Translator Version 2

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: ”What do I need this new instrument for?” — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBris HaShalem* (1797)

A note on the work

The *New Almagest* (Bologna, 1651) is the great Jesuit encyclopedia of seventeenth-century astronomy — a sprawling survey that takes its name from Ptolemy's ancient masterpiece and aims to do for its own age what the *Almagest* did for antiquity. Its author, the Jesuit Giovanni Battista Riccioli (1598–1671), sets out the whole of astronomy as it then stood. This first part, Books I–VII, covers the sphere and the Earth, the Sun, the Moon, eclipses, the fixed stars and the five planets. It contains the map of the Moon, drawn with his colleague Grimaldi, whose crater and sea names — Tycho, Copernicus, Plato, the Sea of Tranquility — astronomers still use today. The second part, with the comets, the systems of the world and the celebrated 126 arguments on the Earth's motion, is a separate volume.

A note on the translation process

This translation was produced with the translation-pipeline. See the linked repository for details on the process.

A note on the references. A scriptural or bibliographic reference given in brackets or parentheses is, in most cases, an **editorial identification of an allusion rather than a citation printed in the source**. Books of this kind quote and weave scripture constantly without naming it, and the identification is supplied here as a convenience to the reader. Where the source does print a reference of its own, it is given as printed. **An identified allusion is not evidence that the author cited that passage** — look at the original before resting an argument on one.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Acknowledgements

Translated with the assistance of Claude. The translator thanks the Anthropic team for making this work possible.

Notation and abbreviations

A few conventions have been applied uniformly throughout this translation, so that one quantity is always written one way. They change how a value is *written*, never what it is; where the printed source and this translation differ in notation, the source's own form is recorded in the editorial apparatus.

Numerals are Arabic, even where the source sets Roman ones. Roman numerals are kept only in headings, running headers and signatures, which are transcribed as printed.

Dates are given as year, month, day — *1572 November 11*. Dates are Julian, as the source gives them, and have not been converted to the Gregorian calendar.

Times are written with raised unit letters: $7^{h}\ 36^{m}\ 12^{s}$ for seven hours, thirty-six minutes and twelve seconds. An interval longer than a day carries a raised d — $3^{d}\ 7^{h}$. The degree and minute signs below are never used for time.

Angles are written with the conventional signs — 23° 27′ 30″. Early modern astronomy divides the degree sexagesimally and often runs to places for which modern writing has no common symbol; the orders used in this book are:

sign	order	the source's term
°	degrees	*partes*, *gradus*
′	minutes of arc	*scrupula prima*, *minuta*
″	seconds of arc	*scrupula secunda*
‴	thirds	*scrupula tertia*
⁗	fourths	*scrupula quarta*

A **sign** is 30° — one twelfth of the circle — and is written with a raised s: 5^{s} 3° 57′ is five signs and 3° 57′, that is 153° 57′. The source uses the sign both as a place in the zodiac and as a plain unit of 30° for a motion or a distance, and this translation keeps that distinction by writing the count rather than naming a constellation.

The signs of the zodiac. Longitude is reckoned eastward from the first point of Aries.

	Latin	English	longitude
♈	Aries	the Ram	0°–30°
♉	Taurus	the Bull	30°–60°
♊	Gemini	the Twins	60°–90°
♋	Cancer	the Crab	90°–120°
♌	Leo	the Lion	120°–150°
♍	Virgo	the Virgin	150°–180°
♎	Libra	the Scales	180°–210°
♏	Scorpius	the Scorpion	210°–240°
♐	Sagittarius	the Archer	240°–270°
♑	Capricornus	the Goat	270°–300°
♒	Aquarius	the Water-bearer	300°–330°

	Latin	English	longitude
♓	Pisces	the Fishes	330°–360°

The Sun, Moon and planets.

	Latin	English
☉	Sol	the Sun
☿	Mercurius	Mercury
♀	Venus	Venus
♂	Mars	Mars
♃	Iuppiter	Jupiter
♄	Saturnus	Saturn

Abbreviations used in table headings: **Long.** longitude; **Lat.** latitude; **RA** right ascension; **Asc.** ascension; **Arg.** argument.

Where a table in the source spreads one quantity across separate columns for degrees, minutes and seconds, those columns have been joined into a single column and the value written whole. Where a value runs to thirds and beyond, the columns are kept, since there the columns are the notation.

[Non-book page: front cover of the modern binding — mottled brown calf, raised bands on the spine; no printed text.]

[Non-book page: front pastedown, blank paper, with a library mark in pencil at top left: "1529 (Rar)", struck through. No printed text.]

[Non-book page: front free endpaper, blank, with a library shelfmark in pencil at top right: "Rar 9471: 1/1 fol." No printed text.]

Engraved frontispiece

Diagram. The engraved frontispiece, a full-page copperplate within a ruled border, carrying no title text. It is an allegory of the rival world-systems weighed in a balance.

Apex. At the top centre, in the sky, a short pointed Hebrew word of four letters [?] is set above a hand reaching down out of a cloud from the upper right. Rays stream down from the hand's outstretched fingers, which are labelled in three words: **Numerus**, **Mensura**, **Pondus** ("Number, Measure, Weight").

Upper left. Four winged putti in clouds hold up planetary bodies, each marked with its planetary sign: one holds a spotted globe marked with the sign of Mars; one a globe with a dark limb, marked with the sign of Venus; one, lower down, a globe in phase, marked with the sign of Mercury. Between them shines a radiant Sun drawn with a human face. A ribbon-banner unfurls across this group: **Dies diei eructat uerbum** ("Day pours forth speech to day").

Upper right. Against a darker, star-strewn sky, more putti hold the remaining bodies: Saturn drawn with lateral "handles" and marked with its sign; Jupiter, banded and ringed by small companion stars, marked with its sign; a large Moon showing a mottled, cratered face with a dark crescent of shadow; and below them a comet with its tail. A second banner runs across this group: **Et No[?] nocti indicat scientiam** ("and night to night shows knowledge").

Inscribed rays. Two inscriptions run along the rays descending from the divine hand. On the left, rising towards the hand: **Videbo Cælos tuos, opera digitor tuor** ("I will see your heavens, the works of your fingers"). On the right, descending: **Non Inclinabitur in Sæculum Sæculi** ("It shall not be moved, for ever and ever").

The figures. At the left stands a tall, bearded, half-draped man whose body is covered all over with open eyes — the many-eyed Argus. He grasps a long telescope in his left hand and points with his right towards the inscription and the sky. At the right stands a winged woman — Urania — her gown and mantle strewn with stars and her girdle marked with signs of the zodiac (Virgo and Libra are among those visible). In her right hand, raised high, she holds the beam of a balance; in the crook of her left arm she carries an armillary sphere, whose zodiac band shows the signs of Aquarius, Pisces, Aries, Taurus and Gemini, with one more sign not read [?]. Along the beam of the balance runs the inscription **Ponderibus librata suis** ("balanced by its own weights").

The balance. From the left arm of the beam hangs a pan in the form of a large disc showing a heliocentric scheme: the Sun, with a face, at the centre, surrounded by concentric orbits, with the planets marked by their signs around them: Mercury and Venus on the two innermost orbits, then a small globe of the Earth carrying a crescent Moon on a little circle of its own, then Mars, Jupiter and Saturn. This pan rides higher. From the right arm hangs a second, larger disc, which hangs lower — the heavier side: it shows a scheme in which the Sun, carrying small orbits of its own (planetary signs beside it), revolves together with outer planetary orbits about a central body set lower in the disc — a small globe of the Earth, with a crescent Moon on a little circle round it. Mercury and Venus are marked beside the Sun, Mars on the left, and Saturn and Jupiter on the rim.

Below. Between the two figures, at the foot of the balance, an old bearded man in a mantle reclines on the ground, looking up at the pans. Beside his head is engraved **Erigor dum Corrigor** ("I am raised up while I am corrected"). His arm rests on an ornamental cartouche-shield inscribed **Cl. Ptolem.** (Claudius Ptolemy), whose field shows two globes, one of them drawn with a grid of circles. At the centre foreground stands a crowned cartouche bearing a coat of arms with a lozengy (diamond-chequered) field[1]. At the lower right, cast down on the ground at Urania's feet, lies a third disc showing a geocentric scheme of concentric circles about a central body, with signs around them: the Moon nearest the centre, then Mercury, Venus and the Sun, a sign with a crossed stem at the left [?], then Jupiter and Saturn — evidently the discarded system.

Engraver's signature. At the lower left, inside the border: **F. Curtus Bon. Incid.** ("F. Curtus of Bologna engraved it")[2].

Owner's stamp. Across the plate's lower border, an oval blue library stamp, partly legible: "…POLYTECH…" in its upper arc and "…BIBLIOTHEK…" in its lower arc; the centre is not read [?].

Labels and inscriptions read: Numerus; Mensura; Pondus; Dies diei eructat uerbum; Et No[?] nocti indicat scientiam; Videbo Cælos tuos, opera digitor tuor; Non Inclinabitur in Sæculum Sæculi; Ponderibus librata suis; Erigor dum Corrigor; Cl. Ptolem.; F. Curtus Bon. Incid.; the zodiac signs of Virgo and Libra on Urania's girdle; the planetary signs of Mars, Venus, Mercury, Jupiter and Saturn held by the putti.

Labels not read: the four-letter Hebrew word at the apex [?]; the final letter of "No[?]", hidden in the fold of the banner; the individual planetary signs on the three system-discs (present, but not read one by one); the centre of the library stamp.

[1] supplied identification — the arms of the Grimaldi family; the book is dedicated to Cardinal Girolamo Grimaldi

[2] supplied identification — Francesco Curti, the Bolognese engraver

Title page

THE NEW ALMAGEST [ALMAGESTVM NOVVM]

embracing the old and the new astronomy, advanced by the observations of others and by the author's own, and by new theorems, problems and tables;

DISTRIBUTED INTO THREE VOLUMES,

whose contents the following page will set out.

BY FATHER GIOVANNI BATTISTA RICCIOLI [P. IOANNE BAPTISTA RICCIOLO]

OF THE SOCIETY OF JESUS, OF FERRARA,

Professor of Philosophy, Theology and Astronomy.

BOLOGNA

From the press of the heir of Victorius Benatius [Vittorio Benacci], 1651 [M DC LI].

With the permission of superiors.

VOLUME ONE [TOMVS PRIMVS]

contains ten books, whose subjects are listed below.

- **BOOK I.** On the Sphere of the World in General.
- **II.** On the Elementary Sphere.
- **III.** On the Sun.
- **IV.** On the Moon.
- **V.** On Eclipses.
- **VI.** On the Fixed Stars.
- **VII.** On the Minor Planets. This Book is further subdivided into six Sections.
- **VIII.** On Extraordinary Phenomena. Its Sections:
  - I. On Comets.
  - II. On New Stars.
- **IX.** On the Systems of the World. Its Sections:
  - I. On the Creation and Nature of the Celestial Bodies.
  - II. On the Motions and the Movers of the Celestial Bodies.
  - III. On the Systems of the World that Suppose the Earth Unmoved.
  - IV. On the System that Supposes the Earth Moved.
  - V. On the Harmonic System of the World.
- **X.** General Problems Serving Astronomy. Sections:
  - I. A Compendium of Trigonometry, Old and New, that is, Linear and Logarithmic.
  - II. Problems of the Primum Mobile [Primi Mobilis], Collected and Augmented.
  - III. Problems of Time, Collected and Augmented.
  - IV. Geographical and Cosmographical Problems, Augmented.

- V. Problems of Parallaxes, with Theorems, Collected and Augmented.
- VI. Problems of Refractions, Collected and Augmented.

This first Volume is now being published.

VOLUME TWO [TOMVS SECVNDVS]

contains five books, whose subjects are as follows.

I. THE TRIGONOMETRICAL BOOK [LIBER TRIGONOMETRICVS]

It treats the analysis of plane and spherical triangles, with their theory and practice in various forms. Added to it are Tables of Sines, Tangents and Secants, extended to seconds at the beginning and the end of the quadrant, together with the Logarithms of arcs and of absolute numbers.

II. THE INSTRUMENTAL BOOK [LIBER ORGANICVS]

It treats astronomical instruments, their construction and use, and the method to be followed in observing celestial phenomena.

III. THE OPTICAL BOOK [LIBER OPTICVS]

It treats the optical part of astronomy, and especially refractions in the air, in the eye, in spectacles, and in the lenses of telescopes.

IV. THE GEOGRAPHICAL BOOK [LIBER GEOGRAPHICVS]

It treats the mathematical part of geography, especially the correction of latitude and longitude, hydrography, and the art of navigation.

V. THE CHRONOLOGICAL BOOK [LIBER CHRONICVS]

It treats the reckoning of time, the calendars of the nations, and the epochs of years; and also the year and the day of the birth and of the death of CHRIST the Lord. Added to it is an epitome of chronology, confirmed by astronomical criteria [characteribus Astronomicis], with more correct tables of memorable events and persons.

VOLUME THREE [TOMVS TERTIVS]

contains ten books, whose subjects are as follows.

- **I.** Observations of the Sun.
- **II.** Observations of the Moon.
- **III.** Observations of Eclipses.
- **IV.** Observations of the Fixed Stars.
- **V.** Observations of the Minor Planets.

(Books I–V, braced together:) Those of others and our own, with the astronomical conclusions drawn from them.

- **VI.** The Precepts of the Primum Mobile [Primi Mobilis Præcepta].

- **VII.** The Tables of the Primum Mobile.
- **VIII.** The Precepts of the Second Movers [Secundorum Mobilium Præcepta].
- **IX.** The Tables of the Second Movers.
- **X.** The Remaining Tables, serving Astronomy or Cosmography, with their accompanying Precepts.

Among the tables just named are contained not only those which, on the Author's hypothesis, appear more certain, but also the tables of the other astronomers reduced to an epitome, or the equations to be added to or subtracted from the Author's tables in order to reduce them to the tables of the others.

TO THE GREATER GLORY OF GOD [AD MAIOREM DEI GLORIAM].

Dedication title

TO THE MOST EMINENT PRINCE, HIERONYMUS CARDINAL GRIMALDUS [Girolamo Grimaldi]: THE FIRST PART OF THE FIRST VOLUME OF THE NEW ALMAGEST [ALMAGESTI NOVI PARS PRIOR TOMI PRIMI].

Diagram. Engraved armorial plate: the arms of the dedicatee. A cardinal's hat at the top, its cords knotted and looped out to either side and ending in tassels hanging down both flanks; beneath the hat a cross with trefoil ends stands above the shield. The shield is set in a heavy scrolled cartouche of curling leaves; its upper part (the chief) carries a displayed eagle with a small crown above its head, the lower part is lozengy (a field of diamonds). Engraver's signature at lower left of the plate.

- Signature (lower left, inside the plate border): "IIFontana F." — small engraved script: two initials, the surname, and "F." (fecit, "made [this]").
- No other labels.

TO THE MOST EMINENT PRINCE GIROLAMO CARDINAL GRIMALDI [EMINENTISSIMO PRINCIPI HIERONYMO CARDINALI GRIMALDO].

You have seen, MOST EMINENT PRINCE, at the entrance of this volume, Claudius Ptolemy [Claudium Ptolemæum], who was the renowned author of the old *Almagest*. With one hand he holds out a globe that is at once terrestrial and celestial — the insignia, that is, of his twofold primacy in geography and in astronomy; with the other, leaning as it were on the most noble arms of the GRIMALDI family [GRIMALDAE Gentis], he is raised up to the hope of a New Almagest while the old one is being corrected.[3] For on the very frontispiece of the work I chose to seek a shield and protection from that House, to whose liberality and industry I freely declare that I owe the whole mass of this construction, great as it is. That House contributed its wealth and its own talent; let it therefore contribute, too, both its guardianship and its title — that

[3]the play is on *Erigi* / *Corrigitur*, "raised up" / "corrected", both capitalized in the print.

is, the bulwark of patronage and the ornament of an emblem. And from the great number of the nobles of that family, whom should I single out as my patron, if not You in the first place, MOST EMINENT CARDINAL? For, as the panegyrist Pliny says of Trajan, "it was not a matter of searching for someone to be chosen, but of choosing the one who stood out."

Who, then, unless perhaps a man utterly without knowledge, would deny that You stand out among the members of the Grimaldi House — not only those still living, but also those who went before? And this however golden the branches of that tree on which are counted, besides eighteen bishops or archbishops, also seven and perhaps eight most distinguished Cardinals of the Holy Roman Church [S. R. E.]. Namely: Theobaldus, son of Grimaldus II, Prince of Monaco [Monœci], Cardinal of Saints John and Paul, of the title of St Pammachius, created by Urban II. Guido, nephew of Guido II, Prince of Monaco, Cardinal of St Balbina, created by Paschal II. Lucas, nephew of the same Prince, of Saints John and Paul, of the title of St Pammachius, created by Innocent II. Michael Crespinus, descended from Crispinus Ansgothus, son of Grimaldus I, Prince of Monaco, Cardinal of St Stephen on the Caelian Hill, created by Clement V. Girolamo [Hieronymus], sprung from Oberto Grimaldi [Obertus Grimaldus], Prince of Monaco, of the title of St George, created by Clement VII. Agostino Grimaldi [Augustinus Grimaldus], Prince of Monaco, who, while he was guardian of Prince Luciano [Lucianus] and had received Charles V as his guest, was named Cardinal by the same Clement VII at Charles's wish. To these I would most gladly add Angelicus Grimaldi, created Cardinal by his grandfather Urban V, formerly Guillelmus Grimoaldi [Guillaume de Grimoard] — if only, just as one may form a strong conjecture from the family arms and the surname of both, one could likewise show plainly from history that that thrice-greatest Pontiff and his grandson were of those Grimaldi who sprang from the same trunk from which YOU and the Princes of Monaco have taken your origin. But two things stand in the way, which you have never set below the pontifical mitre itself: Modesty and Truth. The first permits nothing exaggerated in its own commendation; the second admits nothing into this genealogy that is not evident, since it does not need conjecture, however strong, for its own nobility.

But You, GIROLAMO, You — last in time among the Cardinals [Cardines] of the Holy Roman Church just listed, yet at length most eminent in title and in merit — have risen to so great a height by climbing not only the steps of offices and duties, but the grand, heroic leaps [assultibus] of the virtues. You were, to be sure, in 1621 Referendary of both Signatures under Gregory XV; in 1625 Vice-Legate of the Province of the Patrimony; in 1628 Governor of Rome. You were in 1632 Nuncio Extraordinary to the Emperor Ferdinand II; in 1634 Governor of Perugia; and in 1636 Pro-Legate of the Duchy of Urbino. You were at last, in 1641, Archbishop of Seleucia and at the same time Nuncio to Louis XIII, King of the French; and then, in 1643, created Cardinal of the Holy Roman Church, of the title of St Eusebius, by Urban VIII. What brought You

here was not the multitude of your achievements alone, but their greatness; not the number of your dignities, but the dignity of your merits: namely, the highest prudence; a penetrating keenness of mind; a hidden maturity of counsel; a timely dexterity in action; a vigilance that looks round upon everything; an expertise in civil and ecclesiastical affairs, and a profound one; and above all these, a singular uprightness of character that needs no proof. It was by these, surely, by these splendours, that the most wise Pontiff judged the purple should be made illustrious — not You by the purple. In this breast the Most Christian Kings have rightly laid up the sum of French affairs and the treasures of their counsels.

For here indeed is the place to recall with the greatest delight by how close a bond You repay to the royal stock of the Franks the vein of dew from which You once drew the moisture of your birth, by an origin as manifest as that of days from suns. With a noble expenditure, I admit, but a just one, You have consecrated these purple labours [sudores] — yet its own — to blood that is royal, yet your own. And oh, how many have heard of it and how few have understood it: by a harmonic tempering of dissonant negotiations You reconcile civil polity with the hierarchy, the palace of kings with the temple of God — in a word, the Church with the Court! And yet this is both most wonderful and not wonderful at all. For what wonder is there if, in such a council and as it were concert of courtly and of heavenly affairs alike, You are not found degenerate from your ancestors? We are ignorant, I suppose, of the Arnoldi and the Arnulfi [Arnoldos … Arnulphos], and the twin Pippins — one of Landen [à Lauda], the other of Herstal [ab Heristallo]; of the Modualdi and the Clodulfi [Modualdos … Clodulphos], the two Grimoaldi, and the Theobaldi — from all of whom, of course, springs the Grimaldi family! Of these, if you except Saints Modualdus and Clodulfus, all were Counts of Gallia Belgica and Counts Palatine, and with that Mayors of the Palace in Francia or in Austrasia; and all without a single exception were at that time Counsellors of the Kings of East or of West Francia, or Prefects of the Kingdom itself. They administered the supreme power in such a way that those who were bishops — and those three most holy men were bishops: Arnulfus and Clodulfus, prelates of Metz, and Modualdus of Trier — consecrated the court of kings into a church, while the others, as dukes, so conducted themselves in the palaces as bishops do in their own churches. For all of them had set themselves to strive earnestly that what belonged to the subjects and the people should be rendered to the people; what belonged to kings, to kings; what belonged to pontiffs, to pontiffs; what belonged to God, to God. From this stock, therefore, no more noble than it was devout, You drew a sap not foreign but native — one that, by spontaneous imitation, You turned for Yourself into the necessity of a most numerous example.

So France, or rather the Christian world, recognizes revived in You its own and equally your own Pippin of Landen [a Lauda] — never to be praised enough [nunquam satis laudandum], because so often and always praiseworthy

[laudabilem] in You — of whom that most beautiful eulogy of Stephanus, Abbot of Liège [Stephani Abbatis Leodiensis], will forever resound: "For he was" (these are that Abbot's words, in the Life of St Modualdus, the cousin of this Pippin) "of most approved life and most pure reputation, a dwelling-place of wisdom, a trea- sury of counsels, a defence of the laws, an end of controversies, a bulwark of the fatherland, an ornament of the court, a way for dukes, a discipline for kings." Nor did You express in your manner and measure of conducting affairs this Pippin alone, but also the Saints Arnulfus and Modualdus, your forebears [maiores tuos] — yet in You no lesser [non minores]. Posterity, then, will go on with the same Abbot Stephanus, and will repeat what he pointedly remarked about the prelates who moved in the court of Dagobert and of the other kings: "It is pleasing now to consider what that time was like, how acceptable, how serene, when kings indeed reigned, but just and God-fearing men ruled the kings together with the kingdom; when justice, faith, truth, modesty and the other good arts were kept in war as in peace; when all the business of royal power was directed by the line of divine equity." And not stopping there, he soon adds: "What a palace that was, how holy, from which the Church received such renowned and such illustrious priests — from which came men who did not seek the courts of kings, but were rather sought by kings!" Your name will take its place among these names, since You so support kings that You serve God alone and no one else besides; You so prevail by foresight and counsel that You do not domineer; You so turn the rights of arms and the hinges of war that, closing the doors on war, You are able to conclude a stable, perpetual and august peace. And yet, though You do all things worthy of kings, You take offence only at your own praises. For I hear that the modesty of your mind, and hence of your mouth and ears, is so singular that, with a brow otherwise most gracious but drawn almost into severity, You at once shut off access to your praisers alone — even though your Virtue and your Fame have opened a vast theatre to their applause and encomia.

I understand, therefore, that I must fear lest I offend the very man by whom I wish to be defended, and imprudently provoke against me the one I have chosen to invoke as my patron. To obtain this the more easily, I appeal once more to the name of the Grimaldi family as a ground — I had almost said a necessary one — for your protection. For over and above the munificence of that House toward me, Father Francesco Maria Grimaldi [P. Franciscus Maria Grimaldus], of our Society, Professor of Mathematics, has spent his effort on this work of ours — or, more truly, has spent his whole self on it. He stood by me as I observed the celestial phenomena, himself a most skilful observer of the stars. He was at my side as I wrote, suggesting from the vein of his own talent things neither few nor to be regretted. Finally, he oversaw the printing of the volumes, with untiring labour, inviolable fidelity, keen judgement, sincere frankness and the most persistent vigilance. But I add nothing more, lest I provoke to anger the modesty of a man who is, in this respect above all, candid and devout. Nor would I have dared to mention even this much, which I have

disclosed very much against his will, had I not been driven to it by the need to show You in what way the Grimaldi House contributed both wealth and talent to whatever this work amounts to — and by what right of confidence I had to seek from that same House a Protector of the most splendid authority. Here, then, MOST EMINENT ONE, is this first Volume of the New Almagest, cast down at your feet, so that — protected, if not in the fold of your purple, then at least by its outermost hem, and wrapped in it once for all — it may begin to be unrolled by the hands of the learned without shame or fear.

FAREWELL [VALE].

Bologna, in the year 1651, on the day of the Assumption of the Virgin MARY into Heaven [Bononiæ Anno M DC LI. die Virginis MARIÆ in Cælum Assumptæ].

YOUR EMINENCE'S [EMINENTIÆ TVÆ]

most devoted and most obedient Io. Baptista Ricciolus [Giovanni Battista Riccioli], of the Society of Jesus.

Licence of the Reverend Father Vincentius Carrafa [Vincenzo Carafa], Superior General of the Society of Jesus [Facultas R. P. Vincentij Carrafæ SOC. IESV Præpoſiti Generalis.]

Three theologians of our Society have examined the first Volume of the *New Almagest* of Father Giovanni Battista Riccioli [P. Ioannis Baptiſtæ Riccioli], priest of our Society, and have approved it for publication. We therefore grant permission for it to be printed, if it so seems good to those whom the matter concerns. In witness of this we have issued this letter, signed by our own hand and secured with our seal, at Rome, 1647 March 12.

Vincentius Carrafa.

Place of the seal [Locus Sigilli].

Licence of the Reverend Father Alexander Bosellus [Alessandro Boselli], Provincial of the Society of Jesus in the Venetian Province [Facultas R. P. Alexandri Boſelli SOC. IESV Prouincialis in Prouincia Veneta.]

Three theologians of the same Society have examined the additions to the First Volume of the *New Almagest*, divided into two parts, by Father Giovanni Battista Riccioli, priest of our Society, and have approved them for publication. We too, having received authority from our Very Reverend Father Goswin Nickel [R. P. N. Goſuino Nickel], Vicar General of the Society of Jesus, grant permission for them to be printed, if it so seems good to those whom the matter concerns. In witness of this we have issued this letter, signed by our own hand and secured with our seal, at Bologna, 1651 August 17.

Alexander Bosellus.

Place of the seal [Locus Sigilli].

Examined by Father Bonaventura Cavalieri [P. Bonauentura Caualerius], and afterwards by Father Francesco Maria Grimaldi [P. Franciſcus Maria Grimaldus], professors of mathematics, on behalf of the Most Eminent and Most Reverend Cardinal Archbishop.

Don Andreas Cuttica [D. Andreas Cuttica], Clerk Regular of St Paul, and Rector of the Penitentiary [Pœniten. Rect.] [?], on behalf of the Most Eminent and Most Reverend Cardinal Archbishop.

IMPRIMATUR [IMPRIMATVR]

Brother Vincentius Pretus of Serravalle [F. Vincentius Prętus à Serraualle], Inquisitor General of the Holy Office at Bologna.

PRÆFATIO AD LECTOREM IN SEPTEM ARTICVLOS DISTRIBVTA.

Preface to the Reader, Divided into Seven Articles

ARTIC. I. Aſtronomiæ Encomium.

Article I. In Praise of Astronomy

If the heavens stand above the Earth and all the elements; if the stars stand above not stones only but gems; if, finally, that pure, unalloyed and everlasting gold of the celestial lights stands above everything of inferior grade, as above baser metals — that is, above any bodily things whatever below the Moon — then surely ASTRONOMY too, crowned with stars, and those its own, raises its head as Queen among all the faculties or natural sciences. For divine Theology, empress of all disciplines, to which Astronomy and every other branch of learning must yield, is not that natural theology which is usually called by another name the science of metaphysics [Greek: τῶν μεταφυσικῶν (tōn metaphysikōn, "of the things after physics")]. It is the theology that discourses of GOD and divine things by the light of supernatural Faith, divinely infused.

[Margin: The eminence of Astronomy above all the natural sciences.]

With this one exception Astronomy surpasses all the rest — whether you consider the dignity of its subject; or the certainty of its method, and its evidence in so lofty a depth of contemplation; or the number of natural faculties that serve it as handmaids, and which it in turn supplies or assists; or the pleasant tranquillity of a most pure pleasure; or, finally, the princely men, eminent in priestly or royal dignity, who have commended it by private study, by public testimony of honour, or by the vote of their wonder.

[Margin: The chief heads on account of which Astronomy excels.]

So our own Caussin [Cauſſinus noſter], in the preface to his books *On the House of God* [in præfat. ad libb. de Domo Dei], rightly laid it down: *Among the other things by which the human mind is nourished and refreshed, as by a pleasant pasture of wisdom, the first rank belongs to the contemplation of the heavenly bodies, by which we enter into the very house of God, as tent-companions of the Angels and candidates of the first light.* Or, with Manilius, *Astronomica* I [I. Aſtron.]:

> ..... *and we, a part of it, behold the parent of things, and, born of it, draw near to the stars.* [Rerumque parentem / Pars ſua conſpicimus, genitique accedimus aſtris.]

To show the excellence of its subject one needs not a tongue but eyes. To have seen the Sun by day, or the stars by night — above all on a night neither moonless nor overcast — is to have been struck with wonder; the spectacle itself is at once a marvel. The very tongue of God bears witness to it, saying: *The firmament of the height is its beauty, the appearance of heaven in a vision of glory*, etc.

[Margin: The dignity of its subject.]

[Margin: Ecclesiast. 43 [Eccleſiaſt. 43.].]

Let Astronomy be allowed to glory — but in a divine gift — from the same source from which GOD himself commends himself, and to say: *Heaven is my seat*; my wealth is the stars, which neither Abraham, at GOD's bidding, could number, nor Abrachys, that is, Hipparchus — however inflated the style in which Pliny the Elder [Plinius] said: *Hipparchus, never praised enough, for no one proved more fully the kinship of the stars with man*, etc., *who dared a task too bold even for God, to count the stars for posterity*, etc., *leaving the heavens as an inheritance to all.*

[Margin: Book 2, ch. 26 [Lib. 2. c. 26.].]

The heavens, I say, are Astronomy's domain: highest in place of all visible things, everlasting in duration, astonishing in the vastness of their mass, most delightful in the splendour and variety of their lights; awe-inspiring in the majesty of a world that glides silently on, most pleasing in the hidden harmony of like and unlike motions; most fruitful in the secret, steady distillation of perpetual influences; and venerable for the wisdom of the Angels, who by a constant law wheel the celestial bodies round at the motion of the First Intelligence, as under a governor [tanquam Harmoſtæ]. The heavens, finally — whether you call them the curtain of the Tabernacle of the Most High or the outer shell of the Empyrean — are nonetheless a vast token of divine glory and of everlasting happiness; so much so that our most holy Patriarch IGNATIUS [IGNATIO] [Ignatius of Loyola] more than once uttered that sigh, sweeter than any song: *Ah, how sordid the Earth is when I look at the heavens!*

[Margin: The mathematical certainty proper to Astronomy.]

The certainty of Astronomy, moreover, is so great that Plato, in Book 7 of the *Republic*, holds that the eye of the mind, clouded in the other disciplines, is healed by its evidence so that it may discern the truth. For when he had decreed that Astronomy must be kept in the City, he says: *By disciplines of this kind a certain instrument of every soul is purged and revived, which had previously been infected and blinded by other pursuits — though it is more worth preserving than ten thousand bodily eyes. For by it alone is truth seen.* And again, in the same dialogues of the *Republic*, that Platonic Socrates says: *Have you noticed that those who are mathematicians by nature appear sharper at almost all disciplines, while those of duller wit, if they are trained in this one, even if they gain no further advantage, nevertheless usually become cleverer than they were before? For you will not easily find any of the rational disciplines, other than this one, that lays heavier labour and care on the one who learns and thinks it through.*

Astronomers, moreover, have been customarily called, both formerly and now, "the Mathematicians" by antonomasia [Greek: ἀντονομαστικῶς (antonomastikōs, "by antonomasia", the name of the genus given to its pre-eminent member)]. And Ptolemy, although the books of his great *Construction* concern astronomy alone, nevertheless entitled them περὶ μαθηματικῆς συντάξεως [Greek: peri mathēmatikēs syntaxeōs, "On the Mathematical Composition"]. It was because of this certainty that the same author turned himself wholly from natural theology and physical speculations to astronomy and geography; for so he addresses Syrus in chapter 1 of Book 1 of the *Almagest*: *Since, then, we have understood from this that two kinds of speculation deserve the name of conjecture rather than of more certain knowledge — the theological, because it is incomprehensible, and the physical, because owing to the instability of matter it can scarcely be grasped, so that we judge that philosophers can never agree about it — while the mathematical alone (if one uses it rightly) yields firm and unchangeable knowledge*, etc., *we resolved to support this kind as far as our strength allows, and above all that part of it which concerns divine and heavenly bodies. For this part alone considers things everlasting, which are always the same.*

Nor is it so very surprising that simple arithmetic and geometry, separated from all the inconstancy of sensible matter, or those subordinate sciences, at once mathematical and physical, which fall more closely under our senses, attain a greater degree of certainty than bare physics. So much so, that Plato in the *Timaeus* asks of the natural philosopher probable reasons, but of the mathematician and the divine reasons that can be neither refuted nor overthrown; and Aristotle, *Posterior Analytics* 1, text 30 [1. Poſter. tex. 30.], asserts: *It belongs to those who use the senses to know the very "that", but to the mathematicians to know the very "why".*

[Margin: The heroic labours of astronomers.]

But this surpasses all wonder: that astronomers, amid such perplexity and anomaly of the celestial motions, and amid planetary coils so abstruse — coils that stand so far from human sense, mark no trace of their course in the liquid aether, and do not all complete their revolution within the lifetime of a single observer — could, I say, find so happy a way out of the windings of that aetherial labyrinth by the thread of Uranian subtlety, and reach such evidence, that they are able, by a sure foreknowledge that varies only by very few minutes [ſcrupulis], and those mostly negligible, both to foresee long beforehand themselves and to foretell to others without fear the places of the stars, their risings and settings, their conjunctions and digressions, and finally all their configurations and syzygies. There is no art — and I declare this most firmly, having weighed and surveyed everything — there is surely no art that has joined more happily those two things, τὸ χαλεπὸν, καὶ τὸ φανερὸν [Greek: to chalepon kai to phaneron, "the difficult and the evident"], the Arduous and the Evident; none that has advanced so far through so many reefs and shoals of difficulty, and has held, down to this day, harbours so inaccessible. Not even that art which, having conquered the most turbulent monster of the Sea and sailed round the

whole globe, consecrated its Victory as a trophy. For astronomy did not join lands to lands, separated by the dividing Ocean, but heaven to earth — driven through the immensity of the aetherial air by the sails and oars of industry and wit, rather than by wings not given to man, or by Babylonian towers, or by the Giants' ladders of mountains.

Happy the souls whose first care it was to know these things and to climb up to the dwellings above! We may believe that they raised their heads alike above human vices and jests. Neither Venus nor wine broke those lofty hearts, nor the duties of the forum, nor the toil of soldiering; nor did shallow ambition, or glory dyed with false paint, or hunger for great riches trouble them. They brought the distant stars near to our eyes, and set the aether beneath their own intellect. SO IS HEAVEN SOUGHT — not that Olympus should bear Ossa and the peak of Pelion touch the highest stars.

[Margin: Ovid, bk. 1, *Tristia*. [Ouid. l. 1. Trift.]]

Indeed, to accomplish these things one needs not strength and "triple bronze about the breast," but a genius and an intellect that are plainly heavenly — as Plato wisely observes in the *Epinomis*: *"Do not be unaware," he says, "that astronomy is something supremely wise. For the true astronomer must necessarily be, not the one who, following Hesiod and others of that kind, considers setting and rising, but rather the one who will have examined the eight circuits, and how the seven revolve beneath the first, and in what order each completes its circles. And this no nature, unless a wonderful one, will ever easily have looked into."*

[Margin: Plato's praise of astronomers.]

Nor is such a nature reckoned merely wonderful, but something more sublime than human, above all when, by a prediction of eclipses issued in advance, it takes terror away from the minds of mortals. For this reason Livy said of Sulpicius Gallus, who freed from anxiety the army of Paulus Aemilius when it was already dismayed by an eclipse of the Moon: *"When the Moon was eclipsed at the hour he had announced, the wisdom of Gallus seemed almost divine to the Roman soldiers."* Or, conversely, it strikes a salutary terror — the means by which Columbus, when the barbarians of Jamaica denied him access and provisions, threatened them with the eclipse of the following night, and through that portent, once it was seen, obtained not only supplies but obedience and even veneration, as one fallen from Heaven.

[Margin: Bk. 4, Decade 5. [L. 4. Dec. 5.]]

Rightly therefore Pliny the Elder, having recalled Thales, Sulpicius Gallus and Hipparchus — Hipparchus, who *"foretold the eclipses of both luminaries for six hundred years, as the age bears witness, as though he were a sharer in the counsels of nature,"* burst out into that epiphonema: *"Great men, above the nature of mortals, who discovered the law of such great divinities and released the wretched mind of men"*; and a little further on: *"Bravo for your genius, you interpreters of heaven, capable of grasping the nature of things, discoverers of a reasoning by which you have conquered gods and men!"* He had said, moreover, in chapter 11: *"This reasoning draws mortal minds up into heaven, and, as though to those who contemplate from there, it discloses the magnitude of the three greatest parts of the nature of things."*

[Margin: Pliny the Elder, bk. 2, ch. 12. [Plin. l. 2. c. 12.]]

Plato had said this very thing beautifully in that seventh dialogue of the *Republic*. For he had said: *"I went straight on to astronomy, which consists in the motion of depth itself"*; and presently he adds: *"For I think it is plain to everyone that this directs the eyes of the soul to higher things, and leads it from here to there."* — provided, that is, that the astronomer does not stop at the merely apparent motions of the heavenly bodies, but rises to the exemplar of them that shines in the divine Archetype. For he continues: *"Must we not, then, use the variety of the heavenly bodies as a kind of example for the contemplation of things above? — just as if someone were to see figures wrought by Daedalus."* And after a few words he goes on: *"Let us suppose that the true astronomer will do the same when he looks upon the motions of the stars, judging, namely, that the heaven itself and the things that are in it were fabricated most beautifully by the very founder of heaven,"* etc.

[Margin: Astronomy raises the soul to heavenly and divine things.]

To this affinity of astronomy with Heaven and divine things one could adduce that faculty of divining the future, and the power of prognostics [Greek: προγνοστικῶν (prognostikōn, "of prognostics, of foretelling")], on account of which the Athenians publicly set up in the Gymnasium a statue with a gilded tongue to Berosus the astrologer — had not the genethliacs [Genethliaci, casters of nativities] tried, beyond *effects*, to predict *outcomes* as well, and future contingents — a venture always struck out by the sacred Laws, yet never extinguished; or had not the astrologasters, by stooping to every trifle, won infamy instead of fame for this heavenly discipline. Let us nevertheless hear that exordium of Manilius:

[Margin: From Pliny the Elder, bk. 7, ch. 37. [Ex Plinio l. 7. c. 37.]]

By song to draw down from heaven the divine arts, and the stars privy to fate, which vary the diverse fortunes of men — the work of heavenly reason — I undertake.

[Margin: Bk. 1, *Astronomicon*. [L. 1. Aſtronomicon.]]

He called it an *art* in his own judgement, and he also attributed its invention to the Kings of Egypt, when a little later he sang as follows:

It first deigned to move royal souls, souls touching the summits of things, next to heaven, etc. These alone knew such glory, and were the first, by art, to see the fates hanging on the wandering stars, embracing long ages in unremitting labours: through varied practice experience made the art, with example showing the way.

[Margin: The usefulness of astronomy.]

But there is another fruit of astronomy, and a far more manifest one. Just as astronomy advances attended by very many sciences, as if by handmaids — I mean Arithmetic and Geometry, then Optics and Gnomonics, Harmonics and Organics, and finally Geography and Chronology — so in turn it is both an ornament to them and a protection and support, no less than to Medicine, Agriculture, Navigation and Hydrography; but above all to Geography and Chronology, whose parts, which otherwise hold together only with difficulty, it binds with the firmest bonds of the phenomena, and confines within fixed limits of places and times. Moreover the proper distribution of years and months

— without which neither the order of civil business nor the solemnities of sacred rites can stand — depends, in its entirety, on the judgement of astronomers.

