated; but not absolutely, nor in such a way that the disagreement of the observations with a calculation assuming a circle could not be referred partly to the Sun's eccentricity, partly to other causes, rather than to the neglect of the ellipse. *In Mercury the ellipse is most perceptible, but it is not seen, in our parts, at those places from which we could infer with full certainty that the matter is so.* These are Boulliau's words, alluding to the nearness of the Sun and of the horizon, close to which Mercury is always observed, with the suspicion of a refraction whose quantity in its case has not yet been reliably determined.

[Margin: 2. Reason a priori for the ellipse.]

XI. But as for the second argument, a priori, we so far have none that is evident. Kepler himself, in the *Mars*, admits that he sang an empty triumph, and says at the end of chapter 55: *And so the physical causes of Chapter 45 go up in smoke.* Neither there nor in the *Epitome* does he adduce any that are apodictically derived from what all grant or must grant; so that Boulliau, Book 1, chapter 13, rightly said: *But the physical reasons that Kepler adduces display ingenuity of mind; they do not reveal the truth.*

[Margin: Boulliau's censure of Kepler.]

Boulliau, in the same place, tries to establish the elliptical path of the planets by other reasons, from prior and general conditions of the celestial motions.

[Margin: Boulliau's foundations for the ellipse.]

For he assumes that the planets move with a single regular motion, compounded of regular motions, perpetual and returning into itself, and therefore along a single line returning into itself, but one arising from circular motions, because it is accomplished by the laws of circles; and that their revolutions have a principle of equality, which they regard of themselves; but that the apparent inequality must be referred to the centre of the zodiac, that is, to the Sun as the point of inequality. Half of this inequality is to be attributed to the eccentricity of the orbit, or to the distance between the points of apparent and mean motion, the other half being thrown on another cause, which makes the planet slower

at aphelion and swifter at perihelion, with the equality of motion about its own centre preserved. And therefore the equal motion answers to several parallel circles, growing from aphelion to perihelion, all of which the apparent motion embraces in one surface, but eccentric to all of them and inclined to all, so that the individual parts of the apparent motion answer to all the parts of the equal motion. These conditions, he assumes, cannot stand together unless the planet describes an ellipse about a scalene cone. He proves this by excluding the sphere, the elliptical spheroid, the parabolic and hyperbolic solids, and the cylinder: although an ellipse can be cut in a cylinder, yet all the circles described in it are equal, and some of them concentric with the ellipse, whereas they must be unequal. These circles Boulliau calls equant circles, which we have already indicated in Book 3, chapter 23, no. 6; read that passage again. On the resolution of the ellipse into two circles we have spoken in the same place, no. 10, and will speak below, when we treat of the equations of the first inequality.

[Margin: Another reason for the ellipse.]

To others this elliptical path might, in brief, seem probable for the following reason. Supposing the necessity, or the very great probability, of an orbit eccentric to the world, so that the apparent inequality of a motion equal in itself may be referred to the distance of the centre about which the equal motion takes place from the centre from which the motion is viewed, and supposing the bisection of the eccentricity, of which in the following proposition: neither in a circle nor in any other figure bounded by a single line returning into itself is there found any point outside the centre worthy of being regarded by the planet or by the planet's mover, and from which a reason could be given why the motion is also ordered about that point and not only about the centre of the figure. But in the ellipse alone, besides its centre, there are two notable points, which Apollonius calls the points from the comparison, Kepler the foci and Boulliau the umbilici, endowed with notable properties. Therefore this figure seems of itself most suited to the motions of the planets, provided that between the centres of apparent and of mean or equal motion stands the very centre of the ellipse, and one umbilicus is the centre of mean motion, and the other the centre of apparent motion, at the centre of the world. But we ought not to be so devoted to this figure as not to think that the motions of the planets can be carried out and explained by a perfect circle; especially since Copernicus in Book 1, chapter 4, Tycho in tome 1, p. 11, and Longomontanus in Book 2, chapter 9, adopt as an astronomical axiom that the celestial motions are either circular or compounded of circular motions, and do not subscribe to Kepler on this.

[Margin: Axiom on the circular figure of the celestial motions.]

Propoſitio 4. Eccentricitas, in qua fundatur Prima Inæqualitas motus Planetarij biſecanda eſt bifariàm; ſeu dimidium illius inæqualitatis Eccentricitati Deferentis tribuendum eſt, alterum verò dimidium cauſæ alteri phyſicè ac realiter retardanti vel acceleranti motum Planetæ; ac proinde opus eſt Aequante.

Proposition 4. The eccentricity on which the first inequality of planetary motion is founded must be bisected in two; that is, half of that inequality must be attributed to the eccentricity of the deferent, and the other half to another cause physically and really retarding or accelerating the planet's motion; and therefore there is need of an equant.

XII. How Ptolemy bisected the eccentricity and introduced the equant, whose centre, or point of equal motion, is as far from the centre of the planet's deferent as the centre of the deferent is from the centre of the world, we have already explained in chapter 1, scholia 1 and 2. That the same must be done in the orbit of every planet is taught by Kepler in the *Mars*, chapters 19, 24, 32, and in the *Epitome of Copernican Astronomy*, p. 712, and by Boulliau in Book 1, chapters 13 and 22, and Book 11, theorems 1, 4 and 5. For you to understand their foundations, it must be explained again more clearly what it is to bisect the eccentricity and to use an equant.

[Margin: What the bisection of the eccentricity is.]

This is nothing other than to place the centre of the orbit that carries the planet, either by itself or by means of some other device such as an epicycle, exactly midway between the point of apparent motion, or the centre of the universe (which for Ptolemy and Tycho is the centre of the Earth, and for Copernicus, Kepler and Boulliau the centre of the Sun's body), and the point of mean or equal motion. Therefore if, by means of the mean motion compared with the apparent, the eccentricity of the point of equality (which is therefore called the centre of the equant) from the centre of vision, or of the world, has been found to be, for example, 3600 parts, of which the radius of the planet's orb is 100000, the eccentricity of the planet's deferent (whether it is a circle or an ellipse), or the distance of the centre of the deferent from the centre of the world, must have only half of that, namely 1800 parts. And so the difference between the planet's greatest distance from the centre of the world, which is made up of the radius of the eccentric orb, or mean distance, and the eccentricity of that orb, and its least distance, which remains on subtracting the eccentricity from the radius, or mean distance, is only half of that eccentricity which is deduced from the mean motion compared with the true or apparent. Conversely, if the eccentricity of the planet's deferent is gathered from the planet's distance and the equations needed to reconcile the mean motion with the apparent, it must be doubled to obtain the eccentricity of the point about which the mean motion takes place. From this it follows that the foundation of the whole inequality, which is contained in the planet's motion in longitude independently of the

syzygies of the Sun, is the whole eccentricity, and the angle opposite it is the difference between the mean and the apparent motion; but the foundation of the merely apparent, or optical, inequality is half the eccentricity, and the other half is the foundation of the physical and real inequality, arising from some cause that now speeds the planet up and now holds it back in the heaven, independently of the observer's eye or of the centre of vision, whatever that cause may be.

[Margin: Arguments for the bisection of the eccentricity.]

XIII. With these things laid down: of the arguments by which the proposition stated above is built up, some are proper to individual planets, some common to all or to several. In the case of the Moon, Tycho, from distances observed through parallaxes, finding their difference smaller by almost half and the intervals contracted, as we said in Book 4, chapter 26, from no. 7, imitated the bisection of the eccentricity. In the case of the Sun, what moved Tycho to suspect, and Kepler and his followers to assert, that its eccentricity must be bisected I touched on in Book 3, chapter 22, no. 5, but did not approve; for the difference of only 1′ in the Sun's apparent diameter at apogee and perigee, which is one of Kepler's chief foundations, conflicts with observations evident to me and to very many others.

[Margin: Arguments against the bisection.]

Nor, in eclipses of the Moon, which, as Kepler says in the *Epitome*, p. 712, seem to demand a smaller variation of the shadow from the Sun at apogee to the Sun at perigee, is the bisection of the Sun's eccentricity and of the dif-

ference of the distances founded securely enough, as is clear from what was said in Book 3, chapter 7, no. 8.

[Margin: ☿ and ♀: bisection of the eccentricity.]

As for Venus and Mercury, no one has so far demonstrated it; and Kepler asserted that their eccentricity must be bisected only topically and through general considerations, in the *Mars*, chapter 32, saying: *Nothing prevents us from believing the same of Venus and Mercury.* In Mars, however, Kepler in the place cited above and Boulliau in theorem 1, and in Saturn in theorem 5, seem to have shown it, chiefly from observations of Mars in □ aspect with the Sun, which cannot be reconciled except with a geometrical calculation using half the eccentricity; otherwise the parallaxes of the annual orb come out very different from those observed.

[Margin: ♂: by whom its eccentricity is not bisected.]

Yet Copernicus, Book 5, chapter 16, did not exactly bisect the eccentricity of Mars, and he attributed the reason for not bisecting it not, indeed, to Ptolemy's errors, for he thought that in Ptolemy's time it should be bisected, but to the variation and diminution of the Earth's eccentricity; and he held that Mars in its eccentricity imitates the Earth's eccentricity. Longomontanus also thought this of ♂, Book 2 of the *Theorica*, chapter 8; and therefore, in his own hypothesis and the Tychonic one, he assigned to the second small circle not a third part of the whole eccentricity, as in ♄ and ♃, but only a fourth. And before him

Tycho, as Kepler relates in the *Mars*, chapter 16, did not assume the eccentricity of Mars but investigated it from his own observations, and made the centre of the deferent eccentric 13680 parts distant from the centre of vision, or of the universe, and the centre of the equant 3780 from the centre of the deferent; which, in the Ptolemaic radius of the orb, would be to make the former to the latter as 9900 to 7560, and so the whole eccentricity 17460, but the eccentricity of the equant alone 7560.

[Margin: ♄: whether its eccentricity is to be bisected.]

Finally, Johannes Phocylides Holwarda, in his examination of Lansbergen's astronomy, p. 143, declares that he has demonstrated from acronychal observations that the eccentricity of ♄ should not be bisected, and that in Lansbergen's form the least eccentricity of Saturn is 8600, but the greatest not double this, but 11400. So to this day this bisection seems to be disputed.

[Margin: The physical cause moving the planets, according to Boulliau.]

The remaining points that seem proper to this hypothesis have partly been discussed in Book 3, chapter 23, and Book 4, chapter 27, where we treated of the Sun's magnetic force carrying the planets round, according to the arrangement of the magnetic fibres that are in the planets and according to the principles of the balance and the lever, causes which Boulliau nevertheless refutes, Book 1, chapter 12; they will partly be discussed shortly, when we treat of the equations; and they partly concern the harmonic proportions of the intervals, of which we will speak either in the last section of this book or in the harmonic system, Book 9.

De Prima Inæqualitate eiuſque Aequationibus.

On the first inequality and its equations.

XIV. Let the figure of Book 4, chapter 27, no. 3 be repeated here. In it the centre of the Sun and of the universe, and one umbilicus of the ellipse, is A; the line of apsides and axis of the ellipse is PR, in which B is the centre of the circle PDRC, in which is inscribed the ellipse PERV, on whose circumference the planet moves from the aphelion P, through HEO, toward the perihelion R.

Diagram. A figure set into the left column, interrupting the sentence between P and R. A large circle with a vertical diameter from P at the top to R at the foot encloses an ellipse inscribed along the same axis. A small circle is drawn about the point A on the axis. Horizontal lines cross the figure through B and through A, and further oblique straight lines run from A, and a dotted line runs down to the lower right.

- Top: P, with F and S below it on the axis.
- Upper left: G and H.
- Left: D and E, level with B.
- Right, level with B: V and C.
- Right, below that: K, L and T.
- Left, below D: M, then Z, then N and O at the lower left.

- Centre: B, with I below it and A below that.
- Lower axis: Q.
- Lower right: Y.
- Foot: R.

Labels read: A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, V, Y, Z. Labels not read: none.

When perpendiculars are drawn through the centres A and B to the circumferences, EV is called the Diacentros and the minor or conjugate diameter of the ellipse, and MT the Dihelios. The other umbilicus, or focus, is S, as far from B as is the eccentricity of the centre B from the Sun A. This umbilicus is the centre of mean motion and stands in place of the centre of the equant.

[Margin: The physical cause moving the planets, according to Kepler.]

The Sun, in Kepler's opinion, by a rotation of about 27 days about the centre of its body toward the east, sends out from itself a certain image spread with its light in every direction, which resembles magnetic effluvia; and this, seizing the planets, carries them round eastward, faster or slower according to their lesser or greater distance from the Sun, and their lesser or greater passive resistance, or inclination or inertia toward such a motion, and according to the arrangement and position of the magnetic fibres, whose diagrams we have already set out when treating of the Moon, Book 4, chapter 27, and in its scholia. For Kepler imagines in the bodies of the planets two poles, about which the planets rotate, one of them in the Sun-seeking part, or the part friendly to the Sun, which at the beginning of the world was turned toward the Sun; the other in the Sun-fleeing, or hostile, part, then turned away from the Sun toward the fixed stars. So when, in the periodic motion in longitude, the part friendly to the Sun is turned toward the Sun, the planet is attracted by the Sun and descends from the aphelion, and becomes nearer and nearer to the Sun, and nearest at the perihelion R; once this is passed, the hostile part begins to turn toward the Sun, and then the planet is repelled by the Sun and moves away toward the aphelion. But Boulliau thinks these are empty fictions, Book 1, chapter 12, and holds that the planets move on the ellipse by their own intrinsic form; we will say more of this in Book 9. Meanwhile they agree that the planet moves unequally on the circumference of the ellipse, and is librated in proportion to its distances from the Sun, so that the ratio of the greater distance to the lesser is the same as that of the planet's slower daily motion to its faster daily motion; and that the daily motions of the same planet about the Sun, with the eye placed in the Sun, appear in the duplicate ratio of their distances from the Sun.

[Margin: The measure of the planetary stay, from the area of the ellipse.]

But the measure of the stay and time on any arc of the ellipse is taken not from the arc itself but from the area and areal segment of the ellipse. For if the circumference of the circle circumscribed about the ellipse is divided into equal parts by lines applied in order to the axis, or perpendicular to the axis, so that if the planet is at H the division is made by GHF, the arcs of the ellipse are found to be unequal among themselves, smaller around the apsides P and R,

largest around the mean longitudes, that is, around the points E and V. At these points, a quadrant having been completed, the nearly greatest equations occur, and AE, the planet's distance from the focus or Sun A, is the mean, or equal to the major semidiameter of the ellipse, BP; as is clear from the properties of the ellipse demonstrated by Apollonius. Therefore the time and stay of the planet at H, on the arc PH, are measured by the area enclosed by the straight lines AP and AH and the curve HP. For Kepler shows in the *Mars*, chapter 59, and in the *Epitome of Copernican Astronomy*, from p. 665, that as the planet's whole periodic time is to the whole area of the ellipse, divided into equal parts, say 360, so is the part of the time and stay on an arc of the ellipse to the part of the area enclosed by that arc and the straight lines drawn from the Sun to the ends of the arc.

XV. For ease of calculation, however, Kepler assumes a circle circumscribed about the ellipse, and tries to demonstrate the equipollence of the circular plane with the plane of the ellipse, because the elliptical circumference cannot be divided geometrically into equal parts. Therefore in the *Mars*, chapter 59, and in the *Epitome of Copernican Astronomy*, p. 671, he teaches that as the area of the sector PGA is to the area of the whole circle, so is the arc of the elliptical segment PHA to the area of the whole ellipse, and likewise for the rest. So he would have it that, if the circular arc PG is of 30°, the arc PH too is denominated 30° and is in power as great as the circular arc PG, because by means of the area of the ellipse enclosed by it we arrive at knowledge of the angle HAP, which measures the planet's distance from the aphelion. With these things supposed, the remaining terms and definitions used by Kepler for the equation of the first inequality are these.

[Margin: What is the libration of a planet?]

Libration of the planet is the difference of distance between the mean longitude, where the motion is swiftest, and the other longitudes, in which the motion is slower; such is the difference between AE, the mean longitude of the planet placed at E, and AH, the longitude of the planet situated at H.

[Margin: Mean anomaly.]

Mean anomaly is the span of time that the planet consumes in completing an arc of its orbit, reckoned from the aphelion, reduced to parts of which the whole anomaly is worth 360. Its measure is the area of the sector of the circle that denominates and determines the arc of the elliptical orbit: an area enclosed by the arc of the circle and the straight lines connecting the ends of that arc with the Sun, and reduced to parts of which the planet's whole periodic time is worth 360. So if the planet is at H and the arc PG denominates and determines the arc PH, the area of the sector enclosed by the arc PG and the straight lines PA and GA is the measure of the mean anomaly, because of its equivalence with the area HAP.

[Margin: Eccentric anomaly.]

Eccentric anomaly is the arc of the eccentric circle counted from the aphelion in the order of the signs as far as the perpendicular drawn through the body

of the planet to the line of apsides. So if the planet is at H and you draw GHF through it perpendicular to PR, the arc PG is the eccentric anomaly, because it is equivalent to the arc PH.

[Margin: Coequated anomaly.]

Coequated anomaly is the angle made at the centre of the Sun by the line of apsides and another straight line, drawn through the body of the planet, if the anomaly does not exceed two right angles; but if it does exceed them, it is the complement of that angle to four right angles. Thus if the planet is at H, the coequated anomaly is the angle HAP; but if it were at Y, it would not be the angle YAP but that angle's complement to 360°.

[Margin: Eccentric place.]

The *eccentric place of the planet* is the point of the zodiac on which falls the straight line drawn from the Sun through the planet: such is the straight line AH, if it is produced all the way into the zodiac.

[Margin: Equation of the eccentric place.]

The *equation of the eccentric place* is the difference between the mean anomaly and the coequated anomaly. Thus if the mean anomaly, or the value of the area PAG, is 45°, and the angle PAH, of the equated anomaly, is 40°, the equation will be 5°. This equation is served by the equating triangle [triangulum Æquatorium] GAB, because of its equivalence with the triangle HAB; and the area of this triangle is called by Kepler the *physical equation*, while its angle at or near the planet is called the *optical equation*: namely the angle AGB.

[Margin: Physical and optical equation.]

Kepler teaches in the *Epitome of Copernican Astronomy*, from p. 694, that in the upper semicircle CPD, above the Diacentros, the physical equation is a little greater than the optical, but in the lower, DRC, a little smaller; that the physical equation, taken by itself, is greatest at the points D and C; but that the optical, taken by itself, would be greatest at the points of the Dihelios line, that is, at O and at Y, if the orbit were a circle, whereas because it is an ellipse it is greatest between D and O and between Y and C. The one compounded of both, however, is greatest between D and E and between V and C.

Methodus Aequationis Primæ Inæqualitatis ex Keplero.

Method of the Equation of the First Inequality, from Kepler.

XVI. Kepler gives this method in the *Mars*, chapter 60, in the *Epitome of Copernican Astronomy*, Book 5, part 2, and in the Rudolphine Tables, chapter 20; it runs as follows.

[Margin: 1. Step, for the distance of the planet from the Sun.]

First, find from the tables the mean motion in longitude of the planet and that of the aphelion or apogee, and subtract the latter from the motion in longitude, for what remains will be the eccentric anomaly, that is, the arc PG (if the planet is at H). Find its second sine, which is BF, in the tables of sines; multiply this by the given eccentricity and divide the total by the radius BP,

for the quotient will be the libration. Add this to the radius BP as long as the planet is in the upper semicircle, or above the Diacentros DBC, but subtract it if the planet is below, and you will have the distance of the planet from the Sun.

[Margin: 2. Step, for the coequated anomaly.]

Second, add the second sine already mentioned, that is, BF, to the eccentricity AB, and the result is AF, which is a side of the triangle AFH, right-angled at F, in which the base AH, that is, the distance of the planet from the Sun, has already been found. So the angle HAF will not remain unknown; this is the coequated anomaly, and the place of the apogee added to it will give the planet's eccentric place.

[Margin: 3. Step, for the greatest physical equation.]

Third, multiply half of the eccentricity AB by the radius BD, and you will have the area of the greatest equating triangle ABD, in parts of which the whole area of the circle is, for Kepler, 31,415,926,536, or of which the radius BP is 100000. Then let it be: as the area of the whole circle is to the time, or span, of 360° resolved into seconds, that is, to 1296000″, so is the area of the triangle ABD to another quantity; and you will find the value of the greatest triangle, or of the greatest physical equation, which is equipollent to the value of the triangle AEB.

[Margin: 4. Step, for the other physical equations.]

Fourth, since the arc PG is given, as above, the value of the area of the sector GBP is also given; and it is of as many degrees, of those of which the whole area of the circle is 360, as there are degrees in the arc PG. In addition, the sine of the arc PG is given, which is GF. Now as DB, the whole sine, is to the sine GF, so the area of the greatest triangle ABD is to the area of the equating triangle AGB. Therefore multiply the value of the greatest triangle, found above in the third step, by the sine GF, and divide it by the radius BD, 100000, or strike five figures from the end of the total, and there will remain the degrees and minutes of the value of the triangle AGB, or the physical equation, which is equivalent to the triangle AHB.

[Margin: 5. Step, for the mean anomaly.]

Fifth, add the physical equation to the sector GBP, that is, to the degrees and minutes of the arc PG, if the arc PG does not exceed a semicircle; but if it does exceed it, subtract the equation from the sector. This will make or leave the mean anomaly, that is, the whole area GAP, in parts of which the whole circle is 360°.

[Margin: 6. Step, for the optical equation.]

Sixth, in the triangle AGB the eccentricity AB is given, and the radius BG, and the angle ABG, because it is the complement to two right angles of the angle PBG, which measures the given arc PG. So the angle AGB will not remain unknown; it is the measure of the optical equation, and is always somewhat smaller than the angle AHB.

So much for this method, if you wish to construct tables geometrically or quasi-geometrically and to distribute in them the anomalies and equations already mentioned. Otherwise, to obtain the planet's eccentric place, the first and second steps of the calculation suffice, since if you add the place of the apogee to the coequated anomaly you will have the planet's eccentric place.

[Margin: Imperfection of Kepler's method.]

I said "quasi-geometrically" because geometrical rigour is not preserved in these, since the elliptical circumference cannot of itself be cut geometrically into equal parts, as Kepler admits in the *Epitome*, p. 780; just as, given the mean anomaly, there is no geometrical method of finding the coequated anomaly, and from there the eccentric anomaly. The same author admits this in the *Mars*, chapter 60, concluding in these words: "This is my view; and the less geometrical beauty it will seem to have, the more I urge geometers to solve for me this problem: TO CUT THE AREA OF A SEMICIRCLE from any point of the diameter in a given ratio. It is enough for me to believe that it cannot be solved a priori, because of the ἑτερογένειαν [Greek: heterogeneia, "difference in kind"] of the arc and the sine. Whoever shows me the way, wandering as I am, will be a great Apollonius to me." In the same way, in the letter to Magini that survives in Magini's *Supplement to the Ephemerides*, p. 244, he had admitted the difficulty in these words: "But the calculation will not be made easier for that. On the contrary, the plainer this form of astronomy is to grasp, the more laborious it is to compute, and the more intricate to discover." After this he implores Magini's help. So it is not undeservedly that Boulliau says of Kepler, Book II, theorem 14: "It is true that that man was most ingenious and an astronomer; but I pity him in this place and grieve at the ἀγεωμετρίαν [Greek: ageōmetria, "lack of geometry"] with which he often struggles."

Methodus Eiuſdem Aequationis ex Bullialdo.

Method of the Same Equation, from Boulliau.

XVII. Boulliau proposes two methods of equating the first inequality in the planets, in Book I of the *Astronomia Philolaica*. One is in chapters 17, 18 and 19; we have already set it out in treating the Sun, Book 3, chapter 23, number 8, and he himself admits at the end of chapter 19 that it is rather long and too troublesome. He therefore substitutes the other in chapter 20, resolving the ellipse into two circles; I indicated this too briefly in Book 3, chapter 23, number 10, and now wish to set it out more exactly. Let A be the Sun and umbilicus of the ellipse to be described or already described, B its centre, C the other umbilicus, and DF the axis or major diameter; and let MN be the conjugate diameter, or minor diameter. Let both of these be given, and so let their difference be DG, or KM, and half of it EG, or KH. Use this half as the semidiameter of the small circle or epicycle DG, OQ, KM, and of similar and equal ones to be described from their centres, taken on the periphery of the circle EHSI, whose semidiameter BH exceeds the conjugate semidiameter BM

by the quantity HM, that is, by half of the difference between the semidiameters of the ellipse. Now let the planet be at D, at the aphelion and at the apogee of the epicycle DG, and let it move at double the motion of the centre E, but in the opposite direction, so that while the centre E travels to T, in the order of the signs, the planet moves from D to V. For in this way it will come about that, when the centre of the epicycle has completed the semiquadrant ET, the planet will have completed a quadrant OP of the epicycle and be at P. When the quadrant ETH has been completed, let the planet be at M, the perigee of the epicycle; when the semicircle ETS has been completed, let the planet be again at F, the apogee of the epicycle, where however it will be perihelial; and when the arc EHSI has been completed, the planet will again be at N, the perigee of the epicycle. With these things laid down, Boulliau demonstrated in that place that the planet describes an ellipse by its motion, or that if a curved line is drawn through the planet, set in any number of positions, for example through the points D, P, M, F, N, D, this line is the elliptical periphery; and consequently that the ellipse has been resolved into two circles, namely EHSI and the epicycle already mentioned, and that the method of calculation has been reduced to the customary solution of triangles.

Diagram. Boulliau's resolution of the ellipse into two circles, set into the left column with the opening lines of text running down its left side. A vertical diameter runs from D at the top to F at the bottom, and a horizontal line crosses it at B from K to L. A large circle is drawn about B, and small circles (epicycles) stand on it at the top, left, bottom and right and at a position in the upper left. Straight lines run from O through T to B, from T to P, and to P from B and from A, and a dotted line runs from P to C.

- D (top of the vertical line, on the rim of the upper epicycle)
- E (centre of the upper epicycle)
- V (right side of the upper epicycle)
- G (on the vertical line, just below the upper epicycle)
- C (on the vertical line, end of the dotted line from P)
- B (intersection of the vertical and the horizontal)
- A (on the vertical line, below B)
- R (on the vertical line, just above the lower epicycle)
- S (centre of the lower epicycle)
- F (bottom of the vertical line, on the rim of the lower epicycle)
- O (rim of the upper-left epicycle)
- P (rim of the upper-left epicycle)
- T (centre of the upper-left epicycle)
- Q (lower part of the upper-left epicycle)
- K (left end of the horizontal, on the rim of the left epicycle)
- H (centre of the left epicycle)
- M (right rim of the left epicycle)
- N (left rim of the right epicycle)
- I (centre of the right epicycle)

• L (right end of the horizontal, on the rim of the right epicycle)

[Margin: 1. Step of the calculation.]

First, then, let the planet be given at P, and let there be from the tables the eccentric anomaly ET, or the angle EBT; for double this will be the angle OTP, which measures the arc OP and whose complement to two right angles will be the angle BTP, in the triangle BTP, in which TP, the semidiameter of the epicycle, is given, and the radius BT. So neither the side BP nor the angle TBP will remain unknown; in this place the angle TBP, subtracted from the angle of anomaly EBT, will leave the angle EBP. But if the centre of the epicycle were below the Diacentros HI, it would have to be added.

[Margin: 2. Step of the calculation.]

Second, in the triangle APB the eccentricity AB is given, as I suppose, and the side BP, found above, and the angle ABP, which is the complement to two right angles of the angle EBP just found. So neither the distance of the planet from the Sun, AP, will remain unknown, nor the angle APB, which is the optical part of the equation. Subtracted here from the angle EBP, this will give the angle EAP, that is, the coequated anomaly; and this, added to the place of the aphelion D, will give the planet's eccentric place, seen from the Sun A. But if you were to draw the line CP from the other umbilicus, the angle BPC would be the physical equation, which can be known because in the triangle BPC the eccentricity BC, equal to AB itself, is given, and the side BP, found above, and the angle CBP, that is, EBP, likewise found above. Note, however, that the compound equation is not correct if you double the optical, as Kepler notes in the *Mars*, chapter 40, pp. 194 and 195. Further, Boulliau regularly calls the equations arising from the greater and lesser circles already mentioned the equations of the equant circles.

De Calculo Geometrico pro Aequatione Orbis, ſeu ſecundæ Inæqualitatis.

On the Geometrical Calculation for the Equation of the Orb, or of the Second Inequality.

XVIII. The annual motion of the Earth produces the second inequality. For this, let the figure be repeated from number 4, and let Saturn be at X and its centric place B, namely on the line drawn from the Sun A through the planet X; but let the Earth be at T, and let the planet's place as it appears to the Earth be V, on the line TXV drawn through the planet from the Earth. Then, according to Kepler in the *Epitome of Copernican Astronomy*, Book 6, part 2, from p. 750, three angles are to be considered.

[Margin: Angle at the Sun, or anomaly of commutation.]

The *first* is the angle at the Sun, which is called the *anomaly of commutation.* It is the arc of the ecliptic counted from the true place of the Sun to the eccentric place of the planet in the ecliptic, following the order of the signs, if it does not exceed a semicircle; otherwise its complement to the circle is taken in its

place. Thus, because in our case the eccentric place of Saturn is B, and the place of the Sun A, seen from the Earth T, is D, the angle at the Sun will be BAD, which becomes known by subtracting from the true place of the Sun the planet's eccentric place reduced to the ecliptic, or the place of the Sun from the planet's eccentric place.

[Margin: Angle at the Earth, or elongation from the Sun.]

The *second* angle is at the Earth and is called the *elongation of the planet from the Sun*. It is the arc of the ecliptic counted from the true place of the Sun to the apparent place of the planet, following the order of the signs, unless it exceeds 180°; otherwise it is its complement to the circle. Thus, because in our case the true place of the planet, as apparent to the Earth T, is V, and that of the Sun D, the elongation from the Sun is the angle DTV.

[Margin: Angle at the planet, or parallax of the orb.]

The *third* angle is the angle at the planet, such as AXT, which is called the *parallax of the great or annual orb*, and it is the difference of the angles of commutation and elongation. This parallax is least in Saturn, moderate in Jupiter, greatest in Mars; and in each of them it is smaller at aphelion, greater at perihelion. And if the motion of the apsides were unequal, the parallax would not be the same in all ages. This parallax, or annual commutation, is the equation of the orb, which Ptolemy calls the equation of the epicycle, the Alphonsines and Magini the equation of the argument, and others simply the equation of the orb.

XIX. In the triangle ATX, then, the angle at the Sun or its complement is given, for when the planet's eccentric place is subtracted from the true place of the Sun, or the latter from the former, the angle TAX becomes known. The distance AT between the Sun and the Earth is supposed given, and the side AX, the distance of the planet from the Sun, has been found, or in Boulliau's figure the side AP. So with the aid of trigonometry you will find the parallactic angle AXT. Add this to the angle TAX and subtract the sum from 180°, for the angle ATX, of the true elongation of the planet from the Sun, will become known. Add this to the true place of the Sun if the planet's eccentric place is greater than the true place of the Sun; subtract it if smaller; and the true place of the planet as seen from the Earth will result.

How the elongation already mentioned is found in the Rudolphine Tables by means of the index, or mystical, number, and how tables of the equations of the orb are constructed, I shall say in chapter 12, number 15.

De Menſuris ad hanc Hypotheſim ſpectantibus.

On the Measures Pertaining to This Hypothesis.

XX. The periods of the motions are given in Kepler's *Epitome of Copernican Astronomy*, Book 6, p. 731, and the other numbers of the motions in the Rudolphine or Philolaic Tables. The measures of the radii, eccentricities and so on are given in part by Kepler in the *Epitome of Copernican Astronomy*, p.

733, and in the tables of equations of the Rudolphine Tables; by Boulliau in the *Astronomia Philolaica*, Book 1, chapter 9, Book 6, chapter 1, Book 7, chapter 2, Book 8, chapter 4; and by Hérigone in volume 5 of the *Cursus Mathematicus*, p. 580. In part we have computed them from what they give, and we have added the semidiameters of the Earth. But you must be warned of several things.

First, Hérigone, taking the intervals and eccentricities from Kepler's *Epitome of Copernican Astronomy*, reports them as though they were referred to the same radius, although Kepler expressed the intervals in parts of which the radius of the great or annual orb is 100000, but the eccentricities in parts of which the radius of each planet's orb is 100000. So Boulliau, Book 1, chapter 9, more prudently derives other eccentricities from Kepler in parts of the radius of the annual orb.

[Margin: Kepler's disagreement with himself.]

Second, Kepler himself in the Rudolphine Tables gives the aphelial distance from the Sun as ♄ 1005147 and ♃ 545074, the perihelial as ♄ 896860, ♃ 494926, and the mean as ♃ 520000, in parts of which the radius of the annual orb is 100000. This does not agree with the measures given in the *Epitome*, nor does the mean distance hold the arithmetical mean. But I have decided that the figures of the *Epitome* should be followed, since they are derived from the parallaxes of the annual orb and agree better with the intervals established by him in the *Mysterium Cosmographicum* and in Book 5 of the *Harmonica*. But for the distances that depend on the intervals of the Sun from the Earth, we have built the last two columns: one that supposes, from the *Ephemerides* and the *Commentaries on Mars*, a greatest distance of the Sun from the Earth of 1800 and a mean distance of 1768 semidiameters of the Earth; the other that supposes, from the *Epitome* and the Rudolphine parallaxes, a greatest distance of the Sun from the Earth of 3469 and a mean of 3381 semidiameters of the Earth, following what was said in Book 3, chapter 7, number 15. Boulliau, however, sets the mean at 1460 and the greatest at 1486.

[Margin: Threefold case of distances from the Earth, as one may choose.]

Third, the greatest and least distances from the Sun are constant in this hypothesis, but the distances from the Earth vary. So if anyone requires the greatest and least distances of the planets from the Earth, with the mean distance of the Sun from the Earth supposed everywhere, let him seek them from the antepenultimate and pre-antepenultimate column of the following table, where we use the radius GQ. But if he wants them with the greatest distance of the Sun from the Earth supposed, that indeed will never happen, because the lines of apsides of the Sun and of these planets, and the places of the apogees, have never concurred since the foundation of the world and never will, according to what was said in chapter 1, scholium 6. Since such concurrences are nevertheless possible in this hypothesis, we have set them in the penultimate and last triads of the table. Finally, if anyone wants the greatest and least distances of the planets from the Earth that belong to any given time, then for the greatest he must look to the planets in conjunction with the Sun, occurring when the planet

is at the apogee of its eccentric, and for the least to their opposition, when the planet is at the perigee of its eccentric. Then, from the place of the Sun standing under the planet's aphelion, he must derive the elongation of the Sun from its own apogee, that is, its anomaly, so as to learn from this the distance of the Sun from the Earth. For if this is added to the planet's aphelial distance, or subtracted from its perihelial, the result will be, in the one case, the apogeal, in the other, the perigeal distance of the planet from the Earth.

[Margin: Rule for the minor semidiameter of the ellipse.]

Fourth, the minor semidiameter of the ellipse, FH, is derived from the major, FX, in the figure set out at numbers 3 and 4, if the eccentricity from one of the foci, that is, AF, is given. For by proposition 49 of Book 1 of Euclid, if you subtract the square of the line AF from the square of the line AH, the square of the line FH remains; and from Apollonius in the *Conics*, AH is equal to FX, that is, to the major semidiameter, or semiaxis, of the ellipse.

MENSVRÆ AD KEPLERI ET BVLLIALDI Hypotheſim ſpectantes.

Measures Pertaining to the Hypothesis of Kepler and Boulliau.

For these lines see the figure set out at numbers 3 and 4	Planets	In parts of which the radius of the planet's orb is 100000: Kepler	In parts of which the radius of the planet's orb is 100000: Boulliau	In parts of which the radius of the annual orb is 100000: Kepler	In parts of which the radius of the annual orb is 100000: Boulliau	Semidiameters of the Earth: Boulliau	Semidiameters of the Earth: Kepler, in the *Ephemerides* and the *Commentaries on* ♂	Semidiameters of the Earth: in the *Epitome of Copernican Astronomy* and the Rudolphine Tables

If with Boulliau the ellipse is resolved into two circles, the semidiameter of the orb comes out for Boulliau as Saturn 99916, Jupiter 99941, Mars 99795, and the semidiameter of the epicycle, in such parts, as Saturn 84, Jupiter 59, Mars 205: parts, that is, of which the semiaxis of the ellipse is 100000.

[Margin: In these tables K stands for Kepler and B for Boulliau.]

Ad initium verò Mundi vt cenſet Keplerus, Anno ante CHRISTVM 3993. in meridie diei 24. Iulij Vraniburgi Radix motuum fuit.

At the beginning of the world, however, as Kepler holds, in the year 3993 before Christ, at noon on 24 July, the root of the motions at Uraniborg was:

	Planet	Sign	Deg.	′	″	‴	⁗
Of the aphelion	♄	♑	28	24	6	0	0
	♃	♋	23	34	18	0	0
	♂	♉	15	0	0	0	0
Of longitude	♄	♎	5	29	57	0	0
	♃	♍	7	3	21	0	0
	♂	♋	10	43	52	0	0

PERIODVM ſub Fixis ſtellis, ex Kepleri Epitomes lib.6. part.2. Abſoluunt

They complete the period under the fixed stars, from Kepler's Epitome*, Book 6, part 2:*

	Planet	Egyptian years	Days	Hours	′	″	‴
Period of longitude under the fixed stars	♄	29	174	4	58	25	30
	♃	11	317	14	49	31	56
	♂	1	321	23	31	56	49

Subtract the motion of the apogee from the motion of longitude, and the eccentric anomaly will remain. The motion of the anomaly of commutation is not given in the tables, because it is obtained by subtracting the true motion of the centre from the true motion of the Sun, and each of these is irregular, or unequal.

SCHOLIA.

Scholia.

[Margin: The hypothesis of Kepler and Boulliau: its merits and defects.]

I. The hypothesis of Kepler and Boulliau has many perfections. These are the simplicity of the planetary path, along one single elliptical line; physical causes of the first inequality, from or around points of the orbit that are not idle but notable, of which kind are the centre of an ellipse and its two foci or umbilici; and the relation of the second inequality to the true place of the Sun, and true syzygies with it. And those physical causes were certainly devised with the highest ingenuity: the Sun, namely, swinging the planet round in a circuit by the laws of the lever and the steelyard, in proportion to the distance and to a magnetic disposition in the planet's body, and doing this through a magnetic power diffused in all directions together with light. But against it Ptolemy would object its contempt for the perfect circular path without evident necessity, as is clear from what was said in ch. 5, nos. 10 and 11. Copernicus and Tycho would object the admission of a physical inequality in celestial motion; Tycho, in addition, the motion of the Earth, on which this theory rests; and all of them the difficulty and ageometry in the calculation, and the vain attempt to demonstrate by a geometrical method the equations and places of the planets, as was said in nos. 15 and 16, at the end, even granting that Boulliau brought some remedy to this difficulty by resolving the ellipse into two circles, as we said in no. 17. Finally, they measure the mean motion not from the other focus of the ellipse but from the centre of the ellipse, although they maintain that that umbilicus is equivalent to the point of equality.

[Margin: The hypothesis of David Fabricius.]

II. Nor did the hypothesis of David Fabricius please Kepler, in the *Epitome of Copernican Astronomy*, p. 674, or in the Rudolphine Tables, ch. 20. For Fabricius librated the centre of the eccentric ellipse by means of a small circle along the transverse diameter of the ellipse, or along a line parallel to it, so as to represent the planet's ingress at the sides toward the centre of the orbit; but at the same time he librated the apsides up and down, and dislocated the eccentric. Moreover, he needed a motion compounded of contraries, and he attained

neither pure uniformity of motion, nor precision or ease of calculation, nor, finally, the force of the physical causes moving the planet. He therefore fixed a cross upon ingenuity, and imposed blindness on the eye of reason as it asks for physical causes.

[Margin: Cavalieri's attempt at the equations in elliptical form.]

III. Nor again did Father Bonaventura Cavalieri, in his *Directorium*, ch. 4, p. 149, apply a sufficient remedy to the ageometric equations of this elliptical hypothesis, although he brought some help and came closer to geometrical truth. In this figure, he says, let the line of apsides be AP, and on it let the centre of the semicircle ANP be C, whose eccentricity CS from the Sun S is given, in parts of which the radius CM is 100000. And let the mean anomaly be given, for which take the arc AN, counted from the aphelion A, or the angle ACN. For when NS is drawn, in triangle CNS the angle NCS will be given, being the complement of angle ACN to two right angles, and also the sides containing it, CN and CS. Therefore, by the laws of triangles, both the planet's distance SN from the Sun and the angle CNS will become known, and this angle he affirms to be very nearly the physical equation. To bring it almost to a geometrical polish, he draws CM parallel to SN, joins the point M to S by the straight line MS, and draws the chord MN, which he bisects at V; and he connects the point V with C and S. He says, then, that the space or area MSA is very nearly equal to the sector NCA, and that if the little space SVM is added to it, the space ASV is most nearly equal to the sector NCA, which he demonstrates in the same place. To obtain its quantity he squares the little area NVM, multiplying the second sine of the arc NM that has been found into the first sine, and subtracting the product from what results from multiplying the radius into half the arc MN, reduced to parts of the radius; for in this way the little area NVM remains. Next, as the area of the circle, which in Kepler is 31415926536 in parts of which the radius is 100000, is to the little area found, so he makes 360 to a fourth term, that is, to the arc MV; and thus, he says, is the whole circle to the sector VCM. Then, as the radius is to the difference of the sines of the arcs AM and AV, so he makes the greatest equating triangle, of which we spoke in ch. 5, no. 16, step 3, to the small difference to be subtracted from the arc MV; so that there remains a most thoroughly corrected small equation to be taken from the arc MN, so that the arc NV remains, measuring the physical equation, that is, the triangle CVS; and let AV be the eccentric anomaly, as great as the sector ACV is. He confirms this by an example in Mars.

Diagram. A semicircle set into the right column beside the text of paragraph III, its straight diameter upright at the right with A at the top and P at the bottom, and its arc bulging to the left. C and S stand on the diameter, C near the middle and S below it. On the arc, reading down from A, stand M, V, N and O. Solid lines run from M to C and to S, from N to C and to S, from O to C (level) and from O towards S; the chord joins M and N, and two dotted lines run from the chord near V to C and to S.

- A (top of the diameter): aphelion
- M (upper arc)
- V (on the arc side of the chord MN)
- N (arc, below V)
- O (arc, level with C)
- C (diameter): centre
- S (diameter, below C): Sun
- P (foot of the diameter)

[Margin: The hypothesis of Antonín Maria Šírek.]

IV. Of the hypothesis of Antonín Maria Šírek, devised not for the real cause of the motions but for calculation, by means of a transferred ecliptic, you have a specimen under the Moon, ch. 27, no. 20.

CAPVT VI.

Chapter 6.

De Noſtra Trium Superiorum Hypotheſi Duplici.

On our double hypothesis of the three superior planets.

I. I have already indicated, in Book 4, ch. 27, scholium 9, and ch. 28, no. 3, and in this Book 7, sect. 1, last ch., that the physical cause of the inequality and apparent variation in the motion of the planets is not to be sought from the material necessity of describing a geometrical figure, or of purely mathematical proportions, or of mutual magnetic attraction, but above all from the end and good that GOD destined for sublunary things from the beginning. And just as cithara-singers, singers and dancers keeping time, although by their motions they do eventually trace certain figures in the air, nevertheless do not essentially and primarily geometrize, or have some point fixed beforehand in their minds around which they move tongue, hands or feet regularly or in a uniformly difform manner, but rather follow rhythmic laws and harmonic proportions, so the Intelligences that move the planets act in accordance with a harmony, not of the ears but of the intellect and of Divine Providence, foreknown through images divinely infused. They raise or lower the planets, urge them on or hold them back, advance or draw them back, according to the diversity of those effects that GOD has willed to come about at fixed times in this nature of things; and they do not essentially and primarily strive for the elegance of some figure to be described in the aether. Yet since GOD has willed, for his own glory, to impart to men some knowledge of these motions, in which they should advance more and more as the centuries pass, and has so ordered the planetary motions that men could devise various hypotheses by which the motions could be brought back to fixed laws and then carried over into tables for the common use of calendars and ephemerides, it has therefore seemed good to divide these hypotheses into two kinds.

[Margin: The difference between Angelic and human hypotheses.]

The first kind comprises the real and true hypotheses, which we call Angelic because the Intelligences alone know them perfectly and carry them out; they are entangled in an incredible winding of spirals and in labyrinths of twists almost inextricable to us. The second contains the human hypotheses, which are mere fictions sprung from the fertility of our ingenuity, but which imitate, or at any rate represent without great errors, the revolutions of the celestial motions. So that our own effort should not be missing in this place, although we have found almost all the forms already taken by astronomers, we have nevertheless devised a certain new hypothesis, and a twin one at that: one for the hypothesis of the Earth moved around the Sun, of which we shall speak in the Scholia; the other for the truer hypothesis of the immobile Earth, whose properties I wish to set out in distinct propositions.

Propoſitio 1. Motus Planetarum præcipui per circulos potiùs quàm per alias figuras regulares explicandi ſunt.

Proposition 1. The principal motions of the planets are to be explained by circles rather than by other regular figures.

II. This is urged not only by the authority of Aristotle and of all ancient astronomy, which laid down that this figure suits the heaven and the celestial motions, as being the most apt for the revolutions of motions returning into themselves and for framing their laws and rules, but also by the very appearance of the observations, which have found that these motions take place through circles, or just as if they took place through circles.

[Margin: Rejection of rectilinear figures in the motions of the planets.]

Therefore, if anyone were to try to reduce these motions to rectilinear figures, such as hexagonal, pentagonal and so on, then either he would say that their angles are imperceptible to us because of their excessive distance, and so would fall back on a figure circular as far as the senses go; or, if he made those angles perceptible, he would introduce sudden changes of motion that conflict with the observations. I afterwards found this noted in Kepler, in ch. 16 of the *Commentaries on Mars*, where he says: *For if a planet were to proceed along straight lines forming angles (as if it walked the sides of a five-angled figure, thoughts I once entertained), then, by reason of the lines, there would sometimes be a sudden change of faster motion into slower with an evident difference, and this would happen not at one but at several places of the zodiac, according to the number of the sides.* By this, however, I wish to be understood here either perfect circles, or spirals composed of one circle after another, rather than the ellipses of Kepler or Boulliau. For just as they rightly say that the point which is the centre of the planetary system must, in the hypothesis of the moving Earth, be set in the Sun itself rather than in another point outside the Sun but very close to it, so we, having noticed that the ellipses they posit depart almost imperceptibly from a circle, have considered that there is no reason why we should depart from perfect circles; especially since the eccentricity is not to be bisected, and

since they devised the ellipse to represent this bisection and its causes, or tried to show the bisection of the eccentricity in order to establish the ellipse in these motions, as we shall presently say.

Propoſitio 2. In Hypotheſi Humana motus Regulares Planetarum potiùs quàm Irregulares circa propria centra ponendi videntur.

Proposition 2. In the human hypothesis, regular rather than irregular motions of the planets seem to be what should be posited around their own centres.

[Margin: The choice of regular motion.]

III. For, other things being equal, it is easier to grasp, more amenable to laws, less absurd to the ears of ordinary astronomers, and less exposed to those complaints with which Copernicus and Tycho press the hypothesis of Ptolemy, who admits a physical inequality. Granted that the true and Angelic hypothesis, all things reckoned, may in fact consist of unequally equal motions, and that this inequality is not merely not unfitting but highly congruent with the end of Divine Providence, as I shall show clearly in Book 9. But let this be said chiefly of the motion of the centre of the epicycle, for if the motion of the planet in the epicycle follows the true motion of the Sun, it is certainly unequal.

Propoſitio 3. Abſidum linea in hypotheſi Terræ ſtantis per centrum Terræ ducenda eſt.

Proposition 3. In the hypothesis of a stationary Earth, the line of apsides is to be drawn through the centre of the Earth.

[Margin: Through which point of the world the line of apsides is to be drawn.]

IV. For by the same arguments, or similar ones, by which Kepler and Boulliau taught that in the hypothesis of the Earth going round the Sun the line of apsides is to be drawn through the very centre of the Sun, as was said in ch. 5, no. 5, it can be taught that in the hypothesis of the motionless Earth it is to be drawn through the centre of the Earth, which is the centre of the universe. In addition, the minor planets in their first inequality are free from the Sun's relations and aspects, and they move under the zodiac and the fixed stars, and complete their periods, just as if there were no Sun. Hence the eccentricity of the eccentric orbs, if it is used to set out the anomaly of this motion, must be sought from the centre of the Earth itself rather than from the Sun itself, or from a point around which the equal motion either of the Sun or of the Earth is supposed to take place. See Kepler on Mars, ch. 16, p. 105, where he says he has shown that the planet moves slowest at the apogee of the eccentric if we follow the Ptolemaic hypothesis, but at the aphelion if the Copernican.

Propoſitio 4. Secundæ Inæqualitatis motus ex Vero Solis motu potiùs quàm ex Medio metiendus eſt.

Proposition 4. The motion of the second inequality is to be measured from the true motion of the Sun rather than from the mean.

[Margin: The true motion of the Sun is to be preferred to the mean in estimating the second motion of the planets.]

V. This has been sufficiently shown, both by Kepler and by Boulliau, ch. 5, no. 6, and their arguments hold good in the hypothesis of a stationary Earth as much as of one going round. For that mean motion, and the mean conjunction or opposition with the Sun, are fictions, which neither in fact agree with the true motion except very rarely, nor, when assumed by hypothesis, satisfy the observations. If, on the other hand, the motion of the second inequality and the anomaly of the epicycle, commonly called the anomaly of the orb, is taken by subtracting the coequated first motion from the true motion of the Sun, the equations of the orb are found to be much more exact and closer to the observations. Therefore, just as in the first and slower motion they look to and imitate a stationary Earth, so in the second and swifter motion they look to and imitate a moving Sun.

Propoſitio 5. Eccentricitas horum Planetarum Non eſt neceſſariò Biſecanda, ſed potiùs varianda, ſi non varietur Epicycli ſemidiameter.

Proposition 5. The eccentricity of these planets need not necessarily be bisected, but should rather be varied, if the semidiameter of the epicycle is not varied.

VI. Suppose that the first inequality of the motion of these planets is to be explained by an eccentric. If the whole and always the same eccentricity of the deferent carrying the planet or the epicycle is used to investigate the equations of the centre, these often come out wrong and do not agree with the observations, but around the perigee of the eccentric are greater than is right. Again, if the whole eccentricity is employed in determining the greatest and least distance of the centre of the epicycle from the centre of the universe, and from these distances of the orb or epicycle or second motion the equations are constructed, always using a semidiameter of the epicycle of one and the same perpetual quantity, they are found to disagree with the observations, and, much more evidently, to be greater around the perigee of the eccentric than the observed places of the planets allow.

[Margin: The origin of the bisected eccentricity.]

Hence it came about that Ptolemy, to moderate their excess, did indeed use the whole eccentricity in regulating the first motion, with respect to the centre of the motion made or feigned equal, which is called the centre of the equant; but with respect to the centre of the deferent of the epicycle, the vehicle of the second inequality, he cut the eccentricity in two and allowed only half of

it to the deferent, offering no demonstration, for the three superior planets, of why he divided it in two rather than in three or in some other proportion. Copernicus and Tycho, however, rejecting the equant and the bisection of the eccentricity, used another division of it, yet in such a way as to represent the equivalence of that quantity. Since, moreover, an ellipse has two foci or umbilici equally distant from its centre, and the bisection of the eccentricity greatly favours that equidistance, Kepler and Boulliau, moving the planets on an ellipse, strove with all the zeal and effort we have seen, ch. 4, to urge the bisection of the eccentricity, as may be seen even from ch. 42 alone of the *Commentaries on Mars*. But if we set aside the partiality that comes from love of the ellipse, the bisection of the eccentricity is by no means necessary, although the same eccentricity ought not always to be used, but a lesser one for the equations of the centre around the perigee, and a greater around the apogee of the eccentric.

[Margin: The eccentricity is not to be bisected but varied in another way.]

Indeed Kepler himself, on Mars, ch. 16, from 4 acronychal observations and using a perfect circle, had concluded thus: *Let the whole eccentricity, then, remain of 18564 parts, that of the eccentric 11332, and that of the equant 7232.* Therefore the distance of the centre of the equant from the centre of the eccentric deferent is much less than the distance of the centre of the deferent from the centre of the world. And in ch. 20 he shows that one eccentricity results at the apogee, another at mean longitude, and another at the perigee, especially when acronychal observations are considered, even if he uses this to pave his way to the bisection. Let these words of his be noted: *Hence it is certainly concluded that there is no certain and fixed point in the planet's eccentric around which the planet perpetually completes equal angles in equal times.* And earlier too Copernicus had detected the inequality of this distance in Mars, Book 5, ch. 16, even if he attributed the cause to a variation of the solar eccentricity brought on by Mars. And Johannes Phocylides Holwarda, in his examination of Lansbergen's astronomy, shows the same thing from the acronychal observations of Saturn: namely, that the distance of the centre of the deferent from the centre of the world is less around the perigee of the eccentric than around the apogee.

We, however, after long and much weighing of the equations of the centre needed for the place of these planets, observed near the true conjunctions with the Sun and at the true oppositions themselves (in which they are stripped of the second inequality), to agree with the calculation of the tables, have not only recognized this variation of the eccentricity, though it is less than a bisection, but also that the anomaly of the eccentricity follows the anomaly of the second sines corresponding to the mean anomaly of the eccentric, as we shall explain below, through a libration up and down. After I had devised the hypothesis, I found this libration indicated but rejected by Kepler, ch. 20 of *Mars*, in these words about the centre of the eccentric: *For it would altogether (if indeed we were to keep the other of the assumptions about the circular orbit of the star) have to be librated by us on the line of apsides up and down: and how this can be reconciled with*

natural reasons I do not see. It appears, therefore, that if a circular figure is chosen, a variation of the eccentricity and a libration of the centre of the eccentric up and down often satisfy the heavens; and they would have satisfied Kepler himself, if he had judged that the physical cause of unequal motion was to be sought from the end of these motions rather than from a magnetic attraction of the planets by the Sun and from the necessity of a geometrical figure. But if the semidiameter of the epicycle is varied, the necessity of varying the eccentricity is not yet evident.

Propoſitio 6. Epicycli Semidiameter in Hypotheſi Ptolemæi reformata, Varianda eſt, præſertim ſi Eccentricitas non varietur.

Proposition 6. In Ptolemy's reformed hypothesis the semidiameter of the epicycle is to be varied, especially if the eccentricity is not varied.

VII. I have quite often wondered why Ptolemy, in using the whole of one and the same eccentricity, on finding a conflict between the equations of the eccentric on the one hand and of the epicycle on the other, took nothing from the epicycle and laid the whole cause on the eccentric and its eccentricity. Yet astronomical equity seemed to demand that this contest and conflict be settled more or less evenly, and that one portion of that variation be assigned to the eccentric, the instrument of the first inequality, and the other to the epicycle, the instrument of the second: that is, that the semidiameter of the epicycle too be varied.

[Margin: The occasion on which the anomaly in the semidiameter of the epicycle was detected.]

Indeed, even in my very apprenticeship in astronomy, when I heard and repeatedly read that the greatest digressions of Venus and Mercury from the Sun are not perpetually of the same quantity, I used to picture this variation to myself in diagrams by a line like a spiral, along which the planet would describe around the centre of the epicycle now a looser circle, now a tighter one. Later, having examined the greatest equations of the orb or epicycle, at the apogee of the eccentric on the one side and at its perigee on the other, which astronomers lay down, and having used there the greatest, here the least distance of the centre of the epicycle from the centre of the world, by the analysis of a right triangle, of which I shall speak in the penultimate chapter of this section, I recognized that a different semidiameter of the epicycle results in the Ptolemaic form: evidently greater at the apogee of the eccentric, and less at the perigee. Before I had read of Kepler's suspecting this, therefore, I had resolved within myself to introduce an anomaly of this kind into the theory of the five minor planets.

[Margin: Kepler's suspicion of this anomaly.]

[Margin: And Tycho's opinion.]

I was afterwards confirmed by Kepler in the *Commentaries on Mars*, ch. 22, which is entitled: *The epicycle or annual orb does not move equally around the point of equality*; and by the words of Tycho that he reports in the same place from Tycho's letter sent in the year 1598 to Kepler in Styria, where he wrote thus: *The annual orb according to Copernicus, or the epicycle according to Ptolemy, does not seem to be always of the same magnitude with respect to the eccentric itself, when the comparison is made; but it brings in an alteration, perceptible in all three superior planets, so much so that the angle of difference in Mars grows to 1° 45′.* Tycho himself indicates this in the appendix to the *Mechanica*, and Kepler concludes it from some observations: namely, that the Ptolemaic epicycle, whose role in the Copernican hypothesis is performed by the single annual orb of the Earth, is not of the same measure in the same planet, but wider around the apogee and narrower around the perigee. Yet he attributes this to other causes. Nor did I grieve that what I had thought was first devised by me had occurred to the minds of others; rather, glad of the agreement out of love of the truth, I began more keenly, from observations especially of Mars, of which there are a great many in Kepler, to investigate the measure of this anomaly, until it appeared to satisfy most observations and the more select ones. Accept this hypothesis, then, and use it securely for as long as the evidence of other most certain and corrected observations has not proved that its measures must be emended, though with the substance of the figure retained. But consult what I shall say in Scholium 5.

Proponitur Nouæ Hypotheſis Trium Superiorum Prima forma.

The first form of the new hypothesis of the three superior planets is set out.

[Margin: The theory of the first inequality.]

VIII. In the attached figure let the line of apsides be DAC, on which A is the centre of the Earth and of the world; and let I be the centre of the small circle BZ, which contains the laws of the anomaly of the eccentricity. On its diameter BZ let the centre of the eccentric be librated up and down, according to the increase and decrease of the second sines corresponding to the degrees of the mean anomaly of the eccentric; on this condition, that when the centre of the epicycle is at C, the apogee of the eccentric, the centre of the eccentric is then at the apogee of the small circle already mentioned, that is, at B, and the eccentricity is then greatest, AB. When the centre of the epicycle is a quadrant distant from the apogee, the centre of the eccentric is at I, the centre of the small circle, and the eccentricity is then mean, namely AI. Finally, when the centre of the epicycle is at D, the perigee of the eccentric, the centre of the eccentric is at Z, the perigee of the small circle, and it then has the least eccentricity, AZ. Therefore, for the prosthaphaereses of the first inequality, or for the equations of the centre, one eccentricity after another will be needed.