[Margin: Bk. 7, *Laws*. [7. de Legib.]]

To this end Plato, in that *Republic* of his, laid down that this part must necessarily be learned, in these words: *"Likewise those things must be thoroughly learned which are useful from the divine circuits of the stars, and of the Sun and the Moon, since with respect to these the whole city must be ordered. Of what things, you will ask? Of the order of days into the month, and of months into the year; and so the seasons, festivals and sacrifices, arranged as is fitting by a kind of natural guidance, will render the city alive and wakeful."* Who arranged the calendars and cycles for the Greeks and Asiatics? Meton, surely, Euctemon, Oenopides, Cleostratus, Eudoxus and Callippus, each of them most expert in the stars. Who took in hand the year, put out of joint by the negligence or the guile of the Roman priests, if not Julius Caesar the Dictator? Although he relied a great deal on Flavius the scribe and on Sosigenes, the Alexandrian astronomer, he was himself, as presider over and director of so great a work, not ignorant of it, and in Lucan he speaks of himself in this way — not more boastfully than truly:

..... In the midst of battles I have always found leisure for the stars, and the regions of heaven, and the gods above; nor shall my year be surpassed by the Fasti of Eudoxus.

That sacred and holy Council of Nicaea, in which, after the condemnation of Arius, so serious an inquiry was held by the three hundred and eighteen Fathers concerning the lawful time for celebrating Easter, entrusted that business above all to the Bishop of Alexandria, since it was agreed that this city had been the Metropolis of astronomy from the time of Hipparchus and Ptolemy. Later, when the Calendar had collapsed — or rather, when the Equinox had slipped back toward the beginning of the year by nearly ten days, and the golden cycle of the Moon and the Sun was degenerating into a leaden one — and when those learned in the stars and the times were protesting from the whole Christian world, the controversy over how to reform it was debated long and much, above all in the Councils of Basel and Constance. Then indeed the very sacred purple of the Cardinals blushed, when it saw so few among ecclesiastical persons initiated into astronomy — even though at that time four distinguished Cardinals were uncommonly learned in it: Petrus Aliacensis [Pierre d'Ailly], Nicolaus Cusanus [Nikolaus von Kues], Bessarion of Nicaea [Bessarion Nicenus], and Nicolaus Schombergerus [Nikolaus von Schönberg]. These men — though at different times — the Supreme Pontiffs judged must be heard, together with all the other most skilled astronomers, especially Io. Lucidus [Giovanni Lucido], Paulus, Bishop of Fossombrone [Paulum Epiſcopum Foroſempronienſem; Paul of Middelburg — identification supplied], Lucas Gauricus [Luca Gaurico], Bishop of Civitate, Albertus Pighius [Albert Pigge], Petrus Pittatus [Pietro Pitati], Io. Stoeflerus [Johannes Stöffler], and Iosephus Moletius [Giuseppe Moletti]. But since, among the others of his own time, Io. Regiomontanus stood out as far

as cypresses usually rise among the pliant viburnum,

Sixtus IV summoned him to Rome above all others for this business, holding out the hope and promise of the Bishopric of Ra- tisbon [Regensburg]. Had Regiomontanus lived — had not either the poison of Trapezuntius [Trapezuntis; George of Trebizond — identification supplied] or a star hostile to him from his very horoscope snatched him away when he was barely in his 41st year — he would surely have undertaken something royal for the correction of the year and of the cycles. Evidently this had been reserved by divine providence for Gregory XIII, so that, with the victory of the art of navigation sailing across the whole globe on the one side, and astronomy now triumphing through the whole Heaven on the other — at nearly the same point of time at which three Japanese princes from the farthest East, imitating as many holy Magi, happily put in at the feet of the Roman Pontiff as at a harbour — he should, having gathered the opinions of distinguished astronomers from every quarter (something the new star in the Chair of Cassiopeia had perhaps foretold ten years before), choose the Lilian form for restoring the Calendar; and that, using our Clavius [Clauio; Christoph Clavius] — or rather his own — as a key [claue] held out to him from heaven, he should open to us a golden age, and that order of the times which God himself was to seal with the most splendid miracles.

[Margin: Miracles in favour of the Gregorian Calendar.]

A witness to what I say is that noble blood which every year at Naples, in the presence of the venerable head of St Januarius the Martyr, liquefies and boils up on September 19 — but on the 19th that belongs to the Gregorian Calendar, the miracle having been moved ten days earlier — just as if blood once shed in testimony to the Roman faith were poured out again and again for the authority of the Roman Pontiff. Again, there is a certain small tree in Swabia which Blessed Birgitta planted in the little garden of her nuns on the night of the Nativity of Christ the Lord, in honour of the threefold Virginity of MARY, ever Virgin before, in, and after childbirth; and by her prayer she obtained that the tree should put forth leaves, flower and bear fruit at distinct intervals of hours within that same night. Afterwards it was accustomed to renew that prodigy every year on the night falling between the 24th and the 25th day of December; and in that very year 1582, which was the first of the Calendar's restoration [reparationus], and ever since, it has followed the Gregorian Calendar. We have learned from Baronius [Cesare Baronio] that by miracles of the same kind, in the fonts of holy Baptism, the Catholics' time for celebrating Easter was confirmed against the Quartodecimans.

Since these things redound in some part to the praise of astronomy, there is no reason why it should try to beg its nobility from the favour or the testimony of princes of every age. For why should it list the Kings and Magi of the Persians together, or the Monarchs of the Chaldaeans, Assyrians and Egyptians — among whom Osymandyes ordered a circle of 365 cubits, as many as there are days in the year, made of solid gold, with the rising and setting of the stars for each day engraved on it, to be placed in his Mausoleum? Nor is there any need to repeat here other dynasts or kings: Atlas of Mauretania, Janus of Italy, Cepheus

of Ethiopia, Numa of Latium, Almamon [al-Maʾmūn] of Arabia, Albategnius [al-Battānī], and Abilfedea [Abū al-Fidāʾ] of Syria, Alphonsus [Alfonso X] of Castile, Matthias of Hungary, Frederick II and Christian of Norway and Denmark. Of these, Alfonso contributed four hundred thousand gold pieces as a kind of dowry for Astraea; Matthias presented Io. Regiomontanus, for a single table of the primum mobile, with a most sumptuous robe and eight hundred Hungarian gold pieces; and Frederick, finally, built Uraniborg [Vraniburgum] for Tycho with royal munificence.

Why, finally, should it appeal to the Caesars — Gaius Julius, I mean, Hadrian, Antoninus, Frederick III, Maximilian I and II, Charles V, Matthias I, Rudolf II, and Ferdinand I and II — who received Urania into their courts as a Queen, with such great honour? Maximilian, indeed, drew mathematical figures with his own hand for his Petrus Appianus [Peter Apian] as he was preparing the *Astronomicum Caesareum*; and Ferdinand I, as Iouius [Paolo Giovio] relates, sent as a gift to Solymanus [Suleiman], Emperor of the Turks, a silver machine of exquisite and admirable workmanship, in which, besides the intervals of the hours, the monthly conjunctions of the Moon and the Sun and the motions of the remaining planets were exactly shown. This work is said to have been the Emperor Maximilian's, and the Turk was wonderfully delighted with the gift, since he had thoroughly learned astronomy and cosmography from Hammon, a physician born in Baetica. Furthermore, how highly the Kings of the Chinese esteem all mathematicians — but astronomers and cosmographers above all — whether by ancestral law or by the custom of the realm, is well known above all to the men of our Society, to whom through these very disciplines an entrance has gradually opened for pouring the light of the Gospel into the darkness of that East; and one of these, Father Matthaeus Riccius [Matteo Ricci], on that account a most honourable Mausoleum from that King earned, even in death. Emulating their munificence, the King of Canciani (he is one of the dynasts of Caucincina [Cochinchina]) is said to repay mathematicians with an estate for each eclipse they foretell — just as King Dionysius once paid a talent of silver to Helicon of Cyzicus for predicting an eclipse of the Sun. Yet more precious than all gold and silver, and more delightful, is to carry the globe of the Earth and the whole heaven itself about with one, enclosed in one's mind, and to contemplate it, as often as one pleases, as if at a single glance. Virgil, certainly, wished for this part of wisdom in the first place, as the way to a happy life, when he sang:

[Margin: Georg.]

> *But me, before all things, may the Muses, sweet above all, whose sacred emblems I bear, struck with a great love, receive, and show me the paths of heaven and the stars, etc. why winter suns hasten so to dip themselves in Ocean, or what delay stands in the way of the slow nights. But if the cold blood about my heart should bar me from approaching these regions of nature, may I love the rivers and the woods, inglorious.*

ARTIC. II. De recto Aſtronomiæ vſu, & Dilutio Obiectorum in illam, præcipuè a SS. Patribus.

Article II. On the Right Use of Astronomy, and the Refutation of the Objections against It, Chiefly from the Holy Fathers

[Margin: 1. Abuſus ſiderum adoratio. — 1. An abuse: the worship of the stars.]

What wonder is it if those who abused heaven — whether impious or ignorant — provoked the arms of heaven against themselves? If, darkening the splendour of the stars with the darkness of superstition, they forged the stars into thunderbolts for themselves? The first crime was to offer, of their own accord, to the stars the worship of latria owed to the one Creator of the stars — as though divinity were divided among them in small portions, or as though all the good and ill of mortals hung from them as from a golden chain of the Fates. Jeremiah laments this folly in chapter 9, in those *who sacrificed to all the host of heaven, and poured out drink-offerings to strange gods*; and in chapter 10 he warned: *Do not fear the signs of heaven, which the Gentiles fear.* God himself threatens them through Sophonias [Zephaniah], chapter 1, saying: *I will destroy from this place the remnant of Baal, and the names of the temple-keepers with the priests, and those who worship the host of heaven upon the housetops.* Holy Job, in chapter 31, judged this impiety the foulest of all, in these words: *If I saw the Sun when it shone, and the Moon moving brightly, and my heart rejoiced in secret* — as though the brightness of day or of night portended happiness to him, or were a sign of a divinity hidden in the Luminaries — *and I kissed my hand with my mouth*, which was a sign of adoration and of giving thanks; *which is a very great iniquity, and a denial against the most high God.* Isaiah mocks them in chapter 47, saying: *Let the augurs of heaven stand and save you, who gazed at the stars and reckoned the months, so that from them they might announce to you what is to come.* The Apostle fears for them in Galatians 4: *You observe days and months, etc. I fear for you, lest perhaps, etc.*

[Margin: 2. Abuſus Genethliacorum temeritas. — 2. An abuse: the rashness of the genethliacs.]

Next to this was the error of the genethliacs [Genethliaci], the casters of nativities, who dared to predict from the position of the stars not merely an inclination — arising from the natural temperament of the humours — toward this character or way of life rather than that, but even future contingents, and events that depend on the mere freedom of the will of one or of several persons. They are a race of men which, as Tacitus says in the *Annals* [in annalib.], *will always be forbidden in the City, and always retained* — he would have said more truly, *in the world*. Though they are false, and deceivers, a thousand times over, if once or twice they have divined by chance and not by art, they gain more fame from a single success of their rashness than infamy from so many utterly manifest lies. For it is not as with *the errors of physicians*, which, as Pliny the Elder observes, *the earth covers*, since the dead, who perished through the physicians' unskill, cannot refute them: *the errors of the astrologasters* [Aſtrologaſtrorum] *are*

not so *covered by the sky* that they cannot everywhere be convicted of manifest falsehood.

[Margin: Concil. Bracar. Can. 9. — Council of Braga, canon 9.]

Against these stand the most wise decrees of the sacred canons, of the councils, and of the supreme pontiffs, above all of Sixtus V and Urban VIII. Hence the phrase so often found in Livy and the other writers of Roman history: *the mathematicians were expelled from the City.* For since astronomy is the most excellent of the mathematical sciences, and the genethliacs twisted it into judicial astrology concerning chance and free events — selling, on the strength of the certain prediction of eclipses, an equal certainty in other matters — therefore of the mathematicians under the name, those astrologers and genethliacs were classed. For magic, as Pliny the Elder says in book 30, chapter 1, *in order to creep in more easily, also mixed in the mathematical arts for show — since no one is not eager to know the future concerning himself, and everyone believes that it is most truly sought from heaven.* Hence the accusations against the mathematicians made long ago by Eudoxus and later by Sextus Empiricus; and afterwards Io. Picus [Giovanni Pico della Mirandola] and our own Alexander de Angelis [Alessandro de Angelis] attacked them in whole volumes. Hence too Aquila of Pontus — although a distinguished mathematician, around the one hundred and thirtieth year of Christ — was driven from the Church because he would not abstain from genethlialogy, as Epiphanius reports in his book *On Measures* [lib. de mensuris]; he deserted to the Jews and translated the Old Testament into Greek far from faithfully, staining the heavenly books, he who had already branded so many marks upon the heavenly art. Hence, finally, the censures of the Fathers against such rogues and against the dregs of the Priscillianists, who, as St Leo says in Letter 71, *believe that the souls and bodies of men are bound to the fatal stars*; who, as St Augustine testifies in book 2 on Genesis, *treat of heaven, and while they treat of it are strangers to the Father who is in heaven.* Indeed, as the same author says in the book of 83 Questions, q. 5 [lib. 83. quæſt. q.5.], they are *men who wish to subject our acts to the heavenly bodies, and to sell us to the stars.* For this whole reasoning, as he also notes in book 2 of *On Christian Doctrine*, chapter 24, *is full of pestilent curiosity, tormenting anxiety and deadly servitude.*

St Ambrose, finally, harries them very often, but above all in book 1 of *On Duties*, chapter 26. There he also rebukes a churchman, or sacred teacher, for excessive study of these matters — one who, in order to overcome the obscurity he supposed to lie in cosmography, fails in his duty or in his own salvation, especially if he goes astray among uncertainties — saying: *What is so unseemly as to venerate pieces of wood which they make themselves? What is so obscure as to treat of astronomy and geometry, as they approve, and to measure the spaces of the deep air, and to enclose heaven also and the sea in numbers — to abandon the cause of salvation and seek that of error? Did not Moses, learned in all the wisdom of the Egyptians, put these things to the proof?* — that is, he tried them by experience. *But he judged that wisdom a loss and a folly, and turning away from it he sought God with his inmost affection; and so he saw him, questioned him, and heard him*

speaking. Who is wiser than he whom God taught, who by the power of his work made void all the wisdom of the Egyptians and all the powers of the arts? He did not hold unknown things for known, and rashly assent to them. You see that what he condemns is the rashness of Egyptian or Chaldaean astrology.

[Margin: Exod.3.& 8. Act. 7. Habr.11. [recte: Hebr.] — Exodus 3 and 8; Acts 7; Hebrews 11.]

Add to this that in the first times of the Church, because of the danger of paganism and of ingrained superstition, the outlines of geometrical figures drawn in the dust or on papyrus were regarded by some as conjuring tricks or necromantic drawings. Then too, as our own Caussinus [Nicolas Caussin] says in book 3 of *De Domo Dei*: *Astrology, of whatever kind it was, was not listened to, while Prophecy resounded and the Spirit poured forth. It would then have been a monstrous sacrilege to read the poets, and to name Jove or Apollo with lips so often consecrated to Christ.* But once Satan had been triumphed over and the idols crushed, the Church was not ashamed to acknowledge God as Lord of all the sciences, and to purge the arts that the errors of the Gentiles had infected. Then not only poetry and rhetoric began to serve as soldiers of Christ, but also philosophy and astronomy — indeed astrology too, restricted to the foreknowledge of natural things — and to recover that dignity which Solomon, in Wisdom 7, proclaims he received from God, saying: *For he himself gave me true knowledge of the things that are, so that I might know the disposition of the world and the virtues of the elements; the beginning and the end and the middle of the times; the alternations of the turnings and the changes of the seasons; the courses of the year and the dispositions of the stars.*

[Margin: Trident. Reg. 9. de lib. prohib. — Council of Trent, Rule 9 on prohibited books.]

[Margin: Auctores pro ſana Aſtrologia. — Authors in favour of sound astrology.]

Therefore, if you learn or teach astronomy for the establishment of the civil and the ecclesiastical calendar; if you seek a deeper knowledge of it so as to defend more solidly the literal sense of Sacred Scripture, which the Copernicans abuse, and the decrees of the Sacred Congregation issued against them or against the genethliacs; if you handle astrology soberly and prudently for the use of agriculture, navigation or medicine, as the Sacred Council of Trent and Sixtus V permit, and abstain from foretelling determinately — even by conjecture — future contingents or free actions: then no Augustines, no Ambroses, no Leos will rebuke you. Indeed St Thomas will be your patron — 1 p., q. 1, art. 5; and 3 *Contra Gentiles*, chapter 85; opusculum 21, or *On the Judgements of the Stars* [de iudicijs aſtrorum]; and opusculum 28; and in book 2 on Genesis — and so will Scotus on book 2, distinction 14, and Panormitanus [Niccolò de' Tudeschi] on book 5 of the Decretals, title on sortilege [de ſortil.], chapter *Ex tuarum tenore*; and those who most recently, on behalf of sound astrology — on its use and its defence — have written: Petrus Ciruellus [Pedro Ciruelo], against Pico, in a large and learned work; Father Carolus Gontranus [?], Doctor of the Sorbonne,

in a little book on this subject; and our own Caussinus, in book 3 of *De Domo Dei*. Indeed, before them, St John Damascene, book 2 *On the Faith*, chapter 7; Boethius, *On the Consolation*; Seneca, *To Marcia*; Chalcidius, on Plato's *Timaeus*; and Plato himself in the *Timaeus* and in book 7 of the *Laws*.

That the astrologers of old introduced fate against freedom, and were condemned for that reason, is taught by St Augustine on Psalm 61; by Bardesanes in Eusebius, book 6 of the *Preparation for the Gospel*; by Saints Ambrose and Basil; and by Tatian, an ancient author — but above all by Tertullian in his book *On Idolatry*, who for that reason concludes:

[Margin: 3. Abuſus inanis gloriatio. — 3. An abuse: vain boasting.]

O divine sentence, persistent even to the earth! The mathematicians are expelled, like their angels; the City and Italy are forbidden to the mathematicians as heaven is to the angels. I too shall conclude this article, finally, against the vainglory of certain astronomers who do not, from the heaven, come to acknowledge Heaven, or the Lord of heaven and the Father of lights. I conclude it with St Augustine, *Confessions* book 5, chapter 3: *Those who know these things exult and are lifted up; and, withdrawing through impious pride and falling away from your light, they foresee an eclipse of the Sun so long beforehand, and do not see their own in the present; for they do not ask religiously from where they have the intellect with which they search these things out.*

ARTICVLVS III. De Origine Aſtronomiæ.

Article III. On the Origin of Astronomy

I would not dare to deny that astronomy arose almost together with the stars themselves, and that, of all that was divinely infused into Adam, it was the first to be brought into act and into experiment. For by what earlier or more powerful spectacle could the theatre of the newborn world, amid so great a variety and novelty of divine works, have drawn the eyes of our first parent to itself, than by the very eyes of the world, the lights of heaven, which at once showed him God already watching over his work? These were the first cradle of this art among the Hebrews. Since the patriarchs lived so long that the revolutions of the planets could be recognized and recognized again through frequently repeated experiment, the art grew up until the descendants of Seth. They, as Josephus asserts in book 1 of the *Jewish Antiquities*, chapters 3 and 8, reduced this art — handed down from Adam himself — to an epitome and carved it on twin columns, so that it should not perish in a cataclysm or an ecpyrosis [ecpyrôſi], a conflagration, of the whole world: one column of brick, against the force of fire; the other of stone, against floods of water. Suidas also affirms that Seth obtained the name "divine" because he had distinguished the stars by their own names.

But whether astronomy flowed first from the Hebrews to the Egyptians, and from them to the Chaldaeans, or Babylonians, and to the Greeks; or rather from the Chaldaeans to the Egyptians and the Greeks; and which of these peoples (leaving the Hebrews aside for the moment) were its inventors — this was an

old controversy even long ago, as Achilles Tatius notes at the beginning of his *Introduction to the Phaenomena of Aratus* [Iſagoges ad Arati Phęnomena]: *They say that the Egyptians were the first of all to measure both the heaven and the Earth, and that they handed down the knowledge of it to posterity carved on columns. The Chaldaeans, however, transfer the glory of this discovery to themselves and attribute it to Belus. But the wiser among the Greeks try to ascribe it partly to the gods, partly to the heroes, and partly to those wise men who came after them.* So Tatius.

[Margin: Chaldaicæ Aſtronomiæ antiquitas. — The antiquity of Chaldaean astronomy.]

Josephus, in book 1 of the *Jewish Antiquities*, chapter 15, seems to stand for the Babylonians or Chaldaeans, as does Diodorus Siculus, book 2, chapter 8, where he says: *All grant this, that the Chaldaeans are skilled in astrology beyond the rest, since they have been occupied with it longer. The number of years for which they claim to have devoted themselves to this kind of study of the stars, no one would easily believe. For they count four hundred and three thousand years, down to the coming of Alexander, from the time when they say their observations of the stars were begun.* But he had said in book 1 that the year was once of 30 days, that is, equal to the lunar period; so 403,000 such years make 33,583 solar years. Epigenes, however — who was among the Babylonians for the sake of study together with Apollonius of Myndus, as Seneca reports in book 7 of the *Natural Questions*, chapter 3 — and Berosus, himself a Chaldaean, reported a much smaller number of years. For Pliny the Elder says, in book 7, chapter 56: *Epigenes, an authority of the first weight, teaches that among the Babylonians there were observations of the stars covering 720 [DCCXX.] years, inscribed on baked bricks; those who give the least, Berosus and Critodemus, 480 [CCCCLXXX.] years: from which an eternal use of letters is evident.* Hipparchus, however, in Ptolemy, observa-

tions made at Babylon concerning eclipses he traces back as far as the year 27 of Nabonassar, which was the year 720 before Christ. But if we believe Porphyry, when Babylon had been taken by Alexander the Great, Callisthenes, at Aristotle's request, carried from that city into Greece observations covering 1903 years. But it is one thing for the Chaldaeans to have existed — and indeed to have been devoted to this science from ancient times — and another for them to have been the first of all. For on behalf of the primacy of the Egyptians, after the Hebrews, there stand the journeys of Thales, Pythagoras, Plato, Eudoxus and others into Egypt, which Laërtius reports, made so that they might be initiated, among other things, into the mysteries of the science of the stars. The same is suggested by the obelisks and the most ancient Pyramids, erected in Egypt not only for ornament or display but also for taking the altitude of the Sun by means of their shadows; the same by the 360 priests in the city of Acanta across the Nile, who used to measure the course of the Sun and the ascensions of the signs with water-clocks; the same by the hierophants of all Egypt, especially those of Memphis and Heliopolis, who had learned this art from Mercury.

[Margin: Antiquity of Egyptian astronomy.]

For this reason Clement of Alexandria says of them, in book 6 of the *Stromata*: *The Egyptians pursue a philosophy of their own; and this is shown above all by their sacred ceremonies. For first comes the Singer, etc. After the Singer comes the Horoscopus, who holds in his hand a clock and a palm, the symbols of astrology. He must always have on his lips the books of Mercury that treat of astrology, which are four in number: one of them is on the order of the fixed stars that are visible; another on the conjunction and illumination of the Sun and Moon; the rest on their risings.* Nor does Diodorus Siculus stand in the way; rather, he unties the knot, in book 1, part 2, chapter 2, when he says: *The Egyptians relate that Belus, son of Neptune and Libya, led colonists into Babylonia, and established priests (the Babylonians call them Chaldaeans) to observe the stars after the manner of the Egyptians.* Lucian confirms this as well, in the dialogue *On Astrology*. Cicero too, in book 1 of *On Divination*, although he seems to favour the Assyrians because of the flatness of their plains and the clearness of their sky, nevertheless adds: *But the Egyptians, as people who profess to be older than the rest of mortals, are said to have acquired this same art of the stars over almost countless ages, that is, over four hundred and seventy thousand years.* But before him Plato touched on a twofold cause in the *Epinomis*, when he says: *The first observer of these things was a barbarian; for an ancient region nourished those who, because of the clear weather of summer, were the first to study them. Such were Egypt and Syria, where all the stars, so to speak, are always seen clearly, since neither rain nor clouds cut off the view of the sky.* Nor does he dare to grant this to the Greeks, but adds: *But because we are further than the barbarians from the clear weather of summer, we came to understand the order of these stars later. Yet whatever the Greeks received from the barbarians, they rendered better.*

Away, then, with the fable of the sons of the Sun, born on Rhodes and brought to Egypt, where they are supposed to have taught astronomy, which Diodorus Siculus brings forward in book 5; and away with the fiction of Lucian in the dialogue *On Astrology*, which ascribes its invention to Orpheus. Besides the authorities already cited, Seneca also condemns him, in book 7 of the *Natural Questions*, chapter 3, saying: *Eudoxus was the first to bring these motions from Egypt into Greece. Yet he says nothing about comets; from which it is evident that not even among the Egyptians, who took greater care of the heavens, was this part worked out. Conon afterwards, himself a diligent inquirer, collected the eclipses of the Sun that had been recorded by the Egyptians.* Finally, that this science flowed from the Egyptians to the Greeks is reported by Herodotus in the *Euterpe* and by Theon of Alexandria in his commentary on Aratus.

Who first taught the Egyptians astronomy is equally disputed. Eupolemus, in Eusebius, book 9, chapter 4, and Nicolaus of Damascus say: *Abraham lived in Heliopolis with the priests, and from him the priests learned astrology; yet he admitted that he had not discovered it himself, but that it had been handed down by succession from Enoch.* Josephus suggests the same thing in book 1 of the *Antiquities*, chapters 8 and 9. But Salianus [Jacques Salian] thinks this scarcely probable, because Abraham's stay among the Egyptians was too short — barely three months — and he assigns this office rather to the patriarch Joseph: see him

at the year of the world 2470, no. 28. Since, however, Mercury was later not only than Abraham but also than Joseph, and indeed than Moses, who is known to have been learned in all the wisdom of the Egyptians; and since that other Mercury called Trismegistus was the grandson of the Mercury who was the grandson of Atlas, as Eusebius testifies in book 9, chapter 4, and St Augustine in book 18 of *The City of God*, chapter 8; and Atlas, the brother of Prometheus, was the maternal

grandfather of the elder Mercury, flourished in the time of Moses — it follows that those are mistaken who attribute to Mercury the first invention of astronomy among the Egyptians. Among them are Iamblichus, in his book *On the Mysteries of the Egyptians*; Firmicus, who adds that his disciples were Petosiris, Nechepso, Anubis and Aesculapius; and Manilius, in book 1 of the *Astronomica* [Aſtronomicωn], in these verses:

> *You, Cyllenian, first and author of so great a sacred art: Through you heaven is now known on earth, and the stars, etc.*

They would certainly have erred less had they conferred this prerogative either on Theuth, under Thamus, king of Egypt, as Plato confers it in the *Phaedrus*, or on Atlas, king of Mauretania, of whom Diodorus Siculus tells the following in book 4 of the *Historical Library*: *They say that Atlas was most skilled in astrology, and was the first among men to discuss the sphere; from which it came about that he was thought to hold up the heavens on his shoulders, the invention of the sphere giving room to the fables.* St Augustine also reports this fable, in the book *The City of God*, chapter 8.

[Margin: Inventors of the sphere.]

[Margin: Atlas.]

Pliny the Elder too says, in book 2, chapter 8: *Anaximander of Miletus is reported to have been the first to understand the obliquity of the zodiac — that is, to have opened the doors of things — in the fifty-eighth Olympiad. Then Cleostratus marked the signs in it, first those of Aries and Sagittarius; the sphere itself Atlas had found long before.* And yet, forgetting this, in book 7, chapter 56, where he relates who invented what, he says: *Astrology was invented by Atlas, son of Libya — or, as others say, by the Egyptians; or, as others, by the Assyrians. The sphere within it, by Anaximander of Miletus, etc. The observation of the stars in navigation, by the Phoenicians.* Some hold that the invention of the sphere is owed to Eunolpus [?]. For Archimedes and Posidonius, whose sphere is praised by Cicero in book 2 of *On the Nature of the Gods*, are judged not so much to have devised it as to have perfected and enlarged it.

[Margin: Or Anaximander.]

[Margin: Perfecters of the sphere.]

It could, however, have happened that different men were the first inventors of this art among different nations. So Prometheus, in Aeschylus, in the *Prometheus*, sings of himself:

[Margin: Prometheus.]

For they had as yet no fixed boundary of winter, nor of flowery spring, nor of fruitful summer: but they did everything at random, until I showed them the risings of the stars, and their settings, hard to discern.

Servius supports this on the seventh Eclogue of Virgil, saying: *Prometheus first disclosed astrology to the Assyrians; he had discovered it, dwelling on the very high mountain Caucasus, by excessive care and attentiveness. This mountain, situated near the Assyrians, is almost neighbour to the stars; and so it also displays the greater stars, and shows their risings and settings carefully.* Others say that Hercules carried astronomy from Egypt into Greece, and that for this reason, in the fables, he alone took Atlas's place in holding up the heavens. Others celebrate Palamedes for this, as Sophocles does in the tragedy *Palamedes*, saying:

[Margin: The height of the Caucasus.]

[Margin: Hercules.]

[Margin: Palamedes.]

He showed and unfolded what was unknown before, and found the measures of the stars, and their revolutions, the guardians of sleep, and the heralds of the dawn.

It is surely fair to believe that observations began from observing the daily revolution and the rising and setting of the stars. Theon, in his commentary on Aratus's *Phaenomena*, teaches that their parapegmata, or hemerologia [day-calendars], with the prognostics for the day noted, were customarily displayed on tablets and posted in public already from the time of Meton. Even so, Plato in the *Epinomis* calls the observers of these things not so much astronomers as [Greek: ἀστρονομοῦντας (astronomountas, "those who star-gaze" — practising astronomy in the loose sense)]; and Geminus, in his *Elements of Astronomy*, says that this part of astronomy — namely astrology — is [Greek: ἄτεχνον (atechnon, "without art" — not a proper art)], and not worthy of discussion.

ARTICVLVS IV. De Progreſſu Aſtronomiæ.

Article IV. On the Progress of Astronomy

Whether astronomy flowed from the Hebrews to the Chaldaeans and from them to the Egyptians, or from the Egyptians first to the Chaldaeans of Babylon and then to the Greeks, it is certain from history that the Chaldaeans and the Egyptians contributed more to establishing it than the Greeks did before the death of Alexander the Great. For, apart from the few things that Thales and Anaxagoras touched on concerning eclipses, the rest of the Greeks were wholly occupied with the rising and setting of the fixed

stars, in observing them, and in adapting cycles of the Moon and the Sun to the establishment of the civil year — the purpose for which they observed the solstices and equinoxes. Such were Oenopides, Cleostratus, Harpalus and Democritus, whose trieteris and octaeteris are famous; such were Meton, Euctemon and Eudoxus, who besides calendars and prognostics devised the cycle of 19 years, by quadrupling which Callippus established the period of 76 years. But we know of nothing that the Greeks of that time knew or set down about

the proper motion of the fixed stars, or their determinate distances from one another; nothing about the revolutions of the planets; nothing about the periods in which the restitution [apocataſtaſis] of the lunar anomaly and of the latitude is completed.

The Chaldaean and Egyptian priests, by contrast — the former at Babylon, the latter at Memphis, at Heliopolis and in the city of Acanta across the Nile, where 360 priests observed with water-clocks the length of the days and the ascensions of the Sun and of the signs — noticed more about the Moon, and much about the other planets as well. Plato admits this in the *Epinomis*, and Diodorus Siculus pursues it more fully in book 2, chapter 8, where he also gives the cause of this difference. For he says of the Chaldaeans: *Both because they are trained in that learning from their tender years, all care for other things set aside, and because, persevering in it for a long time, they turn out most learned. Among the Greeks, for the most part, men come to philosophy late, and after lingering in it a little they turn to making money: very few dwell in it, turning to other occupations for the sake of gain. But the barbarians always dwell in the occupation they have taken up. The Greeks, for the sake of gain, always bent on new opinions and quarrelling among themselves about the greatest disciplines, make their disciples uncertain, and force their minds, doubtful through all their lives, to wander with no settled view. Thus, if anyone carefully examines the schools of the most illustrious philosophers, he will find them very much at odds, and contrary to one another on the greatest matters.*

After Alexandria had been founded by Alexander the Great, however, and the kings his successors had opened a gymnasium in that city for all the disciplines, astronomy returned to Egypt — or rather came back to life — and that glory began to be shared by the Egyptians with the Greeks; for Egypt was by now becoming Greek, no differently from Babylon. So there flourished, at Babylon, Berosus the younger; and at Alexandria, Aristyllus, Timocharis, Eratosthenes, Conon, Hipparchus, Sosigenes and Theon the elder, Ptolemy, Paul of Alexandria, Theon of Alexandria the younger and Hypatia his daughter, Pappus, Diodorus of Alexandria, and the bishops Saints Theophilus and Cyril. Thus from 300 years and more before the birth of Christ to about the year 500 after it — that is, for about eight hundred years — astronomy reigned at Alexandria. Even so, some distinguished men observed the heavens elsewhere too: Aristarchus, Helicon, Archimedes, Cleomedes, both Agrippas, Manilius and Menelaus.

But this discipline owes more to none of these than to Hipparchus and Ptolemy. For Hipparchus was the first to notice the proper motion of the fixed stars about the poles of the ecliptic, and from it the precession of the equinoxes, and the difference between the tropical year and the sidereal year. By comparing eclipses of many centuries observed at Babylon and at Alexandria, he also determined the lunar periods in longitude, latitude and anomaly, and the intervals of eclipses, as close to the truth as possible; he discussed the length of the year and the cycles of the Moon and the Sun far more accurately than Meton and Callippus; he set the places of the fixed stars in order; and he did

much else, which Ptolemy does not deny. Ptolemy, for his part, gathered the parts and members of this science — scattered, as it were, in Hipparchus and others — into the body of a single art, with a truly most beautiful method and symmetry. Just as he was the first to establish geography, so he was the first to establish astronomy, so that the work he himself called the *Mathematical Construction* — by the Greeks, however, [Greek: μεγάλη σύνταξις (megalē syntaxis, "great composition")], the *Great Construction*, and by the Arabs, or the Graeco-Egyptians, the ALMAGEST — was not undeservedly called *that greatest*, or *most perfect, work*. What he handed down about the five minor planets, however, rests almost entirely on Ptolemy's own observations and reflections. Yet he candidly admits, in book 2, chapter 2, book 7, chapter 3, and book 9, chapter 2, that he did not have observations covering so long a time that no notable error could be feared, after many centuries, in the length of the year and in the motion of the fixed stars and planets that he had established. For this reason, since the Ptolemaic tables were by now manifestly at variance with the heavens, al-Battānī, in the

ninth century of Christ; in the tenth, Azophi [al-Ṣūfī]; and in the eleventh, Arzachel [al-Zarqālī] and Geber [Jābir ibn Aflaḥ] of Seville [Hispalenses] — and the Persian mathematicians, the Tybenenses [?], as well — all set their minds to restoring the account of the celestial motions. Alexandria had by then been taken by the Saracens, and astronomy had already been carried off elsewhere, to the Arabs, like a captive. And the Jews contended with the Arabs no less about establishing Cabbalistic superstition, or the ravings of astrology, through the motions of the stars, than about the motions of the heaven themselves. Out of this jumble Alfonso X ordered the Alphonsine Tables to be constructed, and he published them in the year 1252; but he issued them again, revised to the standard of al-Battānī, in the year 1256 — the year in which Johannes de Sacrobosco brought out his *Sphere* at Paris.

But since those Tables rested on opinions gathered from here and there rather than on observations taken over the length of time that was required, not much later they were found to be utterly at variance with the heavens [toto cælo diſſentire], above all in the fixed stars and the minor planets. At the same time it was noticed that the equinox, on which the reckoning of Easter and of the movable feasts depends, was falling many days before 21 March, the day fixed by the Council of Nicaea and the bishops of Alexandria. So work began in earnest on correcting both the Alphonsine Tables and the calendar. Celestial observations, which had lapsed after Thebith [Thābit ibn Qurra], Gulielmus de S. Glodialdo [Guillaume de Saint-Cloud] and Profatius [Jacob ben Machir ibn Tibbon], were taken up again by Rabbi Levi [Gersonides], Petrus Alliacensis [Pierre d'Ailly], Nicolaus Cusanus [Nikolaus von Kues], Io. Blanchinus [Giovanni Bianchini], Georgius Purbachius [Georg Peuerbach], Regiomontanus, Bernhard Walther, Io. Vernerus [Johannes Werner], Abraham Zagutus [Avraham Zacuto], Dominicus Maria [Domenico Maria Novara], Gemma Frisius, Pietro Pitati, and Copernicus, from whose springs the Prutenic

Tables flowed. How many have written about the errors of the Alphonsines and about restoring the calendar can scarcely be told; I shall list the chief of them in the chronicle that follows. In the restoration of the calendar, however, just as the Church chose the Alphonsine length of the year, so in the lunar cycles it preferred to follow the Prutenic Tables; and Stadius, Iunctinus [Francesco Giuntini] and Molletius [Giuseppe Moletti] kept to the Prutenic Tables in their own tables.

Further, since neither set agreed with the heavens at every point, especially in the places of the fixed stars [Affixarum] and of the planets, and since a new and huge star had appeared in the Chair of Cassiopeia in the year 1572, and not a few comets in the following years, a good many astronomers began to turn their eyes to the heavens. The foremost of them were William, Landgrave of Hesse, Mœstlinus [Michael Mästlin], and Tycho Brahe. From Tycho's observations two lights of his school constructed tables: Longomontanus the Danish Tables, Kepler the Rudolphine. At the same time Philippus Lansbergius [Philips van Lansbergen], with Hortensius [Maarten van den Hove], put together astronomical tables partly from the Prutenic and partly from the Danish hypotheses, adding a few observations of his own but comparing them at length with the old and new observations of others; these tables are not inferior to the Danish and the Rudolphine, and in places they are even better.

Just as Maginus [Giovanni Antonio Magini] had gathered the Alphonsine and Prutenic Tables into a better form, and later, before his death, had composed some Tychonic-Copernican ones; and as Nicolaus Mulerius presented tables of the Moon and the Sun drawn from Ptolemy, Alfonso, Copernicus and Tycho — so Vincentius Reinerus [Vincenzo Renieri] brought five kinds of tables together into one volume, in a form that is not without use: namely the Alphonsine, the Prutenic, the Danish, the Lansbergian and the Rudolphine. Lastly Ismael Bullialdus [Ismaël Boulliau], chiefly from the observations of Tycho, of Gassendi and his own, and also from some hidden away in the King's Library at Paris, and with incredible labour of geometrical inquiry, built for us the Philolaic Tables (the newest of all that we have). In ease of use and in agreement with the heavens they are to be put on a level with the Rudolphine, Danish and Lansbergian Tables, and in places preferred to them, though in some places they fall short. I would say the same of the Atlantic Tables of Gotifredus Vuendelinus [Govaert Wendelen], built on eclipses observed from the year 1573 to the year 1643.

Besides these, sunspots and the orbits of the satellites of Jupiter have been observed by Galileo, Simon Marius, Scheinerus [Christoph Scheiner] and Vincenzo Renieri; the lunar spots and librations by Michael Florentius Langrenus [Michael Florent van Langren], Io. Heuelius [Johannes Hevelius] and Petrus Gassendus [Pierre Gassendi], together with the eclipses, on which the astronomy-lovers of this century never cease to fix their attention. And D. Vincentius Mutus [Vicenç Mut], in Majorca, labours almost wholly at astronomical observations. But if anyone wishes to know of a treatment of the

origin and progress of this art other than ours, let him consult the oration of Lucas Gauricus [Luca Gaurico] delivered at Ferra-

ra in praise of astronomy; Petrus Ramus [Pierre de la Ramée] in books 1, 2 and 3 of the *Scholae Mathematicae*; Clavius at the front of his *Sphere*; Barocius [Francesco Barozzi] in the preface to his *Cosmographia*; Io. Roias [Juan de Rojas] at the front of his *Planisphere*; and Longomontanus, Kepler, Lansbergen and Boulliau in the prefaces or prolegomena to their several *Astronomies* or *Tables*. But it will be worth the trouble to run through our *Chronicle*, which is to be placed after this preface and the Index of Chapters.