IX. For the other inequality, however, let there be described on the periphery of the eccentric (which here, as a single one, or in a single position

[Margin: Theory of the second inequality.]

to avoid confusion we have described from centre I) other epicycles, larger and smaller. At the apogee of the eccentric the largest is GE, whose semidiameter is CG or CE, and at the perigee the smallest is KL. To conceive the whole variation of the epicycles, however, describe both at the apogee the smallest epicycle HN and at the perigee the largest PF, so that the whole difference of the epicyclic semidiameter is GH or PL, and the variation of the spiral keeps within these limits. It is carried out on this law: when the centre of the epicycle is at C, the apogee of the eccentric, the planet describes the largest epicycle, whether the planet is then at G, the apogee of the epicycle, or elsewhere, as at E; but when the centre of the epicycle has been carried through O to the perigee D, in the order of the signs, it describes the smallest. And in describing it, it is likewise carried in the order of the signs on the upper part, that is, from G to E, by a motion as great as the elongation of the epicycle's centre from the true conjunction with the Sun. Further, the decrease of the epicycle's semidiameter is to imitate the decrease of the eccentricity, and the increase of the former the increase of the latter, to this extent: that it grows or shrinks according to the growth or diminution of the second sines corresponding to the mean anomaly of the eccentric, although elsewhere I may have judged that the coequated anomaly should rather be used. Lastly, at every true conjunction with the Sun, let the planet be at the true apogee of the epicycle then described, or temporary epicycle, and at every true opposition at its perigee. For example, if the centre of the epicycle is at O and the Sun's annual orb is VS, and the apparent conjunction of the planet with the Sun takes place with the Sun placed at V, the planet is to be at R; but if the opposition takes place with the Sun placed at S, the planet is to be at T. The line drawn from the centre of the Earth through the centre of the epicycle marks the epicycle's true perigee T and its apogee R, and it is from this apogee that the anomaly of the orb is to be counted.

Diagram. Standing in the left column, interrupting the sentence at "describe". A large eccentric, on which stand four small epicycles and, at its top and foot, a pair of concentric circles each. A vertical line runs from the top of the upper pair down through the small circle at the middle and through the world's centre to the foot of the lower pair. Around the point A is drawn a broken (dotted) circle, the Sun's annual orb. A small circle with centre I stands above A on the vertical line. Straight lines join the points on the small circle and A to the epicycle centres, and a dotted line descends from E towards the small circle.

- Top pair, on the vertical line: G (top of the outer circle), H (top of the inner circle), C (centre, the eccentric's apogee), N (foot of the inner circle), with E on the outer circle at its left
- Upper left epicycle: R (top), O (centre), Q (left), T (lower right)

- Upper right epicycle: δ (upper right), Y (centre), M (lower left)
- Small circle on the vertical line: B (top), κ (below B), I (centre), ω (below I), Z (foot)
- Broken circle: V (upper left), S (lower right); A at its centre
- Lower left epicycle: X (upper left), θ (centre), λ (lower left)
- Lower right epicycle: γ (centre), ε (right, printed like a reversed 3), β (below)
- Bottom pair, on the vertical line: P (top of the outer circle), L (top of the inner circle), D (centre, the eccentric's perigee), F (foot of the outer circle), with K on the inner circle at its left

To determine the greatest prosthaphaereses of the orb, lines tangent to the epicycle are to be drawn from A, the centre of the world; for when the planet is placed at the points of contact already mentioned, the epicycle's greatest equation for that position on the eccentric occurs. Hence the greatest at the apogee of the eccentric is the angle CAE, and at the perigee DAK.

It is no wonder, then, if Mars, which quickly completes the variation of its epicycles, describes few and rather loose spirals, and undergoes that evident difference which many astronomers have until now begged from an uncertain variation and distance of the Sun's eccentricity; whereas Saturn describes very many epicycles, most closely akin to one another, which produce a sensible difference only with time.

Methodus Calculi Geometrici in hac forma.

The method of geometrical calculation in this form.

[Margin: ist step, for the true place of the epicycle's centre.]

X. Let the centre of the eccentric be at κ, the centre of the epicycle at O, and the planet at Q. *First*, then, find the eccentricity Aκ, as follows. When the motion of the eccentric's apogee has been subtracted from the planet's mean motion, which is given in the tables, there remains the anomaly of the eccentric, or the arc CO, which the angle CκO measures. For this anomaly, then, look up the second sine in the tables of sines, multiply it by BI, the semidiameter of the small circle, which we shall shortly give in tables, and divide the total by the whole sine. Add the quotient to the mean eccentricity AI, likewise to be set out shortly in tables, and the result will be the eccentricity Aκ. But if the anomaly of the eccentric were in the fourth quadrant, as if the centre of the epicycle were at Y, the second sine of the arc CY, that is, of the complement of the anomaly to the circle, would have to be used, and the rest carried out as above. If, however, the anomaly were in the second or third quadrant of the eccentric, as if the centre of the epicycle were at θ or at γ, then in the former case the complement of the anomaly to the semicircle is to be used, in the latter its excess over the semicircle; the second sine of these is to be multiplied by the semidiameter IZ, the total divided by the whole sine, and the quotient

subtracted from the mean eccentricity AI, so that the eccentricity Aω becomes known.

[Margin: 2nd step.]

Second, when the eccentric's radius κO has been drawn, and from the world's centre the line AOR, of the true apogee, through the epicycle's centre, the triangle AκO arises. In it the radius κO is given, in the parts we have been accustomed to use, 100000, and in the same parts the eccentricity Aκ has been found; and the angle contained by these, AκO, is known, for it is the complement of the mean anomaly to the semicircle if that anomaly does not exceed 180°, or to the circle if it exceeds 270°, or it is the excess over the semicircle if the anomaly exceeds 180° but is less than 270°. These three being given, find by the doctrine of triangles the angle AOκ, which measures the equation of the centre, to be taken away from the planet's mean motion if the centre of the epicycle is in the prior semicircle of anomaly COD, so that the true place of the epicycle's centre, seen from the Earth along the zodiac by way of the line AO, is obtained. Thus, if the centre were at Y, the equation would be AYκ; if the centre were at θ, the equation would be Aθω; if the centre were at γ, the equation would be the angle Aγω; and similarly for the rest. Using the occasion of these same data, look for the distance AO of the epicycle's centre from the centre of the world, and keep it.

[Margin: 3rd step, for the equation of the orb.]

Third, when the epicycle RQT has been described from O, its semidiameter OQ is to be found. So take the second sine, mentioned above, of the mean anomaly of the eccentric when it does not exceed a quadrant, multiply it by the difference, set out by us in the tables, between the mean and greatest epicyclic semidiameters, and divide the total by the whole sine. Add the quotient to the mean semidiameter of the epicycle given in the tables, and the semidiameter of the epicycle suited to that position of its centre on the eccentric will be known. The same is to be done if the anomaly of the eccentric is greater than 270°, but the second sine of the complement of the anomaly to the circle must then be used. But if the anomaly of the eccentric is greater than a quadrant, use the second sine either of the complement to the semicircle or of the excess over the semicircle, multiplying a sine of this kind by the difference of the semidiameters and dividing the total by the whole sine; and in both these cases subtract the quotient from the mean semidiameter, so as to obtain the epicycle's semidiameter sought.

[Margin: 4th step.]

Fourth, compile from the corrected tables of the Sun the Sun's true place, and from it (adding a whole circle if that is needed for the subtraction) subtract the true place of the planet's centre, already known by the 2nd step; for the remainder will be the anomaly of the epicycle, which astronomers now commonly call the anomaly of the orb, the Alphonsines the true argument, and the Copernicans the anomaly of commutation. You will count this anomaly on the epicycle, in the order of the signs, from the true apogee of the epicycle, and

in this way the point of the epicycle at which the planet stands will become known. For example, if this anomaly is 50°, it will be the arc RQ, counted from the apogee R, and the planet will be at Q; and to it from A, the centre of the Earth, draw the line of the planet's true place, in our case the line AQ.

Fifth and last, in the triangle AOQ you have now found, by the

[Margin: 5th step.]

second step, the side AO, and by the third the side OQ; and by the fourth the angle AOQ is known, as being the complement of the anomaly of the orb, which the angle QOR measures. So with the help of trigonometry find the angle OAQ, namely the equation of the orb, to be added to the planet's eccentric place, or true place of the centre, if the anomaly of the orb is in the first semicircle of the epicycle, as if the planet is at Q or at M; but to be taken away if it is in the other, as if it is at X or at β. And thus the planet's true place along the zodiac, in its own orbit, seen from the Earth, will be known. It is afterwards to be reduced to the ecliptic by means of the latitude, as will be said in Section 4.

EXEMPLVM in ♂.

Example, in Mars.

[Margin: Example from Tycho's observation of Mars.]

XI. Kepler relates, in his *Mars*, ch. 53, that Tycho observed Mars at Uraniborg at ♋ 17° 40′ 30″, with north latitude 4° 7′, in the year of the Lord 1582 December 26, in the style of the old calendar, at 8^{h} 30^{m} after noon. For that moment the motions of the Sun and of Mars, from our tables, stood as follows.

	Value
True place of ☉	9^{s} 14° 59′ 57″
Mean motion of ♂	3^{s} 8° 31′ 30″
Motion of the apogee of ♂	4^{s} 28° 39′ 43″
Therefore, anomaly of the eccentric	10^{s} 9° 51′ 47″

[Margin: 1st step, example.]

First, then, in the preceding figure the anomaly was the arc CODY, of 10^{s} 9° 51′ 47″, and so the arc CY, as also the angle CκY, was 50° 8′ 13″; the centre of the epicycle was at Y and that of the eccentric at κ. Further, the second sine of 50° 8′ 13″ is 64095. Multiplied by the semidiameter BI, which for me is 1365 of the parts of which the radius κY is 100000, it gives the total 87,489,675. When this is divided by the whole sine 100000, there remains the difference κI, of 875 parts, to be added to the mean eccentricity of Mars, which for me is 18635; and so the eccentricity Aκ at this position comes out at 19510 parts.

[Margin: 2nd step, example.]

Second, when AYδ and κY have been drawn, there are given in the triangle AκY the eccentricity Aκ, the radius κY, and the angle AκY of 129° 51′ 47″, as being the complement of the angle CκY. Therefore, as the geometry of

triangles establishes, the equation of the centre comes out, that is, the angle AYκ, of 7° 34′ 55″. Added at this position to the mean motion of Mars, it makes the true eccentric place, or the place of the centre, 3ˢ 16° 6′ 25″. And in the same triangle the distance AY is found, of 115720 parts, which is to be kept aside for the time being.

[Margin: 3rd step, example.]

Third, the mean semidiameter of the epicycle of Mars is for me 66057 parts, and the greatest 70957, so that their difference is 4900. By this, then, the second sine of the anomaly of the eccentric mentioned above, that is 64095, is multiplied, giving the total 314,065,500. When this is divided by the whole sine there remains the difference 3141, to be added at this position to the mean semidiameter; and so the epicycle's semidiameter MY becomes 69198 parts, of which the eccentric's radius is 100000.

[Margin: 4th step, example.]

Fourth, since the true place of the Sun was 9ˢ 14° 59′ 57″, and the true place of the centre of Mars was found to be 3ˢ 16° 6′ 25″, when the latter is subtracted from the former there remains the anomaly of the orb, 5ˢ 28° 53′ 32″, namely the arc δM, in the prior semicircle of the epicycle. So the angle MYδ is of that size, and its complement to two right angles, by proposition 32 of the first book of Euclid, is the angle AYM, 1° 6′ 28″; and Mars was at the point M.

Fifth, when the line AM has been drawn the triangle AYM arises, in which are now given the distance AY, by the second step, of 115720 parts, MY of 69198 parts, and the angle they contain, AYM, of 1° 6′ 28″. Trigonometry therefore gives the angle MAY as 1° 38′ 52″, which is of course the equation of the orb, to be added at this position to the eccentric place of Mars, namely 3ˢ 16° 6′ 25″.

[Margin: True place of Mars.]

And so at length the true place of Mars becomes 3ˢ 17° 45′ 17″, or ♋ 17° 45′ 17″. But Tycho found it at 3ˢ 17° 40′ 30″. The calculation therefore exceeds the observation by 4′ 47″, an excess that can be referred no more to our hypothesis than to the observation.

[Margin: The difference between us, Kepler and Magini.]

Kepler, however, in that chapter 53, computed from his hypotheses the place of Mars at ♋ 17° 44′ 19″. But Magini, examining his equations of the orb in the *Supplement to the Ephemerides*, p. 17, gathered from this observation ♋ 17° 40′ 48″. This place is, moreover, a slippery one because of the smallness of the angles MAY and MYA; so if there is an error of some minutes in the Sun's place, and hence in the anomaly of the orb, a notable error will also result in the place of Mars. By a similar method we examined other places of Mars observed by Tycho and related by Kepler in chs. 42 and 53, at various positions on the eccentric, so as to test the reliability of our hypothesis; and in some places, I admit, it does not satisfy them exactly. But it must be remembered that Tycho, in determining the places of the planets from distances of the fixed stars, used a theory of the Sun that assumes excessive solar parallaxes; and that

in the distances of fixed stars taken by him and by us a discrepancy of one or more minutes is sometimes found, which can alter the places of the planets. We therefore await with great longing the edition of Tycho's observations, so that we may examine them more deeply, and bring the measure of our hypotheses, from those observations and from our own, which we are still pursuing, to the final polish. Meanwhile, take the measures we have obtained.

[Margin: Second form of our hypothesis.]

XII. The other hypothesis is that the same eccentricity is always retained, namely the one we have called mean, so that the hypothesis is simpler; nor, without evident necessity, does it seem that this labour should be imposed on astronomers, that to work out the equations of the centre they must first seek one eccentricity after another. And the observations that favour this supposition are not few. In that case, however, the anomaly of the epicycle's semidiameter will perhaps have to be set up differently, so as to satisfy all or nearly all observations. On this matter we cannot pass a definite judgement until we have obtained more trustworthy observations at more positions on the eccentric.

XIII. There now follows the table of our measures and numbers. As to the numbers, we have found the Danish tables accurate enough for the mean motion of Saturn and Jupiter, and the Rudolphine for the mean motion of Mars; the rest we have built up from our own investigations, by a method partly to be indicated and partly to be set out more fully hereafter. We also lay down, roughly with Copernicus and with Kepler in the *Epitome of Copernican Astronomy*, that the mean distance of Saturn from the Earth is tenfold the Sun's mean distance from the Earth, that of Jupiter fivefold, and that of Mars about one and a half times that same distance of the Sun. What the Sun's mean distance is for us appears from Book 3, ch. 7.

SCHOLIA.

Scholia.

[Margin: On the geometry of our epicycle.]

I. I know, of course, that our hypothesis does not have geometrical exactness [acribiam] in the measurement of the epicycle's semidiameter, since it cuts that

continuous spiral into several circles as if they were distinct. But I preferred to serve the ease of a calculation that comes as close as possible to the truth rather than to multiply small circles or lines by some other, more intricate scheme. However, that difference among the epicycles could be represented by a small circle which would either roll the epicycle round on its circumference or librate it up and down on its diameter, according to the increases of the second sines; and it would then have to be weighed whether the sines of the coequated anomaly of the eccentric would be more useful than those of the mean anomaly.

[Margin: Another form of our hypothesis.]

One could also imitate the webs of spiders, which, by a kind of leaping passage from a smaller to a larger circle, sometimes weave their webs from several circles, or from chords of several circles. But I have judged that we should abstain from these and similar windings. What should rather be considered is whether some other anomaly of the semidiameter can be found which alone, without the anomaly of the eccentricity, would satisfy very many observations, all of them. For that, however, we need more observations than we have, and I have therefore judged that this business should be deferred to volume 3.

[Margin: The hypothesis of two concentrics, without any epicycle.]

II. Among the hypotheses that can be devised, one seems to have been omitted which consists of two concentrics without any epicycles. But this one cannot represent the apparent stations and retrogressions of the planets unless, in place of the epicycles, it substitutes the annual orb of an Earth going round the Sun; and for this reason I have passed it over. Still, I should like to set out what occurred to me in this hypothesis of a moved Earth. In the following figure let the line of apsides be BC, on which let S be the Sun at the centre of the world, and let the mean eccentricity of the planet's orb be AS, and half of it AO. From A let two circles concentric with each other be described: one deferent of the planet's body, DLEM, the other drawn through the outermost surface of the planet's body, BHCN, standing so far from the deferent that BD equals AO, half the eccentricity.

[Margin: Note on the size of the planet's body.]

With centre D let the small circle BG be described, and with centre E the small circle CF, containing the whole substance of the planet, which consists of the nucleus, that denser and more opaque part which we see, and of the remaining thinner part, which we perhaps experience in its effects but do not perceive with the eyes. For just as flame and the whole air have a twofold portion, one denser, fatter and visible, the other rarer and more transparent, which we do not see with the eyes, so it does not seem incongruous with the vastness of the heavens and the power of the planets that they should occupy with the substance of their body a far larger sphere than the one that appears to our eyes. On these assumptions, the physical cause of the whole eccentricity from the Sun would be the diameter of the planet's body BG, as large as AS. Unless someone should likewise prefer to imagine, in the substance of the solar

globe, which is much greater than what appears to us as a nucleus, three regions or markedly differing portions: one farthest from the centre, on whose surface would be the centre of Saturn's eccentric; another nearest the centre of the Sun, which would turn the centre of Mars's eccentric; and one midway between these, which would turn Jupiter's. And so the Sun's power, communicated to these planets along straight lines, would be weaker in Saturn, more vigorous in Mars and more temperate in Jupiter, and this would be the cause of the eccentricity's being greater in Saturn than in Jupiter, and in Jupiter than in Mars. But whatever may be the case with these fictions, let us proceed to the measures and the form of the calculation.

Diagram. Standing in the right column, interrupting the word *Eccentricitas* at the line end. Two large concentric circles. On the vertical diameter stand two small circles, each hatched with rays round a dark central nucleus, one at the top between the two large circles and running inwards, one at the foot likewise. Straight lines cross the figure among the labelled points on the circles and meet about the centre and below it; a horizontal line runs across the inner circle through O.

- Vertical line, top to foot: B (top of the outer circle and of the upper small circle), D (centre of the upper small circle), G (foot of the upper small circle), A, O, S, F (top of the lower small circle), E (centre of the lower small circle), C (foot of the lower small circle and of the outer circle)
- Upper left: H (on the outer circle), I (on the inner circle)
- Upper right: N (on the outer circle), K (on the inner circle)
- Interior: R (left), T (right)
- Horizontal line: L (left, on the inner circle), O, M (right, on the inner circle)
- Lower left: P
- Lower right: Q
- Lower right of S: V, at the end of a short line from S

[Margin: The method of calculation in]

III. Let AB be, then, the radius of 100000 parts, by which the remaining lines are to be measured; but the distance of the centre of the pla- [Margin: this form, for the equations of the centre.]

net AD is to be the remainder of the radius AB once BD, that is, half the eccentricity, has been taken away. The given anomaly of the eccentric, then, is to be counted in the inner orb from the apogee D, in the order of the signs, towards I. Thus, if the centre of the planet has reached I, the arc will be DI, measuring the angle DAI, whose complement to two right angles is the angle SAI. With this angle, the eccentricity AS and the line AI, which is the remainder of the radius shortened by half the eccentricity, the angle AIS is to be found. This is the equation of the centre, to be subtracted in the earlier semicircle of the anomaly and added in the later, so as to give the planet's centric place as seen from the Sun. Moreover, the whole eccentricity that is to be used and bisected here is not the one that other hypotheses call the whole, but the one we call

the mean: for instance, in Mars, 18635 of the parts of which AB is 100000. And so the line AI, like AP, AQ and AK, will always be 9317 parts shorter than the radius, that is, of 90683 parts, so that the equations of the centre may come out more correct; though would that they answered the observations everywhere in this form!

[Margin: Method for the equations of the orb.]

IV. For the equations of the second inequality, let us place the planet at I, and the Earth at V at the planet's conjunction with the Sun, and at R at its opposition. For then the same line IRSV will be the line of the centric place and of the planet's place, and indeed of the place of the Sun or its opposite, as seen from the Earth, and no equation of the orb will be needed. Now let the planet be outside the true ☌ and ☍ with the Sun, say at K, and the Earth at T, which is to be joined to the Sun and the planet by the straight lines ST and TK. For in the triangle KST, the planet's centric place subtracted from the Sun's true place will give the anomaly of the orb, from which you will learn the angle at the Sun, S, and at the Earth, T, exactly as we showed in the hypothesis of Copernicus and Kepler. But through the triangle ASK, by which you found the equation of the centre, or the angle AKS, you must work out from the same data the planet's distance from the Sun, that is, the side KS, and take from the solar tables the Earth's distance from the Sun, that is, the side ST. For from these two sides and the angle S or T you will be able to find the angle TKS, namely the equation of the orb, to be added to the planet's eccentric place in the earlier semicircle of the anomaly of the orb and subtracted in the later, so as to give the planet's apparent place as seen from the Earth; here, as seen along the line TK.

The whole difficulty of this hypothesis lies in the measure of the eccentricity AS, which must satisfy all the equations of the centre and, by its half, establish the correct semidiameter of the inner circle.

CAPVT VII.

Chapter 7.

De Mutua Transformatione Hypotheſium Præcedentium, traductis vniuſcuiuſq. menſuris ad aliam quamuis formam Hypotheſeos. Vbi Epilogus Hypotheſium, & Hypotheſis Electiua mediocritatis inſinuatur.

On the Mutual Transformation of the Preceding Hypotheses, the measures of each being carried over to any other form of hypothesis. In which a recapitulation of the hypotheses and an Elective Hypothesis of the mean are introduced.

I. Two things above all are considered in a hypothesis of the planets. The first is the form itself, or figure, by which their motions are represented; this is, as it were, the substance and essential part of the hypothesis. The other is

the size of the orbs, the eccentricities and so on, which is an accident, but a principal one. Now it may be that one hypothesis is better, or better suited to someone's cast of mind, as regards form, but is at fault in its measures, and that a student of astronomy wishes to investigate whether the measures of another hypothesis, when used in that form, satisfy the celestial phenomena. To satisfy him, therefore, we present in the following table the measures of each of the rather more celebrated astronomers, to be carried over to the form of each. For this purpose it must be recalled that

[Margin: The Ptolemaic hypothesis.]

Ptolemy gave the whole eccentricity to the circle around whose centre the planet's equal motion is imagined, the circle called the equant, but gave half of it to the deferent that carries the centre of the epicycle bearing the planet's body.

[Margin: The hypothesis of Copernicus.]

Copernicus, however, correcting Ptolemy's whole eccentricity somewhat from his own observations and dividing it into four parts, gave three of them, or three-quarters [dodrantem], to the eccentricity of the deferent of the epicycle, and the remaining part to the semidiameter of the epicycle, in his first form.

[Margin: And that of Lansbergen.]

In the second form, which is also Lansbergen's, he gave three-quarters of the whole eccentricity to the mean eccentricity, and the remaining quarter to the semidiameter of the small circle that carries the centre of the eccentric and produces the anomaly of the eccentricity, so that the minimum eccentricity was half the maximum, except in Mars.

[Margin: The hypothesis of Tycho and Longomontanus.]

Lastly, in the third form, which Tycho and Longomontanus followed, though with corrected measures, he assigned three-quarters of the whole eccentricity to the semidiameter of the larger epicycle, and the remaining quarter to the semidiameter of the smaller epicycle.

[Margin: The hypotheses of Kepler and Boulliau.]

Kepler and Boulliau, however, assign half of the whole corrected eccentricity to the centre of the ellipse that carries the planet on its periphery, and they place the centre of the world in the motionless Sun, which they locate at one of the foci, or umbilici, of the ellipse, and from which they measure half the eccentricity; the other focus they imagine to be the point about which the planet moves equally. Hence, from the properties of the ellipse demonstrated by Apollonius, the square of the distance of the foci from the centre, or of the semi-eccentricity, taken from the square of the radius, or major semidiameter, leaves a square whose root is the minor semidiameter of the ellipse. Furthermore Boulliau, for ease of calculation, resolves the ellipse into two circles and, bisecting the difference of the major and minor semidiameters of the ellipse, on the one hand gives half of it to the semidiameter of the epicycle carrying the planet, and on the other adds it to the minor semidiameter of the ellipse so as to make the semidiameter of the larger circle. The centre of this circle is the

same as the centre of the ellipse, and stands off by half the eccentricity on one side from the Sun, the centre of the world, and on the other from the point of equal motion.

[Margin: Which is the centre of the world and of the planetary system?]

II. It must further be recalled that the centre of the universe and at the same time of the planetary system, from which, that is, as from a limit, the eccentricities of the orbs are taken or measured, is for Ptolemy and for us the centre of the Earth. For Copernicus and Lansbergen, however, it is that point which stands as far from the centre of the solar body as the eccentricity of the Ptolemaic solar eccentric stands from the Earth, although they do not recoil from the Sun itself; indeed this agrees better with their hypothesis. Therefore for Kepler and Boulliau that centre is the centre of the very body of the Sun. But with Tycho and Longomontanus the centre of the world is indeed the centre of the Earth, but the Sun, or a point near the Sun, is the centre of the system of the five minor planets. In addition, all the old astronomy, as well as Lansbergen, and Tycho and Longomontanus in their first exercises, thought that the planet is stripped of its second inequality at mean conjunctions and oppositions with the Sun: that is, when the planet's true place was under that place of the zodiac, or under its opposite, under which, or under whose opposite, lay the place of the Sun, not the true place but the one marked by the Sun's mean motion. But the more recent astronomers, namely Tycho and Longomontanus in their later studies, Kepler and Boulliau, and we along with them, have judged that the planet is free of the second inequality at the moments of true ☌ or ☍ with the Sun. And so, to obtain the anomaly of the orb, the planet's eccentric or first-coequated place must be subtracted from the true motion of the Sun, and the planet's second motion must be reckoned not from the line of the mean but from that of the true solar motion, or from the true line of the syzygies. Finally, in the hypothesis of a moved Earth the annual orb takes the place of the Ptolemaic epicycles.

III. But since someone might wish to choose out of all the measures the one that is the mean between the extremes, and to use it in any form of the hypotheses, as the safer course, with the lesser error, we have added the last two columns: in the second-to-last are the measures absolutely mean between the old and the recent, and in the last the means among the most recent, from Tycho inclusive. This hypothesis may indeed be called the Elective Hypothesis of the mean [Electiua mediocritatis].

IV. Further, so that the measures of my newest hypothesis may be transferred to the forms of others, not our whole but our mean eccentricity, which comes closer to the whole eccentricity of the others, is to be bisected or cut into four, so that three-quarters of it and a quarter may be given to whatever each form requires. Likewise the mean semidiameter of the Ptolemaic epicycle between our extremes is to be used. The conversion of other measures to our form, however, is somewhat more laborious. For to obtain the difference of the epicycles, one must, from the maximum equation of the orb set down in each

author's tables, both at the apogee and at the perigee of the eccentric, find by analysis of triangles the maximum and minimum semidiameter of the epicycle. The anomaly of the eccentricity, for its part, is deduced only with difficulty from the eccentricities of others. Yet if anyone wants it close to the truth, let him take of the whole eccentricity found among the others the 17th part for ♄, the 24th for ♃ and the 14th for ♂, and assign it to the semidiameter of the small circle of the anomaly of the eccentricity.

V. However, so that the measures set out below may be applied more readily to each form, it seemed best to use capital letters, as characteristic marks of the hypotheses; the rules for them will be given after the table, together with their use.

SYNOPSIS MENSVRARVM & ÆQVIPOLLENTIÆ HYPOTHESIVM

Synopsis of the Measures and Equivalence of the Hypotheses.

In partibus, qualium Radius Orbis Planetæ eſt 100000.

In parts, of which the radius of the planet's orb is 100000.

The mean semidiameter of Mars's epicycle for Longomontanus is 65497, but with the Sun and Mars at apogee 67962, and at the perigee of both 63028. For us, however, the mean semidiameter of Mars's epicycle is 66057, the maximum 70957 and the minimum 61157.

Regulæ Pro Vſu præcedentis Tabulæ.

Rules for the Use of the Preceding Table.

[Margin: Rule 1, for the hypothesis of Ptolemy.]

VI. The hypothesis of PTOLEMY. For the eccentricity of the equant, consult letter A; for the eccentricity of the deferent, letter B; and for the semidiameter of the epicycle, letter C. But measure the eccentricities from the centre of the Earth.

[Margin: Rule 2, for forms 1, 2 and 3 of Copernicus.]

The hypothesis of COPERNICUS, in the first form. For the eccentricity of the deferent see letter D, and for the semidiameter of the epicycle letter E. In the second form, for the maximum eccentricity letter A; for the minimum eccentricity letter B; for the mean eccentricity letter D; and for the semidiameter of the small circle that varies the eccentricity letter E. Lastly, in the third form, for the semidiameter of the larger epicycle see letter D, and for the semidiameter of the smaller epicycle letter E. But in the first two forms measure the eccentricities from the Sun, or from the point about which the Earth is imagined to move with its annual motion around the motionless Sun; in the third, let the centre of the concentric be the Sun or the point already mentioned.

[Margin: Rule 3, for the hypothesis of Lansbergen.]

The hypothesis of LANSBERGEN. See the second form of the Copernican hypothesis, and measure the eccentricities from the Sun, etc.

[Margin: Rule 4, for the hypothesis of Tycho and Longomontanus.]

The hypothesis of TYCHO and LONGOMONTANUS. See the third form of the Copernican hypothesis, and let the centre of the concentric be the Sun, but let the centre of the universe be the centre of the Earth.

[Margin: Rule 5, for the hypothesis of Kepler and Boulliau.]

The hypothesis of KEPLER and BOULLIAU. For the whole eccentricity, or the distance of the foci, or umbilici, of the ellipse from each other, see letter A; for the distance of the centre of the ellipse from either focus, letter B; for the major semidiameter of the ellipse, the radius 100000; and for the minor semidiameter of the ellipse, letter F. But at one of the foci let the Sun stand, as the motionless centre of the universe, and measure the eccentricities from it.

[Margin: Rule 6, for the second hypothesis of Boulliau.]

The later hypothesis of BOULLIAU. For the whole eccentricity, or the distance of the point of equality from the centre of the universe, that is, from the Sun, see letter A; for the eccentricity of the centre of the ellipse from either umbilicus, letter B; for the minor semidiameter of the ellipse, letter F; for the semidiameter of the epicycle (if you resolve the ellipse into two circles), letter G; and for the semidiameter of the larger circle, letter K.

OUR hypothesis. For the mean eccentricity consult letter A; for the semidiameter of the small circle of the anomaly of the eccentricity, letter L; for the mean semidiameter of the epicycle, letter C. For the difference of the semidiameter of the epicycle, consult the foot of the table or the advice given at number 4, taking from the table of chapter 12 the maximum equations of the orb at the apogee of the eccentric, and you will have the angle opposite the semidiameter sought. To the radius add half the eccentricity found among the others, in the row of letter B, and you will have the base. Then add together the logarithm of the angle already mentioned and the logarithm of the base, and the sum will be the logarithm of the semidiameter of the epicycle placed at the apogee of the eccentric. Again, from the last table of chapter 12 take the maximum equation of the orb at the perigee, and you will have the opposite angle; from the radius, however, subtract half of the eccentricity, and you will have the base. Therefore add the logarithm of the angle to the logarithm of the base, and the result will be the logarithm of the semidiameter of the epicycle at the perigee of the eccentric. In this way the difference of the semidiameters will be known, half of which comes into use in our hypothesis.

Vſus Præcedentis Tabulæ Exemplis declaratus.

The Use of the Preceding Table Explained by Examples.

[Margin: Example 1, of the Ptolemaic scheme in the measures of Kepler.]

VII. Suppose someone wishes to derive the true motions of Saturn by geometrical calculation from the Ptolemaic scheme, according to the method given in chapter 1, number 10, yet does not wish to use Ptolemaic measures, but Keplerian ones, that is, such as Kepler, from his own observations or from considerations of Tycho's observations, would supply to a Ptolemy wishing to represent the motions of the planets by two eccentrics with an epicycle. Then from Rule 1, at number 6, he needs the measures indicated by the letters A, B and C. So, proceeding rightward from letter A as far as the column headed with the name of Kepler, he will find the whole eccentricity of the equant answering to ♄ at 11400 parts, of which the radius or semidiameter of Saturn's orb is 100000. From letter B, likewise under Kepler, he will find the eccentricity of the deferent of ♄, 5700 parts. And finally from letter C he will find under Kepler the semidiameter of the epicycle of ♄, 10515 parts, of which the radius of Saturn's orb is 100000. With these measures, then, according to Kepler's thinking but in the Ptolemaic scheme, the calculation for ♄ is to be completed,

but taking the mean motion of longitude and of the apogee, the root of both, and the Sun's distances from Kepler or from the Rudolphine Tables.

[Margin: Example 2, of the Keplerian scheme in the measures of Ptolemy.]

VIII. Conversely, let there be someone who would like to undertake the geometrical calculation of the motion of ♃ in the scheme of Kepler or Boulliau, that is, by the ellipse, but prefers, for the sake of experiment, to use Ptolemaic measures. Now, from what was said in chapter 5, from number 17 on, where this calculation is treated, and from Rule 5 of this chapter, he needs the measures indicated by the letters A, B and F. So, from A, under Ptolemy's column, he will find the whole eccentricity, or the distance of the foci in the ellipse of ♃, 9167 parts; from B, likewise under Ptolemy, the bisected eccentricity, or the distance of the centre of the ellipse of ♃ from one of the foci, 4584 parts; and from letter F, under Ptolemy, the minor semidiameter of the ellipse of ♃, 99896 parts, of which the major semidiameter, or radius of the elliptical orbit, is 100000. Let him therefore use these measures, with the mean motions, roots and solar distances taken from Ptolemy, and carry out the calculation in the form of the Keplerian hypothesis.

[Margin: Example 3, of the Lansbergian scheme in the measures of Longomontanus.]

IX. Now suppose someone likes the second form of Copernicus, or the scheme of the Lansbergian hypothesis, but wants, in tracking down the place of ♂, to use the numbers and measures of Longomontanus. Now, from what was said in chapter 4, number 3, and from Rule 3 of this chapter, he needs the letters A, B, D, E: that is, the maximum eccentricity of ♂, which from letter A he will find under Longomontanus as 18550; the minimum eccentricity, which from letter B he will find under Longomontanus as 9775 parts; the mean eccentricity, which from letter D he will see to be 8721 under Longomontanus; and the semidiameter of the small circle, which from letter E he will get under Longomontanus as 2907 parts, of which the radius of the orb of ♂ is 100000. Therefore, with these measures and the other numbers taken from the *Astronomia Danica* and transferred to Lansbergen's scheme, let him seek the place of ♂.

[Margin: Example 4, of the Tychonic scheme in the measures of Lansbergen.]

X. Conversely, suppose someone wishes, in order to investigate the place of ♄, to use form 3 of Copernicus, which is also that of Tycho and Longomontanus, but prefers to use the measures that Lansbergen would prescribe for this scheme from his own store. Since, from what was said in chapter 3, number 7, and from Rule 4 of this chapter, he needs the measures indicated by the letters D and E, that is, the semidiameters of the two epicycles, he will therefore at once see, from letter D, under the name of Lansbergen, the semidiameter of the larger epicycle of ♄, 8550 parts, and from letter E, likewise under Lansbergen, the semidiameter of the smaller epicycle of ♄, 2850 parts, of which the radius of

Saturn's orb is 100000. So, taking the remaining numbers from Lansbergen's tables, let him complete the calculation of the motion of ♄.

[Margin: Example 5, of Boulliau's scheme in the measures of Copernicus.]

Lastly, there will be no lack of someone who is wonderfully pleased with that form of the ellipse resolved into two circles, which we gave from Boulliau in chapter 5, number 17, but who is pleased to use Copernicus's measures and to seek in them the place of ♃. Now, from what was said there and from Rule 6 of this chapter, he needs the whole eccentricity, or the distance of the umbilici, which from letter A, under the name of Copernicus, he will see to be 9150 parts for ♃; next the eccentricity of the centre of the resolved ellipse, which from letter B under Copernicus he will have for ♃ as 4574 parts; third, he needs the semidiameter of the epicycle, which from letter G he will find under Copernicus as 51 small parts [particularum]; and finally the semidiameter of the larger circle, which from letter K he will find answering to ♃ as 99949 parts, of which the major semidiameter of the ellipse is always to be 100000. So, taking the remaining numbers from Copernicus or from the Prutenic Tables, let him carry out the calculation in Boulliau's scheme. And so for the rest.

CAPVT VIII.

Chapter 8.

De Methodo inueſtigandi Primam Inæqualitatem trium Superiorum Planetarum; videlicet Motum Medium, Eccentricitatem, & Locum Apogei vel Aphelij.

On the Method of Investigating the First Inequality of the Three Superior Planets; namely the Mean Motion, the Eccentricity, and the Place of the Apogee or Aphelion.

[Margin: The difficulty of this method, and its cause.]

I. This method is much more laborious in these three planets than in the others. In the Sun, which undergoes a single inequality, the inquiry is made by a simple eccentric or epicycle. In the Moon, the manifest variation of the parallaxes, and hence of the distances, reveals the eccentricity to us at once; its mean motion is accurately deduced from eclipses, as that of the Sun is from the comparison of equinoxes. Lastly, in Mercury and Venus, the fixed digression from the Sun and the concomitance by which they move with the Sun offer an easier way of reaching the eccentricity and the other elements of the first inequality. But these three superior planets are so entangled in a double inequality of motion that they are not released from the second, which is tied to the syzygies of the Sun, except at conjunctions and oppositions with the Sun, whether mean according to the old astronomy or true according to the recent. The moments of the conjunctions, however, cannot be observed because of the nearness of the Sun, which with its brightness hides the planets from their heliacal setting to their heliacal rising. And the moments of the oppositions themselves have not yet, so far as I know, been learned by immediate

observation, or with the certainty with which full Moons are learned from the beginning and end of eclipses of the ☾. For it would be necessary that, at the very moment at which the apparent place of these planets is observed with instruments in their acronychal shinings, the opposition with the Sun should occur, that is, that the Sun should then be at the opposite place of the ecliptic. But all the observations that we have so far obtained among others, or have made ourselves, have fallen outside the moments of opposition, and were taken some hours or minutes before or after the opposition with the Sun. Consequently, in order to reduce them to the moments of the observations, it was necessary to know beforehand, in some fashion, the mean motion and the anomaly, or distance of the planet from the apogee, and so the place of the apogee, and from these and the eccentricity to gather the prosthaphaereses of the eccentric place, or the equations of the first inequality; yet these are the very things we are seeking. So it seems that one falls into a vicious circle and supposes as known what is being investigated as unknown; or at least that these things cannot be known except from the drawbacks that would follow if what is so supposed stood very differently; or that, by trying which quantity of mean motion and of eccentricity, and which place of the apogee supposed in the calculation, better satisfies the observed places of the planets, one comes nearer to the truth through smaller and smaller differences of the equations, but, as in the thirst of Tantalus, never grasps it.

[Margin: Johannes Regiomontanus's confession on the difficulty of this method.]

II. Hence that old complaint, or candid confession, of astronomers, especially of Regiomontanus in Book 10 of the *Epitome of the Almagest*, proposition 13, where he says: *But there is no way of knowing these small arcs unless the place of the aux of the eccentric is had: the one indeed depends on the other. It will, however, be easier and more certain, since there is no power of proceeding by a straight and exact path, to find these small arcs from the place of the aux known by estimate, than with these small arcs taken by estimate, to seek the place of the aux, and to test whether the rest agree with experiments.*

[Margin: And of Copernicus.]

Copernicus himself felt nothing different about the ancients, and experienced nothing different. For in Book 5, chapter 5, he said: *Those men, then, deprived of the means of demonstration, strove a posteriori and by roundabout ways towards those things to which no access lay open directly and a priori.* And in chapter 6: *Although this does not suffice, yet, brought to close quarters, we reach the truth more easily.*

[Margin: Kepler's confession on the same matter.]

Kepler stuck on the same sandbanks in the *Commentaries on Mars*, chapter 16, when, anxious about this method, he says: *The solution is not geometrical.* And soon after: *There will arise keen geometers like Vieta* [François Viète]*, who will think it a great thing to demonstrate this method's* [Greek: ἀτεχνίαν (atechnian, "artlessness, lack of art")]*; for that is what was charged against Ptolemy, Copernicus and Regiomontanus in this business by Vieta. Let them go, then, and solve the figure*

geometrically themselves, and they will be great Apollos to me. For my part it is enough, for building up four or five conclusions from one argument, in which four observations and two hypotheses are contained, that is, for retracing the way out of the labyrinth, to have shown, in place of geometrical light, an [Greek: ἄτεχνον (atechnon, "artless")] *thread (by which you may nevertheless be guided to the exit). If the method is difficult to grasp, the investigation without a method is much more difficult.*

[Margin: Boulliau's censure of Kepler.]

And these, surely, are the words Boulliau alluded to when, in Book 1 of the *Astronomia Philolaica*, chapter 22, having rejected the method of Ptolemy and Copernicus, he added: *Kepler, in his Commentaries on the star of Mars, what great things he labours at? What divinity does he not invoke? He awaits some god* [Greek: ἐκ μηχανῆς (ek mēchanēs, "from the machine")] *to determine an indeterminable problem; and at last, after long windings of calculation, and with every by-way surveyed, he fixed the places of the aphelia and perihelia.* As if Boulliau himself supposed nothing in this treatise, and did not try, by a long and often repeated calculation, using the arithmetic mean between various excesses and defects, to come as near as possible to a truer place of the aphelion and a more correct eccentricity.

Astronomers must therefore be forgiven, and the circle is not to be reckoned useless, if you can first know beforehand in a coarser fashion, on the one hand the difference of motion, from the smallness of the equations of the second inequality required in order that the places of the planet observed near oppositions with the Sun may answer to the calculation; and on the other the mean motion, from some ancient opposition together with a recent one, separated from each other by a long interval, in much the same way as we sought the Sun's mean motion from two equinoxes in Book 3, chapter 17; and then to inquire into these same things more exactly, with a greater approach to the truth day by day.

So it was not unskilfully that Ptolemy, in Book 9, chapter 3, and Copernicus, in Book 5, chapter 1, before the more subtle examination of the apogee, the eccentricity and the mean motion, set out first the tables of the mean motion of the five minor planets; and then tried to polish those three things: Ptolemy for ♂ in Book 10, chapters 8, 9 and 10, for ♃ in Book 11, chapters 1, 2, 3, and for ♄ in Book 11, chapters 5, 6 and 7; Regiomontanus in the same places in the *Epitome*; Copernicus in Book 5, chapters 6, 7, 11, 12, 16 and 17; and the others soon to be adduced.

Primus Modus inueſtigandi Apogeum trium Planetarum Superiorum, & Eccentricitatem inquirendi aut examinandi ex Copernico.

First Way of investigating the apogee of the three superior planets, and of inquiring into or examining the eccentricity, from Copernicus.

III. Ptolemy, in Books 9, 10 and 11 of the *Almagest*, and Regiomontanus, in the *Epitome* of those books, lacked a means of demonstrating the eccentricity and the apogee a priori, both for the causes indicated in numbers 1 and 2, and because, in using mean oppositions with the Sun, they were using unknown angles as though they were known. Therefore, as Copernicus observes in Book 5, chapter 5: *They strove a posteriori and by roundabout ways towards those things to which no access lay open directly and a priori. Thus Ptolemy, in carrying these things out in lengthy discourse, spread himself over a huge multitude of numbers, which I think it tiresome and superfluous to review, especially since in what follows in our own work too we shall imitate almost the same method.* So, passing over that farrago of Ptolemaic figures, which attain the goal no more happily, we shall begin from the Copernican method, from which one will nevertheless be able to judge sufficiently of the Ptolemaic.

Copernicus, then, in Book 5, gave the warning in chapter 1 that the motions of the planets are to be numbered not from the equinoctial points but from the first star of Aries, and that in measuring the revolutions of the planets one should use not equinoctial or tropical solar years but sidereal ones, which he thought more uniform and constant than those; he set out first the mean motions of the 5 minor planets; in chapter 2 he condemned the Ptolemaic equant and the physical inequality Ptolemy admitted in these planets; and in chapter 4 he substituted three hypotheses that preserve equality of motion, but that, as to the measure of the orbs and the difference of the distances, are equivalent to the bisection of the eccentricity, because he had made the semidiameter of his epicycle a third part of the remaining eccentricity of the eccentric. These things, I say, being supposed, in chapters 5, 6, 10, 11, 15 and 16 he examines three acronychal oppositions of each of the three superior planets with the Sun, once observed by Ptolemy, and another three observed by himself. He assumes the whole eccentricity of these planets as found by Ptolemy and, dividing it into four equal parts, assigns three of them to the eccentricity of his eccentric and the fourth to the semidiameter of the epicycle. He then investigates, from the difference of the mean motions from the true, both the place of the apogee and whether the presupposed eccentricity agrees with the equations, that is, yields the equations necessary for the mean motions, when reduced to the true, to agree with those observed. And so he professes that he is examining and testing a posteriori an eccentricity already known, not hunting down an unknown one a priori. In Mars, however, he found that this measure must be varied to some extent, as we have already said in chapter 5, number 13.

Diagram. Woodcut set in the right column, with the text running down its right side. A large eccentric circle centred at D, with the line of apsides drawn vertically from F at the top through D and E to G at the bottom. Three small epicycle circles stand on the circumference, centred at A (upper right), B (upper left) and C (lower left). Straight lines join A, B and C to the centres D and E; further lines run from E out to the points N, O and P on the epicycles, and short radii join A to N, B to O and C to P.

- F (top of the vertical line): apogee
- G (foot of the vertical line): opposite end of the line of apsides
- D (on the vertical line, above E): centre of the eccentric
- E (on the vertical line, below D): centre of the great orb
- A (upper right): centre of the epicycle; N and K on or beside that epicycle
- B (upper left): centre of the epicycle; O and L on or beside that epicycle
- C (lower left): centre of the epicycle; P and M on or beside that epicycle

Let there be, then, three centres of the epicycle, called the centric places of the planet, observed at the three mean oppositions with the Sun, A, B, C, on the circumference of the eccentric described from centre D; and let the line of apsides be FDG, in which the centre of the great orb of the Earth is E; and let those points A, B, C be connected by straight lines with the centres D and E, so that the lines of mean motion are AD, BD and CD, and the lines of the true centric place are AE, BE and CE. Then let the true place of the planet on the epicycle be, in the first observation the point N, in the second the point O, in the third the point P, which are connected with the centre E by the straight lines NE, OE, PE. And from the centre of the epicycle to the planet let the semidiameters AN, BO and CP be drawn, which is a third part of the eccentricity DE. With these things laid down, you will carry out the business through the following steps.

[Margin: 1st step.]

First, in triangle ADE, the eccentricity DE is given from Ptolemy, in parts of which AD is 100000, as we set out in chapter 1, number 11, in the table; and also the angle ADE, as being the complement to two right angles of the angle FDA, which is known from the mean anomaly of the eccentric. So by the aid of trigonometry you will find both the side AE and the angles DEA and DAE.

[Margin: 2nd step.]

Second, in triangle AEN: since the arc NK, that is, the motion of the planet on the epicycle, is as great as the arc AF, the motion of the centre of the epicycle from the apogee of the eccentric F, and so the angle NAK is known from the mean anomaly of the eccentric, if you add to it the angle found, DAE, the whole angle NAE will be known in that same triangle, in which the side AE has been found and AN is given, a third part of DE. So the angle AEN will not lie hidden. When it is subtracted from the angle AED, found earlier, the angle NED, or NEF, will become clear, by which the apogee F, but under the fixed stars, is distant from the true place of the planet observed at N. Therefore, when the true place of the planet is known and the angle FEN is added to it, it will be known whether the place of the apogee observed under the fixed stars answers to the place of the apogee assumed.

[Margin: 3rd step.]

Third, in the second acronychal observation and the triangle BDE, the sides ED and DB are given, as above, and the angle BDE, the complement of the anomaly of the eccentric, or of the angle FDB. Seek, then, the side BE and the angles DBE and BED.

[Margin: 4th step.]

Fourth, in triangle BEO, since the arc LO, that is, the angle

LBO, is as great as the arc FB of the mean anomaly, if you add to it the angle DBE, already found, the whole angle OBE will be known in triangle OBE, in which you have already found the side BE, and BO is given, a third part of the eccentricity DE. So the angle BEO will not lie hidden; when it is taken from the angle BED, the angle OEF will be manifest, by which the apogee F is distant, under the fixed stars, from the place of the planet observed at O.

[Margin: 5th step.]

Fifth, in the third acronychal observation and in triangle CDE, DC and DE are given as above; and the angle CDE is known, because it is the complement to a semicircle of the angle FDC, known from the mean anomaly of the eccentric. So by the solution of triangles you will easily find the side CE and the angles DCE and CED.

[Margin: 6th step.]

Sixth, in triangle PCE, the arc MP, that is, the angle PCM, is as great as the arc FBC of the mean anomaly of the eccentric. So when the angle found, DCE, is added, the angle PCE will become known in triangle PCE, in which the side CE was found, and PC is given, a third part of DE. Accordingly the angle CEP will become manifest; when it is subtracted from the angle CED, what remains will be the angle PED, by which the apogee F is distant from the true place of the planet P.

[Margin: Conclusion of the practice.]

When this is done, combine the angles FEN and FEO into one angle NEO. For if it is equal to the difference between the true places of the planet observed in the first and second acronychal observations, the measure of the eccentricity and the semidiameter of the epicycle assumed are correct. This will be confirmed if the angle OEP too is equal to the difference between the true places of the planet observed in the second and third acronychal observations. Copernicus, in Book 5, chapters 5, 10 and 15, affirms, indeed teaches by geometrical calculation, that in the three acronychal observations of Saturn, Jupiter and Mars made by Ptolemy, from the hypothesis already mentioned, as assumed, the already mentioned angles come out equal to the difference of the true places observed by Ptolemy. So if those observations are to be stood by, the measure of the Ptolemaic eccentricity and the place of the apogee he found are correct. Yet you may see in Copernicus the numbers for Saturn very corrupt, whether by a fault of the autograph or by a fault of the printer. For he puts the whole Ptolemaic eccentricity of Saturn at 1016 parts, of which the radius of the orb is 10000, and says that a quarter of it is 285, and three quarters now 854, now 864, which are false. In Mars, however, he thinks the cause of the discrepancy arose from a variation in the Sun's eccentricity.

But the same Copernicus, in Book 5, chapters 6, 11 and 16, having found that the numbers and measures of the Ptolemaic hypothesis did not answer to the places of these three planets observed by himself from the year of Christ 1513 to

1539, was forced to correct somewhat the Ptolemaic eccentricities and the places of the apogees. And so that no one should attribute this discrepancy to the form of the Copernican hypothesis, in which the motion of the centre of the epicycle is equal around the centre of the deferent, he first examined his three observations of each planet in the form of the Ptolemaic equant. Noticing that not even in that form did the measures and apogees answer to the observations, he corrected both as far as the agreement of the observations required. Then, distributing the whole eccentricity of the Ptolemaic equant into four parts, he gave three of them to the eccentricity of his deferent and the fourth to the semidiameter of the epicycle, so as to transform it into his own hypothesis. But the way in which he hunted down the eccentricity and the apogee in the Ptolemaic form is longer and more obscure, though similar to the second way, to be given below from Hérigone; therefore we have passed it over and will substitute Hérigone's way for it.

[Margin: Imperfection of this method, from Copernicus's own confession.]

Copernicus also confesses, in Book 5, chapter 5, that in this method the angle NEO, of the true places of the planet, is not measured by the arc of the mean motions BA, known from the time between the two observations A and B; just as the measure of the angle PEO is not the arc of mean motion BC, because they are not described from the same centre. He confesses too that the arc AB subtends an unknown angle AEB, just as BC subtends an unknown BEC; and that the differences of the angles AEN, BEO and CEP cannot be known unless the arcs AF, FB and FAC are established through the mean anomaly, which supposes a known mean motion from the mean apogee of the eccentric, and hence a place of the apogee known approximately; and that these things thus contain a mutual dependence. Therefore one must take refuge in demonstrations a posteriori, and explore by feigned suppositions whether through them the true places observed in the planets can be represented, as we said above in number 1. Yet a great part of this imperfection arose from these astronomers' having chosen the mean oppositions of the planets; for if they had chosen the true ones, the planet would have been for them at the points K, L and M, and they would have come nearer to the truth.

Secundus Modus Eccentricitatis & Apogei inueſtigandi ex Herigonio.

Second Way of investigating the eccentricity and the apogee, from Hérigone.

[Margin: Hérigone, volume 5 of the *Cursus Mathematicus*, in the *Theorics*, Book 1, chapter 3, proposition 12, and Book 3, proposition 27.]

IV. In the following diagram let there be three places of the same planet, observed at the moment of true opposition with the Sun: let them be, I say, A, B and C, on a circle whose centre of the equal motion made from A to B is E. And from the conjecture I spoke of in number 3, let the place of the apogee H be approximately known, from which through E let the line of apsides HEF be

drawn, in which let the eccentricity being sought be ED; and let the point, or centre of the world, from which the centric place of the planet, or in Ptolemaic terms the centre of the epicycle, is viewed, be D. And let the three observed places be connected with each centre, E and D, by the straight lines AE and AD, then BE and BD, then CE and CD; and with AD produced as far as G, let the point G be connected with the points B and C by the straight lines GB and GC; and finally let the three chords AB, AC and BC be drawn. Next, from the interval of time between the observations, let the mean motions be known, and hence their differences, namely the arc AB, which measures the angle AEB, and the arc BC, which measures the angle BEC. And from the true places of the planet under the zodiac (understand it here as described from D), let the difference of the arcs of the zodiac between those three places be known, and hence the angle ADB, known from the difference of the true places under which the planet was when at A and when at B; and the angle BDC, known from the difference of the true places under which the planet was when it stood at B and at C. From these givens [Greek: δεδόμενοις (dedomenois, "things given")], then, by the solution of five triangles, you will obtain a more exact place of the apogee and the eccentricity desired.

Diagram. Woodcut set in the right column, with the text running down its right side. A circle with A at the upper left, H at the top, B at the upper right, C at the right, G at the foot, F at the foot just left of G, and M at the lower left, all on the circumference. A vertical line runs from H through E and D to F. E stands on it above D, with K just to the right of D. Solid lines join A, B and C with E and with D, and the chords AB, AC and BC are drawn; a line runs from C through D to M. Dashed lines run down to G from E, from B and from C.

- H (top): place of the apogee
- A, B, C (circumference): the three observed places
- E (on the vertical line, upper): centre of equal motion
- D (on the vertical line, lower): centre of the world
- F (foot of the vertical line): other end of the line of apsides
- G (foot of the circle): end of AD produced
- K (beside D), M (lower left): named on the block; not named in the text on this page

[Margin: 1st step.]

First, then: since the angle ADB, the difference of the true place A and B, is given, its complement to two right angles BDG is also given [Margin: by 13 of the first of Euclid]; and since the angle AEB, the difference of the mean motions of the planet placed at A and B, is given, the angle at the circumference AGB is also given, because it is half of that one [Margin: by 20 of the third of Euclid]. So in triangle BDG the angles BDG and BGD are known. Assume, then, the side BD as 200000 parts (for you will reduce these afterwards to the radius of the circle), and from these three givens seek the side DG.

[Margin: 2nd step.]

Second, in triangle DCG, the side DG has been found, and the angle DGC at the circumference is known, because it is half of the angle AEC at the centre, known from the difference of mean motion between A and C. The angle GDC is also known [Margin: by 20 of the third of Euclid], because it is the complement to two right angles of the angle ADC, known through the difference of the true places of the planet observed at A and C. So from this seek the side DC.

[Margin: 3rd step.]

Third, in triangle BDC, the side DC has been found, and BD has already been assumed as 200000 of the same parts, and the angle BDC is known from the difference of the true places B and C. Seek, then, both the side BC and the angle DBC.

[Margin: 4th step.]

Fourth, in the isosceles triangle BEC, the base BC has been found, and the angle BEC is known from the difference of mean motion between B and C. So the sum of the angles at the base is known, as being the complement to two right angles, and hence each of the angles at the base, as being equal to each other [Margin: by 32 of the first of Euclid and by 5]. Seek, then, the side BE, and from the angle EBC subtract the angle DBC found in the 3rd step: for the angle DBE will be left.

[Margin: 5th step.]

Fifth, in triangle EDB, there are known both the side DB, assumed as 200000, and the side EB, and the angle contained by them, through the 4th step. So seek DE and the angle EDB, which measures in the zodiac the distance of the true place of the planet observed at B from the true place of the apogee H. Therefore, since the point of the zodiac under which the planet observed at B stood is known, the point of the zodiac under which the planet's apogee stood at that time will also become known; it will be called the aphelion if the Sun is supposed at the centre D. Further, if it is made: as EB, in the parts found, to DE, so the radius EB, of 100000 parts, to another, the eccentricity DE will be known, in parts of which the radius of the eccentric circle is 100000. These were the two things to be investigated.

[Margin: Confirmation of the conclusion found.]

It would also be possible, for confirmation, with the side EC found (which is equal to the side EB and AE) in the isosceles triangle AEC, and with the angles at the base known from the angle AEC, that is, from the difference of the mean motions of the planet at A and C, and with the base AC found, for the angle DAE to be known, if the angle DAC had been found; for EAC subtracted from this would give DAE. Now the angle DAC can be found with the base AC found, as above, and with the angle ADC known, which is the difference of the true places A and C, and with the side DC found, as in the 2nd step; and in the same triangle the side AD can be found. So with the sides AD and AE known, together with the contained angle DAE, the eccentricity ED would not lie hidden, nor the angle ADH, measuring the distance of the true place

of the planet A from the true place of the apogee, but in the zodiac. You see now that in this method two things are supposed as known beforehand, about which, however, the question stands, namely the mean motion of longitude and the place of the apogee; and that it is only a posteriori that one explores whether they agree in every respect with the observed places.

EXEMPLVM.

Example.

[Margin: Example in ♂ from the observations of Tycho.]

V. *As Longomontanus reports in Book 2 of the* Theorica*, chapter 8, Tycho observed Mars at Uraniborg in three acronychal shinings and true ☍ with the ☉: in the year 1585 January 30, at $19^h\ 15^m$ p.m., in ♌ 21° 35′ 10″; in the year 1587 March 6, at $7^h\ 20^m$, in ♍ 25° 42′; and lastly in the year 1589 April 14, at $6^h\ 20^m$, in ♎ 4° 23′. Let these three places, in order, be A, B, C in the preceding figure. So the difference of the first and second true places, that is, the angle ADB, was 34° 6′ 50″, which is the amount from the place in ♌ to the already mentioned place in ♍. And the difference of the second true place from the third, that is, the angle BDC, was 38° 41′. The time from the first to the second observation was 2 common years, 34 days, $12^h\ 5^m$, to which there corresponds from the Rudolphine Tables a mean motion of Mars, that is, the angle AEB, after the casting out of the whole circle, of 40° 39′ 13″. From the second opposition to the third there were 2 years, $39^d\ 23^h$, counting the leap day of the year 1588, to which there corresponds a mean motion of 43° 30′ 45″, which was the size of the arc CB, or the angle BEC. Let them therefore be set in the following synopsis.*

Diagram. Woodcut set in the left column, with the italic text of the example running down its left side. A circle with A at the upper left, H at the top, B at the upper right, C at the right, G at the foot, F at the foot just left of G, and M at the lower left, all on the circumference. A vertical line runs from H through E and D to F, with E above D and K just to the right of D. Solid lines join A, B and C with E and with D, and the chords AB, AC and BC are drawn; a line runs from C through D to M. Dashed lines run down to G from E, from B and from C. It has the same labels and arrangement as the figure of the second way.

- H (top), F (foot of the vertical line), G (foot of the circle), M (lower left)
- A, B, C (circumference): the three places of ♂ in the example
- E (on the vertical line, upper), D (on the vertical line, lower), K (beside D)

Angles and sides (ANGVLI, LATERA).

[Margin: 1. For triangle DBG.]

Angles	° ′ ″	Sides	Parts
ADB	34° 6′ 50″	BD	20000
BDG	145° 53′ 10″		

Angles	° ′ ″	Sides	Parts
AEB	40° 39′ 13″		
AGB	20° 19′ 36″		
DBG	13° 47′ 14″	Therefore DG	13721

[Margin: 2. For triangle DCG.]

Angles	° ′ ″	Sides	Parts
AEC	84° 9′ 59″	DG	13721
DGC	42° 4′ 59 1/[?]″		
ADC	72° 47′ 50″		
DCG	30° 6′ 51″	Therefore DC	18329

[Margin: 3. For triangle BDC.]

Angles	° ′ ″	Sides	Parts
BDC	38° 41′ 0″	BD	20000
		DC	18329
Therefore DBC	63° 34′ 42″	And BC	12792

[Margin: 4. For triangle BEC.]

Angles	° ′ ″	Sides	Parts
BEC	43° 30′ 45″	BC	12792
EBC	68° 14′ 38″		
DBC	63° 34′ 42″		
Therefore DBE	4° 39′ 56″	And BE	17256

[Margin: 5. For triangle EBD.]

Angles	° ′ ″	Sides	Parts
DBE	4° 39′ 56″	BE	17256
		DB	20000
Therefore EDB	25° 36′ 52″	And ED	3247

[Margin: Apogee of ♂ in the year 1587.]

♂ was, moreover, in the second opposition B, in ♍ 25° 42′. So with the angle HDB, 25° 36′ 52″, taken away, there remains ♍ 0° 5′ 8″, in which stood the apogee H of ♂ in the year 1587 March 6, old style, at 7^h 20^m after noon at Uraniborg.

[Margin: Eccentricity of ♂.]

Next, if it is made: as EB 17256 to the same radius EB 100000, so ED 3247 to another, the eccentricity ED will be 18817 parts, of which the radius, or semidiameter of the planet's orb, is 100000; and its half 9408. But this way is slippery, as I shall soon say.

Tertius Modus Eccentricitatis & Apogei inquirendi ex Keplero.

Third Way of inquiring into the eccentricity and the apogee, from Kepler.

[Margin: Imperfection of the first and second ways.]

VI. The first and second ways set out above, relying on only three acronychal observations, are judged slippery by Longomontanus, in Book 2 of the *Theorica*, chapter 2, by Kepler, in the *Commentaries on Mars*, chapter 16, and by Boulliau, in Book 8 of the *Astronomia Philolaica*, chapter 3. For if in the already mentioned figure you solve the triangles CDE and ADE, you will find neither the same eccentricity DE nor the same place of the apogee.

[Margin: Boulliau's opinion of those ways.]

So Boulliau there, from three acronychal and true oppositions of ♂ with the ☉ observed and reported by Longomontanus in Book 2 of the *Theorica*, chapter 8, page 342, gathers, but by his own method, a whole eccentricity of ♂ of 19402 parts, and a half of 9702, of which the radius of the orb of ♂ is 100000. But the place of the apogee from the first opposition, which was in the year 1604 March 28, at 16^h 20^m p.m., with ♂ placed in ♎ 18° 36′, he gathers to be in ♍ 1° 28′ 28″; but from the second, of the year 1608 July 24, at 2^h 0^m, with ♂ in ♒ 11° 10′, he gathers it in ♍ 1° 25′ 59″; and lastly from the third, of the year 1610 October 8, at 16^h 50^m, with ♂ in ♈ 25° 10′, he gathers it in ♍ 1° 9′ 4″. He thinks this place of the apogee too far advanced, because, to be sure, in chapter 1, from four other acronychal shinings observed by Tycho, he had obtained the aphelion of ♂, from three of them in ♌ 29° 0′, and from the fourth in ♌ 29° 4′. But he confesses that this disagreement found in the three Longomontanian observations arose from the admission of a small error of about 3′ in the observation; and nevertheless he condemns this method, *Because it is completed with only three points on the circle*; and he concludes: *Hence it is manifest that three places assumed are by no means sufficient for investigating the first inequality*. This he had charged against Ptolemy and Copernicus for using three points and observations, in Book 1, chapter 22, especially because Ptolemy had used three points in such a way that he had first decided that the eccentricity was to be bisected.

[Margin: Kepler's opinion of the same.]

Kepler too, in the passage cited, says: *Since Ptolemy, with three* [Greek: ἀκρονυχίοις (akronychiois, "acronychal")] *observations, and with this preconceived opinion about the proportion of the eccentricities, established both the place of the apogee and the correction of the mean longitude, and finally also the quantity of the eccentricities, I saw that if this problem were weakened, with the axiom about the proportion of the eccentricities removed* (that is, about the doubleness of the eccentricity of the equant to the eccentricity of the deferent) *it would be uncertain, and not of a single case, and must accordingly be strengthened in turn by a fourth* [Greek: ἀκρονυχίῳ (akronychiō, "acronychal")] *observation besides.*

[Margin: Regiomontanus's view of this method, and another way.]

But the most sharp-sighted Johannes Regiomontanus had seen this earlier, in Book 10 of the *Epitome of the Almagest*, proposition 21, where he says: *All the things mentioned above suppose this one thing, never demonstrated: that the centre of the eccentric deferent is equidistant from the two centres, namely of the world and of the equant, and lies on one straight line with them. But if something uncertain is mixed into a fine demonstration, the intellect will be sickened by it.* He adds, however, a remedy, but an arduous one, saying: *But if you wish to escape this, embrace this way; yet here the difficulty will perhaps produce no less trouble than uncertainty does elsewhere. Four configurations, their extremes known, we shall observe such that the intervals of time between each pair are equal; for this condition will show the aux to be midway between the paired configurations.* So if it were given to observe four acronychal positions whose paired intervals of time were equal, the point of the ecliptic at which the arc enclosed between the extreme places was bisected would be the place of the apogee. But since hardly any astronomer will meet with such good fortune, let us consult Kepler's earlier method.

[Margin: Kepler's earlier method.]

VII. With centre B, describe the eccentric HEDG, in which the diameter of the apsides is HI; suppose it to be as if unchanged for some years, so that the place of the apogee stays sensibly at the same point of the zodiac. On that line let A be the centre of vision, and C the centre of the equant, that is, the point about which the planet is taken to move uniformly.

Diagram. A circle, the eccentric, set into the left column with the text running down its left side. Point labels stand around the circumference and on the interior vertical line. Straight lines run from the circumference points to the interior points, and chords join the circumference points.

- H (top of the circle): apogee
- F (upper left, on the circle): place of the planet
- E (left, on the circle): place of the planet
- G (right, on the circle): place of the planet
- I (bottom of the circle, left of D): perigee
- D (bottom of the circle, right of I): place of the planet
- C (interior, uppermost of the three on the vertical line): centre of the equant
- B (interior, below C): centre of the eccentric
- A (interior, below B): centre of vision

Let the 4 places of the planet in oppositions with the Sun be F, G, D, E, so that the planet, stripped of the second inequality, appears to the eye at A along the lines FA, GA, DA, EA. Let these places be joined to the two other centres, B and C, by straight lines, and indeed to one another by the chords FG, GD, DE, EF. For although only in the opinion of the ancient and Ptolemaic astronomy is our sight at A, the centre of the Earth, while in the opinion of Copernicus, Tycho and the moderns A is the Sun or a point near the Sun, yet according to these too the sight, or the centre of the Earth, is in true oppositions on the lines AF, AG, AD, AE.

With this laid down, we hold two things as certain: namely the angles at A, which are FAG, GAD, DAE and EAF, known from the difference of the true places of the planet observed in the zodiac; and likewise the angles at C, namely FCG, GCD, DCE and ECF, known from the difference of the mean motion that the interval of time elapsed between the observations yields. But the place of the apogee H, or the position of the line HI, is uncertain, or known only roughly; uncertain likewise are the mean motion and, from it, the anomaly; uncertain also the whole eccentricity of the equant, namely AC; and lastly it is uncertain whether B, the centre of the planet's deferent, is on the same line with the centres A and C, and whether at the exact midpoint, or rather, as Copernicus detected in Mars, nearer the centre of the equant than the centre of vision.

Since, however, from the ancient method, resting on three acronychal positions, both the nearly true mean motion and the place of the perigee I and of the apogee H can be known beforehand, for example for ♂ at the end of ♌ towards the end of the preceding century, or about the year 1600, let such a place be assumed that from its distance from the observed places of the planet the anomalistic angles FCH, GCH, or GCI, DCI and ECI are known; and finally let AC be assumed, for ease, as 10000 parts. With this laid down, what must be made clear is whether the assumed place of the apogee, and the angles depending on it, allow the four points F, G, D, E to be on the same circle, and B, the centre of that circle, to be on the line CA; and how great AC must be to obtain this; indeed how great AB, if B must be exactly at the midpoint of AC, as Ptolemy supposes. AC could also be assumed as a determinate quantity, in parts of which BH is 100000, known in some fashion from the earlier methods; but for the sake of easier calculation Kepler assumes it as 10000, and afterwards reduces it to parts of the radius AH. With these things laid down, then, use the following steps.

[Margin: Step 1.]

First, in the triangles CFA, CGA, CDA and CEA, seek the sides AF, AG, AD, AE, in parts of which their common side AC was assumed; for in them the angles at A and C are given. For example, in triangle CFA, AC is given as 10000, and the angle FAC from the distance of the planet observed at F from the assumed place H of the apogee, and FCH from the anomaly of the eccentric, that is, from subtracting the place of the apogee from the planet's mean longitude belonging to it by the tables at the time when it was observed at F; and likewise for the others.

[Margin: Step 2.]

Second, in the triangles FAG, GAD, DAE and EAF, in which the sides have now been found by the preceding step and the angles they enclose are given, being known from the difference of the true observed places of the planet, seek therefore each angle at the base of each triangle, and join them to the neighbouring angles so as to have four angles, namely EFG, FGD, GDE and DEF. For if all together equal four right angles, and any two opposite ones

between them equal two right angles, the four points F, G, D, E, bounding the quadrilateral FGDE, will be on the circumference of the same circle, and that quadrilateral will be inscribed in that same circle, by proposition 22 of Book 3 of *Euclid* and its scholia; and the things assumed above, up to this point, will not be false. But if those four angles do not equal four right angles, and those pairs do not equal two right angles, the assumption is false. Yet it will be uncertain which of those assumptions is false, namely the mean motion or the place of the apogee.

[Margin: Step 3.]

Third, therefore, keeping the mean motion used above, move the place of the apogee forward or back a little, and so increase or decrease the angles at A made by the line of apsides and by the lines along which the planet is seen from A; and repeat the first and second steps, until, with no sensible difference, the four angles of the quadrilateral FGDE equal four right angles, and each two opposite ones equal two right angles. And so you will have the four places of the planet on the same circumference of a circle, which was the first thing to be explored.

[Margin: Step 4.]

Fourth, to find out whether B is at the midpoint of the line AC, join into one the angles GAD and DAE, which are known from the difference of the true places of the planet observed at the three places G, D, E, so that the angle EAG becomes known; and in triangle EAG, in which the sides are now known by the first step, alone or repeated, seek the base GE.

[Margin: By 20 of Book 3 of Euclid.]

Next, since in triangle EFG the angle at F is known from the second or third step, and this must be half the angle at the centre, namely the angle EBG, therefore in the isosceles triangle EBG the base EG and the angle opposite it are given;

[Margin: By 5 of Book 1 of Euclid.]

therefore the angles at the base, BEG and BGE, are given.

[Margin: Step 5.]

Fifth, then, in triangle EBG, from the given or found EG and the angles at the base, seek the radius of the circle, that is, the side EB, in parts of which AB was assumed. And since the angles BGE and AGE have now been found, and the sides BG and AG, if you take AGE from BGE itself (or the latter from the former, if the latter should come out smaller than the former), AGB will remain. Therefore in triangle AGB, in which the sides AG and BG and the enclosed angle AGB are given, the angle BAG is sought. If it disagrees with CAG, assumed above, that is a sign that B does not fall, as it should, within the line AC.

[Margin: Step 6.]

Sixth, therefore, the mean motion, which you had not changed above, must be changed, as must the place of the apogee, and the preceding steps must be repeated for as long as it takes until the four points of the observed places are

on the circumference of the same circle, that is, until the opposite angles of the quadrilateral already mentioned together equal two right angles. Then you will work by other steps until you find BAD as great as you had assumed CAD, or HAD, in that operation. When you have achieved this, you will then take the radius BD as 100000 parts, and in triangle BAD you will seek, by means of the angles now found, the eccentricity of the deferent, AB, and the eccentricity of the equant, AC; and at last you will declare that the place of the apogee and the mean motion assumed are right.

[Margin: Imperfection of this method.]

Kepler, however, admits that this is not a geometrical solution, and that there will be keen geometers like Viète who will charge Ptolemy, Regiomontanus and Copernicus with this method's lack of art [Greek: ἀτεχνίαν], as Viète did; and that an artless [Greek: ἄτεχνον] thread, by which you may retrace your way out of this labyrinth, is better than none; and that it is nothing unusual for geometers to hunt the true from the false and, by arguments to the impossible, the truth that stands in the middle between defect and excess; and that, out of weariness with this method, the *Commentaries on Mars* were drawn out into a fifth year. Finally, having brought forward an example of this practice, from four acronychal positions of Mars he concludes the whole eccentricity of ♂, AC, to be 18564 parts, but that of the deferent alone, or AB, 11332, and BC 7232. In the Copernican and Tychonic form this would amount to giving the semidiameter of the epicycle a value, for the greater one, of 14948 parts, or, on account of the maximum equations, a more correct 14988; and for the lesser, 3616 or 3628. But he reserves the examination of these quantities for another place, namely not on a perfect circle but on an ellipse; which he does in the *Commentaries on Mars*, chapter 42, by a method soon to be set out.

Quartus Modus inueſtigandi Eccentricitatem, Aphelium, & correctionem Motus Medij ex Keplero.

Fourth way of investigating the eccentricity, the aphelion and the correction of the mean motion, from Kepler.

VIII. When Kepler, reducing the eccentric places of Mars to the law of a circle, saw that they did not yield the same aphelion, and from this came to suspect that the planet's path is not a circle, he resolved in chapter 42 to inquire, from his own observations, yet outside acronychal position, into the distances of the planet from the Sun at any place whatever, especially when it is near the aphelion and perihelion; and from them to inquire into the genuine eccentricity and proportion of the orbs, the most certain place of the aphelion, and the correction of the mean motion. This he does by the following method. In the following figure let A be the centre of the world, that is, the Sun, and IT the line of apsides; and with centre B describe the eccentric ICTF, in which I is the aphelion and T the perihelion. With centre A, moreover, describe the

annual orb of the Earth DKH; and let AK be the line of the equinoxes, along which the Earth at K sees the Sun A under the beginning of Aries.

[Margin: Kepler's later method.]

Now let the Earth, according to the various times at which the planet was observed, be at G, D, E, K, Z, M, H; of these let D, G, H be on the left-hand parts of the eccentric, and the remaining places on the right. For those times let the true place of the Sun be given, and its anomaly, with which gather from the tables of the Sun the distances of the Earth from the Sun, which are to be the lines AG, AD, AE, AK, AZ, AM, AH. And since the line IT is the line of apsides, on which now lie the planet as seen from the Sun and the planet's eccentric place, if the true place of the planet, seen along the lines GI, DI, EI, etc., is established from observation, and the true place of the Sun or Earth from calculation, then the angles at the Earth will also be established, namely the angles AGI, ADI, etc. These become known by subtracting the eccentric place of the planet from the true place of the Sun, or the latter from the former, according as the Earth is heading towards the opposition or towards the conjunction of the planet and the Sun, that is, is on the left or on the right side of the annual orb. For example, if the Earth is at M and the planet at T, the angle AMT will be known by subtracting the true place of the Sun A, seen from M, from the place of the planet T, seen from M; and you will have the angle AMT. But if the Earth is at H, subtract the planet's eccentric place from the true place of the Sun, and you will have the angle AHT. With these things supposed:

Diagram. Two circles set in the left column. The larger is the eccentric, with I at its top and T at its bottom. The smaller, inside it, is the annual orb about A, its circumference carrying the Earth's stations. Straight lines radiate from A to the stations; lines run from I to stations on the upper arc and from T to stations on the lower arc. Three planetary signs stand in the space between the two circles.

- I (top of the larger circle): aphelion
- T (bottom of the larger circle): perihelion
- C (left, on the larger circle)
- F (right, by the larger circle)
- ♂ (upper left, between the circles): planetary sign
- ♃ (upper right, between the circles): planetary sign
- ♄ (lower left, between the circles): planetary sign
- B (interior, above A): centre of the eccentric
- A (interior, on the vertical line): the Sun, centre of the annual orb
- D (upper arc of the smaller circle)
- G (upper left of the smaller circle)
- E (upper right of the smaller circle)
- K (right of the smaller circle)
- Z (right of the smaller circle, below K)
- L (lower right of the smaller circle)

- M (lower right of the smaller circle, below L)
- P (bottom of the smaller circle)
- H (lower left of the smaller circle, beside P)

[Margin: Step 1, for the true place of the aphelion.]

First, assume the distance of the planet, whether of the aphelion, AI, or of the perihelion, AT, already known beforehand in some fashion; for example for Mars AI as 166700 and AT as 138400, in parts of which the radius of the annual orb is 100000; and by means of trigonometry seek the angles at I and at T, for example the angles AIG, AID, AIE, etc. Finally, add these angles to the observed place of the planet, if the Earth is in quadrant GD and the planet at I; subtract if in quadrant EK; and you will have the place of the aphelion. But if the planet is at T and the Earth at H, subtract the angle ATH from the observed place of the planet; if, however, the Earth is at Z, or L, or M, add; and you will have the place of the perihelion. Thus either from all these operations the line TI is restored to the same place of the zodiac, that is, the same place of the aphelion or perihelion always results, and that is a sign that the assumed distance is correct; or the same does not result, but the difference is greater than the difference of the precession of the equinoxes allows, on account of the different times at which the planet was observed against the fixed stars, and another distance a little greater or smaller must be assumed, until that difference of the places of the aphelion and perihelion gathered from several observations is found to be very small. Then that little error must be distributed among the individual operations, and so the true place of the aphelion must be fixed, which for ♂ Kepler finds, in 1588 November 22, at ♌ 28° 50′ 44″.

[Margin: Step 2, for the correction of the mean motion.]

Second, since the mean motion changes when the place of the aphelion is changed, from the change of the former you will gather the change of the latter. For if, at the time when Mars, for example, was thought to fall on the aphelion and to lack all equation of the eccentric place, it had at that same time passed the aphelion by 11′, then to this anomaly there corresponds an equation of 4′ to be subtracted; and so by its mean motion it had passed that earlier mean place by 4′; and these must be added to the mean motion usually set in the tables. But if it fell short of the aphelion, and the equation was additive, they will have to be subtracted.

[Margin: Step 3, for the eccentricity.]

Third, combine the distances corrected as above, the aphelial AI and the perihelial AT, into one line IT, and its half, BI or BT, will be the radius or semidiameter of the planet's orb, in parts of which the radius of the annual orb is 100000. Then subtract the perihelial distance AT from the radius BT, and there will remain the eccentricity AB, that is, the distance of B, the centre of the circle or ellipse carrying the planet, from A, the centre of the world. Doubled, this will give the whole eccentricity, or the distance from the centre of the world of the point about which the planet is imagined to move uniformly. Finally, if you want these measures in parts of which the planet's orb BI is

100000, multiply them by 100000 and divide the sum by BI, known in the earlier parts. Accordingly, *Kepler*, in that chapter 42, concludes thus about ♂.

In parts of which the radius of the annual orb is	100000
Aphelial AI	166780
Perihelial AT	138500
Sum IT	305280
Half BI	152640
Eccentricity AB	14140

Now as 152640 is to 100000, so the eccentricity 14140 is to the eccentricity 9264, but in parts of which the radius of the orb of Mars is 100000. Its double is the whole eccentricity, 18528, which is certainly more correct than the one we gathered by Hérigone's method, that is, by the second way, where we also overshot in the place of the aphelion. Kepler, however, corrected the places of Mars observed by Tycho, and used the daily motion, taken at the time from Magini's *Ephemeris*, and the distances of the Sun from the Earth, which he had computed in chapter 30 from the bisected eccentricity of the Sun. The same eccentricity he confirmed in chapter 54 from the aphelial and perihelial distances of Mars from the Sun.

Quintus Modus Eccentricitatis & Aphelij inquirendi ex Bullialdo.

Fifth way of inquiring into the eccentricity and the aphelion, from Boulliau.

IX. Most recently *Boulliau*, in Book 1 of the *Astronomia Philolaica*, chapter 21, having shown in his hypothesis of the ellipse, which the planet describes about a scalene cone, that the first inequality is distributed through circles in the ratio of the right sines counted from the aphelion or perihelion, in chapter 22 rejects the way of Ptolemy and Copernicus, and of Kepler. He adds, however, that by another, new path, from Viète's problems, he will derive the measure of the first inequality from three or four points. Yet afterwards, in Books 6, 7 and 8, he uses four acronychal positions, and in Book 8, chapter 3, teaches that it does not suffice to employ three points of the circle, that is, three observed oppositions of the planet with the Sun, as I have already said in number 6. Moreover, Boulliau's method is the same one we set out in Book 3, chapter 24, in the 4th method of the solar eccentricity, after number 4; and so we refer the reader there, for examining three acronychal positions; but for four, let the following scheme stand, for the true oppositions of Mars with the Sun observed by Tycho and reported by Kepler in the *Commentaries on Mars* and by Longomontanus in Book 2 of the *Theorica*, chapter 8. They were as follows, the days being counted in the old style.

Phaſes Martis Acronychiæ, ſeu Oppoſitiones cum vero Solis loco, obſeruatæ Vraniburgi.

Acronychal phases of Mars, or oppositions with the true place of the Sun, observed at Uraniborg.

[Margin: Order of the observations.]

	Year	Month	Day	Time	True place of ♂
1	1582	Dec.	28	$4^h\ 0^m$	♋ 16° 54′
2	1587	March	6	$7^h\ 20^m$	♍ 25° 42′
3	1591	June	8	$7^h\ 45^m$	♐ 26° 42′
4	1593	Aug.	25	$17^h\ 30^m$	♓ 12° 15′

So let these four places be on a circle in the same order, B, C, D, E; from them, to the diameter FN, cut at right angles by the diameter AL, let the perpendiculars BG, CIS, DK and EHQ be dropped, and let the four places be joined to one another both by the chords BC, CD, DE, EB and by the diagonals BD and CE.

Diagram. A circle set into the left column, the text running down its left side. A vertical diameter runs from A at the top to L at the bottom, and a horizontal diameter from F at the left to N at the right, crossing at O. The four places B, C, D, E stand on the circumference, joined by chords and diagonals, with perpendiculars dropped to the horizontal diameter.

- Q (top, on the circle, left of A)
- A (top, on the circle): aphelion
- B (upper left, on the circle): first place
- C (upper right, on the circle): second place
- D (right, on the circle, below N): third place
- E (bottom, on the circle, left of L): fourth place
- L (bottom, on the circle): perihelion
- S (lower right, on the circle)
- F (left end of the horizontal diameter)
- N (right end of the horizontal diameter)
- O (interior, at the crossing of the diameters)
- G (on the horizontal diameter, between F and H)
- H (on the horizontal diameter, between G and O)
- I (on the horizontal diameter, right of O)
- K (on the horizontal diameter, between I and N)
- M (interior, below I)
- P (interior, upper left of O, below X)
- X (interior, near the top, between B and A)
- Z (interior, lower right, above S and left of D)

And since the place B of the first observation was in the middle of ♋, and that of the second about 26° ♍, and we know from tables and observations,

however coarsely weighed, that the aphelion of ♂ at that time was about the end of ♌, the line of the aphelion, AOL, therefore falls between B and C. The aim is to investigate the true place of the aphelion A and of the perihelion L, that is, the distance of the points B, C, D, E from the points A and L; and the quantity of the line FO, which represents the eccentricity of the centre O from F, the centre of vision, or from one of the umbilici. For this we have these Data.

[Margin: Data for the solution of the problem.]

From the first opposition to the 2nd are 4 common years, $69^{d}\ 3^{h}\ 20^{m}$; and, the circles being cast off, the apparent motion is 68° 48′, the mean motion 81° 22′ 41″, and the difference of the mean motion from the true 12° 34′ 41″.

From the 2nd opposition to the 3rd, 4 years, $95^{d}\ 0^{h}\ 25^{m}$; true motion 91°, mean 94° 56′ 25″, difference 3° 56′ 25″.

From the 3rd opposition to the 4th, 2 years, $79^{d}\ 9^{h}\ 45^{m}$; true motion 75° 33′, mean 64° 11′ 10″, difference 11° 21′ 50″.

Since, however, as *Boulliau* teaches, the whole first inequality of the planet is founded on the distance FN of the elliptical umbilici, but half of it is to be taken, the planet must therefore be considered as seen not from the umbilici but from the centre O, which is exactly midway between the umbilici. The arithmetic mean between the mean and apparent motions must therefore be taken. For example, in the first interval the half of the difference between the true, or apparent, and the mean motion was 6° 17′ 20″; these, then, added to the true motion, because it was less than the mean motion, that is, to 68° 48′, make for the interval BC 75° 5′ 20″, whose arithmetic mean likewise is 37° 32′ 40″; and so for the other intervals. Once these are corrected we shall have the angles standing on them and set at the circumference, since by 20 of Book 3 of *Euclid* they are half of such arcs. Finally we shall seek from the tables of sines both the sines of the half-arcs already mentioned and the sines corresponding to the half-differences of the apparent and mean motions. Thus, then, we shall set out these Data, with the half-differences considered on the diameter FN.

Arcs	Measure	Angles	Measure
BC	75° 5′ 20″	BEC, EDC	37° 32′ 40″
CD	92° 58′ 13″	CBD, CED	46° 29′ 6″
DE	69° 52′ 5″	DCE, DBE	34° 56′ 3″
EB	122° 4′ 22″	EDB, ECB	61° 2′ 11″
BCD	168° 3′ 33″	BCD	95° 58′ 13″
CDE	162° 50′ 18″	CDE	98° 34′ 51″
DEB	191° 56′ 27″	DEB	84° 1′ 46″
EBC	197° 9′ 42″	EBC	81° 25′ 9″

But in parts of which the radius is 100000.

Half-arcs	Sines		Half-differences	Measure	Sines
BC	60937	1	GI	6° 17′ 20″	10945
CD	72519	2	IK	1° 58′ 13″	3488
DE	57263	3	KH	5° 40′ 55″	9901
EB	87493		GK	8° 15′ 33″	14365
DB	99457		GH	2° 34′ 38″	4497
EC	98880				

[Margin: Step 1.]

First, then, with the given quantities [Greek: διδομένοις (didomenois, "the given quantities")] arranged as above, in triangle BCD let it be as GK is to BD, so IK to MD, of 23803 parts.

[Margin: By 20 of Book 3 of Euclid.]

Therefore, given in triangle MCD the sides MD and CD with the enclosed angle, which is 37° 32′ 40″, the angle MCD will be 15° 7′ 38″, and the arc SD, its double, 30° 15′ 16″. From this the nearly equated anomalies at the four oppositions of ♂ will be given, by a way that *Boulliau* does not even deign to indicate, but it is as follows. Since the arc CD is given as 92° 58′ 13″, and SD, just found, is 30° 15′ 16″, therefore the whole CDS is 123° 13′ 29″. Its complement to the semicircle is 56° 46′ 31″; this is the sum of the arcs AC and SL. But since CS is parallel to AL by construction, the arc AC is as great as LS, and so half of the sum just mentioned, that is, 28° 23′ 15″ (not 33′, as Boulliau's text has on p. 289), which is the anomaly of the place C, counted from the aphelion A. With the arcs AC and CD joined, there results the anomaly of the place D, that is, the arc ACD, 121° 21′ 28″, whose complement to the semicircle, namely the arc DL, is 58° 38′ 32″. Subtracted from the arc DE, given above as 69° 52′ 5″, this leaves the arc EL, 11° 13′ 33″. Therefore, adding the semicircle ANL, there results the anomaly of the place E, ANE, 191° 13′ 33″. Finally the arc AC, 28° 23′ 15″, subtracted from the arc BC, given as 75° 5′ 20″, leaves the arc AB, 46° 42′ 5″, whose complement to the circle is 313° 17′ 55″; this is the arc ANLB, which is the anomaly of the place B.

[Margin: Step 2.]

Second, since the arc AB has been found as 46° 42′ 5″, GO, its sine, is given as 72778; and since the arc DL was found as 58° 38′ 32″, its sine KO is therefore 85393, and the whole GK 158171. So let it be as GK is to the radius FO, 100000, so GK, estimated above at 14365 parts, is to FO, the eccentricity of the umbilicus F from the centre of the ellipse O, of 9082 parts. And since the arc AB was found as 46° 42′ 5″, and Mars at the first opposition B, observed by Tycho in 1582 December 28 at 4^{h}, was at ♋ 16° 54′, if you add the arc BA to this place the aphelion will fall at ♍ 3° 36′ 5″.

[Margin: Step 3.]

Third, in triangle BED he directs that BP be found by the same proportion, as 31135 parts, and from it the angle BEQ, 16° 3′ 5″, whose double is the arc BQ, 32° 6′ 10″. Joined to the arc EB this gives the arc QFE; and half its complement

to the semicircle gives the arc EL, which with the semicircle ANL makes up the anomaly of the place E, 192° 54′ 44″. Taking the arc ED from this, the arc AND remains, 123° 2′ 39″, for the anomaly of the place D; and taking the arc CD from this again, the arc AC remains, 30° 4′ 26″, for the anomaly of the place C. And adding the arc EL, or AQ, to BQ itself, there results AB, which is the complement to the circle of the anomaly of the place B, which will be 314° 59′ 6″; and the arc AB will be 45° 0′ 54″, whose sine GO is 70728; and the arc DL will be 56° 57′ 21″, whose sine OK is 83825. Therefore the whole GK is 154553. So let it be as GK, 154553, is to the radius FO, of 100000 parts, so GK, set earlier at 14365, is to another, and the eccentricity FO will come out as 9294 parts. And adding the arc AB, 45° 0′ 6″, to the place of ♂ at B, which was ♋ 16° 54′, the aphelion will come out at ♍ 1° 54′ 6″.

[Margin: Step 4.]

Fourth, using the same proportion for triangle CBE, you will find BX, of 25037 parts, and the angle BEQ, 16° 28′ 0″, and its double arc, 32° 56′ 0″, and QA, 12° 29′ 49″; and the anomalies: for the place B, 314° 34′ 11″; for C, 29° 39′ 21″; for D, 122° 37′ 44″; and for E, 192° 29′ 49″; and the arc AB, 45° 25′ 49″, whose sine OG is 71240; and the arc AC, 29° 39′ 21″, whose sine OI is 49483. And so the whole GI is 120723. Let it be, then, as GI, 120723, is to the radius FO, 100000, so GI, set above among the half-differences at 10945, is to another; and FO will come out at 9074 parts. And if the arc AB, 45° 25′ 49″, is added to the place of ♂ at B, as above, the aphelion will come out in ♍ 2° 19′ 49″.

[Margin: Step 5.]

Fifth, by a similar proportion for triangle CDE, you will find ZD, of 19884 parts, and the angle ZCD, 14° 35′ 57″, and its double, the arc SD, 29° 11′ 54″; and from this the anomalies: for B, 313° 49′ 37″; for C, 28° 54′ 57″; for D, 121° 53′ 10″; and for E, 191° 45′ 15″; and the sine OH, 20371, and the sine OK, 84911, and so the whole HK, 105282. If this is made to 100000 as HK, set above at 9901, is to another, FO will arise, the eccentricity, of 9404 parts. And the arc AB will be 46° 10′ 23″, which, added to the place of Mars at B, will give the aphelion in ♍ 3° 4′ 23″.

[Margin: Step 6.]

Sixth, since in the steps already mentioned different anomalies, and from them different eccentricities, have been found (which *Boulliau* says arises from the form of the ellipse sought in the circle, and from the optical inequality, which is greater in the lower part of the orbit and smaller in the upper than the part of the inequality arising from the equant circles), he therefore directs that the arithmetic mean be taken both of the anomalies found and of the eccentricity FO. And so, using the half-differences, after some limitations of the excesses and defects and a repeated calculation, he finally arrives at FO, an eccentricity of 9239 or 9242 parts, and the aphelion of ♂ at ♌ 29° 3′ 54″. Later, in chapters 4 and 5, he teaches how to seek the same things in the case where all four places of opposition given lie in the upper part of the orbit, or all in the lower; and from this he concludes the aphelion of ♂ for January of the year

1586 to be at ♌ 28° 53′ 16″, and the eccentricity to be 8988 and 9129. So, with the arithmetic mean chosen, he appears to use an eccentricity of 9056 parts. But in the table of equations for ♂ he uses an eccentricity of 9239, whose double gives the distance of the umbilici, 18478, or the difference between the greatest distance of ♂ from the Sun, which he sets at 109239, and the least, 90765.

So you see that not even this method is wholly geometrical a priori, and that, with the mean motion assumed, it strives toward the truth more and more through various excesses and defects and arithmetic means; and with how great an effort astronomy still labours to exhaust this depth.

Sextus Modus Noſter Inueſtigandi primam Inæqualitatem trium ſuperiorum Planetarum.

Our sixth way of investigating the first inequality of the three superior planets.

X. Just as in chapter 6 we proposed our hypothesis not as something new but as one that accommodates its measures to all, so now we offer no new diagram, but use indifferently the schemes of any astronomer, set out in chapters 1, 2, 3 and 4. For in Ptolemy's figure one can investigate the whole eccentricity of the equant; in Copernicus's first form, the eccentricity and the semidiameter of the epicycle; in the second form, which is Lansbergen's, the difference between the greatest and the least eccentricity; in the third, which *Tycho* and *Longomontanus* chose, the semidiameter of the greater and of the lesser epicycle; and in the form of the ellipse, the whole eccentricity of the foci, or the eccentricity of the centre of the ellipse from one of the foci. But to give an example in at least one of them, the one that seems to us simpler and easier, namely Copernicus's second form, let observations be chosen of true oppositions of the planet with the Sun, such as those which *Kepler* above all has on Mars, chapter 15; *Longomontanus* in Book 2 of the *Theorica*, chapters 2, 5 and 8; and after them *Boulliau* in Books 6, 7 and 8; or others that are Tychonic, or ours, or those of any more exact observer, when they come out. And if two can be had, with the planet placed once in the aphelion and again in the perihelion, the way will be far better and quicker. We assume, moreover, that astronomy has by this time advanced so far that no sensible error can lie hidden in the place of the aphelion, whose motion is very slow, and in the mean motion.

These things set down, in the present figure let the line of apsides be AB, in which the aphelion is A, the perihelion B, and C the centre of the eccentric ADBE; and let the centre of the world be M. And let at least four acronychal places of the same planet be observed, F and G in the upper part of the eccentric and H, K in the lower; let these be connected by straight lines with the centres C and M, and by the chords FLG and HPK.

Diagram. At the head of the right column, inset to the right of the narrowed text: a large circle, the eccentric, with the vertical diameter AB. A horizontal chord joins F and G at the upper part, crossing the diameter at L, and a horizontal chord joins H and K at the lower part, crossing it at P. On the diameter below

L stands the point C, then O, the centre of a small circle drawn about it, then I at the foot of that small circle, then M. Straight lines run from F and from G to C and to M, and from H and from K to C and to M. From D, on the left of the circumference, two dotted lines run inward, one to the small circle about O and one to M. E stands on the right of the circumference, with no line drawn to it.

- A (top of the circle, on the diameter)
- L (on the diameter, at the upper chord)
- F (upper left of the circumference)
- G (upper right of the circumference)
- C (on the diameter, top of the small circle)
- D (left of the circumference)
- E (right of the circumference)
- O (centre of the small circle)
- I (on the diameter, foot of the small circle)
- M (on the diameter, below the small circle)
- H (lower left of the circumference)
- K (lower right of the circumference)
- P (on the diameter, at the lower chord)
- B (foot of the circle, on the diameter)

First, then, let the planet be at F. For from recent tables there will be given both the mean motion in longitude and the planet's distance from the apogee, or anomaly of the eccentric, which is the arc AF, measuring the angle ACF; and therefore its sine FL and its second sine CL will be given. And since, from the apparent motion, or the true place known by observation and compared with the mean motion, the angle MFC is known, that is, the equation of the centre, or of the eccentric place (for in true oppositions no other equation comes in than that of the first inequality), the angle FMC will also be known, by 32 of Book 1 of *Euclid*; for it is the difference by which the angle MFC differs from the angle of anomaly FCL. In triangle FML, right-angled at L, from the given angle FML and the sine FL, seek the side ML, and subtract from it the second sine CL. For if MC, the eccentricity, is equal to the eccentricity which the tables suppose in this hypothesis for that time, that eccentricity is correct as regards that position. We assume in this diagram, moreover, that the eccentricity varies and librates up and down on the diameter CI of the small circle, since it is not necessary in this procedure that the centre of the eccentric always be at the apogee C or the perigee I of this small circle.

But if you do not wish to test the assumed eccentricity but to seek it, which is certainly better, use the triangle MFC, in which let there be given the radius CF, of 100000 parts, and the angle FCM, the complement of the angle FCA, known from the anomaly of the eccentric, and MFC, known from the difference of the true motion from the mean; and seek the side MC, namely the eccentricity. And do likewise with the places H, K, G, or others of the planet known in the eccentric by observation of a true opposition with the Sun. But if the planet is

at H, the angle HCM will become known from the complement of the anomaly to the semicircle; if at K, the angle KCM will be the excess of the anomaly above the semicircle; if at G, the angle GCM will become known by subtracting the complement of the anomaly ACG, to the circle, from 180°. Further, if in the triangles HMP or KMP you do not seek but test the eccentricity, you must subtract from the second sine PC the side found, MP, and from this discern whether the remainder CM is equal, as it should be, to the assumed eccentricity CM.

When this is done you will find the eccentricity greater near the apogee of the eccentric and smaller near the perigee. And if you choose a pair of acronychal positions, in one of which the planet was at the apogee of the eccentric and in the other at the perigee, or as nearly as possible, such as *Kepler* supplies for Mars in chapter 42 in the *Commentaries on Mars*, you will have the greatest eccentricity at the apogee and the least at the perigee; and their half-difference will be the semidiameter OC, that is, of the small circle, which by its libration varies the eccentricity, according to our hypothesis set out in chapter 6.

XI. You could, however, without labour follow an elective hypothesis, whose measures we have set in the last columns of the table of chapter 7, but especially the one that has been derived from the most recent observations of Tycho and of others after him by Longomontanus, Kepler and Boulliau; and choose a mean eccentricity between their extremes. In this matter very little industry indeed lies hidden, but not very little security.

EXEMPLVM.

Example.

[Margin: Example in ♂.]

XII. *In the year 1589, as Longomontanus reports in Book 2 of the Theorica, chapter 8, Tycho observed the true ☍ of ♂ with ☉ on April 14 at 6^h 20^m after noon at Uraniborg, when ♂ was in ♏ 4° 23′ and ☉ in ♉ 4° 23′. But for me, who recognize a far smaller parallax in the Sun, the Sun was then at Uraniborg in ♉ 4° 28′. So, with the daily motion of Mars, retrograde, which was about 24′, and the daily motion of the Sun computed, the truer opposition was there at the hour 4^h 35^m, in ♏ 4° 24′. For that moment the mean longitude of ♂ from the Rudolphine Tables was 7^s 14° 22′, and the aphelion 4^s 28° 47′; when this is subtracted from the mean longitude, the anomaly of the eccentric remains, 75° 35′, that is, the arc AF, or the angle ACF, with Mars at F. But the difference of the mean motion, that is, of 7^s 14° 22′, from the true motion, that is, from the 7^s 4° 24′ in which ♂ stood, is the equation of the centre to be subtracted from the mean motion, that is, the angle CFM, which, subtracted from the angle ACF, 75° 35′, leaves the angle CMF, that is, FML, in triangle FLM, right-angled at L. Now the sine of the angle FCL, or the side FL, is 96851, of parts of which CA is 100000, and the second sine CL is 24897. And by analysis of the triangle FLM the side LM is found, 43447; when the sine LC, 24897, is subtracted from it, there remains the*

whole eccentricity MC, 18550, of parts of which the radius AC is 100000. And so for the others.

In this way, from the Rudolphine Tables or from Magini's Keplerian tables for ♂, you will find at an anomaly of the eccentric of ♂ of 1° an eccentricity of 20000 parts, at an anomaly of 90° one of 18600 parts, and at an anomaly of 179° one of 17060 parts. The mean of these is 18530, which Kepler chose, and gathered by another method with the greatest industry and a most troublesome search.

XIII. Now, so that you can use observed acronychal positions, consult the observations set out below. It must be admitted, however, that in those observations, made at another time and reduced to the moments of true opposition with the Sun, some minute lies hidden, both because of the Tychonic motion of the Sun, which, owing to the excessive parallax of the Sun assumed by Tycho and not demonstrated, errs in the ecliptic by some minutes, and because of the distances of the planets from the fixed stars, whose right ascension and declination here and there need a slight correction, as can be established from the distances of the fixed stars from one another, diligently observed by us, from Book 6, chapter 10. So if Tycho's observations were extant, we could more easily apply some correction to the following acronychal positions. Meanwhile, however, we shall enjoy them, until astronomy undergoes the final file, as observations of others and our own are added; we have not a few of these, but we await more, at more places of the eccentric. Those listed below up to the year 1600 were observed by Tycho; the other acronychal positions partly by Kepler and Longomontanus, partly by David Fabricius. *Longomontanus*, moreover, adds the computation from his own tables, using the true precession of the equinoxes.

[Margin: ♂. Acronychal positions from Kepler, ch. 15.]

♂ Veræ Oppoſitiones cum Vero Loco Solis ex Kepleri Comm. de Marte; & Obſeruationibus Tychonis, Kepleri, ac Fabricij. Ad Vraniburgum habitis vel reductis.

True oppositions of ♂ with the true place of the Sun, from Kepler's Commentaries on Mars, and from the observations of Tycho, Kepler and Fabricius, made at Uraniborg or reduced to it.

CAPVT IX.

Chapter 9.

De Motu Medio trium Superiorum Planetarum.

On the mean motion of the three superior planets.

I. When they had examined the mean oppositions of the three superior planets with the Sun, that is, with the mean place of the Sun, observed by the most ancient astronomers, and compared them with those which Hipparchus, Ptolemy and Copernicus observed in their own time, and when they had computed the intervals of years and the whole periods of the planet's revolutions both in the zodiac and with respect to the Sun, they found that as much time is required to complete the revolutions listed below (whole with respect to the Sun, but with an appendix after the whole revolutions completed under the zodiac or under the fixed stars) as you see in the following small tables, from *Ptolemy*, Book 9, chapter 3, and *Copernicus*, Book 5, chapter 1. He calls motion of commutation the motion by which the equal motion of the Earth either exceeds the mean motion of ♄ ♃ ♂ or is exceeded by the motion of ☿ and ♀, known through the greatest digressions and the revolutions with respect to them, as I shall say in Section 3, chapter 10, although it pleases me now to embrace all the planets here in one synopsis.

[Margin: Foundations of the mean motion of the planets.]

I. TABELLA EX HIPPARCHO, ET PTOLEMÆO

Table 1, from Hipparchus and Ptolemy.

Planets	In solar years: Years	Days, hours	Or: days, hours, minutes	Revolutions under the zodiac	Plus	Revolutions with respect to the Sun	Revolutions with respect to ☉, resolved into degrees of the epicycle
♄	59	1d 18h	21551d 7h 12m	2	1° 45′	57	20520
♃	70	360d 4h	25927d 14h 48m		355° 10′	65	23400
♂	79	3d 4h	28857d 21h 12m	42	3° 10′	37	13320
♀	7	362d 18h	2919d 16h 0m	7	357° 45′	5	1800
☿	46	1d 1h	16802d 9h 36m	46	1° 0′	145	52200

II. TABELLA EX COPERNICO

Table 2, from Copernicus.

Planets	In solar but sidereal years: Years	Days, hours, minutes, seconds	Revolutions in the zodiac under the fixed stars	Plus	Periods of the commutations, or revolutions
♄	69 [recte: 59, per the book's errata; corrected by hand to 59 in this copy]	1d 2h 55m 12s	2	1° 5′ 50″	57, Earth to planet
♃	70	364d 7h 32m 28s	5	blank	65, Earth to planet
♂	79	2d 9h 54m 24s	42	blank	37, Earth to planet
♀	7	363d 0h 16m 4s	12, around the Sun	357° 36′ 31″	planet to Earth
☿	46	0d 10h 0m 0s	191, around the Sun	0° 21′ 53″	45, planet to Earth

From these they gathered those mean motions of which we have shown a specimen in the tables at the ends of the chapters. Comparing these with the periods and intervals between observed oppositions of the same planet, they confirmed or emended them: *Ptolemy* for ☿ in Book 9, chapter 10; for ♀ in Book 10, chapter 4; for ♂ in Book 10, chapter 9; for ♃ in Book 11, chapter 3; and for ♄ in Book 11, chapter 7; and *Copernicus* in Book 5: for ♄ in chapter 7, for ♃ in chapter 12, for ♂ in chapter 17, for ♀ in chapter 23, and for ☿ in chapter 29. Another small table for ♀ and ☿ I shall give at the end of Section 3.

II. But since the practitioners already mentioned used oppositions with the mean place of the Sun, when the true ones should rather have been used; and since more recent observations are rightly judged more accurate than the ancient ones, and stand at a longer interval from the ancient ones, it is no wonder if the mean motions among the more recent authors have come out somewhat different from the ancient ones and more accurate. Now I said that true oppositions should be used because in them the motion of the second inequality ceases and only the first, which we are investigating, has force. Granted that, because we are investigating mean motions, a mean opposition might seem the one to choose; but it is one thing to employ an opposition with

the mean place of the Sun, which we deny should be done, and another to investigate the mean motion of the planet for the time of the true opposition, which we do not deny. And so *Longomontanus*, in Book 2 of the *Theorica*, from acronychal positions observed by Ptolemy and compared with Tychonic ones, gathers the mean motion from the interval of the mean places of the planet at the true oppositions with ☉: for ♄ in chapters 4 and 5, for ♃ in chapter 7, and for ♂ in chapter 10. We indicated these in chapter 3, in the table at the end of the chapter. In the same way *Kepler*, likewise from Tychonic acronychal positions, emended the mean motions: for ♂ in the *Commentaries on Mars*, chapters 42 and 69, and for it and the rest in the Rudolphine Tables, of which you have a specimen in chapter 5, number 20, in the table, as also of those of *Boulliau*, who indeed corrected the mean motions of ♄ in Book 6, chapter 5, of ♃ in Book 7, chapter 7, and of ♂ in Book 8, chapter 13. From which observations *Lansbergen* gathered the mean motions of these planets indicated in the table in chapter 4, he himself teaches at the end of the *Treasury of Observations*. We meanwhile, until other observations of Tycho come out and ours are more numerous than those we have, shall use mean motions derived from ancient and recent observations by a device similar to the one we used for the mean motions of the Sun in Book 3, chapter 17, with the true motions of the planets reduced to the mean ones for the moment of the true oppositions with the Sun.

CAPVT X.

Chapter 10.

De Loco & Motu Apogei & Aphelij trium ſuperiorum Planetarum, eorumq. diſcrimine.

On the place and motion of the apogee and aphelion of the three superior planets, and on the distinction between them.

I. The way of investigating the place of the apogee of the eccentric, or of the aphelion, of these planets has already been indicated in chapter 8, on the occasion of the eccentricity. Different astronomers in their own times found this place differently; from which it became plain that the motion of the auges is indeed very slow, but not as great as the motion of the fixed stars, as, with *Ptolemy* in Book 9, chapter 5, *al-Farghānī* in *differentia* 17, *al-Battānī* in chapter 47, and the whole school of the Arabs and Alphonsines, down to *Copernicus*, thought. In Book 5, chapters 7, 12 and 16, Copernicus was the first to find the motion of the apogee of Saturn and of Mars faster than the ordinary motion of the fixed stars, but that of Jupiter slower. After him this was also found by *Longomontanus*, in Book 2 of the *Theorica*, chapters 4, 7 and 10; by *Kepler* in the *Commentaries on Mars*, chapters 17, 42, 59 and 69, in which he corrects what he had said in chapter 17, and in the *Epitome of Copernican Astronomy*, p. 733; and by *Boulliau*, Book 6, chapter 2, Book 7, chapter 7, and Book 8, chapter 13. Besides these one can see *Jean Fernel*, Book 1 of the *Cosmotheoria*, p.

32; *Wurstisen* on Peuerbach's *Theoricae*, p. 255; *Magini* in the *Secunda Mobilia*, canon 35; *Hérigone*, volume 5 of the *Cursus Mathematicus*, pp. 529 and 584; and *Lansbergen* in the *Theoricae*, chapter 10. From these we have gathered the places of the apogees and aphelia for the times listed below into the following table. As for the annual motion of the apogees, we have already set it in the tables at the end of each hypothesis, from chapter 1 to chapter 5.

APOGEI, vel APHELII LOCVS In Annis CHRISTI infrà notatis & Completis.

Place of the apogee, or aphelion, in the years of Christ noted below, and completed.

[Margin: The distinction of the apogee from the aphelion.]

II. *Kepler*, however, in the *Epitome*, p. 733, says that in Ptolemy's time, with the eccentricity of the annual orb set at 1800 of the parts of which its radius is 100000, and with a line drawn from the centre of the annual orb through the centre of the eccentric of the planets, parallel to Ptolemy's lines of apsides, the aphelion of ♄ was in ♏ 23° 34′, that of ♃ in ♍ 15° 7′, and that of ♂ in ♌ 0° 42′. But today, he says, the aphelion of Saturn is in 25° 48′ ♐, that of Jupiter in ♋ 7°, and that of Mars in ♌ 29° 20′; though he regards Ptolemy's observations as suspect, especially concerning Jupiter. But, you will say, how is the place of the aphelion to be distinguished from the place of the apogee? Let there be, then:

Problema 1. Datis Apogei loco, Eccentricitate à Terra, ac Solis à Terra Diſtantia; Inueſtigare locum Aphelij & Eccentricitatem à Sole.

Problem 1. Given the place of the apogee, the eccentricity from the Earth, and the distance of the Sun from the Earth: to investigate the place of the aphelion and the eccentricity from the Sun.

III. We shall employ Copernicus's second form, as the one best suited to this business, and, with Mästlin on chapter 15 of Kepler's *Prodromus*, we shall represent the situation of the centres of the eccentrics with respect to the Sun and the Earth, as it suits the planets at this time. So let AB be the line of apsides of the Sun, S, and of the Earth, T; and TA the line of the Sun's apogee, such that A marks about the 6th degree of Cancer; and TB the line of the Earth's aphelion; and ST the greatest distance of the Sun and the Earth. Next let the centres of the small circles that vary the eccentricity be: for ♂, C; for ♃, F; for ♄, I; for ☿, M; and for ♀, P. Through these let a pair of lines be drawn from the Sun and from the Earth as far as the ecliptic, although here, for want of room on the page, they are not extended that far. And let the lines of the aphelia drawn from the Sun be SD, SH, SO, SL, SR; and let the lines of the apogees drawn from the Earth be TE, TG, TN, TK, TQ. With this laid down, to give an example in Mars, consider the triangle CTS, in which let there be given ST, the greatest distance between the Sun and the Earth; and CT, the mean eccentricity of Mars from the Earth; and the place of the apogee of Mars, marked by the

line TCE. For if you subtract that place from the place of the Sun's apogee, the angle ETA, that is, CTS, will be known. Therefore, by solving the triangle already mentioned, one can find both CS, the mean eccentricity of the planet from the Sun, and the angle TCS, by which the place of the apogee differs from the place of the aphelion. That place will be known if the quantity of the angle at C is added to the place of the apogee already found, when the place of the planet's apogee is in the first semicircle, counted from the Sun's apogee in the order of the signs; but in the second semicircle let it be subtracted.

Diagram. In the right column, interrupting the word *lo-cus* near the head of the column. A vertical line AB, with A at the top and B at the foot. On it stand S and, below it, T. About the line are five small circles, each with its planet's sign: at upper left a circle with the sign of ♂ and the centre C, with lines running out from it to D and E; at left a large circle with the sign of ♃ and the centre F, with lines running out to G and H; below T and to the left a circle with the sign of ☿ and the centre M, with lines running out to N and O; at right of S a small circle with the centre P, with the sign of ♀ above it and Q and R beside it; and below, a large circle with the sign of ♄ and the centre I, with lines from S and T running through it to K and L, which stand side by side at the foot, left of B. Straight lines join S and T to these circles.

- A (top of the vertical line); B (foot of the vertical line)
- S (on the vertical line, upper); T (on the vertical line, lower)
- C, with ♂ (upper-left circle); D, E (ends of the lines beyond it)
- F, with ♃ (large circle at left); G, H (ends of the lines beyond it)
- M, with ☿ (circle below T); N, O (ends of the lines beyond it)
- P, with ♀ (small circle to the right of S and T); Q, R (ends of the lines beyond it)
- I, with ♄ (large circle at the foot); K, L (ends of the lines beyond it)

Labels read: A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, and the signs ♂ ♃ ☿ ♀ ♄. Labels not read: none.

Problema 2. Datis Aphelij loco, Eccentricitate media à Sole, maximaq. diſtantia Telluris à Sole, eiuſdemq. Aphelio; Inuenire Apogei locum, & Eccentricitatem à Terra.

Problem 2. Given the place of the aphelion, the mean eccentricity from the Sun, the greatest distance of the Earth from the Sun, and the Earth's aphelion: to find the place of the apogee and the eccentricity from the Earth.

IV. In the same triangle CTS, let there be given ST, the greatest distance of the ☉ and the Earth; and SC, the mean eccentricity of Mars from the Sun; and the Earth's aphelion, marked by the line TB, with its opposite, the perihelion, toward A. Subtract its place from the aphelion of Mars, marked by the line SD; for the angle ASC will be left, whose complement to two right angles will be the angle CST. From these three givens, then, seek CT, the eccentricity from the Earth, and the angle TCS, which is to be subtracted from the given place

of the aphelion when the planet's aphelion is in the first semicircle, counted from the Earth's perihelion in the order of the signs, but added when it is in the second, so that you may have the place of the apogee of the eccentric. And do not let the difference of the points T and S, from which the ecliptic is described, disturb you; for both because of the parallelism, on which see Kepler above, and because in the second Problem the centre of the world is transferred from T to S, no error is committed. From what has been said it is clear that those who have put the apogee for the aphelion in the more recent tables have not acted accurately.

[Margin: A corollary against some of the moderns.]

CAPVT XI.

Chapter 11.

De Secũda ſeu Annua inæqualitate Trium Superiorum Planetarum.

On the second, or annual, inequality of the three superior planets.

I. The second inequality of these planets depends on the places of the planet observed outside the acronychal position, and on the Sun's approach to the planet and withdrawal from it, not the mean approach, as with the ancient astronomers, but the true; enough was said about this motion in Book 3. For when the true place on the eccentric of the planet is taken from the true place of the Sun, there remains the anomaly of the orb, or of the commutation, which concerns the second inequality. It depends besides on the distance of the planet from the Sun, which we have taught how to investigate in the form of a geometric calculation, according to any one of the celebrated hypotheses; and lastly it depends on the distance of the Sun from the Earth. And since all these measures are to be reduced to the same kind, namely to parts of which the radius of the planet's orb is assumed, for example, as 100000, or of which the mean distance of the Sun and of the planet from the Earth is known in terrestrial semidiameters, the investigation of the second inequality therefore consists chiefly in seeking the proportion of the semidiameter of the annual orb of the Sun or of the Earth to the semidiameter of the planet's orb. But in the Ptolemaic hypothesis it consists in seeking the semidiameter of the epicycle, which supplies the commutations of the annual orb. For this, observations outside the acronychal position are needed, since at acronychal positions the second inequality ceases.

[Margin: The second inequality depends on the proportion between the semidiameters of the annual orb and of the planet's orb.]

[Margin: Authors of the method for finding this proportion.]

The method of seeking the proportion of the orbs from those observations is taught by Ptolemy, Book 10, chapter 8, and Book 11, chapters 2 and 6, where he demonstrates the sizes of the epicycles of ♂ ♃ ♄; by Regiomontanus, Book 10

of the *Epitome of the Almagest*, proposition 23, and Book 11, propositions 7 and 16; by Copernicus, Book 5, chapters 9, 14 and 19; by Longomontanus, Book 2 of the *Theorica*, chapters 3, 6, 9; and by Boulliau, Book 6, chapter 2, Book 7, chapter 3, and Book 8, chapter 6. Nor is this procedure difficult, if you have already learned the way of finding the equation of the second inequality; for the same triangle is to be used here, and the same figures set out earlier for the geometric calculation. I shall not repeat those figures in this place, but I shall still indicate them, together with the way of solving this Problem by means of them.

[Margin: The way by Ptolemy's figure.]

II. *First*, in Ptolemy's figure set out in chapter 1, no. 2, with the planet placed at *n*, consider triangle AI*n*. In it, from the place observed outside the acronychal position, and from the place of the centre I, gathered by tables or by the geometric calculation given in the same place, there is given the difference of the two, that is, the equation of the epicycle, or the angle IA*n*; and the side IA was found in the same place, and the angle *n*IA, which is the complement of the angle *n*IT, known from the distance of the planet from the true apogee of the epicycle, as we taught in the same place. Therefore I*n* will not stay hidden, that is, the semidiameter of the epicycle, which is the foundation of the second inequality, in parts of which DI, the radius of the eccentric, is 100000.

[Margin: The way by Copernicus's figure.]

Second, in Copernicus's second form, treated in chapter 2, no. 4, imagine the planet at G and the Earth at P; and suppose the distance GE of the planet from the Sun, given or found, and the angle EGP, which is the difference between the place observed outside the acronychal position and the eccentric place of the planet derived from the tables, and finally the angle GEP, at the Sun, or the anomaly of commutation, known by subtracting the eccentric place from the true place of the Sun. From these the radius EP of the annual orb will appear, which is the mean distance of the Earth from the Sun.

[Margin: The way by the other figure of Copernicus.]

Third, in Copernicus's form 3, which *Tycho* and *Longomontanus* chose, and which we treat in chapter 3, no. 4, let the planet be at H and the Earth at L, a point of the annual orb MI; and in triangle HLA, as we taught there in steps 1 and 2, let AH be found, which is the distance of the planet from the Sun; and through the anomaly of the orb let the angle HAL be found. Given, then, the angle already mentioned, and the distance AH, and the angle HLA, which is the complement to two right angles of the angle CLH, known from the difference between the observed place of the planet and its eccentric place, or the place of the centre C, the side AL will not stay hidden, that is, the semidiameter of the annual orb that was sought. *Tycho* and *Longomontanus*, however, adapted this form to a motionless Earth, as we said there in no. 6.

[Margin: The way by the figures of Kepler and Boulliau.]