ARTICVLVS V. Quid in Astronomia Recentiori desiderari videatur, & de Erroribus præcipuis Præcedentium Astronomorum.

Article V. What Seems to Be Wanting in More Recent Astronomy, and on the Chief Errors of the Astronomers Who Came Before.

[Margin: In Fixis quid desideretur. — What is wanting in the fixed stars.]

No part of astronomy handed down so far fails to need something for its completeness, or at least to need the file. I shall point this out briefly, running from the fixed stars down to the Moon.

The longitude and latitude of the fixed stars were corrected by Tycho from right ascensions and declinations he observed himself; but the right ascensions depended on Venus, as is clear from volume 1 of the *Progymnasmata*, from p. 152. Yet Tycho used too large a parallax of Venus in its true declination, because of the excessive parallax of the Sun, as Kepler admits in the foundations of his *Ephemerides*, p. 15, where he says that the dispute between the Landgrave of Hesse and Brahe over a difference of 6′ in the motion of the Sun from the fixed stars is still undecided. Many distances of the stars from one another, besides those Tycho observed, are also wanting, so that the places of the planets could be derived from them more easily. The apparent diameters of the fixed stars, too, are very uncertain, and greater evidence is needed on them. Finally, the number of the fixed stars, which appears far greater through the telescope, must be increased by adding the stars that this instrument discovers in each constellation [astro]. Besides, observed distances of fixed stars are sometimes found to disagree with those Tycho observed with sextants, or with those derived by the working of triangles from their longitudes and latitudes, or from their right ascension and declination. As for their places in the Alphonsine and Prutenic Tables being wrong, sometimes by as much as a whole degree, enough has been said by Cardinal Cusanus in table 53 of the fixed stars arranged by himself and by the cardinals of Nicaea [Niceno: Bessarion] and d'Ailly [Alliacensi]; by Reinhold in the *Theoricae*, p. 248; by Nonius [Pedro Nunes] in his first annotations on the *Theoricae* of Peuerbach; and by Tycho in the *Epistolae*, from p. 54, and in volume 1 of the *Progymnasmata*, p. 146. Nor has anyone after Tycho undertaken this correction except Lansbergen, and he sets

in his tables, p. 102, only 25 stars observed by himself. The rest follow Tycho in this with blind eyes, so to speak; and Boulliau himself adds nothing except the places of certain fixed stars dug out of the older Persian tables.

[Margin: In Saturno quid desideretur. — What is wanting in Saturn.]

Saturn, the slowest of the planets, does not complete its revolutions to the same conditions of celestial place within the lifetime of a single man. It is no wonder, then, that with something like an old man's cunning it has so often deceived astronomers, and that a small error in it has brought forward or put off its aspects with the other planets by many days. The great conjunction of Saturn and Jupiter, which the Alphonsine Tables expected in the year 1563 on 25 September at Leo 4° 25′, was nevertheless seen on 24 August by Iunctinus at Aurange [?] at 14^{h} 30^{m} after noon, with the more northerly Jupiter covering almost the whole of the more southerly Saturn, as he himself relates in the preface to his astronomical tables. There he adds that in the year 1536, on 19 May, at about the second hour of the night, a meeting of Mars with Saturn was observed by his teacher Iulianus Ristoricus [Giuliano Ristori], in which Saturn was almost entirely covered by Mars; and yet the Alphonsine Tables, in Stöffler's *Ephemerides*, had set it down for 25 May. Tycho likewise says in the *Mechanica*, p. 39, that in the year 1563, when he was observing the conjunction of Saturn and Jupiter, the Alphonsine calculation was out by a whole month. Earlier, too, Stoeflerus [Johannes Stöffler] had predicted from the Alphonsine Tables that the conjunction of Saturn and Mars would occur in the year 1536 on 25 May; but Pietro Pitati saw it on the 20th. Tycho reports in the *Epistolae*, p. 56, that in the year 1587, on 9, 14 and 15 January, Old Style, he observed Saturn 2° west of its Alphonsine place, but about 10′ east of its Prutenic place. Longomontanus, for his part, says in book 2 of the *Theorica*, chapter 13, that Saturn was observed at Uraniborg [Vraniburgi] in the year 1591, on 17 March, at $7\frac{1}{3}^{h}$ after noon, at Gemini 22° 43′, and that it was shown by the Da-

nish Tables at 22° 46′, by the Prutenic at 22° 23′, and by the Alphonsine at 25° 7′. Boulliau's tables usually represent the motions of Saturn and Jupiter more exactly than the Rudolphine. The motions of Saturn's satellites, however, and their appearances, occultations and separations [diuaricationes], have not yet been investigated, and centuries are needed before they can be determined with certainty.

[Margin: In Ioue quid desideretur. — What is wanting in Jupiter.]

The star of Jupiter, being faster than Saturn's, has deceived astronomers less. Yet Tycho, as he says in the *Epistolae*, p. 56, found it standing off from its Alphonsine or its Prutenic place by about a third of a degree; and Longomontanus, in book 2 of the *Theorica*, chapter 13, found it 1° [fraction: ?] east of its Alphonsine place but 20′ west of its Prutenic place. As for the periods of its four satellites, whose observation was begun by Simon Marius and by Galileo, D. Vincentius Reinerus [Vincenzo Renieri], an Olivetan and a pupil of Galileo, had observed them for many years. He had gathered all of Galileo's observations and his own into a full volume and had constructed ephemerides of these

motions, when premature death snatched him from us — and someone or other snatched that work, among the spoils, from him and from posterity. This part, therefore, remains for astronomers to complete.

[Margin: In Marte quid desideretur. — What is wanting in Mars.]

The star of Mars, once called unobservable by Pliny the Elder (book 2, chapter 17), has violated the laws of the older tables beyond all measure — those of the Alphonsine and Prutenic Tables by 2, 3, 4 and almost 5°. This is shown from observations compared with both calculations by Gemma Frisius in chapters 19 and 20 of the *Annulus Astronomicus*, by Giuntini in the preface to his tables, by Tycho in the *Epistolae*, p. 56, by Longomontanus in book 2 of the *Theorica*, chapter 13, and by Kepler in the introduction to his *Commentaries on Mars* and in the preface to the Rudolphine Tables. From these we learn that in the year 1544, on 31 October, Mars fell short of its Alphonsine place in the zodiac by 2° 16′; that in the year 1587, on 15 January, it exceeded the Alphonsine place by 2° 30′; that in the year 1593, in August and September, it exceeded the Prutenic place by almost 5°, as it did again in the year 1625 in the month of October; and that in the year 1608 it did so by nearly 4°. And this was not because of the mean motion but because of the prosthaphaereses, which Reinhold wrongly thought permanent and correct. Although after Tycho's observations Kepler, Longomontanus, Lansbergen and Boulliau bound Mars with tighter chains, it still resists at times and does not let itself be wholly bound. Thus in the year 1632, on 5 February, Mars at its acronychal rising [acronychius] should not, by the Rudolphine Tables, have been covered by the Moon; and yet, as Petrus Gassendus observed at Paris and Martinus Hortensius at Leiden, it was covered by it — helped in this, perhaps, by the small parallax of Mars, smaller than Kepler sets it, let alone Tycho.

[Margin: Venus in quo deficiat. — Where Venus falls short.]

We do not, it is true, find errors of *Venus* in the more recent tables as manifest as those of Mars or Mercury. Yet we have very few observations of its retrogradations and greatest digressions taken over several consecutive days before and after. This part must therefore be helped by more observations, especially by observing its conjunctions with the Sun, of which we have only one observed by Tycho. Anyone who wants a specimen of the disagreement between its true place and the Alphonsine or Prutenic place should read Tycho's *Epistolae*, p. 56. Hortensius, too, observed a conjunction of Venus and Mercury in the year 1632, on 31 July, at about the 11½th hour of the night, when by Longomontanus they should have been 2° 53′ apart.

[Margin: In Mercurio quid desideretur. — What is wanting in Mercury.]

Mercury, rather, is a treacherous star, almost always hidden under the rays of the Sun and appearing only among the vapours of the horizon; Copernicus never observed it, because of the vapours [vapiditatem] of the Vistula. It must be caught by the snares of astronomical skill, so that the tables can be cleared of the disgrace under which they have laboured to this day. Giuntini, in the preface to his *Tabulae resolutae*, rightly called intolerable a discrepancy of ten

or eleven degrees in the place of Mercury between the Alphonsine and the Prutenic calculation. For more tolerable is the discrepancy of 2° or 3° between its true place and the place assigned by Alfonso or Copernicus that Tycho found, in the *Epistolae*, p. 56. Longomontanus, in book 2 of the *Theorica*, chapter 20, laments that between the Alphonsine and the Copernican calculation a discrepancy is found that is *immense, and at times rises beyond 7°*. And although he admits that observations of Mercury made by himself or by Tycho were rare, because of the obliquity of the Danish horizon and this planet's short and quick digressions from the Sun, he nevertheless boasts that from 9 observations he has so restored and reformed its hypothesis that the discrepancy between the calculation and the heavens never exceeds a sixth of a degree.

But the conjunction of Mercury with the Sun that Pierre Gassendi [Petrus Gassendus] observed at Paris on 1631 November 7 — seeing it with the help of a telescope in such a way that Mercury appeared beneath the disc of the Sun — made that boast empty. For, as Martinus Hortensius points out in his dissertation with Gassendi on Mercury seen beneath the Sun, the Danish tables, that is Longomontanus's, strayed from the true place of Mercury by 7° 13′ (a discrepancy that Longomontanus had called *immense* [immensam] between the Alphonsine and the Copernican calculation). The Prutenic tables erred by 5°, the Ptolemaic by 4° 25′, the Lansbergian by 1° 21′, the Rudolphine by 14⅔′, and the Philolaic tables of Boulliau differed from these by not even two minutes. Boulliau therefore rightly dedicated to Gassendi, for so fortunate an observation, the whole of book 10 of his *Astronomia*, in which Mercury is treated; and because of this very observation Natalis Duretus [Noël Duret], who had derived ephemerides from 1637 to 1642 from the tables of Lansbergen, went over to the Rudolphine tables for the motion of Mercury.

Yet see Kepler in the *Ephemeridum fundamenta*, pp. 15 and 18, on the extreme difficulty of observing conjunctions of Mercury and Venus with the Sun. There he admits that all the observations of Mercury made by Tycho over 20 years fall within a single third of its eccentric, and that the remaining two thirds stay unobserved in this century and hemisphere. He therefore adds: *In the conjunctions of Mercury, which have great force in meteorology* [in Meteoris]*, I would not dare affirm that my calculation always stays within the limit of that very day, since in so much time the commutation can sometimes vary by five degrees, and the apparent place of Mercury, when it is retrograde, by one degree and a third or a half.*

[Margin: In Sole quid desideretur. — What is lacking in the case of the Sun.]

The theory of the Sun, moreover, which because of the clarity and frequency of its observations might have seemed already complete in every respect, has by no means escaped the hazard of all controversy. For some dispute still remains among astronomers over its apogee and eccentricity, over the greatest declination [maxima declinatione] — that is, the obliquity of the ecliptic — over the length of the year and its uniformity, and over the apparent diameter; but

above all over its parallax and distance. Its parallax — which Hipparchus and Ptolemy once called into doubt, whether it was perceptible at all, and afterwards, from conjectures based on eclipses, extended somehow to about 3 minutes — Copernicus and Tycho assumed without confirming it by any demonstration from their own observations or those of others. Yet the parallax of Mars at perigee, which ought to be greater than the Sun's, since Mars at perigee was found by Copernicus and Tycho themselves to be much nearer the Earth than the Sun, scarcely rises to one minute; from this the Sun's distance is inferred to be three times greater than the Tychonic. And if the lunar dichotomies are considered, the Sun's distance turns out far greater still, and not less than six thousand semidiameters of the Earth. This must therefore be investigated more carefully, since on the Sun's distance depend the distances from the Earth of all the stars (the Moon alone excepted), their parallaxes and true magnitudes, the true magnitude and velocity of the Sun itself, and many other theorems and problems most worth knowing.

I pass over for now the errors of the Prutenic tables for the Sun, greater than those of the Alphonsine, as Clauius [Christoph Clavius] points out in the *Kalendarium Gregorianum*, and Magini in the letters he reports in his *Directiones*, pp. 75 and 95½, adding that the Prutenic tables sometimes err by one whole degree. I pass over the errors of the Alphonsine tables themselves in the equinoxes and in the Sun's apogee, which Nonius pursues in his first annotations on Peuerbach's *Theoricae*. The theory of the solar spots, however, our Scheiner has perfected so far that, on the testimony of Renatus Cartes [René Descartes], Boulliau, Hevelius and many experts, scarcely anything more accurate could be hoped for.

[Margin: In Luna quid desideretur. — What is lacking in the case of the Moon.]

Finally the Moon, which Pliny the Elder (book 2, chapter 9) called the teacher of almost everything we know about the heavens — he is indignant that it is still unknown, though so near the Earth; and Kepler, in precept 171 of the Rudolphine Tables, calls it a stubborn star, still rejecting laws in some places. Writing to Magini on 1601 June 1 [Iunij Kalendis], Kepler also admits that the theory of the Moon gave great difficulty to Tycho, to whom he had by then come in Bohemia, and that it seemed it had to be begun from the parallaxes. He sets out two ways of observing these without a vicious circle, in such a way as to indicate that they had not been observed in that way before that time. But he died in the same year, Tycho. Therefore the parallaxes must be investigated afresh, his and those of others who followed him, especially since the distance and parallax of the Sun also depend on them — and, through the Sun, those of the remaining planets.

There remains, too, a dispute over the motion in latitude and of the nodes, over the lunar eccentricity, and over the apparent semidiameter. Above all, however, it concerns that variation, the third anomaly, which the Moon displays chiefly in the octants, that is, between the syzygies and the quadratures, and

because of which the tables not seldom disagree among themselves, and with the heavens, by almost a whole degree. Moreover, the incredible multitude of the spots observed with the telescope, and the variety of phases in them, require more and more careful observations than have been made so far, in order to perfect the selenography begun by Michael Florentius van Langren and Hevelius — to say nothing of others of lesser note. Still more accurate observations are required by that wonderful libration, by which the Moon, in alternating monthly turns about the centre of its globe, nods towards the Earth and away from it with the same limb. Lastly, the phase of dichotomy, most useful for determining the Sun's distances far more surely than up to this day, and before us left almost untouched and unobserved by everyone, must be weighed with all possible industry and circumspection, and with frequent observations.

[Margin: De Eclipſibus. — On eclipses.]

Eclipses of the Sun and Moon, besides the variety they have separately from the theory of the luminaries, also require their own particular care in the making of observations, especially by the method of the more recent astronomers. That al-Battānī [Albategnius] noticed, in chapter 30, from the observation of two or three eclipses, an error of 45 or 50 minutes of time in the Ptolemaic canons, and the Sun obscured a little more than half, when by Ptolemy's reckoning it ought to have been obscured entirely — that is not at all surprising after an interval of almost 700 years. But is it to be marvelled at or lamented that there is so great a discrepancy among the tables of the more recent astronomers themselves, and between the observations and the calculation of the tables — indeed among the very observations of one and the same eclipse — as the reader will be able to gather from our *Catalogue of Eclipses*, to be placed at the end of book 5, chapter 19? From this, and from chapter 20, he will learn how far Tycho and his followers erred in excluding total eclipses of the Sun, or in not handling annular ones correctly. How little, moreover, the hypotheses of al-Battānī, Copernicus, Tycho, Longomontanus and Kepler agree with one another in fitting together the parallaxes and diameters of the luminaries and the angle and apparent diameter of the Earth's shadow, and how these parts conflict within the hypothesis of one and the same astronomer, will be told in book 3, chapter 11.

Returning now to eclipses: Tycho wondered at the Prutenic error of half an hour in the eclipse of the year 1588, and Kepler, in the *Optics*, chapter 9, at the imperfection of the parallactic tables of Reinholdus [Erasmus Reinhold]. But Vendelinus [Govaert Wendelen] noted Tycho's own errors in several eclipses in his little work on eclipses; and Kepler admitted them in the *Fundamentum Ephemeridum*, p. 11, adducing the testimony of Simon Marius and of other observers at Linz and Munich. Wendelen likewise notes Kepler's errata in this matter, as he does Lansbergen's — whose good faith, too, Wendelen, Phocylides [Johannes Phocylides Holwarda], Boulliau and we ourselves have sometimes found doubtful in these and other observations: he flaunted, rather than showed,

that his tables nowhere and never disagree with the phenomena of the heavens (which he certainly wished too much). Nor did Wendelen, by removing the equation of natural days, bring a sufficient remedy to this discrepancy; indeed his Atlantic calculation sometimes strays further than the Lansbergian or the Tychonic, as D. Vincentius Mutus pointed out very recently. Lastly, Boulliau had scarcely published his *Philolaic Tables* when he was grieved that the eclipse of the Sun of 1645 August 21 differed markedly from his tables.

ARTIC. VI. De Aſtronomiæ nouis ſemper Difficultatibus nouo ſemper ſtudio, & ardore exantlandis.

Article VI. On the Ever-New Difficulties of Astronomy, to Be Overcome with Ever-New Zeal and Ardour.

What has been said so far is aimed not at detracting from this most noble art, or from its practitioners themselves, whom we look up to and revere as the lights of astronomy, nor at casting despair into those who will observe in the future. It is aimed rather at sharpening their industry on this very whetstone of difficulties, and at the same time at making it plain that it will not be labour wasted [actum agere] if anyone is willing to toil in the astronomical dust and, as far as lies in him and as the inconstancy of physical causes permits, to remove its imperfections from this art by filing and polishing — or at least to distinguish between those that can be removed and those that can be tolerated but not removed. For what Kepler admits of his Rudolphine Tables in the dedication, the rest need not blush to admit: *These tables both contain and publicly confess certain imperfections, detected in the very subject of the celestial motions, which cannot be made good or overcome by any art, especially before sufficient experience of the centuries to come.* And in the preface to the reader he says: *The very nature of the mean motions has not yet been thoroughly explored.* And again: *You have below, in the doctrine of eclipses, clear proofs, even from the observations of this time, that the motions of the Sun, the Moon and the primum mobile are not uniform to mathematical exactness, but receive very small physical intensifications out of order.*

The subtlety and difficulty of this art are increased, moreover, when observations over a long time are lacking, or have to be compared with ancient ones that we may doubt. For Ptolemy, most cautiously, in book 2 of the *Magna Constructio*, chapter 2: *We therefore judge it enough if we too try to contribute to these restorations as much as the time elapsed between our own observations and the collected observations of the ancients can contribute; and let us not wilfully neglect an accurate examination. The truth, however, that can be had from the whole perpetuity of time, or from a manifold time of observations, we think must be left to others.* Have you seen the noble resolve of an upright mind, neither despairing nor presuming too much? Hear the same man's candour in book 9, chapter 2, where he says: *The time from which we have observations of the planets is so short, compared with the magnitude of the things, that they make a prediction over a long time weak.*

Al-Battānī recognized things plainly similar in the very slow motion of the eighth sphere, in determining its uniformity or non-uniformity, and the length of the year that depends on it, in chapter 52. His words are: *In this superinduction, if Hipparchus and Ptolemy were deceived because of the instruments with which they observed these things, we too are necessarily deceived in the same way, since the consideration of our observation cannot be completed without their observations. But if this difference arises from some celestial motion still hidden from them and from us, it is fitting that whoever diligently seeks the truth should always observe precisely, and correct what he has found to be faulty in the way our predecessors corrected others.* Johannes Regiomontanus [Io. Regiomontanus], having copied these words almost verbatim in the *Epitome* of the *Almagest*, book 7, chapter 6, himself concluded as well: *It will be expedient to keep an eye constantly on the fixed stars, and for posterity likewise to weigh the considerations that have been written down.*

Here, though, and in all other matters of this kind, one ought to have, if it were possible, as many eyes as Argus has, or as many stars as Astraea shines with all around her. Not in vain did our Scheiner give this warning in book 2 of the *Rosa Ursina*, chapter 10: *He must play Argus who would make faultless observations of the Sun at this time of midday.* Indeed Athanasius Kircher, in book 2 of the *Magnetic Philosophy*, pointing out the causes of slips in observing that arise from many sources — but first of all *from the organs of sight, and the varying dilation of the pupil, and from the medium and its various refractions* — adds: *And if every deception is to be avoided, one must be an angel, not a man.*

To hint at this at the very gateway and frontispiece of the work: on the left side of the picture, Astraea [Astream], furnished with angelic wings and sparkling with stars on every side; on the right, Argus, not content with a hundred eyes but, by a [Greek: προχρονυσμοῦ (prochronismou, "prochronism", i.e. anticipation in time)] [recte: προχρονισμοῦ] and an anticipated use, bringing the telescope to the eye on his knee rather than to the eye of his cheek, so that in seeing the works of God's fingers he seems at the same time about to bend the knee to venerate them.

For God himself so disposed all these things in number, weight and measure as both to fix a cross for the astrologers and genethliacs, who forever wander in the labyrinth of the celestial motions, and to raise the minds of every age to the heavens with ever-new phenomena and subtleties, so that astronomers should not think they may doze securely in future. For those words of God in Job 38 can bear this sense: *Who will declare the reason of the heavens, or who will make the harmony of heaven sleep?* For just as the heavens are said to praise the Lord objectively, because they rouse us to praise him, so they would in a way be sleeping if, bringing forth nothing new from time to time, they invited us to sleep and to neglect of observations. Let us indeed say with Seneca, book 7 of the *Naturales Quaestiones*, chapter 31: *Many things unknown to us the people of a coming age will know. Many things are reserved for ages yet to come, when the memory of us will have faded.*

The world is a paltry thing, unless the whole world finds in it something to investigate. Or rather, let us conclude with our most wise old Clavius [Christoph Clavius], on chapter 4 of Sacrobosco's *Sphere*, p. 452 in my copy: *It is extremely difficult to define the periods of the motions so that they do not deviate from the truth over many centuries of years, since no mortal has ever been able to determine the period of even one planet so exactly that no small fractions are left over or missing — fractions which, over a great interval of years, introduce a noticeable error. So it is truly a wonder that God, Best and Greatest, chose to obstruct the motions of the planets with such great difficulties that no human being can grasp them perfectly, but always finds something to admire in so great an artifice of such noble bodies, and in so great a harmony and concord of their motions, celebrating their founder and mover with perpetual praises. So much so that it seems to have been written by Ecclesiastes, chapter 3 — "And he has handed the world over to their disputation" — above all on account of the constitution of the heavens and their motions, in which there always seems to remain something to be investigated with the utmost diligence by the most skilful searchers of celestial things: lest, that is, if men had ever perfectly understood the number, order, constitution and motion of the heavens, they should cease to investigate and admire the works of God, and their minds, deprived of any occasion for exercise, should grow torpid through idleness.*

This is the same old man who, near the end of his life, having considered the new phenomena of the heavens that had begun to be discovered by Galileo with the Belgian spyglass [perspicillo Belgico] and were being announced through the *Sidereus Nuncius* [Nuntium sidereum], broke out into these words: *Let the astronomers see how the celestial orbs are to be arranged so that these phenomena can be saved.* Empty, therefore, and drawn from poetic fiction is that encomium of Manilius on his Mercury:

Through you the heavens are now [brought] down to earth; now the stars are known. [Per te iam cælum in terras; iam fidera nota.]

For to this very day the heavens have not been brought down to earth, nor are they known as if those celestial things had been called down to earth. Rather, what is true is what Truth itself — namely God — says in Job 38: *Do you know the order of the heavens, or will you set out its reason on earth?*

ARTICVLVS VII. Auctoris in hoc opere Scopus & Ordo indicatur.

[Article VII. The author's aim in this work, and its arrangement, are set out.]

As I reflected both on the matters I set out in Articles 5 and 6 and on what I had repeatedly heard about astronomical subjects, there was put into me, from the very beginning of my studies, a great desire to build an astronomical work which could serve as a kind of library for the men of our Society, and for others who lacked either a large number of books of this kind or the leisure to read them all through — a work into which I might gather, with all the learning I could muster, the whole of astronomy, old and new, together with

the controversies belonging to it. My superiors were at first undecided whether to assign me to teach philosophy publicly or rather mathematics; afterwards they chose to keep me in the chair of philosophy for nearly six years, and in that of scholastic theology for a full ten. Yet that ardour for astronomy, once kindled in my mind, could never be lulled to sleep, much less extinguished. On the contrary, having obtained from them a release from the office of teaching theology, I devoted myself wholly to astronomy; and they themselves, having weighed the reasons for my aim, urged me of their own accord to complete what I had long since begun.

To this was added a spur from certain persons. Some, made bolder by the success of their philosophical talent, scarcely greeted astronomical questions from the threshold, yet did not hesitate to pronounce on them, and fell into shameful errors. Others, by contrast, were of so narrow and cautious a mind that, adhering to Tycho alone, or to some other writer on the sphere, and drawing from him the measures of the motions, distances and magnitudes of the celestial bodies, they thought it a sin to depart from him by even a single unit or the smallest jot. Some, again, so disparaged the observations of the celestial phenomena that they asserted that one could not come even close to the truth by means of them. Others held all astronomical conclusions to be so thoroughly demonstrated that one must go over bodily to the opinion of any approved astronomer, with no prior selection or examination. I noticed, too, that the controversy between the Peripatetics and the Tychonians over the location of comets and new stars was being settled by most people on the mere authority of Tycho and his followers, because no one could, or would, weigh on the scale of trigonometry the prolixity of the Claramontian calculation set out in the *Antitycho* and in the other books of Scipio Claramontius [Scipione Chiaramonti].

Finally, in the question most celebrated in this century, concerning the system of the world — whether one supposes the Earth immobile, with most people, or mobile, with the Philolaics and Copernicans — I saw that many, by hurling weak arguments at their opponents, rather confirmed them in their opinion; and that the Copernicans everywhere kept repeating that the sacred censors, versed only in Peripatetic philosophy and in theology, or perhaps also in knowledge of the Holy Bible and the canons, had issued decrees on astronomical matters against Copernicus that were neither just nor valid, or not at all necessary. These things, I say, and others like them, with which my ears constantly rang, provoked me — it is incredible to say how sharply — to meet them and answer them with all my strength, especially since what is at issue in this Copernican dispute is the literal sense of Sacred Scripture.

Therefore, having called upon the Divine Majesty so that I should not give way under this Atlantean burden, I girded myself for the work. Having explored the heavens for many years with new and very large instruments, and having read through every volume on this subject I could obtain, I built this *New Almagest*. Its first Tome, subdivided into two parts, now appears; the

remaining two will be brought to light in their own time, if God, in whose hands are my lots, prolongs my life. Their subject, and the whole arrangement of the work, I have already indicated sufficiently at the very entrance of this volume.

I would only have the reader warned of this: in this first Tome I have not delivered my final verdict on astronomical numbers and measures, but have merely chosen, as occasion arose, many values that seemed to me more correct for the time being. For I reserve the finished hypotheses for the third Tome, once both the Tychonic observations — which I hear are sweating under the press — and those of others have reached my hands, and our own have become more numerous and more certain.

Whether I have merely stitched together a patchwork from other people's opinions and plundered other people's book-chests, or whether I have rather searched out whatever in this discipline seems worth knowing in such a way that, having gathered it in an easier method and in no more obscure a style, I have from time to time enriched it with a stock of newly found theorems — the reader will judge from the course of the work itself, or from the index of Books and Chapters itself. I hope, too, that I shall be pardoned for a prolixity that was almost necessary: in presenting so great a diversity of opinions, in citing authors, and in repeating nearly the same matters, which I suspected readers would look for in some other place rather than in the one where I had once touched on them. For my errors, if any are detected, I ask correction rather than pardon — but from the expert, and from lovers of the Truth, which, after the greater Glory of God, I have set before myself as my sole end.

INDEX RERVM Ad Theologiam vel Sacræ Scripturæ Interpretationem pertinentium, Quæ in hoc Tomo I. tractantur.

[Index of matters pertaining to theology or the interpretation of Sacred Scripture that are treated in this Tome I.]

- Praises of the Sun from Sacred Scripture: Book 3, chap. 1, p. 92.
- Praises of the Moon from Sacred Scripture: Book 4, chap. 1, p. 184.
- Censure of those who assert that the Moon is inhabited: Book 4, chap. 2, pp. 187, 188.
- The admirable Providence of God in eclipses of the Sun and Moon: Book 5, chap. 2, p. 289.
- On the miraculous eclipse at the death of Christ the Lord, which comprises ten miracles; and on preternatural eclipses, and whether they portend the last day of the world or its night: Book 5, chap. 18, p. 357.
- Praises of the fixed stars from Sacred Scripture: Book 6, chap. 1, p. 393.
- Exposition of the Hyades and the Pleiades named in Sacred Scripture: Book 6, chap. 3, p. 399.
- Exposition of Arcturus, named in Sacred Scripture: Book 6, chap. 4, p. 405.

- Exposition of Orion, named in Sacred Scripture: Book 6, chap. 5, p. 408.
- The ancient number of the stars compared with the endowments of the Most Blessed Virgin Mary: Book 6, chap. 6, p. 413.
- The names of the seven angels assigned to the same number of planets, etc.: Book 7, sect. 1, chap. 1, p. 481.
- On the wonderful star which foreshowed to the three holy Magi the birth and the cradle of Christ the Lord; what the holy Fathers and Doctors of the Church thought of it: Book 8, sect. 2, chap. 19, p. 179.
- The errors of some concerning the Star of the Magi are reported and refuted, but above all those of the genethliacs; where the natal horoscope of Christ the Lord, cast with little piety by certain persons, is discussed: Book 8, sect. 2, chap. 20, p. 186.
- On the creation of the heavens and the production of the stars, or on the divine works of the first, second and fourth days of the world, from Sacred Scripture and the Fathers, at length and with care: Book 9, sects. 1 and 2, pp. 193 to 250.
- On the motion of the Sun and the immobility of the Earth, from Sacred Scripture and the Fathers; where the literal sense, and the authority of the Sacred Congregation in the censures it has issued on matters of this kind, are discussed at length, and the authority of both is defended: Book 9, sect. 4, chaps. 36 to 40, or pp. 479 to 500.

INDEX RERVM Ad Physicam in Materia de Cęlo, & Elementis, aut in Meteorologia pertinentium, quæ hoc Tomo I. pertractantur.

[Index of matters pertaining to physics, in the subject of the heavens and the elements, or in meteorology, that are treated in this Tome I.]

- On the roundness of the heavens, and the circular motion of the heavens and the stars: Book 1, chap. 2, p. 3.
- Whether there are antipodes: Book 1, chap. 20, in the Scholia, p. 26.
- On the figure of the Earth and water, the coincidence of their centre with the centre of the world and of heavy bodies, and on the Earth's immobility, with many corollaries bearing on the centre of heavy bodies or of gravity: Book 2, chaps. 1 to 6, or pp. 47 to 57.
- On the magnitude of the Earth, and the extent of the known Earth: Book 2, chaps. 6, 7, 8, 9, or pp. 57 to 64.
- On the distance of sight, the levelling of canals, the height of mountains and their decrease, and the argument drawn from this for a finite duration of the world: Book 2, chaps. 10, 11, 12, or pp. 64 to 68.
- On the origin of springs and rivers; the measurement, levelling, speed, swelling and overflowing of waters: Book 2, chap. 13, or pp. 68 to 71.
- On the threefold dimension of the sea, and the comparison of the mass of the waters with the mass of the Earth, and their equilibrium; and on

the motions of the sea, especially the tide: Book 2, chaps. 14 and 15, or pp. 71 to 74. On the tide again, more fully: Book 9, sect. 4, chaps. 14 and 15, or pp. 360 to 381.

- On the winds and anemography, their old and new nomenclature, their force and sphere: Book 2, chap. 17, pp. 75 to 80.
- On the height of the regions of the air, of clouds, of rainbows, and of the elementary sphere: Book 2, chap. 19, or pp. 81 to 83; and Book 8, sect. 1, chap. 14, pp. 58 to 62.
- On the natural motion of a pendulum [Perpendiculi]: Book 2, chap. 20, or from p. 84.
- On the speed of heavy and light bodies, the increase of that speed, and its proportion: Book 2, chap. 21, or from p. 89; but again more fully on these matters, with new experiments adduced: Book 9, sect. 4, chaps. 16 and 17.
- On the qualities of the Sun, its spots, faculae, illumination, and the cause of its heat: Book 3, chaps. 2, 3 and 4, or pp. 93 to 100; but on the spots again, more fully: Book 9, sect. 4, chap. 12.
- On the power of the Moon over these lower things: Book 4, chap. 1, in the Scholia, or p. 185.
- On the substance of the Moon, its phases, its primary and secondary light, its spots, and the whole of selenography: Book 4, chaps. 2 to 9, or pp. 186 to 215.
- On the prognostics of eclipses: Book 5, chap. 2, especially p. 292.
- On the substance and qualities of the fixed stars — namely their figure, light, twinkling, etc.: Book 6, chap. 2, or pp. 394 to 397.
- Which of the Dogs is Canicula, and what the effects of the Dog Days are and where they come from, and what the limits of the Dog Days were formerly and are now: Book 6, chap. 5, from p. 409, and chap. 22, from p. 469.
- On the Galaxy, or Milky Way: Book 6, chap. 23, or from p. 474.
- The analogy of the planets with physical things: Book 7, sect. 1, chap. 1, or from p. 481.
- On the aspects of the planets to one another, and their force, especially on the Great and Greatest Conjunctions: Book 7, sect. 5, chaps. 7, 8, 9 and 10, or pp. 463 to 680.
- On the distances, magnitudes and speeds of the planets and the fixed stars [Siderum Inerrantium], their mutual eclipses, etc.: Book 7, sect. 6, the whole.
- On the time in which a body would descend to the Earth from the heavens, with a non-uniform or a uniform motion: Book 2, chap. 21, p. 90, and Book 7, sect. 6, chap. 5, p. 697.
- On comets, with the greatest precision: Book 8, the whole of sect. 1; but those who shrink from the subtler mathematics should read at least chaps. 1 to 15 and chap. 23.

- On new stars, with the greatest exactness: Book 8, sect. 2, the whole; but let at least chaps. 1, 2, 11, 16, 17 and 18 be consulted.
- On the number of the elements: Book 9, sect. 1, chap. 1, from p. 200.
- On the simplicity of the heavens, their matter, generability, corruptibility, animation and fluidity: Book 9, sect. 1, chaps. 5, 6, 7, 8, or pp. 232 to 246.
- On the infinite, the infinity of the heavens being disputed on this occasion: Book 9, sect. 1, chap. 9, or p. 246.
- On the movers of the heavens and their number: Book 9, sect. 2, chap. 1, or from p. 247; and sect. 3, chap. 5, or p. 285.
- On the number of the heavens: Book 9, sect. 3, chap. 1, or p. 275.
- On the motion or rest of the Earth, with the greatest precision: Book 9, sects. 3 and 4, the whole; but if anyone is wearied by so long a controversy, let him read at least sect. 4, chaps. 1, 2, 3, 4, 33, 34, 35, 36, 37, 38, 39 and 40.

INDEX LIBRORVM ET CAPITVM Cum Scholijs, Tabellis, Theorematibus, & Problematibus in ijs contentis.

[Index of the books and chapters, with the scholia, small tables, theorems and problems contained in them.]

- Preface to the Reader: on the praises of astronomy, its right use, its origin, its antiquity, and its progress down to the present day.
- Chronicle I: of astronomers, cosmographers, etc., in order of time.
- Chronicle II: of astronomers, cosmographers, etc., in alphabetical order, with the things about them most worth knowing added.
- Index of matters pertaining to theologians or to natural philosophers.

LIBER I. DE SPHÆRA IN COMMVNI.

[Book I. On the sphere in general.]

- Authors who have written on the sphere, etc. — p. 1.

CAPVT. [Chapter.]

- I. What astronomy and cosmography are, and which sciences or arts they require. — p. 2
- II. On the roundness of the heavens, and the circular motion of the heavens or of the stars. — 3
    - Seven scholia. — 3 and 4
- III. Suppositions on the shape, position and size of the Earth. — 4
- IV. Definition, properties and dimensions of the circle. — 4
    - The more notable properties of the circle. — 5
    - Dimensions of the circle. — 5
- V. On the division of the circle into degrees, and of degrees, days and hours into minutes [Minutias], and on their reckoning [Logiſtica]. — 6
    - Rule I, with an example of addition. — 6

- Rule II, with an example of subtraction. — 7
- Rule III, with an example of multiplication. — 7
- Rule IV, with an example of division. — 7 and 8
- Scholium on the ancient use of fractional minutes [Minutiarum]. — 8
- Small table of the parts of the *as* [Affis] of the circle, adapted to the parts of the hour or of the day. — 8

• VI. Definition, properties and dimensions of the sphere. — 8
- The more notable properties of the sphere. — 8 and 9
- Dimensions of the sphere. — 9

• VII. On the circles of the natural and the artificial sphere in general, and their properties. — 7
- What and how many are the great circles in the sphere. — 10
- The more notable properties of the circles of the sphere in general. — 11

• VIII. On the rational and the sensible horizon. — 12
- Four scholia. — 13

• IX. On the meridian circle. — 13
- Two scholia. — 13

• X. On finding the meridian line, and the magnetic declination. — 14
- Four scholia. — 14

• XI. On the equator, and the motion of the primum mobile [Primi Mobilis]. — 14
- Two scholia. — 15

• XII. On finding the altitude of the pole and of the equator. — 15
- Five scholia. — 16

• XIII. On geographical latitude and longitude. — 16
- Four scholia. — 17

• XIV. On the ecliptic and the zodiac, where the motion of the second mobile [Secundi Mobilis] and the obliquity of the ecliptic are treated. — 18
- Small table of the twelve signs. — 18
- Eight scholia. — 19 and 20
- Small table of the houses of the planets. — 20

• XV. On the colures. — 20
- Two scholia. — 21

• XVI. On the tropics, the polar circles, and the zones. — 21
- Six scholia. — 22

• XVII. On the circles of perpetual apparition [Circulis ſemper Apparentium]. — 22
- Six scholia. — 23

• XVIII. On the climes and their parallels. — 24

• XIX. On the threefold position of the sphere, and the diversity of days and nights in it. — 24

- XX. What the Antipodes, Antoeci, Perioeci, Antiscii, Amphiscii, Heteroscii and Periscii are; and on the shadows of gnomons, and their varying position and shape. — 25
    - Five scholia. — 26
- XXI. On the other circles of the sphere named in chapter seven. — 27
- XXII. Definitions of the arcs and angles pertaining to the circles of the sphere, and of the circles themselves, in alphabetical order. — p. 28
- XXIII. Select rules on the ascensions of the signs and of the points of the ecliptic. — 30
    - Scholion. — 31
- XXIV. On the distinction of natural days from artificial and civil days. — 31
    - Three scholia. — 31
- XXV. On the inequality of natural days. — 32
- XXVI. On the inequality of artificial days. — 32
    - Three scholia. — 33
- XXVII. On finding the quantity of the semidiurnal and seminocturnal arc, given the altitude of the pole and the degree of the ecliptic in which the Sun stands. — 33
    - Small table of the Sun's ingress into the signs. — 33
- XXVIII. On the various beginnings of the natural days, from which come the four kinds of hours, and on their conversion into one another. — 34
    - Five scholia. — 35
- XXIX. On unequal or temporal hours, and their conversion into equal hours. — 36
    - Two scholia. — 36
- XXX. On the planetary hours, and the characters of the planets. — 36
- XXXI. On twilight. — 37
    - Table of the quantity of twilight. — 38
    - Table of opinions on the Sun's depression at the beginning of twilight, and on the height of the vapours [Halituum]. — 39
    - Four scholia. — 39
- XXXII. On the rising and setting of the stars, and on the arc of vision, on the occasion of heliacal rising and setting. — 40
    - Small table of risings and settings appropriate to the planets and the fixed stars. — 41
    - Small table of the arc of vision. — 42
    - Scholion. — 42
- XXXIII. On the aspects and mutual radiations of the stars. — 43
    - Two scholia. — 43
- XXXIV. On the division of the celestial houses, and the erection of a celestial figure [Thematis]. — 43
    - Table of the various nomenclature of the houses. — 44

- XXXV. On parallaxes. — 44
  - Four scholia. — 45
- XXXVI. On refractions. — 45
  - Three scholia. — 46

LIBER II. DE SPHAERA ELEMENTARI. Ac præcipuè de Globo Terraqueo.