Fourth, to set before your eyes here at least one figure ready to hand, suited to the form of Kepler and Boulliau: let A be the Sun, AC its eccentricity, and

PR the line of apsides; and from C let the annual orb RHPF be described. Let the centre of the planet's orbit be B, from which the orbit EINK is described, and let its line of apsides be DE. Further, let the place of the planet observed outside the acronychal position be at N, for a certain time, and let the Earth be at G, and the distance of the planet from the Sun be AN, along which line the eccentric place of the planet is seen from the Sun; but let the true place of the planet observed from the Earth be along the line GN; and so the angle ANG is the angle of commutation, or of annual parallax. With this laid down, for that time find, as we have set out in the form of Kepler or of Boulliau, besides the true place of the Sun and its equated anomaly, and from that the distance AG of the Sun from the Earth; find, I say, both the eccentric place of the planet, so that you may have the angle GNA by comparing that place with the observed place, and also the distance NG of the planet from the Earth, and also the angle GAN, that is, at the Sun, which becomes known from the anomaly of the orb by subtracting the true eccentric place of the planet from the true place of the Sun. For in the triangle AGN, from those three givens you will find the side AG, in parts of which BE, the radius of the planet's orb, is 100000.

Diagram. In the right column, inset to the right of the narrowed text. A large outer circle, inscribed along its arc with the signs ♄ ♃ ♂, and a smaller inner circle lying within it, its top near the top of the outer circle. A vertical line runs through the inner circle from R at its top to P at its foot, passing C and A. B stands to the right of C, on a line drawn from D at the left of the outer circle to E at its right. From A, dotted lines run in opposite directions, one up to L and down to G, the other up to F and down to H. Solid lines run from A to M, to I, to E, to N and to K; a line runs from L to M, from D to H, from F to E, from N to P and from N to G, and from G to K.

- M (upper left of the outer circle); R (top of the inner circle); L (upper left of the inner circle)
- F (upper right of the inner circle); C (above A, on the vertical line); B (right of C)
- D, I (left of the outer circle); E (right of the outer circle)
- A (centre of the figure); H (lower left of the inner circle); P (foot of the inner circle); G (lower right of the inner circle)
- N (lower left of the outer circle); K (lower right of the outer circle)

Labels read: A, B, C, D, E, F, G, H, I, K, L, M, N, P, R, and the signs ♄ ♃ ♂.
Labels not read: none.

Finally, set up the following analogy, saying: if AG, the distance of the Sun from the Earth, of so many parts of which the radius CP of the annual orb is 10000 [recte: 100000], contains so many parts of the kind of which the radius BE of the planet's orb is 100000, then the radius CP itself, of 100000 parts, will contain parts of the radius BE, etc. The same can be done in semidiameters of the Earth, if AG and the radius CP are known in semidiameters of the Earth. But the rule must be illustrated by an example.

EXEMPLVM.

Example.

[Margin: Example in ♄.]

III. Longomontanus, as he himself relates in Book 2 of the *Theorica*, chapter 3, reports that from the Earth at G the place of Saturn at N was observed in ♊ 7° 32′, in the year 1590 February 8, old style, at the 8th hour of the evening at Uraniborg. For that time the true place of the Sun on the line AL, according to Boulliau, was ♓ 0° 1′ 41″; and so the place of the Earth, G, seen from the Sun along the line AG, was ♍ 0° 1′ 41″; and the equated anomaly of the ☉ was 7^s 23° 49′; and the distance of the Sun from the Earth 98953, of the parts of which the radius CP of the annual orb is 100000; and the eccentric place of ♄ seen from the Sun along the line AN was ♊ 13° 49′ 18″. Therefore, when the place of Saturn is subtracted from the eccentric place, the angle of commutation AHG [recte: ANG] remains, 6° 17′ 18″. And the distance of ♄ from the Sun, that is AN, was 94338, of the parts of which the radius BE is 100000. And when the true eccentric place of ♄ is subtracted from the true place of the Earth, the angle NAG is found, 76° 12′ 23″. Therefore in triangle ANG the side AG comes out at 10423 parts, of which the radius BE is 100000. But AG was of 98953 parts, of which the radius CP is 100000. So it is made: as 98953 to 10423, so 100000 to 10533. Therefore the radius of the annual orb is 10533 parts, of which the radius, or semidiameter, of Saturn's orb is 100000.

IV. It will be useful, however, following the example of Longomontanus and Boulliau, to examine several other places observed in different places of the eccentric, and above all in opposite ones, and to choose the mean of the extreme measures. So Boulliau chose 10480 parts for ♄, 19138 for ♃, and, with Kepler, 65638 for ♂, as we said in chapter 5, no. 20, in the table, if anyone holds the heresy [hæresi] of thinking that the semidiameter of the annual orb in the planetary system, or of the Ptolemaic epicycles, must always be of the same measure. But I have already shown that this is false, in chapter 6, proposition 6. You will also learn this a posteriori, if from the last table of the following chapter you gather the greatest equations of the orb, and through them find the semidiameter of the epicycle according to the rule given in chapter 7, at the end of no. 6, and to be repeated in chapter 12, no. 19.

CAPVT XII.

Chapter 12.

De Maximis Aequationibus, earumq. locis, & de Tabulis Aequationum ritè conſtruendis. Vbi de imperfectione veteris Aſtronomiæ in hoc negotio.

On the greatest equations and their places, and on the proper construction of tables of equations; where the imperfection of the old astronomy in this business is treated.

[Margin: The greatest equation of the centre.]

I. First, the equation of the centre in the zodiac, or of the eccentric place, in the Ptolemaic hypothesis, is greatest at the points of mean longitude; that is, when the centre of the epicycle is at those points of the deferent from which a perpendicular can be drawn to the line of apsides, bisecting the eccentricity of the deferent; that is, in the following figure, at the points ε and Y, from which εB is drawn, cutting DA at B. For it is there that the greatest prosthaphaereses occur, as *Reinhold* demonstrated on Peuerbach, p. 100. These points are found by means of the rectilinear triangle BεD, whose side Dε equals the radius of the eccentric, and whose base BD equals BD, the half of the eccentricity AD, or the fourth part of the whole eccentricity AE; for the angle BεD is equal to the alternate angle HDε, which measures the arc εH, and by this arc the point ε, where the greatest equation of the centre occurs, exceeds the quadrant HF of the anomaly.

Diagram. In the left column, interrupting the sentence between *angulus* and BεD. A large outer circle, and within it a second circle drawn on a centre above the centre of the outer circle, its top touching the top of the outer circle. Small circles stand on the inner circle: at the top about F; at upper left about I; at left two overlapping about H and ε; at lower left about K; and at the foot about M. A vertical line runs from the top through F, a, E, D, B and A down through M and b to the foot of the outer circle. Lines radiate from A, past the small circles, to the rim of the outer circle. A dotted line runs from H to D.

- L, T, G (together at the top, outside the outer circle)
- M, L (upper left, at the rim of the outer circle)
- I (centre of the small circle at upper left); c (beside that circle on the inner circle's arc, towards F); F (centre of the small circle at the top); a (below F, on the vertical line)
- c (below the small circle about I)
- E, D, B, A (down the vertical line, A at the point from which the lines radiate)
- X (right, on the inner circle); Y (right, outside the inner circle, at the outer circle)
- N, V, L (left, at the ends of the radiating lines); Z, H, ε (in and beside the small circle at left); c (below ε)
- K (centre of the small circle at lower left); c, c (between K and M); M (centre of the small circle at the foot); c (right of M); S (below M to the right); b (below M, on the vertical line)
- O, L, P, R, Q, L (around the foot of the outer circle, left to right)

Labels read: A, B, D, E, F, G, H, I, K, M (twice), N, O, P, Q, R, T, V, X, Y, Z, L (five times), c (six times), a, b, S, and the Greek letter ε. Labels not read: none.

Since, moreover, we taught in chapter 6, no. 13, how to transform the quantities of any hypothesis into the Ptolemaic form, the place of the greatest equation of the eccentric can easily be found in each hypothesis by this one

figure, if the fourth part of the whole eccentricity is taken for the base BD. Granted, we may point out this place from time to time in explaining the hypotheses of others; and it may be more prudent to use each author's own figure.

Once the place of the greatest equation of the centre has been found, and so the arc of the anomaly of the eccentric at whose end it occurs, the greatest equation is to be investigated by exactly the same method by which we taught how to investigate the other equations of the centre, according to each one's hypothesis and the geometric calculation that rests on it.

[Margin: The greatest equation of the orb.]

II. The greatest equation of the argument, or of the orb, or of the annual or second inequality, in the Ptolemaic hypothesis, occurs at the points of contact of the epicycle; that is, with the planet placed at those points on the circumference of the epicycle through which straight lines drawn from the centre of the world are tangent to the circumference of the epicycle, as in the preceding figure if the planet is at the points C, wherever at length the centre of the epicycle may be. But when the variety in the situation of the epicycle's centre is considered, the greatest equations of the orb themselves vary, and the least of the greatest occur when the centre of the epicycle is at F, the apogee of the eccentric, and the planet at the point of contact C. The measure of this equation is the angle FAC, which is known in the triangle FAC, right-angled at C, in which are given the semidiameter of the epicycle FC and the base AF, made up of the radius DF and the eccentricity of the deferent AD. But the greatest of the greatest occur with the centre of the epicycle placed at M, the perigee of the eccentric, and the planet at the contacts C; and the quantity of this greatest equation is investigated through the triangle AMC, right-angled at C, in which are given MC, the semidiameter of the epicycle, and AM, that is, the remainder of the radius DM when the eccentricity AD has been taken away. For the angle MAC, when found, is the measure of the greatest equation of the orb. When the angle FAC has been found, its complement to a right angle is the angle AFC, measuring the arc C*a*; and this, subtracted from the semicircle GC*a*, leaves the arc GC of the anomaly of the orb or of the epicycle, at whose end C the greatest equation of the orb or of the argument occurs. So the greatest equation of the orb itself, added to a quadrant, will at once give the point of the anomaly of the epicycle, or the distance from the apogee of the epicycle, where the least of the greatest equations of the orb occurs. Similarly, with the centre placed at M, the angle MAC added to a quadrant will give the anomaly of the orb at which the greatest of the greatest equations of the orb occurs. So when the measures of any hypotheses whatever have been reduced to the Ptolemaic form, according to what was said in chapter 6, no. 13, it will not be difficult to draw the greatest prosthaphaereses from them.

III. In Copernicus's form 2 and his figure, explained in chapter 2, no. 4, which *Lansbergen* claimed for himself, and in others that use the annual orb, the greatest equations of the orb occur at the points of contact of the annual

orb; that is, when the anomaly of the orb is so great that the Earth is at those points on the circumference of the annual orb through which a straight line can be drawn from the planet tangent to the annual orb. So in the adjoining figure, in which A is the centre of the world, that is, the Sun; C the centre of the annual orb; and MGO the annual orb; let B be the centre of the planet's eccentric orb KPL, and KBL the line of apsides, in which L is the apogee of the eccentric and K the perigee. The straight lines LO, LG, KM, KI, drawn from these on each side, tangent to the annual orb at the points O, G, M and I, mark the places where the greatest equations of the orb occur, there for the apogee and here for the perigee of the eccentric. These consist in the angles at the planet, for instance in the angle OLA,

Diagram. In the right column, interrupting the sentence between OLA and *vel GLA*. An outer circle KPL, carrying the signs ♄ ♃ ♂ inverted along its lower inside arc; within it two further circles and, inside those, a small circle about C. K stands at left on the outer circle and L at right; the line KBL runs between them through A. From K a line runs to M and a line to I, and from L a line to O and a line to G, each tangent to an inner circle. Lines from the point at A run to M, N, O, S, I, H, G.

- K (left, on the outer circle); L (right, on the outer circle); P (foot of the outer circle)
- M, N (together at the top of the inner circles); S (upper right, on the inner arc); O (upper right, at the rim of the inner circle)
- C (above A); A (at the point from which the lines radiate); B (right of A, on the line KL)
- I (lower left, on the small circle); H, G (together at the foot of the inner circles); Q (below G, on the circle next inside the outer circle)

Labels read: A, B, C, G, H, I, K, L, M, N, O, P, Q, S, and the signs ♄ ♃ ♂. Labels not read: none.

or GLA, as in MKA and IKA. They become known in the triangles right-angled at the points of contact, as in the triangle LOA, right-angled at O, in which are given the base AL, that is, the greatest distance of the planet from the Sun, and AO, the radius or semidiameter of the annual orb, in parts of the same kind.

But because, especially in Mars, the proportion of the annual orb to the radius of Mars varies sensibly, just as in the Ptolemaic hypothesis reformed according to what was said in chapter 6, proposition 6, the semidiameter of the epicycle is not the same, three annual orbs are therefore marked in this figure: the mean MGO, the least IG, and the greatest MQO. For the rest, the greatest equation of the orb at the apogee and perigee will be set out below, at the end of this section, gathered from the tables of the astronomers.

[Margin: Authors who treat the construction of tables of equations.]

IV. Further, the way of constructing and applying tables of the equations of the centre, or of the eccentric place, and of the orb, is handed down by *Ptolemy*, Book 11, chapter 10; by *Copernicus*, Book 5, chapters 33 and 34; by *Fernel*, Book

2 of the *Cosmotheoria*, chapter 3; by *Reinhold* on Peuerbach, from p. 99 to 106; by *Wurstisen* in the same place, from p. 158 to 171;

by *Magini* in the *Theoricae*, chapters 6, 11 and 12, and in the *Supplement to the Ephemerides*, p. 21; by *Longomontanus* in Book 2 of the *Theorica*, chapter 12; by *Kepler* on Mars, chapter 60, and in the *Epitome of Copernican Astronomy*, Book 5, part 2, and Book 6, p. 749, and in the Rudolphine Tables, precepts 85 and 96; and by *Cavalieri* in the *Directorium Uranometricum*, from p. 144 on. And the equations of the eccentric are collected through all the degrees of the semicircle of the anomaly of the eccentric, in the way I taught in the geometrical calculation, according to each hypothesis: granted that Ptolemy collected them by sixes or by threes, and Copernicus by threes of degrees of this anomaly. In the other semicircle of the anomaly, moreover, the equations are equal at an equal distance from the apogee or from the perigee. But it is not enough to construct the equations of the orb, or of the argument, etc., for the single degrees of the anomaly of the orb, because each of them varies with the varying position of the centre of the epicycle, that is, with the varying anomaly of the eccentric. Thus in the preceding figure, no. 1, with the centre placed at F, one table would have to be constructed for the equations of the epicycle for the single degrees of the epicycle; with the centre placed at I, another table; and so for the other positions. Consequently 180 tables would have to be constructed, for the single degrees of the semicircle FHM, which

Diagram. In the left column, interrupting the sentence between *quod* and *esset*. A large outer circle, and within it a second circle drawn on a centre above the centre of the outer circle, its top meeting the top of the outer circle. Small circles stand on the inner circle: at the top about F; at upper left about I; at left two overlapping about H and ε; at lower left about K; and at the foot about M. A vertical line runs from the top through F, a, E, D, B and A, on through M and b to the foot of the outer circle. Lines radiate from A, past the small circles, to the rim of the outer circle. A dotted line runs from H towards D.

- Labels read, top of the figure: L, T, G.
- Upper left: M and L outside the rim; I in its small circle; c beside that circle and c below it.
- On the vertical line: F, a (italic), E, D, B, A, M, b (italic).
- Left: N, V, L outside the rim; H; ε; Z; c.
- Lower left and foot: K; c, c; O; L; c and S beside the lower small circle; P, R, Q, L along the foot of the rim.
- Right: X within the rim; Y outside it.
- Labels not read: none noticed.

would be far too laborious and of monstrous bulk. To avoid this, the old practitioners, from Ptolemy on, used proportional minutes [Scrupulis proportionalibus] and the excess, as is plain in the tables of *Ptolemy*, *Alfonso* and *Copernicus*, in the Prutenic Tables, and in those of *Longomontanus* and *Lansbergen*. The device is of this kind.

Problema 1. Scrupula Proportionalia in Tabula Aequationum Centri diſtribuere.

Problem 1. To distribute the proportional minutes in the table of the equations of the centre.

[Margin: On proportional minutes and the excess.]

V. *First*, with the centre of the epicycle placed at the single degrees of the semicircle FHM, or of the mean anomaly of the eccentric, say at F, I, ε, K, M, etc., collect the greatest equations of the epicycle in the triangles right-angled at C, in the way the remaining equations of the epicycle are usually collected, namely by means of the distance of the centre of the epicycle from the centre of the world, A. *Second*, value as 60 the excess of the greatest of the greatest equations, that is PR, which the angle PAR measures, over the least of the greatest, namely the arc GL, measured by the angle GAL. To that proportion reduce the excesses of the greatest equations over the least of the greatest: that is, the excess of the arc LM, or of the angle LAM, the greatest epicyclic equation when the centre is at I, over the arc GL; and when the centre of the epicycle is at ε, compare the excess of the arc NL, again over the arc GL; and when the centre of the epicycle is at K, compare the excess of the arc OL over the arc GL, reducing these excesses to sixtieth parts, or to parts such that the excess of the arc PR over the arc GL is 60 of them. These proportional minutes, or sixtieths of the excess, write in the third column of the equations of the centre, opposite the degrees of the mean anomaly of the eccentric; and the 60 minutes themselves write opposite 180°, or 6^{s}, of the anomaly.

EXEMPLVM.

Example.

[Margin: Example of proportional minutes in ♄.]

VI. Let the centre of Saturn's epicycle be at the apogee of the eccentric, F, and Saturn at the point C of the epicycle, where the greatest epicyclic equation for that position occurs; and let that equation, that is, the arc GL, be 5° 28′. Next let the centre of the epicycle be at the perigee, M, and Saturn at the contact C, where the greatest equation of the epicycle comes about; and let this, that is, the arc PR, be 6° 8′. The greatest excess between the equations at the contacts, or the greatest equations, will then be 40′. Keep this, then, and value it as 60 minutes. Now let the centre of the epicycle be at ε, and let the arc Fε, of the mean anomaly of the eccentric, be 94°; and let Saturn be at the point of contact C, where the greatest equation of the epicycle placed at this position on the eccentric occurs; and let that greatest equation be 5° 46′, so that the arc NL exceeds the arc GL by 18′. Therefore make as 40 is to 60, so 18 to another number, namely to 27: the proportional minutes to be written in the table of the equations of the centre, opposite 94°, or 3^{s} 4°, of the mean anomaly of the eccentric. And so for the rest.

Problema 2. Aequationes Orbis ſeu Epicycli in Apogeo Eccentrici poſiti, ad eiuſdem Aequationes in quocumq. ſitu Eccentrici redigere. Seu Tabulam vnicam Aequationum Orbis, cum Exceſſu earum congruenti conſtruere.

Problem 2. To reduce the equations of the orb, or of the epicycle placed at the apogee of the eccentric, to its equations at any position on the eccentric; or, to construct a single table of the equations of the orb, with the excess that agrees with them.

[Margin: Step 1.]

VII. *First*, with the centre of the epicycle placed at F, collect the equations of the orb for the single degrees of the semicircle GCa of the epicycle, counted from the apogee of the epicycle, G, in the order of the signs towards C. Write them in the second table, which is headed *Prosthaphaereses of the Orb*, opposite the degrees of the true anomaly of the orb. For example, if the planet is imagined at T, and the arc TG, that is, the anomaly of the orb, or the angle GFT, is 30°, the angle AFT, the complement to two right angles, will be 150°, in the triangle AFT. In this triangle FT is given, that is, the semidiameter of the epicycle, according to the measures of each hypothesis reduced to the Ptolemaic form by chapter 6, no. 13. Also given is the greatest longitude of the centre of the eccentric, which is the side AF, since it consists of the radius DF and the eccentricity of the deferent, AD. Therefore from these sides comprehending the known angle AFT you will collect trigonometrically the angle TAF, that is, the arc of the ecliptic GT, which is the equation of the orb, to be written opposite 30° of the anomaly of the orb in the second column. It also serves 330°, because at an equal distance of the planet from the apogee the prosthaphaereses of the orb are equal. In the first column are placed the degrees of the anomaly of the orb itself.

[Margin: Step 2.]

Second, with the centre of the epicycle placed at the perigee, M, for the single degrees of the former semicircle of the epicycle, counted from the apogee of the epicycle, b, towards C, you will collect the equations of the orb that agree with such a degree of the anomaly of the orb. Write these separately in another table, distinct from the table of the prosthaphaereses of the orb. For example, if the planet is at S, and the arc of anomaly bS is given, that is, the angle bMS, the angle AMS will be known, as the complement to two right angles. Therefore in the triangle AMS, if the semidiameter of the epicycle MS is given, and the nearer longitude of the centre, AM, that is, the remainder of the radius DM after the eccentricity AD has been taken away, the angle ASM will not stay hidden, that is, the arc RQ, which is the prosthaphaeresis of the orb that suits that degree of the anomaly of the orb.

[Margin: Step 3.]

Third, subtract the equations of the orb collected at the apogee from the equations of the orb collected at the perigee, comparing them at the same degree of anomaly; and write the excess of the perigean equations in the third column

of the prosthaphaereses of the orb, opposite the degrees of the anomaly of the orb against which you have already written the apogean, or least, equation.

EXEMPLVM.

Example.

[Margin: Example in ♄. See the table of chapter 6, no. 12.]

VIII. Let the eccentricity of the deferent of ♄, AD, from the measures of *Lansbergen*, but in Ptolemaic form, be 5700 of the parts of which the radius DF is 100000, and let the semidiameter FT of the epicycle of ♄ be 10070; and so the line AF will be 105700 parts, and AM 94300. And let Saturn be now at T, at a distance of 30° from the apogee G, and now at S, likewise at a distance from the a- pogee b, of 30°. For in the triangles AFT and AMS the angle AFT will be 150°, no differently from the angle AMS. Therefore, given FT and MS, each of 10070 parts, and AF of 105700, but AM of 94300, the angle FAT, or the arc GT, will come out as 2° 31′, but the angle MAS, that is, the arc RQ, as 2° 48′, which exceeds the arc GT by 17′. So in the table of the prosthaphaereses of the orb, in the first column you will set the degree 30 of the anomaly of the orb; opposite it, in the second column, which is titled *Prosthaph. of the orb*, 2° 31′; and in the third column, which is titled *Excess*, you will write 17′. And so for the rest. Remember, moreover, that the prosthaphaereses of the orb are to be added to the eccentric place of the planet, or the place of the centre, in the first semicircle of the anomaly of the orb, and subtracted in the second, so as to have the true place of the planet, the one apparent to those observing it from the Earth. The equation of the eccentric place, by contrast, is to be subtracted in the first semicircle of the anomaly of the eccentric and added in the second.

Problema 3. Aequationes Maximas Centri, earumq. Locum ſeu Gradum Anomaliæ ex Tabulis Aequationum colligere.

Problem 3. To collect from the tables of equations the greatest equations of the centre, and their place, or degree of anomaly.

IX. In the preceding figure, no. 1, let the centre of the epicycle be at ε, where the greatest equation of the centre occurs. Consult, then, the table of the prosthaphaereses of the centre made for each planet, running through the second column until you find in it the greatest number of degrees and minutes. That will be the greatest equation of the centre, and in the first column you will have the degree of anomaly at which that greatest equation comes about. Thus in *Lansbergen's* table of the prosthaphaereses of the centre of Saturn, which he sets out on p. 108, you will see that the greatest equation is 6° 31′, opposite 94°, or 1 sexagene 34° [Sexag.1. Gr.34.].

Problema 4. Aequationes Maximas Orbis, in quocumq. loco Eccentrici Epicyclus ſit, ex Tabulis Aequationum colligere, nec non Locum illarum in Epicyclo.

Problem 4. To collect from the tables of equations the greatest equations of the orb, at whatever place on the eccentric the epicycle may be, and also their place on the epicycle.

[Margin: Case 1. For the apogee of the eccentric.]

X. *First*, if the centre of the epicycle is at the apogee of the eccentric, the second table itself, that of the prosthaphaereses of the orb, will show the greatest equation of the orb, if, running through its second column, you observe what the greatest number of degrees and minutes is; and opposite it in the first column you will see the degree of the anomaly of the orb to which that greatest equation belongs. That place, however, will be had more exactly if the greatest equation is added to 90°. Thus in *Lansbergen's* table of the prosthaphaereses of the orb of Saturn, which he has on p. 110, the greatest equation of the orb at the apogee, that is, the arc GL, is 5° 28′, which corresponds to several degrees of the anomaly because the seconds are omitted. Therefore, by adding 5° 28′ to 90°, the truer place on the epicycle at which that greatest equation occurs is 95° 28′ of the anomaly. In the tables of *Ptolemy* and *Alfonso*, however, from the greatest equation at the mean longitude must be taken the greatest difference set in the column of the longer longitude.

[Margin: Case 2. For the perigee of the eccentric.]

Second, if the centre of the epicycle is at the perigee of the eccentric, collect as above, from the table of the prosthaphaereses of the orb, the greatest equation in the second column and the excess in the third. Add the excess to the greatest apogistic equation, and the greatest perigistic, or absolute, equation will result. Then add this to 90°, and you will have the degree of anomaly to which this greatest equation belongs and at which it comes about. Thus in the already mentioned table of *Lansbergen*, beside the greatest equation of the orb of Saturn, 5° 28′, an excess of 40′ is set in the third column. Therefore the greatest equation at the perigee of the eccentric, that is, the arc PR, is 6° 8′, and the place on the circumference of the epicycle that suits it is 96° 8′, reckoned from the apogee of the epicycle. In the tables of *Ptolemy* and *Alfonso*, however, to the greatest equation sought in the column of the mean longitude must be added the greatest difference found in the column of the nearer longitude.

[Margin: Case 3. Away from the apogee and perigee.]

Third, if the centre of the epicycle is elsewhere, say at ε, with the mean anomaly of the eccentric seek in the first table of the equations of the centre, but in its third column, the proportional minutes; and in the second table, which is that of the equations of the orb, seek as in case 2 both the greatest equation of the orb (which I call apogistic) and the greatest excess, which is to be found in the third column. Then multiply this greatest excess by the proportional minutes, and divide the resulting sum by 60. For the quotient, added to the greatest apogistic equation, will make up the greatest equation of

the orb that suits the planet for that place of the centre of the epicycle. Added to 90°, this will give the place on the epicycle to which that equation belongs. One must proceed a little differently in the tables of *Ptolemy* and *Alfonso*.

EXEMPLVM.

Example.

XI. Let the centre of the epicycle of ♄ be at ε, and Saturn at C, and let the mean anomaly of the eccentric, or the arc Fε, be 94°, to which in *Lansbergen's* table there correspond 27′ of proportional minutes. Since, from the second table of the same author, of the prosthaphaereses of the orb of ♄, the greatest equation is 5° 28′ and the greatest excess 40′, 27 multiplied by 40 makes 1080′; these divided by 60′ leave 18′. Add, then, 18′ to 5° 28′, and the greatest equation, that is, the arc NL, is 5° 46′; and the degree of the epicycle at C, counted from the apogee of the epicycle, to which this equation belongs, is 95° 46′.

Problema 5. Proſthaphæreſes tum Centri tum Orbis ex Tabulis continentibus Scrupula proportionalia, & Exceſſum colligere.

Problem 5. To collect the prosthaphaereses both of the centre and of the orb from tables containing the proportional minutes and the excess.

[Margin: Step 1.]

XII. *First*, with the mean anomaly of the eccentric seek the equation of the centre and also the proportional minutes, and keep them. Subtract the equation of the centre from the planet's mean motion in longitude in the first semicircle of the anomaly, and add it in the second. For the result will be the place of the centre of the epicycle, or the true centre, or the eccentric place of the planet.

[Margin: Step 2.]

Second, subtract the eccentric place of the planet from the mean motion of the Sun according to the old astronomy, or from the true motion according to recent astronomy, and there will remain the true anomaly of the orb, otherwise called the annual argument. With this, in the table of the prosthaphaereses of the orb, seek the equation of the orb in the second column, which is the one that would occur if the centre of the epicycle were at the apogee of the eccentric; and in the third column the excess of the equation of the orb, namely that by which the equation of the orb, with the planet placed at the same degree of anomaly but the centre of the epicycle placed at the perigee of the eccentric, exceeds the equation of the orb with the centre placed at the apogee. Multiply this excess by the proportional minutes found in step 1, and divide the resulting sum by 60. For there will result the excess, always to be added to the equation of the orb that was found, so as to have the corrected equation. This, added to the eccentric place of the planet in the first semicircle of the anomaly of the orb and subtracted in the second, will give the true place of the planet as seen from the Earth.

De Imperfectione Aequationum Orbis præcedenti methodo inueſtigatarum.

On the imperfection of the equations of the orb investigated by the preceding method.

XIII. The device already mentioned rests on a certain proportion [Analogia], close to the truth indeed, but not exactly true. For in the preceding figure let the centre of the epicycle be now at F, now at ε, now at M; and let the planet at these three places be once at the contacts C, where the greatest equation of the epicycle comes about, and at another time be at T, at Z and at S, yet in such a way that the arcs of anomaly TG, ZH and bS are equal, say of 30° each. With this laid down, the old astronomy supposes that as the greatest equation, or the arc RL, is to the greatest GL, so the equation or arc RQ is to the equation or arc GT; or that as the excess of the arc RL is to the arc GL, so too is the excess of the arc RQ to the arc GT. Similarly it holds that as the arc NL is to the arc GL, so is the arc NV to the arc GT. But this is not so, because the arcs of the epicycle that correspond to the greatest equations are not (as is here supposed) equal, wherever on the eccentric the centre of the epicycle is set. And already in the examples brought from *Lansbergen* for ♄ at no. 10 we saw that the arc GC is 95° 28′, the arc HZC 95° 46′, and the arc bSC 96° 8′.

[Margin: Cause 1 of the imperfection already mentioned.]

Although, therefore, in the method already mentioned the excesses of the other equations of the orb are compared with one another with respect to the same anomaly of the orb, the excesses of the greatest equations, and the proportional minutes derived from them, are nevertheless not with respect to the same anomaly of the orb. And this indeed is the first cause why equations of the orb collected by such a method differ by some minutes from the exact prosthaphaeresis: granted that *Ptolemy*, *Alfonso*, *Copernicus*, *Longomontanus*, *Lansbergen*, *Giuntini*, *Stadius*, *Magini* in the canons of the *Secunda Mobilia*, and almost all the older astronomers have used it.

[Margin: Authors who recognized this imperfection.]

But its imperfection, though they did not disclose the cause, was at length recognized by *Magini* in the *Supplement to the Ephemerides*, canon 12, and, in his pages, by *Ricardus Forsterus* [Richard Forster], the most learned physician and mathematician of London; and by *Cavalieri* in the *Directorium*, p. 145. *Magini's* words are: *For I am not alone in having often found by experience that the form of calculation handed down by our predecessors for computing the equations of the orb by proportional minutes and the excess is deceptive and erroneous; others have too.* He then adds words from a letter of Forster, writing to Magini himself: *I have examined the calculation of the most learned Erasmus Reinhold in ♂, and it strays by 16′ 20″ from the true value according to his own hypothesis, by the doctrine of triangles, in the parallaxes of the orb. I attribute this difference to the operation by proportional minutes and the excess, which is almost never done exactly.*

[Margin: Cause 2 of the imperfection.]

[Margin: The opinion of Boulliau and Kepler.]

The second cause is that the ancients referred the apparent motion of the planet on the epicycle to the centre of the mean motion of the Sun; and therefore, to investigate the anomaly of the orb, they subtracted the central place of the planet from the mean motion of the Sun. Hence for them the method of calculation was constant. But since their motion ought to be referred to the Sun, while the true place of the Sun varies perpetually, as does its true distance from the Earth, it comes about that the proportion of the annual orb in the planets, that is, the semidiameter of the Ptolemaic epicycle, varies perpetually. Therefore a single table cannot be constructed that would show, by proportional minutes and the excess, correct equations of the orb, especially in ♂, as *Boulliau* learnedly points out in Book 8 of the *Astronomia Philolaica*, chapter 9. And this is what *Kepler* obscurely indicated in the *Epitome of Copernican Astronomy*, p. 751, in these words: *Because it cannot be that we refer the parallaxes of the orb to the semidiameter of the orb, as is done in the old astronomy, therefore in place of the double proportional minutes and the excess of the parallax of the orb, or of the variation of the diameter, a number has been introduced indicating what the proportion is of the sum of the intervals of the Sun and the planet, and of the Earth, to the difference.* But *Longomontanus* and *Lansbergen* too tried to correct the equations of the orb of Mars, as I shall indicate in Scholium 1.

Primus Modus condendi exactiùs Tabulas Aequationum Orbis, eaſq. adhibendi ex Magino.

First way of composing the tables of the equations of the orb more exactly, and of applying them, from Magini.

[Margin: Step 1.]

XIV. *First*, from Magini in the *Supplement to the Ephemerides*, canons 12 and 13, collect for the single degrees of the mean anomaly of the eccentric the greatest equation of the orb by means of a right-angled triangle, as I indicated above in no. 5. Add it to 90°, and you will have the point of contact, which divides the half-arc of direction from the half-arc of retrogradation, that is, the half-arc of the epicycle on which the planet is direct from the half-arc on which it is retrograde.

[Margin: Step 2.]

Second, with the eccentric place of the planet subtracted from the place of the Sun, either mean, according to the old astronomers, or true, according to the more recent, obtain the true anomaly of the orb. If this is less than the half-arc of direction, or greater than the sum of the half-arc of direction and the whole arc of retrogradation, it is a sign that the planet is in the upper part of the epicycle, or direct, and that the half-arc of direction is to be used. But if the anomaly of the orb is greater than the half-arc of direction, but not greater than the sum of the half-arc of direction and the whole arc of retrogradation, the planet will be retrograde, and the half-arc of retrogradation is to be used.

[Margin: Step 3.]

Third, consult the General Table of Positions which *Magini* sets out in the Tables of Directions of the primum mobile, from p. 137 on, and in it seek in the left margin the half-arc of direction or the half-arc of retrogradation, just as if it were a semidiurnal arc; and in the body of the table [area] opposite it look for the equated anomaly of the orb. For above that, at the head of the table, you will have the head number [numerum frontalem], whose difference from the true anomaly of the orb will be the equation of the orb sought. Magini, moreover, constructed and set out in the *Supplement to the Ephemerides*, from p. 202 to 216, tables in whose third column you have the greatest equations of the five minor planets, derived from the hypothesis of Copernicus, for the single degrees of the anomaly of the eccentric. Therefore from these and from the General Table of Positions the whole business of the equations of the orb can be completed.

Secundus Modus condendi Tabulas Aequationum Orbis exactiùs, eaſq. adhibendi ex Magino & Keplero.

Second way of composing the tables of the equations of the orb more exactly, and of applying them, from Magini and Kepler.

[Margin: Magini's way 2.]

[Margin: Kepler's way.]

XV. *Magini* barely and thinly indicates this way in the *Supplement to the Ephemerides*, canons 12 and 14. It consists both in the search for the mystic number [numeri Myſtici] and in the construction of a general table of the equations of the orb. The mystic number arises from the commensuration of the orbs of the planet and of the Sun (or, for Copernicus, of the Earth), and under it, with the true anomaly of the orb, the desired equation of the orb is collected in the general table of equations. So Magini, in the same *Supplement*, from p. 202 to 216, puts the mystic number in the last column, and from p. 218 sets out the General Table of the Equations of the Orb. He calls it by that name because, given the mystic number arising from any hypothesis and measures of the orbs, the same table serves all hypotheses, and indeed for any planet. That mystic number is the proportion of the difference of the intervals or distances of the planet from the Earth and of the Sun from the Earth to the sum made up of the same intervals, but in parts of which the sum of the distances is 60, as *Magini* employs it, or in parts of which the sum of the distances is 100000, as *Kepler* employs it in the *Epitome of Copernican Astronomy*, p. 751, where he simply calls this number the *Index*.

[Margin: Step 1.]

First, therefore, collect for the single degrees of the semicircle of the anomaly of the eccentric the distance of the planet from the Sun, as we taught in the calculation by geometrical forms, according to each hypothesis. To it add the mean distance of the Sun from the Earth, or at least, for Mars, the true one, and you will have the sum of the intervals. But if you subtract that distance

of the Sun from the Earth from the distance of the planet from the Sun, you will have the difference. Multiply this difference either by 60 or by 100000, and divide the resulting sum by the sum of the intervals. For the quotient will be the index of the proportion already mentioned, in parts of which the sum of the intervals has been taken as 60 or as 100000. *Kepler* admits, however, in the same place that in the Rudolphine Tables he set, in place of the quotient already mentioned, its logarithm, under the interval of the planet from the Sun.

[Margin: Step 2.]

Second, as *Kepler* teaches there, multiply the tangent of half the true anomaly of the orb by that Index, but found in parts of which the sum of the intervals is 100000; and you will have the tangent of the arc to be added to that half in the superior planets and taken away in the inferior, so as to have the angle of elongation of the planet from the Sun. But if, as in the Rudolphine Tables, a logarithm stands in place of the Index, add to this logarithm the mesologarithm of half the true anomaly of the orb, and there will result the mesologarithm of the arc to be added to the half-anomaly itself in the superior planets, and taken from it in the inferior, so that the elongation of the planet from the Sun visible under the ecliptic results, or the angle at the Earth.

[Margin: Step 3.]

Third, if the eccentric place of the planet is less than the true place of the Sun, subtract the elongation already mentioned from the true place of the Sun; but if greater, add it; and the visible place of the planet in the ecliptic results, or the place apparent to those observing the planet from the Earth. In *Magini's* general table of the equations of the orb, however, under the mystic number you have the equations of the orb to be added to or taken from the eccentric place of the planet, as the titles at the head of the table indicate. For other, more troublesome precepts of the Rudolphine Tables, see the Rudolphine Tables, chapter 22.

Tertius Modus Condendi & Adhibendi Tabulas Aequationum Orbis ex D. Vincentio Reinero, & D. Petro de S. Legier, & Iſmaele Bullialdo.

The third way of constructing and using tables of the equations of the orb, from D. Vincenzo Renieri, D. Petrus de S. Legier [?] and Ismaël Boulliau.

XVI. *D. Vincenzo Renieri*, in the newly reissued *Tabulae Mediceae*, p. 243; *D. Petrus de S. Legier* [?] of Avignon, in a double table of the equations of the orb published at Avignon in 1640 and sent on to me from there by Father Théophile Raynaud; and lastly *Ismaël Boulliau*, in the *Philolaic Tables* from p. 98 on, have published a general table of the equations of the orb, suited to all planets affected by the second inequality and to all hypotheses, provided that the true anomaly of the orb is given, and the greatest equation of the orb corresponding to the anomaly of the eccentric. For the anomaly of the orb is looked up at the sides, the greatest equation of the orb at the head, and the equation of the orb in the

common area. As for the greatest prosthaphaeresis, *Renieri* and *Boulliau* give it in special tables of the prosthaphaereses of each planet, because it depends on the particular commensuration of the orbs themselves. That general table of the equations of the orb, moreover, is constructed by solving an oblique-angled rectilinear triangle in which there are given the proportion of two sides, namely the distance of the Sun from the Earth and of the planet from the Sun, and the angle they contain, which is called the angle of the anomaly of the orb, or of commutation. It becomes known by subtracting the true eccentric place of the planet from the true place of the Sun, or the latter from the former, etc. For one of the angles at the base found in that triangle, namely the angle at the planet, is the equation of the orb. The more exact table, however, is D. de Legier's second, because it contains degrees, minutes and seconds.

Quartus Modus Conſtruendi Tabulas Aequationum Orbis ex P. Bonauentura Caualerio.

The fourth way of constructing tables of the equations of the orb, from Father Bonaventura Cavalieri.

XVII. From Father Bonaventura Cavalieri's *Directorium Uranometricum*, part 2, chapter 4, p. 144, collect the distance of the planet from the Sun for the single degrees of the semicircle of the anomaly of the eccentric. Beneath those distances, or opposite them, write the arithmetical complement, or residual of the logarithm; and beside the distances of the Sun from the Earth write the logarithm. For the sum of the residual already mentioned and the logarithm is the logarithm of the greatest equation of the orb; and that same sum, sought as a mesologarithm, will give an angle whose residue to 45° is the mystic angle [angulus Myſticus] (for so he calls it, imitating Magini), an angle common to all the equations of the orb to be found for a given interval. Indeed, the mesologarithm of the mystic angle, joined to the mesologarithm of the half-anomaly of the orb, makes up the mesologarithm of the angle to be taken from the half-anomaly, so as to have the lesser angle, or to be added, so as to have the greater angle. In these angles the equation of the orb consists: in the lesser, when the distance of the Sun from the Earth is less than the interval of the Sun and the planet; in the greater, when it is greater.

EXEMPLVM.

Example.

[Margin: Example in ♄.]

XVIII. Let there be, from the Rudolphine Tables, as Cavalieri sets it, a distance of Saturn from the Sun of 971197, of parts of which the radius of the annual orb is 100000; a distance of the Earth from the Sun of 101546 of those parts; and an anomaly of commutation, or of the orb, of 155° 49′ 13″, with its half 77° 54′ 36″. You will therefore set out the first operation thus.

Dist. ♄ from ☉ 971197.	Res. Logar.	401273
Dist. ☉ from Earth 101546.	Logarith.	500680
Angle 5° 58′ 17″.	Mesol.	901953

Next, with the angle 5° 58′ 17″ subtracted from 45°, there remains the mystic angle 39° 1′ 43″. The second operation is therefore to be set up thus.

Mystic ang. 39° 1′ 43″.	Mesol.	990881
Half-anomaly 77° 54′ 36″.	Mesol.	1066918
Angle 75° 11′ 54″.	Mesol.	1057799

Therefore, with the angle 75° 11′ 54″ taken from the angle of the half-anomaly, 77° 54′ 36″, because Saturn's distance from the ☉ is greater than that of the Sun from the Earth, there remains the most exact equation of the orb, 2° 42′ 42″.

Quintus Modus Noſter Conſtruendi Tabulas Aequationum Orbis Maximarum.

The fifth way, our own, of constructing tables of the greatest equations of the orb.

XIX. *First*, a place of the planet observed both at the apogee and at the perigee of the eccentric, or as nearly as possible, is to be chosen, and the eccentric place of the planet and the true place of the Sun are to be sought from the tables. For the former subtracted from the latter will give the anomaly of the orb, while the difference of the eccentric place of the planet from the observed place will give the equation of the orb required. Go therefore to the general table of the equations of the orb, of which I spoke at no. 16, and in its area [arealiter] seek the equation of the orb already mentioned, opposite the anomaly of the orb: for at the head of the table you will have the greatest equation of the orb, but the proportional part must be used with exactness. Having thus obtained the greatest equation already mentioned, both apogeal and perigeal, look up the logarithm of each and reserve it.

Second, from our table of measures placed at the end of chapter 6, collect the distance of the centre of the epicycle from the centre of the Earth, both the apogeal or greatest, which is called the longer longitude, and the perigeal, which is called the nearer longitude; and look up the logarithm of each. Then add together the logarithm of the greatest equation of the orb and the logarithm of the distance of the centre of the epicycle, first at the apogee, then at the perigee, and you will have the logarithm of the semidiameter of the epicycle, greatest at the apogee and least at the perigee. The latter subtracted from the former will give the difference of the semidiameters of the epicycle; reserve half of this.

Third, with the mean anomaly of the eccentric given or assumed, look up both the distance of the centre of the epicycle from the centre of the Earth, according to the method given in chapter 6, no. 10, at the end of step 2, and the temporary semidiameter of the epicycle, or that suited to the anomaly already mentioned, according to the precept given in the same place in step 3, using half the difference of the semidiameters. For if you join into one sum the logarithm of the semidiameter of the epicycle and the residual of the logarithm of the distance of the centre of the epicycle, the result will be the logarithm of the greatest equation of the orb to be applied in that position of the eccentric, so as to obtain, by means of the general table of the equations of the orb, the equation of the second inequality.

EXEMPLVM in ♂.

Example in ♂.

[Margin: Step 1, for the greatest equation of the orb at the apogee of the eccentric.]

XX. On 1587 January 5, Old Style, as *Kepler* relates in the *Commentaries on Mars*, chapter 42, Tycho observed Mars at ♎ 2° 8′ 30″, at 9^{h} 31^{m} p.m. at Uraniborg. At that time, for me, the Sun was at ♑ 25° 24′, and the mean motion of ♂ from the Rudolphine Tables was 4^{s} 29° 27′, and the motion of the apogee of ♂ 4^{s} 28° 43′. Therefore, with the latter subtracted from the former, the anomaly of the eccentric was 0^{s} 0° 44′, so that Mars was almost at the very apogee of the eccentric. The equation of the centre from my tables was 7′ 20″. This, subtracted from the mean motion of ♂, leaves the eccentric place of ♂ as 4^{s} 29° 19′ 40″. That place, taken from the true place of the Sun, gives the anomaly of the orb, 4^{s} 26° 4′ 20″; and taken from the true place of Mars, it leaves the equation of the orb, 32° 58′ 50″. In the general table of the equations of the orb, opposite the anomaly 4^{s} 26° 4⅓′, this equation is found only under the head number 36° 17′. Therefore the greatest equation of the orb suited to Mars at a distance of 44′ from the apogee of the eccentric is 36° 17′; so at the apogee itself it is prudently set at 36° 15′.

[Margin: Step 2, for the greatest equation of the orb at the perigee of the eccentric.]

XXI. Again, on 1593 July 31, as *Kepler* reports in the same chapter 42, Tycho observed Mars at ♓ 17° 39′ 30″, in the morning, at 1^{h} 15^{m} after midnight at Uraniborg. At that time, for me, the Sun was at ♌ 17° 13′, and the mean motion of ♂ from the Rudolphine Tables, which we follow in this, was

10^{s} 26° 15′, and the motion of the apogee of ♂ 4^{s} 28° 50′. With this subtracted from the former, the anomaly of the eccentric remains 5^{s} 27° 25′, so that Mars was only 2° 35′ from the perigee of the eccentric. At that time, moreover, the equation of the centre was, for me, 32′ 20″, and therefore the eccentric place of ♂ was 10^{s} 25° 42′ 40″. This, subtracted from the true place of the Sun, leaves the true anomaly of the orb, 5^{s} 21° 30′ 20″; while the difference of the eccentric

place from the observed place, that is, the equation of the orb required, was 21° 56′ 50″. In the general table of the equations of the orb, opposite the anomaly already mentioned, this is found only under the head number 47° 36′. From this and from other similar observations I found that the greatest equation of the orb suited to Mars at the very perigee of the eccentric is 47° 40′.

[Margin: Step 3, for the greatest and least semidiameter of the epicycle.]

XXII. Further, from the table of chapter 6, the longer longitude of the epicycle of ♂ is, for me, 120000 parts, and the nearer longitude 82730. The logarithm of the number 120000, which is 507918, joined to the logarithm of the angle 36° 15′, which is 977181, makes the sum 485099 (with unity taken away on the left, as is customary). This is the logarithm to which there corresponds in the table of logarithms the apogeal semidiameter of the epicycle, 70957 parts, of which the radius of the orb of Mars is 100000. Next, the logarithm of the number 82730, which is 491766, added to the logarithm of the angle 47° 40′, which is 986879, makes the sum 478645 (with unity taken away on the left). This is the logarithm of the number 61157, which is evidently the semidiameter of the epicycle of Mars at the perigee of the eccentric. The difference of the two is 9800 parts, and half of it 4900.

[Margin: Step 4, for the distance of the centre of the epicycle and its semidiameter.]

XXIII. Now let there be given a mean anomaly of the eccentric of 100°, or 3^{s} 10°. Its complement is 80°, and their second sine is 17365; and the semidiameter of the small circle of the eccentricity of ♂, from the table of chapter 6, is 1365. Let it therefore be: as the whole sine, 100000, is to 17365, so 1365 is to 237. With these taken from the mean eccentricity of Mars, which for me is 18635, there remains the eccentricity of Mars suited to such an anomaly, 18398. With this and with the radius 100000, as sides containing the angle of 80°, there is found the equation of the centre, 10° 36′ 8″; and, with these given, the distance of the centre of the epicycle from the centre of the Earth, 98486 parts, of which the radius of the orb of Mars is 100000. Again, let it be: as the whole sine, 100000, is to the same second sine, 17365, so the half-difference of the epicyclic semidiameters, 4900, is to 851. This number, taken from the mean semidiameter of the epicycle of Mars, which for me is 66057, leaves the semidiameter of the epicycle suited to Mars in that position of the anomaly, 65206 parts, of which the radius of the orb of ♂ is 100000.

[Margin: Step 5, for the greatest equation of the orb.]

XXIV. Finally, the logarithm of the number 65206, that is, of the semidiameter of the epicycle, which is 481429, joined to the residual of the logarithm of the distance 98486, which is 500663, makes the logarithm 982092, to which in the logarithmic tables of arcs there corresponds the angle 41° 28′. So great is the greatest equation of the orb suited to Mars at an anomaly of the eccentric of 100°. Know, then, that our tables have been constructed by this device.

SCHOLIA.

Scholia.

I. Since the distance of the Sun from the Earth bears a more sensible ratio to the distance of Mars, therefore, when the Sun's distance varies, whether annually because of its recession from the apogee, or from age to age, so to speak, because of the varied eccentricity, according to many astronomers, the prosthaphaereses of the orb of Mars also vary sensibly: especially in its acronychal shinings, when it is in ♒, ♓, ♈ and ♉, in which the distance of Mars from the Earth is far less.

[Margin: Lansbergen's correction of the equations of Mars.]

For this reason *Lansbergen*, in precept 16 of his tables, advises that the equations of the centre be corrected thus: With the centric longitude [Longitudine centrica] (just as if it were the anomaly of the eccentric), look up the prosthaphaeresis of the centre, and keep it. Next, with the anomaly of the orb, just as if it were the anomaly of the eccentric, look up the proportional minutes. Multiply these by the prosthaphaeresis of the centre and divide the sum by 60: for from the quotient there results the equation to be added to or taken from the centric longitude, as the titles of the table indicate.

[Margin: And Longomontanus's.]

Longomontanus, in Book 2 of the *Theorica*, chapter 9, judged that on this account a libration should be introduced, either of the eccentric or of the annual orb of Mars, to account for this sub-anomaly of the annual anomaly; and he constructed a table in which there is the analogy of the distance of the Sun from the apogee in the annual orb of Mars. On its use consult him, chapters 9 and 12. But they needed this remedy because they had first hunted for the equations of the orb in the old way, through proportional minutes and the excess, though in vain, especially for Mars.

[Margin: Boulliau's consideration for the greatest equations of the orb.]

II. *Boulliau*, however, in Book 8, chapter 9, and in the tables, pp. 17, 33, 47, 65 and 83, considering that the least distance of the Earth from the Sun, compared with the radius of the planet's orb, appears greater at perihelion, especially of ♂, than at aphelion, called this excess the increment of the side from the Sun to the Earth [Incrementum lateris à Sole ad terram], for it grows from aphelion to perihelion; and he set it in the tables, but distinguished a first increment from a second. He calls first that by which the distance of the Sun from the Earth grows of itself from the Sun's perigee to its apogee, in parts of which the radius of the planet's orb is 100000, or in parts of which the radius is 60. He calls second that by which the ratio of the side of the distance of the Sun from the Earth grows in relation to the decrease of the distance of the planet from the Sun. With the help of the side and the increment already mentioned he hunted down the greatest parallaxes of the orb, which are necessary for the use of the general table of the prosthaphaereses of the orb. He gives the practice of using the table of equations on p. 435, and we, after him, in the practical part of this volume.

III. The longitude of the planet found through the equations of the orb must still be refined, also because of the reduction of the planet from its orbit to the ecliptic, a correction that has joined to it the curtation of the distance of the planet from the Sun. But of this, since it depends on the latitude and the motion of the nodes, we shall have to speak below, in Section 5. Meanwhile consult *Kepler* on Mars, chapter 9, and in the *Epitome*, p. 701; and *Hérigone*, volume 5 of the *Cursus Mathematicus*, p. 559.

IV. Ptolemy calls proportional minutes [Greek: ἐξήκοστα μέρη ἐπιβάλλοντα (hexēkosta merē epiballonta, "sixtieth parts falling to it")]; and the excess of the greatest equations of the orb at other places of the eccentric, over the greatest at the apogee of the eccentric, is called [Greek: ὑπεροχὴ τῶν προσθαφαιρέσεων (hyperochē tōn prosthaphaireseōn, "excess of the prosthaphaereses")]. In its place the Alphonsines and Peuerbach have the diversity of the diameter [Diuerſitas Diametri], on which see *Reinhold* on Peuerbach, pp. 105 and 132, and *Wurstisen*, p. 178. It is that by which the mean longitude, or distance of the centre of the epicycle, exceeds the least or is exceeded by the greatest. For that whole excess, converted into 60 small parts and compared with the excesses of the remaining distances, produces the proportional minutes of which I spoke at no. 5, but with this difference, that the greatest number, namely 60, is placed at the beginning of the anomaly of the centre. The Alphonsines also differ in seeking the proportional minutes by means of the coequated anomaly of the eccentric, which *Reinhold* censures there, p. 106, since *Ptolemy* uses the mean anomaly. The remaining differences in arranging the tables of proportional minutes and excesses are plain from a mere inspection of the older tables. One is notable, however: Ptolemy and Alfonso set the equations of the orb suited to the epicycle at mean longitude, with the difference on either side in two columns, one for the longer longitude, or the interval from the mean distance to the apogeal, the other for the nearer longitude, or the interval from the mean distance to the perigeal. The others, by contrast, usually set the equation of the orb fitting the apogee of the eccentric, with the excess suited to the recession from the apogee all the way to the perigee.

[Margin: On the table of the greatest equations.]

V. It is now my pleasure, at the end of this section, to append a table of the greatest equations, but with the measures brought over to the Ptolemaic form, which uses an eccentric for the first inequality and an epicycle for the second (to the former belongs the equation of the centre, to the latter the equation of the orb), so that comparison of the opinions may be easier. These equations we have derived partly from the tables of the astronomers listed below, partly from what is given by *Ptolemy*, Book 11, chapter 10; *Copernicus*, Book 5, chapter 33; *Mästlin* in the *Appendix* to Kepler's *Prodromus*; *Magini* in the *Theoricae* of these planets, chapters 6 and 11; and *Longomontanus*, Book 2 of the *Theorica*, chapter 12. Remember, moreover, that the greatest equation at the apogee of the eccentric is the least of the greatest equations of the orb. Further, for

the greatest equations of the orb on our hypothesis we have taken the greatest distance of the planet from the Sun, at aphelion, and the least, at perihelion, and the mean distance of the Sun from the Earth, 7300 semidiameters of the Earth. ♂ is an exception: for the apogeal greatest equation we took the least distance of the ☉ from the Earth, which for us is 7000, and for the perigeal the greatest, which is 7600 semidiameters of the Earth.

SECTIO TERTIA DE MOTV LONGITVDINIS VENERIS ET MERCVRII.

Section Three. On the motion in longitude of Venus and Mercury.

CAPVT I. De Hypotheſi Veneris ac Mercurij Ptolemaica, vel Antiqua vſq. ad Copernicum.

Chapter 1. On the Ptolemaic hypothesis of Venus and Mercury, or the ancient one down to Copernicus.

[Margin: Authors on the hypothesis of ♀ and ☿.]

I. The hypothesis of ☿ is explained by *Ptolemy*, Book 9, from chapter 7 to the end, and that of ♀ in Book 10 of the *Magna Constructio*, from chapter 1 to 5; by *Geber*, Book 7, chapter 2; by *al-Farghānī*, from Difference 14 to 17; by *Regiomontanus* in the *Epitome of the Almagest*, Books 9 and 10, from proposition 1; by *Jean Fernel*, Book 1 of the *Cosmotheoria*, chapters 5 and 6; by *Johannes Schöner* in the *Aequatorium Astronomicum*, pp. 14 and 17; by *Peuerbach* in the *Theorica* of ♀, and there by *Reinhold*, from p. 107 to 113; by *Wurstisen*, from p. 186 and from 207; by *Osualdus*, from p. 180; by *Alessandro Piccolomini*, Book 2 of the *Theoricae*, chapter 5; by *Langius* in the *Theoricae Planetarum*, chapter 12; by *Magini* in the *Theoricae*, from p. 41, and in the *Secundum Mobile*, canon 33; by *Christoph Clavius* at the end of the *Sphaera*; by *Hérigone*, volume 5 of the *Cursus Mathematicus*, pp. 533 and 539; and by *Gassendi*, Book 2 of the *Institutio Astronomica*, chapter 7.

This old theory, moreover, is very like the hypothesis of the three superior planets set out in chapter 1 of Section 2, to which one must go back for the figure and the definitions.

[Margin: See the figures set out in Section 2, chapter 1, nos. 2 and 5.]

The hypothesis of Venus and Mercury therefore consists of four orbs, with one circle besides: namely, two deferents carrying the apogee and perigee of the eccentric in the order of the signs [in conſequentia]; the equant eccentric, which is not an orb but a mere circle; the eccentric deferent carrying the epicycle in the order of the signs; and the epicycle carrying the planet, above in the order of the signs and below against that order [in præcedentia]. Of these, according to the opinion of the authors who use solid orbs, the outermost two are eccentric to the centre of the world in a certain respect [secundùm quid]; for the su- rfaces, the convex surface of the highest and the concave of the lowest, are concentric with the world, while the concave surface of the highest and the convex of the lowest are eccentric to the world, though concentric with each other. The deferent, within whose thickness are contained both the equant circle and the epicycle, is eccentric to the world in both its surfaces. The definition of the lines and of the apogees, and the method of the geometric calculation that calls for the equation of the centre and then that of the orb or argument, are entirely the same as in Saturn, Jupiter and Mars, provided

the eccentricity is established. There is no need to repeat them here; chapter 1 of Section 2 should be consulted. Venus also agrees with the three superior planets as regards the bisection of the eccentricity: the centre of its equant is twice as far from the centre of the Earth and the world as the centre of the deferent of the epicycle, or in other words the centre of the deferent lies precisely midway between the centres of the world and of the equant. Finally, Venus and Mercury agree with the three superior planets in being slowest at the apogee of the eccentric and swiftest at its perigee as regards true motion, just as, in the second motion, they are swift and direct towards the apogee of the epicycle, and slow and retrograde towards its perigee.

[Margin: See Section 2, chapter 1, from no. 6 for the definitions and from no. 10 for the geometric calculation.]

De Proprietatibus, quibus Venus ac Mercurius ſic Differunt à trib. Superioribus, vt inter ſeſe Conueniant.

On the properties by which Venus and Mercury so differ from the three superior planets that they agree with each other.

II. First, the apogees of the eccentrics of Saturn, Jupiter and Mars always incline to the north and their perigees always to the south, and they never intersect or cross the ecliptic. But the apogee of Venus and Mercury, and likewise the perigee of the eccentric, undergo every alternation: they take now a northern latitude, now a southern, and sometimes they coincide with the plane of the ecliptic.

[Margin: 1. Property, in the quarter of the apogee.]