[Book II. On the elementary sphere, and especially on the terraqueous globe.]

CAP.

- I. On the shape of the Earth and the water together. — p. 47
  - Four scholia. — 48
- II. That the Earth is the centre of the world, and at the centre of the highest, starry heaven, at least as far as the senses can tell. — 49
  - Three scholia. — 50
- III. On the immobility of the Earth. — 51
  - Two scholia. — 52
- IV. That the centre of the Earth is the common centre of all heavy bodies. — 52
  - Twelve corollaries from the centre of gravity and of magnitude of the Earth. — 53
- V. Digression on gravitation, and on the natural motion of the elements and of mixed bodies away from and toward the centre of the universe; and on bodies floating in a liquid. — 55
- VI. That the Earth is like a point in relation to the heavens, although in relation to us it is large. — 56
  - Five scholia. — 57
  - Small table of the angle under which the Earth would be seen from a given distance. — 58
- VII. On the absolute size of the Earth, and first on the measures of distances. — 58
  - A very recent and twofold method of measuring the Earth. — 59
  - Nine scholia, in which the opinion of others on the size of the Earth is treated. — 61
  - Table of the opinions on the quantity of the Earth, corrected. — 62
  - Table of the opinions on the quantity of the Earth, as they stand in the authors. — 63

CAP.

- VIII. Certain corollaries deducible from the size of the Earth. — 63
- IX. On the quantity of the Earth as known formerly and now. — 64
- X. On the distance of sight, or the extent of the sensible horizon, where the height of an object visible on the Earth and the levelling of waters are treated. — 64
  - Table of the distance of sight, and of the height of an object visible from the surface of the sea. — 66

    - Four scholia. — 66
- XI. On the height of mountains. — 66
- XII. On the diminution of mountains and the change in the roundness of the Earth, and on the argument drawn from this for the finite duration of the world. — 67
- XIII. Select points for cosmographers: on springs and rivers, their origin, measure, velocity and overflow. — 68
    - On the origin of springs. — 68
    - On the measure of waters. — 69
    - On the levelling of canals and rivers. — 69
    - On the velocity of waters. — 70
    - On the measurement of the swelling and the overflow of rivers. — 71
- XIV. On the threefold dimension of the sea, the comparison of the terrestrial waters with the bulk of the Earth, and the equilibrium of waters. — 71
- XV. On the motions of the sea. — 72
    - Five scholia. — 73
- XVI. Certain points on navigation, indicated for beginners in cosmography. — 74
- XVII. On the winds, and anemography. — 75
    - Table I of the winds, from Vitruvius. — 76
    - Also the order of the winds, and their ancient names compared with the recent ones. — 77
    - Table II of the winds, according to four recent authors. — 78
    - Table III, the more recent names of the winds. — p. 78
    - The order of the rhumbs. — 79
    - Three scholia. — 89
- XVIII. On the declination of the magnetic needle, the compass, the sea chart, sailing by the great circle [Hiſtiodromia] and loxodromes: certain points indicated for beginners. — p. 89
    - Table of the more notable declinations of the magnetic needle. — 81
- XIX. On the height of the regions of the air, of clouds, of rainbows, and of the whole elementary sphere. — 81
    - A twofold method of measuring the height of clouds. — 82
    - Four scholia. — 83
- XX. On the oscillations of the pendulum, suited to measuring motion and times finely. — 84
    - Fifteen propositions and seven problems on pendulums. — 85 and 88
    - Twofold table of the time corresponding to the vibrations of a pendulum. — 87, 88

- XXI. On the velocity of heavy bodies descending with natural motion, and the proportion of the increase of their velocity. — 89
    - Five propositions on these. — 90
    - Three scholia. — 91

LIBER III. DE SOLE.

[Book III. On the Sun.]

- I. On the names, substance and praises of the Sun. — 92
- II. On the qualities of the Sun, above all its light, and its round or elliptical shape. — 95
    - Three scholia. — 95
- III. On the spots and faculae of the Sun. — 95
    - Three scholia, where Mercury seen under the Sun is treated. — p. 98
- IV. On the rotation [Motu Vertiginis] of the Sun, its trembling, etc., where the rotation of the other planets is treated. — 98 and 99
- V. On the illumination and heating of the Sun; the figure of the solar ray, and the parallelism of the rays. — 99
    - Scholium. — 100
- VI. On the place of the Sun and the Earth in the world, on which occasion the more notable systems of the world are set out. — 101
    - Appendix on the place of the Sun and the Earth, and on the manifold motion of the Earth according to the hypothesis of Copernicus. — 103
    - Two scholia. — 105
- VII. On whether the distance of the Sun from the Earth is changeable or unchangeable. — 105
    - Problem 1. On the distance of the Sun by parallaxes. — p. 105
    - Problem 2. On the distance of the Sun by eclipses. — 106
    - Problem 3. On the distance of the Sun by the distance of the Moon and its dichotomy. — 107
    - Small table of the greatest and least distance of the Sun, deducible from the dichotomy. — 109
    - Table of opinions on the threefold distance of the Sun from the Earth. — 110
    - Five scholia, where obsolete opinions on the solar distances are treated. — 111
    - Father Grimaldi's problem on the distance of the Sun. — p. 112
- VIII. On the parallaxes of the Sun. — 112
    - Table of opinions on the horizontal parallax of the Sun. — 113
    - Two scholia. — 114
- IX. On the refractions of the Sun. — 114
    - Two scholia, on the causes and the remarkable effects of refractions. — 115

- X. On the apparent size of the Sun. — 116
  - Five principal methods of observing the Sun's diameter. — 116 and 119
  - Table of opinions on the apparent diameter of the Sun. — 119
  - Four scholia. — 119 and 120
  - Small table of the diameter of the Sun as seen from the planets. — p. 120
- XI. On the true size of the Sun, and the other quantities that depend on its distance and apparent diameter. — 120
  - Problem 1. On the true diameter of the Sun from the apparent. — 120
  - Problem 2. On the apparent diameter of the Sun from the true. — 121
  - Table of opinions on the size of the Sun. — p. 121
  - Problem 3. How large is the portion of the Sun seen by us from the Earth. — 121
  - Problem 4. How large is the portion of the terrestrial hemisphere illuminated by the unrefracted rays of the Sun. — 122
  - Small table of opinions on this portion. — 122
  - Problem 5. How large is the angle of the cone of the terrestrial shadow enclosed by the unrefracted rays of the Sun. — 122
  - Small table of opinions on the said angle. — 123
  - Problem 6. To derive the horizontal parallax of the Sun from the semi-angle of the terrestrial shadow and the visual semidiameter of the Sun, and conversely the semi-angle of the shadow from the parallax. — 123
  - The disagreement of three astronomers on this. — p. 124
  - Problem 7. To find the semi-angle of the shadow in another way. — 124
  - Problem 8. To find the axis of the cone of the terrestrial shadow enclosed by the unrefracted rays of the Sun. — 124
  - Table of opinions on the axis of the Earth's shadow. — 125
  - Nine theorems gathered from what has been said. — 125
  - Three scholia. — 125
- XII. On the diurnal motion of the Sun from rising to setting, and on its velocity, or the Earth's, if it moved in that way. — 126
  - Table of opinions on the velocity of the Sun, or of the Earth. — 127
  - Scholium. — 127
- XIII. On the annual motion of the Sun, and the kinds of years. — 127
  - Five scholia. — 129, 130
- XIV. On the observation of the equinoxes and solstices, and on the four cardinal points of the year. — 130
  - Method of observing the solstices, where the great gnomon of Bologna is treated. — 131 and 132

- Three methods of observing the equinoxes. — 133, 134
- Table of the equinoxes of Hipparchus and Ptolemy. — 134
- Two scholia. — 135

• XV. Method of gathering the quantity of the equinoctial or tropical year. — 135
- Method 1, by the sidereal year. — 135
- Method 2, by the lunisolar cycles. — 135
- Method 3, by the solstices. — 137
- Method 4, by the equinoxes. — 137
- Table of opinions on the quantity of the equinoctial year. — 139
- Scholium. — 139

• XVI. On the quantity of the sidereal year. — 139
- Table of opinions on the quantity of the sidereal year. — 140

• XVII. On deriving the mean annual, daily, etc., motion of the Sun from the tropical year, and distributing it into tables. — 140
- Table of opinions on the annual and daily motion of the Sun. — 140

• XVIII. On the intervals between the four cardinal points of the year, and on the annual inequality of the Sun's motion. — 141
- Table of opinions on the motion of the Sun in each semicircle of the ecliptic. — 141
- Table of the four seasons of the year. — 141

• XIX. On the ancient hypotheses by which the apparent inequality in the Sun's annual motion is excused or explained. — 142
- On the concentric with epicycle [Concentrepicyclo]. — 142
- On the eccentric. — 143

• XX. Definitions, rules and properties relating to the hypothesis of the epicycle and the eccentric. — 144
- Two scholia. — 146

• XXI. On investigating the equations, or prosthaphaereses, of the Sun's motion, and distributing them into tables. — 147

• XXII. What the equant circle is, and what the physical and the optical equation are, and how each is investigated separately. — 147
- Two scholia. — 148

• XXII. On the hypotheses devised by the moderns to explain the anomaly of the Sun's motion. — 149
- Three scholia. — 151

• XXIV. On investigating the apogee and eccentricity of the Sun, or the diameter of its epicycle. — 152
- Methods 1 and 2. — p. 152 and 153
- Method 3, our own. — 153
- Method 4, Bullialdus's [Ismaël Boulliau]. — 154
- Method 5, Kepler's. — 156
- Scholion. — 156

- Table of opinions on the apogee of the Sun, its greatest equation, and its eccentricity. — 156, 157
- XXV. On the motion of the Sun's apogee. — 157
  - Small table of opinions on this motion. — 158
- XXVI. On the change of the eccentricity and of the greatest equation of the Sun, and their anomaly, and that of the motion of the apogee. — 158
  - Two scholia. — 159
- XXVII. On the greatest declination of the Sun and the obliquity of the ecliptic, and their change and anomaly. — 159
  - Method 1 of observing the greatest declination of the Sun. — 160
  - Method 2. — 160
  - Table of observations and opinions on the greatest declination of the Sun. — 161, 162
  - Whether the obliquity of the ecliptic really changes. — 162
  - Authors and arguments for the immutability of the obliquity of the ecliptic. — 163
  - Five scholia. — 164, 165
- XXVIII. On the precession of the equinoxes and the motion of the eighth sphere. — 165
  - Our opinion on this precession and its anomaly. — 167
  - Table of opinions on the annual motion of the fixed stars, or of the equinoctial points. — p. 168
- XXIX. By what hypothesis or theory the anomalies of the Sun's eccentricity, of the obliquity of the ecliptic, and of the precession of the equinoxes are usually explained. — 168

CAP.

- The hypothesis of Lansbergius [Philips van Lansbergen]. — 168
- The hypothesis of Kepler. — 169
- The hypothesis of Longomontanus. — 170
- The hypothesis of Copernicus. — 170, 171
- The hypotheses of Maginus [Giovanni Antonio Magini], Wernerus [Johannes Werner], Purbachius [Georg von Peuerbach], and others. — 172, 173
- Scholion. — 173
- XXX. On the inequality or equality of the equinoctial year. — 173
  - Our opinion on the equality of the year. — 174
  - Three scholia. — 176
- XXXI. On the inequality of natural days, and their equation. — 176
- XXXII. The opinion of the more recent astronomers on the inequality of natural days, and their equation. — 179
  - Four scholia. — 181
- XXXIII. On establishing the epochs, or radices, of the Sun's motions, and on arranging the solar tables. — 182

- The beginning of the year, differing according to different astronomers. — 182
- The radix of the Sun's mean motion according to different astronomers. — 183

LIBER IV. DE LVNA.

[Book IV. On the Moon.]

CAP.

- I. On the names and praises of the Moon, and the variety with which it has exercised the wits of astronomers until now. — 184
  - Five scholia. On the Moon's force upon these lower things. — 185, 186
- II. On the substance of the Moon, and whether it is another Earth, and has its own atmosphere and its own inhabitants. — 186
- III. On the different phases of the Moon, and their variety. — 188
  - On the first phase of the Moon. — 189
  - On the interval between new moon and the last or the first phase. — 190
  - On the difference of the phases in the quadratures or the syzygies. — 191
- IV. Problems relating to the phases of the Moon. — p. 192
  - Problem 1. On finding the age of the Moon. — 192
  - Problem 2. For how many hours the Moon shines at night. — 193
  - Problems 3, 4, 5 and 6. What fraction of the Moon shines at night, or is illuminated by the Sun, or is seen by us, etc. — 193
  - Problem 7. How long before the first quadrature, or after the second, the Moon shines on us halved. — 193
  - Problem 8. When the Moon comes to the nonagesimal. — 194
  - Problem 9. To predict the day of the first and of the last phase. — 194
  - Three scholia. — 194
- V. Whether the Moon shines with its own light or the Sun's, and whether it reflects that light to us like a mirror. — 195
  - On the opacity of the Moon. — 197
- VI. Whether the Moon has some secondary light of its own, and where its light in eclipses comes from, etc. — 198
  - On the bright ring around the Moon. — 198
  - On the secondary light of the Moon near new moon, and in an eclipse of the Sun. — 199
  - On the light of the Moon in its own total eclipses. — p. 201
  - Four scholia on annular eclipses of the Sun, and on the light of the Moon in eclipses of the Sun or of the Moon. — p. 203
- VII. Selenography, or a description of the lunar surface as most recently observed with telescopes, and of its spots. — 203

- VIII. What the old and the new spots are, and on the roughness of the Moon, its mountains, caverns, valleys, islands, etc. — 206
  - Two scholia on the measurement of the lunar mountains. — p. 212
- IX. On the motion of the lunar libration, and the mutual aspect of the Moon and the Earth. — 213
- X. On the place of the Moon in the world. — 216
- XI. On the method in general by which the parallaxes of the Moon, and from them those of the other planets, are sought without a vicious circle. — 216
  - Scholion. — 217
- XII. On observing the greatest latitude of the Moon for the sake of the parallaxes. — 217
  - Four methods of observing the latitude of the Moon. — 218, 219
  - Given the greatest latitude of the Moon, to find the remaining latitudes. — 219
  - Opinions on the greatest latitude of the Moon. — 219
  - Three scholia. — 220
- XIII. On the distance of the Moon from the Earth from its parallaxes, and on deducing the parallaxes themselves from observation. — 221
  - Nine methods of observing the parallaxes of the Moon. — 222
- XIV. Select observations of the lunar parallaxes, by others and our own. — 222 to 225
  - Table of opinions on the parallaxes of the Moon. — p. 226
  - Four scholia. — 226
- XV. On the refractions, and the elliptical shape of the Moon on the horizon. — 227
- XVI. On the apparent size of the Moon. — 227
  - The optical equation of the lunar diameter. — 229
  - Various foundations for the lunar diameter, from observations or from elsewhere. — 230 to 232
  - Table of opinions on the apparent diameter of the Moon. — 233
  - Two scholia. — 223
- XVII. On the true size of the Moon compared with the Earth and the Sun, and the other quantities that depend on it or on the apparent size. — 233
  - Table of opinions on the size of the Moon. — p. 234
  - What part of the Moon is seen by us, with a small table of opinions. — 234
  - What part of the Moon is lit by the Sun, with a table of opinions. — 235
  - The angle and axis of the lunar shadow, with a table of opinions. — 235, 236
  - How large the diameter of the Earth appears from the Moon. — p. 236

- What portion of the Earth is illuminated by the Moon. — p. 236
- Five theorems and three scholia. — 237

• XVIII. On the various motions of the Moon. — 237
- The velocity of the Moon's diurnal motion. — 239

• XIX. On lunar months and years, epacts, the great lunisolar cycles, and the first device for investigating the motions of the Moon, by these cycles. — 241
- An account of the lunisolar cycles and periods. — 241
- Table of the cycles of Meton. — 242
- Scholion. — 244

• XX. On the second device, by which astronomers investigated the revolutions and motions of the Moon. — 244

• XXI. On the third device, by which the motion of the Moon in longitude and its first inequality are demonstrated, on which occasion the semidiameter of the epicycle is sought. — 247
- Eighty-six selected eclipses of the Moon, from which the motion of the Moon was investigated. — 250 and 251

• XXII. On investigating the motion of latitude, and of the nodes of the Moon. — 252

• XXIII. Rules and examples for investigating the remaining motions of the Moon from the revolutions. — p. 253, 254
- Synoptic table of opinions on the annual and daily motion of the Moon in longitude, in elongation from the Sun, in anomaly, in latitude and of the nodes, p. 255; and of the apogee. — 256
- Table of opinions on the mean lunar year and month. — 256

• XXIV. On establishing the epochs of the lunar motions. — 256

• XXV. On the second inequality of the Moon, and on the hypothesis by which Ptolemy explained it and the first inequality. — 257
- The orbs of the Moon, and the definitions and rules relating to the Ptolemaic hypothesis of the Moon. — p. 258, 259

• XXVI. The lunar hypothesis of Copernicus, Magini, Tycho and Longomontanus. — 260

• XXVII. The lunar hypothesis of Kepler, of Father Curtius, of Fabricius, Boulliau, Lansbergen, Vendelinus [Govaert Wendelen] and others. — 266 to 275
- Ten scholia in favour of Kepler's hypothesis. — 275 to 278

• XXVIII. Recapitulation [Anacephaleoſis] of the preceding hypotheses, a judgement on them, and an indication of our own. — 278 to 282

• XXIX. The theory of the Moon's latitude. — 283

• XXX. On the reduction of the Moon to the ecliptic. — p. 284

LIBER V. DE LVNÆ, ET SOLIS ECLIPSIBVS.

[Book V. On the eclipses of the Moon and the Sun.]
CAP.

- I. On the name and the false causes and kinds of eclipses in all the heavenly bodies, and on the excellence of detecting them and of predicting the true eclipses. — 286
  - The fictions of the poets about eclipses. — 286
  - Praises of astronomers for the prediction of eclipses. — 288
  - Three scholia on eclipses of other heavenly bodies, true or spurious. — 288, 289
- II. On the admirable providence of God in eclipses, and on their manifold use, effects and portents. — 289
  - Chronicle of notable eclipses, with the effects that have been attributed to them. — 292 and 293
- III. Definition, causes, kinds and varieties of lunar eclipses. — 293
  - Four scholia. — 295
- IV. On the threefold measure of the Earth's shadow enclosed by the unrefracted rays of the Sun. — 295
  - Twelve methods of investigating the semidiameter of the terrestrial shadow, etc. — 296 to 299
  - Table of opinions on the semidiameter of the terrestrial shadow. — 300
  - Three scholia. — 300
- V. On the penumbra of the Earth, and the various phases or colours of the Moon in eclipse or near eclipse that arise from the refraction of the rays. — 301
  - Four problems and five propositions on the penumbra of the Earth, and the variety resulting from it in eclipses. — 303 to 308
  - Four scholia, and a table of the colours of eclipses. — p. 308, 309
- VI. The limits, magnitude, duration and middle of lunar eclipses. — 309
  - Problem 1. To define the limits of lunar eclipses. — p. 309
  - 2. To determine the magnitude of lunar eclipses. — 310
  - 3. To determine the duration of eclipses and its parts. — 311
  - 4. To find the arc between the centres of the Earth's shadow and the Moon. — 311
  - 5. To determine the minutes [Scrupula] of incidence, of immersion [Repletionis], of half-totality [Moræ dimidiæ], etc. — 312
  - 6. To find the hourly motion of the Moon from the Sun. — p. 312
  - Table of opinions on the hourly motion of the Moon from the Sun. — 313
  - 7. The greatest duration of eclipses and of totality, with small tables of opinions. — 313
  - Five scholia. — 313, 314
- VII. On setting the figure of a lunar eclipse graphically before the eyes, and on the quarters and the curvature of the darkness, and the inclinations. — 315
  - Scholion. — 316

• VIII. What an eclipse of the Sun is and how many kinds there are, and how it differs from an eclipse of the Moon. — 316 and 317
• IX. On the shadow and penumbra of the Moon, and the various phases of solar eclipses arising from them. — p. 318
  • Eight problems on the lunar shadow, with small tables of opinions. — 318 to 322
  • Four scholia. — 322
• X. On the parallaxes of the luminaries, and their
CAP.
effects and uses in eclipses of the Sun. — p. 323
• Definitions and theorems of parallaxes. — p. 324, 325
• Five problems of parallaxes. — 326, 331
• Four scholia. — 332
• XI. On the limits, duration and moments of solar eclipses. — 332
  • The limits of eclipses, and tables of opinions. — p. 333, 334
  • The magnitude of solar eclipses. — 334
  • The duration of solar eclipses, and small tables of opinions. — 335, 337
  • Three scholia. — 337
• XII. On the eclipse of the Earth, darkened by the lunar shadow or penumbra, and as seen from the Moon. — 338
  • Eleven problems concerning the eclipse of the Earth. — 338 to 343
• XIII. On drawing the figure of an eclipse of the Earth and of the Sun, and on the inclinations of these phases. — 344
  • Three scholia. — 345
• XIV. Sixteen theorems on the intervals, number and revolution of eclipses of the Sun and Moon. — 349
  • Five scholia. — 350
• XV. On the method of observing eclipses, and on the causes of the disagreement between observations and the astronomical tables. — 350
  • 8 problems concerning the observation of eclipses. — 351 to 354
  • Three scholia. — 355
• XVI. A comparison, or antithesis, of eclipses of the Moon and of the Sun, set out as a table. — 356
• XVII. On the use of our geographical cross for predicting eclipses, and for transferring the calculation to other places on the Earth. — 356
• XVIII. On the miracle of the eclipse of the Sun at the death of Christ the Lord, and on preternatural eclipses before the end of the world. — 357
• XIX. A history of the eclipses of the Sun and Moon observed from the year 772 before Christ down to the year of Christ 1647, with their magnitude and duration indicated here and there from the astronomical tables. These are truly a vast treasury for astronomy, geography and chronology, from p. 361 to 385.
  • Eclipses before Christ. — 361 to 367

    - Eclipses after Christ. — 367 to 385
    - But to these must be added those that we have added in the Appendix to this book and to this chapter. — 385
- XX. Total and annular eclipses of the Sun, confirmed from the preceding history and by the authority of astronomers; and on the affinity with total eclipses that eclipses of the Sun near the horizon have. — 385
    - Total eclipses of the Sun. — 385, 386
    - Annular eclipses of the Sun. — 386, 387
    - Morning and evening eclipses of the Sun. — 387
    - 10 notable theorems on eclipses of the Sun. — p. 388
- XXI. A catalogue of eclipses from the ephemerides, from the year of Christ 1485 to 1700.

LIBER VI. DE STELLIS FIXIS.

[Book VI. On the fixed stars.]

CAP.

- I. On the name and excellence of the non-wandering stars [Siderum Inerrantium]. — 393
- II. On the substance and qualities of the fixed stars. — p. 394
    - On the light of the fixed stars. — 395
    - On the twinkling of the fixed stars. — 396
    - Three scholia. — 397
- III. On the form of the constellations [Astrorum] that lie in the zodiac, and the number of the stars composing them; with a short summary of the fables, and varied learning. — 397
    - Three scholia. — 402
    - The positions of the zodiacal constellations, formerly and now. — 402
    - The Arabic, Chaldean, Hebrew and Egyptian names of the zodiacal constellations. — 402
- IV. On the northern constellations outside the zodiac, with a short summary of the fables, etc., and sacred and profane learning. — 403
    - Appendix on the Pole Star and its approach to the pole. — 403 to 407
    - 10 notable observations of the Pole Star. — 404
- V. On the southern constellations outside the zodiac, with a short summary of the fables, and sacred and profane learning. — 407 to 410
    - Which of the two Dogs is Canicula, and what the effects of the dog days [dierum Canicularium] are, and where they come from. — 409
    - Twelve new southern constellations. — 410
- VI. On the number of the constellations, and of the stars in them or outside them, both relative to the six classes of apparent magnitude or to

the regions of the world, and absolutely; and on changing their figures or names. — 410
    - The number of stars observed without a telescope, according to various astronomers. — 412
    - Two scholia, and a rule of combinations. — 413
- VII. On the place and distance of the fixed stars, and their parallax. — 414
    - The Pythagorean, Platonic and Bettinian intervals of the heavenly bodies. — 415, 416
    - The distance of the fixed stars as asserted or deduced by the Copernicans. — 419
    - The diurnal speed of the fixed stars. — 419
    - Eight scholia on the parallax, or the infinite distance, of the fixed stars. — 420, 421
- VIII. On the refractions of the fixed stars, and their use. — 421
- IX. On the apparent and the true magnitude of the fixed stars. — 422
    - Eight ways of observing the apparent diameter of the fixed stars. — 423
    - Table of opinions on the apparent diameter of the fixed stars. — 425
    - Tables of opinions on the true magnitude of the fixed stars. — 424
    - Four scholia. — 424, 425
- X. On the distances of the fixed stars from one another, of which many were observed by Tycho, more by us, and very few by others, while some were deduced by means of calculation. — 425
    - A table of more than 500 distances of the fixed stars from one another. — 426 to 430
- XI. On observing the declination and right ascension of the fixed stars, or gathering them from observation. — 431
    - Ten problems with examples. — 431 to 435
    - Two scholia. — 435
- XII. On observing the longitude and latitude of the fixed stars, or deriving them from observation, and from these extending the right ascension and declination to other years. — 435
    - Eight problems concerning this. — 436
- XIII. Rules for the increase or decrease in the right ascension and declination of the fixed stars, with some of their properties. — 439
- XIV. On the table of the right ascension, declination, longitude and latitude of the fixed stars constructed by us, and how it differs from Tycho's and from those of others. — 439
- XV. Whether the fixed stars change their latitude of themselves, or incidentally, following the change in the obliquity of the ecliptic. — 441
    - A synoptic table of the Tychonic calculation for the change in the latitude of the fixed stars. — 441, 442
    - Scholium. — 443

- XVI. How great the motion of the fixed stars in longitude is, and how long their period. — 444
  - Three scholia. — 447
  - Table of opinions on the annual motion and on the period of the fixed stars. — 448
- XVII. What kind of motion the fixed stars have, and how many-fold it is: whether it is always direct, or retrograde, with trepidation; uniform or non-uniform? — 449
  - Table of ancient observations for the motion of the fixed stars. — 449, 450
  - Table of the Fracastorian anomaly. — 451
- XVIII. The theory of the motions of the eighth sphere, and on reconciling its apparent motions toward opposite regions of the world. — 451
  - Our own opinion and hypothesis on the motion of the fixed stars. — 454
  - Three scholia. — 456
- XIX. Selected problems, with new ones here and there, concerning chiefly the declinations and the right or oblique ascensions of the fixed stars. — 457 to 464
- XX. That the right ascension of some fixed stars decreases as their longitude increases; and of which stars, and for how long? — 459, 460
- XXI. Definitions and rules of the risings and settings of the stars, set out with fuller teaching than before. — 465
- XXII. On the risings and settings of the stars noted among the poets or the polymaths, examined both for the first Julian year and for other years; with the authors who have arranged the risings and settings of the fixed stars into tables or into calendars [Faſtos]. — 468
  - Table of the sixfold rising and setting for the year 45 before Christ. — 469
  - A select history of the risings and settings of the stars from Pliny the Elder, Varro, Columella, Ovid, Virgil and others. — 470 to 474
  - The rising and setting of Canicula in various ages. — 471
- XXIII. On the Galaxy, or Milky Circle: its names, its position in the sky, and the opinions of the poets and of the natural philosophers. — 474
- XXIV. A table of seventy fixed stars verified by us for the completed year of Christ 1644, with its use and its extension to other times. — 476 to 479

LIBER VII. DE QVINQVE PLANETIS MINORIBVS.

[Book VII. On the five minor planets.]

SECTIO I. De Planetis Minoribus in Communi.

[Section I. On the minor planets in general.]

CAP.

- I. On the names, symbols and analogies of the planets, with other things distinguished by the number seven. — 480
- II. On the shape of the five planets, and their belts, spots and companions, as observed with the telescope. — 483
- III. On the satellites of Jupiter, or the Medicean Stars, and, on that occasion, on the number of the planets. — 489
    - Five scholia. — 492
- IV. On the order and system of the planets. — 493
- V. On the light of the minor planets. — 495
- VI. On the manner and difficulty of observing the places of the minor planets exactly, and on the error of the ancient tables. — 497
- VII. On the kinds and varieties of motion observed in the five minor planets. — 499
    - Four scholia. — 502
- VIII. The hypotheses by which the motions of the minor planets are usually explained, and the machines by which they are usually represented, are indicated. — 503

SECTIO II. De Motu Longitudinis Saturni, Iouis, & Martis, eiusque Theorica.

[Section II. On the motion in longitude of Saturn, Jupiter and Mars, and its theory.]

CAP.

- I. On the ancient or Ptolemaic hypothesis down to Copernicus, set out in several diagrams. — 505 to 514
    - Table of the dimensions and motions belonging to the Ptolemaic or Alphonsine hypothesis. — 511, 512
    - Eight scholia. — 512
- II. On the threefold hypothesis of Copernicus and of the

CAP.

followers of his. — 514

- Table of the dimensions and motions belonging to the hypothesis of Copernicus. — 517, 518
- Seven scholia. — 519
- III. On the hypotheses of Tycho and of Longomontanus. — 519
    - Dimensions and motions belonging to the Danish hypothesis. — 522
    - Four scholia. — 523
- IV. On the hypothesis of Philips van Lansbergen [Philippi Lanſbergij]. — 523
    - Dimensions and motions belonging to this hypothesis. — 525
    - Five scholia. — 525
- V. On the hypothesis of Kepler and of Boulliau [Bullialdi]. — 527
    - Dimensions and motions belonging to these hypotheses. — 534
    - Four scholia. — 535

- VI. On our own provisional hypothesis of the three superior planets. — 535
  - Dimensions and motions belonging to it. — 539
  - Four scholia. — 540
- VII. On the mutual transformation of the preceding hypotheses, the dimensions of each being carried over into the form of any other hypothesis. Here too an epilogue of the hypotheses, and the elective hypothesis of the mean [Hypotheſis electiua Mediocritatis]. — 541
- VIII. On the method of investigating the first inequality of the three superior planets, that is, the mean motion, the anomaly, the eccentricity and the place of the apogee. — 543
  - Six methods indicated in the same place.
- IX. On the mean motion of the three superior planets. — 551
- X. On the place and motion of the apogee, or aphelion, of the three superior planets. — 552
- XI. On the second, or annual, inequality of the three superior planets. — 553
- XII. On the greatest equations, their places and astronomical tables, with a discussion of the imperfection of the old astronomy in this matter. — 555
  - Five scholia. — 560
  - Table of opinions on the greatest equation of the three superior planets. — 561

SECTIO III. De Motu Longitudinis Veneris, & Mercurij.

[Section III. On the motion in longitude of Venus and Mercury.]

CAP.

- I. On the Ptolemaic, or ancient, hypothesis of Venus and Mercury, down to Copernicus. — 561
  - Dimensions and motions belonging to this hypothesis. — 565
  - Three scholia. — 566
- II. On the Copernican hypothesis of Venus and Mercury. — 567
  - Dimensions and motions belonging to it. — 570
- III. On the Lansbergian hypothesis of Venus and Mercury. — 571
  - Dimensions and motions belonging to it. — 573
- IV. On the Tychonic, or Longomontanian, hypothesis of Venus and Mercury. — 574
  - Dimensions and motions belonging to it. — 576
- V. On the Keplerian and Boulliauian [Bullialdica] hypothesis of Venus and Mercury. — 577
  - Motions and dimensions belonging to it. — 579
  - Two scholia. — 579
- VI. On our own hypotheses of Venus and Mercury. — 579
  - Dimensions and motions belonging to them. — 582

- Two scholia. — 583
- VII. On the greatest digressions of Venus and Mercury from the Sun, and on the equations of the orb. — p. 583
  - Table of the greatest digressions. — 585
  - Table of opinions on the greatest equation of Venus and Mercury. — 586
- VIII. On the technique of investigating the apogee of Venus and Mercury, and its motion and radix. — 586
- IX. Our own attempt at determining the apogee of Venus and Mercury. — 593
  - Two scholia. — 597
- X. On the technique of investigating the eccentricity and the commensuration of the orbs of Venus and Mercury; on which occasion, the greatest digressions again. — 597
  - Three scholia. — 604
- XI. On the motion and epoch of the mean anomaly of the orb, or epicycle, of Mercury and of Venus. — 604
  - Table of the revolutions of Venus and Mercury. — 607

SECTIO IV. De Passionibus Quinque Planetarum in Latitudinem.

[Section IV. On the affections [Paſſionibus] of the five planets in latitude.]

CAP.

- I. Observations and hypotheses of the ancient astronomers on the latitude of the five planets. — 607
  - Tables of the latitudes and of the motion of the nodes. — 611
  - Six scholia. — 611, 615, 618, 620, 622, 626, 631
- II. On the hypothesis of Copernicus and of his followers concerning the latitude of the minor planets. — 612, 630
  - Two scholia. — 616
- III. On the Lansbergian hypothesis concerning the latitude of the minor planets. — 617
- IV. On the Danish hypothesis of the latitude of the minor planets. — 618
  - Three scholia. — 623
- V. On the Keplerian hypothesis concerning the latitude of the minor planets. — 623
  - Five scholia. — 626
- VI. On Boulliau's hypothesis concerning the latitude of the minor planets. — 627
  - Two scholia. — 630
- VII. Our own provisional hypothesis on the latitude of the minor planets. — 630
- VIII. On the technique of investigating the node, the inclinations of the orbit, and the latitudes of the minor planets. — 631
  - 19 problems.

- IX. On the reduction of the place of a planet to its orbit or to the ecliptic, and on curtation. — 641
- X. On the tables of latitude, and their use. — 643

SECTIO V. De Passionibus Planetarum Minorum in Longitudinem.

[Section V. On the affections of the minor planets in longitude.]

CAP.

- I. When are planets said to be slow, swift, increased or diminished in number? — 644
- II. On direct and retrograde planets and their stations. — 645
  - Table of the arcs of station and of retrogradation. — 647, 648
- III. The theory and causes of stations, directions and retrogradations according to the opinion of the ancients. — 648. Here there are 9 theorems and 6 problems.
  - Three scholia. — 653
- IV. The theory and causes of stations, directions and retrogradations in the hypothesis of the moving Earth. — 654. Here there are five theorems and two problems.
  - Five scholia. — 657
- V. On planets that are oriental, occidental, increased or diminished in light, hypaugi [Hypaugis] or combust, and on their emersions, occultations and arc of vision. — 658
  - Three scholia. — 661
- VI. On the rising and setting of the minor planets. — 662
- VII. On the aspects of the planets with the Sun and with one another. — 663
  - Table for the reduction of aspects. — 665. And six problems.
- VIII. On the harmonic configurations, and on the foundation of the aspects in harmonic proportions. — 667
  - Table of aspects. — 669
- IX. On the revolutions of the planets, and the great and greatest conjunctions, and their effects. — 670
  - Table of the great conjunctions. — 673
- X. A history of the great conjunctions and of the changes in the world attributed to them; on which occasion their force is disputed. — 675
  - Two scholia. — 679

SECTIO VI. De Passionibus Planetarum secundùm Altitudinem.

[Section VI. On the affections of the planets according to altitude.]

CAP.

- I. Whether the distance of the planets from the centre of the Earth, or of the world, varies. — 680

- II. How great, and how various, the distance of the minor planets is from the centre of the Earth and from the Sun, according to the different hypotheses. — 681 to 686
  - Table of opinions on the distance of the planets from the centre of the Earth. — 686, 687
  - Table of opinions on the distance of the planets from the Sun. — 687, 688
  - Two scholia. — 688
- III. On the distances of the planets from one another, or from the fixed stars. — 689
  - Table of opinions on the greatest and least distance of the planets from one another and from the fixed stars. — p. 690, 691
  - Table for the shadows of the planets. — 691
- IV. On the altitude, thickness and circuit of the heavens within which the planets wander. — 692
  - Table of opinions. — 692, 693
  - Six scholia. — 694
- V. On the time in which a body moving with uniform motion would descend from the highest heaven of each planet, or from the fixed stars. — 697, with a table of opinions.
- VI. On the speed of the planets, with a table of opinions on it. — 698
  - Three scholia. — 698
- VII. On the parallax of the minor planets, with a table of opinions. — 699, 700
  - Two scholia. — 700
- VIII. Problems on the apparent and the true magnitude of the five minor planets. — 701
  - On the proportion of the bodies of the world, and on the density and bulk of the planets. — 703, 705, 706
  - Three scholia. — 707
- IX. The methods are indicated by which the diameters of the minor planets have been observed, or can be observed, together with the opinions of authors on them and on the true magnitude. — 707
  - Table of opinions on the apparent diameter of the minor planets. — 708
  - Table of opinions on the true magnitude of the minor planets. — 709
- X. Our own observations of the apparent diameter of the minor planets, with their true magnitude. — 710
  - A double table on these. — 713
  - Six scholia. — 715
- XI. Our own and others' observations of the apparent diameter of the fixed stars, deduced from the diameters of the planets, with the true magnitude of the fixed stars. — 715

    - Various tables for these. — 716, 717
- XII. On the size of the greatest digressions of the Jovian satellites from Jupiter, and of Venus and Mercury from the Sun. — 717
- XIII. On the apparent magnitude of the planets, the fixed stars, the Earth and certain orbs, if they were viewed from somewhere other than the Earth. — 718
    - Various tables for these. — 720
- XIV. On mutual and non-mutual eclipses of the planets, through the interposition of bodies or of shadows; with a discussion of the length of the shadows of the planets. — 720
    - Four scholia on the shadow of Saturn and of its companions. — 723

CHRONICON DVPLEX ASTRONOMORVM, VEL ASTROLOGORVM COSMOGRAPHORVM, AVT POLYHISTORVM, Qui Astronomica, vel Cosmographica propiùs attigerunt.

[A twofold chronicle of the astronomers, or astrologers, cosmographers or polymaths, who have dealt more closely with astronomical or cosmographical matters.]

I. PARS Ordine Temporum constructa.

[Part I, arranged in order of time.]

Years before Christ	Entry
1990	Zoroaster [Zoroaſtres], king of the Bactrians.
1590	Prometheus, brother of Atlas.
1580	Atlas, king of Mauretania.
1520	Mercury the Elder [Mercurius Maior].
1480	Hermes the Egyptian.
1445	Endymion of Latmus.
1345	Cepheus, king of the Ethiopians.
1012	Solomon, king of the Jews.
640	Thales of Miletus is born. Polemon flourishes.
570	Thales of Miletus dies, aged 70.
560	Oenopides of Chios.
548	Cleostratus flourishes.
544	Anaximander of Miletus flourishes; born in the year 600.
540	Pythagoras flourishes.
530	Anaximenes of Miletus.
520	Harpalus.
479	Pythagoras is killed, aged 63.
480	Anaxagoras begins to philosophize.
470	Democritus of Abdera.
432	Meton and Euctemon.

Years before Christ	Entry
430	Philolaus of Croton.
428	Plato is born.
420	Anaxagoras dies, aged 72.
405	Archytas of Tarentum, and Timaeus of Locri [Timęus Locrus].
404	Helicon of Cyzicus.
390	Euclid the elder [Euclides ſenior].
384	Aristotle is born.
368	Eudoxus.
360	Metrodorus.
348	Plato dies, aged 81.
330	Callippus [Calippus] begins his period.
322	Aristotle dies, aged 63. Theophrastus succeeds him.
320	Pytheas [Pitheas] of Massalia.
300	Aristyllus, Autolycus, Timocharis [Timochares].
289	Archimedes is born. Archelaus flourishes.
286 [recte: 196, per the book's errata]	Eratosthenes dies, aged 80. [Margin: in a later hand, in ink, "19[6?]" in the left margin, the printed 286 struck through and a curved pen stroke running from the figure up to the 289 entry]
285	Dionysius the astronomer.
284	Euclid of Megara, the younger.
281	Berossus [Beroſus] the Chaldean, until 260.
280	Aratus of Soli, and Aristarchus of Samos.
260	Conon.
240	Apollonius of Perga.
230	Isidorus the cosmographer.
214	Archimedes is killed, aged 75.
168	C. Sulpicius Gallus.
162	Hipparchus of Rhodes, until 128.
136	Hipparchus of Bithynia.
86	M. Varro, and Taruntius Firmanus. M. Tullius Cicero [M. Tull. Cicero].
83	Geminus the astronomer.
60	Posidonius [Poſſidonius].
52	Theodosius of Tripoli.
45	Sosigenes of Alexandria.
40	Cleomedes the elder.
38	M. Agrippa.
35	Manilius the astronomer.
30	Dionysius Afer.
20	Strabo the geographer. Artemidorus the cosmographer.