Second, although *Messhala* [Māshāʾallāh], in the book *De Orbibus*, rightly said that all the planets are tied to the Sun as if by a chain or rope, the three superior planets are tied to the Sun as regards the second motion, that is, the revolution of the epicycle, and free as regards the first motion, that of the eccentric. Venus and Mercury, by contrast, are free of the Sun's motion as regards their own motion on the epicycle, and tied to the Sun as regards the motion of the eccentric. For the mean motion of the centre of the epicycle, which is carried by the eccentric deferent but moves regularly about the centre of the equant in the order of the signs, is precisely as great as the Sun's mean motion, and indeed is to be computed uniformly from the same starting point. It follows that the line of the mean motion of these planets falls on the same points of the zodiac as the line of the Sun's mean motion; that they are always in mean conjunction with the Sun; that once the Sun's mean motion has been found, the mean motion of Venus and Mercury in longitude is known at once; and that no special tables are needed for it, the canons of the Sun's mean motion being enough. *Reinhold*, moreover, in his commentary on Peuerbach, p. 117, set out the theory of the line of mean motion of the Sun, Venus and Mercury with this diagram, in which D is the centre of the world,

[Margin: 2. Property, in the motion of the eccentric.]

[Margin: Reinhold's diagram.]

Diagram. Reinhold's diagram, set in the left column between the two parts of its sentence: a large outer circle, the ecliptic, with concentric-looking and eccentric circles inside it, a vertical line from A at the top to K at the bottom, an oblique line from H at the lower left to I at the upper right, and several parallel oblique and horizontal lines joining the inner centres to points on the circles. A rayed Sun sign stands at L on the second circle, a tilted ♀ sign stands at the upper right of the Venus circle, and a tilted ☿ sign stands at the left of the small Mercury circle.

- A (top of the outer circle): start of the line of apsides ADK; beginning of Cancer in the text
- G (just below A, on the vertical line): point on the Sun's orb
- B (upper, left of the vertical line): point on the orb of Venus; centre of Venus's epicycle when the Sun is at G
- ♀ (upper right): planetary sign of Venus
- I (upper right, at the end of the oblique line): end of Mercury's line of apsides
- T (above centre, on the vertical line): centre of Mercury's epicycle when the Sun is at G
- ☿ (left of centre): planetary sign of Mercury
- E (centre, above D): centre of the Sun's eccentric
- C (small letter, directly below E): centre of Venus's eccentric
- D (centre): centre of the world
- P (just below and to the left of D, on the oblique line): centre of Mercury's eccentric
- L, with ☉ (right, on the Sun's orb): the Sun
- O (right, to the left of L): centre of Venus's epicycle when the Sun is at L
- S (right of P; the letter stands reversed): centre of Mercury's epicycle when the Sun is at L
- F (right, on the outer circle): beginning of Aries
- M (lower left, on the Sun's orb): the Sun when Mercury's epicycle stands under H
- Q (lower left, beside M): centre of Venus's epicycle in that case
- X (below centre, left of the vertical line): point on Mercury's orb
- R (bottom, on the vertical line): point on the orb of Venus
- N (below R, on the vertical line): point on the Sun's orb
- H (lower left, on the outer circle): beginning of Scorpio; Mercury's apogee
- K (bottom of the outer circle): end of the line of apsides ADK; beginning of Capricorn in the text

and from that centre the ecliptic AHKF is described, in which the beginning of Aries is F and that of Cancer is A. The centre of the Sun's eccentric is E, from which the Sun's orb GMNL is described, and the centre of the eccentric of Venus is C, from which the orb of Venus BR is described. These three

centres lie on one and the same line of apsides ADK, because Peuerbach and the Alphonsines held that the apogee A of Venus and of the Sun is the same, and the perigee K likewise, standing under the same place of the zodiac, namely the former at the beginning of Cancer, the latter at the beginning of Capricorn. But because they placed the apogee of Mercury under the beginning of Scorpio, H, the line of apsides of Mercury is HI, with the apogee on it under H, the perigee under I, and the centre of the eccentric at P, from which the orb of Mercury STX is described. So the eccentricity of the Sun is DE, that of Venus DC and that of Mercury DP. Now with the Sun at G, the centre of the epicycle of Venus is at B and that of Mercury at T. In this case the line TX is the line of the mean motion of Mercury only, while AK is at once the line of the mean and of the true motion of the Sun and of the centre of Venus's epicycle, supposing that they share the place of the apogee. Now let the Sun be at L. The line of the Sun's mean motion will be EL; DF, parallel to it from the centre of the world, will mark on the ecliptic the point F, the place of the mean motion. The line of the mean motion of Venus will be CO, with the centre of the epicycle at O, and the line of the mean motion of Mercury will be PS, with the centre of its epicycle at S. Both are parallel to the lines EL and DF, and so the mean motion of these three planets will be at the beginning of Aries, F. Now let the centre of the epicycle of Mercury be under the apogee H, that is, on the line of its apsides, and occupy the beginning of Scorpio. Then, by the same agreement, the Sun will be at M and the centre of the epicycle of Venus at Q, and the lines of the mean motions of the Sun, EM, and of Venus, CQ, will be parallel to each other and to the line DPH, which in this case is the line both of the mean and of the true motion of Mercury as regards the motion of the centre. From these you will easily learn all the other cases. In one year, therefore, each completes a single revolution on the eccentric; and just as in the three superior planets the line of the mean motion on the epicycle is parallel to the line of the Sun's mean motion, so in the inferior planets is the line of the mean motion on the eccentric.

Third, as I have already indicated, they differ from the three superior planets as regards motion on the epicycle. The three superior planets complete one revolution in one year, and once each year the Sun is joined to them in mean conjunction when they are placed at the apogee of the epicycle, and once is opposed to them in mean opposition at its perigee. But Venus and Mercury, free of this relation as regards their own motion on the epicycle, complete their synodic revolution in a different time. By its mean motion Venus completes the epicycle in about 19 months, or $583^{d}\ 22^{h}\ 15^{m}$, whereas 19 solar months contain $578^{d}\ 7^{h}\ 13^{m}$. Mercury completes its epicycle by its mean motion in about $115^{d}\ 21^{h}\ 5^{m}$, repeating the variations of the epicycle more than three times a year. So in the number of its motions Mercury is swifter than Venus, since in the time that Venus runs through its epicycle once, Mercury flies around its own about five times, even though in the distance and size of its arc it may be slower. For the arc that Venus completes in one day, taken absolutely, is greater than

the arc Mercury completes in 5 days, each on its own epicycle; and by the Ptolemaic measures one degree of Venus's epicycle almost equals ten degrees of Mercury's.

[Margin: 3. Property, in the motion of the epicycle.]

[Margin: Whether ☿ is swifter on its epicycle than ♀.]

Fourth, the three superior planets, being slower than the Sun in mean motion on the eccentric, and indeed in true motion too, are so left behind by the Sun that at times they stand a whole semicircle of the zodiac away from it and are opposite to it, and can be observed in their acronychal positions [in Acronychijs] wholly free of the second inequality. Venus and Mercury, by contrast, because with the centre of their epicycle they perpetually keep the Sun's mean motion and the mean conjunction with it, and do not revolve on an epicycle so great that it encloses the Earth within itself, can neither digress from the Sun by a whole semicircle of the zodiac nor ever be opposite to it. Indeed, Venus does not digress even 50° on either side of the Sun, nor Mercury 30°. So it comes about that they are joined with the Sun not only at the apogee of the epicycle but also at the perigee, rising there cosmically once again, whereas on the contrary the three superior planets are opposite the Sun at the perigee of the epicycle, and rise there acronychally. From this follow other properties concerning morning and evening risings and settings, but these are the chief. First, since they are freed of the second inequality only at their two conjunctions with the Sun, and at those times lie hidden under the Sun's rays, they can never be observed by us except when entangled in the second inequality. Second, they appear swiftest when in the morning they

[Margin: 4. Property, in the elongation from the Sun.]

verge to their heliacal setting, or in the evening to their heliacal rising, phases which the three superior planets lack. But when they are heading in the evening to their heliacal setting and in the morning to their heliacal rising, in which case the three superior planets are swiftest, the inferior planets on the contrary are heading for their stations, namely after the evening greatest elongations from the Sun and before the morning ones. But see Scholium 3 below.

Fifth, although according to some ancient astronomers the three superior planets are so called because they are always carried above the Sun, and Venus and Mercury are called inferior because they are carried below it, yet according to others, not only more recent but older ones as well, they revolve now above and now below the Sun, as was shown in Section 1, chapter 4.

[Margin: 5. Property, as regards order in the system.]

Sixth, if you believe Copernicus, who reformed Ptolemy and Alfonso, the eccentricity of ♀ is variable, as is that of ♂, according to the varying eccentricity of the Sun.

[Margin: 6. Property, in the eccentricity.]

Seventh, according to the same Copernicus, in the superior planets the apogees and perigees are determined by reference to the planets in the annual

orb itself, whereas conversely in these inferior ones they are determined with respect to the centre of the Earth, wherever it may be, and by the Earth's annual motion they are carried through all the places of the deferents. The epicycles of the three superior planets are commensurable with the radius of their own eccentric, whereas the epicycle of these with the radius of the great orb.

[Margin: 7. Property.]

De Proprietatibus folius Veneris.

On the properties of Venus alone.

III. Apart from the measures of the orb and the numbers of its own motions, which are treated at the end of the chapter, *Alfonso*, and with him *Peuerbach*, held that the apogee of Venus is always the same under the zodiac as that of the Sun, and shifts with an equal motion. So since the mean motion of the Sun and of Venus is the same, the mean anomaly of the centre of Venus's epicycle (which they call the mean centre) is as great as that of the Sun, that is, as great as the Sun's argument. But Ptolemy found the apogee of Venus at 25° ♉ and the apogee of the Sun at 6° ♊, and now too they are in different places, as we shall say later. Again, in Ptolemy's time, the ratio that the eccentricity of the Sun had to the radius of the solar orb was the same as the ratio that the total eccentricity, or that of the equant, had to the semidiameter of the eccentric of Venus, as Ptolemy shows. The Alphonsines too, although they changed the measure, kept this ratio, and gave the equant of Venus an eccentricity equal to the solar one, namely 2° 16′ 6″, in parts of which the radius of the eccentric is 60, and half of that to the eccentricity of the deferent, namely 1° 8′ 3″. If the centre of the equant were the carrier of the epicycle, as it is the regulator of the mean motion, this ratio would make the equations of the centre of Venus and of the Sun's argument equal; so if the place of the apogee of the Sun and of Venus were the same, the true place of the Sun and the true place of the centre of Venus's epicycle would be the same, as the Alphonsines wished. But because both of these assumptions are false, there is some difference between the equations already mentioned. Venus also has this property: what happens to Mercury when it declines to the south happens to Venus, in the same way and by the same laws, when it inclines to the north. According to Copernicus, however, it is proper to Venus that its apogee is always 48° 21′ from the first star of ♈ and does not move, unless the fixed stars are supposed to move, which he does not suppose, and that Venus at apogee is at perihelion and at perigee at aphelion. Recent astronomy requires this, as I shall say in chapter 3, no. 5, and chapter 4, no. 6.

[Margin: Whether ☉ and ♀ have the same apogee.]

[Margin: Whether ☉ and ♀ have the same eccentricity.]

[Margin: The fallacy of this analogy.]

De Proprietatibus folius Mercurij.

On the properties of Mercury alone.

IV. None of the minor planets is more entangled in its motions than Mars and Mercury, or involves greater tangles in its theory, especially as regards the shifting of the eccentricity and of the apogee, so much so that this heavenly Mercury has tormented astronomers no less than the earthly one eludes alchemists. See what Copernicus himself admits about himself in chapter 2, no. 9, below, in our text, and recall the errors of the old astronomy concerning this star, of which I spoke in Section 1, chapter 6, no. 5. To make these things understood, they must be illustrated by two or three figures. The first is the one also used by Copernicus, Book 5, chapter 25, and *Lansbergen* in the *Theoricae*, chapter 13, though these enclose it within the annual orb of the Earth. But *Peuerbach*, and *Reinhold* on him, p. 114, *Wurstisen*, p. 204, *Osualdus*, p. 205, and *Magini* in the *Theoricae*, p. 46, enclosed it within the ecliptic, stuffing the orbs of Mercury with solid matter, whereas *Ptolemy*, Book 9, chapter 7, and *Longomontanus*, Book 2 of the *Theorica*, chapter 20, represented those orbs bare and in mere circles.

Let C, then, be the centre of the Earth and the world, from which is described the convex surface ALFM of the outermost black orb and the concave surface VGX of the innermost black orb; and let D be the centre of the equant

Diagram. A figure set in the right column: a broad black ring (solid orb) with a thin white band of circles inside it, and within those a second black ring around a white central disc. A vertical line runs from A at the top to F at the bottom; two near-horizontal lines cross the whole figure, the upper from Z to P and the lower from L to M, with a third line through R and Q. A small circle stands in the white band directly under A, and a small circle (circellus) stands at the top of the central white disc on the vertical line.

- A (top, outside the black ring): upper end of the vertical line
- small circle under A (on the vertical line): O (top, left of the line), T (top, right of the line) and I (below the crossing line); a small star-shaped mark stands at its left edge
- S (upper left, in the white band): standing on the circles; not cited in the text so far on this page
- N (upper right, in the white band)
- Q (left, in the white band)
- R (right, in the white band)
- Z (far left, outside the ring): left end of the upper horizontal line
- P (far right, outside the ring): right end of the upper horizontal line
- L (far left, outside the ring, below Z): left end of the lower horizontal line
- M (far right, outside the ring, below P): right end of the lower horizontal line
- E (centre, at the top of the small circle)
- B (centre, in the small circle)

- D (centre, at the foot of the small circle)
- C (centre, below D, where the vertical and lower horizontal lines cross)
- V (white disc, left of C)
- X (white disc, right of C)
- G (white disc, on the vertical line below C)
- K (lower, on the vertical line, in the white band)
- H (lower, immediately left of K)
- F (bottom, outside the black ring): lower end of the vertical line

circle HNI, at a distance from the centre of the world of 3 of the parts of which the radius DI of the eccentric is 60. Let B, the centre of the small circle that causes the anomaly of the eccentricity, be the same number of parts from the centre of the equant, so that ED, its diameter according to Ptolemy, is 6 parts. At its apogee E let there be the centre of the deferent TQKR, 9 parts from the centre of the world. On its circumference this deferent has T, the centre of the epicycle carrying Mercury. Through O, the apogee of that epicycle, with the centre of the deferent set at the apogee E of the small circle, is described the concave surface OQHR of the outermost black orb; and through the perigee I, from the same centre at E, the convex surface IN of the innermost black orb. These black orbs are called the deferents of the apsides, or of the apogee and perigee. But each is subdivided into two portions: of both the innermost and the outermost black orb, the outer portions carry the apogee of the equant, while the inner portion of each carries the apogee of the deferent. Let LCM be the axis of the orbs carrying the apogee of the equant in the order of the signs, following the motion of the eighth sphere, or of the fixed stars; QER the axis of the deferent of the epicycle; and ZBP the axis of the orbs carrying the apogee of the eccentric. Now on the small circle of the anomaly of the eccentric let the centre of the deferent of the epicycle move above against the order of the signs and below in the order of the signs, with an annual motion equal to the Sun's mean motion, so that once a year it is united with the centre of the equant D, and once is at its greatest distance from it at E. But the line of the apogee of the equant, which is ADF, and the centres D and B on it, move very slowly, and only with the motion of the eighth sphere. The line of the apogee of the eccentric deferent of the epicycle, however, is always the one drawn from the centre of the world through the centre of the deferent of the epicycle as far as the circumference of the equant. In the part within which the centre of the equant lies, it marks the apogee of the deferent, which in this diagram is the point T, and in the other, opposite part it marks its perigee K. This line is not fixed like the line of the apogee of the equant, but is driven to and fro by a certain reciprocal motion, one that nevertheless agrees with the periodic motion of the eccentric. Moreover, the centre of the epicycle, following the motion of the deferent, moves in the order of the signs with the same mean motion as the Sun.

V. From what has been said it follows, first, that the point under which the apogee of the equant stands and that under which the apogee of the eccentric

stands are not always the same, as they are in the other planets, the point from which the anomaly of the eccentric is accordingly counted, but are usually different; and that the anomaly of the eccentric by which the equation of the centre is taken from the tables is counted from the apogee of the equant, and not, strictly speaking, from the apogee of the deferent, inasmuch as from a

[Margin: Porisms or corollaries.]

[Margin: 1. Mercury's difference from the others.]

more certain and stable point, movable only with the motion of the fixed stars. Second, it comes about that when the apogee of both is on the same line AF, the apogee of the deferent is nevertheless not farthest from the centre of the world, nor its perigee nearest. For when the centre of the deferent is united with the centre of the equant, the apogee of the deferent comes nearer the centre of the world, and the perigee farther from it, by 6 parts of the 60 of the radius, than when the centre of the deferent is at the apogee E of the small circle. Third, it comes about that the centre of the equant is not twice as far from the centre of the world as the centre of the deferent, as it is in the other planets, nor is their distance from each other always as great as the distance of one of them from the centre of the world. Rather, the centre of the deferent is usually farther from the centre of the world than the centre of the equant; once a year it is equally far, and once three times as far. But this is not yet the end of the differences and variations. There remain those that depend on the unequal and reciprocal motion of the true apogee of the eccentric deferent of the epicycle, and the resulting disagreement with the other planets in the greatest equations of the orb and in the proportional minutes. To explain these we shall use the following figure.

[Margin: 2. Difference of ☿.]

[Margin: 3. Difference of ☿.]

VI. The following figure is set out by the commentators on Peuerbach's *Theoricae*: *Reinhold*, p. 121, *Osualdus*, p. 211, *Wurstisen*, p. 227, and *Magini* in his *Theoricae*, p. 51, though not without some errors and with omission of the geometric calculation, which we shall add. In it A is

Diagram. A figure set in the left column, showing an egg-shaped closed line round the Earth's centre A, with a vertical line from the top through H, P, C, B, D and A to G. A curved crescent-shaped line runs through M, O, P, I and L beneath an arc through N, H and K. Small circles stand at H (top), F (left), E (right) and G (bottom), and a small circle round B stands above A, with straight lines radiating from A and from D to the points on the curves.

- λ (top, above the small circle at H): cited on the following page as Hλ, the semidiameter of Mercury's epicycle
- H (top, inside the small circle)
- N (upper left, on the arc)
- K (upper right, on the arc)
- P (on the vertical line, below H)
- M (left, at the end of the crescent-shaped line)

- O (left of P, on the crescent-shaped line)
- I (right of P, on the crescent-shaped line)
- L (right, at the end of the crescent-shaped line)
- a mark shaped like the numeral 2 (far left, on the outer circle of the equant) [?]
- β (far left, on the egg-shaped line, joined by a line to R through V): cited on the following page as the place of the centre of the epicycle when the centre of the deferent is at R
- V (upper left of the small central circle)
- C (top of the small central circle, on the vertical line)
- R (upper right of the small central circle)
- B (centre of the small central circle)
- S (left of the small central circle)
- D (foot of the small central circle)
- Q (right of the small central circle, in a decorated form)
- A (below D, where the radiating lines meet)
- F (lower left, in a small circle)
- a mark shaped like ε (right of F) [?]
- E (lower right, in a small circle)
- a mark shaped like a reversed ε (left of E) [?]
- Y (below A, left of the vertical line)
- Z (below A, right of the vertical line; the letter is imperfectly formed)
- X (lower left, on a small arc)
- T (lower right, on a small arc)
- G (bottom, inside the small circle)

the centre of the world, B the centre of the small circle CD of the anomaly of the eccentricity, divided into 12 signs, and D the centre of the equant, from which the equant PG is described and divided into twelve signs. The line of the apogee of the equant is GP, its apogee P and its perigee G. On this line, when the centre of the deferent is at the apogee C of the small circle, the apogee of the deferent is H and its perigee between Y and Z. But if the centre of the deferent is at V, the line of the apogee of the deferent is NZ, with the apogee at N and the perigee at Z on it. If the centre is at R, the apogee is K and the perigee Y. If it is at the point Q or S, where the line of the apogee touches the small circle, the apogee is at L in the one case and at M in the other, and the perigee at X or T. The motion of the centre of the deferent, moreover, equal to the Sun's mean motion, takes place against the order of the signs from C to R, even though the motion of the centre of the epicycle, likewise equal to the Sun's mean motion, takes place in the order of the signs. And because the semidiameter BD of the small circle is as great as AD, it comes about that the straight lines ASM and AQL, which touch the small circle, enclose the arc SDQ of 120°, or a third of the small circle, and that the upper portion SCQ of the small circle is 8^{s}, or 240°. With this set out, one must understand that the apogee and perigee of the eccentric do not make whole circuits under the zodiac, but through the

whole periodic time are contained and move back and forth within the already mentioned tangents MSAT and LQAX, that is, within the arc of the zodiac enclosed by those lines when produced, even though the centre of the eccentric runs through the whole small circle of the anomaly of the eccentricity. So when the centre of the eccentric runs through the upper part of the small circle from S, through VCR, to Q, the apogee of the eccentric deferent too is carried against the order of the signs from M, through NHK, as far as L, and the perigee likewise against the order of the signs from T, through Z, as far as X. But when the centre of the deferent is carried through the lower portion from Q, through D, to S, following the succession of the signs, the motion of the apogee takes place from L, through IPO, to M, and that of the perigee from X, through G, to T. Accordingly, when a whole period is completed, the apogee marks out a line [Greek: μηνοειδὲς (mēnoeides, "crescent-shaped")], namely MNHKLIPOM, resembling the sickle Moon, while the perigee marks out a line nearly [Greek: κογχοειδὲς (konchoeides, "shell-shaped")], that is, resembling a shell, or rather a rose petal. From this it also follows that the motion of this apogee is slowest when the centre of the eccentric is at the apogee of the small circle, but swiftest when it is at its perigee.

VII. Given, then, the double motion already mentioned, namely of the centre of the epicycle in the order of the signs and of the centre of the deferent against that order, it comes about, first, that when the centre of the deferent occupies the apogee C of the small circle, the centre of the epicycle is at H and at its farthest from the centre of the world, namely 69 parts, of 60 of the radius; and if Mercury is then at the apogee of the epicycle, it has the greatest distance from the Earth that it can have anywhere, which now happens in the month of October, about the beginning of Scorpio. But when the centre has come round to D, the apogee of the deferent is at P, the apogee of the equant. Second, when the centre of the deferent has sunk to the western point of contact Q, which now happens in February, about the beginning of ♓, after passing through the four signs of the arc CRQ, the apogee of the deferent stands as far as possible from the apogee of the equant, and the perigee from the perigee. The centre of the epicycle, having completed four signs in the order of the signs, comes to be at F, with the line FQ drawn through the centres of the equant and the deferent. And although F is at the perigee of neither eccentric (taking perigee for the point G, opposite the apogees H and P), it is nevertheless nearest the Earth, so much so that it could not be nearer, and so F is equivalently the perigee of the deferent. For the distance AF of the centre of the epicycle from the centre of the world is then 55° 33′ 30″, in parts of which DP is 60. But when the centre of the deferent is at D, the centre of the epicycle is united with the fixed perigee G of the equant, yet it stands from the centre of the world by the amount AG, that is, 57 parts, namely after subtracting from the radius DG the 3 parts of the eccentricity AD; this now happens in April, shortly after the beginning of ♉. In the same way, when the centre of the deferent has climbed to the eastern point of contact S, the point E, where the centre of the epicycle is, will be equivalent

to the perigee, and it will again come nearest to the Earth by the amount of the line AE, namely 55° 33′ 30″; this now happens in June, shortly after the beginning of ♋. Third, it follows from what has been said that in one annual revolution the centre of the epicycle is at its farthest from the centre of the Earth only once, and comes nearest to it twice, because of the double equivalent perigee, and yet at those times it is not at the fixed perigee, that is, the one belonging to the ordinary line of apsides, and indeed not at the perigees of the eccentric XT, etc. These things could seem absurd at first hearing, but they are handed down by Ptolemy, Book 9, chapter 8. Fourth, it comes about that only once in one period the centres of the equant and of the deferent meet at D, the perigees of both meeting then, once, at G; at other times those centres are always apart, and most of all at C. And so, considering the direct motions of the centre of the epicycle and the retrograde motions of the centre of the deferent, the centre of the epicycle moves more slowly towards the perigee of the equant and more swiftly towards the apogee in relation to the centre of the deferent (in which it differs from Venus and the superior planets), although with respect to the centre of the zodiac it is carried more slowly around the apogee of the equant and more rapidly around the perigee, in which it agrees with those planets. Fifth, it comes about that the movable perigee of the deferent, away from the apogee or perigee of the equant, is always in that semicircle of the zodiac in which the centre of the epicycle is, though sometimes preceding and sometimes following the centre of the epicycle. Sixth, it happens that the centre of the epicycle by its motion does not describe a circular circumference, but [Greek: ᾠοειδὲς (ōoeides, "egg-shaped")], or almost oval, wider at the apogee and narrower at the perigee, such as the line HMFGELH. Seventh, it happens that the equations of the argument or orb (which become greatest when the centre of the epicycle to the centre of the world

[Margin: 1. Corollary, and 4th difference of ☿.]

[Margin: 7. Corollary, and 8th difference of ☿.]

comes nearest) do not occur at the perigee of the eccentric deferent of Mercury's epicycle, as in the others, but at two other points, namely F and E, that is, when the centre of the deferent reaches the two points of contact of the small circle, Q and S; and the greatest digressions occur at those same places. Ptolemy, Book 9, chapter 8, finds that these occur in the morning in Aquarius and in the evening in Gemini. For the same reason it was necessary to construct tables of the equations of the orb of ☿ different from those of the other planets; and the proportional minutes of which we spoke in Section 2, chapter 12, number 5, must be arranged so that they are least at the apogee and whole, or 60, against 4 and 8 completed signs of anomaly, and decrease in

order from those places as far as the semicircle of anomaly, or the perigee, at which for Copernicus they are only 52′ 21½″. Eighth, Venus has the least and Mercury the greatest eccentricity in proportion to the radii of their orbs, so that the two eccentricities of the inferior planets equal those of the Sun and of the three superior planets. Hence the daily eccentric motion of Venus is of the least variation and that of Mercury of the greatest, so much so that Mercury's daily perihelial motion is more than double its daily aphelial motion. Therefore the old astronomy could err little in predicting the place of Venus, but a great deal in Mercury, as Kepler points out in the *Epitome of Copernican Astronomy*, page 768.

[Margin: 8. Corollary, and 9th difference of ☿.]

The remaining properties by which it differs from Venus in the Copernican hypothesis I shall indicate in chapter 2, number 7.

Methodus inueſtigandi Eccentricitatem Mercurij extra Apogeum & Perigeum.

The method of finding the eccentricity of Mercury outside the apogee and perigee.

VIII. I said above that the form of the geometric calculation by which the true place of a planet is sought is exactly the same in ♀ and ☿ as in the three superior planets, as set out in Section 2, chapter 1, from number 10, provided that the eccentricity is known. Since in Mercury it varies, it remains for us to teach the method of finding it, which the authors have omitted. So, in the figure immediately preceding, when the centre of the deferent is at C or at D, there is no need of an equation of the centre; but when it is elsewhere, an equation of the centre is needed. Let the centre of the deferent, then, be at R, with two signs of the small circle completed. For then the centre of the epicycle, by its mean motion, has completed two signs in the order of the signs, to be reckoned in the equant, that is, the arc Pγ. So, when the semidiameter of the deferent is drawn from R towards γ, the centre of the epicycle will fall at β. From β draw the straight line βA to the centre of the world, and the straight line AR, namely the eccentricity to be found; and from the centre of the small circle of the anomaly of the eccentricity draw to the centre of the deferent the straight line BR. For there will arise the triangle ABR, in which there is given AB, the eccentricity of the centre B, which is 6 parts, and the semidiameter BR of the small circle, half of it, or 3 parts, of which the radius Rβ is 60; and the angle they contain, ABR, is the complement of the angle CBR, which measures the arc CR. Therefore, with trigonometry as your guide, you will find the eccentricity AR; and with it, the radius Rβ and the angle ARβ, which is the complement of the angle IRβ, that is, of the anomaly of the eccentric counted from the apogee I, you will find in the triangle ARβ the equation of the centre, that is, the angle AβR, and Aβ, the distance of the centre of the epicycle from the centre of the world, which is needed for finding the equations of the orb. But if the centre of the deferent is at the points of contact S, Q, which are a

third of the circle apart from each other, the straight line drawn from them to the centres of the epicycle, namely SDE and QDF, passes through D, the centre of the equant. Therefore in the triangles ADQ and ADS the side AD is given, its eccentricity of 3 parts, and each of the sides DQ and DS is just as much. For since the arcs DQ and DS are 60°, the angle BDQ is 60°, and the chord DQ equals the semidiameter BQ, which likewise is 3 parts. So the eccentricity AQ, or AS, will not be hidden.

[Margin: By 15 of Book 4 of Euclid.]

IX. It remains for us, in our usual manner, to present the measures and numbers that are the foundations of the geometric and logistic calculation in this hypothesis, from Ptolemy, Books 8 and 9, from the Alphonsine Tables, and from the other authors brought forward in numbers 1 and 6. Of these, Magini takes the measures and numbers from Copernicus, although he uses the Ptolemaic or Peuerbachian hypothesis as regards the figure and the immobility of the Earth; and with Copernicus he supposes that the apogee of Venus is always 48° 21′ from the first star of ♈. When the precession of the equinoxes, or the motion of the fixed stars from the equinox, is added to these, the motion of the apogee of ♀ from the equinox becomes known. Besides these authors, the same measures are given by *al-Battānī*, chapter 50; *Egnazio Danti*, in his tables, from page 33; *Barocius*, Book 1 of the *Cosmographia*, page 48; *Maurolico*, at the end of his *Cosmographia*, and from him *Clavius*, at the end of the *Sphere*; *Baranzanus*, from Giuntini and Mauro Fiorentino, in part 1 of the *Uranoscopia*; *Tycho*, volume 1, page 468; and *Kepler*, in the *Epitome of Copernican Astronomy*, page 494. Note, however, that the measures listed below, as regards the semidiameters of the Earth, are set down according to Ptolemy by Maurolico, Clavius and Barozzi, rather than according to Alfonso, because Maurolico declares that the Ptolemaic distances of the Sun are more convenient for exhibiting the distances of the inferior planets.

	Alfonso	♉	20	37	0	0
☿	Ptolemy	♌	1	10	0	0
	Alfonso	♌	19	51	11	41

For Ptolemy the motion of the apogees of the 5 planets is of the same quantity as that of the fixed stars, namely 36″ a year, as he teaches in Book 9, chapter 7. For Alfonso, however, the motion of the apogee of Venus and of the Sun is the same, both as motion and in quantity; that of the others is the same as that of the eighth sphere, on which see Book 6, chapter 16. In his own time Ptolemy observed the apogee of Venus at 25° of Taurus and that of Mercury at 10° of Libra.

On the greatest digressions and equations it will be more fitting to speak below in chapter 7, and on the periods on the epicycle at the end of this Section.

SCHOLIA.

Scholia.

I. Among the hypotheses of the older astronomy, one is that of al-Biṭrūjī, which I touched on in the last chapter of Section 1 of this Book, and which is treated in the Book of Systems; another, commonly rejected by those more skilled in astronomy, is that of homocentric, or concentric, orbs, which Amicus, Girolamo Fracastoro and a few others tried to introduce. For even if it were equivalent to the others as regards logistic calculation, it can uphold the increases and decreases of the apparent diameter, especially in Venus and Mercury, and those phases that the telescope has revealed, only with the greatest violence,

since that hypothesis supposes that the planet's distance from the Earth is always the same. So there is no reason for us to dwell on these. On Mercury's greater nearness to the Earth at the sextants from the perigee, see what is to be said in chapter 4, Scholium 3.

[Margin: On the hypotheses of Alpetragius and Girolamo Fracastoro.]

II. That Venus and Mercury, in the Ptolemaic hypothesis, can be so near the Earth that Venus at perigee can undergo a parallax of 20′, and Mercury, at its greatest approach to the Earth, as great a parallax as the Moon at apogee, does indeed conflict with the phenomena: for it does not come nearest to the Earth at the sextile counted from the perigee, although it digresses most there. This was the occasion of Ptolemy's error, as Copernicus, Book 5, chapter 28, and Longomontanus, Book 2, chapter 20, point out. Further, the old astronomy must be pardoned, since neither through the telescope nor through other better observations did it have arguments for raising Venus and Mercury higher and arranging them around the Sun. From this, and from the difficulty of observing Mercury, and from what was said in number 7, Corollary 8, arose the error in the Alphonsine and Ptolemaic calculation of Mercury, as great as we said in Section 1, chapter 6, number 5. On the fallacy of using the Sun's mean place rather than its true place, we shall speak in the Scholia to chapter 2, since Copernicus shared it. On the inequality of motion about its own centre, which is admitted most of all in ☿, enough has been said in the Scholia to chapter 1, Section 2.

[Margin: On the excessive parallax of ♀ and ☿.]

[Margin: On the errors of this hypothesis.]

III. Among the properties by which the stars of Venus and Mercury are distinguished from the superior planets, of which we spoke in number 2, Pliny the Elder touches on the fourth, Book 2, chapter 17, in these words: "From this, too, the reversed pattern of their motions is understood. For the superior planets are carried most swiftly at their evening setting, these two most slowly; the former are at their highest from the Earth when they move most slowly, the latter when they move most swiftly, because just as in the former the nearness of the centre speeds them up, so in the latter does the extremity of the circle. The former begin to lessen their speed from their morning rising, the latter to increase it. The former run their retrograde course from the morning station to the evening one; the star of Venus from the evening one to the morning one. It begins, moreover, to climb in latitude from its morning rising, and to climb in altitude and follow the Sun from its morning station, being swiftest and highest at its morning setting. It begins to depart in latitude and to lessen its motion from its morning rising; to go backward, and at the same time to depart in altitude, from its evening station. The star of Mercury, again, begins in both respects to climb

[Margin: Pliny the Elder's view of the properties of ♀ and ☿.]

from its morning rising, but to depart in latitude from its evening one; and when the Sun has caught up with it to an interval of 15°, it stands almost motionless for four days, etc."

CAPVT II.

Chapter II.

De Hypotheſi Copernicæa Veneris ac Mercurij.

On the Copernican hypothesis of Venus and Mercury.

Theorica Veneris.

The theory of Venus.

I. If you have had a first taste of the Copernican system in Book 3, chapter 6, number 3, and have understood the theory of the three superior planets given in this Book, Section 2, chapter 2, number 4, you will more easily understand the hypothesis of Venus, which is set out by *Copernicus*, Book 5, from chapter 20 to 25; by *Rheticus*, in his *Narratio*; by *Kepler*, in the *Epitome of Copernican Astronomy*, Book 6, part 3, from page 757; by *Michael Mästlin*, in his notes on Kepler's *Prodromus*, chapter 15, and in his Appendix to the same book; and by *Longomontanus*, Book 2 of the *Theorica*, chapters 17 and 18. According to these authors, then, the Earth is moved around the Sun, which is motionless at the centre of the world, along the annual orb towards the east; and Venus, within the annual orb, along an orb eccentric to the Sun, but varying its eccentricity by means of a small circle, is likewise moved to the east, but leaping ahead of the Earth and with a swifter motion. For it completes its course in about 9 or 8½ months, but returns to the Earth in 19 months; yet in such a way that this eccentric stands in place of the Ptolemaic epicycle, while in place of the eccentric deferent, on which it is believed to be moved in its mean motion of longitude, stands the annual orb of the Earth itself. And they think this is the genuine reason why the three eccentrics of the old hypothesis, namely of the Sun, Venus and Mercury, have equal revolutions and why their mean motion is the same: namely because they themselves do not revolve, but in their place the Earth alone. So by the single annual motion of the Earth and the single motion of the epicycle, or, as Rheticus calls it, of the second eccentric, they explain all the appearances of Venus and Mercury. For if these planets stayed as fixed as the Sun, we, they say, who are carried around them by the motion of the great orb, would still think that they move like the Sun and travel through the zodiac. But because observations attest that Venus and Mercury, beyond the mean motion of the Sun, move on their orbs with their own motions, and now precede the Sun, now follow it, and are conjoined with it now above and now below, we therefore assign them epicycles, which with their centre complete the zodiac at an equal pace with the Sun. This motion, then, compounded of two equal motions but appearing unequal to us, could indeed be exhibited in the threefold

form that we set out in Section 2, chapter 2, namely by an eccentrepicycle, or, as *Tycho* and *Longomontanus* later imitated it, by two epicycles; but it is better managed by an eccentric of the eccentric [Eccentri Eccētrum], that is, by an eccentric varying its eccentricity and position. For *Copernicus* himself chose this one, Book 5, chapter 22, in these words: "This star, however (he is speaking of ♀), has something different from those (that is, from the three superior planets) in the order and commensuration of their motions; and this will be shown more easily and conveniently, in my opinion, by an eccentric of the eccentric."

[Margin: Preparation for this hypothesis.]

II. Let, then, according to the wish of Copernicus[61], in the following diagram of Mästlin, the centre of the world, that is, the Sun, be E, or the point of the Earth's mean motion, around which let the great or annual orb of the Earth be RLQ; and let the diameter RAQ be set for the line of apsides of Venus, on which let the least eccentricity of the orb of Venus from the Sun be EM and the greatest EN, double EM, and their difference MN, which, bisected at A, is to have there the centre of the small circle MN, carrying on its own circumference the centre of the eccentric in the order of the signs, on this condition: that whenever the Earth is at the apogee of Venus Q or the perigee R, or whenever it falls on the line of apsides, the centre of the eccentric of Venus is at the least eccentricity from the centre of the world, that is, at M; but when the Earth is at the mean apse, or a quadrant away from the apogee or perigee of Venus, as if it is at L, the centre of the eccentric of ♀ is at the greatest eccentricity, that is, at N. From this it necessarily follows that in the time in which the Earth once travels through its annual orb, the centre of the eccentric of ♀ revolves twice

Diagram. Mästlin's diagram for the Copernican hypothesis of Venus, set in the right column between the two parts of its sentence: a large outer circle, with a vertical diameter from R at the top to Q at the bottom; small circles on that diameter at the top (about I and D), at the centre (about A) and at the bottom (about F and B), and a fourth small circle at the right about C. Further circles, solid and dashed, lie inside the outer circle. Straight lines run from Q up to the left and to the right, from R down to the right and to Y, from L through the centre region to the upper right, from L to the diameter, and horizontally from P to the right-hand small circle.

- R (top of the outer circle): perigee of Venus in the text; the Earth at the perigee
- I (just below R, on the diameter, within the top small circle): cited in the text in IPGO
- D (below I, within the top small circle): not cited in the prose on this page
- H (on the diameter, below D): cited in the text in AH and HXG
- Y (upper left, inside the circles): foot of the tangent from R in the text

[61] the page prints *plani* here, which does not construe in this clause

- O (upper right, on the dashed circle; a small sort): cited in the text in IPGO
- T (right, above the small circle at C): not cited in the prose on this page
- N (on the diameter, above A): the greatest eccentricity EN in the text
- A (centre of the central small circle): centre of the small circle MN in the text
- C (centre of the small circle at the right): not cited in the prose on this page
- P (left, on the dashed circle): cited in the text in IPGO
- L (far left, on the outer circle): the Earth at a quadrant from the apsides in the text
- V (right, below the small circle at C): not cited in the prose on this page
- M (on the diameter, below A): the least eccentricity EM in the text
- E (on the diameter, just below M): the centre of the world, the Sun, in the text
- F (on the diameter, just above the bottom small circle): not cited in the prose on this page
- X (lower left, on an inner circle): Venus at the tangent from Q in the text
- B (on the diameter, within the bottom small circle): not cited in the prose on this page
- G (on the diameter, below B): cited in the text in IPGO and HXG
- Q (foot of the outer circle): apogee of Venus in the text

in the small circle MN. Copernicus, however, states, Book 5, chapter 22, that the greatest eccentricity EN was in Ptolemy's time 416 parts, of which the radius of the great orb is 10000, but that in his own time he found it to be 350 parts, just as, in Copernicus's opinion, the eccentricity of Mars too decreased, because of the diminished eccentricity of the Sun. And so Reinhold computed the equations of Venus on the supposition of an eccentricity of 350, as Mästlin demonstrates above from the Prutenic Tables. From what has been said it is clear that the eccentric of Venus does not describe a single path, and that there is not a single eccentric in the heaven but one after another, and that it wanders through all the places enclosed by two circles, one of which you have marked with points in the diagram, namely IPGO, while the other you are to imagine described from A at the interval AH.

III. So the greatest prosthaphaeresis of the centre occurs at 90° of the anomaly of the eccentric, computed on the annual orb from the line of apsides, as if the Earth is at L. The anomaly of the eccentric will be the arc RL, or the angle REL, and the greatest equation of the centre the angle ELN, because its foundation is the greatest eccentricity EN. The greatest prosthaphaereses of the orb, or elsewhere of the epicycle, which Copernicus calls prosthaphaereses of the parallax of the annual orb, occur when a straight line drawn from the centre of the Earth to Venus touches the orb of Venus and makes a right angle with the semidiameter of that orb. Therefore the greatest equation of the orb at

the apogee of the eccentric, Q, is, for example, the angle MQX, and it occurs with the Earth placed at Q and Venus at X (and understand the same of the other, similar place on the right), where the straight line QX touches the orb HXG and makes with the radius MX the right angle QXM. But the greatest one at the perigee, which is the greatest of all the greatest, is the angle MRY, in the triangle MYR, right-angled at Y, where RY touches the same orb of Venus as above.

[Margin: The places of the greatest equations.]

Methodus Calculi Geometrici in hac Hypotheſi Veneris.

The method of geometric calculation in this hypothesis of Venus.

IV. In the following figure let the line of apsides of Venus be ABD, on which let B, near the Sun, be the centre of the annual orb AED, and let the small circle of the eccentricity of Venus be CFL, whose centre K is distant from B by the amount BK, that is, three fourths of the whole or greatest eccentricity BL; and let the remaining fourth part be the small circle's semidiameter KF, if you follow the old hypothesis of Copernicus. For if you follow the recent one, BK will be 246 parts, which in the old was 312; but CK, in both, is 102 parts, of which the radius BE of the annual orb is 10000. Now let the Earth be at E, distant from A, the apogee of Venus according to mean motions, by the amount of the arc AE. This you will learn by subtracting the place of the apogee of ♀ from the mean place of ☉, and the mean anomaly of Venus will be known, and thus the angle ABE. Count, then, from the line AD, in the order of the signs, the arc CF of the small circle, which is to be double the arc AE; for the centre of the orb of Venus will be at F, from which you will describe the orb MING, and its eccentricity will be BF. Then from the Earth E draw three straight lines: namely EB, to the centre of the annual orb; EK, to K, the centre of the small circle; and EF, to F, the centre of the orb of ♀. Through F and through the centre B draw the straight line PFQ; and through the same centre F draw the straight line IH, parallel to the line BE of the mean motion of the Earth and of Venus (for the annual orb stands in place of the eccentric of ♀ and ☿). For H will be the mean apogee and I the mean perigee of the orb, but G the true apogee. Finally, let Venus be now at N, from which draw the straight lines NE, to the Earth, and NF, to the centre of the orb of ♀; and now at M, and draw the straight lines ME and MF. With these things laid down:

[Margin: Copernican diagram from Longomontanus, Book 2, chapters 17 and 18.]

Diagram. Set in the left column, inside the sentence naming the line EK. A large outer circle with a vertical diameter from A at the top to D at the foot. Inside it, a second circle about F, passing through N on the left, M on the right, I at the upper left, H at the lower right and G at the foot; N and M are marked by small stars. Inside that, a small circle about K, with L at its foot. From E on the outer circle at the upper left, straight lines run to N, to F, to K, to B and

to M. A dotted line runs from P on the outer circle at the upper right down through B and F to the outer circle at the lower left. Straight lines also run from N to F, from I through F to H, from F to K and from F to M.

- A (top of the outer circle)
- E (upper left of the outer circle)
- P (upper right of the outer circle)
- I (upper left of the second circle)
- B (on the vertical diameter, above the small circle)
- M (right of the second circle)
- N (left of the second circle)
- F (centre of the second circle)
- K (centre of the small circle)
- L (on the vertical diameter, foot of the small circle)
- H (lower right of the second circle)
- G (on the vertical diameter, foot of the second circle)
- Q (lower left of the outer circle, at the foot of the dotted line; a small sort with its tail crossed by the circle)
- D (foot of the outer circle)
- [?] (a very small sort just left of B, on the dotted line)

V. *First*, in the triangle BEK, BE is given, the radius of the annual orb, marking the mean place of the Earth E as seen from B; the place opposite to it in the zodiac is the mean place of the Sun as seen from the Earth. BK is also given, and the angle KBE contained by them, for it is the complement to two right angles of the angle ABE, known from the anomaly of the eccentric. From these, therefore, you will find both the angle BEK and the side KE; and the third angle, BKE, will be the complement of the other two to two right angles.

[Margin: Step 1, for the equation of the centre.]

[Margin: By Book 1, 32 of Euclid.]

Second, in the triangle KEF, the side KE has now been found, and FK is given, the semidiameter of the small circle, since it is a quarter of the whole eccentricity BL. The angle contained by them, FKE, becomes known if from the angle FKB, known from the doubled anomaly of the eccentric, you subtract the angle BKE already found. From these three givens, then, find both the side FE and the angle KEF. Add that to the angle BEK and the result will be the angle BEF: namely the whole prosthaphaeresis of the eccentricity, to be subtracted from the mean motion of the Earth, that is, from the motion opposite to the Sun's mean motion, in this first semicircle of the anomaly, AEQ, but to be added in the other, so as to give the place of the centre of ♀, coequated and seen from F, the centre of the orb of Venus; opposite to this is the place of the centre F, seen from the Earth E along the line EFG, etc.

[Margin: Step 2, for the same.]

Third, if Venus is at N, then in the triangle FEN the side FE has now been found; and FN is given from the table at the end of this chapter, otherwise the radius of the epicycle, now of the orb of Venus, in the parts in which BE,

the radius of the annual orb or the mean distance of the Earth and Sun, was known or assumed. The angle NFE is known from the anomaly of the orb, or of commutation, which here is the arc HIN, counted in the order of the signs from H, the apogee of the orb (otherwise of the epicycle). In our case, then, casting off the semicircle HMI leaves the arc NI, that is, the angle NFI, to which must be added IFE; because the lines HI and BE are parallel, IFE is equal to the angle BEF, that is, to the prosthaphaeresis of the centre already found, and so the whole NFE will be known. By means of trigonometry, therefore, both the side EN will be found, which is the distance of Venus from the Earth, and the angle at the Earth, or FEN, which is the prosthaphaeresis of the orb, or the equation of the parallax of the annual orb. In this position, namely in the later semicircle of the anomaly of the orb, it must be subtracted from the equated place of the centre, or the eccentric place of the planet, so as to give the true place of the Earth seen from Venus along the line NE, to which the true place of ♀, seen from the Earth and computed from the mean equinox, stands diametrically opposite in the zodiac. If the prosthaphaeresis of the equinoxes is applied to it, the place of the same planet from the true equinox will be obtained. Now imagine Venus at M. For the triangle MEF will have to be solved, in which the radius FM is given, and the side FE has been found, as before; and the angle MFE will become known as follows. The anomaly of the orb is the arc HM, namely the angle HFM; its complement to two right angles is the angle MFI. If from this you take away IFE, equal to the angle BEF, or the prosthaphaeresis of the centre, because the lines HI and BE are parallel, MFE will be left. You can therefore find ME, the planet's distance from the Earth, and the angle FEM; subtracting from it the angle BEF leaves BEM, the equation of the orb, to be added in the first semicircle of the anomaly of the orb to the coequated place of the centre itself, so as to give the true place of the Earth, seen from Venus along the line ME, to which is opposed in the zodiac the place of Venus seen from the Earth E, etc.

[Margin: Step 3, for the equation of the orb, or of commutation.]

[Margin: The other case, for the other position of Venus.]

VI. I pass over examples, both because I have now set out this method clearly and distinctly, so that the obscurity found until now in other authors seems to me to have been removed, and because after Section 2 has been understood I take the student of astronomy to be so trained and advanced as not always to need the support of examples. You can, however, see them sketched in *Copernicus*, Book 5, chapter 23, and in *Longomontanus*, Book 2 of the *Theorica*, chapters 17 and 18, or from me below, chapter 11, numbers 7 and 8, where this diagram is explained more clearly.

[Margin: Authors in whom examples of this method are found.]

Prior Theorica Mercurij.

The first theory of Mercury.

VII. The Copernican hypothesis of Mercury is set out by *Copernicus*, Book 5, from chapter 25 to 32; by *Rheticus* and *Mästlin*, and by *Kepler*, in the places cited for the hypothesis of ♀ in number 1; and by *Longomontanus*, Book 2 of the *Theorica*, chapters 20 and 21. Now, besides the various differences by which ☿ differs from ♀, related in chapter 1, number 7, the following must be added from the Copernican hypothesis. In it ♀, if its apogee were the same as the Sun's, would be at perihelion when at apogee and at aphelion when at perigee, contrary to the way of Mercury and the others; for when the Earth falls on the line of apsides of these planets, Venus has its least eccentricity and Mercury its greatest. The least of ♀ is half the greatest, but that of ☿ is less than half; and ♀ lacks the epicycle that ☿ has. But to grasp these and other points, in the following diagram of *Copernicus*, Book 5, chapter 25, and of *Longomontanus*, page 419, let G be the centre of the great orb AB, whose diameter and line of apsides of Mercury is AB. On it, between G and B, take GF, and divide it into four parts, or approximately so, according to what is to be said about the measures in number 11; let three of them be GI, and the fourth IF, the semidiameter of the small circle FE described from I. This is called the small circle of the anomaly of the eccentricity, and the centre of the orb of Mercury has at E its least, at I its mean, and at F its greatest eccentricity from G, the centre of the world and of the annual orb. With the centre placed at F, then, describe the eccentric of Mercury, CH (in the old theory, otherwise, the epicycle); and with the centre made at C, describe the epicycle LK, on whose diameter Mercury is to librate. Let the beginning of the revolutions be at K, the perihelion of the epicycle, when the centre of the eccentric is at F, the aphelion of the small circle, and let the planet be moved from K upward to L; but let the centre of the eccentric be moved on the small circle FE in the order of the signs, yet with a double revolution to one revolution of the Earth. For from this it will come about that whenever the Earth is at A or B, the centre of the orb of Mercury is at F, with the greatest eccentricity; but when the Earth has completed a quadrant by its mean motion, the centre of the orb of ☿ is at E, the point of least eccentricity, the semicircle FE of the small circle having been completed; and one position of the eccentric after another is marked out. To understand these, and the motions along the diameter of the epicycle, I shall set below this other figure, from Mästlin.

[Margin: Copernicus's diagram.]

Diagram. Set at the right of the right column, with the text running in a narrow measure beside it. A large outer circle with a vertical diameter from B at the top to A at the foot. Inside it, a second circle whose top is near K and C and whose foot is at H. On the diameter near the top, a small circle about C, between L above and K below. On the diameter near the centre, a very small circle, drawn clearly only on its left side, about I, between F above and E below.

- B (top of the outer circle)
- L (on the diameter, top of the small circle about C)

- C (centre of that small circle; a small sort)
- K (on the diameter, foot of that small circle)
- F (on the diameter, top of the very small circle)
- I (within the very small circle)
- E (on the diameter, foot of the very small circle)
- G (on the diameter, below E)
- H (on the diameter, foot of the second circle)
- A (foot of the outer circle)

VIII. Let the annual orb of the Earth be BCD, whose centre is A, and let its diameter, for the line of apsides, be BAD. On this let the whole eccentricity of the orb of Mercury from A be AF, and approximately three-quarters of it AE, and the quarter part EF, for the semidiameter of the small circle. When the Earth is at the apogee of Mercury, B, or at the perigee D, the centre of the orb is at F, and the orb of Mercury is HI; Mercury itself is on the epicycle DK, at the perigee K, or at the perigee L. So the path of Mercury is then KML (for in this figure the right-hand side is the east, towards which the Earth, the centre of the orb and the centre of the epicycle are all moved in the order of the signs), that is, the narrowest circuit of all in breadth.

[Margin: Mästlin's diagram.]

Diagram. Set in the left column, inside the sentence ending at K. A large outer circle with a vertical diameter from D at the top to B at the foot. Several large circles of different centres lie inside it, overlapping near the top and the foot. Small circles stand on the diameter: one near the top about H and K; one below it about P and N; one at the centre about E, with F just above it and G below it; and two near the foot, one about I and one about O, with Q below. From C on the left of the outer circle, two straight lines run to the diameter, one near E and one near A. A straight line runs through F to M at the right and on to the left. From B two straight lines rise, one to the left and one to M.

- D (top of the outer circle)
- H (on the diameter, within the topmost small circle)
- K (on the diameter, foot of the topmost small circle)
- P (on the diameter, within the second small circle)
- N (on the diameter, foot of the second small circle)
- S (upper left of the outer circle, beside a small mark)
- F (on the diameter, above the central small circle)
- M (right of the diameter, on an inner circle)
- E (within the central small circle)
- G (on the diameter, below E)
- A (on the diameter, below G)
- C (left of the outer circle)
- R (right, between the inner circles and the outer circle)
- L (left of the diameter, below A)
- I (within the upper of the two lower small circles)
- O (within the lower of the two lower small circles)

- Q (on the diameter, below O)
- B (foot of the outer circle)

But when the Earth is at mean elongation from the apsides, that is, a whole quadrant from Mercury's apogee and perigee, as at C, the centre of the orb of ☿ is at G, and the equation of the centre is the angle ACG; and its eccentric is NO. Mercury, however, holds the highest summit of its epicycle, and is either at P or at Q, and describes a path and, as it were, a very loose spire, which is PRQ. Moreover, when the Earth is at B, the apogee of Mercury, the prosthaphaereses of the orb, or of Mercury's parallax, are the least of all, because of the narrowness of Mercury's path and the very great distance from Mercury, so that the greatest of them then does not exceed the angle FBM. But with the Earth placed at the perigee D, although the orb of Mercury is at its narrowest, it nevertheless appears larger because of the nearness of the Earth. In the quadratures, as at C, that orb, although it is looser, does not appear larger, because of Mercury's great distance from the Earth. But at about a third of the circle counted from the apogee, as at S, the end of the arc BCS, or about a sixth from the perigee D, it appears greatest, in the opinion of Ptolemy and Copernicus, and requires the greatest prosthaphaereses, by which Mercury differs and digresses furthest from the Sun, that is, from its own mean place; this arises from the mutual compensation of distance and true size. Therefore, although the parallaxes of the annual orb are least at Mercury's apogee, the greatest excess is nevertheless not at the perigee but at a sixth of the circle counted from the perigee. And *Mästlin* rightly warns that proportional minutes are not to be trusted at all here, but that one must proceed by another route, in constructing the tables or in deriving the dimension of the orbs from tables already constructed. Finally, Copernicus measures the libration of Mercury on the diameter of the epicycle in the same way as the libration of the equinoctial points, according to what I said in Book 3, chapter 29, number 10. But in Book 5, chapters 28 and 30, adding a diagram, he himself weighs this libration by the rule of second sines; and he teaches that Mercury's digressions and the parallaxes of the annual orb become greater at about the side of the hexagon, that is, at a sixth of the anomaly of the eccentric counted from the perigee, than at the perigee, not because the orb of the planet comes nearer to the Earth, as Ptolemy thought, but because the planet describes a larger circle. So what gave Ptolemy occasion to err, and to place Mercury so near the Earth in that position, was the size of the equations of the orb, as *Longomontanus* also notes, Book 2 of the *Theorica*, chapter 20. You will, however, understand and admire Copernicus far better when you read, in chapter 9, his demonstrations, illustrated by me, on the commensurations of the orb of Mercury and on that hexagonal position, from problem 3 to problem 6.

[Margin: The unreliability of proportional minutes in ☿.]

[Margin: Ptolemy's error corrected.]

[Margin: Where is Copernicus illustrated below?]

Posterior Theorica Mercurij.

The later theory of Mercury.

IX. It is remarkable with what ingenuity Copernicus tried to cast Mercury, like Proteus, into the chains of astronomical geometry, though he could not catch it with his eyes and observe it. For he says in Book 3, chapter 30, speaking of Ptolemy's observations: "The ancients certainly showed us this way of examining the course of this star, but they were helped by a clearer sky, where, as they say, the Nile does not breathe such airs as the Vistula does among us. For to us who inhabit a colder region nature has denied that advantage, where calm air is rarer, and where, moreover, because of the great obliquity of the sphere, it lets us see Mercury more rarely, even at its greatest distance from the Sun. For in Aries and Pisces it does not rise into our view, nor again does it set in Virgo and Libra; nor does it show itself in any way in Cancer or Gemini, when there is only twilight or dawn at night and never true night, unless the Sun has withdrawn a good way into Leo. For this reason this star has tormented us with many windings and labours, in order that we might scrutinize its wanderings." And he adds that he was forced to take refuge in the observations of Bernhard Walther and Johannes Regiomontanus made at Nuremberg. And in chapter 32 he says: "So indeed has nature played about this star, and with so wonderful a variety, yet one she has confirmed with a perpetual, certain and immutable order." But Copernicus did not allow Mercury to remain as unconquered by him as it was unseen or unobserved, nor to slip from his hands as it did from his eyes. So in the same chapter 32 he proposes this new theory, serving chiefly the greatest digressions of ☿ from ☉, as follows.

[Margin: Mercury unseen by Copernicus, but not entirely unconquered.]

Let there be a circle GHKP, cut into four parts at the centre F by the diameters GK and HP; let the small circle ML be concentric with it. With the centre made at L, and the interval LO taken, equal to the semidiameter FG or FH, let the circle OHRP be described, and let Mercury then be at O. And let these circles be supposed to be moved about F in the order of the signs, with their intersections, that is, the lines GFR and HFP, daily by about 2° 7′, namely by as much as the motion of commutation of Mercury, or of the anomaly of the orb, exceeds the mean motion of the Earth (or, in other authors, of the Sun), counted from the apogee of Mercury's eccentric. Mercury itself, however, is to be moved from the line of apsides GK along the orb OR, and to supply the remaining motion, almost like the motion of the Earth, by an annual revolution; meanwhile, in that revolution, the centre of the orb OR, which carries the star, is to be carried up and down, by a motion of libration and reciprocation, along the diameter ML of the small circle, twice as great as the one we assumed above. With these things laid down, when the centre of Mercury's eccentric is at L and Mercury itself at O, the planet will be at its least distance from the centre F, and will describe the smallest circle, and the least semidiameter of the eccentric will be FO. But when Mercury is at about the mean apsis, it will be

at H, and at its greatest distance from F, and will describe the greatest windings and a circle whose semidiameter will be FH; for [?] then the deferent OR will coincide with the orb GH, because the centre F is the same for both. Now let the Earth proceed towards the perigee, until the centre of the orb OR falls at M; for the orb will be raised above GK, and the star, at R, will again be least distant from the centre F, between K and L. Here, then, 3 mutually equal revolutions coincide: namely that of the Earth relative to the apogee of the orb of Mercury's eccentric; the libration of the centre along the diameter LM; and the motion of the planet on the eccentric from the line FG back to the same FG. From these, however, the motion of the intersections GH and KP from the apsis of the centre differs. And so in the middle spaces of the quadrants GH and KP the star does not pass through without a difference of longitude, and there it would undergo its greatest prosthaphaeresis, if that instability of the centre did not stand in the way; nor does it allow that prosthaphaeresis to occur which the eccentricity FL would otherwise have required, since as the centre of the eccentric approaches F the prosthaphaeresis gradually diminishes, until it vanishes entirely at about the middle intersections HP.

Diagram. Set at the right of the right column, with the text running in a narrow measure beside it. Large circles overlap, meeting near H on the left and P on the right. A vertical line runs from G at the top down to the foot, with R printed below it; a horizontal line runs from H to P, crossing the vertical at F. A small circle stands about F, with M above it and L below it.

- G (top, above the uppermost circle)
- O (on the vertical, below G; a small sort)
- M (on the vertical, top of the small circle)
- F (centre of the small circle)
- H (left end of the horizontal)
- P (right end of the horizontal)
- L (on the vertical, below the small circle)
- K (on the vertical, on a circle near the foot)
- R (below the foot of the lowest circle)

Methodus Calculi Geometrici in Hipotheſi Mercurij.

The method of geometric calculation in the hypothesis of Mercury.

X. As regards the equations of the centre, the method is exactly the same as the one given for Venus in number 4. For the equations of the orb, or of commutation, it is indeed the same, but the semidiameter of the orb of Mercury is needed in the parts in which the radius of the annual orb was assumed; and that semidiameter varies according to the libration made either on the diameter of the epicycle, in Copernicus's earlier form, or on that of the small circle, in his later form. This semidiameter must therefore be equated, and the rest then carried out entirely as we taught there. To equate that semidiameter, however, three elements are needed: namely that there be given the least semidiameter of

the orb of Mercury; the least semidiameter either of the epicycle in Copernicus's first form, or of the already mentioned small circle in the 2nd, in the same kind of parts; and the anomaly of the eccentric. For the second sine of this anomaly doubled must be found; or, if it exceeds a quadrant, the second sine of its complement to the semicircle; or, if it exceeds a semicircle, the second sine of the excess; or finally, if the anomaly exceeds three quadrants, the second sine of its complement to the circle. Then that second sine must be multiplied by the semidiameter of the epicycle or small circle, and the sum divided by the whole sine. If the anomaly belongs to the 1st or 4th quadrant, the quotient must be added to the semidiameter of the small circle or epicycle, for this gives the addition to be made to the least semidiameter of the orb of Mercury, which we need in order to obtain the prosthaphaereses of the orb. But if the anomaly belongs to the 2nd or 3rd quadrant, that quotient must be subtracted from the semidiameter of the epicycle or small circle, and the remainder added to the least semidiameter of the orb. See this procedure illustrated by an example in chapter 10, problem 6.

De Numeris ac Menſuris ad Hypotheſim Veneris ac Mercurij Copernicæam ſpectantib.

On the numbers and measures relating to the Copernican hypothesis of Venus and Mercury.

XI. Although *Copernicus* gives the numbers of the motions in Book 5, chapter 1, and the measures of the orbs of Venus in chapters 21, 22 and 23, and of Mercury in chapters 27 and 30, *Mästlin* nevertheless decided, on Kepler's *Prodromus* or *Mysterium Cosmographicum*, chapter 15, and in his appendix to the same *Prodromus*, to fish them out from the Prutenic prosthaphaereses, so that it might be known whether and where Reinhold had corrected them. For Reinhold admits in the preface to the Prutenic Tables that they need correction, because Copernicus, by then an old man, slipped in calculation more than once; I shall give a sample of such a slip below, chapter 8, number 6. We therefore decided to present these measures from both, that is, from Mästlin, just as if they were Reinhold's, and from Ptolemy, as they stand. But to make their comparison readier, we have added one zero to all the measures of Copernicus, because Copernicus uses a radius of the annual orb of only 10000 parts, whereas Mästlin uses one of 100000 parts. So if one zero is taken away from the Copernican measures set out in the following table, you will at once have them as they stand in Copernicus's book. Recall, besides, that the whole eccentricity of the equant of Venus suited to the time of Ptolemy was found by Copernicus to be 416 parts, of which the radius of the Earth's annual orb is 10000; that it was therefore bisected, as in the superior planets; and that half of it, 208 parts, was given to the least eccentricity of the deferent, and a quarter, 104 parts, to the semidiameter of the small circle producing the anomaly of the eccentricity. Afterwards, however, in his own times, Copernicus found the

whole eccentricity of the equant to be 350 parts. This he did not bisect; rather, keeping the semidiameter of the small circle at 108 and the diameter at 208, he gave the remainder of the 350, that is, 142, to the least eccentricity of the deferent; and the distance of the centre of that small circle from the centre of the annual orb, which he had earlier made 312, he made 246 in his own time. Nor is the least eccentricity of Mercury in this hypothesis exactly half of the whole or greatest eccentricity. For Copernicus the least is 524 and the greatest 948, of which the radius of the annual orb is 10000; for Mästlin, who uses a radius of 100000, the former is 5231 and the latter 9460. Further, neither of them presents these measures in semidiameters of the Earth, so it fell to us to derive them from the semidiameter of the annual orb, that is, from the mean distance of the Sun from the Earth, which Copernicus makes 1142, Mästlin 1160. The greatest, however, Copernicus makes 1179 in his own time, with the Sun's eccentricity almost least, as does Mästlin too; but with the eccentricity greatest, Copernicus makes the greatest 1190, Mästlin 1208½. In this place, however, we shall indicate only some distances of these planets from the Earth, both in Ptolemy's age and in Copernicus's, taking their eccentricity from the centre of the annual orb and considering the Earth on the line of apsides of each planet. Distances from the Sun, because of the many comparisons they involve, we reserve for Section 6, chapter 2, number 3, where we shall give several rules about them; for in considering the idea of this hypothesis, these distances can be viewed by taking the Sun's eccentricity now greatest, now least, and in either case supposing either that the apogees of these planets coincide with the Sun's apogee at the same point of the zodiac, or that they stand diametrically opposite the solar apogee. For these cases we shall give there rules and perfectly complete tables. Meanwhile we shall set below only the solar distances, collected from Mästlin's numbers as given to the radius of the annual orb, and suited to the time of Ptolemy.

[Margin: The authors from whom the following table is taken.]

[Margin: Note on the eccentricity of ♀ and ☿.]

MENSVRÆ AD COPERNICI Hypotheſim ſpectantes

Measures relating to the hypothesis of Copernicus

Where ♀ has M, the measures there agree with its greatest eccentricity, which it had in Ptolemy's time.	Planets	Parts of which the radius of the annual orb is 100000: Copernicus	Semidiameters of the Earth: Copernicus	Semidiameters of the Earth: Mästlin
Whole eccentricity of the centre of the orb from the centre of the annual orb: EN	♀	3500	40	40
	♀ M	4160	48	48
AF	☿	9480	108	110
Least eccentricity of the centre of the orb from the centre of the annual orb: EM	♀	1750	20	20
	♀ M	2080	24	24

Where ☿ has M, the measures there agree with its greatest eccentricity, which it had in Ptolemy's time.	Planets	Parts of which the radius of the annual orb is 100000: Copernicus	Semidiameters of the Earth: Copernicus	Semidiameters of the Earth: Mästlin
AG	☿	5240	60	61
Semidiameter of the small circle of the eccentricity: MA	☿	875	10	10
	☿ M	1040	12	12
GE	☿	2120	24	24½
Semidiameter of the epicycle: DH	☿	1900	21½	22
Semidiameter of the orb of the planet: MV	☿	71930	821	834
Mean	☿	37630	428	436
Greatest: GR	☿	39530	451	459
Least: FL	☿	35730	405	413
Semidiameter of the annual orb: EL	☿	100000	1142	1160
AC	☿	100000	1142	1160
Greatest distance from the centre of the Earth: HQ	☿	173680	1983	2014
HQ	☿ M	174010	1987	2018
BK	☿	145210	1655½	1683
Least distance from the centre of the Earth: GQ	☿	26320	301	306
GQ	☿ M	25990	297	302
BL	☿	54790	629	637
		Mästlin		
Eccentricity from the ☉ of the centre of the small circle of the eccentricity	☿	1262		15
	☿	10270		119
Greatest distance from the Sun, or aphelion	☿	74232		861
	☿	48114½		558
Least distance from the Sun, or perihelion	☿	69628		708
	☿	23345½		271

Mästlin derives from the Prutenic Tables Mercury's whole eccentricity as 9460 parts, its least as 5231, and the semidiameter of the small circle of the eccentricity as 2114. In all the remaining measures of the former column he agrees with Copernicus, but in the third column he disagrees, both because of the disagreement just mentioned and because he makes the semidiameter of the great orb 1160 semidiameters of the Earth.

[Margin: For ☿ see the figure in number 3, and for ☿ number 8.]

[Margin: That is, of the small circle of the anomaly of the eccentricity.]

[Margin: For the time of Ptolemy.]

MOTVS MEDIVS Seu Aequalis.

RADIX MOTVVM ad Primum CHRISTI Annum Ad locum & diei momentum, de quo sect. 2. cap. 2. ad finem.

Root of the motions for the first year of Christ, for the place and moment of the day discussed in Section 2, chapter 2, at the end.

		Sign.	Deg.	′	″	‴	⁗
Of commutation	♀	4	6	46	31	35	37
	☿	1	16	53	1	26	57
Of the apogee	♀	1	18	21	0	0	0
	☿	6	6	34	48	41	0

These motions are counted from the first star of Aries. If you add to them the Copernican precession of the equinoxes, that is, the apparent motion of the fixed stars, you will have the motions counted from the mean vernal equinox. The apogee of Venus, however, perpetually keeps the same distance from the first star of Aries, 48° 20′ or 21′. I shall speak of the periods of the motions at the end of the Section, and of the greatest digressions and the equations in chapter 7.

SCHOLIA.

Scholia.

I. Just as Copernicus preferred to use an epicycle of an epicycle in the Moon, and eccentrepicycles in the three superior planets, so in the two inferior planets he preferred to use eccentrics of the eccentric, as being more convenient for demonstrating the commensuration of the motions; although, because of their mutual equivalence, he could have used any of the three forms set out in Section 2, chapter 2, indifferently. By these he achieved that neither Venus nor Mercury should undergo that insane parallax which they would have to suffer in the Ptolemaic and Alphonsine hypothesis. For in that hypothesis Venus at perigee is sometimes no more than about 200 semidiameters of the Earth away from the Earth, and Mercury no more than 65; whereas in the Copernican hypothesis

Venus is removed by more than 340, and Mercury by more than 383, however near their perigee they may be.

[Margin: The difference between the hypothesis of Ptolemy and that of Copernicus in parallaxes.]

II. Kepler, however, in Book 6 of the *Epitome of Copernican Astronomy*, page 766, believes that the eccentrics of the eccentric were introduced into the theory of Venus and Mercury only to compensate in turn for the amount by which Copernicus varied the distances of the Earth from the Sun beyond what was due, since he did not know the true eccentricity of the great orb, which, as Kepler would have it, is half of what Copernicus, together with the ancients, believed. The evidence is that Copernicus librates the eccentric of the eccentric of Venus through a space as great as that superfluous half in the eccentricity of the great orb, and the eccentric of Mercury through a slightly smaller space, because in Venus the line of apsides coincides very nearly with the line of apsides of the Sun, whereas in Mercury it departs further from it. For that reason the apogee of Venus was raised too high for him because of the excessive eccentricity of the great orb, and that of Mercury was depressed too far. But these conjectures of Kepler, ingenious as they may be, still do not establish what he wants; nor has the bisection of the eccentricity in the Sun yet been shown.

[Margin: Kepler's censure of Copernicus.]

III. Yet it may seem inelegant in this hypothesis that it measures the anomaly of the eccentric from the mean motion of the Sun or Earth rather than from the true motion, since this motion is fictitious and does not actually take place. But this difficulty is general, in all the planets. What seems rather to destroy the physical cause of the motions and the plan of providence is that, because of the doubled motion which Copernicus assigns to the small circle varying the eccentricity, the eccentricity is the same both at the apogee and at the perigee of the eccentric. For what is the purpose of varying the eccentricity if at the greatest and least distance, where the difference ought to be greatest, there is nevertheless no difference at all? Or what probable reason could there be for this motion to differ not at all at the extremes and greatly in the middle? The same seems to be objected to the variation of the epicycle of Mercury, whose semidiameter is put as least at apogee and perigee alike. But if, all things computed, the observations cannot be satisfied without this hypothesis, we shall have to swallow what seems to us this inelegance. Yet Copernicus ought rather to have built this hypothesis of his on more recent observations; but after citing only three of Mercury and one or two of Venus, he builds everything else on observations made or reported by Ptolemy. *Mästlin* raised this complaint against him in the letter to Kepler that stands among the additions to the *Mysterium Cosmographicum*, chapter 19.

[Margin: Three objections to the hypothesis of Copernicus.]

CAPVT III.

Chapter III.

De Hypotheſi Lansbergiana Veneris ac Mercurij.

On the Lansbergian hypothesis of Venus and Mercury.

De Theorica Veneris.

On the theory of Venus.

I. We place this hypothesis next after the Copernican one, because in it *Lansbergen*, in his *Theoricae motuum Caelestium*, chapters 11 and 12, emulated the Copernican hypothesis; and it differs from that one only in the measures of the orbs and the numbers of the motions. So look at the figure added here. In it, near the Sun, A is the centre of the great orb GH; GH is the line of apsides of Venus; on that line C is the centre of the small circle DB of the anomaly of the eccentricity, whose diameter DB is 204 parts, of which AG, the radius of the great orb of the Earth, is 10000; the semidiameter CD is 102; AB, the least eccentricity, is 145; and AD, the greatest, 349. Therefore, with the Earth placed at H, the ☉ is between D and E, because the ☉'s eccentricity is greater.

Diagram. Set at the right of the right column, with the text running in a narrow measure beside it. A vertical line runs from G at the top to H at the foot. Two large circles lie about it, one inside the other, and a small circle stands on the line about C. The labels read down the line are G, E, D, C, B, A, F, H: D stands at the top of the small circle and B at its foot; A is just below B; F is below the foot of the inner large circle.

- G (top of the line): G
- E (on the line, below G): E
- D (top of the small circle): D
- C (centre of the small circle): C
- B (foot of the small circle): B
- A (below B): A
- F (lower part of the line): F
- H (foot of the line): H

Now the centre of the eccentric of Venus is moved on the circumference of the small circle DB in the order of the signs, but with a motion swifter than the mean motion of the Earth in longitude (which is the same as the mean motion of Venus and Mercury), counted from the apogee of ♀, which is called the motion of the anomaly of the centre. Whenever the Earth falls on the line of apsides of Venus, that is, is at G or at H, the centre of the orb of Venus is at B, the point of least eccentricity; but with the Earth 90° distant from G or from H, that centre is at D. Therefore let the eccentric orb of Venus, EF, now be described from B, its perihelion E with respect to the Sun placed near A, and likewise its apogee with respect to the Earth placed at H. Let F be the aphelion,

and indeed also the perigee with respect to the Earth stationed at G. But it is the mean one [?], if it is reckoned from the mean equinox.

[Margin: An explanation of aphelion and apogee, omitted by Lansbergen.]

Methodus Calculi Geometrici in hac ♀ Hypotheſi.

The method of geometric calculation in this hypothesis of ♀.

II. In the following diagram, A is the centre of the great orb PO, and BD is the small circle of the anomaly of the eccentricity, discussed above. Let there be given, for example, a mean motion of the Sun of 196° 6′ 5″, counted from the mean equinox, and let the equal motion of the apogee of Venus from the same point be 46° 14′ 40″. When this is subtracted from the mean motion of the Sun, there remains the anomaly of the centre, 149° 51′ 25″. These degrees, counted from the line PO of the mean apogee in the order of the signs, give at M the mean place of the Sun, opposite which stands I, the place of the Earth (the mean place), on the line MAI. The same anomaly, doubled, gives the motion of the centre of the orb. Let 149° 51′ 25″ doubled, then, that is, 299° 42′ 50″, be counted from the point B, rightward towards D; for the arc corresponding to them will be BDE. So the centre will be at E; from it describe the orb of Venus GKN. Next, through the centre E draw the straight line LN parallel to the line IM of the mean motion of the Sun, and on it let N be the apogee of the orb of ♀ and L the perigee. Now imagine Venus to be at K. We must therefore find the place of the centre, and then its apparent place, that is, as seen from the Earth.

First, for the arc EB, the remainder of the circle DEB, find the versed sine BF (which is obtained by subtracting the second sine FC from the whole sine) and the first sine EF. Multiply EF and FB each separately by the semidiameter CB, which is 102 parts, and divide the total by the whole sine; for you will then have EF and BF known in parts of which the radius AP of the great orb is 10000. Add BF, so known, to the least eccentricity AB, that is, to 145 parts, and AF will be known in the same kind of parts. Now when EH is produced towards P until the perpendicular IH from the Earth I falls on it, GH will be equal to FE.

[Margin: 1st step, for the equation of the centre.]

Diagram. Set in the left column, inside the sentence ending at FE. A large outer circle with a vertical line from P at the top to O at the foot. Inside it, a second circle, passing through K at the upper left, L at the upper right and N at the lower left. On the vertical line, a small circle about C, with D above it and with B at its foot. From I on the outer circle at the upper right, a dotted line runs horizontally to G on the vertical line, and a solid line runs to K; solid lines also run from I to E and from I down through the centre region to M on the outer circle at the lower left, where a rayed Sun stands beside the letter. A straight line runs from L through E to N, and another from K to E. A dotted

line runs down from H to E. A short line runs from E to F. The sign ♀ stands in the lower right of the band between the two large circles.

- P (top of the outer circle): P
- G (on the vertical line, at the top of the second circle): G
- H (left of G, at the head of the dotted line): H
- I (outer circle, upper right): I
- K (second circle, upper left): K
- L (second circle, upper right): L
- D (vertical line, above the small circle): D
- C (centre of the small circle): C
- F (inside the small circle, below C): F
- E (left of the foot of the small circle): E
- B (vertical line, foot of the small circle): B
- A (vertical line, just below B): A
- N (second circle, lower left): N
- ♀ (lower right, between the two large circles): the sign of Venus
- M (outer circle, lower left, beside the rayed Sun): M
- O (foot of the outer circle): O

Second, because the complement MO of the anomaly of the centre, that is, of the arc PM, is given, and PI is equal to it because of the equal angles at the vertex A, find the sine IG of the arc PI and its second sine AG, in parts of which the radius AP of the great orb is 10000. Then add HG to GI, so that the side HI may be known. Conversely, take AF away from the sine AG, and FG will remain, that is, HE, which is equal to it, known in the same kind of parts. Next, when EI is drawn, the triangle EHI will be formed, right-angled at H, in which from the given sides about the right angle, HI and HE, the angle HIE is obtained by means of trigonometry. Likewise in the triangle AGI, right-angled at G, from the given GI and AG you will seek the angle AIG; take EIH from it, and AIE will remain, that is, the prosthaphaeresis of the centre, to be subtracted from the mean motion of the Sun M, because the anomaly of the centre is less than a semicircle, so that the true place of the centre, or the centric longitude of Venus, may be known. In addition, the base EI must be sought in the same triangle.

[Margin: 2nd step.]

Third, from the tables find the mean anomaly of the orb of Venus and count it in the order of the signs from the apogee of the orb N, through L, as far as K, where Venus is; for when the semicircle LN is taken away, the arc KL remains, which the angle KEL measures. The angle IEL, because of the parallelism of the lines LN and IM, is equal to the angle AIE, that is, to the equation of the centre. This, then, added to the angle KEL, gives the angle KEI. With this, with the side EI already found, and with the radius EK of the orb of Venus known in parts of which the radius of the great orb is 10000, the angle EIK is found, that is, the prosthaphaeresis of the orb, subtractive, because the anomaly of the orb ends in the second semicircle. When this is subtracted from the

centric longitude of Venus, there will remain the place of Venus K as seen from the Earth I, from the mean equinox, and, with the prosthaphaeresis of the equinoxes, from the true equinox.

[Margin: 3rd step, for the equation of the orb.]

Finally, fourth, in the same triangle EKI, from the same data you will find, if it is needed, the side KI, that is, the distance of Venus from the centre of the Earth. You have this example worked out in numbers and completed in *Lansbergen's Theoricae*, chapter 12; turn to it, if you wish.

[Margin: 4th step, for the distance of the planet.]

De Theorica Mercurij.

On the theory of Mercury.

III. This, likewise, was taken from Copernicus by *Lansbergen*, chapters 13 and 14 of the *Theoricae*, but with the measures corrected. So in the following little diagram A is the centre of the great orb of the Earth, near the Sun; GRLP is the great orb; and GL is the line of apsides of Mercury, on which C is the

Diagram. Set across the right column, inside the sentence naming C. A large outer circle with a vertical line from G at the top to L at the foot, and R and P inside it at the left and the right. Inside it, a second circle, with M at its left and N at its right. At the top of the vertical line, a small circle about E, with K just below it; at the lower part of the line, where the second circle meets it, a small circle about F, with I just above it. Near the middle of the line, a small circle about C, with D above it and B below it, and with A on the line lower down.

- G (top of the line): G
- E (centre of the small circle at the top): E
- K (below that circle): K
- D (above the middle small circle): D
- C (centre of the middle small circle): C
- B (below the middle small circle): B
- A (below B): A
- M (second circle, left): M
- N (second circle, right): N
- R (left, inside the outer circle): R
- P (right, inside the outer circle): P
- I (above the small circle at the foot of the second circle): I
- F (centre of that small circle): F
- L (foot of the line): L

centre of the small circle of the anomaly of the eccentricity, whose semidiameter CB is 212 parts, of which the radius AG of the great orb is 10000. The greatest eccentricity of the orb of Mercury from the centre of the great orb is AD, 947 parts; the least is AB, 523 parts; BD is 424; and the least semidiameter of the orb of Mercury is 3573 such parts. The Sun, moreover, is between A and

B. Now let the centre of the orb be at D, and from it let the orb EMFN be described, carrying the centre of the epicycle E in the order of the signs, from E to M, which is called the motion of the anomaly of the orb, to be computed from the line of apsides GL. The semidiameter KE is 190, and the diameter GK 380 parts; on this diameter Mercury is moved up and down, its motion beginning from K. The centre of the orb, further, is moved on the small circle BD, beginning from D, in the order of the signs, with a motion twice as swift as the motion of the anomaly of the centre, that is, the mean motion of the Earth, computed from the mean apogee G; and the reciprocal motion on the diameter of the epicycle is also as great. So when the Earth falls on the line of apsides of Mercury, the centre of the orb of Mercury is at D, and then the semidiameter of the orb is least, namely as great as DK.

Methodus Calculi Geometrici pro Mercurio.

The method of geometric calculation for Mercury.

IV. *Lansbergen* himself puts this example before the eyes in other words. On the line of apsides of Mercury, PO, let A be the centre of the world, nearest the Sun, and let C be the centre of the small circle BD of the anomaly of the eccentricity. Let the mean motion of the Sun be 147° 1′ 53″, and the mean motion of the apogee of Mercury 179° 4′ 59″. This, subtracted from the motion of the ☉ (a whole circle being taken in, as is customary), leaves the anomaly of the centre of ☿, 327° 56′ 54″. Counted in the order of the signs from the mean apogee O, through IP, this shows the Sun at M and the Earth at I. Doubled, with a whole circle cast off, it gives the motion of the centre of the orb of ☿, 295° 53′ 48″. These degrees, then, counted in the order of the signs from D through B, show the place of the centre at E, from which the orb of Mercury LQN is to be described. Through that centre the diameter LN must be drawn parallel to the line IM of the mean motion of the Sun or Earth, and on it L will be the apogee of the orb. Further, let Mercury be supposed at K, and let the Earth I be joined to K and E by the straight lines IK and IE; finally, from D draw the perpendicular DF to IM. With these preparations made:

[Margin: Chapter 14 of the *Theoricae*.]

[Margin: These were the motions in the year of Nabonassar 486, on the 30th of Pauni, in the evening.]

First, the arc OM, that is, 32° 3′, is the complement of the arc PM, and its measure is the angle OAM, whose complement to a right angle is FDA, 57° 57′, since AFD is a right angle. Therefore in the triangle ADF, right-angled at F by construction, from the said angle and the base AD of 947 parts, the trigonometer will find the side AF, of 802½ parts, and DF, of 502½.

[Margin: 1st step, for the equation of the centre.]

[Margin: By 32 of Book 1 of Euclid.]

Second, in the triangle BDE, right-angled at E because of the parallelism already mentioned, from the angle DBE, 32° 3′, because

[Margin: By 29 of Book 1 of Euclid.]

it is equal, because of the same parallelism, to the angle DAF, and from the common BDE, 57° 57′, and from BD, 424 parts, you will find DE, 225 parts. When these are taken away from DF, EF remains, 277½.

[Margin: 3rd step.]

Third, in the triangle IEF, right-angled at F, the side EF is now given; and IF, made up of the radius AI of the annual orb and the side AF found above, 802½, is 10802½. You will therefore find the angle FIE, 1° 28′, that is, the equation of the centre, to be

[Margin: In this diagram correct the engraver, by imagining the line NL to be drawn through the points B, E of the circumference of the small circle.]

Diagram. Set across the left column, inside the sentence ending at the base IE. A large outer circle with a vertical line from O at the top to P at the foot. Inside it, a second large circle. At the left, on the second large circle, a small circle about K, with H at its left and G at its right. Near the centre, on the vertical line, a small circle about C, with D above it, E at its right and B [?] below it; A stands on the vertical line lower down. A straight line runs from G through the small circle to E, and a short line from D to E. Straight lines run upward to the right across the centre: one from I at the lower left to the rayed Sun beside M on the outer circle at the upper right, and one from N to L. A further straight line rises from I to the small circle about K. F stands below and to the right of E. Q stands below the small circle about K. The sign ☿ stands in the lower right of the band between the two large circles.

- O (top of the outer circle): O
- D (above the middle small circle): D
- L (upper right, on the second circle): L
- M (outer circle, upper right, beside the rayed Sun): M
- H (left of the small circle at the left): H
- K (centre of that small circle): K
- G (right of that small circle): G
- Q (below that small circle): Q
- C (centre of the middle small circle): C
- E (right of the middle small circle): E
- B [?] (below the middle small circle, with lines crossing it): B
- F (below and to the right of E): F
- N (lower left, on the second circle): N
- A (vertical line, below the middle small circle): A
- I (outer circle, lower left): I
- ☿ (lower right, between the two large circles): the sign of Mercury
- P (foot of the outer circle): P

added to the mean motion of the ☉, so that the centric longitude of Mercury, or the place of the centre E, comes to 148° 29′ 53″. In the same triangle you will find the base IE, 10805 parts.

Fourth, from the tables of *Lansbergen*, for the time noted in the margin, the anomaly of the orb of Mercury was 114° 17′. These degrees, counted in the order of the signs from the apogee L as far as Mercury K, give the arc LK, that is, the angle KEL, and the remainder KEN, 65° 43′. If you add to this IEN, which is equal to the equation of the centre FIE because of the parallelism so often mentioned, the angle IEK will be 67° 11′.

[Margin: 4th step, for the equation of the orb.]

Fifth, on the small circle GH, because the motion of its anomaly is as great as the motion of the centre of the orb on the small circle BD, that is, in our case 295° 54′, to be counted from G, the perigee of the epicycle, this arc will be GHQ, and the remaining arc QG 64° 6′. Its versed sine KG is 5632 parts, of which the whole sine of the epicycle is 10000. So when the sine KG is multiplied by the semidiameter of the epicycle, 190 parts, and the total divided by the whole sine, KG comes out as 107 parts, of which the radius of the great orb is 10000. When these are added to the least semidiameter of the orb of ☿, 3573, the semidiameter KE becomes 3680.

[Margin: 5th step.]

Sixth, then, in the triangle KIE, in which the side KE has just been found, the side IE by the third step and the angle IEK by the fourth, you will seek the angle KIE, that is, the prosthaphaeresis of the orb, 19° 53½′. This, added to the centric longitude of Mercury, will give the place of Mercury, 168° 23′ 23″ from the mean equinox, but, with the prosthaphaeresis of the equinoxes, 169° 11′ 14″ from the true equinox, that is, in ♍ 19° 11′ 14″. Now Hipparchus, in the year of Nabonassar 486, on the 30th of Pauni, saw Mercury in the evening preceding Spica by a little more than 3°. Spica, for *Lansbergen*, was then in ♍ 22° 26′ 4″; so ☿ preceded it by 3° 14′ 50″. If you want the distance of Mercury from the Earth, that is, the side KI, you can hunt it down in the same triangle KIE from the data above.

[Margin: 6th step.]

[Margin: From Ptolemy, Book 9, chapter 7.]

De Numeris ac Menſuris ad Hanc Hypotheſim ſpectantibus.

On the numbers and measures relating to this hypothesis.

V. *Lansbergen* gives the numbers of the motions, with their roots, in his tables, pages 135 and 143, and at the end of the *Thesaurus*, page 185; the measures of the eccentricities and the semidiameter of the orbs he gives in the *Theoricae*, chapters 11 and 13. From these, however, and from the semidiameter of the great orb, that is, the mean distance of the Sun from the Earth, which he holds to be 1498 33/60 semidiameters of the Earth, we shall draw out many more measures, relating to a full knowledge of this hypothesis, both in semidiameters of the Earth and in parts of the radius of the annual orb.

[Margin: The foundations of the following table.]

Do not be surprised that *Lansbergen* here gave measures proportioned to the radius of the great orb, whereas he made the measures of the three superior planets proportioned to the radius of their own orbs; for in the theory of the two inferior planets the radius of the great orb of the moving Earth plays the part of the eccentrics of Venus and Mercury. Now, in the distances from the Sun, we shall suppose that the Sun and these planets have the same line of apsides, and that the apogees of all of them lie under the same point of the zodiac, so that it may appear how far the measures of this hypothesis can be extended or contracted. In that case, because, with the Sun and the Earth placed on the line of apsides, the centre of the orb of ♀ would be at its own least eccentricity but the centre of the orb of ☿ at its greatest, and because the eccentricity of the Sun, however great it may be, is less than any eccentricity of Mercury, Mercury, when at apogee, would therefore also be at aphelion and at its greatest distance from the Sun; when at perigee, however, it can be at perihelion. Not so with Venus. For the greatest eccentricity of Venus, for *Lansbergen*, is almost as great as the least of the Sun; so Venus at apogee would be at perihelion, and at perigee can be at aphelion. Therefore ♀ and ☿ have inverted apsides with respect to the Sun according to the idea of this hypothesis, and indeed of the Copernican too.

[Margin: Note the remarkable difference between ♀ and ☿ in their distance from the Sun.]

Hence, besides the rules for the distances of these planets from the Earth given in chapter 2, number 11, there arise others for the distance from the Sun. For from the radius or semidiameter of the orb of ♀ must be subtracted the difference between the greatest eccentricity of Venus, which for *Lansbergen* is 422, and the least, which is 349, so that in either case the least or perihelial distance of Venus from the Sun may be known. The same difference, added to the semidiameter of the orb of ♀, will give its aphelial distance. The aphelial distance of ☿, on the other hand, is known if you subtract from its apogeal distance the aggregate of the radius of the annual orb and the eccentricity of the Sun. The perihelial distance of ☿, finally, is known if you subtract from the least semidiameter of the orb of Mercury the difference between the eccentricity of the Sun and the whole eccentricity of Mercury.

[Margin: Rules for the distances of ♀ and ☿ from the Sun.]

	☿	$6^s\ 7°\ 25'\ 6''$

I shall speak of the greatest digressions and the equations more opportunely in chapter 7.

SCHOLIA.

Scholia.

I. In the year of the Lord 1491, on September 3, in the morning, Bernhard Walther deduced the place of Mercury, in ♍ 3° 5′, from the distance of Mercury from Aldebaran taken with armillaries, supposing Aldebaran in ♊ 2° 35′. But Lansbergen, in reporting this in the *Treasury of Observations*, page 181, corrects the place of Aldebaran, saying that it was in ♊ 3° 12′, and accordingly that Mercury was in ♍ 3° 42′; and from his own tables he gathers that it was in 3° 39′. Yet I should like to know why he does not likewise correct the place of Venus, which in the same *Treasury*, page 173, he reports from Ptolemy, Book 10, chapter 4, as observed in the year of Christ 138, on December 24, by the same Ptolemy, in ♏ 6° 30′. For Ptolemy asserts that it was deduced from the distance of Venus from Spica; and in his own time he reckoned Spica to be in ♍ 26° 40′, as is clear from his catalogue in Book 7. According to the tables of Lansbergen, however, it was in ♍ 26° 59′; so Venus should have been placed by Lansbergen in ♏ 6° 49′. But he passed over this correction in silence, because it conflicted with his tables and his hypothesis of Venus, from which, in the same place, he gathers that Venus was then in ♏ 6° 31′. In vain, then, does he boast that his tables answer to this observation. And elsewhere we have more than once noticed this dissimulation in Lansbergen, when observations, if they were corrected as he is otherwise accustomed to correct them, contradict his tables.

[Margin: Either forgetfulness or crafty dissimulation on Lansbergen's part in reconciling his tables with observations.]

II. But I make no complaint about the disagreement of the Lansbergian calculation from the Danish or Longomontanian, which in Venus sometimes extends to a degree and a half and more, as may be seen in the year 1643 on February 12 and March 9, and in Mercury to 5°, 6°, 7°. For there will be

someone who would rather shift the blame onto Longomontanus, who, it is agreed, erred in Mercury in the year 1631, on November 6, by more than 7°.

[Margin: The disagreement between Lansbergen and Longomontanus.]

III. The Lansbergian theory of Mercury can be reduced to Lansbergen's hypothesis, as transformed by Hérigone, in volume 5, Book 1 of the *Theoricae*, proposition 12, into the hypothesis of a stationary Earth, with a second epicycle added and the eccentricity taken not from the centre of the annual orb but from the Earth. The hypothesis of Antonín Maria Šírek, in Book 3 of the *Radius Sidereomysticus*, is also akin to the Lansbergian: although he uses a zodiac transferred into the system of each planet, he nevertheless follows the measures of Lansbergen, varies the eccentricity with him, and uses the mean motion of the ☉. Here, then, are the measures that Šírek sets down. Of the parts of which the radius of the annual orb is 10000, the semidiameter of the orb is, for ♀, 7193, and for ☿, 3573; and the eccentricity of ♀ is least 145, mean 247, greatest 350; but of ☿, least 523, mean 784, greatest 947.

[Margin: The Lansbergian hypothesis of ☿ transferred by Hérigone to the hypothesis of a stationary Earth.]

[Margin: Šírek's hypothesis.]

[Margin: And the measure.]

CAPVT IV.

Chapter IV.

De Tychonica ſeu Longomontanica Hypotheſi Veneris ac Mercurij.

On the Tychonic or Longomontanian hypothesis of Venus and Mercury.

Theorica Ptolemaica reformata.

The Ptolemaic theory reformed.

I. In Book 2 of the *Theorica*, from chapter 17, Longomontanus begins the hypotheses of these planets, proposing a threefold form. The first is the Ptolemaic, but reformed, which he calls conformable to geometry; the second is the Copernican, which we have already set out with him in chapter 2, number 4; and the third the Tychonic. First, then, the Ptolemaic. In it AB is the semidiameter of the orb AED of Venus or Mercury, described from the centre B, and C is the centre of the Earth, from which B is distant by the quantity BC, that is, by the eccentricity, not the whole Ptolemaic one but three-quarters of it. The remaining fourth part of the eccentricity is EL, the semidiameter of the lesser epicycle KFL, whose centre is sometimes at the apogee A of the eccentric, sometimes at the perigee D, and sometimes, indeed usually, elsewhere. Let it now be at E, distant from the apogee, for example, by the arc AE of 45°, which is called the anomaly of the eccentric. Let the diameter KL of the epicycle,

however, remain always parallel to the line of apsides AD. The lesser epicycle, moreover, is to carry on its circumference the centre of the greater epicycle HMI, and to revolve it with a revolution double the motion of the anomaly of the centre in ♀ and triple in ☿, but in such a way that when the centre of the lesser is at A, the centre of the greater is at K, the perigee of the lesser epicycle. The greater, finally, is to carry the planet on its circumference, the motion of the anomaly of the orb being computed from the apogee H in the order of the signs.

Diagram. Set at the right of the right column, with the text running in a narrow measure beside it. A straight vertical line runs down the right side from A at the top through B and C to D at the foot. A large arc leaves A leftward, passes over to E, and a large curve runs down the left side to D at the foot, so that the figure stands as a half circle on the line AD. About E stands a small circle, passing through L above and K below and through F at the right. About F stands a larger circle, with G and H at its upper left, N at the right and M at the lower left, with star-shaped marks on the circle at N and M, and P where several lines cross it. Straight lines run down from the region of E and F to C and B, and from M to B and C; further lines run from N and from F down to C, one of them passing P and I. A short dotted line joins E and F.

- I (right of P): I
- M (larger circle, lower left, below a star-shaped mark): M
- B (vertical line): B
- C (vertical line, below B): C
- D (foot of the vertical line): D

Methodus calculi Geometrici in hac Forma.

The method of geometric calculation in this form.

II. Let the centre of the lesser epicycle be, as I said, at E, distant from A by 45°. Therefore, with twice as many degrees, that is, 90°, counted from the perigee K in the order of the signs, the centre of the greater epicycle HI will be at F, if we are speaking of ♀ (otherwise the arc KF in ☿ ought to be of 135°). The angle KEF is therefore given, which in ♀ is double the angle ABE; and because of the parallelism of the lines AD and KL, the angle KEB is always equal to the alternate angle ABE. When the straight lines CE and CF are

drawn, then, from the centre of the Earth to the centres of the epicycles, and the straight line BE from the centre B to the centre of the lesser, two triangles arise, to be solved for the equation of the centre.

[Margin: By 29 of Book 1 of Euclid.]

First, then, in the triangle BEC, the radius BE and the eccentricity BC are given, as is supposed from the measures of this hypothesis, and the angle CBE, as being the complement of the angle ABE. So the side CE will not be hidden from one skilled in triangles, nor the angle BEC; and this angle, added in this place (for sometimes it is to be subtracted) to the angle BEF, gives the angle CEF.

[Margin: 1st step, for the equation of the centre.]

Second, then, in the triangle CEF, in which the angle CEF is given, and the side CE as found, and, from the measures of the hypothesis,

[Margin: 2nd step.]

the semidiameter EF of the epicycle, find the angle ECF, that is, the equation of the centre, in this first semicircle of the anomaly to be subtracted from the mean motion of the Sun, which is the same as the mean motion of ♀ and ☿, so that the longitude of the centre F from the mean equinox may be known. In the same triangle you will also seek out FC, the distance of the centre of the greater epicycle from the Earth; and when HI is drawn parallel to BE, and CF is produced to G, HFG will be equal to the angles BEC and FCE, already found, taken together.

Third, imagine the planet to be at M, to which draw the straight lines MF to the centre of the greater epicycle and MC to the centre of the Earth. For in the triangle MFC the semidiameter MF is given from the measures of the hypothesis, and the side FC has already been found; and the angle CFM is the complement of the angle MFG, which is as great as the anomaly of the orb counted from the true apogee G. This is known if you add the angle HFG to the mean anomaly of the orb HM. So the angle MCF will not be hidden, that is, the prosthaphaeresis of the orb, in this first semicircle GMP to be added to the centric place of the planet, so that the true or apparent place of the planet from the mean equinox may become known. But if the planet were at N, with FN and CN drawn, the triangle CFN would have to be solved, and then the mean anomaly of the orb would be the arc HMN, whose complement to the circle would be the arc HGN. From this the arc HG would have to be taken away, and the angle GFN so left would reveal the angle CFN. With this, and with the semidiameter FN and the side CF found as above, the angle FCN would have to be sought, to be subtracted from the centric place of the planet to obtain its true place from the mean equinox, and, with the prosthaphaeresis of the equinoxes, from the true equinox. Finally, if the planet is at N or M, as at the points of contact at which the straight lines CN and CM touch the orb, it will be at greatest digression, morning at N, evening at M. These will be known from the triangles FCN and FCM, right-angled at N and M, if the

semidiameter FN or FM is given and the distance CF is sought out as above, as will be said in chapter 7, Problem 2.

[Margin: 3rd step, for the equation of the orb.]

[Margin: The method for the greatest digression of the planet is indicated.]

Tychonica Hypotheſis pro Venere & Mercurio.

The Tychonic hypothesis for Venus and Mercury.

III. In place of the eccentricity, two epicycles are substituted here, proportionally, as we said in the third Copernican form, Section 2, chapter 2, number 5, and chapter 3, number 4. In the following diagram, then, let ABD be the line of apsides, and on it let B be the centre of the Earth, from which the concentric AMD of these planets is to be described, carrying the centre E of the greater epicycle, whose diameter KR is to be always parallel to the line AD. With the centre placed at its apogee K, let the lesser epicycle LC be described, whose diameter CL is to be kept in the same position as KR. Further, while the centre E of the greater moves in the order of the signs from the apogee A, the lesser epicycle meanwhile, with a revolution double in ♀ and triple in ☿ relative to it, that is, twice or three times greater than the anomaly of the centre, is to carry in the order of the signs the centre of the orb of the planet, namely the centre F, beginning its revolution in ♀ from the perigee C of the lesser epicycle towards F, but in ☿ from the apogee L. Next, through F, the centre of the orb, draw BFG, and through the same point draw the diameter HI of the orb, parallel to the straight line BE. For the mean apogee of the orb will be H and the true apogee G, from which the motion of the planet on the

Diagram. Set in the left column, with the text running in a narrow measure at its left. A straight vertical line runs down the right side from A through B to D at the foot. A curve leaves A leftward, passes through the region of E and M, and runs on down to D. A large circle stands about F, passing H and G at its upper left, N near A at the right, I at the lower right and M at the lower left. A middle circle stands about E, with P at its upper left and R inside its foot; a short vertical line runs from K through the small letter c and E to R. A small circle stands about K, with L above it and F at its right. Straight lines: from H through F to I; from G through F to B; from P through E to B; from M to B; from F horizontally to N; from N to B.

- G (large circle, upper left, above H): G
- H (large circle, upper left): H
- L (above the small circle): L
- F (right of the small circle, centre of the large circle): F
- A (head of the vertical line): A
- K (centre of the small circle): K
- N (right, near the vertical line): N
- P (upper left of the middle circle): P
- c (foot of the small circle, set small): C

- E (centre of the middle circle): E
- I (large circle, lower right): I
- R (foot of the middle circle): R
- M (lower left, where the curve meets the large circle): M
- B (vertical line): B
- D (foot of the vertical line): D

Ptolemaic epicycle is counted in the order of the signs, that is, the mean anomaly of the orb if counted from H, the true if from G. Finally, let the planet itself be imagined now in the first semicircle HMI of the anomaly of the orb, say at M, and now in the second, as at N. The anomaly of the eccentric, moreover, is obtained here too by subtracting the mean motion of the apogee of the planet from the mean motion of the Sun. And here too, whether BN and BM touch the orb, and the planet is at N in morning greatest digression or at M in evening, will be distinguished as I taught above at the end of number 2, and below in chapter 7, problem 2.

Methodus calculi Geometrici in hac Hypotheſi.

The method of geometric calculation in this hypothesis.

IV. First, with straight lines drawn to the centre of the orb from the two centres of the epicycles, that is, EF and KF, the side EF is sought in the triangle KEF. For in it are given the semidiameters EK and KF of the epicycles and the angle EKF, which is as great as the arc CF, that is, as great as the doubled anomaly of the eccentric; this is made known by subtracting the motion of the apogee from the mean motion of the Sun. But in ☿, LCF is the tripled anomaly. Moreover, the angle KEF is sought. Next, because by the parallelism of the lines KR and AD the angle KEB is equal to the angle DBE, that is, to the complement of the anomaly of the eccentric, if you take the angle KEF from it, the angle BEF will be known in the triangle BEF, in which the side EF has been found and the radius BE is given. So the side BF will not be hidden, nor the angle EBF, which is the equation of the centre, here to be subtracted from the mean motion of the planet, that is, from the mean motion of the Sun, so that the centric place of the planet may be had.

[Margin: 1st step, for the equation of the centre.]

[Margin: Here Longomontanus is very obscure, and so must be made clear by us.]

Second, if the planet is at M, count from the mean apogee H the mean anomaly of the orb, the arc HM, and add the equation of the centre to it, so that you may have the coequated or true anomaly of the orb, that is, the arc GHM, which the angle MFG measures; its complement will be MFB. With this, and with the semidiameter FM of the orb and the side FB already found, you will obtain the angle MBF, that is, the prosthaphaeresis of the orb, here to be added to the centric place of the planet, so that its true place in the zodiac may be had. But if the planet were at N, the complement to the circle of the

mean anomaly HMN would be HGN; the arc GH, that is, the equation of the centre, taken from it, would leave GN, the complement of the true anomaly; and the complement of this to two right angles would be the angle BFN, with which, and with the semidiameter FN and the side BF, you would find FBN, the prosthaphaeresis of the orb, in such a case to be subtracted from the centric place, etc.

[Margin: 2nd step, for the equation of the orb.]

De Menſuris ad Hypotheſim hanc ſpectantibus.

On the measures relating to this hypothesis.

V. So that the calculation already mentioned can be carried out and the distances of these planets determined, we shall fish out the numbers of the motions from the tables of the *Astronomia Danica*, and the measures of the eccentricities or semidiameters from Longomontanus, Book 2 of the *Theorica*, chapter 18, for ♀, and chapter 20, for ☿. From these, and from the mean distance of the Sun, which is the radius of the annual orb, equivalent to the eccentric or rather the concentric of these planets (from that distance, I say, which Longomontanus puts at 1288 semidiameters of the Earth), and from the greatest, 1334, and the least, 1242, we shall construct other measures, neglected by Longomontanus; since not Tycho but he himself completed this hypothesis. For conceiving these measures on the line of apsides, however, he adds this diagram, especially for Mercury. In it the concentric AFKH, described from the centre of the Earth C, carries A, the centre of the epicycle PQ, whose semidiameter AI in ♀ contains three-quarters of the whole eccentricity and has on its periphery I, the centre of the lesser epicycle DV, whose semidiameter DI is the remaining fourth part

Diagram. Set in the right column, with the text running in a narrow measure at its left. Two large circles stand one above the other and overlap. The upper has E at its top, B at its left and G at its right. The lower has F at its left, H at its right and K at its foot. Where they overlap stands a middle circle about A, with P at its left and Q at its right; above it, and overlapping it, stands a small circle with I inside it and D above it, and with V in the overlap below I. A vertical line runs from the small circle at I through V, A, M and C to K. M stands just below the middle circle. A short curved line runs from Q towards the right, along the edge of the lower circle.

- E (top of the upper circle): E
- B (left, inside the upper circle): B
- D (above the small circle): D
- G (right, inside the upper circle): G
- I (inside the small circle): I
- V (below I, in the overlap): V
- P (left of the middle circle): P
- Q (right of the middle circle): Q

- A (centre of the middle circle): A
- M (on the vertical line, below the middle circle): M
- F (left, inside the lower circle): F
- C (centre of the lower circle): C
- H (right, inside the lower circle): H
- K (foot of the lower circle, on the vertical line): K

[Margin: Longomontanus, 2 *Theorica*, chapter 20.]

of the whole eccentricity. But in ☿, AI has four-fifths, and DI a fifth part, of the whole Ptolemaic eccentricity. And finally, this epicycle carries at its perigee V the centre of the orb, or greatest epicycle, of Venus, but at its apogee D the centre of the orb of Mercury, which orb is to be EBMG. The motion of the epicycle DV, moreover, is in ♀ doubled relative to the motion of the anomaly of the eccentric, counted from A to F; therefore, when the centre A comes to K, the centre of the orb returns to V, the perigee of the lesser epicycle. But in ☿ it is tripled; and so, when the centre A has descended to K, the centre of the orb, which had been at D, will be at V. But because this diagram is mutilated and does not distinctly represent the apogeal and perigeal distances of these planets, we shall substitute another.

[Margin: The difference between ☿ and ♀.]

[Margin: The imperfection of Longomontanus's diagram.]

VI. In the line of apsides AD, then, let the centre of the Earth be C, from which the Sun A or D is at a mean distance, so that the annual orb of the Sun is ABBDEE; and let both A and D be the centre of the greater

Diagram. Set across the left column. A vertical line runs from O at the top to S at the foot. A large circle about C occupies the middle of the line, its top at A and its foot at D. On it, above and below, stand two like groups of circles, each cut by the large circle at B on the left and E on the right. The upper group: an outer circle from O to Q through B and E; within it, a circle with R at its top and T near its foot; within that, a small circle about A, with F at its left and G at its right; and, overlapping that small circle above, a smaller circle about I, with K above it and L below it. The lower group: an outer circle from P to S through B and E; within it, a circle with V at its top and X near its foot; within that, a small circle about D, with F at its left and G at its right, and with Z just below it; and, overlapping that small circle above, a smaller circle about H, with N above it and M below it. The sign ♀ stands on the outer circle of the upper group at the upper left, and the sign ☿, set aslant, on its inner circle at the upper right.

- O (top of the vertical line): O
- ♀ (outer circle of the upper group, upper left): the sign of Venus
- R (top of the circle within): R
- ☿ (that circle, upper right, set aslant): the sign of Mercury
- K (above the smallest circle of the upper group): K
- I (centre of that circle): I
- L (below I): L

- F (upper group, left of the small circle): F
- A (upper group, centre of the small circle): A
- G (upper group, right of the small circle): G
- B (upper group, left, where the circles cross): B
- T (on the line, below A): T
- E (upper group, right, where the circles cross): E
- Q (foot of the outer circle of the upper group): Q
- C (centre of the large circle): C
- P (top of the outer circle of the lower group): P
- V (top of the circle within): V
- N (above the smallest circle of the lower group): N
- H (centre of that circle): H
- M (below H): M
- B (lower group, left, where the circles cross): B
- E (lower group, right, where the circles cross): E
- F (lower group, left of the small circle): F
- D (lower group, centre of the small circle): D
- G (lower group, right of the small circle): G
- Z (on the line, below D): Z
- X (on the line, below Z): X
- S (foot of the vertical line): S

epicycle FG; and let this carry I or H, the centre of the lesser epicycle KL or MN; and let this epicycle finally carry at its perigee L, or apogee M, the centre of the orb that carries Venus, which orb is to be OBQE when Venus is at the apogee O of its orb (otherwise called the Ptolemaic epicycle), but PBSE when it is at the perigee P. But let the lesser epicycle at its apogee K or M carry the centre of the orb that carries Mercury, which orb is to be RT when Mercury is at the apogee R, but VX when it is at the perigee V of its orb. For in this way the differences of the distances will appear better. This too is worth knowing: in this hypothesis, because of the varying annual distance of the Sun from the Earth, or because of the varied eccentricity, the distances of these planets from the Earth change, but not those from the Sun, because the eccentricity is taken from the Sun, as from the centre of this planetary system, and the annual orb of the Sun stands in place of the eccentric. In the Copernican hypothesis, on the other hand, because of the change in the distance of the Earth from the Sun and in the eccentricity of the Earth, it is not the distances from the Earth that vary but the distances from the Sun; because in that case the annual orb of the Earth stands in place of the eccentric of these planets, and from its centre the eccentricities are measured.

[Margin: The difference between the Copernican and Tychonic hypotheses in the distances.]

[62] In this copy the row Distance from the Sun, least, carries pen corrections. The printed 73852½ on the ☿ row is struck through; a handwritten figure beside the row, in the outer margin, reads 705[?]5; and the last two digits of 910 are overwritten. On the ☿ row the printed letters VD are struck through and TA is written beside them.

RADICES motuum ad Annum 1. CHRISTI Hafniæ in Meridie primi diei Ianuarij

Roots of the motions for the year 1 of Christ, at Copenhagen, at noon on the first day of January.

		Root
Anomaly of the orb	♀	$4^s\ 6^\circ\ 21'\ 20''$
	☿	$1^s\ 18^\circ\ 13'\ 48''$
Apogee	♀	$1^s\ 22^\circ\ 36'\ 26''$
	☿	$6^s\ 13^\circ\ 49'\ 16''$

I shall speak of the greatest digressions and the equations more opportunely below, in chapter 7.

SCHOLIA.

Scholia.

I. Besides what was said about these Tychonic hypotheses in the common discussion in section 2, chapter 3, in its scholia, Longomontanus admits (Book 2 of the *Theorica*, chapter 17) that the superior planets and the Moon look to the true course of the Sun, but these inferior planets to its mean motion. But Kepler, in the *Epitome of Copernican Astronomy*, p. 762, contends that these too depend, in the eccentric anomaly, on the true motion of the Sun, just as the superior planets do in the anomaly of the orb. For this reason Tycho's old hypothesis, which considers here a point other than the centre of the Sun's body, is called uncorrected by Kepler. Added to this is the excessive parallax of the Sun and Venus employed by Tycho, which Kepler criticises in the *Ephemerides*, p. 15.

[Margin: Correction of this hypothesis.]

II. Although the eccentricity of Venus has been found smaller in this age than in Ptolemy's, it does not follow from this that it has become smaller, as Copernicus thought. For, as Longomontanus says (Book 2 of the *Theorica*, chapter 18), this can be ascribed to the defect of the ancient observations: both because of the refractions, in which Venus is generally observed wrapped, which they omitted, and because of the uncorrected motions of the Sun and the fixed stars used by the ancients. So it is no wonder if, for this reason, the Ptolemaic eccentricity has decreased by more than half a degree. As for that remarkable appearance of ♀ seen by Tycho in Denmark, although it was joined to the Sun almost at the very perigee of the epicycle, Longomontanus testifies to it in Book 2, chapter 18, saying that it was seen in 1587 February 21 in the evening, and afterwards in the morning on the 24th, on account of a northern latitude of 9°.

[Margin: Was the eccentricity of ♀ once greater than now?]

[Margin: ♀ seen by Tycho at the perigee of the epicycle.]

III. This is certainly worth noting in this Danish hypothesis: Mercury, because the revolution of the centre of its orb is triple the anomaly of the

eccentric, has its centre nearest the Earth not only at the perigee of the eccentric, and farthest at the apogee, but at other places of the eccentric as well. For Longomontanus (Book 2 of the *Theorica*, chapter 20) does not subscribe to Ptolemy, who thought that Mercury is found nearest the Earth only in the sextants from the perigee of the eccentric, and that there it runs into the greatest digressions of all, in the morning in Aquarius, in the evening in Gemini. He says that Ptolemy's observations, when corrected and weighed against the emended motion of the Sun and the fixed stars, conflict with the Ptolemaic hypothesis and with the equations set at that place of the eccentric. Boulliau, however (Book 10 of the *Astronomia Philolaica*, chapter 1), denies that all the observations of Mercury can be represented by a revolution of the orb repeated three times. Certainly the error that Hortensius assigns to Mercury in the Danish calculation is huge — I reported it in Book 3, chapter 3, at the end of Scholium 3 — since they strayed from the true place of Mercury by 7° 13′, even though Longomontanus (Book 2, chapter 20) says that his hypothesis does not err in ☿ by more than 10′. Indeed, it sometimes errs by 9°.

[Margin: Ptolemy's correction in the hypothesis of ☿.]

[Margin: Longomontanus's error in ☿.]

CAPVT V.

De Kepleriana, & Bullialdica Hypotheſi Veneris, ac Mercurij.

Chapter 5. On the Keplerian and Boulliauan hypothesis of Venus and Mercury.

I. Kepler, in Book 6 of the *Epitome of Copernican Astronomy*, part 3, and Boulliau, in the *Astronomia Philolaica*, Book 9 on Venus and Book 10 on Mercury, touch on this hypothesis in few words, because it is the same as that of the three superior planets, sufficiently explained by us, with its properties, in section 2, chapter 5. Thus, in their opinion, Venus and Mercury move on the circumference of an ellipse, in one of whose foci or umbilici stands the motionless Sun, as at the centre of the universe. The line of apsides is drawn through the centre of the Sun; the motion of the second inequality is reckoned not from the mean but from the true motion of the Sun; and the planet's path runs along an elliptical line, which Boulliau teaches is manifest in Mercury (Book 11, theorem 13). Again, their eccentricity is to be taken from the Sun and bisected, one half of it being given to the centre of the ellipse and the other half to the other of the foci, which is to be the point of equal motion, for the reasons brought forward in that chapter 5, from number 5 to 14.

[Margin: Epilogue of this hypothesis.]

II. Yet the theory of these planets differs from that of the superior planets. First, because those are carried outside the Earth's annual orb and these inside it. Second, because in the three superior planets the eccentric orbs, or their ellipses, differ from the ellipse of the annual orb, and are named eccentrics because they perform the office of eccentrics in representing the inequality of the first motion; while the annual orb of the Earth, by its motion, supplies in them the

place of the Ptolemaic epicycles and displays the commutations of the second motion. But in Venus and Mercury the annual orb of the Earth performs the function of the eccentric, because the mean motion in longitude is the same for the Earth, ♀ and ☿; and conversely the orb proper to these planets, that is, each one's own ellipse, eccentric to the Sun and referred to the motion and place of the Earth, produces the second inequality. Therefore the one great or annual orb has taken from the old astronomy the three epicycles of the superior planets and the three eccentrics of the Sun and the inferior planets. Now the apogee of Venus is at present at about 1° ♋, that of Mercury at about 2° ♐, and that of the Earth at about 7° ♑. On these assumptions, consider the following figure, in which, for ease, let the line of apsides of ☉ and ♀ be imagined as the same.

[Margin: The difference of the theory of the inferior planets from that of the superior.]

III. Let A be the Sun, the centre of the world, from which the ecliptic BXC has been described, whose diameter BC is to be the line of apsides of the Earth; and let the bisected eccentricity of the Earth's annual orb be AI. With centre I let the Earth's ellipse ETG be described, in which the Earth at E, aphelial under Capricorn at B, is to see the Sun A as apogee from itself under Cancer; and the same Earth at G, having become perihelial, is to see the Sun A as perigee to itself under Capricorn.

Diagram. A geometric figure of single-column width in the right column. An outer circle, the ecliptic, carries the twelve zodiacal signs round its rim, read clockwise from the top: ♋ above C at the top, ♊ by F, ♉, ♈, ♓, ♒, ♑ below B at the foot, ♐ by L, ♏, ♎, ♍, ♌. A vertical diameter runs from C at the top through G, O, A, K, I, N, H, E down to B. Three nested curves stand inside the ecliptic. A slanting line runs from F at the upper right down through Y and S to R and L at the lower left. A nearly horizontal line runs from X at the left rim through T to N; other straight lines fan from T towards A, Q and P, and a short line runs from T to V. Lying sideways to the right of N, on the two inner curves, stand the signs ☿ (inner curve) and ♀ (middle curve).

- Rim, top: C, with ♋ above it
- Rim, upper right: F, with ♊ above it
- Rim, foot: B, with ♑ below it
- Rim, lower left: L, with ♐ below it
- Rim, left: X, with Z below it
- Vertical line, top to foot: C, G, O, A, K, I, N, H, E, B
- Slanting line: F, Y, S, R, L
- Inside, left of the vertical line: T, V, Q, P
- Labels read: A, B, C, E, F, G, H, I, K, L, N, O, P, Q, R, S, T, V, X, Y, Z, the signs ☿ and ♀ inside the figure, and the twelve zodiacal signs. Labels not read: none noted.