Years of Christ	Entry
15	Strabo is still living, and Germanicus.
40	Straton of Amasea [Straton Amaſenus].
45	Columella.
47	Pomponius Mela.

Years of Christ	Entry
60	Andromachus, and Marinus of Tyre.
68	Seneca is put to death.
78	Plutarch flourishes, until 104.
70	Ptolemy is born; or 69.
34	St Dionysius the Areopagite, aged 25, observes the miraculous eclipse that took place at the death of Christ; in the year of Christ 52 he is converted to the faith; and at over a hundred, or almost 111 years old, in the year 120 he becomes a martyr.
72	Hyginus, author of the *Poeticon Astronomicon* [Poetici Aſtronomici ſcriptor].
80	Pliny the Elder [Plinius maior], who perished at Vesuvius aged 55.
84	Proclus the elder.
92	Agrippa, an observer in Bithynia.
97	Menelaus, or Milleus.
130	Aquila of Pontus.
132	Theon of Alexandria the elder, and Phlegon.
135	Sextus Empiricus.
147	Ptolemy dies, aged 78.
230	Andruzagar the astrologer.
238	Censorinus of Rome.
298	Rabbi Adda.
314	Julius Firmicus Maternus [Iulius Maternus Firmicus].
320	Valens the astrologer.
360	Theon of Alexandria, father of Hypatia.
378	Paul of Alexandria [Paulus Alexandrinus].
380	Philosophus, an astronomer [Philoſophus Aſtronomus].
390	Cleomedes the younger.
395	Sextus Avienus Ruffus. Macrobius.
400	Pappus of Alexandria.
415	Hypatia is torn to pieces.
434	Aëtius of Amida.
444	St Cyril of Alexandria dies; he had begun his cycle in the year 437.
466	St Prosper of Aquitaine dies.
467	Victorinus.
469	Theodoret [Theodoretus].
490	Cassiodorus, until 528.
500	Simplicius, and Thius of Athens.
514	Proclus Diadochus.
526	Dionysius Exiguus.
600	Martianus Capella.
636	St Isidore of Seville dies.
770	Albinus Flaccus, also called Alcuin.
776	Bede dies, aged 106.
827	al-Maʾmūn [Almamon, ſeu Maimon], king of the Arabs.
846	Egmundus the astrologer.
860	Māshāʾallāh [Meſhala] the Arab.
870	Paul, philosopher and astronomer.
880	al-Battānī [Albategnius] of Raqqa [Aracenſis].
890	Achilles Tatius.

Years of Christ	Entry
936	al-Ṣūfī [Azophi, ſeu Elzuphi].
950	al-Farghānī [Alfraganus] the Arab.
956	ʿAlī ibn Abī al-Rijāl [Haly Aben Ragel].
980	al-Fārābī [Alfarabius] the astrologer.
1024	ʿAlī ibn Riḍwān [Haly Aben Rodoan].

Years of Christ	Entry
1030	Campanus of Novara [Campanus Nouarienſis].
1050	Isaac Argyros [Iſaacius Argyrus].
1070	al-Zarqālī [Arzachel] the Spaniard.
1072	Ibn al-Haytham [Alhazen].
1090	Jābir ibn Aflaḥ [Geber] of Seville.
1100	al-Kindī [Alkindus].
1115	Rabbi Avraham [Rabbi Abraham].
1140	Almeon [Almęon].
1141	Robert of Lincoln [Robertus Linconienſis].
1142	Ioannes Hispalensis.
1149	al-Biṭrūjī [Alpetragius].
1150	Avraham ibn Ezra [Abraham Auen Ezra].
1160	Averroes.
1166	Abū Maʿshar [Albumaſar].
1170	Humenus the Egyptian.
1198	al-Fārābī [Alfarabius] the physician.
1199	Omar the astrologer.
1200	Leopold of Austria [Leopoldus de Auſtria].
1220	Nikolaos Kabasilas [Nicolaus Cabaſilla].
1252	Rabbi Yitzchak Hazan [Rabbi Iſaac Hazan].
1255	Albuassin, or Alboazen.
1256	Johannes de Sacrobosco [Ioannes de Sacroboſco].
1256	King Alfonso X [Alphonſus X. Rex] issues his tables for the second time; he was born in the year 1203, and dies in the year 1284.
1269	Witelo [Vitellio], the Thuringian Pole [Thuringo-Polonus].
1275	Thābit ibn Qurra [Thebit Choræ filius].
1282	Guido Bonatti [Guido Bonatus] the astrologer.
1290	Hendrik Bate [Henricus Baten].
1300	Jacob ben Machir ibn Tibbon [Profatius] the Jew.
1310	Yitzchak Yisraeli [Iſaac Iſraelita].
1317	Pietro d'Abano [Petrus de Apono].
1322	Abū al-Fidāʾ [Iſmael Abilfedea].
1322	Until 1325: Cecco d'Ascoli [Cichus Aſculanus].
1335	Rabbi Levi [Rabbi Leui].
1346	Gherardo da Cremona [Gerardus Cremonenſis].
1360	Marco Beneventano [Marcus Beneuentanus].
1377	Giovanni Boccaccio [Ioannes Boccacius].

Years of Christ	Entry
1380	Johannes de Saxonia [Ioannes de Saxonia].
1381	Jean de Lignières [Ioannes de Linerijs].
1397	Heinrich von Hessen [Henricus de Haſsia] dies.
1416	Pierre d'Ailly [Petrus Aliacenſis].
1423	Georg von Peuerbach [Georgius Purbachius] is born.
1436	Regiomontanus [Io: Regiomontanus] is born.
1438	Gazulus of Ragusa [Gazulus Raguſęus].
1440	Georgios Trapezountios [Georgius Trapezuntius] flourishes; born in the year 1396, he will die in 1486.
1442	Ioannes de Egmunda.
1453	Ermolao Barbaro [Hermolaus Barbarus] is born.
1458	Giovanni Bianchini [Ioannes Blanchinus].
1457	Until 1495: Giovanni Gioviano Pontano [Io. Iouianus Pontanus].
1460	Michael Scot [Michael Scotus].
1462	Peuerbach [Georgius Purbachius] dies, aged 39.
1463	Alessandro Achillini [Alexander Achillinus] is born.
	Giovanni Pico della Mirandola [Io. Picus Mirandulanus] is born.
1464	Cardinal Nikolaus von Kues [Nicolaus Cuſanus Cardin.] dies, aged 63.
1468	Johannes Werner [Io. Vernerus] is born.
1473	Cardinal Bessarion [Beſſarion Cardinalis] died.
1474	Avraham Zacuto [Abraham Zagut].
1475	Ludovicus Vitalis [Ludouicus Vitalis].
1475	Until 1504: Bernhard Walther [Bernardus Valtherus].
	Giovanni Battista Capuano [Io. Baptiſta Capuanus].
1476	Regiomontanus [Io. Regiomontanus] dies, aged 40.
1479	Theodoros Gazes [Theodorus Gaza].
1484	Domenico Maria of Ferrara [Dominicus Maria Ferrarienſis] flourishes, and dies in 1514.
1493	Columbus sets sail for America.
1494	Iacobus Faber.
1495	Christianus Molitoris.
	Lucio Bellanti [Lucius Bellancius].
	Pico della Mirandola [Io. Picus Mirandulanus] dies, aged 33.
	Raffaele Volterrano [Raphael Volaterranus] flourishes.
1499	Marsilio Ficino [Marſilius Ficinus] dies, aged 66.
1500	Stephanus Rosinus.
1501	Jacob Milich [Iacobus Milichius] is born.
1503	Ioannes Muntz.
1506	Bartolomeo Vespucci [Bartholomęus Veſpucius].
1508	Henricus Lindauth.
1510	Johannes Stöffler [Ioannes Stœflerus].
1512	Johannes Angelus [Io. Angelus] the Bavarian dies.
1513	Agostino Ricci [Auguſtinus Riccius], and Paulus of Middelburg [Paulus Middelburgenſis].
1514	Georg Joachim Rheticus [Georgius Ioachimus Rheticus] is born; 1550. A condemned author.
1515	Albert Pigge [Albertus Pighius].
1518	Johannes Homelius [Ioannes Homelius] is born.
1520	Andreas Stiborius.
1523	Francesco Giuntini [Franciſcus Iunctinus] is born.

Years of Christ	Entry
1525	Francisco Sarzosa [Franciſcus Sarzoſus].
	Caspar Peucer [Gaſpar Peucerus] is born.
1526	Heinrich Rantzau [Henricus Ranzouius] is born.
1528	Iacobus Homelius is born.
1530	Johannes Vögelin [Io. Vogelinus] flourishes.
	Peter Apian [Petrus Appianus] flourishes.
	Johannes Garcaeus [Ioannes Garcæus] is born.
	Giovanni Battista Benedetti [Io. Baptiſta Benedictus] is born.
1531	Prosdocimo de' Beldomandi [Proſdocimus de Beldomando] flourishes.
	Oronce Finé [Orontius Finæus] flourishes.
	Luca Gaurico [Lucas Gauricus], until 1557.
1534	Gemma Frisius.
1535	Giovanni Lucido [Ioannes Lucidus].
	Girolamo Fracastoro [Hieronymus Fracaſtorius].
1536	Sebastian Münster [Sebaſtianus Munſterus] flourishes, a condemned author; Johannes Schöner [Io. Schinerus], born in 1477, likewise flourishes.
1536	Until 1542: Giuliano Ristori [Iulianus Riſtorus].
1537	Giovanni Battista Amico [Io. Baptiſta Amicus]; Pietro Pitati [Petrus Pitatus].
1538	Alessandro Piccolomini [Alexander Piccolomineus].
1540	Giovanni Pierio Valeriano [Io. Pierius Valerianus], and Pietro Catena [Petrus Catena].
	Francesco Maurolico [Franciſcus Maurolycus], until 1572.
1542	Lilio Gregorio Giraldi [Lilius Gregorius Gyraldus].
1543	Nicolaus Copernicus dies, aged 71.
1544	Michelangelo Biondo [Michael Angelus Blondus].
1545	Sixtus ab Hemminga.
1546	Tycho Brahe is born.
1547	Heinrich Glarean [Henricus Glareanus].
1549	Ariel Bichardus.
1550	Juan de Rojas [Io. Roias], and Johannes Stabius [Io. Stabius].
1552	Giovanni Antonio Delfino [Io. Antonius Delphinus].
1552	Pedro Nunes [Petrus Nonius] is living; he was born in the year 1492.
1553	Erasmus Reinhold [Eraſmus Reinoldus] dies; he was born in the year 1611[4]
1554	Élie Vinet [Elias Vinetus].
1557	Giovanni Battista Carelli [Io. Baptiſta Carellus].
	Gioseffo Zarlino [Ioſephus Zarlinus].
1558	Jean Fernel [Io. Fernelius] dies.
1560	Valentin Naibod [Valentinus Naiboda]. Federico Commandino [Federicus Commandinus].
1561	Michael Neander, and Daniel Santbech.
1562	Giuseppe Moletti [Ioſephus Moletius].
1563	Lucillo Filalteo [Lucillus Philalthæus].
1566	Pierre de la Ramée [Petrus Ramus], Io. Esler.
1568	Titus à Popma, and Christian Wurstisen [Chriſtianus Vurſtiſius].
1570	Abraham Ortelius [Abrahamus Ortelius].
	William, Landgrave of Hesse [Gulielmus Lantgrauius Haſſiæ].

[4]so printed; a death in 1553 cannot follow a birth in 1611 — Reinhold was born in 1511. In this copy a pen stroke runs through the second figure, and a handwritten figure, apparently a 5, is written above it.

Years of Christ	Entry
	Gerardus Mercator.
1570	Jerónimo Girava [Hieronymus Giraua].
	Francesco Barozzi [Franciſcus Baroccius].
1572	There flourish: Adam Ursinus [Adamus Vrſinus], Andreas Nolthius, Bartholomäus Reisacher [Bartholomæus Reiſacherus], Cornelius Gemma, Cornelius Frangipanius, Cyprián Lvovický [Cyprianus Leouitius], Elias Camerarius, Francesco Maurolico [Franciſcus Maurolycus], Guillaume Postel [Gulielmus Poſtellus], John Dee [Io. Dee], Jerónimo Muñoz [Hieronymus Munoſius], Michael Mästlin [Michael Moeſtlinus], Paul Fabricius [Paulus Fabricius], Paul Hainzel [Paulus Hainzelius], Philipp Apian [Philippus Appianus], Reinhold the Younger [Reinholdus Iunior], Tadeáš Hájek [Thaddęus Hagecius], Theodorus Gramineus, Wolfgang Schuler [Vuolfangus Sculerus].
1576	Erasmus Osualdus [Eraſmus Oſualdus], a condemned author; Sisto da Siena [Sixtus Senenſis]. Daniele Barbaro [Daniel Barbarus], Egnazio Danti [Egnatius Dantes]; Girolamo Cardano [Hieronymus Cardanus] dies, aged 75.
1577	There flourish: Bartholomäus Scultetus [Bartholomæus Scultetus], Giovanni Maria Fiornovelli [Io. Maria Fiornouellus], Nikolaus Winkler [Nicolaus Vuinklerus]; Johannes Praetorius [Io. Prætorius].
1582	Luigi Lilio [Aloyſius Lilius] flourishes.
	Christoph Clavius [Chriſtophorus Clauius].
	Mario Bettini [Marius Bettinus] is born on February 6.
1586	Niccolò Cabeo [Nicolaus Cabæus] is born on February 26.
1587	Joseph Justus Scaliger [Ioſephus Scaliger].
	Giovanni Battista Benedetti [Io. Baptiſta Benedictus].
1588	Ioannes Auria.
	Gellius Sasserides [Gellius Saſſerides].
1589	Giuseppe Scala [Ioſephus Scala], and David Origanus [Dauid Origanus] — but the latter is a condemned author.
1590	Mauro Fiorentino [Maurus Florentinus].
1591	Jacob Christmann [Iacobus Kriſtmannus].
1592	Christoph Rothmann [Chriſtophorus Rothmannus] dies.
1598	Giovanni Battista Riccioli [Io. Baptiſta Ricciolus] is born on April 17.
1600	François Viète [Franciſcus Vieta], Bartolomeo Crescenzio [Bartholomęus Creſcentius].
1603	Johann Bayer [Ioannes Bayerus].
1605	Ioannes Heckius.
1606	Georg Henisch [Georgius Heniſchius], Baldassare Capra [Balthaſar Capra].
1608	Bernardino Salino [Bernardinus Salinus].
	Gulielmus Iansonius [Gulielmus Ianſonius].
	Simon Stevin [Simon Steuinus].
1610	Simon Marius.
	Willebrord Snellius [Villebrordus Snellius].

Years of Christ	Entry
1610	Henricus Samerius, S.J. [Societatis Ieſu], dies, aged 70.
	Matteo Ricci [Matthæus Riccius], S.J., dies; he was born in the year 1552.
1611	Nicolaus Mulerius.
1612	Christoph Clavius [Chriſtophorus Clauius] dies, aged 75.

Years of Christ	Entry
	Joseph Lange [Iosephus Langius].
	Giulio Cesare Lagalla [Iulius Cæsar Lagalla].
	Johann Georg Herwart [Io. Georgius Heruartus].
1614	John Napier [Ioannes Neperus].
1615	Henry Briggs [Henricus Briggius].
	David Fabricius [Dauid Fabricius].
	Rudolf Goclenius [Rodulphus Goclenius].
1617	Redento Baranzano [Redemptus Baranzanus].
	Giovanni Antonio Magini [Io. Antonius Maginus] dies, aged 62.
	François d'Aguilon [Franciscus Aguillonius] died, aged 50.
1618	Johann Baptist Cysat [Io. Baptista Cysatus], S.J.
	Jean Leurechon [Io. Leurechomius], S.J.
1619	Carolus Piso [Carolus Piso].
	Orazio Grassi [Horatius Grassus], S.J.
	Camillo Gloriosi [Camillus Glorioſus].
	Benjamin Ursinus [Beniamin Vrſinus].
	Johannes Deckers [Io. Dekerius], S.J., dies, aged 59.
1620	Alessandro de Angelis [Alexander de Angelis], S.J., dies, aged 58.
1621	Christianus Severinus Longomontanus [Chriſtianus Seuerinus Longomontanus].
1622	Georg Schönberger [Georgius Schombergerus], S.J.
1624	Giuseppe Biancani [Iosephus Blancanus], S.J., dies.
	Io. Adamus, S.J.
1625	Andreas Zergol, S.J.
	Pierre Gassendi [Petrus Gaſſendus].
1626	Vincislaus Pantaleo, S.J.
1627	Kepler [Ioannes Keplerus] issues the Rudolphine Tables [Rudolphinas]; born already from the year 1596 [natus iam ab anno 1596].
	Julius Schiller [Iulius Schillerus].
	Albert Curtz [Albertus Curtius], S.J.
1628	Adriaan Vlacq [Adrianus Vlacq].
1630	Jean-Baptiste Morin [Io. Baptiſta Morinus].
	Peter Crüger [Petrus Crugerus].
	Wilhelm Schickard [Vuilhelmus Schickardus].
	Andrea Argoli [Andreas Argolus].
	Charles Malapert [Carolus Malapertius], S.J., dies.
1632	Adam Tanner [Adamus Tannerus], S.J., dies, aged 60.
1632	Philips van Lansbergen [Philippus Lansbergius] issues his Tables.
1633	Galileo [Galilæus] is forced to abjure his opinion on the motion of the Earth.
	Jacob van Lansbergen [Iacobus Lansbergius] writes in favour of the motion of the Earth.
	Melchior Inchofer, S.J., against the motion of the Earth.
	Martinus Hortensius [Martinus Hortenſius].
1634	Andreas Arzet, S.J.
1635	Johannes Phocylides Holwarda [Io. Phocylides Holuuarda].
1636	Henricus Philippi, S.J., dies, aged 71.
	Christoph Grienberger [Chriſtophorus Griembergerus], S.J., dies.
1640	Johannes Hevelius [Io. Heuelius].
	Fortunio Liceti [Fortunius Licetus].
	Carolus Gontranus.

Years of Christ	Entry
	Balthasar Conradus [Balthaſar Conradus], S.J.
	Willem Blaeu [Gulielmus Blaeu].
	Adriaan Metius [Hadrianus Metius].
1643	Paul Guldin [Paulus Guldin], S.J., dies, aged 56.
1644	Giovanni Antonio Roffeni [Io. Antonius Roffenus] dies, aged 63.
	Pierre Hérigone [Petrus Herigonius].
	Michael Florent van Langren [Michael Florentius Langrenus].
	Giorgio Polacco [Georgius Polaccus].
	Govaert Wendelen [Gotifredus Vuendelinus].
	Albert Linemann [Albertus Linemannus].
1645	Lorenz Eichstadt [Laurentius Eichſtadius].
	Marin Mersenne [Marinus Merſennius].
	Anton. Maria de Reitha.
	Emmanuel Maignan [Emmanuel Maignanus].
1647	Bonaventura Cavalieri [Bonauentura Caualerius] dies.
1649	Francesco Montebruni [Franciſcus Montebrunus] dies.
1650	Christoph Scheiner [Chriſtophorus Scheinerus], S.J., dies.
	Niccolò Cabeo [Nicolaus Cabæus], S.J., dies, aged 64.
1651	Nicolas Caussin [Nicolaus Cauſſinus] dies, aged 70.
	Scipione Chiaramonti [Scipio Claramontius] is living, aged 86.
	Mario Bettini [Marius Bettinus], S.J., is living, aged 69.
	Denis Pétau [Dionyſius Petauius] is living, aged 69.
	Carlo Antonio Manzini [Carolus Antonius Manzinus] is living.
	Niccolò Zucchi [Nicolaus Zucchius], S.J., is living.
	Girolamo Sersale [Hieronymus Sirſalis], S.J., is living.
	Albert Curtz [Albertus Curtius], S.J., is living.
	Georges Fournier [Georgius Furnerius], S.J., is living.
	Vicenç Mut [Vincentius Mutus] is living.
	Io. Drie[?]es, S.J., is living, aged 59.
	Giovanni Battista Riccioli [Io. Baptiſta Ricciolius], S.J., aged 54, issues Volume 1 of the *New Almagest* [Tomum 1. Almageſti Noui].

CHRONICI PARS II. ORDINE ALPHABETICO ET AMPLIORI ERVDITIONE DIGESTA.

[Part II of the Chronicle, arranged in alphabetical order and set out with fuller learning.]

A

Abilfedea: see *Ismael Abilfed.*

Abomasus [Abomaſus], a cosmographer somewhat older than Alhazen [Alhazeno].

Abraham Aben-Ezra [Avraham ibn Ezra] — or, as others write it, *Auen-Hezre*, that is, "son of Ezra" — astronomer and philosopher. He flourished in the year of Christ 1144 or 1150. He wrote a book entitled *Mispate hamazaloth*,

that is, *On the Judgments of the Signs*; the book *Taamin*, that is, *Of Astronomical Reasons*; and a book *On the Luminaries and Critical Days*.

Abraham Zaguth [Avraham Zacuto], most learned in astronomy and a public professor at Carthage in Africa, published the *Great Composition* [Magnam compoſitionem]. Afterwards he taught astronomy at Salamanca, and in both places Agostino Ricci [Auguſtino Riccio] attended his lectures. In his treatise *On the Motion of the Eighth Sphere*, chapters 5, 43 and 46, Ricci makes honourable mention of him, and says that in the year of Christ 1474 Zacuto observed Spica [Spicam Virginis] at 17° 10′ of Libra.

Abraham Ortelius [Abrahamus Ortelius] of Antwerp, Royal Geographer, who deserved supremely well of geography, both by his *Theatrum orbis terrarum*, published in 1570, and by his *Thesaurus geographicus*, a very rich dictionary, which he published in 1587.

Achilles Tatius, bishop of Alexandria, wrote a book *On the Universe*, which contains a most learned *Introduction* [Iſagoge] to Aratus's *Phaenomena*; our Pétau [Petauius] has recently translated it from Greek into Latin in his *Uranologion*, from p. 121. He flourished around the year of the Lord 890; but before he became a Christian he had written love stories about Leucippus and Clitophon [de Leucippo, & Clitophonte]. Photius mentions him in the *Bibliotheca*, codex 87, where he calls him not Statius, as the corrupt codex of Suidas has it, but Tatius.

Adam Tanner [Adamus Tannerus], S.J., of Innsbruck [Oenipontanus], a distinguished theologian and a most vigorous assailant of the heretics,

and for that reason [ob idque] very dear to the Emperor Ferdinand II [Ferdinando II. Cæſari Auguſto] and to the Duke of Bavaria; he was most celebrated at Munich, Ingolstadt and Vienna, where he taught publicly. He also wrote a most learned *Dissertation on the Heavens* and an *Astrologia Sacra*, and he died at sixty, of dropsy and lethargy, on 1632 May 25, in the town of Unken [Vncken] in the Tyrolese domain.

Adam Ursinus [Adamus Vrſinus] of Nuremberg wrote a prognostication on the new star of the year 1572; on it see Tycho's critique in volume 1 of the *Progymnasmata*, p. 781.

Adriaan van Roomen [Adrianus Romanus], a Belgian knight, flourished about the year 1615. He wrote an *Uranographia*, an *Idea mathematica*, *Exercitationes cyclicae*, a work on spherical triangles, and one on Archimedes's book *On the Measurement of the Circle*.

Adriaan Vlacq [Adrianus Vlacq] of Gouda published in 1628 the *Arithmetica logarithmica*, or a hundred chiliads of logarithms, with the logarithms of sines, tangents and secants, for solving astronomical, geometrical and arithmetical problems with wonderful brevity.

Adriaan Metius [Adrianus Metius] of Alkmaar wrote learnedly on the use of the globe in 1640.

Aëtius of Amida [Aetius Amidenus], count and physician, wrote a *Hemerologium on the Significations of the Stars*. Cornarius translated it from

Greek into Latin from the third discourse [ſermone 3.] of the *Tetrabiblos*, chapter 164, and Pétau has recently published it in the *Uranologion*, p. 421. This author flourished in the year of Christ 434.

Agrippa observed the stars in Bithynia in the year of Nabonassar 840 and the twelfth of Domitian, as Ptolemy reports in *Almagest* VII.3 — that is, in the year of Christ 92.

al-Battānī [ALBATEGNIVS], called *Mahometus Tinen* or *Mahumedes Aracensis*, son of Geber Auchanus [Gebri Auchani], son of Cruenus [Crueni], ruler [Dynaſta] of Syria, observed the stars both at Raqqa [Aractæ] and at Antioch in Syria. He corrected Ptolemy, since in his own age the Ptolemaic canons already plainly disagreed with the sky; he therefore constructed new tables of the celestial motions. He wrote a book *On the Science of the Stars*, comprised in 57 chapters, which Plato of Tivoli [Plato Tiburtinus] translated from Arabic into Latin, and which Regiomontanus [Io. Regiomontanus] illustrated with some notes. This author flourished in the year of Christ 879 — that is, of Nabonassar 1627, and the first of Antoninus — as he himself testifies in chapter 51.

Albert Pigge [Albertus Pighius], a German, native of Kampen [patria Campenſis], wrote on the observation of the solstices and equinoxes; on the restoration of the calendar, addressed to Pope Leo X in 1515; a defence of astrology; and a work against certain prognosticators.

Albert Curtz [Albertus Curtius], S.J., a Bavarian born at Munich. In 1627 he put forward a new system of the heavens for disputation at Dillingen. Kepler [Io. Keplerus] admired his talent in the theory of the Moon as a rival to his own, and praised it in his Rudolphine Tables, chapter 25. Now, by order of the Emperor, he is in charge of revising and publishing Tycho's observations. I obtained a few of them from him, thanks to the truly noble generosity of spirit with which he is endowed.

Albert Linemann [Albertus Linemannus], a Prussian by nation and a native of Fischhausen [Fiſchhuſinus], public professor of mathematics at the University of Königsberg [Academia Regiomontana] in Prussia. Recently, in 1644, he published a short work of certain astronomical observations, chiefly of eclipses, which he entitled *Memoria saecularis* [Memoriã Sæcularem].

Albinus Flaccus, surnamed Alcuin [Alcuinus], English by nation, a pupil of Bede and the teacher of Charlemagne [Caroli Magni], learned in every branch of knowledge, flourished in the year 770.

Albohazen, or **Albuassin** [Albuaſſin], wrote a book *On the Motion and Places of the Fixed Stars*, which Rabbi Yehudah [Rabbi Iuda] translated from Arabic into the language of Seville [Hiſpalenſem] and presented to King Alfonso. Moved by its authority, the King adopted al-Battānī's [Albategnij] view of the motion of the fixed stars, as confirmed in that book, and in 1256 substituted other, more correct tables for those issued in 1252 — as Agostino Ricci relates in his book *On the Motion of the Eighth Sphere*, chapter 46, on the report of Avraham Zacuto [Abrahami Zaguthi].

Albubater, an Arab astrologer, is recognized by Giuntini [Iunctino] as belonging to the year 500 before Christ.

Abū Maʿshar [Albumaſar], an Arab astrologer called Jaʿfar [Iaphar], wrote eight treatises *On the Great Conjunctions* and *On the Revolutions of the Years*. He is said to have observed a comet above Venus in the year of Christ 844. But since in that work he says that the sect of the Arabs, or of Mahomet — which is known to have begun in the year of Christ 622 — would not last beyond 544 years, and that its end was imminent, he must have flourished not long before the year of Christ 1166 — even though Sanseuinus [Sanſeuinus] draws him back to the year 830, and Biancani [Blancanus] to the tenth century of Christ. But perhaps there were different astrologers of the same name. Much older was that other one — if indeed he is another — whom Giuntini places, by conjecture, in the year 540 before Christ.

al-Qabīṣī [Alcabitius] the astrologer, or **Alchabich**, set out the elements of astrology in four *Differentiae*, or treatises, which Valentin Naibod [Valentinus Naiboda] illustrated with commentaries.

al-Kindī [Alkindus], philosopher and astrologer, wrote a work *On the Changes of the Seasons* [de Temporum mutationibus], and flourished in the year of the Lord 1100.

Alcuin [Alcuinus]: see Albinus Flaccus.

Alessandro Achillini [Alexander Achillinus] of Bologna, philosopher, wrote *On the Celestial Orbs*; he was born 1463 October 29, at 17^{h} 20^{m} after noon.

Alessandro Piccolomini [Alexander Piccolomineus] of Siena wrote four books *On the Sphere of the World* and one *On the Fixed Stars*, in Italian, which he dedicated in 1539 to the lady Laudomia Forteguerri [Laudomiæ Matronæ Forteguerræ]; and also a *Theory of the Planets*, likewise in Italian, addressed to Cosimo de' Medici [Coſmum Mediceum] in 1558.

Alessandro de Angelis [Alexander de Angelis] of Spoleto, S.J., professor of theology and prefect of studies at the Roman College, wrote five books *Against the Conjecturing Astrologers* [in Aſtrologos coniectores]; he died at Ferrara in 1620, aged 58.

Algazel Abukamad, philosopher and astronomer, wrote in Hebrew a book *On the Lights*, called *Haoroth*.

al-Fārābī [Alfarabius], astronomer, lived in the year of the Lord 980; the other, who was a physician, flourished in 1200.

al-Farghānī [Alfraganus Mahumedes] — or, as it stands in the Palatine Library, *Ametus*, or *Ahemed*, or *Muhamed* son of Ametus [filius Ameti] — was called al-Farghānī from the city of Fragana, according to Jacob Christmann [Iacobus Kriſtmannus]. Christmann shows in chapters 6 and 26 of his commentary that he flourished about the year of Christ 950, in which year he observed the Sun's greatest declination as 23° 35′, and the equinox on the 16th day of the month Adar, or March. He wrote elements of astronomy and chronology, compiled chiefly from Ptolemy. Rabbi Yaakov Anatoli [Rabbi Iacob Antolius]

translated these elements into Hebrew, and Ioannes Hispalensis into Latin from the Arabic in 1142; Conradus Gisnerus [Conradus Giſnerus] and Jacob Christmann illustrated them with commentaries.

Ibn al-Haytham [ALHAZEN], or **Alhazenus**, an Arab, son of Alahizenus [Alahizeni] — a name that means "good man" — wrote seven books of *Optics* and one *On Twilight*. He flourished in the year of Christ 1072, or about 1100, as Friedrich Risner [Federici Riſneri] conjectures; Risner illustrated him with figures and commentaries, and records that there were three other distinguished Arabs of the same name.

al-Maʾmūn [Almamon], or **Alamon**, or **Maimon**, emperor of the Arabs, reigned in Baghdad [Baldach]. In the year of Christ 827 he ordered Ptolemy's *Almagest* to be translated into Latin [in Latinum ſermonem]. Fifty years before al-Battānī [Albategnium], that is, in the year 830, he observed the Sun's greatest declination as 23° 35′, as al-Farghānī [Alfraganus] reports in *Differentia* 6 — where Christmann notes that most writers confuse him with Almeon [Almæone], of whom presently. He is the one who, on the testimony of Abū al-Fidāʾ [Abilfedea] and al-Farghānī, summoned the most skilled geometers of the Arabs and ordered them, in the plains of Fingar [Campis Fingar] near the direct route of the Red Sea, to measure how many Arabic miles are contained in one degree of a great circle of the Earth, as we shall explain in its place. Below, where we treat of Ptolemy, we shall show that the first translation of the *Almagest*, made from Greek into Arabic in the year of Christ 827, is owed to this Maimon.

Almeon [Almæon], son of Albumasar [Albumaſaris], as Christmann has it, or of Almansor [Almanſoris], as Reinhold has it in his *Theory of the Eighth Sphere*, is said to have observed the Sun's greatest declination in the year of the Lord 1140 — or, as others say, 1150 — as 23° 33′ 30″.

Luigi Lilio [Aloyſius Lilius] of Verona, and his brother Antonio Lilio [Antonius Lilius]: among the many who devised a form of a perpetual lunar cycle and of a fixed seat for the equinoxes, he carried off the palm with Gregory XIII, who followed him in the reform of the calendar, so that Clavius [Clauio] and Biancani rightly called him a second Sosigenes of our age. He flourished, accordingly, in 1582.

al-Biṭrūjī [Alpetragius] of Morocco [Marrocitanus], astronomer, flourished between the years of Christ 1145 and 1154; his physical *Theory* was translated from Arabic into Latin by Calo Calonymus of Naples [Parthenopæus].

Alfonso X [ALPHONSVS X.], King of Castile and León, the less fortunate son of the most holy and most fortunate King Ferdinand, yet surnamed the Wise for his skill in philosophy and astronomy. While his father was still living, he had from the year 1240 summoned all the most learned Moors, Arabs and Jews to restore the astronomical tables. He is said to have spent four hundred thousand gold pieces on books, instruments and the maintenance of those men, as Ramus reports in book 3 of the *Scholae mathematicae*, Reinhold in the preface to the *Prutenic Tables* [Prutenicas], and Tycho in the preface to Rudolf II in volume 1

of the *Progymnasmata* — although Boulliau [Bullialdus], in the prolegomena to the *Astronomia Philolaica*, puts 4000 in place of 400000. He succeeded his father, who died at Seville, in 1252, on May 30 [3. Cal. Iunij] — the year in which the Alphonsine Tables first appeared. As regards the motion of the eighth sphere and of the apogees [augium], however, the tables relied on Cabbalistic fictions, since the compiling of them had been directed by Rab- bi Isaac Hazat [Iſaac Hazat], cantor of the synagogue of Toledo [Toletanæ Synagogæ cantor]. But when the King had read the book that Abuassim [Abuaſſim] presented to him, he changed his mind, followed al-Battānī [Albategnium], and in 1256 published more correct tables of the said motion and of the places of the fixed stars. Avraham Zacuto [Abraham Zagutus], in Ricci's treatise *On the Motion of the Eighth Sphere*, and Cardinal Nikolaus von Kues [Cuſanus] testify that they saw these tables. Egnazio Danti [Egnatius Dantes] adds, in part 4 of his *Astrolabe*, that he saw Alfonso's *Book of Instruments* [Librum inſtrumentorum], translated from Arabic into Castilian and from Castilian into Latin. In 1257, at the diet of Frankfurt, Alfonso was elected King of the Romans by some of the electors, while others chose Richard the Englishman [Richardum Anglum]. He never ceased to seek and work for his anointing and confirmation, and to petition the supreme pontiffs Urban IV, Clement IV and Gregory X for the diadem; and, having been rebuffed, he remained hostile to them and to Richard until 1275. In 1260 he had suffered a great defeat at the hands of the Moors, yet in 1263 he wrested from them the island of Galaecia [inſulam Galaeciam], settled colonies of Christians there, built a church of the Holy Cross, and chose it for his burial place. In 1266, moreover, he subdued the Moors of Granada, and he promised a hundred thousand gold pieces to his father-in-law James, King of Aragon, who was preparing a crusade [ſacram expeditionem] to the Holy Land.

Whether because he saw his astrological judgements turn out badly, or because he could not master the anomalies of the celestial motions, he is said to have broken out into the blasphemy of saying that he would have ordered the heavens far better than God had made them, if that charge had been his; and when a holy hermit rebuked him for this in vain, he fell into madness — so some report from the *History of Spain* of Juan de Mariana [Io. Mariannæ]. But Sancius, in part 4 of the *History of Spain*, chapter 5, and after him the *Cathechismus historialis* under the word "Alphonsus", say that he was struck and terrified by a sudden storm of rain-clouds and lightning, summoned the hermit who had admonished him, and confessed his sins with great grief; that at the very moment of absolution the storm ceased; and that he amended his life. I do not know whether this happened before he sinned against the Church. For he unjustly seized church possessions from the Archbishop of Compostela, and for that was rebuked by Pope Nicholas, with threats of anathema and interdict added. And although as an old man he took up a dire war with his son Sancho [Sanctio], yet, so as not to be captured by the Moors at Córdoba, he fled secretly to Seville, and struck his son with a dire curse and with deprivation of

the kingdom — all of which Bzovius [Bzouius] recounts at length in the *Annals* under the year 1282. At last he died at Seville in 1284, on April 21 [11. Calend. Maij], fortified by penance and the Eucharist, aged 81; for he had been born at Medina in 1203, at the sixth hour of the morning, as Giuntini [Iunctinus] has it in his *Astrological Calendar* [Kalendario Aſtrologico]. He ordered that his heart be buried on Mount Calvary. He had read the whole Holy Bible ten times, and four times with its glosses, as Génébrard [Genebardus] has it under Urban IV, and Trithemius in the *Catalogue* under the year 1270.

Anaxagoras of Clazomenae [Anaxagoras Clazomenius] began to philosophize in the twentieth year of his age, which was the first year of the 75th Olympiad, or 480 before Christ; and he died aged 72, namely in 428 before Christ, in the 88th Olympiad — granted that the corrupt codex of Laertius has 78. Apollodorus, however, says in the *Chronicles* that he lived only 62 years. On the testimony of Plutarch in the *Nicias*, he incurred the hatred of the Athenians and was thrown into prison because he was the first to teach openly that an eclipse of the Moon is a privation of the light received from the Sun. Laertius, by contrast, says this happened because he had been accused of impiety by Cleon for having said that the Sun is a glowing plate [candentem laminam]; and that, though defended by Pericles, he was nevertheless fined five talents and exiled. He used to say that there are valleys, mountains and dwellings in the Moon.

Anaximander of Miletus [Anaximander Mileſius] was in his 64th year in the second year of the 58th Olympiad, and died shortly afterwards. If we follow Apollodorus in the *Chronicles*, he was born in the third year of the 42nd Olympiad, namely 610 before Christ, and flourished in 544. He said that the Moon shines with light from the Sun, and that the Sun is equal in size to the Earth. He was the first to set up a gnomon, at Sparta [Lacedæmone], for observing the equinoxes and solstices by the shadow of the Sun, as Laertius relates. Pliny the Elder adds, in book 2, chapter 8, that in the 58th Olympiad he was the first to detect the obliquity of the zodiac, and so in a manner opened the doors of astronomy. He was the first to publish a map of the world [de ſitu orbis tabulam], as Strabo says in book 1. Giuntini wrongly draws him back to the year 737 before Christ.

Anaximenes of Miletus [Anaximenes Mileſius], a pupil of Anaximander, said that the stars move in a circle not above the Earth but around it. In a letter he wrote to Pythagoras he complains that he was prevented from searching out the secrets of the heavens by constant fear of death at the hands of the tyrants of Miletus, or of slavery under the king of the Medes. He flourished about 530 before Christ.

Andreas Nolthius of Einbeck [Embeccenſis], mathematician, wrote on the New Star of 1572 at about the same time, addressed to the Landgrave of Hesse; on him see Tycho, volume 1 of the *Progymnasmata*, p. 750.

Andrea Argoli [Andreas Argolus], devoted to astronomy and astrology, wrote *Ephemerides* from 1630 to 1700, and also the *Pandosium sphaericum*; he was still living in 1646.

Andreas Arzet, of the Society of Jesus, of Konstanz [Conſtantienſis], published a *Clavis mathematica* in 1634, and observed the stars, very diligently indeed, for as long as his business and his gout [chiragram] allowed — as I noticed from the observations he most generously shared with me, above all those of eclipses.

Andreas Stiborius [Andreas Stöberl], a Bavarian [Boius], a most acute philosopher, theologian and astronomer, canon of Vienna, wrote an epitome of al-Battānī [Albategnij], of the *Almagest* and of Jābir ibn Aflaḥ [Gebri], and much else. He flourished under the Emperor Maximilian.

Andreas Zergoll, of the town of Santa Croce [S. Cruce] in the territory of the Carni [in finibus Carnorum], of the Society of Jesus, taught mathematics, moral theology and Sacred Scripture at Graz [Græcij] in Styria. In 1625 he put forward *Chronological Theorems* on the years of the birth and death of Christ, maintaining that Christ was born in the Julian year 40 and died in 74, on March 25.

Andromachus of Crete [Andromachus Cretenſis] flourished in the first century of Christ and, if we believe Clavius [Clauio], was the first inventor of the *Theoricae*.

Andruzagar, an astrologer, flourished in the year of Christ 230, as Giuntini has it in his *Catalogue*.

Anton Maria Schyrleus de Rheita [Antonius Maria Schyrlæus de Reitha], a Capuchin preacher and an astronomer of some note, wrote in 1645 a book on astronomy entitled *Oculus Enoch et Eliae*, or *Radius sidereomysticus*.

Apollonius of Myndus [Apollonius Myndius], on Seneca's testimony, studied with Epigenes among the Chaldaeans, among whom, he said, there were observations of 720 years inscribed on baked tiles [coctilibus laterculis].

Apollonius of Perga [APOLLONIVS Pergęus], born at Perga, a city of Pamphylia, called the great geometer, wrote four books of *Conics*, in which he also advanced astronomy. He flourished under Ptolemy Euergetes, about 240 before Christ, as Heraclius says in the *Life of Archimedes*.

Aquila Ponticus, a native of Sinope, the homeland of Diogenes, was a distinguished mathematician under the Emperor Hadrian, about the year of Christ 130, as is gathered from St Epiphanius's book *On Measures and Weights*. But at length, expelled from the Church for the vanity of judicial astrology, he went over to the Jews, was circumcised, and translated the Old Testament into Greek with little integrity.

Aratus, an astronomical poet, son of Athenodorus and Letophila, was not of Tarsus by birth, as Asclepiades held, but of Soli — that is, of the city of Pompeiopolis in Cilicia, formerly called Soli — as most hold of him, with Callimachus. He flourished under Antigonus Gonatas, King of Macedonia, that is, in the 125th Olympiad, which was celebrated in 280 before Christ. He wrote the *Phaenomena*, or appearances of the risings and settings of the stars, with

prognostics, which many have illustrated with commentaries or expositions — above all Germanicus, Rufus Festus, Cicero, Hyginus and Achilles Tatius. Giuntini, however, in his *Catalogue* moves Aratus back as far as 588 before Christ.

Archelaus, a geographer, described the part of the world traversed by Alexander the Great, and flourished shortly after him. Diogenes Laertius [Diog. Laert.].

Archimedes of Syracuse [ARCHIMEDES Syracuſius] was distinguished not only in arithmetic — by which he comprehended the number of the sand even if it filled the whole world — and in geometry, in which he above all investigated the circle, the sphere, the cylinder and the parabola, but also for his skill in astronomy. "For when Archimedes" — the words are Cicero's, *Tusculan Disputations* 1 — "*bound the motions of the Moon, the Sun and the five wandering stars into a sphere, he did the same as the god in Plato's* Timaeus *who built the world, so that a single revolution governed motions most unlike in slowness and speed*." Claudian sings in his celebrated epigram that this sphere was of glass:

Iuppiter in paruo cùm cerneret æthera vitro &c. ["When Jupiter saw the heavens in a little glass," etc.]

The same Tully asserts in *Tusculan Disputations* 5 that when he was quaestor in Sicily he discovered at Syracuse, by the Agraian gates [ad portas Agraianas], the tomb of Archimedes with the sphere and the cylinder. And Livy too, in book 24, describing Syracuse besieged by Marcellus, says: "*And the undertaking, begun with such force, would have succeeded, had not one man been at Syracuse at that time: it was Archimedes, a unique observer of the sky and the stars, but more wonderful as an inventor and builder of engines of war and siege-works*," etc. On his machines and his other distinctions, however, see Pliny the Elder, book 7, chapters 8 and 37; Vitruvius, book 9, chapter 5; Proclus, book 2, chapter 3; Petrus Ramus, book 1 of the *Scholae mathematicae*; and David Rivault [Dauid Riualtus] in the *Life of Archimedes*. It is agreed, moreover, that Archimedes was killed in the storming of Syracuse, against the will of Marcellus, while he was intent on contemplating certain figures drawn in the dust, in 212 before Christ. Archimedes was of the royal stock of Hiero, on Plutarch's testimony; and from the stock of Archimedes sprang St Lucy, the renowned virgin and martyr, as Rivault teaches, who adds that he was born in 289 before Christ and killed in 214, though others say 212. Ob- servations of Archimedes on celestial matters are also mentioned by Ptolemy, *Almagest* III.2.

Archytas of Tarentum [Archytas Tarentinus], a noble Pythagorean and most expert in mathematics, whom Plato sailed to Italy to meet, together with Timaeus, as Cicero reports. He excelled in mechanics, and by their power defeated his enemies in battle five times — to say nothing of the wooden dove that he made fly by means of counterweights [libramentis]. That he also excelled in cosmography and practical geometry is indicated by the lines of Horace, *Odes* book 1:

Te Maris ac Terræ numeroq; carentis arenæ Menſorem cohibent Archyta. ["You, Archytas, measurer of the sea and the land and of the sand that has no number, are confined…"]

Ariel Bicard [Ariel Bicardus] published in the year of our salvation 1549 a collection of his own *Questions on the Sphere of Sacrobosco* [quæſtiones in Sphæram Sacrobuſchi], and dedicated it to his fellow godfather [compatri ſuo] Anton Müller [Antonio Mullero].

Aristarchus of Samos [ARISTARCHVS SAMIVS] flourished 140 years before Hipparchus, that is, about 280 before Christ. For, as Ptolemy relates from Hipparchus in *Almagest* III.2, Aristarchus observed the solstice in the 50th year of the first Callippic period, which began in 330 before Christ. From this I gather that the Cleanthes who, on Plutarch's testimony in the book *On the Face in the Moon*, summoned Aristarchus to trial for having moved the sacred Hearth of Vesta [Sacra Veſtę] from its place — that is, for having asserted that the Earth moves around the Sun — was the one who succeeded Zeno the Stoic in the 129th Olympiad, that is, in 264 before Christ. There survives, moreover, a most learned little work of Aristarchus *On the Distances and Magnitudes of the Sun, the Moon and the Earth*; and there is mention of him, as moving the Earth and removing the fixed stars to an immense distance, in Archimedes's *Sand-Reckoner* [Arenario]. Less correctly, Biancani [Blancanus], in the *Chronology of the Mathematicians*, makes Aristarchus 200 years older than Hipparchus.

Aristyllus [Ariſtillus], an astronomer, observed the fixed stars around the time of Timocharis, as stated in Ptolemy, *Almagest* VII.3 — namely about 300 before Christ.

Aristotle [Ariſtoteles], who deserved not badly of astronomy in his books *De caelo*, was born in the 99th Olympiad, that is, in 384 before Christ, and died at Chalcis aged 63, in the third year of the 114th Olympiad, namely 322 before Christ, as is gathered from Laertius.

Artemidorus, an ancient cosmographer, is mentioned by Pliny the Elder and Strabo, who praises his geographical work; and he was himself a contemporary of Strabo.

al-Zarqālī [Arzachel], a Spaniard, 190 or 193 years after al-Battānī [Albategnium], observed the Sun's greatest declination as 23° 34′ — that is, in the year 1070 or 1073 before Christ [ante Chriſtum]. Ibn Ezra [Aben Ezra] writes of him, in the book entitled *Initium sapientiae* [The Beginning of Wisdom], that no one in that age was to be compared with al-Zarqālī in observing the motions of the heavens, and he acknowledges that he himself was 71 years later. Some make him a native of Toledo; he was also called Abraham Elzara Keel. Georg Joachim Rheticus [Georg. Ioachimus Rheticus], in the preface to his *Ephemerides*, says that he was the author of the Toledan Tables, and that he left 402 solar observations for establishing the Sun's apogee.

Ascanio Martinengo [Aſcanius Martinengus] of Brescia [Brixianus], Abbot General of the Lateran Canons: besides what he most learnedly published, about

the year 1600, in the *Glossa magna* on the heaven and the stars created by God, he also wrote a *Geography of the Holy Land* and composed a notable *Chronology*.

Athanasius Kircher [Athanaſius Kircher], of the Society of Jesus, a native of Fulda [patria Fuldenſis], astonishingly expert in philosophy, in mathematics, and in the Hebrew, Greek, Arabic and Egyptian languages and several other Oriental ones, and now very well known throughout Europe for works of varied and recondite learning, is still living and flourishes at Rome, esteemed by the Emperor and by the Supreme Pontiff. To me he is above all a friend in astronomy [amicus Vranicus], to whom I acknowledge that I owe, among many things, a great many observations collected from everywhere, especially of eclipses. Of his works, those that come closest to astronomy or cosmography are an excellent work *Magnes*, another entitled *Ars magna lucis et umbrae*, and the very recently published *Musurgia*.

Atlas, King of Mauretania, is held by Pliny the Elder, book 2, chapter 8, and by Diodorus Siculus, book 4, to have been the inventor of the sphere, and for that reason to have held up the heavens on his shoulders. If you listen to Eusebius, he flourished about 1640 before Christ; Sansovino [Sanſouinus] puts him in 1715; but more truly he flourished about 1580, when Moses had already been born, according to our *Chronology*.

Averroes [Auerrhoes] would deserve a place in this catalogue on no other ground than that he reduced Ptolemy's *Almagest* to an epitome, in the twelfth century of Christ.

Agostino Ricci [Auguſtinus Riccius] of Casale [Caſalenſis] published in 1513, in the city of Casale Sant'Evasio [Caſalis Sancti Euaſij], a most learned treatise *On the Motion of the Eighth Sphere*, which he dedicated to William, Marquis of Montferrat [Gulielmo Marchioni Montiſferrati]. In that work he declares that he learned astronomy at Carthage and Salamanca from Avraham Zacuto [Abrahamo Zagutho]. He also wrote to Galeotto del Carretto [Galeotum de Carreto], of the marquises of Savona, a letter *On the Authors of Astronomy*, showing that astronomy derived from the Hebrews.

Autolycus of Pitane [Autholycus Pritanęus], from Aeolis [ex Acolide], the teacher of Arcesilaus, flourished in the 120th Olympiad, on the testimony of Laertius in the *Arcesilaus* — that is, about 300 before Christ. He wrote both *On the Moving Sphere* and *On the Various Risings and Settings of the Stars*.

al-Ṣūfī [Azophi], or **Elzuphi**, or **Ebennezophim**, an Arab, author of the Persian Tables, in which the figures and the places of the stars are set out, flourished in the year of the Lord 1062, as some think; but Boulliau [Bullialdus], in the prolegomena to the *Astronomia Philolaica*, draws him back to the year 936.

B

Baldassarre Capra [Balthaſſar Capra] published in 1606 at Padua the *Tyrocinia astronomica*.

Balthasar Conrad [Balthaſſar Conradus], of the Society of Jesus, of Neisse [Niſſenſis], taught philosophy and mathematics at Olomouc [Olomuncij], and in 1640 published a new method of cosmographical maps in a right cone, whose base is the equator. I also have an observation of an eclipse that he sent me.

Bartolomeo Crescenzio [Bartholomæus Creſcentius], a Roman, brought out in 1602 the *Nautica Mediterranea*, a work not without use to cosmographers.

Bartholomäus Pitiscus [Bartholomæus Pitiſcus] of Grünberg [Grumbergenſis] in Silesia: besides the *Great Canon of Sines, Tangents and Secants* [Magnum Canonem Sinuum, Tang. & Secantium], which he extended, at the beginning and end of the quadrant, to every single second, using a radius of 12 figures [Radio cyphrarum 12.], he published in 1612 ten books, partly on the measurement of triangles, partly of geodetic, altimetric, geographical, gnomonic and astronomical problems.

Bartholomäus Scultetus [Bartholomæus Scultetus Gorlicienſis] of Görlitz wrote astronomically and astrologically on the comet of 1577; on it see Tycho's critique in volume 2, p. 369.

Bartholomäus Reisacher [Bartholomæus Reiſacherus], professor of mathematics at Vienna in Austria, wrote on the new star of 1572; on him see Tycho, volume 1 of the *Progymnasmata*, pp. 530 and 746.

Bartolomeo Vespucci [Bartholomæus Veſpuccius] of Florence wrote on the *Sphere* of Sacrobosco and, in 1506, *On the Praises of Astrology*; and he professed astronomy at Padua.

The Venerable Bede [Beda Venerabilis], an Anglo-Saxon from Cambridge [ex Cantabrigia], was steeped in the whole circle [Encyclopedia] of very many sciences, and above all knowledgeable in astronomy, as his books *On the Sphere*, *On the Reckoning of Time* and *On the Cycles of the Moon* show, together with very many other small works of this kind. Trithemius says that he died aged 72, in the year of the Lord's Incarnation 732, on May 31 [pridie Calend. Iunij], and that he was not blind; Sixtus of Siena, however, says that he died in 734, aged 62; but Baronius and Spondanus prove from Bede's own letters that he died in 776, aged 106.

Benjamin Ursinus [Beniamin Vrſinus], of the Mark [Marchicus], an astronomer, flourished in 1619.

Bernardino Salino [Bernardinus Salinus], of the Society of Jesus, from the diocese of Vercelli, died in 1608. Among other things he wrote on various astronomical problems; his works are preserved at Genoa in our College. He taught philosophy three times at Milan, and was a man of wonderful simplicity and of no common zeal against the heretics.

Bernhard Walther [BERNARDVS VVALTHERVS] of Nuremberg, a pupil of Regiomontanus [Io. Regiomontani] and continuer of his observations at Nuremberg, with both armillary spheres [Armillas] and parallactic rules [Regulas Parallacticas], did not cease, from 1475 to 1504, to observe both the meridian altitudes of the Sun and the places of the other planets. The last of these observations was made on 1604 May 30 [30. Maij Anni 1604.] [recte:

1504 — the entry itself runs his observations from 1475 to 1504, and he died a few days after the last], of Mars at about 20° of Leo. Not many days after it he died, an excellent old man — just as Tycho too stepped toward death from an observation of Mars. His observations, together with those of Regiomontanus, were first published at Nuremberg, and afterwards, together with the Hessian and Tychonic observations, by Willebrord Snellius [Villebrordo Snellio].

Berossus the Chaldaean [Berosus Caldæus] flourished in the times of Antiochus Soter, about the 130th Olympiad, namely from 281 to 262 before Christ. On his assertion, the Chaldaeans preserved astronomical observations of 480 years inscribed on baked bricks — granted that Alexander the Great, when Babylon was taken, preferred to all the spoils the observations of 1903 years made and found there. We shall explain his opinion about the Moon in its place, from Vitruvius, book 9, chapter 4, where Vitruvius says that he spread the mathematical disciplines from Chaldaea into Asia. Pliny the Elder, moreover, in book 7, chapter 37, relates that the Athenians, on account of his divine predictions, publicly set up a statue with a gilded tongue to Berossus the astrologer in the Gymnasium. Take care not to confuse him with that most ancient Berossus — whether historian or fabulist — whom Eusebius places in 1272 before Christ, as a contemporary of Orpheus and Musaeus.

Bessarion [Beſſarion Cardinalis Nicænus], Cardinal of Nicaea, Patriarch of Constantinople, among other things wrote a canon of the stars with the Alphonsine numbers corrected. He founded at Venice a notable library, of which Marcantonio Sabellico [Marcus Antonius Sabellicus] is the keeper. He died in 1437 [Anno 1437.].

Boethius [Boetius]: see Severinus [Seuerinum].

Bonaventura Cavalieri [Bonauentura Caualerius] of Milan, a Jesuate [Ieſuatus], a pupil of Galileo [Galilæi], principal professor of mathematics in this University of Bologna. He published an *Uranometria*, a *Practica astrologica*, and a *Centuria problematum*, among which are many astronomical and cosmographical problems, and much else, by which he left the keenness of his talent and judgement on record. He would have left more monuments, had not gout of the hands and feet [chiragra, & podagra] confined him repeatedly to his bed for nearly 12 years, and at last snatched him from us — from us, I say, who often found in that most friendly and most learned man no mean help and encouragement in our astronomical studies. He died at Bologna on 1647 December 3.

C

Callippus of Cyzicus [CALIPPVS CYZICENVS], a distinguished astronomer — on his system of the celestial spheres, Aristotle, *Metaphysics* 12, text 47. He devised a lunisolar cycle or period of 76 years, compounded of four Metonic cycles, but corrected. He began its first year from the beginning of the monarchy of the Greeks, that is, from 330 before Christ, when he himself flourished together

with Alexander the Great and Aristotle. His period is frequently mentioned by Ptolemy in the *Almagest*, especially III.2 and VII.2 and 3.

Camillo Gloriosi [Camillus Glorioſus Gifonenſis], of Giffoni, professor of mathematics at Padua, wrote learnedly on comets in 1619.

Campanus of Novara [Campanus Nouarienſis], an astrologer and astronomer famous in his own age — that is, in the year of Christ 1030, not 1200 — devised a particular method of erecting a celestial figure by division of the prime vertical, which Gazulus followed. He wrote a *Theorica planetarum*, *On the Sphere*, *On the Computus*, etc.

Carlo Antonio Manzini [Carolus Antonius Manzinus] of Bologna, doctor of philosophy, most expert in astronomy, and a very dear friend of mine, published in 1626 *Tables of the Primum Mobile* [tabulas primi Mobilis] with a new art of directing and a compendium of directions. He is now preparing *Theoricae planetarum* with tables, does not cease from astronomical observations, and is still flourishing in 1651.

Carolus Gontranus, doctor of the Sorbonne, General of the Congregation of the Oratory, distinguished for learning and piety, wrote a little book in favour of astrology — but sound astrology — and flourished in 1640.

Charles Malapert [Carolus Malapertius], a Belgian, native of Mons [domo Montenſis], of the Society of Jesus, born in 1581, taught mathematics in Poland and at Douai [Duaci], and was to teach at Madrid [Matriti] had he not died on the journey — at Vitoria [Victoriæ], in November 1630. Among other mathematical monuments he published a little work on sunspots, which he entitled *Austriaca sidera heliocyclia, astronomicis hypothesibus illigata*.

Carolus Piso [Carolus Piſo], a Frenchman, wrote a *Speculum cometae* [ſpeculum Cometæ] in 1619.

Cassiodorus [Caſſiodorus], a man of consular rank and *clarissimus* under the Emperor Anastasius and King Theodoric, flourished from 490 to 528. When Theodoric was dead, he became a monk of the monastery of Classe [Claſſenſis Cęnobij], and wrote a few things on astronomy and on the ecclesiastical computus.

Censorinus [Cenſorinus], a Roman, wrote *On the Birthday* [de die Natali], addressed to Q. Caerellius [Q. Cærellium], in the year 1014 from the first Olympiad, that is, of Christ 238, as is had from his own chapter 8. In that little work, full of learning, some things bear on the harmonic system of the heavens, and more on the reckoning of time.

Cepheus, King of the Ethiopians, was translated into the heavens with his wife Cassiopeia and his daughter Andromeda because he was a distinguished observer of the stars, as stated in Lucian, *On Astrology*, and in Tycho, volume 1 of the *Progymnasmata*, p. 309. He flourished in 1345 before Christ.

Claudius Ptolemy [Claudius Ptolemæus]: see under the letter P, Ptolemy [Ptolemæum].

Cleomedes: there were two. One flourished shortly after Posidonius [Poſſidonium], in the century before Christ, and wrote two books *On the Sphere*,

entitled κυκλικῆς θεωρίας μεθεωρῶν [Greek: kyklikēs theōrias metheōrōn, printed thus for meteōrōn, the usual form of the title, "of the circular theory of the heavenly bodies"], as well as an *Arithmetic* and a *Harmonics*. The other flourished under Theodosius the Younger, about the year 390. But Robert Balfour [Robertus Balforeus], his scholiast, places the former between Posidonius and Ptolemy; although Kepler [Keplerus] and Mästlin [Mœſtlinus] confused the later with the former, and for that reason were rightly charged with parachronism [parachroniſmi] by our Bettini [Bettino], as we shall say in book 5, chapter 5, number 16.

Christianus Molitoris of Klagenfurt [Clagenfurtenſis], a distinguished astronomer, wrote astrological opuscula at Vienna, and died of the plague at Vienna in 1495.

Christian Wurstisen [Chriſtianus Vurſtiſius] of Basel [Baſileenſis], professor of mathematics in the Academy of Zurich [in Academia Tigurina], wrote in 1568 learned *Questions on the Theoricae of Peuerbach* [quæſtiones in Theoricas Purbachij].

Longomontanus [Chriſtianus Seuerini LONGOMONTANVS], a Dane, Tycho's companion and helper in restoring astronomy, and professor of mathematics in the University of Copenhagen [Academia Hafnienſi]. For eight whole years at Uraniborg [Vraniburgi] he not only took part in Tycho's astronomical labours [laboribus Vranicis] but for the most part directed them; and he helped Tycho above all in reforming the catalogue of the fixed stars [canone Fixarum], and in the theory of the Moon, which was then begun and afterwards completed in Bohemia in 1599 and 1600. His *Astronomia Danica* survives, a truly outstanding work, with an appendix on the new phenomena of the heavens, which he published in 1621.

Christoph Clavius [CHRISTOPHORVS CLAVIVS] of Bamberg, of the Society of Jesus, teacher of Grienberger [Griembergeri] and of Biancani [Blancani], revealed his outstanding aptitude for mathematics at Coimbra [Conimbricæ]. Sent from there to Rome, he so excelled in it that certain very learned Germans were glad to go to Rome for this reason too — to meet Clavius in person, among others — while others said that they would rather be blamed by Clavius than praised by others. Tycho by letter, Magini [Maginus], and very many distinguished mathematicians consulted him like an oracle. And Father Petrus Antonius Rauizza, my teacher in theology, used to assure me, when he was urging me to cultivate mathematics as well, that Clavius had brought our Society no less authority and distinction in this science than Suárez [Suario] had in theology. Finally, he alone out of all was chosen by the Supreme Pontiff Gregory XIII to expound the reform of the calendar according to the form of Lilio [iuxta Lilianam formam], which he did most brilliantly; and he defended it admirably against Mästlin [Mœſtlinum] and Joseph Justus Scaliger [Ioſephum Scaligerum]. What he wrote on the *Sphere* of Sacrobosco, on the *Sphaerica* of Theodosius, on the astrolabe, on gnomonics, on arithmetic and practical geometry, on algebra, on the doctrine of triangles, and in other works, is, for

its exceptional clarity joined with solid learning, brighter than the Sun — so that this man's authority has no need of our eulogy. There was in him no less humility of mind and sincerity of most religious conduct than learning. He died at Rome in 1612, on February 5, after midnight, aged 75.

Christoph Grienberger [Chriſtophorus Griembergerus], of the Society of Jesus, born at Hall [Oenohalæ] in the Tyrol, a most deserving pupil of Clavius and afterwards his successor in the Roman chair, contributed much not only to the astrolabe and to sundials, on the testimony of Clavius himself, but also to trigonometry and to astronomy — above all by compiling a catalogue of the fixed stars [Catalogo Affixarum] and comparing their old longitudes and latitudes with the new. He died at Rome on 1636 March 11. He was a man of wonderful candour, gentleness, obedience and humility.

Columbus [Chriſtophorus Columbus], a Ligurian, is called by Biancani in the *Chronologia mathematicorum* the prince of the more recent Argonauts, and is said to have discovered the New World relying on astronomy and geography. Certainly, by threatening the barbarians with an eclipse of the Moon on 1493 October 22, he obtained provisions from them.

Christoph Scheiner [CHRISTOPHORVS SCHEINERVS], of the Society of Jesus, a Swabian, native of Mindelheim [domo Mundelheimenſis], professed the sacred language and mathematics at Freiburg and Ingolstadt. Then, at Rome, for some years he observed with particular care the solar spots that he had earlier discovered at Ingolstadt. Finally, as rector of the College of Neisse [Collegij Niſſenſis] in Silesia, he died in 1650. His more notable works are the *Oculus, sive fundamentum opticum*, the *Sol ellipticus*, the *Disquisitiones mathematicae*, the *Apelles post tabulam*, and the *Rosa Ursina*, in which he wrote on the spots of the Sun so exquisitely and learnedly that Descartes [Renatus de Cartes] and Hevelius [Heuelius] have testified that nothing more excellent could be done in that kind, or be expected from anyone else.

Christoph Rothmann [Chriſtophorus Rothmannus], mathematician of William, Landgrave of Hesse [Vuilhelmi Lantgrauij Haſſiæ], observed the stars at Kassel [Caſſellis] at the same time as Tycho at Uraniborg. In the first volume of Tycho's *Epistolae* there survive many letters of his to Tycho, and of Tycho to him, containing astronomical controversies, besides what he wrote on comets. He died in 1592.

Cecco d'Ascoli [Cichus Aſculanus] wrote on the *Sphere* of Sacrobosco, and taught astronomy publicly at Bologna from 1322 to 1325. He was a most acute physician, philosopher and astrologer — and, as was commonly reported, a necromancer and suspected of heresy — and was burned at Florence in 1328, aged 70. But Sebastiano Antonelli of Ascoli [Sebaſtianus Antonellus Aſculanus], in his *Apology for Cecco*, tries to show that he was unjustly put to death through the envy of a rival.

Cleostratus of Tenedos [Cleoſtratus Tenedius] divided the zodiac into 12 signs, according to Pliny the Elder, book 2, chapter 8, and instituted the octaeteris [Octaeterida] in the 58th Olympiad, that is, in 548 before Christ.

Columella, by forename Moderatus [Moderatus prænomine], in book 9 of *On Agriculture* [de re ruſtica], a calen- dar [darium] of astrology, with prognostics; and he lived about the year 45 of Christ.

Conon, geometer and astronomer, lived under Ptolemy Philadelphus. He invented the story that the Lock of Berenice [Comam Berenices], wife of Ptolemy, had been carried up into heaven, bringing in a new star under her name. He wrote six books on astrology and was a contemporary of Archimedes, who in his book on the quadrature of the parabola laments his death; he therefore flourished about 260 before Christ. Of him Virgil, Eclogue 3: *"In the middle, two signs: Conon, etc."* [*In medio duo ſigna: Conon &c.*]. As Seneca says (*Natural Questions* 7, ch. 3), he collected the eclipses observed by the Chaldaeans.

Cornelius Gemma [Cornelius Gemma Louanienſis] of Leuven, son of Gemma Frisius [Gemmę Friſij], wrote on the new star of 1572; on which see Tycho, *Progymnasmata* vol. 1, p. 553.

Cornelio Frangipane [Cornelius Frangipanus] wrote on the new star of 1572; on which see Tycho's critique, *Progymnasmata* vol. 1, from p. 741.

Cyprián Lvovický [Cyprianus Leouitius], sprung from the Bohemian family of Leowitz [ex Leouitia Bohemorum familia], published astronomical observations together with an astrological judgement on the new star of 1572; on these Tycho should be consulted, *Progymnasmata* vol. 1, p. 705. He is said to have been born in 1524, on July 8, at $21^{h}\ 52^{m}$.

St Cyril of Alexandria [S. Cyrillus Alexandrinus] was made bishop in the year 412 before Christ [ante Chriſtum] [recte: after Christ], and died in 444 on June 9 [5. idus Iunij]. In 437 he began his Paschal cycle of 104 years.

D

Daniele Barbaro [Daniel Barbarus Aquileienſis Epiſcopus], bishop of Aquileia: how knowledgeable he was in astronomy is shown by his most learned commentaries on Vitruvius, above all on Book 9 and toward the end of Book 10, which he published in 1576.

Daniel Santbech of Nijmegen [Nouiomagus] published in 1561 excellent *Problemata Astronomica et Geometrica*, divided into seven sections.

David Fabricius, a Frisian astronomer, wrote prognostications for the years 1615, 1616 and 1617, on which see Kepler in his *Ephemerides*, from p. 16.

David Origanus of Glatz in Silesia [Glacenſis ex Sileſia], professor of mathematics at Frankfurt on the Oder [Francofurti ad Viadrum], constructed new ephemerides from 1595 to 1654, prefacing volume 1 with a very full introduction setting out the chronological, astronomical and astrological foundations. But because of the rashness of his judicial astrology and his assertion of the motion of the Earth, he is listed among the condemned authors.

Democritus of Abdera [Democritus Abderita], or of Miletus, was a contemporary of Anaxagoras. He wrote on the Sun and Moon, on the Great Year, and on astronomy, with a parapegma of prognostics; and he was one year older than Socrates.

Dionysius the Astronomer [Dionyſius Aſtronomus], in Ptolemy, flourished in the year 463 of Nabonassar, that is, 285 before Christ.

Dionysius Afer, surnamed the Geographer, described the situation of the world in a Greek poem, which Priscian translated or imitated. Augustus sent him ahead of his son Gaius, who was being dispatched to the East, to write commentaries on each of those provinces.

St Dionysius the Areopagite [S. DIONYSIVS Areopagita] will be shown by us to have been skilled in astronomy, in Book 5, ch. 18, where we treat of the eclipse at the death of CHRIST, which by its darkness lit his way to the splendour of the Gospel.

Dionysius Exiguus — so surnamed, but great — an abbot, came from Syria to Rome and flourished there in the year of Christ 526. He introduced the cycle of 532 years, and named the years not from the beginning of the most savage tyrant Diocletian but from the Incarnation of the Saviour, and began that reckoning; from him the epoch Christians commonly use is called the Dionysian.

Denis Pétau [DIONYSIVS PETAVIVS Aurelianenſis] of Orléans, of the Society of Jesus, the Varro of our age and most learned in every field, has deserved best of all of theology, chronology and the whole reckoning of times, and of astronomy, as his two volumes *De doctrina temporum*, the *Rationarium temporum*, the *Uranologion*, and the work that has most recently seen the light, the *Theology of the Fathers* [Theologia Patrum], show. And as he is wonderfully accomplished in Greek and Latin letters for humane learning, so through his humanity, modesty and gentleness of manner he lives at Paris most welcome to all, both of our Society and outside it, still in this very year 1651, in his 68th year.

Domenico Maria Novara [Dominicus Maria Nouara Ferrarienſis] of Ferrara, born in 1464, was a distinguished professor of astronomy at Bologna and the teacher of Copernicus. He taught it from 1484 to 1514, and by the words and examples of his own observations spurred his pupils to restore astronomy. He is said to have observed the greatest declination of the Sun as 23° 29′. He died at Bologna aged 50, in 1514 on September 1 [Kalendis Sept.], and was buried in the church of the Friars of Santa Maria Annunziata, where his epitaph is read.

E

Egmundus, an astrologer, lived in the year of Christ 846.

Ignazio Danti [Egnatius Dantes] of Perugia, of the Order of Preachers, public Master of Mathematics in the University of Bologna, flourished in 1576, when he erected the great gnomon in the church of San Petronio for observing the declination of the Sun, as will be described in Book 3, ch. 14. He wrote on the use and construction of the astrolabe, and reduced astronomy together with the other mathematical disciplines to a compendium of tables. At Florence too he erected equinoctial armillae [Armillas Æquinoctiales] on the wall of Santa

Maria Novella for observing the equinox, with the support of Grand Duke Cosimo [Coſmo M. Duce].

Elias Camerarius, professor of mathematics at Frankfurt on the Oder, published a work on the new star of 1572; for Tycho's critique of it read *Progymnasmata* vol. 1, p. 692.

Élie Vinet [Elias Vinctus Santon] [recte: Vinetus, per the book's errata] of Saintes added scholia to the *Sphere* of Sacrobosco in 1554.

Emmanuel Maignan [Emmanuel Maignam], of the Order of St Francis of Paola, recently published an excellent work, *Perspectiva Horaria*, in Books 1 and 4 of which he treated much on refractions that is worth knowing and useful to astronomers.

Manuel Dias [Emmanuel Diaz] of the Society of JESUS observed the comets of 1618 at Cochin in India, and published a treatise against those who hold that comets are sublunary and elementary.

Endymion of Latmus [Endymion Latmius] was so captivated by the contemplation of the Moon, as Pliny the Elder reports (book 2, ch. 9), that he was held to be her lover. He flourished about 1445 before Christ. He is believed to have been the first to observe the course of the Moon, on Mount Latmus in Caria, for 30 whole years — just as Phaethon, and Daedalus and Icarus, observed the course of the Sun, but too inquisitively, and Prometheus, all of whom the fables pretended were punished for their excessive curiosity in searching out heavenly things.

Epigenes, on whom see Seneca in his inquiry on comets, drew astronomy from the Chaldaeans together with Apollonius of Myndus.

Erasmus Oswald Schreckenfuchs [Eraſmus Oſualdus Schreckenfrichſius] of Austria, pupil of Heinrich Glarean [Henrici Glareani], but an author condemned by the sacred censors of the Index, was professor of mathematics at Freiburg, and published *Primi Mobilis Problemata* in 1576 and commentaries on Peuerbach's *Theoricae* [Theoricas Purbachij].

Erasmus Reinhold [ERASMVS REINHOLDVS Salueldienſis] of Saalfeld in Thuringia, son of Johannes Reinhold [Ioannis Reinholdi], pupil of Jacob Milich [Iacobi Milichij], and professor of mathematics at the University of Wittenberg. Johannes Garcaeus [Io. Garcęus], Erasmus's pupil, in his *Methodus Astrologiae*, pp. 38, 126 and 323, places his nativity [Geneſim] in 1511 October 21 at $13^{h}\ 30^{m}$ after noon, under a pole altitude of 50° 46′, with Virgo 28° 29′ ascending, and with a platic conjunction of the Moon with Mercury, which in any sign makes men gifted. But because the luminaries were conjoined in the third house, and in Scorpio — that is, in the house and term of Mars, who was lord of the horoscope — and Saturn was in the same house, the same Garcaeus testifies (pp. 39 and 325) that he died of phthisis [φθίσι], or consumption, in 1553 on February 19, aged 42, that is, in his sixth climacteric. Consequently in Giuntini's *Calendarium Astrologicum*, where he is given as born in 1521 on October 22, in the morning, half an hour before the second hour of the night, the error must be corrected and the year 1511 restored. Erasmus

had published most learned scholia on the *Theoricae Planetarum* in 1542; then in 1551, on July 18, he dedicated the Prutenic Tables to Albert, Margrave [?] of Brandenburg [Alberto Marc[?] i Brandeburgico], Duke of Prussia, of Stettin and of Pomerania — namely to his most generous patron [Mecenati] — tables in the building and correcting of which, and of Copernicus's numbers, he had spent seven whole years. Finally, in 1553, which was his last, he published the *Tabulae Directionum* with the *Canon fecundus* [Canone fecundo], that is, of tangents, and a complete table of oblique ascensions, and new tables of the climates with shadows. He was also at work on confirming and illustrating chronology from eclipses and great conjunctions; but having undertaken to advance the *Canons* of Regiomontanus, he prolonged his own life beyond Regiomontanus's by no more than one year — for Regiomontanus died in his 41st year, as we shall say below. An epicedium for Erasmus, addressed to his surviving father, was written in elegant verse by Villebrochius of Danzig [Villebrochius Dantiſcanus], a pupil of Erasmus.

Erasmus Reinhold the Younger [Eraſmus Reinholdus iunior], son of the Erasmus above, a mathematician and physician of no common sort, as Tycho testifies of him in *Progymnasmata* vol. 1, p. 699. In 1574 he wrote on the new star of 1572; on this writing see Tycho's judgement in the same place.

ERATOSTHENES of Cyrene was born, as Suidas says, in the 126th Olympiad, that is, 276 before Christ, and in his 80th year died of starvation; he was therefore a contemporary of Archi- medes, and he flourished under the Ptolemies Euergetes, Philopator and Epiphanes. He was librarian to Euergetes, that is, prefect of the Alexandrian library, and was called by some "Plato the Younger" [Plato minor], by others "Beta", because he held second place in every kind of knowledge. He observed the greatest declination of the Sun as 23° 51′, whose fallacy we shall discuss in Book 3, ch. 27; on the way in which he measured the circumference of the Earth, see Book 2, ch. 7. Of his poetic, historical, philosophical and mathematical writings nothing survives except a book *On the Zones*, or the arithmetical sieve in Nicomachus, certain harmonic matters in Ptolemy, and the letter to King Ptolemy on the duplication of the cube, with an epigram, and the mesolabe for doubling the cube; these survive in Eutocius on Book 2 of Archimedes' *On the Sphere*, and in Pierre de La Ramée [Petrum Ramum], *Scholae Mathematicae*, book 1. Eratosthenes was so pleased with himself over the duplication of the cube that he consecrated a tablet expounding his splendid invention in the temple of the gods — an ἀνάθημα [Greek: ἀνάθημα (anathēma, "votive offering")] of his genius, forever. Boulliau [Bullialdus] says that the armillae in the portico at Alexandria were set up at his urging.

EUCLID [EVCLIDES Megarenſis] of Megara was a hearer of Socrates, as Cicero says (*Academica*, book 2), and a contemporary of Plato. For, as Laertius relates in his *Socrates*, when his teacher saw him inclined toward lawsuits, he rebuked him with the words: "O Euclid, you will be able to deal with sophists, but not with men." Plato, as Valerius Maximus reports (book 8, ch. 13), sent

the contractors for the sacred altar of Delos to him, to learn its dimensions and form from him. But if we listen to Proclus, Euclid the Geometer flourished as late as Ptolemy, first king of Egypt, who began to reign in the 18th year after the death of Alexander the Great and died in the 124th Olympiad, or 284 before Christ. Accordingly La Ramée (*Scholae Mathematicae*, book 1) and our Clavius, in his prolegomena to Euclid, judge that the Euclid whose geometrical *Elements* survive is a different man from the Megarian — chiefly on this argument, that Diogenes Laertius, speaking of the works of Euclid of Megara, nowhere mentions so outstanding a monument as the books of the *Elements*, nor the *Optics*, *Catoptrics*, *Music*, *Data* and *Phaenomena*. Grant that Euclid, as Proclus held, collected these elements from others, above all from Eudoxus and Theaetetus, adding certain demonstrations where they were lacking: yet this itself is great praise, says La Ramée — to complete what was begun, to make certain what was uncertain, but above all to put in order what was undigested. Nor does Proclus detract from him in calling him not the inventor of the *Elements* but their στοιχειώτης [Greek: στοιχειώτης (stoicheiōtēs, "compiler of elements")], that is, their constructor and demonstrator; by that title many other ancient στοιχειῶται [Greek: στοιχειῶται (stoicheiōtai, "compilers of elements")] have won the palm, and will win it among sensible men in time to come.

EUCTEMON, observer of the solstices with Meton in the 108th year before the death of Alexander the Great, that is, 432 before Christ, is celebrated by Ptolemy (*Almagest*, book 3, ch. 3).

Eudemus, as Theon of Smyrna relates in his *Astronomica*, wrote a *History of Astrology*, which Laertius also confirms in his *Thales*.

EUDOXUS of Cnidus [EVDOXVS Gnidius], as Diogenes Laertius relates in his life, was a pupil of Archytas in geometry, of Philistion the Sicilian in medicine, and of Plato in philosophy. In his 23rd year, though hard pressed by poverty, he moved to Athens, drawn by the fame of the Socratics. From there he went to Egypt, with letters of recommendation from Agesilaus, to King Nectanebus; having stayed there 16 months with chin and eyebrows shaved, he returned to Athens with many disciples, to the vexation of Plato, who had at first sent him away because of his poverty. Then he returned to his homeland, where he was received most warmly. He wrote *On the World*, *De caelo*, and *Phaenomena*, or astrological fasti, with prognostics. Laertius adds that when he was at Memphis he consulted Apis about his fate, and when his garment was licked by the calf Apis, the priests interpreted this to mean that he would be ἔνδοξον μὲν, ἀλλ' ὀλιγοχρόνιον [Greek: ἔνδοξον μὲν, ἀλλ' ὀλιγοχρόνιον (endoxon men, all' oligochronion, "famous, but short-lived")] — that is, famous in name but brief of life; and for this reason he was called Endoxus instead of Eudoxus. And on the authority of another Eudoxus, a physician of Cnidus, he affirms that he flourished about the 103rd Olympiad and died aged 53. Strabo (book 2) says that a watchtower used to be shown at Cnidus from which Eudoxus observed Canopus. If, then, he flourished in Olympiad 103, that is, in 368 before Christ, and was then more than 23 years old,

and lived no more than 53 years, he cannot have been born before 391 before Christ, the second year of Olympiad 97. Eusebius in his *Chronicle* therefore seems to need correcting, when he says at Olympiad 89, year 3, *"Eudoxus of Cnidus is held famous"* [*Eudoxus Gnidius clarus habetur*], and at Olympiad 97, year 1, *"Eudoxus the astrologer is recognized"* [*Eudoxus Aſtrologus agnoſcitur*]. Although Pétau seems to follow him in *De doctrina temporum*, book 2, ch. 6 — where he refutes Scaliger, who among other things ascribes to Eudoxus an age of 103 years — yet in the *Rationarium temporum*, book 3, ch. 13, he follows Diogenes, and corrects what he had said, following Eusebius, in book 13 of *De doctrina temporum*, p. 578. Hipparchus of Bithynia, moreover, expounded the *Phaenomena* of Eudoxus at length; these, together with the octaeteris he instituted [Octieteni-de] [recte: Octieteride], were valued so highly that Caesar in Lucan boasts:

Nec meus Eudoxi vincetur faſtibus Annus. ["Nor shall my year be outdone by the fasti of Eudoxus."]