With the line OH, the line of apsides of Venus, drawn through the Sun, and AK taken in it as half of the whole eccentricity AN, which is to be a little less than AI, and with the centre made at K, let the ellipse of Venus OVH be

described inside the annual orb, and in it let the apogee be O when the Earth is at E, and the perigee H. Then let the line of apsides of Mercury FL be drawn through the Sun, in which its whole eccentricity from the Sun is to be AP, whose half is AQ; and with the centre made at Q, let the ellipse of Mercury RS be drawn, whose apogee is to be R and perigee S, with the Earth placed at Y. Now let the lines of apsides move slowly under the ecliptic in the order of the signs; and in the same direction let the Earth move from G to T with a mean motion, which is to take the place of the mean motion in longitude of these planets. Meanwhile let Venus in its ellipse, and Mercury in its own, move towards the same side with a motion begun from the line of their apsides, as Venus from O to V, and with as great a motion as the anomaly of the orb usually is. Finally, the motion of the Earth, counted from the aphelion of Venus in the order of the signs, as the arc GT if the Earth is at T, or from the apogee of Mercury, as the arc LYT, is and is called the eccentric anomaly.

Methodus Calculi Geometrici in hac forma.

Method of geometrical calculation in this form.

IV. Let the Earth be at T and Venus at V. First, with the straight line NTX drawn from N, the other of the foci, as from a point

[Margin: 1. Step for the equation of the centre.]

of equal motion, and with the straight line ATZ from A, the Sun, the other focus, the angle ATN measures the equation of the centre, to be subtracted in this first semicircle of the anomaly, so that the mean place of the centre, which is Z, is converted into the coequated place, which is X. So when the motion of the planet's apogee is subtracted from the mean motion of the Earth (that is, of the Sun), the arc GT remains, which is the eccentric anomaly. With it, from the given whole eccentricity of Venus AH [recte: AN] and its half AK, hunt out the equation, both the physical, that is, the angle KTN, and the optical, namely the angle ATK, so as to have the whole equation of the centre ATN. Hunt it out, I say, in that proportional way which Kepler teaches for the superior planets, on which see our section 2, chapter 5, numbers 14 and 16. Or, since that way is most troublesome and lacks geometric rigour, take refuge in Boulliau's way and in the ellipse resolved into two circles, on which see the same section, number 17; and do likewise for Mercury.

Second, draw straight lines to Venus at V from the Sun A and from the Earth T. When the eccentric place of the planet, that is, the place equated by the preceding equation, is subtracted from the true place of the Sun (or the place of the Sun from the place of the planet, if the latter is greater), you will have the angle of commutation, or the angle at the Sun (but if it exceeds a semicircle its complement is taken), that is, the angle TAV. With this angle, and with AT, the distance of the Sun from the Earth, known from the Sun's anomaly and the tables containing that distance, and with the semidiameter of the orb of Venus, or rather the interval AV, known from the anomaly of the orb through

the proper tables, you will seek the angle ATV, that is, the equation of the orb, to be subtracted from the eccentric place in the first semicircle of the anomaly of the orb and added in the second, so as to have the true or apparent place of the planet seen from the Earth.

[Margin: 2. Step for the equation of the orb.]

De Menſuris ad hanc Hypotheſim ſpectantibus.

On the measurements pertaining to this hypothesis.

V. Kepler indicates his own in the *Epitome of Astronomy*, p. 765, and in the Rudolphine tables of equations, and from him Hérigone (volume 5, p. 580) and Boulliau (Book 1, chapter 9); while the same Boulliau gives his own in Book 9, chapter 2 for ♀, and in Book 10, chapters 2, 3 and 4 for ☿, and in the tables of equations. But from these we have gathered many other measurements, assuming the distance of the Sun set down by them and reported by us in Book 3, chapter 7, and in Kepler's case a twofold one. The distances from the Earth could be represented for some definite time, at which the lines of apsides do not coincide; yet it seemed best to show them in a possible case, in which the line of apsides of the Sun (or Earth), Venus and Mercury would be the same, and indeed so that the centre of the annual orb lies towards one quarter and the centres of the orbs of ♀ and ☿ towards the other, above the Sun, so that while the Earth saw the Sun at apogee, the planets would attain the greatest distance from the Earth that they can have. Granted that this has never happened, and perhaps never will. So in the following diagram, A is the Sun; I is the centre of the annual orb, whose arcs EF and DG indicate the rest of the annual orb; K is the centre of the orb of Venus, indicated by the arcs LM and NQ; and P is the centre of the orb of Mercury, indicated by the arcs TV and XZ. From this the distances can be derived without difficulty in the case where the centre of the orb of Venus would be between A and I, and so for the others. But take care not to confuse Kepler's measures of the eccentricities: in the *Epitome*, and from it Hérigone, he sets them in comparison with the greater semidiameter of the orb or ellipse which each planet describes about the Sun, taken as 100000, whereas Boulliau, reporting Kepler's, and we below, express them in parts of which the radius of the annual orb is 100000. And join the table written below with the other small table to be placed in chapter 9, number 16.

[Margin: Authors from whom the following table is taken.]

Diagram. A narrow schematic set into the right column. A single vertical line runs from B at the top to C at the foot. Six short arcs cross it, each with a letter at either end: E–F near B, L–M near O, T–V near R, X–Z near S, N–Q near H, and D–G near C. Between the T–V and X–Z arcs the line carries P, K, A, I in that order from the top, each with a short tick.

- On the line, top to foot: B, O, R, P, K, A, I, S, H, C
- Arc ends, left: E, L, T, X, N, D
- Arc ends, right: F, M, V, Z, Q, G

[Margin: Distance from the Earth.]

Appendix ad præcedentem Tabulam.

Appendix to the preceding table.

In the Rudolphine Tables Kepler has the aphelial distance of Venus as 72914 and the perihelial as 71912, and the aphelial distance of Mercury as 46956 and the perihelial as 30656. But when Boulliau's ellipse is resolved into two circles, his semidiameter of the greater circle will be 72394 parts in Venus and 38196 in Mercury, and that of the lesser circle 8 in Venus and 390 in Mercury, of which parts the radius of the great orb is 100000.

If you add the mean motion of the Sun to the anomaly of the orb, the result is the mean motion of Venus and Mercury in longitude, as given in the Rudolphine or Philolaic Tables. Conversely, if you subtract the mean motion of the Sun from the mean motion of these planets, there will remain the motion of the mean anomaly of the orb. But if you subtract the true place of the Sun from the true place of the centre of these planets, you will have the true anomaly of the orb. On the difference between the places of the aphelion and the apogee we must speak below, for they differ greatly in Venus.

SCHOLIA.

Scholia.

I. In the old astronomy, given the dimensions of the orbs, there was not sufficient room between the Luminaries for the orbs of Mercury and Venus. Copernicus removed this imperfection, as Kepler notes in the *Epitome*, p. 765. But because he did not bisect the eccentricity, as Kepler would have preferred, the amount by which the distances of these planets varied because of the whole eccentricity had to be compensated by the Copernican eccentric of the eccentric [Eccentri Eccentricum]. And although the Rudolphine Tables seem to surpass the other tables in the motions of Mercury, because that conjunction of Mercury with the Sun, of which I spoke in Book 3, chapter and scholium 3, could be predicted from them so near the truth, Kepler himself nevertheless admits in the *Ephemerides*, p. 14, that in his hypothesis, which rests on Brahean observations, an error of some minutes, up to a quarter of a degree and more, can be feared in Venus; and that in Mercury his calculation can incur an error of a whole day as to its conjunctions with the Sun, that is, of 5° in the commutation, while the apparent place of Mercury can be off by 1½°. He excuses himself on the ground that all the observations of Mercury written down by Tycho over 20 years, if those that are reliable and undoubted are selected, fall within a single third of Mercury's eccentric; the other two thirds remain unobserved, at least in this age and in our hemisphere; and opportunities to detect the error are very rare, because of Mercury's rare appearances. Finally he warns of a greater variation that occurs in these two planets when they are near their stations or are retrograde.

[Margin: Comparison of the old astronomy with the new in these planets.]

[Margin: Kepler's excuse concerning the motions of ♀ and ☿.]

II. Boulliau, in Book 10 of his *Astronomia*, chapter 3, affirms from the observations of Gassendi and Hortensius that the distance of Mercury and the Sun

defined by Kepler is longer than it should be, and indeed that the mean motion of Mercury in the Rudolphine Tables must be increased in the roots by 11′ 29″. He had said, however, in chapter 1, that before Kepler, when all used a perfect circle, it had been impossible to force the motions of Mercury to the laws of numbers: for no hypothesis, not even Longomontanus's tripled revolution of the centre of the orb, satisfies the phenomena or produces the longer stay of Mercury towards the aphelion and the faster passages through the perihelion that recent and accurate observations require. Finally, in the same chapter 1, he does promise a sufficiently exact proportion of the orbs of ☿ and the place of the aphelion and nodes; but the mean motion, which depends on comparing ancient observations with recent ones, he does not promise as equally certain, because he has not found suitable observations among the ancients, not even in the manuscript codex of Ptolemy preserved at Paris in the Royal Library.

[Margin: Praise of Boulliau in the hypothesis of ☿.]

CAPVT VI.

De Noſtris Veneris ac Mercurij Hypotheſibus.

Chapter 6. On our own hypotheses of Venus and Mercury.

I. How arduous it is to bind Venus and Mercury to the laws of a definite hypothesis I have already indicated in the scholia of the preceding chapters. For although the tables of the other astronomers satisfy a few observations within a fifth or sixth part of a degree, they nevertheless stray from many other observations sometimes by a whole degree and more, whether this is through the fault of the hypothesis or, rather, of the observations. For if we choose to accept the observations handed down so far, there are many which seem to preserve no analogy of the motions, so much so that at the same places of the eccentric and the epicycle they undergo very different measures, not subject to the rules of human geometry. These planets, then, but especially Mercury, describe wonderful and almost labyrinthine spires around the Sun, a specimen of which our excellent old man Giuseppe Biancani used to sketch for us with the following diagram, in which the orb of the Sun is OSQ and the Sun S, around which Mercury N flies, now in a very wide circuit ABCDM, now

[Margin: Excuse for the astronomers in the hypothesis of ♀ and ☿.]

in a very narrow one HIFG, now at a certain middle withdrawal along the line MEF or FLM; and the same is to be understood of Venus, for she does not always digress from the Sun by the same measure. So, then, if we are to leave the angelic theory, the one perceived by the moving Intelligences, which perhaps cannot be grasped by any bonds of our geometry, and are at last to fit to human understanding some form on which tables of the motions may rest, we need far more observations than those that now exist, and indeed observations either undertaken by ourselves or of such a kind that the manner of observing lets us be certain of the correction to be applied to the observed place. Moreover, the roughly 70 observations of Venus and 25 of Mercury that

we have already made are not enough for us. We therefore intend, God the governor of our life granting it, to obtain more, and at the same time to await Tycho's, which now lie under the press at Cologne. Meanwhile we shall use some selected from those we shall report in chapter 9, and on them we shall build the following hypotheses, intending to correct their measures in Tome 3 if a multitude of certain phenomena should compel us to do so.

[Margin: The author's apology for putting off a more perfect hypothesis to another time.]

Diagram. The figure of the spires of Mercury and Venus around the Sun, set into the right of the left column with the text running narrow beside it. A large arc rises from O and Q, the ends of a straight base line. Above it stands a circle headed by A, and within and across these run several curved loops meeting at F and M on either side. A rayed star stands just left of S on the arc through S. Straight lines rise from the middle of the base line to the curves.

- Q (right end of the base line, a swash sort)

Expositio Figuræ Communis Veneri, & Mercurio.

Explanation of the Figure Common to Venus and Mercury.

II. Let A be the centre of the Earth, of the ecliptic and of the world, through which passes CAD, the line of apsides of Mercury and Venus. On this line let I be the centre of the eccentric orb CODX, which carries the epicycles of the planets, whose centres in their various positions are C, F, O, D, X, Q. And let AI be either the eccentricity, if it is unvarying and always the same, or the mean eccentricity, if it varies. In that case, from I describe the small circle BZ containing the anomaly of the eccentricity, and let the variation take place by a libration along the diameter BZ, up and down, but let it take its laws from the circumference of the small circle, according to the analogy of second sines,

as we shall presently say. The radius or semidiameter of the planets' orb is to be as great as the radius of the Sun's annual orb, and the eccentric of these planets is to move with exactly the same mean motion as the Sun, in the order of the signs, from the apogee C toward F, O, etc., and from the perigee D toward X, Q. Finally, let the semidiameter of the epicycle become now larger, now smaller through a certain libration, which takes its laws from a circle, likewise according to the ratio of second sines.

[Margin: Explanation of the former diagram.]

Diagram. The former of the two diagrams common to Venus and Mercury, set across the left column. A large outer circle encloses the eccentric circle, on which six small epicycle circles stand at G–C at the top, F upper left, O left, D at the bottom, X right and Q upper right. A small dashed circle stands about I with B above and Z below. Straight lines run from A, below the small dashed circle, to the epicycles and out to the outer circle; a vertical line runs from G through C, B, I, Z, A, L and D to the bottom of the outer circle.

- G (top, on the outer circle)
- C (centre of the top epicycle)
- E (left of the top epicycle, on the eccentric)
- H (upper left, at the outer circle)
- M (upper left, on the epicycle about F)
- θ (a sort of that shape, inside the epicycle about F, to the right of F)
- F (centre of the upper-left epicycle)
- V (left of the epicycle about F)
- N (below the epicycle about F)
- P (top of the left epicycle)
- O (centre of the left epicycle)
- β (left, on the outer circle)
- B (top of the small dashed circle)
- I (centre of the small dashed circle)
- Z (bottom of the small dashed circle)
- A (below the dashed circle, where the straight lines converge)
- K (left, on the bottom epicycle)
- L (top of the bottom epicycle)
- D (centre of the bottom epicycle)
- π (a sort of that shape, at the foot of the vertical line, on the outer circle)
- S (upper right, at the outer circle)
- T (upper right, on the epicycle about Q)
- δ (left of the epicycle about Q, set with its bowl above and its tail below)
- Q (centre of the upper-right epicycle)
- R (below the epicycle about Q)
- Y (top of the right epicycle)
- X (centre of the right epicycle)
- a swash sort resembling ϙ or a Q (right, on the outer circle) [?]

Now, so that the anomaly of the eccentricity, if it is needed, and of the epicycle's semidiameter may be managed, let A in the small circle added here be the limit of the greatest eccentricity or epicycle-semidiameter, C of the mean, and B of the least. Let the difference AC between the greatest and the mean, or CB between the mean and the least, be known, and let us suppose the greatest to occur when the centre of the epicycle is at the apogee of the eccentric, the least when it is at the perigee, and the mean when it is at the mean longitudes. Therefore, given the anomaly of the eccentric from the tables (it will be given if the motion of the apogee of Venus and Mercury is subtracted from the mean motion of the Sun, or, under another hypothesis to be indicated, from the true motion), transfer it to the small circle added here. If it belongs to the first quadrant AGD or the fourth ALF, that is, if the anomaly of the eccentric is less than 90° or greater than 270°, multiply the second sine of the anomaly just mentioned, or of its complement to the circle, say CI, by the given difference AC, whether of the eccentricity or of the epicycle's semidiameter, and divide the total by the whole sine. For the quotient arising from this, added to the mean eccentricity or semidiameter, will yield the eccentricity or semidiameter to be applied later in finding the equations of the centre and of the orb. But if the anomaly of the eccentric belongs to the second quadrant DHB, that is, if it is greater than 90° and less than 180°, or to the third, BMF, that is, if it is greater than 180° but less than 270°, multiply the second sine, say CK, of the complement to the semicircle or of the excess over the semicircle by the difference CB of the eccentricity or semidiameter. Then, having divided the total by the whole sine, subtract the quotient from the mean eccentricity or semidiameter, so as to leave the desired eccentricity or epicycle-semidiameter. It is not necessary, however, for one and the same small circle to serve both the upper and the lower difference: it may happen that two are needed, that is, that the difference AC is not equal to the difference CB.

[Margin: Explanation of the small circle governing the anomaly of the eccentricity and of the epicycle's semidiameter.]

Diagram. The added small circle, set into the right of the right column with the text running narrow beside it. A vertical diameter AB is crossed by three parallel horizontal chords, GL through I, DF through C, and HM through K.

- A (top)
- G (left, upper chord)
- I (on the diameter, upper chord)
- L (right, upper chord)
- D (left, middle chord)
- C (centre)
- F (right, middle chord)
- H (left, lower chord)
- K (on the diameter, lower chord)
- M (right, lower chord)
- B (bottom)

Proponitur Prior Hypothesis Veneris.

The First Hypothesis of Venus Is Set Out.

III. First, let the eccentricity of Venus either be the same as the eccentricity of the Sun, namely, for us, 3460 parts of which the radius of the eccentric orb is 100000, since many observations favour this position; and accordingly let the measure of the equations of the eccentric be the same at an equal anomaly of the eccentric. Or, if one is willing to undergo a labour that is by no means necessary, let the mean eccentricity AI in the former figure be 3400 parts, the least, AZ, 3300, and the greatest, AB, 3500, so that the difference BI or IZ is 100. And according to the anomaly of the eccentric let the temporary eccentricity be found, by the method just given in the explanation of the latter diagram. With this, with the radius 100000, and with the angle they enclose, which the anomaly of the eccentric itself will reveal, find in the usual way the distance of the epicycle's centre from the centre of the Earth, and the prosthaphaeresis of the eccentric, to be subtracted in the first semicircle of the anomaly and added in the second, so as to obtain the place of the epicycle's centre, which is called the planet's eccentric place, or the centre of the planet. The anomaly of the eccentric itself becomes known by subtracting the motion of Venus's apogee from the mean rather than the true motion of the Sun, for a reason to be indicated in the scholia. The distance of the epicycle's centre, however, is to be kept for use, on which see precept 3 shortly.

[Margin: Method of the eccentric equation.]

Second, for the equations of the orb or epicycle, the epicycle's semidiameter must be found. Attending to many and more correct observations of Venus, this is greatest around the apogee of the eccentric, and nearly as great as far as the mean longitude; it is least around the perigee. Nor, in the meantime, after solving 300 triangles and more, could I discover other, more probable measures than that the greatest semidiameter be 73140 parts and the least 70640, so that the lower difference is 2500 parts, of which the radius of the eccentric is 100000. For the mean between these, 71890, to which geometry otherwise invited us, could not be chosen, since the observations everywhere protest when the epicycle stands near the mean longitudes or above them. Therefore, if the anomaly of the eccentric belongs to the upper semicircle, the same semidiameter of the epicycle, 73140 parts, is always to be applied. But if the anomaly belongs to the lower semicircle, multiply the second sine of the complement to 180° or of the excess over 180° by 2500, divide the total by 100000, and subtract the quotient from the 73140 parts, to obtain the desired semidiameter of the epicycle.

[Margin: Inquiry into the epicycle's semidiameter.]

Third, to the mean anomaly of the orb taken from our tables, add the equation of the eccentric itself if the centre of the epicycle is in the first or left semicircle of the centric anomaly, or subtract it if it is in the second or right semicircle; and the equated anomaly of the orb will result. Its complement to

the semicircle, if it does not exceed 180°, or its excess, if it does, will give the angle enclosed by the distance of the epicycle, found by the first step, and the semidiameter of the epicycle, found by the second. From these three givens, then, you will find trigonometrically the angle set at the centre of the Earth, that is, the angle opposite the epicycle's semidiameter. For this will be the epicyclic equation, or the equation called of the orb, to be added to the eccentric place of Venus if the equated anomaly of the orb is less than 180°, but subtracted if it is greater; and you will have the place of Venus in the zodiac as seen from the Earth. Its later reduction from the ecliptic to the orbit, and conversely, will be discussed in the section on the phenomena of latitude. How many observations of different ages this hypothesis satisfies within a fifth part of a degree I forbear to say here; granted that it may not satisfy some, whether they are suspect because analogy is not preserved or for some other reason. But I am not bound to be much more fortunate in this business than so many and such celebrated astronomers have been. I must, however, bring some light to the precepts by an example.

[Margin: Method of the equation of the orb.]

EXEMPLVM pro ♀.

Example for ♀.

IV. Kepler reports in the *Astronomia Optica*, p. 305, that the Heart of Leo was seen by Mästlin covered by Venus in the morning, at 4^h after midnight of the day 1574 September 16. Now the Heart of Leo was then, according to our tables established in Book 6, last chapter, at ♌ 23° 57′. So Venus was either at that very spot or distant from it by a very few minutes, namely as many as the spread of her rays could hide that star by. At that time the motions of the Sun and Venus from our tables stood as follows.

	Value
☉ Mean motion	6^s 4° 25′
♀ Apogee	2^s 29° 23′
Hence the anomaly of the eccentric	3^s 5° 2′
Mean anomaly of the orb	8^s 21° 8′

With these laid down, in the following diagram let the line of apsides be AD, and on it let the centre of the Earth be C, and let the centre of Venus's eccentric orb be B. Counting from the apogee A, in the order of the signs, 3^s 5° 2′, that is, the arc AK, describe from K the epicycle MHV. Then, drawing from the centre of the eccentric, through the centre of the epicycle, the straight line BK as far as M, M will be the mean apogee of the epicycle; and drawing the straight line CKG through the same centre from the centre of the Earth, G will be the true apogee. Next, counting from the mean apogee in the order of the signs 8^s 21° 8′, that is, the arc MHV, Venus will fall at V. To this point

draw both the semidiameter KV and the straight line CV from the centre of the Earth.

[Margin: Delineation of the diagram for this example.]

Diagram. The diagram for the example, set into the right of the left column with the text running narrow beside it. A vertical straight line runs from A at the top through B and C to D at the foot. A large arc runs from A leftward and down through K to D. About K is drawn the epicycle, with G and M at its left and H at its right; V, marked with a small star, stands at its top. Straight lines run from B through K to M, from C through K to G, from K to V, and from C to V.

- A (top of the vertical line)
- B (on the vertical line, above C)
- C (on the vertical line): centre of the Earth
- D (foot of the vertical line)
- V (top of the epicycle, with a star): Venus
- G (left of the epicycle, on the line from C)
- M (left of the epicycle, below G, on the line from B)
- K (centre of the epicycle)
- H (right of the epicycle, on the line CG)

First, then, since the eccentricity BC is given as 3460 parts of which the radius BK is 100000, and the angle ABK as 95° 2′, and hence its complement KBC as 84° 58′, the angle BKC is found by the doctrine of triangles to be 1° 58′. This prosthaphaeresis, subtracted here from the mean motion of the Sun, that is, from 6^{s} 4° 25′, leaves the centre K, that is, the eccentric place of Venus, at ♎ 2° 27′. In the same triangle BKC, the distance KC is found to be 99780 parts of which the radius BK is 100000.

[Margin: 1st step.]

Second, since the anomaly of the eccentric exceeds a quadrant but not a semicircle, and its complement to the semicircle is 84° 58′, the second sine of this, 8774, multiplied by the lower difference of the semidiameter, 2500, makes 21923000. When this is divided by the whole, 100000, there remain 219 parts to be taken from the greatest semidiameter, 73140, which leaves the epicycle's semidiameter KV as 72921 parts.

[Margin: 2nd step.]

Third, since the subtractive equation of the centre, that is, the angle CKB, was 1° 58′, and this equals the angle GKM, if it is added to the mean anomaly counted from the mean apogee, which was 8^{s} 21° 8′, the equated anomaly counted from the true apogee G, that is, the arc GHV, will be 8^{s} 23° 6′. Therefore, the semicircle GMH being removed, there will be left the arc HV, that is, the angle CKV, of 83° 6′. With this, with the distance CK of 99780 found by the first step, and with the semidiameter KV of 72921 found by the second, the equation of the orb KCV is found to be 38° 30′. When this is subtracted from the centric place of Venus, which was ♎ 2° 27′, the place of Venus is left at ♌ 23° 57′, exactly as Mästlin saw it.

[Margin: 3rd step.]

Indicatur Posterior Hypothesis Communis Veneri ac Mercurio.

The Second Hypothesis, Common to Venus and Mercury, Is Indicated.

V. The second hypothesis is nothing other than that of Kepler and Boulliau, transferred, however, to the hypothesis of a resting Earth: that is, if we use the true place of the Sun, which is to be at one of the foci or umbilici of the ellipse described by Venus and Mercury around the Sun, and the eccentricity of the ellipse's centre from the Sun, and the semidiameter of the ellipse. But since not all observations favour the place of the aphelion established by those authors, it is still in doubt in what position, in such a hypothesis, the ellipse is to be described with respect to the Earth and the Sun together. Indeed, one might doubt whether the axis of the ellipse is to be held always in a position parallel to the line of apsides of the Sun, or whether the minor diameter of the ellipse is to be kept always equidistant from the line of the Sun's true place; and whether the anomaly of the orb is to be counted from the aphelion of the ellipse or rather from the apogee. To determine these things, and the correct measures, more observations are needed. We therefore cannot bring forth the hypothesis we have conceived, and readers should not take it amiss if we have preferred to indicate it rather than suppress it altogether. Certainly, when it has matured, it will represent that apparent diversity of the semidiameter.

Proponitur Mercurij Hypothesis.

The Hypothesis of Mercury Is Set Out.

VI. Let the figure described at number 2 be repeated here, and in it let the greatest eccentricity of Mercury, AB, be 10000 parts of which the radius of the eccentric is 100000, which it is to have when the centre of the epicycle is placed at C, the apogee of the eccentric. Let the mean, AI, be 8000 parts, namely when the centre of the epicycle is at O or X, that is, at the mean longitudes; and let the least, AZ, be 6000 parts, which it is to have when the centre of the epicycle is placed at D, the perigee of the eccentric. Thus the difference of the extreme eccentricity from the mean, that is, the semidiameter of the small circle, BI and IZ, is 2000 parts. And let the eccentricity vary according to the ratio of the second sines corresponding to the anomaly of the eccentric, or to its complement to the semicircle or circle, or to its excess over the semicircle, as I taught at number 2 by means of the second diagram explained there. The semidiameter of the epicycle is likewise to vary according to the same ratio, but so that the semidiameter EC and DK is least when the centre of the epicycle is at C, the apogee of the eccentric, or at D, the perigee, and OP or XY is greatest when that centre is at O or X, that is, at the points of the mean longitudes, which is to say when the centre of the epicycle stands a quadrant from the apogee of the eccentric. Further, let the greatest semidiameter be 45500 parts

of which the radius of the eccentric (which here too is as great as the radius of the annual orb) is 100000, and the least 38500 parts, so that the difference is 7000. Finally, let the anomaly of the eccentric be obtained by subtracting the motion of Mercury's apogee from the mean motion of the Sun, for far more observations favour this

[Margin: Variation of the epicycle's semidiameter.]

than an anomaly derived from the true place of the Sun. In all the remaining matters, as regards the method of finding the prosthaphaereses of the eccentric and of the orb or epicycle, let the procedure be as was said in the hypothesis of Venus, and as will shortly be explained by the example itself.

EXEMPLVM pro ☿.

Example for ☿.

VII. In the year 1631, on the morning of November 7, Pierre Gassendi observed Mercury under the Sun, and from the circumstances of the observation he judiciously determined that the conjunction with it took place at $17^{h}\ 23^{m}$ after noon of the 6th, with respect to Uraniborg, when Mercury was in Scorpio 14° 36′, as he himself reports in the *Institutio Astronomica*, and Boulliau in Book 10, chapter 7. At that moment, from our tables, the motions of the Sun and Mercury stood as follows.

	Value
Mean motion of ☉	$7^{s}\ 16°\ 4'$
Apogee of ☿	$7^{s}\ 29°\ 59'$
Hence the anomaly of the eccentric	$11^{s}\ 16°\ 5'$
Mean anomaly of the orb	$6^{s}\ 6°\ 15'$

Let the former figure of number 2 be repeated here too, and, counting from the apogee C, in the order of the signs, $11^{s}\ 16°\ 5'$, that is, the arc CODQ, let the centre of the epicycle be placed at Q. Since this is a little distant from the apogee, namely by 13° 55′, the eccentricity will therefore be close to greatest, and nearly AB. So, drawing from a point a little below B the straight line BQT, T will be the mean apogee of the epicycle; and drawing AQS from the centre of the Earth, S will be the true apogee. And counting from T through S δ the mean anomaly of the orb, $6^{s}\ 6°\ 15'$, the place of Mercury will fall at R, which is to be joined to the centre of the Earth and of the epicycle by the straight lines AR and QR. With these preparations made:

[Margin: Delineation of the diagram for this case.]

First, in the triangle BAQ, the radius BQ is given as 100000 parts, and the angle ABQ, the complement of the angle CBQ, which we said to be 13° 55′, is 166° 5′. Therefore, if the eccentricity AB is given, there will be enough givens to solve the triangle. Now the second sine of the complement of the anomaly of the eccentric to the circle, that is, of 13° 55′, is 97065; multiplied by

the difference of the eccentricity, 2000, it makes 194130000. This total, divided by 100000, leaves 1941 particles to be added to the mean eccentricity AI of 8000 parts, and the eccentricity AB comes out as 9941 parts. With this, with the radius BQ and with the angle ABQ just mentioned, there is obtained AQ, the distance of the epicycle's centre, as 109680 parts of which the radius BQ is 100000, and the angle AQB as 1° 15′, that is, the prosthaphaeresis of the centre. Added to the mean motion of the Sun, this gives the centric place of Mercury at ♏ 17° 19′.

[Margin: 1st step.]

Second, the complement of the anomaly of the eccentric to the circle was 13° 55′, and its second sine 97065. This, multiplied by the difference of the epicycle's semidiameter, 7000, makes 679455000. When this total is divided by the whole sine, 100000, there remain 6795 parts to be taken from the greatest semidiameter, 45500, and there remains QR, the epicycle's semidiameter, of 38805 parts.

[Margin: 2nd step.]

Third, since the equation of the centre was 1° 15′ and additive, it is therefore applied in the contrary way and subtracted from the mean anomaly of the orb, 6^s 6° 15′, and the equated anomaly of the orb will come out as 6^s 5° 0′. This, counted from the true apogee S, will give the arc SδR; and when 6^s are removed from it, there will be left the angle AQR of 5° 0′. With this, with the distance AQ of 109680 parts obtained by the first step, and with the semidiameter QR of 38805 parts obtained by the second, the angle QAR is found to be 2° 43′, that is, the equation of the orb, to be subtracted from the centric place of Mercury, which was ♏ 17° 19′. And there remains the apparent place of Mercury in the zodiac, ♏ 14° 36′, exactly as Gassendi observed it. How far the tables of others, especially the Danish tables, or those of Longomontanus, have stood from that place, we said in Book 3, chapter 3, scholium 3.

[Margin: 3rd step.]

Would that one could always attain the place of Mercury with such happiness of hypothesis! If we do not attain it, not all the blame is to be thrown on the hypothesis; part of it must also be put on the slippery observations. For it is enough for us to attain by this method, very closely, several places of the more certain observations, until a multitude of clear observations suggests a way of further polishing and perfecting the measures of the orbs of Mercury and Venus. Meanwhile, let the synopsis of our measures and numbers stand in the following table, with the distances, on the supposition that the radius of the annual orb, that is, the mean distance of the Sun from the Earth, is 7300 terrestrial semidiameters, according to what was said in Book 3, chapter 7. In the greatest and least distances, however, we shall assume those which could have been or could be in our hypothesis if the duration of the world had been or were to be so great that the apogees of the eccentrics of the Sun, Venus and Mercury stood under the same or opposite points of the zodiac; even though, in these times, the apogee of Venus is much nearer to the apogee of the Sun

than the apogee of Mercury is, and indeed the perigee of Mercury is much nearer to the apogee of the Sun than the apogee of that same Mercury is.

MENSVRÆ NOSTRÆ Hypothesis Mercurij & Veneris.

Our measures for the hypothesis of Mercury and Venus.

Quantity		Planet	In parts of which the radius of the eccentric is 100000	In semidiameters of the Earth
Eccentricity	Total, AB	♀	3460	263 [recte: 253, per the book's errata]
		☿	10000	730

SCHOLIA.

Scholia.

I. Someone will perhaps wonder why the superior planets, in their epicyclic motion, that is, in the anomaly of the orb, adjust themselves to the Sun's true or apparent motion; and why, accordingly, to obtain the anomaly of the orb, their eccentric place must be subtracted from the Sun's true place according to our opinion, which was in the end that of Tycho and Longomontanus, to say nothing of Kepler and Boulliau; and yet Venus and Mercury, in their eccentric motion, that is, in the anomaly of the eccentric, do not regard the Sun's true motion but rather its mean motion, and, according to our opinion, to obtain their anomaly of the eccentric, the motion of the apogee of these planets must be subtracted from the Sun's mean motion, as all ancient astronomy was accustomed to do. But he will stop wondering if he considers that the superior planets, in their motion around the Sun, do not describe epicycles around the Sun; or that they regard the Sun in such a way that they principally regard the Earth, or the Sun as ordered around the Earth, and therefore follow the motion of the Sun that appears to the Earth; whereas Venus and Mercury, of

themselves and in the first place, regard the Sun, around which they describe their epicycles, and therefore follow the Sun as ordered around the Earth only secondarily, and so regard its motion just as if it were viewed from the centre of the Sun's eccentric. Next, the multitude of observations, which are better represented by this hypothesis, drove us to it. We have, though, also indicated another hypothesis, which can use the Sun's true motion and ellipses described around it.

[Margin: Why in Mercury and Venus we use the mean motion of the ☉.]

II. There will also be those who criticize our hypotheses on the ground that we use the small circle that varies the anomaly of the eccentric in such a way that we assume neither a doubled anomaly nor a motion of the centre made along the circumference of this small circle. But since by this method of ours the geometrical calculation turns out easier, and is supported by no smaller number of observations, it did not seem right to impose that labour on astronomers; and it is expedient to try this method too, and rather to change the measures of the orbs and motions so that they agree with the observations.

[Margin: On the use of the small circle of the anomaly of the eccentric.]

CAPVT VII.

Chapter VII.

De Maximis Veneris ac Mercurij à Sole Digressionibus, & Aequationibus Orbis.

On the greatest digressions of Venus and Mercury from the Sun, and on the equations of the orb.

I. We treat the greatest elongations from the Sun and the prosthaphaereses of the orb together because, in the hypothesis of the Earth going around the Sun and reckoning the anomaly of these planets from the Sun's true place, the greatest equation of the orb, or greatest parallax of the orb, or angle of commutation, and the greatest wandering of Venus and Mercury from the Sun, are one and the same; granted that, in the hypothesis of the Earth at rest, or regarding the Earth's mean motion, they differ. Moreover, the greatest digressions, which the Greeks call [Greek: ἀπόστασεις (apostaseis, "distances")] or [Greek: διάστασεις (diastaseis, "separations")], occur without dispute when Venus or Mercury is at those points of the orb at which a straight line drawn from the centre of the Earth is tangent to their orb, that is, makes a right angle with the semidiameter of the epicycle, or of an orb equivalent to the epicycle. These indeed occur before the first station and after the second, and farther from the stations in ♀ than in ☿. Kepler, in the *Epitome of Copernican Astronomy*, p. 763, lays down a twofold sign of the greatest digressions: the first is if the apparent motion of these planets in an ephemeris is equal to the Sun's true motion; the other, if, observed with a telescope, they appear dichotomous, that is, like a bisected Moon. The size of these digressions and their variety depend

on 3 causes. The *first* is the size of the epicycle or orb and its diameter, which in our hypothesis is not always the same but is variable along a spire; in an elliptical orbit, however, in place of the semidiameter of the orb, the greatest and least distance of the planet from the Sun, one of the foci, is used. The *second* is the distance of the centre of the epicycle or orb from the centre of the Earth, especially if their eccentricity varies, as we more truly judge it does in Mercury; or, in the hypothesis of the Sun at rest, the differing distance of the Sun from the Earth. The *third* is the variation of the Sun's true place. From these three elements, then, let there be

[Margin: Where and when the greatest digressions from the ⊙ occur.]

[Margin: The causes that vary the measure of the digressions.]

Problema 1. Aequationes Orbis Veneris ac Mercurij Maximas Definire.

Problem 1. To define the greatest equations of the orb of Venus and Mercury.

II. In the following diagram let G be the centre of the Earth, and B the centre of the epicycle of Venus or Mercury; and from B as centre let their epicycle, or orb, HDFE be described, which the straight lines GD and GE, drawn from the centre of the Earth, touch at points D and E; for by Euclid III.18 they will make a right angle at the points of contact with the semidiameters of the orb BD and BE. Now let there be given the distance BG of the centre of the orb from the centre of the Earth, both when the centre B is at the apogee of the eccentric and when it is at the perigee; let there also be given the semidiameter of the epicycle or orb in the same kind of parts, or, in the hypothesis of the ellipse, the distance of the planet from the Sun. For in triangle BGD, right-angled at D, or in BGE, right-angled at E, the angle DGB or BGE will be given, measuring the greatest apogeal or perigeal equation of the orb. In brief, let it be: as the distance BG to the whole sine, so the semidiameter BD or BE to the sine of the angle at G; or join the residual of the logarithm of the distance BG to the logarithm of the semidiameter of the epicycle or orb, and the logarithm of the angle measuring the greatest equation of the orb will result. See below the examples and the method of Boulliau to be brought forward at number 9, and another example from Copernicus below, ch. 9, Problems 4 and 6. How, moreover, from the greatest equations of the orb once established at the apogee and perigee of the eccentric the other greatest equations of the orb are derived, or are established by this Problem from other and yet other distances of the centre of the epicycle, is clear from what was said about the equations of the three superior planets in Section 2, ch. 12, to be applied in like manner to these planets.

Diagram. An orb with tangents from the Earth, set into the right of the right column with the text running narrow beside it. A circle with centre B carries a vertical diameter from H at the top through B and F; the line continues down to G, below the circle. Two straight lines descend from the left and right

of the circle to meet at G. An arc runs from A on the left through the region of B to C on the right. Short lines join B to D and to E.

- H (top of the circle)
- B (centre of the circle)
- A (left end of the arc, outside the circle)
- D (left, on the circle, beside A)
- E (right, on the circle)
- C (right end of the arc, outside the circle)
- F (bottom of the circle, on the vertical line)
- G (foot of the figure, where the two straight lines meet)

Problema 2. Digreſſiones Veneris ac Mercurij à Sole Maximas Definire.

Problem 2. To define the greatest digressions of Venus and Mercury from the Sun.

III. In the hypothesis of Kepler and Boulliau, and of others who hold that Venus and Mercury go around the Sun B, unmoved, as one of the foci of an elliptical orbit equivalent to the Ptolemaic epicycle, and who reckon the eccentric anomaly from the Sun's true place, the greatest equations of the orb and the greatest digressions from the Sun of these planets are the same, as I have just said; hence by the first Problem the second has been satisfied. But if you draw from G the arc of the ecliptic ABC, and A is the eastern part and C the western, the angle BGD will measure the greatest evening digression, made at D; and the angle BGE the morning digression, made or to be made at E. In the theory of others, however, which employs an Earth at rest, or subtracts the apogee of these planets from the Sun's mean motion so as to have the eccentric anomaly, one must know the time at which the centre of the epicycle of ♀ or ☿ is at the apogee and at the perigee of the eccentric, and compute for that time the Sun's motion, both mean and true. For the greatest equation of the orb in both places, that is, at apogee and perigee, will be equal to the greatest digression from the line of the Sun's mean motion. Therefore, by adding to it or subtracting from it the equation of the Sun, that is, the difference of the true place from the mean, the greatest digression will be established, according as the Sun is more eastern or more western; and the same is to be done at other places of the eccentric besides the perigee and apogee, since at those places the line drawn through the centre of the epicycle of Venus or Mercury is parallel to the line of the Sun's mean motion. In Mercury, however, which is judged to make the least digressions at the apogee of the eccentric, and greater ones at perigee, but the greatest at the thirds of the circle, what must be done will be clear from what is to be said in ch. 9, Problem 3.

IV. Before we set out in tables a synopsis of opinions on the greatest equations and wanderings, it is worthwhile to indicate in advance what ancient and recent authors have judged about them. Among them, in the first place, Pliny the Elder, Book 2, ch. 8, speaks as follows: "Below, a huge star called that of Venus

circles the Sun, wandering in an alternating course, etc."; and shortly after: "It completes the circuit of the zodiac in 348 days, never standing away from the Sun farther than 46°, as Timaeus holds. In a similar way, but by no means in size or power, the star of Mercury next to it, called by some that of Apollo, is carried in a lower circle" (he would better have said "inner") "with a circuit nine days swifter, shining now before sunrise, now after sunset, never more than 23° removed from the Sun, as this same author and Sosigenes teach." And in ch. 17: "Let it be said first, then, since they are different stars, why the star of Venus never departs from the Sun farther than 46°, and Mercury 23°, and why they often [?] turn back toward the Sun short of those limits: both have their apsides turned the other way, etc." As to Venus's wandering, Martianus Capella supports Pliny the Elder in Book 8 of *De Nuptiis Philologiae et Mercurii*, towards the end, saying: "But Venus, like the Moon, wanders about, departing from the Sun's orb by fifty moments, although it cannot stray more than 46°." But about Mercury he had written a little earlier: "But this same Stilbon, though it accompanies the Sun from different circles, will nevertheless never be able to stray from it beyond 32°, nor to stand off by two signs."

[Margin: Pliny the Elder's opinion, from Timaeus and from Sosigenes.]

[Margin: The opinion of Martianus Capella.]

V. Far more exact is Ptolemy, who, in Book 9, ch. 7, where he treats those of Mercury, and in Book 10, ch. 1, where those of Venus, and in Book 12, ch. 9, where the greatest digressions of both, discusses them first from the Sun's mean place and then from its apparent place, on the basis of the observations of Theon, an astronomer of his own time, and of his own. Ptolemy was more or less followed by al-Farghānī, difference 15; Jābir ibn Aflaḥ, Book 7 of his *Astronomy*, ch. 3, correcting Ptolemy; Regiomontanus, Book 12 of the *Epitome of the Almagest*, propositions 13 and 14; Fernel, Book 1 of the *Cosmotheoria*, ch. 5 and 6; Peuerbach, in his theory of Venus and Mercury, and on that above all Wurstisen, pp. 190 and 218. Ptolemy judged that Mercury makes its least digressions from the Sun in the sign ♎, and greater ones in ♈, yet not the greatest there, but in ♊ and in ♒, as Copernicus gathers in Book 5, ch. 25; although the Ptolemaic table places Mercury's greatest in ♍, and in ♒ the morning ones, in ♌ the evening ones; and he judged that it comes nearer the Earth not at the perigee of the eccentric but at two points a third of the circle distant from the apogee.

[Margin: The opinion of Ptolemy and of the ancients.]

VI. Copernicus himself, in Book 5, ch. 20, subscribing to Ptolemy, teaches that Venus's digressions on both sides are smaller around the apogee and greater around the perigee, but he transfers them to the hypothesis of the moved Earth. In ch. 25, however, he teaches that these digressions vary from the variation of the epicycle, which he admits to be now greater, now smaller; and in ch. 28 he reports that Mercury makes greater digressions around the sides of the hexagon than at perigee, not because the planet there comes nearer the Earth than at the perigee of the eccentric, but because the planet there describes a greater

circle. How large these digressions are can be gathered from the chapters already mentioned, and from what will be said more fully in ch. 9, Problems 4 and 6, and finally from the greatest prosthaphaereses of the orb that Reinhold gives in the Prutenic Tables and Mästlin in the Appendix to Kepler's *Prodromus*, from which Lansbergen in his tables does not depart far; and Magini, of whom presently.

[Margin: The opinion of Copernicus.]

VII. But Giovanni Antonio Magini, in Book 1 of the *Theoricae*, in the theory of Venus, ch. 4, and in the theory of Mercury, ch. 9 and 10, followed the Ptolemaic hypothesis as to the form of the diagram in such a way that he nonetheless corrected the numbers or measures from the Prutenic Tables. He therefore teaches that Venus's elongations from the Sun's mean place are greater at the perigee of the eccentric than at the apogee; that among the perigeal ones the morning ones are greater than the evening ones; but that with the centre of the epicycle at the apogee of the eccentric the morning ones are sensibly equal to the evening ones; and that they are greater than all of these when the centre of the epicycle is 115° from the apogee of the eccentric in the order of the signs and Venus is 7^{s} 13° from the apogee of the epicycle, reckoning in the variation that the true place of the epicycle's centre produces from the mean. If, on the other hand, the elongations of Venus are viewed from the Sun's true place, the morning ones turn out greater than those computed from the mean place when the Sun is in the first semicircle of its eccentric, because the Sun's true motion is less than its mean; and they then become greatest with the Sun holding an anomaly of 92°, and very greatest at the greatest eccentricity. Conversely, the evening ones come out greater from the true than from the mean place of the ☉ when the Sun is in the latter semicircle of its anomaly, and greatest at 268°, and very greatest at its greatest eccentricity. But here Magini errs, putting morning ones for evening ones, and vice versa.

[Margin: The opinion of Magini and Barazanus [recte: Baranzanus].]

[Margin: Magini's slip.]

The greatest digressions of Mercury from the Sun's mean place occur at the points of the eccentric at which the centre of the epicycle is 120° from the apogee on either side, if Mercury is at the points of contact of the epicycle; and both the evening and the morning ones are greater at the western contact of the epicycle than at the eastern. As for the Sun's true motion, they grow in the same way as was said of Venus, according as the Sun is in the first or the latter semicircle of its eccentric, and around 92° and 268° of solar anomaly they become greatest; and still greater at the Sun's greatest eccentricity. Baranzanus follows Magini, in Part 2 of the *Uranoscopia*, from p. 200.

VIII. Longomontanus, in Book 2 of the *Theorica*, ch. 19, corrects the greatest digressions of Venus from the Sun, reported by Ptolemy in Book 10, ch. 1 and 2, according to Tycho's positions of the fixed stars and the corrected mean motion of the Sun, so as to derive from them the motion of the anomaly of the orb. But there and in ch. 20 he uses the Sun's mean motion, which he judges

these planets regard; and in ch. 22 he indicates the structure of the canon of the equations of the orb by proportional minutes, about which we said enough in Section 1, ch. 12, from no. 5. We shall therefore gather the greatest equations from the tables he appends to ch. 22, although they could be gathered from the measures of the orbs he gives and from his diagrams, according to what was said in ch. 4, at the end of numbers 2 and 3. And although Kepler, in the *Epitome of Copernican Astronomy*, p. 763, touches on this matter very lightly, saying that the greatest digression of ♀ is confined within 47° 15′, and that of ☿ at apogee within 29° and at perigee within 18°, yet from his measures, set out in ch. 5, no. 5, and from the Sun's distances in Book 3, ch. 7, we shall gather juster digressions.

[Margin: The opinion of Longomontanus.]

[Margin: The opinion of Kepler.]

IX. Ismaël Boulliau, in Book 9, ch. 4, and Book 10, ch. 6, splendidly defines the greatest equations of the orb of Venus and Mercury at aphelion and perihelion, both theirs and the Earth's, and lays down that they are the same as the greatest digressions from the Sun; for he teaches that the apparent motion of these planets and the line of apsides are referred not to the centre of the annual orb, that is, to the Sun's mean motion, as Longomontanus and Lansbergen held with the ancients, but to the Sun itself, through which the line of apsides passes. In Book 11, theorems 11 and 12, he tries to demonstrate this about Mercury from four of its greatest digressions from the Sun; and he indicates the same demonstration for Venus from what was said in Book 9. For Venus, therefore, he uses this first diagram, in which E is the centre of the annual orb AD, and AED the Earth's line of apsides; the eccentricity from the Sun G is EG; and the Earth is at aphelion at A and at perihelion at D, its distance AG being 101784 parts and DG 98216, of the parts of which EA, the radius of the annual orb, is 100000. With the Earth placed at A, then, and Venus at aphelion at B, the point of contact, and with the tangent AB drawn and Venus's aphelion distance BG of 72973 parts, he gathers the angle BAG, of the greatest digression from the Sun and of the greatest parallax of the orb. Likewise, with Venus placed at H and the tangent AH drawn, from its perihelion distance GH, 71823, he gathers the greatest digression GAH. And with the Earth at perihelion at D, and Venus now at aphelion at C, now at perihelion at I, the tangents being drawn

[Margin: The opinion and method of Boulliau.]

[Margin: The method for the greatest digressions of ♀.]

Diagram. Boulliau's figure for Venus, set into the right of the right column with the text running narrow beside it. A large outer circle has A at its top and D at its foot, joined by a vertical line. Within it stand two smaller circles, a middle and an inner, both off-centre toward the foot and cut by the vertical line. Straight lines run from A to B and to H, and from D to C and to I. Short lines join G to B, H, I and C. The sign ♀ stands in the left of the space between the outer circle and the middle circle.

- A (top of the outer circle)

- B (right, on the middle circle)
- H (right, on the inner circle, below B)
- E (on the vertical line, upper of the two letters above G)
- E (a second E on the vertical line, directly below the first, with a horizontal rule between them)
- G (on the vertical line, below the two letters)
- I (left of G, on the inner circle)
- C (left, on the middle circle)
- D (foot of the outer circle)
- ♀ (left, in the outer space)

DC and DI; and with Venus's aphelion distance CG, 72973, but perihelion distance GI, 71823, he gathers for these positions the angles of the greatest digressions and equations, GDC and GDI, as you will see in the table to be shown presently.

He uses a similar method in Book 10, ch. 6, for Mercury's digressions. The Earth's annual orb ABC is described and the line of apsides AC drawn, on which the Sun is at H; Mercury's orb in aphelion is DEF or IM, and in perihelion KLF; the Earth at aphelion is at A, its distance AH being 101784, and at perihelion at C, its distance being 98216; and Mercury's aphelion distance DH or IH or MH is 46690 parts, its perihelion distance HK or HL 30480 parts. For with the tangents AI, AK, CM, CL drawn, he gathers in the triangles right-angled at the contacts the angles of the digressions HAI, HAK, HCM, HCL, as in the tables below.

[Margin: The method for the greatest digressions of ☿.]

Diagram. Boulliau's figure for Mercury, set into the right of the left column with the text running narrow beside it. A large outer circle has A at its top, B on its left and C at its foot, with a vertical line joining A to C. Within it stand smaller nested circles, off-centre, cut by the vertical line near H. Straight lines run from A down to I and to the inner circle by K, and from C up to M and to the inner circle by L. Short lines radiate from H to D, I, M, K and L. The sign ☿ stands in the upper left of the space within the outer circle.

- A (top of the outer circle)
- ☿ (upper left, in the outer space)
- D (upper right, on an inner circle)
- E (upper left, on an inner circle)
- I (right, on an inner circle)
- L (left, on the smallest circle)
- H (centre, on the vertical line)
- K (right of H, on the smallest circle)
- F (below and left of H)
- B (left, on the outer circle)
- M (left, on an inner circle)
- C (foot of the outer circle)

[Margin: Ptolemy, Book 12, ch. 9.]

Before you come to the following Table III, you must be reminded again, dear reader, of what was said above at no. 7: namely, that Magini, and with him Baranzanus, in this treatment of the greatest digressions, used morning ones for evening ones. For, intending to show that the digressions from the true place of the ☉ are sometimes greater than the digressions computed from the mean place of the ☉, he gives an example in the morning ones, which occur with the centre of the epicycle in the first semicircle of the eccentric, where the true motion of the ☉ and of the centre of the inferior planets is less than the mean; and in the evening ones, which in the latter semicircle, etc. Yet it is certain that a morning planet in the first semicircle of the eccentric is less elongated from the true than from the mean place of the ☉, and the reverse in the latter. We, however, have thought it better to show the digressions with their numbers, as they stand in the author.

[Margin: A notice to the reader regarding the following table.]

III. TAB. DIGRESSIONVM à Sole Maximarum Copernicæarum ex Magino, & Baranzano.

Table III. Of the greatest Copernican digressions from the Sun, from Magini and Baranzanus.

Digressions	From the mean place of the ☉	Distance of the epicycle's centre from the apogee of the eccentric	Distance of the planet from the apogee of the epicycle
♀ Morning	48° 8′ 38″	3ˢ 25°	7ˢ 13°

For us, however, for whom Venus retains and Mercury acquires the greatest semidiameter of the epicycle at the epicycle's mean longitude, the greatest equation of the orb in that position is also, for Venus, 47° 0′ 6″, but for Mercury 27° 3′ 24″.

CAPVT VIII.

Chapter VIII.

De Artificio Inueſtigandi Apogeum & Motum Apogei ac Radicem motus Apogei, Veneris ac Mercurij.

On the technique for investigating the apogee, the motion of the apogee and the root of the motion of the apogee, of Venus and Mercury.

I. Ptolemy (Book 10, ch. 6) and Copernicus (Book 5, ch. 20) judged that, for distinguishing each inequality of the minor planets and the commensuration of the orbs, the method is easier in Venus and Mercury, because of the fixed limits of their greatest digressions from the Sun on either side; and for that reason he dealt with these before the three superior planets. But the opposite seems truer, because the superior planets can be observed in their acronychal oppositions with the Sun, when they are wholly stripped of the second inequality. Venus and Mercury, by contrast, lack the second inequality only in their conjunctions with the Sun, of both kinds, and outside these moments they are always involved in both inequalities, of motion in the eccentric and in the epicycle. In their superior conjunctions, moreover, they hide behind the Sun, and in their inferior conjunctions they are for the most part overwhelmed by the Sun's rays, so that they cannot be seen. In or under the very disc of the Sun they cannot be seen as blackish spots without a telescope, nor except very rarely, and when their apparent latitude is less than the Sun's apparent semidiameter; and it has not so far been established that such a conjunction of Venus was observed, nor will one be easily observable for many centuries. Mercury, however, we know to have been seen once under the Sun by Pierre Gassendi, in accordance with what was said on the spots of the Sun, Book 3, ch. 3, Scholium 3. Venus too very rarely attains so great a latitude in conjunction with the Sun at perigee that it does not fear the Sun's rays and can be observed, though we have shown

that this did happen, ch. 7, Scholium 1. Therefore an aid, necessary indeed but not as certain as in the superior planets, had to be sought from the greatest elongations from the Sun; and how the places of the apogees or aphelia were investigated by means of them must be briefly indicated.

[Margin: Whether the two inequalities are more easily distinguished in ♀ and ☿ than in the three superior planets?]

Problema 1. De Loco & Motu Apogei, & Aphelij Veneris ac Mercurij inueſtigandis, more Ptolemaico.

Problem 1. On investigating the place and motion of the apogee and aphelion of Venus and Mercury, in the manner of Ptolemy.

II. This technique is taught by Ptolemy, Book 9 of the *Magna Constructio*, Book 9 [sic], ch. 7, and Book 10, ch. 1; and there by Regiomontanus in the *Epitome*, Book 9, propositions 11 and 14, and Book 10, propositions 1 and 2; by Copernicus, Book 5, ch. 20 and 26; by Longomontanus, Book 2 of the *Theorica*, ch. 18; by Kepler in the *Epitome of Copernican Astronomy*, Book 6, p. 761; by Hérigone, vol. 5 of the *Cursus Mathematicus*, p. 661, or Book 3 of the *Theoricae*, proposition 31; and by Boulliau, Books 9 and 10 of his *Astronomy*.

[Margin: Authors of this method.]

First, then, you must observe, or select from the observations of others, two greatest digressions of these planets, of equal quantity, one morning, the other evening, either from the Sun's mean place, according to the old astronomy, to which Longomontanus and Lansbergen adhere in this, or from its true and apparent place, according to other more recent authors. We have indicated the signs of the greatest digressions in ch. 7, no. 1; and in those signs their longitude in the zodiac is supposed to be observed, or to have been observed, and likewise the Sun's mean or true place in the zodiac to be known: for from these it is verified whether they stood equally distant from the Sun's place, on this side in the morning digression and on that side in the evening one.

[Margin: Step 1, for the place of the line of apsides.]

Now the greatest digressions of these planets occur at the points of the orb or epicycle to which a straight line drawn from the centre of vision touches the orb and makes a right angle with the semidiameter of the epicycle or orb. So if the angles at the centre of vision, which measure the greatest digressions, are equal, and the semidiameters of the epicycle are equal, the centres of the epicycles will also stand equally distant from the line of apsides and equally distant from the centre of vision, just as the planets too will stand equally distant from that same centre, and the equations of the orb will be equal on both sides. It will therefore be certain that the line of apsides passes through the centre of vision and through the two points of the zodiac at which the arc of the zodiac intercepted between the two places of the Sun, mean or true, where the Sun stood at the time of the already mentioned digressions, is bisected; and that at one of those points of the zodiac is the apogee and at the other the perigee of

the eccentric. The conditions omitted by the ancients, however, which this method, such as it is, needs in order to hold good, we shall add at no. 10 and in the Scholia.

Second, two other greatest digressions of the same planet, equal to each other but unequal to the former, are to be observed or selected, with the places of the planet and of the Sun as above. For if they are individually smaller than the former digressions, they will show that the apogee lies in that arc of the zodiac in which the Sun was at their time; if they are greater, they will show the perigee. The same will be done by two greatest digressions in one of which the Sun's mean or true place stood at one of the already mentioned points through which the line of apsides passes, and in the other at the other; for the greater angle of digression marks out the perigee, and the smaller the apogee.

[Margin: Step 2, for distinguishing the place of the apogee from the place of the perigee.]

Third, then, let the two places of the apogee observed as above be compared, one from antiquity, the other recent, and let the number of degrees, resolved into minutes, be divided by the number of years elapsed from the ancient to the recent observation; for the quotient will show the annual motion of the apogee. But light must be added to these precepts by an example and a figure.

[Margin: Step 3, for the motion of the apogee.]

EXEMPLVM.

Example.

Ex Ptolemæo, & Copernico.

From Ptolemy and Copernicus.

Diagram. Woodcut figure in the left column, standing after the third line of no. III. A large outer circle, the zodiac, centred on A, with G at its top, π at its foot, β at far left and γ at far right. Within it a second circle, the eccentric, on which the centres of six small equal circles (epicycles) stand at C (top), F (upper left), Q (upper right), O (left), X (right) and D (bottom). A vertical line runs from G down through C, B, I and A to D and π. A small dashed circle stands about I, with B above it and a letter below it. Straight lines run from A to the epicycle centres and on to the outer circle, and from A to tangent points on the epicycles.

- G (top of outer circle): zodiac point, the apogee in the text
- π (foot of outer circle): zodiac point, the perigee in the text
- β (far left, outer circle): Sun's mean place
- γ (far right, outer circle): Sun's mean place
- H (upper left, outer circle): Sun's mean place
- S (upper right, outer circle): Sun's mean place
- C (top epicycle, centre); E (at the left end of its horizontal radius)

- F (upper-left epicycle, centre); M, V, N (about its circumference); θ (tangent point)
- Q (upper-right epicycle, centre); δ (tangent point); T, R (about its circumference)
- O (left epicycle, centre); P (tangent point)
- X (right epicycle, centre); Y (tangent point)
- D (bottom epicycle, centre); L (above it, on the vertical line); K (to its left)
- B (top of the dashed circle); I (centre of the dashed circle and of the eccentric); Z (below I, crossed by lines)
- A (centre of the zodiac, where the lines converge)

[Margin: Ptolemy, Book 10, ch. 1; Copernicus, Book 5, ch. 20.]