On the system of the heavens according to Eudoxus's view, see Aristotle, *Metaphysics* 12, text 47. Tully [Tullius], in *On Divination*, says that Eudoxus argued against the predictions of the Chaldaeans.

Eutocius of Ascalon [Eutocius Aſcalonita], later than Theon and Pappus, wrote on the *Conics* of Apollonius and on Archimedes' *On the Sphere and Cylinder*, and flourished toward the end of the 5th century of Christ, about 480.

F

Federico Commandino [Federicus Commandinus Vrbinas] of Urbino rendered select monuments of the Greeks into Latin and expounded them — namely the *Conics* of Apollonius, the works of Archimedes, Aristarchus of Samos, Pappus of Alexandria, the *Analemma* of Ptolemy, etc. He flourished in 1560.

Fortunio Liceti [Fortunius Licetus Genuenſis] of Genoa wrote on comets and on the light of the Moon, and much else besides, about 1640.

François d'Aguilon [Franciſcus Aguillonius] of the Society of JESUS, of Brussels, taught philosophy at Douai and theology at Antwerp, and was the first to introduce mathematical studies into the Belgian provinces. He was a man outstanding in prudence and patience, and died a holy death at Antwerp, where he had been rector, in 1617, aged 50. How much he indirectly helped astronomy is evident from his six books of *Optics*.

Francesco Barozzi [Franciſcus Barocius], a Venetian patrician, flourished in 1570. Besides other notable mathematical works he wrote four books of *Cosmography*, in whose preface he exposed 84 errors of Sacrobosco [Ioannis de Sacroboſco] and his followers.

Francesco Giuntini [Franciſcus Iunctinus], doctor of sacred theology, a Florentine, was born in 1523 on March 7 at $13^{h}\ 20^{m}$ after noon, and in his 51st year published a *Speculum Astrologicum*, packed with astronomical tables and manifold learning, and also a *Sphere*.

Francesco Maurolico [FRANCISCVS MAVROLYCVS Meſſanenſis Abbas], abbot, of Messina, the brightest light of Sicily, shone from 1540, when he published his *Cosmographia*, to the year of Christ 1572, when the new star blazed out in Cassiopeia, on which he also set out his judgement in writing. He was a man of wonderful candour and most polished genius, and deeply learned in the Greek language. To him we owe the canon of secants, or *Tabula Benefica*; dialogues on cosmography; the *Sphaerica* of Theodosius and of Menelaus; the construction of the astrolabe and of other instruments; and much else, partly published, partly to have been published had he lived. We have a long catalogue of these at the beginning of the *Cosmographia* and at the end of the *Opuscula*.

Franciscus Montebrunus, a Genoese patrician, doctor of both laws [I.V.D.], whose friendship I have been granted to enjoy here at Bologna, computed excellent ephemerides for its meridian from the tables of Lansbergen [Lansbergij], from 1641 to 1660. He died at Venice in 1649.

François Viète [Franciſcus Vieta Fonteneenſis] of Fontenay, a distinguished ornament of French mathematics, excelled toward the end of the preceding century, as is evident from the *Cyclometrica*, the *Pseudomesolabum*, the *Apollonius Gallus*, the *Canon Mathematicus* and other monuments of a most acute and profound genius. But neither Clavius [Clauio] nor more judicious men approved of his being so pleased [ita tibi placuerit] [recte: sibi] with that period of his of 3,400 years that, for this very reason, he offered Clement VIII in 1600 a new form of the calendar, asserting that not the Lilian calendar but his own was truly Gregorian. His *Harmonicum caeleste* is named by Boulliau in the Prolegomena to the *Astronomia Philolaica*, p. 21, who says that it is in the hands of Marin Mersenne [Marini Merſennij].

Francisco Sarzosa [Frãciſcus Sarzoſus Cellanus Aragoneus] of Cella in Aragon wrote two books on the *Equatorium of the Planets*, built on the Alphonsine hypothesis, in 1525.

G

GALILEO GALILEI [GALILÆVS GALILÆVS Florentinus], a Florentine, a geometer of sagacious genius and very knowledgeable in astronomy, would have been greater still had he been content to advance the opinion of the motion of the Earth as a mere hypothesis in his *Dialogues* on the system of the world, and had he obeyed the sacred censors once he had been warned by Cardinal Bellarmine — whom, however, he did obey afterwards, when already 70 years old, publicly abjuring that opinion. To him we certainly owe, if not the invention, then surely the perfection and use of the telescope, and many other things hidden from the ancients that were discovered by means of it. He wrote on the spots of the Sun, and on the other things detected through the optic tube, in the *Sidereus Nuncius*, and other short works.

Caspar Peucer the Elder [Gaſpar Peucerus Senior], in medicine and mathematics most learned [ſcientiſſi-lmus], was born at Bautzen [Budiſſinæ] in Germany in 1525 on January 5 at 12^{h} after noon, and had a son of the same

name, on whose skill in astronomy see what Tycho reports in *Progymnasmata* vol. 1, p. 633.

Gazulus of Ragusa [Gazulus Raguſeus], an astrologer, flourished in 1438.

Geber of Seville [Geber Hiſpalenſis], son of Attla [filius Attla] [recte: Affla, per the book's errata], expounds and corrects Ptolemy in nine books on astronomy, written in Arabic but rendered into Latin by Gerard of Cremona [Gerardum Cremonenſem; Gerardo da Cremona]. He was, however, later than Arzachel, whom he names and ranks after Albategnius; and Arzachel lived in the 12th century of Christ. Geber therefore did not live in the 9th century, whatever Blancanus [Giuseppe Biancani] may say in his *Chronologia Mathematicorum* [Chronol. Math.].

Gellius Sasserides [Gellius Saſſerides Hafnianus] of Copenhagen was one of those who assisted Tycho in his observing; his letters survive in Magini's *Directiones*, from p. 78.

Geminus, in Greek γεμῖνος [Greek: γεμῖνος (geminos, "Geminus")], an ancient author, was a Rhodian and lived in the time of Sulla and Cicero, about 83 years before Christ. He wrote a splendid *Isagoge* to the *Phaenomena*, or *Elements of Astronomy*, and is praised more than once by Proclus, whose *Sphere* seems to have been compiled from Geminus's chapters 2, 3, 4 and 12. Edo Hildericus translated him from Greek into Latin; but our Pétau corrected him from two copies and published him at the beginning of his *Uranologion*, where he places him before Christ. Biancani, it is true, in his *Chronologia Mathematicorum*, reports two men named Geminus: one older, 300 years and more before Christ; the other, namely the Rhodian, whom he asserts to have been the teacher of Proclus Diadochus. Proclus, moreover, somewhere ranks him above Euclid. On his date see Pétau, *De doctrina temporum*, book 2, ch. 6, and his notes on Geminus in the *Uranologion* — although Scaliger makes him 120 years later than the Eudoxian solstice.

GEMMA FRISIUS [GEMMA REGNERI FRISIVS], physician and mathematician of Leuven, began to flourish from 1534 onward. Among other things he published books on the use of the globe, on the use of the astronomical ring, on the principles of astronomy and cosmography, on the division of the world, on islands and lands recently discovered, and on the Catholic Astrolabe. He died in 1555, as Genebrardus [Gilbert Génébrard] says under Marcellus II [in Marcello 2.].

Georges Fournier [Georgius Furnerius Gallus], a Frenchman of the Society of JESUS, formerly a most celebrated professor of mathematics at Paris, published in 1643 an outstanding work of *Hydrography*, from which a learning deeper than the sea itself may be drawn — the sea that he made illustrious by so noble a monument. Of his skill in observing phenomena, especially eclipses, it will be shown in its place, also from his letters to me.

Georg Henisch [Georgius Henischius], at the beginning of this century, illustrated the *Sphere* of Proclus with excellent commentaries.

Georg Hartmann [Georgius Hartmannus Norimbergenſis] of Nuremberg, a distinguished instrument-maker [Organopœius], was born in 1489 on February 9, after sunset.

Georg Joachim Rheticus [Georgius Ioachimus Rheticus] was born in 1514 on February 15 at 13^{h} 30^{m} after noon. A follower of Copernicus, he set out his hypotheses in a long *Narratio*, and on his foundations published at Leipzig an ephemeris for the year 1550; there, as also at Wittenberg, he professed mathematics. He also constructed a *Magnus Canon*. But when he despaired of mastering the motion of Mars, he is said to have invoked his Genius, who seized him by the hair, dashed his head against the ceiling above, then flung him down to the floor and mocked him bitterly, saying *"Hic est motus Martis"* ["This is the motion of Mars"] — though Kepler, in the dedicatory epistle of the *Commentaria* on Mars, thinks rather that he rose up raving in a disordered state of mind and dashed his head against the wall. Whatever the truth of it, he himself is numbered among the condemned authors for his astrological vanity and for other reasons.

Giorgio Polacco [Georgius Polaccus Venetus], a Venetian, published in 1644 an *Anticopernicus Catholicus*, in which he defended the rest of the Earth and the motion of the Sun.

Georg Peuerbach [GEORGIVS PVRBACHIVS], born at Peuerbach [Peurbach] on the borders of Bavaria and Austria in 1423 on May 30 at 3^{h} 5^{m} after noon, under a pole altitude of 58° [gr. 58.], died in 1462 on April 8 [ſexto Idus April.], not yet forty years old. He had taught mathematics at Ferrara in Italy and at Vienna; and after the *Theoricae Planetarum*, which he had constructed partly on Ptolemy's principles and partly on those of the Alphonsines, and the *Tables of Eclipses*, he was undertaking the restoration of astronomy by astronomical observations. But as he was dying he bequeathed to his pupil Regiomontanus [Ioanni Regiomontano], as by testament, the task of completing the *Epitome of the Almagest* that he had begun, and he ordered this epitaph to be cut for him in the Cathedral Church at Vienna, where he is buried:

Extinctum dulces quidnam me ſletis amici? Fata vocant: Lacheſis ſic ſua fila trahit. Deſtituit terras animus, cælumque reuiſit: Quæ ſemper coluit liber & aſtra colat.

["Why, sweet friends, do you weep for me, now I am gone? / The Fates call: so Lachesis draws her threads. / My spirit has left the earth and returns to heaven: / free, let it dwell among the stars it always cherished."]

Georg Schönberger [Georgius Schombergerus Oenipontanus] of the Society of JESUS, of Innsbruck, taught moral philosophy and mathematics, and in 1626 published at Freiburg im Breisgau [Friburgi Briſgoiæ] the *Sol illustratus*, in which he defends all the accidents of the Sun, the solar stars, and the fluidity of the heavens; and also a *Centuria* of optical problems. In 1622, moreover, he had published the demonstration and construction of clocks indicating all the hours by a direct ray, by a ray refracted in water, by one reflected in a mirror, and by the magnet alone.

Georgios Trapezountios [Georgius Trapezuntius] was born in Crete in 1396 on April 4 at 12^{h} 20^{m}, under a pole altitude of 36°. He flourished in 1435, when he was Apostolic Secretary. He translated Ptolemy from Greek into Latin; he also wrote on the hundred aphorisms of Ptolemy [Aphoriſmos centum Ptolemæi], on antiscia, and on the falsity of astrological judgements. In extreme old age he forgot all his learning, and he died in 1486, as Génébrard has it under Sixtus IV.

Gerard of Cremona [Gerardus Cremonenſis] translated Geber from Arabic into Latin and expounded the *Theoricae Planetarum*; but Regiomontanus [Io. Regiomontanus] attacked them most sharply in a dialogue devoted to them. He flourished in the 14th century of Christ.

Gerardus Mercator of Rupelmonde [Rupelmundanus], father and son, leading cosmographers of the preceding century, flourished in the year of the Lord 1570.

Germanicus Caesar rendered Aratus's *Phaenomena* into Latin, although Julius Firmicus, in book 2 of his *Astronomicon*, attributes it to Julius Caesar. He was the son of Drusus and was adopted by Tiberius, and he died at Antioch in his 34th year, not without suspicion of poison.

Govaert Wendelen [GOTıFREDVS VVENDELINVS Luminarcanus ex Belgio], from Belgium, a singular astronomer, published in 1644 the *Idea of the Atlantic Tables*, based on very many eclipses observed by himself and by others; and in the preceding year he had published the *Lamp of the Celestial Mysteries* [arcanorum cæleſtium lampadem]. From these small works — great in merit, not in bulk — and from his letters to me, the man's remarkable learning can be discerned, together with the elegance of his style; and I regret that he has been drawn away to other studies and business from the observation of the Moon, to which he devoted nearly all his time. He was born in 1580 on June 6, and was still observing eclipses in 1643, namely in his climacteric year.

Guido Bonatti [Guido Bonatus Foroliuienſis] of Forlì, an astrologer, was living in the year of the Lord 1282.

Guidobaldo del Monte [Guidubaldus ſeu Guidus Vbaldus Marchio ex nobiliſſima familia de Monte], Marquis, of the most noble family del Monte, published, among other notable monuments of mathematics, an *Astrolabium* and *Problemata Astronomica*, and flourished toward the end of the 15th century of Christ [ſub finem ſæculi Chriſti 15.].

Willem Blaeu [Gulielmus Blaeu Hollandus], a Hollander, in imitation of Mercator's *Atlas*, illustrated the whole of geography with very many and most accurate maps, and flourished about 1640.

Gulielmus Ianſonius [Gulielmus Ianſonius Alcmarienſis] of Alkmaar, most celebrated for his geographical maps, flourished in 1608 and after.

William, Landgrave of Hesse [Gulielmus Lantgrauius Haſſiæ], famous for his astronomical observations begun at Kassel [Caſſellis] and kept up for very many years — which Snellius [Willebrord Snel] published, and Tycho in part in his volume of *Epistles* and in part in *Progymnasmata* vol. 2, where he treats

of comets — gave princes a notable example of promoting and enlarging this science. He flourished in 1570 and after.

Guillaume Postel [Gulielmus Poſtellus Barentonius] of Barenton in Normandy, whose geographical volumes Barozzi [Baroccius] mentions, and whose writing on the star of 1572 Tycho subjected to his critique in *Progymnasmata* vol. 1, p. 716, was distinguished not only in mathematics but in philosophy and medicine, and in his knowledge of very many languages. But because of Cabbalistic trifles and astrological ravings he was expelled once and again from the Society, to which he had vowed himself, by our holy Patriarch Ignatius; he fell into open heresies, for which he was sent to Rome bound in chains. He lived to nearly a hundred, and at last is believed to have recovered his senses and to have died in the Catholic faith. Wonderful, but dreadful, are the things that our Daniello Bartoli [Daniel Bartolus] relates of his talent — unstable, however, and steeped in superstitions — in vol. 1 of the *History of the Society of JESUS*, book 3, from p. 371.

Wilhelm Schickard [Gulielmus Schikardus], at Tübingen professor of oriental languages and of astronomy, besides the *Astroscopium*, also published some eclipses he had observed himself. He flourished about 1630.

H

Haly aben Ragel was born in 956 on February 12 at 10^{h} before noon; he is therefore a different man from the one who is said to have lived in 1200.

Haly aben Rodoan flourished in 1024, if we believe Giuntini [Iunctino] and Sansovino [Sanſouino; Francesco Sansovino].

Harpalus instituted the octaeteris [Octoeteridem], or lunisolar cycle, not long after Cleostratus, as Censorinus teaches; on which see Pétau, *De doctrina temporum*, book 2, ch. 3 and 4.

Hecataeus of Miletus [Hecateus Mileſius], shortly after Thales, first, on the situation of the world published a book, as Proclus attests in his commentary on Euclid.

Helicon of Cyzicus [Helicon Cyzicenus], a friend of Plato, was given a talent of silver by King Dionysius for having foretold an eclipse of the Sun to him, as Biancani relates in his *Chronologia*. I think it was the eclipse of the year 404 before Christ, of which we shall speak in the Catalogue of Eclipses.

Henricus Baten of Mechelen [Mechlinienſis] wrote in 1290 on the errors of the Alphonsine tables [tabularum Alphonſi].

Henry Briggs [Henricus Briggius], Savilian professor of geometry in the University of Oxford, altered Napier's logarithms [Neperianos Logarithmos], with Napier's agreement, and elucidated them; on this account alone he deserved outstandingly well of astronomical computation. He flourished in the year of the Lord 1615.

Heinrich Glarean [Henricus Glareanus], geographer, chronologer, musician and physician, a native of the canton of Glarus [ex pago Clarona] in Switzerland, flourished in 1547.

Heinrich von Langenstein [Henricus de Haſſia], a German, died in 1397 on February 11 [3. Idus Februarij] at Vienna, where he had taught theology and astronomy; his skill in astronomy is shown by book 1 of his commentary on Genesis and by his *Theoricae Planetarum* [in Theoricis Planetarum].

Henricus à Lindhout, a physician of Brussels, wrote a *Speculum Astrologiae* in 1508.

Henricus Philippi, of the Society of JESUS, an Ardennais from Saint-Hubert [Arduennas ex S. Huberto], taught philosophy, theology and Sacred Scripture at Graz [Græcij], Vienna and Prague, and in very many works elucidated and corrected the whole of chronology, sacred chronology above all. He was most welcome to Ferdinand and his courtiers, yet took on nothing of the court; he was in the habit of reciting psalms even in his sleep, and was of no common poverty, obedience and patience. He died at Regensburg [Ratiſbonæ] in 1636, on November 30, aged 71.

Heinrich Rantzau [Henricus Ranzouius], viceroy of the Cimbric peninsula [Produx Cimbricus], in 1596, when he was in his 71st year, published a calendar very useful to physicians and astronomers, in which he says he was born in the castle of Steimbrorch in Holstein in 1526, on March 11, at $10^h\ 31^m\ 26^s$. But through his study of judicial astrology he incurred ecclesiastical censures.

Henricus Samerius of Luxembourg, of the Society of JESUS, an outstanding computer of the times from the creation of the world to Christ, died at Luxembourg on January 5, 1610, aged 70.

Hercules Musagetes [Hercules μουσαγητις], that is, the leader of the Muses — so called to distinguish him from the other Hercules — so advanced the doctrine of the celestial sphere that he was said to have succeeded Atlas in holding up the heavens. He flourished in the year 1560 before Christ.

Hermes Trismegistus [Hermes Trimegiſtus], grandson of the elder Mercury, a most ancient astrologer, lived about the year 1480 before Christ, as Giuntini [Iunctinus] places him; but Agostino Ricci, in his treatise on the motion of the eighth sphere [in tract. de oct. ſphæræ motu], says he was older than Ptolemy by 1985 years, so that he flourished in the year 1850 before Christ.

Ermolao Barbaro [Hermolaus Barbarus], a Venetian, patriarch of Aquileia, a man most learned in astronomy as well, was born in 1453 at $12^h\ 45^m$ after noon.

Girolamo Cardano [Hieronymus Cardanus] of Milan was born in 1501, on September 24, at $6^h\ 40^m$ after noon. He flourished above all at Bologna, where he publicly professed medicine and mathematics. As regards astronomy, his writings on Ptolemy and his books *De subtilitate* show well enough what he was; but in many other things he was a suspect author, and was summoned to Rome more than once on grounds of religion, as Alessandro de Angelis says, book 4 [of his work] against astrologers [in Aſtrolog.], ch. 14. He died at Rome in 1576, as Génébrard [Genebrardus] has it under Gregory XIII.

Girolamo Fracastoro [Hieronymus Fracaſtorius] of Verona, poet, physician and distinguished astronomer, published his *Homocentrica* in 1535. To gaze upon

him, Charles V, as he passed along Lake Garda [lacum Benacum], ordered his carriage to stop. He died of apoplexy.

Jerónimo Girava [Hieronymus Giraua] of Tarragona [Tarraconenſis] in 1570 published two books in Spanish, which contain the geography of the whole world, but principally of the New World.

Jerónimo Muñoz [Hieronymus Munoſius], a Spaniard, professor of Hebrew and of mathematics in the University of Valencia, observed the new star of 1572; on which consult Tycho's *Progymnasmata* vol. 1, p. 565.

Girolamo Ruscelli [Hieronymus Ruſſellius] of Ferrara elucidated Ptolemy's *Geography* with notes in the last century.

HIPPARCHUS OF RHODES [HIPPARCHVS RHODIVS], called by some Abrachys, observed the motions of the luminaries and their eclipses, first at Rhodes and then at Alexandria. He collected and weighed the observations of them made long before by the Chaldaeans, corrected the cycle of Callippus, and Eratosthenes' measurement of the Earth's circumference. On the occasion of a new star he observed all the fixed stars and reduced them to a catalogue; and he was at length the first to notice that, besides the motion of the primum mobile [primi Mobilis], they are moved slowly by a motion of their own toward the east about the poles of the ecliptic; and he distinguished the sidereal year from the tropical. He was a man φιλόπονος καί φιλαλιθής [recte: φιλαλήθης] [Greek: philoponos kai philalēthēs, "fond of labour and of truth"], that is, a lover of labour and of truth, as Ptolemy attests (book 3, ch. 2), adding there and in book 7, ch. 1, that his observations seemed to him exquisite. In the same book 7, ch. 2 and 3, Ptolemy reviews Hipparchus' book on the shift of the solstitial and equinoctial points, as also in book 3, ch. 2. Hipparchus' most ancient observation in Ptolemy (book 3, ch. 2) is of the autumnal equinox in the 17th year of the third Callippic period, that is, 162 before Christ. But if the eclipse of the Moon observed at Alexandria in the 54th year of the second period of Callippus, that is, 200 before Christ, was Hipparchus' rather than another's, he would already have begun observing from then as a very young man; for in book 7 of the *Almagest*, ch. 2, he is said to have observed Regulus in the 50th year of the third period of Callippus, that is, 129 before Christ. Astronomy owes Hipparchus so much that it would be unjust to pass over here the double encomium with which Pliny the Elder praised him. For in book 1, ch. 12, after praising Thales and Sulpicius Gallus, he says: *"After them Hipparchus foretold the courses of both luminaries for six hundred years, comprehending the months of the nations, the days and hours, the situations of places and the districts of peoples — time bearing witness — in no other way than as a sharer in the counsels of nature. Mighty men, and above the nature of mortals,"* etc. And in ch. 26: *"Hipparchus, never praised enough, as one than whom no one did more to prove the kinship of the stars with man and that our souls are a part of heaven, detected a new star, and another one born in his own age; and from its motion on the day it shone he was led to doubt whether this happened more often, and whether those stars also move that we think fixed. And he likewise dared a thing presumptuous even for a god — to number*

the stars for posterity and to check off the heavenly bodies by rule, with instruments he devised by which the places and magnitudes of each might be marked, so that from it one might easily discern not only whether they perished or were born, but whether any of them passed by or moved at all, and also whether they grew or diminished — leaving the heaven as an inheritance to all, if anyone should be found to take up that reckoning."

Hipparchus of Bithynia [Hipparchus Bithynus] wrote three books to Aeschrion [ad Æſchrionem] of commentaries on the *Phaenomena* of Aratus and Eudoxus, which our Denis Pétau [Dionyſius Petauius] translated from Greek into Latin and inserted into his *Uranologion* from p. 171. From the many marks of the places in which he records the stars as they were in his time, it is certain that he lived before Christ. For Hipparchus asserts that he observed the last star in the tail of Ursa Minor [poſtremam caudæ vrſę minoris] at a distance of 12° 24′ from the pole of the world, which Marinus of Tyre also affirms of Hipparchus. From this complement of the declination, and from the latitude of this star, which is 66° 2′, and the distance of the pole of the ecliptic from the pole of the equator, 23° 30′, it follows by problem 49 of section 2 of our Book 10 that this star was at Taurus 28° 53′. But we found it, at the completion of the year 1644, at Gemini 23° 38′. It has therefore advanced from Hipparchus to us by 24° 45′, for which, on our motion in longitude, 1780 years are required. Subtracting 1644, there remain 136 years before Christ. Hipparchus of Bithynia was therefore a contemporary of Hipparchus of Rhodes — which was worth knowing, and could not have been investigated by us without the doctrine of triangles and of astronomy.

Orazio Grassi [Horatius Graſſus], of the Society of JESUS, a Ligurian from the city of Savona, long professed mathematics at Rome in our College with great praise. In 1619 he published an astronomical disputation on the three comets of 1618, and the *Libra Astronomica ac Philosophica*, in which he weighs Galileo's opinion on comets. He is, moreover, most expert in architecture [Architecturę, as printed], and a man of great judgement.

Humenus the Egyptian [Humenus Ægyptius] wrote astronomical tables in Arabic in the twelfth century of Christ, which are preserved in the Palatine Library, as Jacob Christmann [Kriſtmannus] reports in his [commentary on] al-Farghānī [in Alfraganum].

Hyginus flourished in the year of Christ 72; his *Poeticum Astronomicum*, on the parts of the world and of the sphere, survives.

Hypatia [HYPATIA], daughter of Theon of Alexandria, flourished under Arcadius and Honorius, and among other things constructed an astronomical canon. Synesius boasts that she was his teacher. But by her eminent learning in mathematics she drew on herself such envy that she was slaughtered by certain Alexandrians, dragged through the whole city and torn to pieces, as Hesychius Illustrius relates in his *Lives of the Philosophers*, and the *Suda* [Suidas]. Her father Theon flourished in the year of Christ 365. But Socrates (book 7, ch. 13) relates that she was killed in 415 by the Alexandrians in a popular riot and

torn apart, because she was thought to have drawn the prefect Orestes away from his friendship with Cyril.

I

Jacques Lefèvre d'Étaples [IAcobus Faber Stapulenſis] wrote a commentary on Sacrobosco's *Sphere*, at the end of which he relates that in the year of Christian salvation 1494, on November 9 [quinto idus Nouembris], he was present at the solemnity at which the body of St Denis [S. Dionyſij], with the bodies of Rusticus and Eleutherius, was brought up [depoſitum fuit] from the crypt in which for

110 years they had lain unexposed. For at that time Charles VIII [Carolus Octauus] had reached the borders of Tuscany with his armies, pressing on toward his Neapolitan expedition; and the kings of France, when they undertook an expedition into foreign provinces, used to order the aforementioned relics of the saints to be exposed.

Jacob Christmann [Iacobus Kriſtmannus] of Johannisberg [Ioannisbergenſis], professor of mathematics and of languages in the University of Heidelberg, besides solar observations wrote in 1590 a commentary on the chronological and astronomical elements of al-Farghānī [Alfragani].

Iacobus Homelius was born in 1528, on July 31, at 15^{h} after noon.

Jacob Milich [Iacobus Milichius], professor of mathematics in the school of Wittenberg [in Schola Vuittembergenſi] and teacher of Erasmus Reinhold, published commentaries on book 2 of Pliny the Elder, which contain much astronomy. He was born in 1501, on February 20, at $12^{h}\ 52^{m}$ after noon, at a pole altitude of 46° 25′.

Jacob van Lansbergen [Iacobus Lanſbergius], a physician, wrote in 1633 an *Apology* for Philips van Lansbergen's [Philippi Lãſbergij] commentaries on the diurnal and annual motion of the Earth, against Froidmont [aduersùs Fromondum].

Johann Adam Schall von Bell [Ioannes Adamus Sciabi], a German of the Society of JESUS, sailed to China [ad Sinas] about the year 1620 with Father Nicolas Trigault [P. Nicolao Trigautio] on his return voyage. He published a treatise on the computation of the lunar eclipse of 1624, and a table of the stars in Chinese.

Johannes Angelus [Ioannes Angelus Bauarus ex Aichem], a Bavarian from Aichach, professor of astronomy at Vienna, died in 1512 on September 29. He wrote ephemerides, prognostications, and a work on the equations of the planets.

Giovanni Antonio Delfino [Io. Antonius Delphinus Caſalenſis è Caſali Maiore] of Casalmaggiore, a Franciscan, wrote in 1559, addressed to Camillo Paleotti [Camillum Palęotum], senator of Bologna, a book on the celestial globes and their motions, full of learning. He was Provincial of the Franciscans and principal Lecturer at Bologna, and died in 1560, aged 54 years, 6 months and 10 days.

GIOVANNI ANTONIO MAGINI [IO. ANTONIVS MAGINVS de Paſqualibus Patauinus] of Padua, professor of mathematics at Padua, published in 1583, in his 28th year, ephemerides derived from the Prutenic Tables for 1581 to 1610, first in Latin and then in Italian, with a very full introduction. Then in 1585 he published *Tabulae secundorum mobilium caelestium*, agreeing with the Prutenic Tables, with the Alphonsine canons added. Afterwards, called in 1588 to Bologna, where he flourished as principal professor of mathematics until his death, he published in 1589 his *Theoricae Planetarum* [Theoricas Planet.]; in 1592 one book on plane triangles and five books on the method of measuring [de Ratione dimetiendi], the fifth of which serves astronomy; in 1596 commentaries on Ptolemy's *Geography* with geographical maps both ancient and modern; in 1604 the tables of the primum mobile [Primi Mobilis] which they call tables of directions; and in 1607 he resumed his ephemerides, for 1610 to 1630, built indeed on the Prutenic Tables, but preceded by a supplement of *Isagogica*, that is, of the reductions of the Sun's motion to the Tychonic, and on the Tychonic equation, with astrological precepts useful for agriculture and navigation, and on the change of the weather. In the same year 1607 he published two books, one on critical days, the other on the legitimate use of astrology in medicine. In 1609 he published the tables of the primum mobile and *Problemata*, and in the same year brought out a description of Italy, which he afterwards enlarged. In 1614 came a supplement to the ephemerides and to the tables of the second movables, containing the Tychonic-Copernican tables with a compendium for calculating eclipses in the Tychonic manner. Finally, in 1620, his son Fabio Magini [Fabius Maginus], in accordance with his father's last will, published the *Italia* with 60 maps, for the most part either constructed or collected by Giovanni Antonio and reduced to a suitable form by twenty years' labour. This distinguished astronomer and cosmographer died at Bologna in 1617, on February 11 — a time he had foreseen from his astrological figure would be fatal to him — and was buried in the portico of the convent of the Dominican Fathers, with an epitaph that Giovanni Antonio Roffeni [Io. Antonius Roffenus] set up to him, adding that he died *"under the hostile aspects of the stars, of the Sun to the body of Mars, which he had foreknown for himself, the Sun running near the opposition [diametrum] of Mars, about the sextile [hexagonum] of Saturn,"* and that he lived 61 years, 7 months, 28 days and 1 hour. Tycho and Kepler had invited him to Germany to build new tables resting on new observations, but his age prevented him and he declined.

Giovanni Antonio Roffeni [Ioannes Antonius Roffenus] of Bologna, a pupil of Giovanni Antonio Magini and a celebrated astrologer, published many astrological discourses. He died at Bologna in the 63rd year of his age and of our salvation 1644. When he had taken to his bed sick with a semitertian fever [ex hemitritęo] and I visited him — for I had formed a friendship with him long before — he declared that he would die of that illness, since his nativity [Geneſim ſuam] and his climacteric year required it; that he was ready for the will of the divine power, and had lived enough and more than enough.

He asked, however, that he might be allowed to open all the hiding places of his conscience to Father Giorgio Giustiniani [P. Georgio Iuſtiniano] of our Society. I promised him this and obtained it at once. And he, knowing that I was already engaged in the labour of the *New Almagest*, out of regard for me bequeathed to our College of Santa Lucia a great part of his books, which have been of great use to me.

Giovanni Battista Benedetti [Io. Baptiſta Benedictus], a Venetian patrician, called from Parma to Turin by the Most Serene Duke of Savoy in 1566, tried after 19 years, that is in 1585, to answer the arithmetical, geometrical, astronomical, optical and musical questions put to him by the Duke and others, by publishing questions and most learned letters. He was born in 1530, on August 15, at 1^{h} 13^{m} after midnight.

Giovanni Battista Amico [Io. Baptiſta Amicus] of Cosenza wrote in 1537 on the motion of the heavenly bodies according to Peripatetic principles.

Giovanni Battista Capuano [Io. Baptiſta Capuanus Sipontinus], of Siponto, or of Manfredonia, a Canon Regular of the Lateran: while he was still a secular and bore the name Francesco, he professed astronomy at Padua in 1475, and then published an exposition of Sacrobosco's *Sphere*, unrevised, which after becoming a bishop he revised and dedicated to his hearers, his fellow canons. He also wrote on Peuerbach's *Theoricae* [in Theoricas Purbachij].

Giovanni Battista Carelli [Io. Baptiſta Carellus] of Piacenza constructed ephemerides from 1557 to 1580, with an introduction and a treatise on astrology.

Johann Baptist Cysat [Io. Baptiſta Cyſatus], of the Society of JESUS, of Lucerne in Switzerland, professor of mathematics in the University of Ingolstadt, besides a revolving cosmographical table [tabulam coſmographicam verſatilem] published in 1619 *Mathemata Astronomica* on the comet of 1618. He is living in this very year 1651.

Jean-Baptiste Morin [Io. Baptiſta Morinus], a Parisian mathematician, wrote on the science of longitudes and a new astronomy, and flourished in 1630.

GIOVANNI BATTISTA RICCIOLI [IO. BAPTISTA RICCIOLVS], of the Society of JESUS, of Ferrara, was born in 1598 on April 17 and entered the Society of JESUS in 1614 on October 6. He taught our members first rhetoric and poetics, then philosophy for nearly six years and scholastic theology for about 10 years, partly at Parma and partly at Bologna, always, however, most devoted to restoring geography, chronology and astronomy by his own observations. At length, having obtained from his superiors exemption from the chair of theology, and as Prefect of Studies at Parma [& Prefectus Studiorum Parmę], he applied himself wholly to the publication of the *New Almagest*, which he had been preparing for many years before, and published its first volume, divided into two parts, in this year 1651, its printing having been begun, however, in 1648.

Giovanni Battista Della Torre [Io. Baptiſta Turrianus] of Verona, a young man of lofty and noble talent and a devotee of the more recondite philosophy,

had already begun to devise the *Homocentrica* that Fracastoro afterwards perfected, as Fracastoro himself attests; dying, he commended to Fracastoro the task of taking up that work. See Fracastoro in the dedication of the work to Paul III.

Johann Bayer [Ioannes Bayerus Rhenanus], from the Rhineland, learned in law and astronomy, published at Augsburg [Auguſtæ Vindelicorum] in 1603 the *Uranometria*, or figures of the stars, with a nomenclature collected from ancient and recent tables and enlarged and corrected by his own astronomical night-watches; of which we shall speak again when we come to Julius Schiller [Iulio Schyllero].

Giovanni Bianchini [Ioannes Blanchinus] of Bologna, a great computer of astronomical tables. When he was general factor, as they say, of the Most Serene Borso d'Este [Borſij Eſtenſis], Duke of Modena and Reggio, Marquis of Este, Count of Rovigo [Rhodigij] and Lord of Ferrara, he dedicated by Borso's order the tables of the celestial motions he had constructed to the Emperor Frederick III, to whom he was known and most welcome. But because the art of printing had not yet prevailed — though invented in 1440 — and few could enjoy those tables, Luca Gaurico later, in 1526, published them corrected and enlarged from the press of Lucantonio Giunta [Lucæ Antonij Iunctæ]. Bianchini flourished at Ferrara in 1458, for which reason Biancani called him a Ferrarese in his *Chronologia* — although Biancani, himself a Bolognese, ought not to have been ignorant of a fellow Bolognese — and there he also wrongly places his floruit after 1500; I believe because Bianchini's tables were afterwards reprinted through Gaurico, as I said.

Giovanni Boccaccio [Ioannem Boccatium] is numbered among the astronomers by our Gualterus in his *Chronicon*, p. 699. He died in 1377.

John Dee [Ioannes Dee] of London, on the occasion of the new star of 1572, published a little book he called *Parallacticae commentationis praxeosque nucleus*, much approved by Tycho, *Progymnasmata* vol. 1, p. 690.

Johannes Decker [Ioannes Deckerius], of the Society of JESUS, a Belgian, native of Hazebrouck [patria Haeſbrouckanus], a pupil of Leonard Lessius [Leonardi Leſſij] in philosophy, taught philosophy at Douai [Duaci], and there and at Leuven scholastic theology. He was chancellor at Graz, and there died on January 10, 1619, aged 59. He was a man of outstanding modesty, obedience and piety. He wrote theorems on the year of the Lord's birth and death, etc.; a chronographical table from the capture of Jerusalem by Pompey to its destruction by Titus; and very many books of sacred chronology not yet published, which are preserved at Graz.

Ioannes Drienes [recte: Derienes, per the book's errata], of the Society of JESUS, a Frenchman, native of Dieppe [patria Diepenſis], was teaching mathematics at Paris [Luteriæ, as printed] in 1643, in his 51st year. He wrote the *Tabulae Canorienses*, or the doctrine of the luminaries.

Johannes von Gmunden [Ioannes de Egmunda], a German, a celebrated theologian and astronomer, taught astronomy at Vienna and died and was

buried there in 1442. He wrote tables of the motions of the planets, and on the eclipses of the luminaries.

Ioannes Essler wrote a *Speculum Astrologicum*, published at Basel in 1568.

Jean Fernel [Ioannes Fernelius Ambianas] of Amiens, first physician to the King, an excellent geometer and astronomer, published among other things in 1528 the *Cosmotheoria*, in which he explains the motion, position, size and theory of the heavenly bodies; he had published the *Monalosphaerium* in 1526. He died in 1558, on April 26, as Génébrard has it under Paul IV.

Johann Georg Herwart von Hohenburg [Ioannes Georgius Heruartus Hohemburgenſis], doctor of both laws [I. V. D.], in 1642 published a *New Chronology* weighed against the astronomical computation of eclipses, etc., which, however, both Pétau and we, in our chronological work, have been compelled to refute.

Johannes Garcaeus [Ioannes Garceus Brandeburgenſis] of Brandenburg wrote a *Methodus Astrologiae*, which he illustrated with nearly 400 nativities; but because he extended his judgements to free actions or future contingents, he was counted among the forbidden authors. He was born in 1530, on December 13, at $13^{h}\ 28^{m}$ after noon.

Ioannes Gazulus of Ragusa [Raguſinus] was an astrologer of great name in 1438.

Ioannes Heremita of Ferrara, an uncommon geometer and astronomer, was born in 1485, on December 23, at $3^{h}\ 32^{m}$ after noon.

Johannes Hevelius [IOANNES HEVELIVS Gedanenſis ſeu Dantiſcanus], of Danzig, or Danzig, professor of mathematics, very recently published the *Selenographia*, or on the spots and libration of the Moon, with copper figures engraved by himself most handsomely and accurately and verified with an exquisite telescope; he flourished from 1630 to 1651.

Ioannes Hispalensis, an astrologer, lived in 1142.

Johannes van Heeck [Ioannes Heckius Dauentrienſis], a physician of Deventer, wrote in 1605 a not inelegant little work on the new star in Ophiuchus [Serpentarij].

Ioannes Homelius, professor of mathematics at Leipzig, was born in 1518, on February 2, about sunrise. For his opinion on the star of 1572, see Tycho, *Progymnasmata* vol. 1.