III. In the attached figure, A is the centre of the zodiac Gβπγ, and I the centre of the eccentric of ♀ or ☿, which is CODX. Theon the mathematician, then, in the 16th year of Hadrian, that is, in the year of Christ 132, on 21 Pharmuthi, namely March 8 [octauo Idus Martij], at the first hour of the following night, observed the evening greatest digression of Venus, which stood at δ and preceded the middle of the Pleiades by as great a longitude as is the longitude of the whole asterism of the Pleiades, and so, according to Ptolemy's table, stood at ♉ 1° 30′, when the Sun's mean place, Q, was at ♓ 14° 15′. The greatest digression of Venus from the Sun's mean place, that is, the angle QAδ, was therefore 47° 15′, as Ptolemy relates. He too, in the 4th year of Antoninus, that is, in the year of Christ 142, on 11 Thoth, as that day was passing and the 12th dawning, namely on the morning of July 30 [3. Kalend. Augusti], observed the greatest digression of Venus, but a morning one, when it stood at θ and was distant from the middle knee of Gemini toward the east by as much as half the Moon; that is, according to Ptolemy, it occupied ♊ 18° 30′, when the Sun's mean place, F, was at ♌ 5° 45′. The greatest digression from the Sun's mean place was therefore at that time also 47° 15′, and so the angle FAθ was equal to the angle QAδ. Now, with the semidiameters Qδ and Fθ taken as equal, and the angles at the contacts δ and θ equal, being right angles, the triangles QAδ and FAθ turn out not only similar but also equal, and the distances AQ and AF equal to each other, just as Aδ and Aθ are equal to each other. From this Ptolemy, in accordance with his own teaching in Book 9, ch. 6, concludes that the line of apsides GAπ passes through the points G and π, at which the arcs HGS and HπS, intercepted between the two mean places of the Sun in the zodiac marked by H and S, are bisected. From S, that is, from ♓ 14° 15′, in the order of the signs, as far as H, ♌ 5° 45′, there are 141° 30′; half of these, the arc SG, 70° 45′, added to S itself, shows the point G at ♉ 25°, and its opposite, π, at ♏ 25°. He therefore concluded that at that period the apogee of Venus lay at one or the other of these points of the zodiac.

[Margin: Per Book 1, proposition 26 of Euclid.]

Second, Ptolemy selected two greatest digressions of Venus. One was a morning digression observed by Theon in the 4th year of Hadrian, at dawn on

the 20th day of the month of Athyr, that is, in the year of Christ 119, on the morning of October 12 [quarto Idus Octobris], when Venus, P, stood at 20′ of the first degree of ♍, and the Sun's mean place at ♎ 17° 52′. The other was an evening digression observed by Ptolemy himself in the 21st year of Hadrian, or the year of Christ 136, on 9 Mechir, which was December 25 [8. Kal. Ianuarij], when Venus, Y, stood at ♒ 19° 36′, and the Sun's mean place, X, at ♑ 2° 4′. Each digression from the Sun's mean place was therefore 47° 32′, and the angle OAP equal to the angle XAY. From this is gathered the arc βGγ, between the two mean places of the Sun in the zodiac, β and γ, of 285° 48′; its half, Gγ, of 142° 54′, added to the Sun's place γ, ♑ 2° 4′, shows the point G at ♉ 24° 58′, that is, very nearly at 25°, as above. But since the angles OAP and XAY were greater than the angles FAθ and QAδ, and the angles at the contacts P, θ, δ, Y are right and equal, and the semidiameters of the epicycles are always assumed equal, it follows that the angle POA was smaller than the angle θFA, just as the angle YXA was smaller than the angle δQA; and so the distances AO and AX of the epicycle's centre were smaller than the distances AF and AQ. Therefore in the two former digressions the centre of the epicycle was nearer the greatest longitude, and the point G was the apogee of Venus, and the point π the perigee. From this, then, he finally inferred that in his time the apogee of Venus was at ♉ 25° and the perigee at ♏ 25°, which he confirmed in Book 10, ch. 2, from two digressions, in one of which the Sun's mean place was now at about ♉ 25° and in the other at about ♏ 25°; for he found the latter greater than the former. By very similar observations of the greatest digressions of Mercury, made by himself, Ptolemy concluded in Book 9, ch. 7, that the apogee of Mercury in his time was at ♎ 10° and the perigee at ♈ 10°; and in ch. 8 he confirmed the same from one greatest digression of Mercury with the Sun's mean place at ♎ 9° 15′, which was the smaller, and from another, with the Sun at ♈ 11° 5′, which was the greater.

[Margin: Example of step 2.]

[Margin: The apogee of ♀ and ☿ in Ptolemy's time.]

Third, Ptolemy, examining in Book 9, ch. 7, equal greatest digressions of Mercury on either side, observed by the ancients 400 years before the time of his own observations and reported by Hipparchus, found that the apogee of Mercury was formerly at ♎ 6°. Because of this he determined that in 400 years it had traversed 4°, namely from ♎ 6° to ♎ 10°, and so advances 1° in 100 years. In the same chapter he affirms that he detected the same motion in the motions of the other minor planets, saying: "From these, then, and from those that we have considered individually in the other planets, we find similarly in the five planets that the diameters which pass through the greatest and least longitudes move about the centre of the zodiac in the order of the signs, and that this motion is equal in speed to the motion of the sphere of the fixed stars. For, as we have demonstrated, that sphere moves very nearly one degree in a hundred years."

[Margin: Example of step 3, for the motion of the apogee.]

IV. Further, the greatest digressions that Ptolemy used to work out both the place and motion of the apogee and other matters concerning the theory of Mercury and Venus are set out below, keeping the order that Ptolemy keeps, for he begins with Mercury. Of these, Ptolemy observed the first four and the last four except the penultimate; Theon the penultimate; Timocharis the fifth and perhaps the 6th, 7th and 8th. Of the observations of Venus, Theon made the first, the second and the fifth; Ptolemy the rest, and he uses the first four of Mercury and the first four of Venus in investigating the apogee.

How Longomontanus corrected some observations of Venus will be clear from no. 7 and from the 3rd table in no. 8; how Boulliau corrected some of Venus and of Mercury I shall say in no. 9; and how, finally, we corrected the observations of each planet I shall say in no. 10. I wish this said here so that no one may think himself compelled to abide by these digressions of Ptolemy, which we set out below in each table, as if they were worthy of unshaken belief and needed no correction whatever.

DIGRESSIONES Mercurij ac Veneris Maximæ à loco Solis Medio Selectæ ex Ptolemæo & ad Vraniburgi seu Bononiæ Meridianum reductæ.

The greatest digressions of Mercury and Venus from the Sun's mean place, selected from Ptolemy and reduced to the meridian of Uraniborg or of Bologna.

[Margin: Book 10, ch. 2 (against rows 4–5).]
[Margin: Book 10, ch. 3 (against row 6).]

V. Regiomontanus subscribed to Ptolemy, *Epitome*, Book 9, propositions 12 and 13, on the basis of the observations made or reported by Ptolemy; so much so that he too concluded in these words: "Therefore, by these and similar indications in the other wandering stars, we are compelled to judge that the longer and nearer longitudes have a connection with the motion of the fixed stars."

[Margin: The opinion of Regiomontanus on the motion of the apogees.]

More universally, al-Farghānī asserted the same of all the planets, difference 17, where he did not hesitate to say: "The revolution of the fixed stars and of the auges of the seven planets, and of their gensahar, traverses the circle of the signs in thirty-six thousand years."

[Margin: And of al-Farghānī.]

Since al-Battānī judged that the fixed stars move 1° in 66 years, he therefore says in ch. 47 that the apogees of the five minor planets also advance by the same amount of motion; and from this, rather than from any observation of his own, he placed in his time the apogee of Venus, as also of the Sun, at ♊ 25° 14′, and that of Mercury at ♎ 21° 58′.

[Margin: The place and motion of the apogee of ♀ and ☿ in al-Battānī's time.]

From this, no doubt, very many Arabs and the Alphonsines thought that the apogee of Venus and that of the Sun are perpetually joined at the same place in the zodiac, and that this moves, together with the auges of the other minor planets, with the motion of the eighth sphere, and completes its period only in 49,000 years. Their error at last became clear, when the apogee of Venus was separated from the apogee of the Sun, and the motion of the latter was detected to be far swifter than that of the apogee of Venus, as we shall presently show. Granted, almost all the followers of Peuerbach subscribed to the Alphonsines in Peuerbach's *Theoricae*; especially Wurstisen, p. 189, and before him Fernel, *Cosmotheoria*, Book 2, ch. 7, and afterwards Clavius, at the end of the *Sphere*, p. 471, assigning the same motion to the auges of these planets as to the fixed stars, and a period of 49,000 years.

[Margin: The opinion of the Alphonsines on these apogees.]

[Margin: The opinion of Peuerbach, Fernel and Clavius.]

VI. The method by which Copernicus investigates, for the times of Ptolemy, the apogee of Venus, Book 5, ch. 20, and of Mercury, Book 5, ch. 26, is exactly the same as Ptolemy's; and from their greatest digressions from the Sun's mean place, observed by Theon and Ptolemy and with nothing corrected, he determines that the apogee of Venus was at ♉ 25°, and gathers that of Mercury to have been at ♎ 10°. But under the sphere of the fixed stars, that is, reckoning the place of the apogee from the first star of Aries, he says that that of Venus was at 48⅓° and that of Mercury at 183⅓°: namely with the precession of the equinoxes subtracted, that is, the recession of the equinoctial points, against the order of the signs, from the first star of Aries, which in Ptolemy's time stood 6° 20′ from the vernal intersection, as Copernicus has it.

[Margin: The opinion of Copernicus on the ancient place of the apogee of ☿ and ♀.]

As for the motion of these apogees and their place in the time of Copernicus, it is gathered from his Book 5, ch. 23, that the apogee of Venus perpetually keeps the same distance, 48⅓°, from the first star of Aries, and so recedes no further from the vernal equinox than the fixed stars themselves recede or seem to recede. For there he adduces two observations of Venus, one of Timocharis, the other his own, made in the year 1529, and examines both by his hypothesis, in the form we gave in ch. 2, no. 4, with the apogee of Venus remaining at 48° 20′ from the first star of Aries; and he reckons it from the equinox for his own time in no other way than by adding to the 48° 20′ the precession of

the equinoxes, of 27° 24′, from which for the year 1529 the apogee of Venus, reckoned from the vernal equinox, comes out at Gemini 15° 44′. Rightly, therefore, do Longomontanus, Book 2 of the *Theorica*, ch. 19, and Magini, in the theory of Venus, ch. 1, and canon 33 of the *Secunda Mobilia*, gather that on Copernicus's hypothesis the apogee of Venus is immobile under the sphere of the fixed stars, and moves away from the equinoxes by no other motion than that by which the fixed stars seem to move away from them, and therefore completes its period just as the fixed stars do.

[Margin: In what way the apogee of ♀ is immobile in the hypothesis of Copernicus.]

As for the motion of the apogee of Mercury, Copernicus, Book 5, ch. 30, brings forward three observations of Mercury, one of the year 1491, made by Bernhard Walther, two of the year 1504, made by Johannes Schöner; and he examines them by the hypothesis and figure that we gave in ch. 2, no. 9, of this section, assuming a more probable place for the apogee, so as to be more certain whether, with that assumed and the rest remaining as they were, namely the commensuration of the orbs, which was in Ptolemy's

[Margin: By what motion the apogee of ☿ moves, in the opinion of Copernicus.]

time, as he had found from Ptolemy's own observations, the observed places of the planets are represented. And so he says: "From these three observations, then, we wish to examine the course of Mercury for the present time. In them we think it must be granted that the commensurations of the circles have remained from Ptolemy even until now, since in the other planets too the good earlier authors are not found to have been deceived in this respect. If along with these we also have the place of the apse of the eccentric, nothing further would be lacking in the apparent motion of this star as well. Now we assumed the place of the highest apse at 211½° [part. CCXI. S.], that is, at 28½° of Scorpio [XXVIII. S. grad. Scorpij]; for we could not accept a smaller one without prejudice to what was observed." When the examination is finished he concludes: "These three places, therefore, agreeing as they do with what was observed, attest beyond doubt that the very place of the highest apse of the eccentric is the one we were assuming, 211½° [part. CCXI. S.] under the sphere of the fixed stars at this our time."

With this laid down, in order to gather the motion of this apogee, he recalls from Ptolemy's doctrines that it stood, in the 21st year of Ptolemy Philadelphus, at 182° 20′ under the sphere of the fixed stars; and from that time to the year 1504 he counts 1768 Egyptian years and 233 days, in which time, he says, the highest apse of Mercury moved 28° 10′ under the sphere of the non-wandering stars. And he closes the chapter with these words: "Now when we compare 28° 10′ [partes XXVIII. Scrup. 10.], through which the apogee of the eccentric has moved, with this time, it will be seen to have moved by one degree in 63 years [LXIII. annis], if indeed it has been uniform."

But a manifold blunder of Copernicus lies hidden here. For with 183° 20′, at which this apogee stood under the fixed stars in the time of Ptolemy the astronomer, subtracted from 211° 30′, those 28° 10′ result; but when the subtraction is made of the 182° 20′ at which he says it stood in the time of Ptolemy Philadelphus, 29° 10′ result. So the occasion of the slip was the ambiguous name of the Ptolemies.

[Margin: Copernicus's blunders and his manifold inconsistency with himself.]

Next, if 1° requires 63 years, then certainly this motion, if indeed it was uniform, as he himself supposes, requires 1774 years for 28° 10′, but 1837 for 29° 10′.

Third, if from the 21st year of Philadelphus to A.D. 1504 there are 1768 Egyptian years and 234 days, that is, 1767 Julian years and 155 days, then the year of Philadelphus fell 264 years before Christ. If you add to these the 136 years after Christ at which Ptolemy the astronomer flourished, that makes 400 years, the very number Ptolemy himself counts. Comparing, then, 182° 20′ and 183° 20′ under the sphere of the fixed stars, it follows that in 400 years the apogee of Mercury completed a single degree under that sphere. How do these things agree with one another?

Fourth, if in Ptolemy's time this apogee was at ♎ 10° and in Copernicus's time at ♏ 28° 30′, then in 1368 years, the number there are from the year 136 to 1504, it completed 48° 30′ from the vernal equinox. From these subtract the difference in the precession of the equinoxes, or in the motion of the fixed stars, due to this interval, namely 21° 4′ (since that precession was 6° 20′ under Ptolemy the astronomer and 27° 24′ in Copernicus's time), and 27° 26′ will remain, which is how far this apogee ought to have moved under the fixed stars. Mästlin saw this inconsistency in Copernicus, but rather confusedly, and therefore reports it differently, just as though Copernicus had set this apogee as immobile from Ptolemy Philadelphus to Ptolemy the astronomer, as I shall say in Scholium 2.

Meanwhile, what is more certain and more worth noting is this: if, from the equinox, or under the zodiac, it completed 48° 30′ from Ptolemy to Copernicus, in 1368 or 1370 years, then it completes one degree in about 28½ years, and in A.D. 1630 it would be at the 2nd degree of Sagittarius, and would complete its period in 10,260 Julian years.

[Margin: The motion of the apogee of ☿ under the zodiac, from the data given by Copernicus.]

Granted, Hérigone, in volume 5 of the *Cursus Mathematicus*, Book 1 of the *Theorica*, proposition 11, says that according to Copernicus's observations this apogee is today at the beginning of Sagittarius, and completes its period under the sphere of the fixed stars in 22,405 Egyptian years and under the zodiac in 11,995 years.

[Margin: The opinion of Hérigone on the Copernican motion of the apogee of ☿.]

Magini, however, says in the theory of Mercury, ch. 2, that the mean apogee completes its period in 22,700 Egyptian years; but in ch. 5 he denies that the true apogee of Mercury can traverse the whole zodiac, since it is in fact confined within fixed limits, because he fuses the Ptolemaic and Alphonsine hypotheses into one, according to the scheme set out in ch. 1, no. 6.

[Margin: The opinion of Magini on this motion.]

Finally, Lansbergen, although a most devoted follower of Copernicus, nevertheless sets the annual motion of the apogee of ☿ at 1′ 55″ and of ♀ at 1′ 26″, and for A.D. 1500 the root of the apogee of ☿ at ♏ 25° 15′ 22″ and of ♀ at ♊ 28° 28′ 29″.

[Margin: The opinion of Lansbergen on the place and motion of the apogee of ♀ and ☿.]

VII. I come to Longomontanus, who in Book 2 of the *Theorica*, ch. 18, excuses the Tychonians on the ground that at other seasons rarely, and in summer scarcely ever, because of the obliquity of the sphere at that altitude of the pole and the perpetual twilights, were they able to continue their observations of Venus and Mercury as they should have done, in order to distinguish, from the immediate increases and decreases of the digressions, the greatest recessions from the Sun, which occur at the contact with the orb, and from them to gather, by the Ptolemaic and Copernican method, the place of the apogee, the greatest equations, and the commensurations of the orbs. He therefore uses another method, a posteriori, and brings forward 9 observations of Venus, seven of Tycho's and two made by himself, which I shall present in the following no. 8.

[Margin: The method of Longomontanus for ♀.]

These observations he examines by geometrical calculation, using both the reformed Ptolemaic scheme and the Copernican, which I have already set out in ch. 2, no. 4, and ch. 4, no. 1. In that examination he takes it as certain that Venus consistently looks to the mean rather than the true motion of the Sun; and applying the Alphonsine and Prutenic tables, he weighs which of them come closer to the observations. From this examination, at first in rough fashion, then with the motions refined and the calculation repeated many times, until the difference of the computed place from the observed stayed within 10′, he gathered the following propositions.

First: from the observations made in December, in which the equality of the digressions on either side of the Sun's mean place shows that they were not far from the perigee of the eccentric, that the apogee of Venus has at this time advanced beyond the place the Prutenic tables fix, and comes closer to the Alphonsine place; and that at the completed year of our Saviour 1585 it stood distant in longitude 89° 15′ from the true vernal equinox, but 89° 8′ from the mean.

[Margin: The apogee in the year 1585.]

Second: from the first and last observations, and then from others, that the semidiameter of the orb of Venus, which for Ptolemy is the epicycle, is greater

than Copernicus set it, by 300 parts, of which the radius of the eccentric orb is 100,000; that is, not 71,930 but 72,248½.

[Margin: The semidiameter of the orb and the eccentricity of ♀.]

Third: that the total eccentricity of Venus is not greater than 3208 parts, and accordingly that in the Tychonic scheme the third part, which belongs to the semidiameter of the lesser epicycle, is 802, and the remaining two-thirds, of the semidiameter of the greater epicycle, are 2406 parts. That this eccentricity is smaller than the Ptolemaic is to be attributed not so much to a change in the eccentricity as to the unreliable and conjectural observations of Theon and Ptolemy.

Fourth: from observations 3 and 4, in which Venus, very close to conjunction with the Sun and almost at the perigee of the epicycle, could be observed by Tycho in Denmark, thanks both to the obliquity of the sphere and to a northern latitude of Venus of 8′ and more [octo & ampliùs minutorum], greater than the tables of Alfonso and of Copernicus allow, because of which it was possible to see Venus in the evening on February 21 and soon afterwards in the morning on the 24th: from these, I say, he gathers that the mean anomaly of the orb, or anomaly of commutation, is greater than the Prutenic by 1° 18′. He confirms this from observation 6, in which Venus was nearer the apogee of the epicycle.

[Margin: The anomaly of the orb of ♀.]

With these four foundations of his hypothesis laid, he compares the observed places of Venus with the places derived by calculation, and shows that they never disagree with one another by more than 12′, as can be seen in table 1 of those that follow, in which the days are given in the style of the old calendar, and the hours as hours after noon at Uraniborg [Vranigurbi].

VIII. Having investigated these matters for his own time, he proceeds to ch. 19, in which he investigates the periodic motions and the roots of the motions of Venus from recent observations, which we shall append in table 1, compared with ancient ones, which Ptolemy thought were made at the greatest digression of Venus from the Sun's mean place. But Longomontanus himself tries to show that they were not the greatest, correcting the places of Venus from his own hypothesis about the places of the Sun and the fixed stars suited to Ptolemy's time; for Ptolemy, Book 10, ch. 1 and 2, recorded both Theon's observations and his own from the distance of Venus from the fixed stars taken by astrolabe. For this correction see the third of the tables that follow, in which the hours are given for the meridian of Alexandria, and the anomaly of the epicycle, or orb, of Venus is added, taken from the Prutenic tables and corrected by a subtraction of 45′, as that period requires, and also the correction of this anomaly, discussed in no. 7 under the Fourth proposition. The Sun's mean place, moreover, is set in the second table from the Ptolemaic tables, and in the third from the Danish tables.

Tab.I. OBSERVATIONES VENERIS Comparatæ cum loco eiusdem ex Longomontani hypothesi supputato.

Tab.II. OBSERVATIONES VENERIS Digreſſionum à medio Solis loco, factę Alexandriæ, quas Ptolemæus maximas putauit.

Table II. Observations of the digressions of Venus from the Sun's mean place, made at Alexandria, which Ptolemy thought were the greatest.

Order	Observers	Years of the emperors	Egyptian months	Completed days	Mean place of ☉	Observed place of ♀	Digressions of ♀ from the mean ☉
1	Theon	Hadrian 16	Pharmuthi	21, evening	♓ 14° 15′	♉ 1° 30′	47° 15′
2	Ptolemy	Antoninus 4	Thoth	11, the following morning	♌ 5° 45′	♊ 18° 30′	47° 15′
3	Theon	Hadrian 12	Athyr	21, the following morning	♎ 17° 52′	♍ 0° 20′	47° 32′
4	Ptolemy	Hadrian 21	Mechyr	9, evening	♑ 2° 4′	♒ 19° 36′	47° 32′
5	Theon	Hadrian 13	Epiphi	2, the following morning	♉ 25° 24′	♈ 10° 36′	44° 48′
6	Ptolemy	Hadrian 21	Tybi	2, evening	♏ 25° 30′	♑ 12° 50′	47° 20′

[63] A is austral, south; B is boreal, north.

[Margin: From Ptolemy, Book 10, ch. 1 (against rows 1–2).]
[Margin: Book 10, ch. 2 (against rows 4–5).]

Tab.III. OBSERVATIONES Prædictæ à Longomontano Correctæ.

Table III. The observations already mentioned, as corrected by Longomontanus.

Order	Current years of Christ	Completed Julian months and days	After noon at Alexandria	Mean place of ☉	Corrected place of ♀	Digression from the mean ☉	Anomaly of the orb of ♀
1	132	March 8	$7^h\ 15^m$	♓ 14° 49′	♉ 1° 39′	46° 50′	4^s 26° 22′
2	140	July 29	$16^h\ 12^m$	♌ 6° 12′	♊ 19° 1′	47° 11′	7^s 26° 13′
3	127	October 11	$17^h\ 20^m$	♎ 18° 20′	♍ 2° 6′	46° 14′	7^s 24° 2′
4	136	December 25	$6^h\ 0^m$	♑ 2° 36′	♒ 19° 36′	47° 0′	4^s 27° 5′
5	129	May 19	$16^h\ 10^m$	♉ 25° 53′	♈ 10° 57′	45° 4′	7^s 25° 16′
6	136	November 18	$6^h\ 10^m$	♏ 26° 9′	♑ 13° 4′	46° 55′	4^s 4° 17′

But because in observation 3 the corrected place of Venus differs from the Ptolemaic by 1° 46′, Longomontanus attributes this either to an error in the day noted by Ptolemy, or to a deliberate error serving the Ptolemaic hypothesis, especially in view of the place of the star at the tip of the southern wing of Virgo, which Ptolemy puts at ♌ 29°, far from the truth; for Theon observed the place of Venus from the distance of Venus from that star.

[Margin: Ptolemy suspected by Longomontanus of astronomical unfaithfulness.]

Now although Longomontanus judges those observations of the ancients uncertain, yet because, with the apogee of ♀ retained at 25½°, roughly where Ptolemy put it in his time, and with the motion gathered from that and the other things laid down, discussed in no. 7, the more recent observations are well represented, he therefore retains it for A.D. 140 at ♉ 25½° from the true equinox, and in his own time, that is, at the completed year 1585, at ♊ 29¼°. But applying the precession of the equinoxes, 20′ at the one date and 7′ at the other, he deduces that in the 1445 Julian years elapsed the apogee of ♀ completed 33° 18′, and therefore 1′ 22″ 57‴ 30⁗ yearly, and 2° 18′ 16″ 12‴ in 100 years. By subtracting these from the Sun's mean motion he gathers the anomaly of the eccentric that you have in the Danish tables.

[Margin: What the anomaly of the eccentric is, and from what it is to be gathered?]

As for the motion of the anomaly of the orb, or epicycle, he does not use the Ptolemaic observation of A.D. 138 December 15, $15^h\ 10^m$ at Copenhagen, or the 2nd year of Antoninus, on the day Tybi 29, in the morning at $4^h\ 45^m$ at Alexandria, by which Ptolemy observed Venus from the fixed stars

in the forehead of Scorpio; for on various conjectures he quite often finds "greater reliability in the Ptolemaic observations" wanting. He uses rather the observation made by Timocharis, as Ptolemy reports in Book 10, ch. 4, in the 13th year of Philadelphus, at the end of the day Mesore 17, the following morning; that is, 272 before Christ, October 11, at 18^h after noon at Alexandria, but 16^h 15^m at Copenhagen. At that time Venus appeared exactly to have obscured the star opposite Vindemiatrix; and this star at that time, and hence Venus, was for Longomontanus at ♏ 3° 10′, with a northern latitude of 1° 16′.

[Margin: Ptolemy again and often suspected by Longomontanus.]

With the Sun's mean motion from the true equinox set, then, at 6^s 16° 6′ 30″, and so the distance of Venus from it at 42° 56′ 30″, and with the apogee of Venus then at ♉ 16° 30′ and this subtracted from the Sun's mean place, he gathers the anomaly of the eccentric as 4^s 29° 56′ 30″. And using the eccentricity and the semidiameter of the orb discussed in no. 7, by way of the scheme of the reformed Ptolemaic hypothesis whose use we explained in ch. 2, no. 4, he derives that the mean anomaly of the orb, or of commutation, or that computed from the mean apogee of the epicycle, was 250° 59′ in the time of Timocharis, whereas the Prutenic tables put it at that time at 252° 6′, and the Ptolemaic at about the same. But this is no wonder, since Ptolemy and Copernicus here used digressions of Venus reckoned to be the greatest, and accordingly a right angle at the contact with the orb, and in that treatment a small error in observation brings a large error into the anomaly of the orb. For it is better, he says, to use observations made near the apogee or perigee of the epicycle, although he admits that Timocharis's observation was not of this kind; but since no other, better observation of the ancients is available, one must settle for this one.

[Margin: The motion of the anomaly of the orb of ♀.]

Finally, therefore, since the same anomaly was found in A.D. 1586 to be greater than the Prutenic by 1° 18′, as I said in no. 7, and in the year before

Christ 272 smaller by 1° 7′, therefore in the interval of 1857 Julian years the motion of the anomaly of the orb of Venus exceeded the Prutenic motion by 2° 25′, and this excess was 4″ 41‴ each year.

This, in summary, is the method of Longomontanus, certainly full of labour and ingenuity, but one in which we nevertheless miss a comparison of the hypothesis with more than 9 observed places of Venus. For these four elements, namely the place and motion of the apogee, the eccentricity, the semidiameter of the orb, and the motion of the anomaly of the orb, can be reconciled in various ways so as to satisfy either these 9 observations or others no less certain, and yet not satisfy many others; just as in fact the Danish tables do not satisfy many, so that here they sometimes deviate from observation by a whole degree and more. Nor can he be excused on the ground that he did not have more observations of Tycho, for more exist in volume 1 of the *Progymnasmata*, besides those in the Tychonic papers. Nor can he say that he used only seven Tychonic ones because they seemed better suited to the purpose, some because of their nearness to the apogee or perigee of the eccentric or epicycle, some because

of their nearness to the contact with the orb and the greatest digression. For he ought to have examined the motion and the size of the orb further, and to have seen whether they agreed with all the other observations, or at least with very many of the more certain ones.

[Margin: A critique of the method and hypothesis of Longomontanus.]

Yet he himself acknowledged a great difficulty in this, in Book 2, ch. 25, which he closes with these words: "And here, by the grace of God, we put an end to the restoration of astronomy, where, in accordance with our plan, we have emended the hypotheses and tables that are to display the celestial phenomena to the infallible observations that could be had by us; and in such a way that we would wish no one to pass judgment on these persistent labours of ours, which we hope will benefit all fair-minded people and those who love these disciplines, that is, to slight them or perversely despise them, except one who takes the trouble to compare them properly with the celestial appearances, so that he may thereby rather pronounce a just censure on them, or, by at last putting his own hand to the tablet [manum tabulæ admouendo], may himself feel how difficult this task has been." This candid confession we cannot receive without commendation.

[Margin: The difficulty of reconciling the hypothesis with the observations.]

But neither do we approve the investigation of the anomaly of the orb from Venus when nearest the perigee of the epicycle: for there she cannot be seen except subject to great refractions, and a small error then does great harm, because of the very acute angles formed at the centre of the epicycle and at the centre of the Earth.

IX. By exactly the same method the same Longomontanus, in Book 2 of the *Theorica*, ch. 20 and 21, investigates a posteriori, by comparing the Prutenic motion with observed places of Mercury, the apogee, the eccentricity, the semidiameter of the orb, and the motion of the anomaly of the orb, assuming after various trials of calculation the values that seem to agree best with the observations; and from this method he sets down the following propositions.

[Margin: The method of Longomontanus for ☿.]

First: Mercury has the same motion of the eccentric as the mean motion of the Sun; but as regards its motion on the epicycle it adjusts itself to the Sun's mean rather than true motion, as Venus also does.

Second: from the Ptolemaic method applied to the digressions of Mercury on either side of the Sun's mean motion, by moderate conjecture, and then from other, more accurate calculations with somewhat more certainty, it is established that at the beginning of this century the apogee of Mercury was near the beginning of Sagittarius, and indeed at the completed year 1585 at ♐ 0° 30′.

[Margin: The apogee of ☿.]

Third: the small circle, along whose straight diameter Copernicus swings and varies the diameter of the orb, is illegitimate, and errs most near the apogee and perigee of the eccentric, where the celestial phenomena require a breadth

of the orb greater than the Prutenic by two degrees and more, and a swifter motion of Mercury. Accordingly, the truer semidiameter of the epicycle, or orb, of Mercury is 38,500 parts, of which the radius of the eccentric is 100,000.

[Margin: The semidiameter of the orb of ☿.]

Fourth: the eccentricity of Mercury varies, so that the radius of the eccentric is carried on the circumference of a small circle, with a motion not double but triple the motion of the anomaly of the eccentric. For it is from this that Mercury appeared to Ptolemy to make its greatest digressions from the Sun in Aquarius in the morning and in Gemini in the evening, and to Copernicus near the sides of the trigon or hexagon. The semidiameter of this small circle is 1137 parts, namely a fifth part of the whole eccentricity from the Earth (or, in the Copernican scheme, from the centre of the great orb), which is 5685 parts, of which the radius of the eccentric is 100,000.

[Margin: The eccentricity of ☿ and the variation of the eccentricity.]

Fifth: the mean anomaly of the orb of Mercury at the end of the year 1585 is greater than the Prutenic by 2° 10′, and so is 1ˢ 13° 2′ 8″.

[Margin: The root of the anomaly of the orb in the year 1585.]

The first seven Tychonic observations, the third from last by the Landgrave of Hesse, and his own last two, from which Longomontanus deduced the theses already mentioned, comparing his calculation with them and supposing the motions and quantities already mentioned, are set out here before your eyes for the meridian of Copenhagen, with the days given in the style of the old calendar, by means of the following table.

Obſeruationes Mercurij comparatæ cum Loco ſupputato ex Hypotheſi Longomontani.

Observations of Mercury compared with the place computed from the hypothesis of Longomontanus.

	Years of Christ	Old style	After noon	Observed place of ☿	Observed latitude	Computed place of ☿	Mean longitude from the true equinox	Anomaly of the eccentric	Anomaly of the epicycle

64

X. He then passes in ch. 21 to inquiring into the mean motion of both the apogee and the anomaly of the orb of Mercury. And for the motion of the apogee he brings forward no observation of the ancients, because he hopes for nothing better from them than from the observations of Venus made by Ptolemy with the astrolabe, fearing from them an error of 10′ and more. Assuming, then, for the completed year 264 before Christ the apogee of Mercury at ♎ 6° 5′ from the mean equinox, and in A.D. 1586 at ♐ 0° 12′ from the same equinox, and so an advance of 54° 7′ in the interval of 1850 Julian years, and 1′ 45″ 18‴ yearly, he says that this motion satisfies the more recent observations; and therefore he concludes that Ptolemy, who placed the apogee of ☿ in the time of Timocharis at ♎ 6°, did better than in placing it in his own time at ♎ 10°.

[Margin: The motion of the apogee of ☿.]

For the motion of the anomaly of the orb, however, he uses an ancient observation, made, as Ptolemy reports in Book 9, ch. 10, in the year 484 of Nabonassar, on the 18th of Thoth, with the 19th following, on whose morning Mercury appeared to stand off from the northern star in the forehead of Scorpio by one Moon toward the west, but by two Moons toward the north. That was the year 265 before Christ, at 17^h after noon of November 14 at Copenhagen. At that time, from his own hypothesis of the fixed stars, he says that the northern star of the forehead of Scorpio was at ♏ 1° 36′ with a northern latitude of 1° 16′, and Mercury at ♏ 2° 35′ with a northern latitude of 2° 20′.

[Margin: The motion of the anomaly of the orb of ☿.]

Therefore, taking from his own tables the mean motion of the Sun, of the apogee, and of the anomaly of Mercury, and the measures of the eccentricity and of the semidiameter of the orb, discussed in no. 9, and applying the figure of the reformed Ptolemaic hypothesis, on which see our ch. 2, no. 4, he gathers the mean anomaly of the orb as 210°, which at that time Ptolemy's tables give as 211° 45′ and Copernicus's as 212° 34′. He rests, moreover, on this observation, because Mercury stood only a little distance from the Sun and was nearer the perigee of the epicycle. So, comparing this motion with the motion recently

[64] B is boreal, north. Crosses stand in the latitude cells of rows 3 and 10 as printed, three in the one and two in the other, and no figure is set there.

found, he gathers that the mean annual motion of the anomaly of the orb, or of commutation, of Mercury is, besides three whole revolutions, $1^s\ 23^\circ\ 57'\ 33''\ 35'''$.

[Margin: Critique of Longomontanus's hypothesis.]

But in this business likewise more observations are still wanted; nor did the ancient ones seem to deserve scorn. For grant that some error in them is to be feared, yet it is not always so great as the error the Danish tables later incurred in Mercury, up to 7°, as we have already said in Book 3, ch. 3, scholium 3; and elsewhere they often differ by several degrees from the observations of Gassendi and others. Be that as it may, for this labour and for his effort, such as it was, to restore astronomy, we owe this man a great deal.

[Margin: Kepler's view on the aphelion of ♀ and ☿.]

XI. Now Kepler was more concerned with distinguishing the aphelion of these planets from the apogee than with determining the place of the apogee more precisely. And so in ch. 15 of the *Mysterium Cosmographicum*, and in the *Epitome of Copernican Astronomy*, Book 6, part 3, or p. 764, he teaches that the apogee of Venus in Ptolemy's age was at ♉ 25° and that of Mercury at ♎ 10°, and that now the former lies in ♊ and the latter in ♏; but that the aphelion of ♀ in Ptolemy's age was in ♍ and is now at ♒ 2°; and that the aphelion of ☿ is found to have once been at ♏ 4° and now at ♐ 15°.

[Margin: And Mästlin's.]

More precisely, Mästlin, in his notes to ch. 15 of the *Mysterium Cosmographicum*, distinguishes the apogee of each from the aphelion as in the following small table.

	Age of Ptolemy: Apogee	Age of Ptolemy: Aphelion	Age of Copernicus: Apogee	Age of Copernicus: Aphelion
♀	♉ 25° 0′	♍ 4° 39′	♊ 15° 44′	♍ 19° 48′
☿	♎ 10° 0′	♎ 29° 42′	♏ 28° 30′	♐ 13° 40′

Kepler continues in the *Epitome*, and from the motion of the aphelion of Mercury in the order of the signs he gathers, as probable, the same about the aphelion of Venus, whose ancient place, however, he holds can be shown only from a distance, because of the small eccentricity of Venus, to which a moderate error in the Sun's true place, and so in the digressions from the Sun, does much more harm than to Mercury, which has a large eccentricity. He likewise ascribes the reason why the aphelion of Venus lies so far from its own apogee and from the Sun's to the eccentricity of Venus, which is much smaller than the eccentricity of the great orb; from this it comes about that Venus is much further from the Sun, and so aphelial, in ♍, where the Earth comes closest to the Sun, than in ♋, where the Earth is farthest from the Sun. Conversely, because the eccentricity of Mercury is much greater than the eccentricity of the great orb, the apogee of Mercury that the old astronomy established is much closer to the aphelion of Mercury than to the apogee of the Sun. From this arises a further doubt about the way of determining the aphelion of Venus and of Mercury, which we resolved in Section 2, ch. 10, nos. 3 and 4. But so that

no one, running through the subjects of the problems, may think it is missing here, let this stand:

Problema 2. Dato Apogeo Planetarum inuenire Aphelium & è conuerso; dummodo detur ipsorum Eccentricitas, & Distantia Solis à Terra.

Problem 2. Given the apogee of the planets, to find the aphelion, and conversely, provided their eccentricity and the distance of the Sun from the Earth are given.

See the solution of the problem in Section 2, ch. 10, nos. 3 and 4.

[Margin: Wendelen's ingenious fiction on the motion of the apsides.]

XII. In Kepler's place we must put Govaert Wendelen, who, contemplating more deeply the foundations of the Rudolphine Tables in his third *Lampas Arcanorum Caelestium*, expounds by this theorem the little verse set at its head,

Apsidibus ratio dat sextantaria legem ["The sextantal ratio gives the law to the apsides"],

namely: *The speeds of the apsides are to one another in the sextantal ratio of their eccentricities.* He calls a ratio sextantal when, for any number proposed, one takes the root which, multiplied six times, produces that number. For example, if 64 and 729 are proposed, their sextantal roots are 2 and 3, as is clear from the six multiplications by 2 and 3 written below.

2	4	8	16	32	64
3	9	27	81	243	729

So if the eccentricities of two planets were to each other as 64 to 729, he says that the speeds of the apsides, or the motions of the apogees, will be to each other as 2 to 3, that is, as their sextantal roots, and indeed most precisely. And so, from the Rudolphine Tables, he lays it down that to complete one degree the aphelia of the planets require the years written below.

The aphelion traverses 1 degree in

	Years	& Months
♄	47	9
♃	49	2
♂	44	1
♀	69	5
☿	38	3

"All of this," he says, "we shall demonstrate to answer to our own trials too, from very many years back; and that this, hitherto unknown to all mortals, is the third marvel of divine wisdom and a wound to genethliac folly." When

Wendelen has demonstrated this with the phenomena saved, then at last he will earn the laurel.

[Margin: Boulliau's method and view.]

XIII. Ismaël Boulliau, in Book 9, ch. 6, investigating the translation of the aphelion of Venus, uses the aphelion's place and its mean motion as taken from the Rudolphine Tables, together with the semidiameter of the orb and the eccentricity of the centre, which he had previously determined from 4 digressions of Venus that he takes to be the greatest; and on these suppositions he examines two ancient observations of Venus. The earlier, reported by Ptolemy in Book 9, ch. 4, was made by Timocharis in year 476 of Nabonassar, on day 17 of Mesori, at hour 12 of the night, or 17^{h} after noon at Uraniborg, when Venus was seen at ♍ 2° 47′ 20″ with north latitude 1° 25′. But Boulliau's calculation, supposing the aphelion of ♀ at that time at ♌ 9° 1′ 26″, shows Venus then at ♍ 2° 9′ 54″. From various circumstances, however, he judges that the motion of the aphelion should be slowed rather than its place moved back. The later, reported in a manuscript codex of the Royal Library, was made at Athens in A.D. 510, and of Nabonassar 1258, August 20, on the evening of which Venus was seen applied to Jupiter and visibly all but conjoined with him; and he examines this application on the supposition of the Rudolphine aphelion. Since he says that the aphelion of ♀ was found, for the year 1597, or 2345 of Nabonassar, at ♒ 5° 19′ 43″, it follows that in the interval of 1868½ years from Timocharis's observation to the year 1597 it advanced 26° 18′ 17″, and annually 50″ 40‴ 50⁗ 36⁗′ 7⁗′′ 38⁗′′′ 37⁗′′′′ 10⁗′′′′′. In this way he probes the place of the aphelion of ♀ a posteriori, and through the most troublesome windings of calculation.

He does no differently with the aphelion of Mercury, which in Book 10, chs. 2 and 9, he places for the year 1636 at ♐ 12° 25′, after examining places of ☿ observed by the Hessians, by himself or by Gassendi, especially near the greatest digressions from the Sun; although in ch. 1 he says that Gassendi's were not observed precisely at the contact of the orb, warning that an error of 3 or 4′ in the place of ☿ produces an error of 2 or 3° in its aphelion, and that such an error, and a greater one, is easily incurred through refractions, to which the observation of Mercury is liable. Again, in ch. 9, he adduces among others an ancient observation made in year 484 of Nabonassar, on day 18 of Thoth, the 19th following, that is, 265 B.C. November 14, at $16½^{h}$ at Uraniborg, when Mercury was seen at ♏ 1° 57′ 30″ with north latitude 2° 6′. And since he had placed the aphelion of ☿ in A.D. 139 at ♏ 3° and in 1632 at ♐ 12° 31′ 3″, he therefore, keeping the proportion of the motion, places this aphelion for that year 265 at ♎ 22° 23′ 3″. With this laid down, however, Mercury comes out for him at ♏ 7° 32′ 32″, whereas it was observed at 1° 57′ 30″; and Mercury cannot be represented in that place unless, for that year 265 B.C., the aphelion of ☿ is set at ♎ 17° 40′. And so, keeping the aphelion for the year 1632 at ♐ 12° 31′ 13″, he gathers in ch. 10 a progress of 54° 51′ and 13″ in an interval of 1896

Egyptian years, and in each single year 1′ 44″ 9‴ 8⁗ 44⁗′ 3⁗′′ 2⁗′′′ 16⁗′′′′ 42⁗′′′′′. This, in summary, is Boulliau's method.

[Margin: Critique of Boulliau's hypothesis.]

But in Boulliau we find more observations wanting, especially of Venus, because it is easy to reconcile the apogee, the eccentricity, the semidiameter of the orb and the motion of the anomaly in such a way that they satisfy 6 or 8 observations, and yet afterwards do not satisfy many others. Then, in Book 9, ch. 1, from only two observations of Iustus Byrgius [Jost Bürgi] and two of Tycho, he wrongly deduces that the greater digression of these was also the greatest and at the contact of the orb; for to determine that, it is not enough for one digression to have been greater than the preceding one; it must also have become smaller on the following day. So at least three observations are required, so that the greatest increase can be gathered from the immediately following decrease. And yet, supposing those to be greatest, he founded the commensuration of the orbs on them. Now, since the observations of the places of ♀ and ☿ selected by him, and emended from his own and Tycho's principles, could be of great use to us, we decided to enter these too in tables. The observations of ♀ are taken from Boulliau's Book 9, and those of ☿ from Book 10, with two added from Book 11, theorems 11 and 13; and they were reduced by him to the meridian of Uraniborg, as you see noted in the table itself.

OBSERVATIONES ♀ & ☿. Selectæ ex Bullialdo eas corrigente iuxta suas de Sole & Fixis hypotheses, & referente locis in margine adductis. Diebus stylo Gregoriano notatis.

Observations of ♀ and ☿. Selected from Boulliau, who corrects them according to his own hypotheses of the Sun and the fixed stars, and who reports them in the places cited in the margin. Days noted in the Gregorian style.

[Margin, set against the rows of this block in order: Boulliau, Book 10 (first row), ch. 9 (second row), the next two rows without a note; then Book 10, ch. 9; Book 10, ch. 1 (six rows); Book 10, ch. 2; then Book 10, ch. 10; Book 10, ch. 7; Book 10, ch. 7; Book 11, theorem 13; Book 10, ch. 5; Book 10, ch. 3; Book 11, theorem 13.]

Add to these the observation of Venus made by Timocharis in the year 272 before Christ, October 11, after noon at Uraniborg $15^h\ 16^m$, which Boulliau places at 2° 31′ of Virgo, with the Sun at 14° 55′ of Libra, as he himself thinks.

CAPVT IX.

Chapter 9.

Conatus Noster pro inquisitione Apogei Veneris ac Mercurij.

Our effort in the investigation of the apogee of Venus and Mercury.

[Margin: Kepler's critique of the ancient astronomers concerning the apogee of ♀ and ☿.]

I. What Kepler said about the aphelion of these planets in the *Epitome of Copernican Astronomy*, p. 763, can be said of their apogee too: namely, that *in ancient times, where the places of these were could be shown only from a distance*, especially in Venus, because it returns more rarely to its greatest digressions, and to its small eccentricity a very small error in the observation, or in the Sun's place, does great harm. And so he admits that the ancients did indeed scent out the places of these apogees, but in such a way that they could have erred by a whole sign, let alone by a degree.

[Margin: Causes of the uncertainty in this matter.]

The cause of this uncertainty is the multiplicity of conditions required in the greatest digressions, if the place of these apogees is to be drawn from them by Ptolemy's method. *First*, we must be certain of the day of the greatest digression, which requires the observation of several days, so that it can be distinguished from the increase and decrease of the elongation from the Sun. On this ground Longomontanus, Book 2, ch. 18, excuses himself and the Tychonians, as I said in ch. 8, no. 7; and Boulliau, Book 10, ch. 1, denies that some digressions observed by Pierre Gassendi were precisely at the contact of the orb, that is, precisely greatest. *Second*, two greatest digressions of the same planet must occur within a few years that are equal to each other, one of them, however, being a morning and the other an evening elongation. *Third*, they must be at a distance as nearly equal as possible from the apogee of the eccentric, for which,

however, some rough knowledge of the place of the apogee is presupposed; and with this granted, the less they stand on either side from the apogee of the eccentric, the less is the danger of error. *Fourth*, the semidiameter of the orb, or of the epicycle, must be supposed unvaried, or equal; but since Copernicus supposes that in Mercury it varies according to the anomaly of the eccentric, therefore, from the equal greatest digressions taken from Ptolemy, he defines the place of the apogee. Therefore, if this variation depends equally on both sides on the distance from the apogee of the eccentric, this condition is included in the third. But it can hardly come about that within the few years in which the place of the apogee is sought, two digressions should occur with the already mentioned conditions concurring, since within those years their equality alone is rarely found, as anyone can see who surveys the tables set out in ch. 8 at the end of nos. 8, 9 and 12, and those to be given at the end of no. 2. Nor have we, although we have many of Venus and many more of Mercury (since it performs six greatest digressions from the Sun every year, and sometimes seven), yet been able to obtain two perfectly equal to each other, one morning and the other evening; these we shall perhaps acquire, God granting, before the third volume appears. But that Ptolemy handed down his own to us as so precisely equal is not free from the suspicion of a concealed difference, which he may have thought could be disregarded, so that we might have some astronomy rather than none.

Since, however, neither Tycho nor we agree with Ptolemy on the places of the Sun and the fixed stars, the places of Venus and Mercury must first be corrected according to our principles, before we apply the greatest digressions from the Sun to the search for the apogee. Of this correction I shall point out one or two examples.

[Margin: Example of the correction of the place of the fixed stars.]

Ptolemy relates in Book 10, ch. 1 of the *Almagest* that Venus was observed near the Pleiades in the 16th year of the Emperor Hadrian, that is, A.D. 132, on day 21 of Pharmuthi, in the evening, that is, March 8; and that she appeared to him to lead the middle or bright star of the Pleiades by as great a space as the whole asterism of the Pleiades occupies, but to be slightly further south than they, when she had made her furthest digression from the Sun. Then he adds: *Since, therefore, the middle of the Pleiades then occupied, according to our principles, 3° of Taurus, and their extent in longitude is 1° and very nearly 30′, it is evident that the star of Venus then held 1° 30′ of Taurus.* But in Tycho's catalogue, taking the first and last of the Pleiades, that asterism occupies 1° 34′. From my own observations, however, and from the catalogue and motion of the fixed stars established in Book 6, ch. 24, the middle of the Pleiades at that time was at 4° 3′ of Taurus. From this I subtract 1° 34′, and there remains the corrected place of Venus at ♉ 2° 29′. In the same way, then, considering the places of other fixed stars from whose distance the ancients or more recent observers estimated the longitude of Venus or Mercury, we have corrected the places of the planets.

[Margin: Timocharis's observation is weighed.]

II. Now the observation of Timocharis deserves particular consideration, made in year 476 of Nabonassar, on day 17 of Mesori, the 18th following, but in the year before Christ 272, October 11, at $15^{h}\ 17^{m}$ after noon at Uraniborg, when, as Ptolemy relates in Book 10, ch. 4, Venus was seen as a morning star, [Greek: κατειληφὼς τὴν ἀντικείμενον τῶν [?]γοτρυγητῆρι [recte: προτρυγητῆρι] ἀκριβῶς], that is, *comprehending exactly the star set opposite the Previndemiatrix*. So he does not say that she covered or obscured that star with their centres joined in the same line with the centre of Timocharis's sight, as Theon explained and as Longomontanus, Book 2 of the *Theorica*, ch. 19, and Lansbergen in the *Treasury of Observations*, p. 172, set down; but that she comprehended, or reached, that star either with her margin or with her rays, as Kepler in the *Astronomia Optica*, p. 304, and Boulliau in the *Astronomia Philolaica*, Book 9, ch. 6, rightly rendered this passage. Boulliau, however, omits the word [Greek: ἀκριβῶς (akribōs, "exactly")], or *exactly*, because on his hypothesis Venus was at 2° 31′ ♍, and that star (namely the leading one among the four in the southern wing of Virgo, as all those already mentioned hold with Ptolemy) was at ♍ 2° 47′, and so 16′ distant from Venus; which Boulliau attributes to the expansion of Venus's rays, occupying so great a space. But Longomontanus puts both stars then at 3° 10′ ♍, and Lansbergen at 3° 21′. We, however, from the motion and roots treated in Book 6, last chapter, put that fixed star at 3° 24′ ♍. And the word *exactly* seems to us to signify the application of Venus's rays to the margin of the fixed star, within which rays it afterwards lay hidden in what one might call an Aphrodisian setting; and her rays could have occupied about 10′, so that Venus was then at very nearly ♍ 14′[65] — if indeed this is the star that Timocharis meant.

For I do not see how it can be said to be set opposite the Vindemiatrix, since the latitude of the Vindemiatrix is 16° and more to the north, while the leading one of those four in the left or southern wing has a latitude of 1° 25′ and is more westerly than the Vindemiatrix by 5° and more. With better right, however, the star following the leading one of the said four is opposed to the Vindemiatrix; for it has the same magnitude and, to the senses, the same longitude, and crosses the meridian at almost the same moment. In Tycho's catalogue its longitude for the year 1600 is ♎ 4° 35′, and that of the Vindemiatrix ♎ 4° 23′; and for us that star was then at ♍ 8° 40′. So Venus, if she reached it with her margin, was at ♍ 8° 39′; if with her rays expanded, at about ♍ 8° 30′. But Ptolemy substituted a different star, with the other astronomers suspecting nothing; nor would we have come to this suspicion, had Ptolemy's star not been most troublesome to us. For I have never been able to reconcile the place of Venus estimated from it with many other places observed at almost the same location on the eccentric and the epicycle. We leave to each their own judgement, however, provided that from this uncertainty, or from the diversity of the place assigned to that

[65]the page sets Gr. with no degree figure before 14′

very star by the authors already mentioned, it is clear that a hypothesis that does not exhibit this place of Venus is not to be condemned straight away.

Again, when Walther says that in 1494 September 18, in the morning, Venus was seen by him to lead Regulus by about 10′, it does not follow that she was in fact only 10′ west of Regulus. For two stars in the horn of Capricorn seen with the naked eye, because of the expansion of their rays, appear to be about one digit apart, but with the telescope at least 3 digits, magnified though these are according to the quality of the tube. So ♀ must have been much further west of Regulus still.

Now let us set out again, in the following table, selected observations of Venus and Mercury reduced to the meridian of Uraniborg or Bologna, with the mark of a small letter *m* added to those digressions that were, or were thought to be, greatest, so that from these we may obtain, if it can be done, the apogee of these planets, and other matters to be treated in the following chapters.

XXXIV. LOCA VENERIS Obseruata cum Digressione à Sole Matutina littera M, & Vespertina litt. V, indicata, & maxima vbi lit.m, vt vel alij vel nos censemus, correctis tamen locis ex nostra de ☉ & Fixis Hypothesi.

XXXIV. Observed places of Venus, with the morning digression from the Sun indicated by the letter M and the evening by the letter V, and the greatest where the letter m stands, as either others or we judge, the places however being corrected from our hypothesis of the ☉ and the fixed stars.

Inquisitio Apogei Veneris Ad Ptolemæi tempus.

Inquiry into the apogee of Venus at the time of Ptolemy.

III. Although Ptolemy's method is not all that exact, yet since we have scarcely a better one a priori, we must try to find, roughly, the place of the line of apsides by bisecting the lesser arc of the zodiac intercepted between two places of the Sun, with Venus or Mercury digressing equally from it on either side. Thus, for example, from what was said in ch. 8, no. 8, the greatest distance of Venus from the Sun's mean place, as corrected by Longomontanus, was 47° 11′ in the morning and 47° 0′ in the evening, and none among them are more nearly equal. Suppose, then, that we bisect the error, which can easily lie hidden, so that each was 47° 5′, and use the Sun's mean places as set down by Longomontanus, which were ♌ 6° 12′ and ♑ 2° 36′. The lesser arc between these is 146° 24′, half of which is 73° 12′. This, then, added to ♌ 6° 12′, gives the line of apsides of Venus in ♎ 19° 24′, though Ptolemy would

have it pass through ♏ 25°. That place is favoured by digressions 2 and 3 of Venus, corrected by us from the Sun's true place, which surpass all the others in nearness to equality: the morning one was 45° 36′ and the evening one 45° 27′, and each may easily be 45° 32′. The Sun's true places, however, were ♉ 26° 44′ and ♓ 17° 2′, and the lesser arc between them was 69° 42′. Half of this, 34° 51′, added to ♓ 17° 2′, gives the line of apsides in ♈ 21° 53′. If the middle value is chosen, therefore, the apogee of Venus seems at that time to have been at 20° 38′ of Aries and the perigee at 20° 38′ of Libra.

[Margin: The apogee of ♀ very different from Ptolemy's.]

It is clear, then, from how far off, as Kepler truly said, this apogee could be discerned from ancient observations, since those observations, not corrected without cause, show it a whole degree and more before Ptolemy's. Granted that Copernicus and others after him, not daring to depart further from Ptolemy, kept it for that time around ♉ 25°, and with that set so tempered the eccentricity, the semidiameter of the orb and the anomaly that this hypothesis satisfied some observed places of Venus. Yet if someone were to achieve the same or a better agreement of calculation by changing these elements and setting the apogee of Venus around ♈ 20° at Ptolemy's time, he would not seem to deserve being hissed off at once, since it was found rather there, by the same method as Ptolemy's and with more correct digressions. Nor is there any doubt that if Ptolemy had used more correct digressions and had established this apogee far elsewhere, his followers would have tried to keep it in that same place as nearly as possible, and would have changed the other elements of the hypothesis as often as it took for the hypothesis to satisfy some selected observations.

Inquisitio Apogei Veneris Ad noſtra tempora.

Inquiry into the apogee of Venus for our own times.

IV. Among the more recent greatest digressions of Venus from the Sun reported in our table, no evening ones can be compared so equally with morning ones as those written below, from which a far different place of the perigee is found, as for brevity's sake you see in the following synopsis; its opposite is the place of the apogee.

[Margin: Evidence for the apogee of ♀ in this century.]

Order of observations	Digressions of ♀	☉ Mean place	Place of the perigee of ♀
13	47° 49′	♎ 3° 49′	♏ 18° 48′
19	47° 48′	♍ 3° 47′	
19	47° 48′	♍ 3° 47′	♐ 21° 12′
32	47° 47′	♐ 8° 37′	
24	47° 1′	♍ 0° 58′	♐ 14° 22′
29	47° 4′	♏ 23° 46′	

We are therefore compelled to wait for other observations, whether ours or others', until two greatest digressions, especially from the Sun's true place,

perfectly equal, one of them morning and the other evening, are made known to us, so that from them a greater light may rise for us in this darkness; and in the meantime to explore which place of this apogee established by other astronomers fits more, and more certain, phenomena.

Inquiſitio Apogei Mercurij Ad Ptolemæi tempus.

Inquiry into the apogee of Mercury at the time of Ptolemy.

V. Among the greatest digressions of Mercury from the Sun, morning on one side and evening on the other, none are more equal to one another than those written below, as will be clear to anyone surveying our preceding table of observations of Mercury. And so, when the lesser arc of the zodiac between the Sun's places is bisected, an apogee of Mercury emerges very different from the one recent astronomers set, as may be seen in the following list, in which, however, we set down the perigee, indicated by the greater digressions; but its opposite indicates the apogee.

[Margin: ☿. The perigee, and from it the apogee, at the time of Ptolemy.]

Order of observations	Digressions of ☿	☉ Mean place	Perigee
7	21° 39′	♒ 10° 30′	♈ 10° 0′
8	21° 35′	♊ 11° 31′	
		☉ True place	
2	26° 36′	♒ 17° 6′	♈ 9° 31′
4	26° 50′	♊ 1° 55′	
6	27° 46′	♌ 10° 54′	♈ 25° 52′
13	27° 46′	♒ 10° 50′	

Therefore, if you prefer the number of testimonies, the first two comparisons favour Ptolemy, who sets the apogee of Mercury in ♎ 10° and the perigee in ♈ 10°. But if you prefer the Sun's true place and the exact equality of the digressions, it seems it must be advanced as far as nearly ♎ 26°.

Inquiſitio Apogei Mercurij Ad noſtra tempora.

Inquiry into the apogee of Mercury for our own times.

VI. Using the same method, you will not find among the preceding greatest digressions of Mercury more suitable comparisons for scenting out its apogee as it fits this century than those written below.

Order of observations	Digressions of ☿	☉ Mean place	Apogee of ☿
34	18° 50′	♎ 12° 51′	♍ 2° 0′
37	18° 44′	♓ 21° 8′	
		☉ True	
27	17° 52′	♒ 23° 38′	♐ 18° 17′
34	17° 52′	♎ 12° 51′	

Order of observations	Digressions of ☿	☉ Mean place	Apogee of ☿
27	17° 52′	♒ 23° 38′	♐ 10° 38′
31	17° 48′	♍ 26° 48′	

Insinuatur triplex ratio aliquid de his Apogeis decernendi.

A threefold way of deciding something about these apogees is suggested.

VII. So far we have hunted the signs and places of these apogees with a looser search, and are not equipped with sufficient observations of whose evidence one can be sure; so we point out a threefold way out of this labyrinth. *The first* way, one well trodden by Longomontanus, Lansbergen, Boulliau, and, as