Giovanni Gioviano Pontano [Ioannes Iouianus Pontanus] of Naples wrote 14 books on celestial matters, and on Ptolemy's *Centiloquium*, and the *Meteora*, these last in most elegant verse. He flourished from 1457, when as a youth he observed a comet, until 1495.

Johannes Kepler [IOANNES KEPPLERVS Vuirtembergicus] of Würtemberg, a pupil of Mästlin [Moeſtlini] and afterwards mathematician to three emperors — Matthias, Rudolf and Ferdinand II — a man of most sagacious and most ardent genius and a most acute investigator of astronomical subtleties, left to posterity various monuments of recondite learning. For he published in 1596 the *Prodromus dissertationum cosmographicarum*, or *Mysterium Cosmographicum*;

in 1604 the *Paralipomena ad Vitellionem*, or the optical part of astronomy; in 1605 on the new star in Ophiuchus; and in 1609 the *Astronomia Nova*, or celestial physics, in commentaries on the motions of the star Mars from the observations of Tycho; in 1610 the *Dissertatio cum Nuncio Sidereo* of Galileo; in 1616 new ephemerides, with their foundations, from 1617 to 1620; in 1618 the first three books of the *Epitome Astronomiae Copernicanae*; and in 1619 the five books of the *Harmonices Mundi* and three books on comets. Again, in 1621, he reprinted the *Mysterium Cosmographicum* revised and elucidated with notes; in 1622 he published books 4, 5 and 6 of the *Epitome*; in 1625 the *Hyperaspistes* of Tycho against Scipione Chiaramonti [Scipionem Claramontium], with an appendix on Galileo's *Assayer* [ex trutinatore Galilæi]; and at last, in 1627, the Rudolphine Tables, built upon Tycho's observations, over which he had toiled for 26 years, but polished to the archetype of his own ideas. In their preface he admits that he was with Tycho only a few months of the years 1600 and 1601. That appendix, too, which is attached to vol. 1 of Tycho's *Progymnasmata*, is Kepler's, as he himself admits on p. 1 of his *Ephemerides* and in his letters to Magini; and so are the *Eclogae Chronologicae*, the *Stereometria*, and the *Trigonometria Logarithmica*.

Jean Leurechon [Ioannes Leurechomius], of the Society of JESUS, a Lorrainer from Bar-le-Duc [ex Barroduco], taught philosophy for six years and mathematics for ten. He wrote the *Hilaria Mathematica*, on sundials, and on the comet of 1618.

Jean de Lignières [Ioannes de Linerijs] and **Johannes de Saxonia** [Io. de Saxonia], German astrologers, flourished about the year of the Lord 1380.

Giovanni Lucido [Ioannes Lucidus Samotheus], from France [ex Gallia], wrote on the emendation of the times, and completed it in 1535.

Io. Maria Fiornouellus of Ferrara wrote a learned little work on comets on the occasion of the comet of 1577.

Ioannes Muntz from Plabeirn [ex Plabeirn], a theologian and astronomer famous in his day and a canon of Vienna, wrote prognostications from the stars, and died at Vienna in Austria in 1503, on December 3 [3. Nonas Decembr.].

JOHN NAPIER [IOANNES NEPERVS Scotus], a Scot, Baron of Merchiston [Baro Merchiſtonij], published at Edinburgh [Endiburgi, as printed] in 1614 that excellent invention of logarithms, that is, of artificial numbers, by which the rule of three is performed by subtraction alone, indeed even by addition alone, and spherical triangles too are resolved by a wonderful shortcut, with such ease of computation that I have quite often managed to work out within one hour 30 or more triangles of this kind, which I could scarcely have finished in six or seven hours by the usual tables of tangents and secants. It is therefore incredible how much he has contributed by that ease to astronomy and to the construction of tables.

Johannes Phocylides Holwarda [Ioannes Phocyllides Holuuarda] wrote an epitome and examination of the *Astronomia Reformata*, and flourished in 1635.

Giovanni Pico della Mirandola [Ioannes Picus Mirandulæ Comes], Count of Mirandola, the phoenix of talents, and amid such loftiness of genius pious and most religious, attacked the judicial astrologers most sharply in 12 books and in disputations. He was, however, challenged to a trial by Lucio Bellanti [à Lucio … Bellancio], the champion of astrology, and after a dispute on this subject he was warned, with a threat, of his death in the very next year, that is, in the 33rd of his age and 1495 of Christ, because of the direction of the horoscope to the body of Mars; and in fact he died aged 33. He had been born in 1463, on February 24, at 2^{h} 42^{m} after noon. Cardano describes his nativity in his book of a hundred nativities, no. 65, but tries to disgrace so great a man with unworthy calumnies — an astrologer, that is, against the enemy of astrologers.

Pierio Valeriano [Ioannes Pierius Valerianus Bellunenſis] of Belluno, the noble expounder of *Hieroglyphica*, wrote an elegant compendium on the sphere, addressed to Cardinal Alessandro Farnese [Alex. Farneſium], still a youth but most devoted to these arts, and Vice-Chancellor of the Holy Roman Church. This author flourished in 1540.

Johannes Praetorius [Ioannes Prætorius Ioachimicus] of Joachimsthal, professor of mathematics at Wittenberg and astronomer of the Nurembergers in the school of Altdorf [in ſchola Altorfiana], wrote, on the occasion of the comet of 1577, a history of comets and on their causes and effects. On him see Tycho's critique, *Progymnasmata* vol. 1, p. 639.

JOHANNES DE MONTEREGIO [IOANNES DE MONTEREGIO Franconiæ], of Franconia, hence called Regiomontanus, the glory of Germany, surnamed the Great, was born in 1436, on June 6, at 4^{h} 40^{m} after noon, at Königsberg [Regiomonti], with the Moon and Saturn in platic conjunction [coniunctis platicè] in Gemini — a conjunction that portends a wonderful sharpness of genius — but with the luminaries conjoined in the same sign, and Mars in the eighth house, so that they were afflicted by Mars and signified a life by no means long. At Vienna he was a pupil of Georg Peuerbach [Georgij Peurbachij], who by his last will charged him with completing the *Epitome of the Almagest*. By King Matthias of Hungary, to whom he dedicated the table of the primum mobile, he was enriched with eight hundred Hungarian gold pieces and a most precious robe, and afterwards with an annual stipend from him and gifts from other princes. Moving to Nuremberg, where he was received with great honour, he observed the heavens for some years, and especially the Sun's declinations. At last he was called to Rome for the correction of the calendar by the Supreme Pontiff Sixtus IV, who had already, in his absence, designated him bishop of Regensburg [in Epiſcopum Ratiſponenſem]. But before the business was done he died — of a pestilential fever, or (as others have suspected) killed by poison by the sons of Georgios Trapezountios [Georgij Trapezuntij] out of envy — in 1476, aged 41, and was buried in the Pantheon. It is incredible how much the whole of mathematics, and astronomy above all, owes to this truly Great man: both for the *Epitome of the Almagest*, the book on comets, and the tables and problems of the primum mobile and of directions;

and for the new editions and translations made or procured by him, especially of Manilius, Ptolemy, Theon, Proclus, Menelaus, Theodosius, Julius Firmicus and Hyginus, and likewise of Archimedes, Apollonius, Serenus, Hero, Vitellio [Vitellionis], Leopold of Austria and Jordanus. So Ramus [Petrus Ramus], in book 2 of the *Scholae Mathematicae*, rightly said that Nuremberg could boast of Regiomontanus more justly than Tarentum of Archytas, Syracuse of Archimedes, Byzantium of Proclus, or Alexandria of Ctesibius. On this occasion he adds that the men of Nuremberg, rivalling the dove of Archytas, had made an iron fly which, released from the craftsman's hand and flying round the guests, flew back into its master's hand; and an eagle, which went out a very long way high in the air to meet the arriving Emperor and escorted him to the city gate.

Juan de Rojas [Ioannes Roias], a Spaniard, in the year 1550 wrote, and dedicated to Charles V, commentaries on the astrolabe, or planisphere.

John of Sacrobosco [Ioannes de Sacroboſco], an Englishman and doctor of the University of Paris, composed his *Sphere*, comprising four books, out of Ptolemy, al-Battānī [Albategnio], al-Farghānī [Alfragano] and the other more ancient authors. Although Barozzi detected 84 errors in it, which he lists at the beginning of his *Cosmographia*, it nonetheless acquired such authority in the schools that a great many men more learned than he illustrated it with commentaries or expositions; I shall list them at the beginning of book 1. But not everyone agrees about when he flourished. Clavius, in the preface to the *Sphere*, says he flourished around the year 1232; Gordon [Gordonus], in his *Chronicon*, in 1245; Biancani between 1200 and 1300. Giuntini, however, in his *Catalogue*, assigns him to the year 1393, and Sansovino [Sanſouinus] in his *Chronologia* to 1389. But these two are beyond doubt mistaken. For Élie Vinet of Saintes [Elias Vinetus Santon], in the dedication of his scholia on this *Sphere*, says that Sacrobosco wrote on the sphere, the astrolabe and the algorism in the year of the Lord 1256 [M CC LVI.], and he confirms it from the verse with which this John's little book on the ecclesiastical computus closes. He adds that John was buried at Paris in the cloister of the Mathurin friars [in Clauſtris ſodalium Matturinalium], and that in the middle of the tomb a sphere can be seen carved, with this epitaph, the token of a barbarous age:

> Of Sacrobosco, John the computist, who divided the times, here lies, by time snatched away. You who follow the times, remember that you will die. If you are wretched, weep; in pity, I beg, pray for me.
> [De Sacro Boſco qui Compotiſta Ioannes / Tempora diſcreuit, iacet hìc à tempore raptus. / Tempora qui ſequeris, memor eſto quòd morieris. / Si miſer es plora : Miſerans pro me precor ora.]

Génébrard, too, under Innocent IV, and our Gualterius in his *Chronologia* place him in the thirteenth century of Christ.

Johannes Schöner [Ioannes Schonerus], mathematician of Nuremberg, was born at Karlstadt [Caroloſtadij] in 1477, on January 16, seven minutes before

the eleventh hour of the night. He published astronomical tables in 1536, which were called the *Resolutae*, and the *Use of the Celestial and Terrestrial Globe* in 1551, and an *Astronomical Equatorium*. But on account of suspect opinions he was rejected by the Sacred Censors among the condemned authors. He had a son, the heir of his father's learning.

Johannes Stabius [Ioannes Stabius], an Austrian, a distinguished cosmographer and astronomer at Vienna under the Emperor Maximilian, flourished around the year 1550.

Johannes Stöffler [Ioannes Stoffler ſeu Stoflerinus, ſeu Stoeflerus Iuſtingenſis], or Stoflerinus, or Stoeflerus, of Justingen, an outstanding doctor of mathematics at Tübingen, published in 1510 an explanation of the construction and use of the astrolabe; in 1518 a Roman calendar; and in 1533 a commentary on the *Sphere* of Proclus, written in the year in which he was in the 79th year of his age; and ephemerides from 1532 to 1551.

Johannes Werner [Ioannes Vuernerus], successor at Nuremberg to Regiomontanus and Bernhard Walther [Bernardi Valtheri], was born in 1468, on January 15, at $5^{h}\ 44^{m}$ after midnight. He wrote on Ptolemy's *Geography*, on the motion of the eighth sphere, and astronomical tables, in which he set out the places of the stars; and in 1514 he gave the Sun's greatest declination as 23° 28′.

Johannes Vögelin [Ioannes Vogelinus] observed the comets of the years 1527 and 1532; he was a pupil of Regiomontanus.

Giuseppe Auria [Ioſephus Auria], a Neapolitan, expounded Autolycus on the sphere and on the risings of the fixed stars, Euclid's *Phaenomena*, and Theodosius of Tripoli on habitations and on days and nights, in 1588.

Giuseppe Biancani [Ioſephus Blancanus] of Bologna, of the Society of JESUS, my teacher in the elements of geometry and of the sphere, once a pupil of Clavius at Rome, taught the mathematical disciplines at Parma up to the year 1624. On June 7 of that year he died, of sheer dissolution and failure of the natural heat, all his organs being found unharmed by the anatomists. He wrote on the mathematical passages of Aristotle and on the nature of the mathematical sciences; a *Chronology of the Mathematicians*; a *Sphere of the World* from more recent observations; an *Introduction to Geography*; an *Apparatus for the Mathematics*; an *Echometria*; and an *Instrument of Sundials* [inſtrumentum Horologiorum], which I was the first to see into print. He was a man of slow but solid judgement, mature in weighing the demonstrations [Apodixibus] of others, of religious candour and charm, and dear to all for the grace of his wit [eutrapeliæ].

Joseph Lange [Ioſephus Langius] of Kaysersberg [Cæſaremontanus], ordinary professor of mathematics and of the Greek language at Freiburg, published in 1612 an *Elementale Mathematicum* of logistic, of both kinds of [vtriuſque] geometry, of astronomy, of the theory of the planets, and of geography.

Giuseppe Moletti [Ioſephus Moletius], professor of mathematics at Padua, wrote commentaries on Ptolemy's *Geography* and enlarged it with new maps in 1562; then, in 1580, the *Gregorian Tables* derived from the Prutenic, for the motion

of the eighth sphere and of the luminaries, on the correction of the calendar and the ecclesiastical computus; and an introduction to the ephemerides.

Giuseppe Scala [Ioſephus Scala], a Sicilian, computed ephemerides from the year 1589, in which he flourished, up to the year 1600.

Joseph Justus Scaliger [Ioſephus Scaliger], son of Julius Caesar [Scaliger] à Burden, flourished at the end of the last century and the beginning of this one. He wrote the *Cyclometrica*; a *Diatribe on the Anticipation of the Equinoxes*; and a most learned work, *De emendatione temporum*, in the year of the Lord 1587. But through the heat of his genius and excessive self-confidence he stumbled in many things, and was deservedly thrashed by the most solidly learned Fathers of our Society, Clavius, Guldin [Guldino] and Pétau; see the judgement on him in Pétau, *Prolegomena* to the *De Doctrina temporum*, chapters 5 and 6. His father had died at Agen [Agenni] in 1558, as Génébrard has it under Paul IV.

Gioseffo Zarlino [Ioſephus Zarlinus], of Fossa Clodia, commonly *da Chioggia*, wrote in 1557 the *Institutioni Harmoniche* [Inſtitutiones Harmonicas], in which he also treats of the harmonic system of the celestial spheres.

Isaac Argyros [Iſaacius Argyrus], a monk, in the eleventh century of Christ wrote on the cycles of the Sun and Moon and on the ecclesiastical computus. Our Pétau translated this work from Greek into Latin and inserted it in the *Uranologion*, p. 359.

Yitzchak ibn Sid [Iſaac Hazan] — *Hazan* meaning cantor of the synagogue of Toledo — a Jew, was the foremost of those whom King Alfonso put in charge of drawing up the Alphonsine Tables, which first appeared in 1252, as Agostino Ricci relates in his treatise on the motion of the eighth sphere, chapter 38.

Yitzchak Yisraeli [Iſaac Iſraelita], of whom Ricci speaks in the same work, chapters 3, 36 and 45, flourished in the year of grace 1310 and wrote the book *Iessod-holam* [Ieſſod-holam], that is, *On the Foundation of the World*, in which he quite often mentions the motion of the eighth sphere.

Isidorus, a geographer and distinguished philosopher mentioned in the Suda [apud Suidam] and in Pliny the Elder, and the teacher of Hypsicles of Alexandria, is set down as having flourished in the time of Apollonius of Perga; see *Apollonius*.

St Isidore of Seville [S. Iſidorus Hiſpalenſis], the Younger, bishop, son of Severianus, duke of Cartagena [Carthaginis], and brother of St Leander, touches on the elements of astronomy in his books of *Origins* and wrote a treatise *On the Sphere*. He died in 636, on January 15 [18. Calend. Februarij].

Abū al-Fidā' [ISMAEL ABILFEDEA ſeu Abulfeda], prince of Syria, Assyria and Persia, as Conrad Gessner [Conradus Giſnerus] says in his *Bibliotheca*, and Christmann after him on al-Farghānī, chapters 10 and 11, was a distinguished cosmographer and eminent in geography. In describing the world subject to the Ishmaelites he takes the beginning of longitudes from the Pillars of Hercules. At the end of the codex Abū al-Fidā' attests that he wrote this *Geography* in the year of the Hegira 721, therefore in the year of Christ 1322. Guillaume Postel

[Gulielmus Poſtellus] brought it from the East and sold it, with other Arabic books, to Otto Henry, Elector Palatine [Ottoni Henrico Principi Palatino]; it is preserved in the Palatine Library.

Ismaël Boulliau [ISMAEL BVLLIALDVS], son of Ismaël Boulliau of Loudun [Iulioduni], who was in the habit of observing the stars, an astronomer of profound research, after his *Philolaus* called up from the dead in 1640, published at Paris in 1645 the *Astronomia Philolaica*. It is built on the hypothesis of the motion of the Earth and of an elliptical orbit described by the planets about a cone, is made illustrious by solid demonstrations, and has the Philolaic tables appended: a work for all students of astronomy, but not to be read without attention. He represented the motions of Saturn, Jupiter and Mercury more accurately than the Rudolphine Tables, and in many respects presented easier tables.

Giuliano Ristori [Iulianus Riſtorius] of Prato, a Carmelite, doctor of sacred theology and an excellent astronomer, and the teacher of Giuntini, observed the planets in 1536 and 1542, as Giuntini relates in the preface to his *Resolved Tables* [tabulas Reſolutas].

Giulio Cesare Lagalla [Iulius Cæſar Lagalla] in 1612 published a disputation on the new phenomena seen by the telescope in the body of the Moon.

Julius Firmicus Maternus [Iulius Firmicus Maternus iunior] the Younger, a Sicilian, flourished under Constantine Augustus, as is clear from his own preface addressed to the proconsul Mavortius Lollianus [Macortium Lollianum] [recte: Mauortium]. He is therefore not absurdly placed in the year of Christ 314 by Sansovino in his *Chronologia*, or in 328 by Giuntini. He wrote eight books of *Astronomica* [Aſtronomicῶn], full of astrological precepts.

Julius Schiller [Iulius Schillerus] of Augsburg in Vindelicia [Auguſtanus Vindelic.], I. V. C., in 1627 published the *Coelum stellatum Christianum*, that is, the stars brought into images of the saints, their profane names being changed into sacred ones; Johann Bayer [Io. Bayero] supplied a new and more accurate *Uranometria*.

L

Lorenz Eichstadt [Laurentius Eichſtadius], doctor of medicine and physic at Stettin [Stetini], and professor of mathematics at Danzig, or Gedanum [Dantiſci ſeu Gedani], flourished in 1645. We shall report some of his observations of eclipses in the *Catalogue of Eclipses*.

Leopold of Austria [Leopoldus de Auſtria], an astrologer of great fame, flourished around the year 1200.

Lilio Gregorio Giraldi [Lilius Gregorius Gyraldus] of Ferrara, whom Lipsius calls the Varro of his age, wrote in 1542 a most learned book on the years, months and other divisions of time of the Romans and the Greeks, with the calendar of both.

Luca Gaurico [Lucas Gauricus], of Giffoni [Geophnenſis] in the Kingdom of Naples, bishop of Civitate [Epiſcopus Ciuitatenſis], professed mathematics in 1531 at the University of Ferrara, and there delivered an oration in praise of

astrology. In the same year, 1531, there appeared at Venice, by his labour and care, many expositors both of the *Sphere* of Sacrobosco and of the *Theoricae* of Peuerbach. In 1552 he wrote, addressed to Paul III, an ecclesiastical calendar; and in 1557 tables of the primum mobile, called tables of directions, with astrological precepts and problems.

Lucillus Philalthaeus [Lucillus Philalthæus] in 1563 wrote splendid commentaries on the books *De caelo*.

Lucio Bellanti [Lucius Bellantius] of Siena wrote 20 questions on astrological truth, and 12 books of a defence of astrology against Giovanni Pico [Io. Picum], whose death he had foretold, in the year 1495, from a celestial figure; to these is annexed a *Dialogue* of Gabriele Pirovano [Gabrielis Pirouani] on the truth of astrology.

Lodovico Vitali [Ludouicus Vitalis], astronomer of Bologna, was born in 1475, on August 23, at 17^{h} 8^{m} after noon.

M

Macrobius Ambrosius Aurelius Theodosius [Macrobius Ambroſius Aurelius Theodoſius], a man of consular rank, by birth of Parma [patria Parmenſis], shows himself not unskilled in astronomical matters in his two books on the *Dream of Scipio*. At the beginning of the fifth book of the *Saturnalia* he indicates that he was a contemporary of Symmachus, who flourished under Theodosius and his sons in the fourth century of Christ, as Jodocus Coccius [Iodocus Coccius] also notes in volume 1 of his *Thesaurus*, in the book on the signs of the Church, article 2. He is therefore wrongly assigned to the second century by Génébrard, Sansovino and Thevet [Theueto], or to the tenth century in the index of the Vatican Library.

Marcus Manilius [M. Manilius] of Antioch wrote for Caesar Augustus five books of *Astronomica* [Aſtronomicω̃n] in heroic verse not to be despised, in which he embraced astronomy and astrology alike. This is the Manlius (the name contracted) who set a gilded ball on the obelisk erected by Augustus in the Campus Martius, so that the shadow, gathered together, might be better bounded and might mark the days of the equinox and the solstice, as Pliny the Elder relates, book 36, chapter 10. Giuntini is therefore not wrong to say that he flourished about the year 48 before Christ.

Martianus Capella [Marcianus Capella], also called Felix Mineus Afer, a little before Heraclius, or about the year of the Lord 600, wrote in the *Marriage of Mercury and Philology* on geometry, arithmetic, astronomy and music.

Marcus Agrippa, son-in-law of Augustus, displayed to the Roman people a map of the world, described in his own commentaries and afterwards painted in a portico, as Pliny the Elder relates, book 3, chapter 2, and book 7, chapter 8. He died aged 51 in the 31st year of Augustus, as Vignier [Vignerus] has it, that is, in the year 12 before Christ.

Marcus Beneventanus [Marcus Beneuentanus] wrote on Thābit [Thebit], on the motion of the eighth sphere; he flourished in the fourteenth century of Christ.

Marin Mersenne [Marinus Merſennius], a Frenchman of the order of St Francis of Paola, touched on many astronomical matters in his most learned commentaries on Genesis; he flourished in 1645.

Marinus of Tyre [Marinus Tyrius], a distinguished geographer, praised by Ptolemy, flourished under Nero. But he must have lived on to Ptolemy's time, that is, to the year of the Lord 69 or 70, since Ptolemy was born in that year, and in book 1 of the *Geography*, chapter 6, says: *"Marinus of Tyre, then, the latest of those who have lived in our time, appears to have applied himself to this part with the greatest zeal; for it is plain that he unrolled very many histories, beyond even those known in earlier times, and read through with the greatest diligence the writings of almost all who preceded him."*

Mario Bettini [Marius Bettinus], of the Society of JESUS, was born at Bologna in 1582, on February 6. Very learned in humane letters and indeed in sacred ones, he taught moral philosophy at Parma, with me among his hearers, and afterwards mathematics publicly. Among other works he wrote the *Apiarium*, or paradoxes of the whole of mathematical philosophy, in whose eighth *Apiarium* he treats chiefly of astronomy, leaving to posterity monuments of his most acute genius; and in the *Euclides applicatus*, or *Aerarium* of mathematics, he touches on the same matters from time to time. He was living in this year 1651, aged 69.

Marsilio Ficino [Marſilius Ficinus], physician, astrologer and philosopher, in writing on Plato's *Timaeus* and his other dialogues discusses astronomical matters in no light way. He died in 1499, aged 66.

Martinus Hortensius [Martinus Hortenſius] of Delft, the colleague and helper of Philips van Lansbergen [Philippi Lansbergij] and no common observer of the stars, as Lansbergen himself declares in his preface to the reader, flourished in the year of Christ 1633. In that year he also published, with Pierre Gassendi [Petro Gaſſendo], a dissertation on Mercury seen in the Sun and Venus unseen.

Matteo Ricci [Matthæus Riccius] of Macerata, of the Society of JESUS, was born in the year of salvation 1552, on October 6, and entered the Society in 1571, on August 15. Having obtained a mission to the East Indies, he left Italy in 1577 and reached Goa in 1576, on September 13. He landed at Macau in 1582, in the month of August, and the following year, entering the kingdom of China, drew a cosmographical map of the whole world in such a way that the kingdom of China occupied the greater part in the middle, while the other kingdoms appeared small at the edges of the oval map. In this he indulged the temper of a nation that thinks magnificently of itself and narrowly of other kingdoms, without damage to geographical truth. He wrote in the Chinese language cosmographical and astrological rules, enriched the cosmographical map with commentaries, and wrote on the sacred calendar and much else in aid of that nation. He died a holy death, as he had lived, at Peking [Pachini], the royal city of the Chinese, in 1610, on May 11, and the King decreed him a most honourable tomb.

Maurus Florentinus, at the end of the last century, described the sphere in the Italian language.

Melchior Inchofer, of the Society of JESUS, of Vienna, who long professed philosophy, mathematics and theology at Messina with praise, published in 1633 a *Tractatus Syllepticus* on the rest of the Earth and the motion of the Sun according to Sacred Scripture and the Holy Fathers; and also an examination of the celestial figures [examen Thematum cęleſtium] of various astronomers up to Tycho, a method of computing eclipses, and a theory of the planets — but these three under another's name, that of the Academicus Vertumnius [Academici Vertumnij]. He died at Milan in 1650.

Menelaus, geometer and astronomer, also called *Mileus* or Milesius, observed the stars at Rome in the first year of Trajan, that is, in the year of Christ 97, as Ptolemy relates, *Almagest* book 7, chapter 3. He wrote six books on chords [de Subtenſis] and three books of *Spherics* on triangles [Sphęricorum triangulorum].

Mercurius the Elder [Mercurius Maior], grandson of Atlas, flourished around the year 1520 before Christ; his grandson Trismegistus around the year 1460.

Māshāʾallāh [Meſshala Arabs], an Arab, a most celebrated astrologer, flourished in the year of Christ 860. He wrote a book on the reckoning of the circle and of the stars and how they act in this world, and on the elements and the celestial orbs.

Meton [METON], astronomer and astrologer of Athens, an observer of the solstices cited by Ptolemy, *Almagest* book 3, chapter 3, wrote *Prognostica*; and he first introduced, or restored, the enneadecaeteris [Enneadecaterida], that is, the cycle of 19 years, which was called the Year of Meton; he made its beginning in the 4th year of the 86th Olympiad, that is, 432 before Christ. But we shall say more of Meton in book 4, chapter 19, number 5.

Metrodorus, philosopher and astronomer, wrote five books on the reckoning of the zones; he was the teacher of Anaxarchus, as Laertius says, and flourished around the 105th Olympiad, or 360 before Christ.

Michelangelo Biondo [Michael Angelus Blondus], a physician, wrote in 1544, addressed to Paul III, on critical days, and, addressed to Rodolfo Pio, Cardinal of Carpi [Rudolphum Pium Cardinalem Carpenſem], on the anticipation of the fixed stars, with their significations.

Michael Florent van Langren [MICHAEL FLORENTIVS LANGRENVS], cosmographer and mathematician to Philip IV, King of Spain, in the Low Countries [in Belgio], published in 1644 a treatise on the true longitude by land and sea through observation of the lunar spots as they are darkened or illuminated, with the censures and approbations of most learned men. In 1645 he began, with plates engraved by himself for this purpose, to publish a selenography, that is, figures of the lunar spots and of the whole lunar disc, to which he gave this title: *Selenographia Langreniana, sive Lumina Austriaca Philippica*. He sent me two copies of it from Brussels, to Parma and to Bologna, to be examined with a special telescope, together with various observations

of eclipses, of the planets and of the fixed stars, and of the diameters of the Moon, in several most courteous letters written to me. He also promises many other figures of the phases of the Moon, with a theory of the other motions and especially of the libration. But, nearly destitute of patrons [Mecœnatibus] and hindered by the great number of children he had to support, he could not publish these sooner and so forestall Hevelius. He is a most excellent man, worthy of a better fortune, to whom, as I owe a very great deal, so I pray from God, best and greatest [D. O. M.], a very great deal of happiness.

Michael Mästlin [Michael Mæſtlinus] of Göppingen [Gæppingenſis], parish priest of the town of Backnang [Bachnang], then professor of mathematics in the University of Heidelberg [Hoidelbergę] and at Tübingen, and Kepler's teacher, wrote on the star of the year 1572, which Tycho reports and strongly approves in volume 1 of the *Progymnasmata*, from p. 544; and on the comet of the year 1577, which Tycho likewise reports in volume 2, from p. 245; then ephemerides from 1577 to 1590 from the Prutenic Tables; and in 1606 *Theses on Eclipses*. He also wrote additions to Rheticus's *Narratio prima*, and an appendix on the dimensions of the celestial orbs according to the opinion of Copernicus. But since he was infected with the Ubiquitarian heresy and hostile to the Roman Pontiff and the Catholic Church, he dared to bark at the Pontiff's authority and at the Gregorian calendar. His barking was silenced, however, by our Clavius, in the *Apologia of the Roman Calendar* addressed to Rudolf II, Emperor of the Romans, written in 1588, which forced him to fall dumb, or to mutter with a secret groan within the sheepfolds of the sectaries.

Michael Scot [Michael Scotus], a diligent observer of the stars, at the request of the Emperor Frederick III published in 1460 questions on the *Sphere* of Johannes de Sacrobosco.

Michael Neander, of Joachimsthal [ex Valle Ioachimica], published in 1561 the *Elementa doctrinae sphaericae* and the *Computi Astronomici materia*.

N

Hicetas [Nicetas ſeu Hicetas Syracuſanus], or Nicetas, of Syracuse, of whom Laertius speaks in his *Philolaus*, said that the Earth moves; his date is not known to me.

Nikolaos Kabasilas [Nicolaus Cabaſilla], a Greek, published a commentary on Ptolemy's *Great Syntaxis* around the year of the Lord 1220.

Niccolò Cabeo [Nicolaus Cabæus] of Ferrara, of the Society of JESUS, was born in 1586, on February 26. Public professor of philosophy at Parma, he wrote, besides the *Philosophia Magnetica*, a commentary on Aristotle's *Meteorologica*, and questions full of recondite learning, in which he repeatedly treats what it is worth an astronomer's or cosmographer's while to know, especially where he deals with comets, the Milky Way, and so on. He died at Genoa, where he was publicly teaching mathematics to great applause, aged 64, in 1650, in the month of July, leaving there a great sense of his loss; and by a death proper to a religious, solidly pious man, constant to himself to the very end, he set the seal on the sincerity of his life.

Copernicus [NICOLAVS COPERNICVS] of Toruń [Torinenſis], canon at Frombork [Fruemburgi] in Warmia [Vuarmia], a region of Prussia, was born in 1472, on January 19, at 4^{h} 48^{m} after noon, as Francesco Giuntini [Franciſcus Iunctinus] records in his *Astrological Calendar*. But Johannes Garcaeus [Io. Garcæus], in his *Astrologiae methodus*, p. 138, says that he was born in 1473, on February 10, at 4^{h} 38^{m} after noon, at a pole altitude of 55°, with the Moon in 7° of Sagittarius regarding by an exact [partiliter] trine aspect Mercury, placed at the beginning of Aries, and with the 16th degree of Libra ascending; he affirms that this aspect was also in Peuerbach's nativity [in Geneſi Purbachij], and that it makes men ingenious. Mästlin, however, in his addition to Rheticus's *Narratio prima*, says that he was born in 1473, on February 19, at 4^{h} 48^{m}, on the Friday before the feast of the Chair of St Peter, and died in 1543, on January 19 [Ianuarij 19.], aged 70, in the very year in which he had seen to the publication of the books of *De revolutionibus*. So either Giuntini is wrong, or the astrologers worked back from the birth to the moment of conception and set that down as the first birth.

Copernicus was, moreover, first a pupil of Domenico Maria Novara of Ferrara [Dominici Mariæ Ferrarienſis], and helped him in his astronomical observations at Bologna, where in 1497, on March 9 [ſeptimo Idus Martij], at the age of 24, he observed the bright star of the Hyades, or Palilicium, occulted by the Moon, as he himself relates in book 4, chapter 27. Then in 1500, now aged 27, he professed mathematics at Rome before a great crowd of students and a circle of great men, as Rheticus reports; and in the same year 1500, in the same place, he observed an eclipse of the Moon on the night after November 5, as he himself reports in book 4, chapter 14. Returning thereafter from Rome to his homeland, he devoted himself wholly to observing the stars and restoring astronomy, choosing Frombork in Prussia for his observations — which lies at the mouth of the river Istula, or Vistula, and which, from eclipses observed in both places, he had found to lie under the meridian of Kraków, as he says in book 3, chapter 19, and book 4, chapter 7 — even though he admits, in book 5, chapter 30, that because of the vapours of the Vistula Mercury could not be observed by him. He teaches in book 3, chapter 2, that he found the pole altitude of Frombork to be 54° 19½′ [gr. 54. min. 19. cum dimidio], and the Sun's greatest declination 23° 28′. But because he omitted refractions, and because he used parallactic rulers — four cubits long, indeed, but of fir wood, with divisions made in ink not very finely — he erred by 2′ and more, as Tycho teaches in volume 1 of the *Progymnasmata*, pp. 34 and 36, where he says that this instrument was sent to him as a gift by Johannes Hannow [Ioanne Hannouio], canon of Warmia [Canonico Var-lmienſi].

For, as Rheticus admits in his preface to the *Ephemerides*, *he wished his researches to be moderate, not excessive*; and when Rheticus quarrelled with him about pursuing the minutes, he replied: *"If I can bring the truth to within sixths of degrees, which are ten minutes, I shall exult in spirit no less than Pythagoras, we are told, did on finding the rule of the right angle [ratione normæ reperta]"*; and he

affirmed that it was possible to get even that far only with difficulty. The first of his observations made at Frombork I find in 1509, concerning an eclipse of the Moon, from his book 4, chapter 13; for the other eclipses, of which he speaks in book 4, chapter 5, were observed in 1511, 1522 and 1523. In 1512 he observed Mars at acronychal rising [acronychium], in 1514 Saturn, and in 1520 Jupiter, likewise acronychal, from book 5, chapters 6, 11 and 16. In 1515 he observed Spica and the Sun's greatest declination, from book 3, chapter 2; in 1522 and 1524 the parallaxes of the Moon, from book 4, chapter 16; in 1525 Spica again; and finally, in 1539, a conjunction of the Moon with Venus. Urged by letters sent from Rome in 1536 by Nikolaus von Schönberg [Nicolao Schombergio], Cardinal of Capua, and also by Tiedemann Giese [Tidemanno Giſio], Bishop of Kulm [Culmenſi], he permitted in the last year of his life, which was 1543, the publication of the books of *De revolutionibus*, which he had kept back for 36 years, as he himself admits in the dedication to Pope Paul III. Tycho, in his *Letters*, p. 240, reports that Copernicus painted his own portrait with his own hand from a mirror; Tycho had it from the chest upwards only, and so he closed an epigram on him thus:

> But the body, you will say, is seen in an image only half-length, not enough for so great a man. Of course: he who carried the whole Earth into the aether — not even the whole Earth itself can hold the whole of him.
> [At corpus, dices ſpectatur imagine ſaltem / Dimidiâ, haud tanto ſufficiente Viro. / Scilicet is, totam qui geſſit in Æthera Terram, / Tota nec hunc totum Terra vel ipſa capit.]

Nicolas Caussin [Nicolaus Cauſſinus], of the Society of JESUS, of Troyes in France [Trecenſis ex Gallia], wrote most recently *De Domo Dei*, that is, on the heaven, and wrote against the astrologers very acutely and learnedly. He died in this year 1651, aged 70.

Nikolaus von Kues [Nicolaus Cuſanus] was born at Kues [Cuſæ], a village on the bank of the Moselle in the diocese of Trier [Teuerenſi]. He was Cardinal of the title of St Peter in Chains, papal legate to Germany and Bishop of Brixen [Brixinenſis]: a philosopher, theologian and mathematician of most subtle genius, skilled in three languages, Latin, Greek and Hebrew. Besides other works that do not concern us, he wrote on the reform of the calendar, on the canon of the fixed stars, and on mathematical complements. He died in 1464, on August 11, aged 63, and was buried at Rome; his heart, however, was sent to Kues, to the hospital of St Nicholas which he had built, and is preserved in the middle of the choir.

Nicolaus Mulerius [Nicolaus Mulerus], physician and rector of the gymnasium at Leeuwarden [Leouuardiæ], published in 1611 the *Tabulae Frisicae Lunae-Solares quadruplices*, namely of Ptolemy, Alfonso, Copernicus and Tycho, with the old Roman calendar.

Nikolaus Winckler [Nicolaus Vuincklerus], physician of Schwäbisch Hall [Hale Sueuorum], wrote in 1577 on the comet of that year.

Niccolò Zucchi [Nicolaus Zucchius], of the Society of JESUS, of Parma, taught philosophy and theology with great praise; at Rome he was the helper and instigator of Father Scheiner in observing the spots of the Sun. He will shortly send to the press the first part of his *Optical Philosophy*, in which he also treats of celestial refractions from appearances through the telescope. Of the keenness and depth of so great a man it is better to be silent than to say a little.

O

Oenopides of Chios [Oenopides Chius] was so great in mathematics that Plato commended him in the *Lovers* [in amatoribus]. Proclus, propositions 12 and 13 [pr. 12. & 13], and Theon of Smyrna in his *Astronomica* attribute to him praise in astronomy [Aſtrologiæ laudem], Theon adding that Eudemus asserts that he first noticed the obliquity of the zodiac and the constitution of the great year. Aelian, in book 7 of the *Varia historia*, chapter 10, relates that when he dedicated a table of laws at Olympia, he inscribed on it an astronomy [Aſtrologiam] of 59 years, affirming this to be the great year; Censorinus, chapter 7, calls him Vaenopides [Vęnopidem]. The obliquity of the zodiac [ſigniferi], however, is said to have been discovered by Anaximander, as Pliny the Elder says, book 2, chapter 8, or by Pythagoras, as Plutarch relates, book 2 of the *Placita*, chapter 12.

ʿUmar al-Ṭabarī [Omar, ſeu Haomar Tiberinus], an astrologer — that is, from Tiberias — son of Belnalfargdianus [Belnalfargdiani], wrote three books on nativities, around the year of the Lord 1200.

Oronce Finé [Orontius Finæus] of the Dauphiné [Delphinas] flourished in 1531 and was Royal Professor of Mathematics at Paris. He wrote on the sphere of the world, or *Cosmographia*, the *Theoricae* of the planets, and astronomical canons, or problems of the primum mobile, and on finding the difference of longitude by the Moon, and many other small works; but Pedro Nunes [Petrus Nonius] published a book on the errors of Oronce.

Osymandias [Oſymandies], king of Egypt, as Dionysius of Halicarnas- -sus, in his books of *Antiquities*, ordered his tomb to be girded with a circle of solid gold, 365 cubits in circumference — as many as there are days in the year — with the risings and settings of the stars and their yearly effects.

P

Pappus of Alexandria [PAPPVS Alexandrinus], around the year of the Lord 390 or 400, wrote eight books of *Collections*, which Federico Commandino [Federicus Commandinus] translated from Greek into Latin and illustrated with commentaries; also a commentary on book 5 of the *Almagest*, and a universal description of the world.

Paul of Alexandria [Paulus Alexandrinus] wrote an *Introduction to Astronomy* [iſagogem Aſtronomiæ] in the year of Christ 378.

Paul Fabricius [Paulus Fabricius], imperial mathematician and physician, wrote a few things on the star of the year 1572, about which see Tycho, volume 1 of the *Progymnasmata*, p. 528.

Paul of Middelburg [Paulus Middelburgenſis], bishop of Fossombrone [Foroſempronieſis], wrote in 1513 to Pope Leo X on the correct celebration of Easter, and to the Emperor Maximilian a most learned work on the day of the Passion of Christ the Lord.

Paul Guldin [Paulus Guldin], of the Society of JESUS, a native of St. Gallen [Sancto-Gallenſis], was born in 1577, on June 12, and was called Habakkuk [Habacuc]. He was brought to the Catholic faith at Freising [Friſingę] and admitted at Munich in 1597 as a temporal coadjutor, taking the name Paul. But when his outstanding aptitude for mathematics was discovered, he was called to Rome, studied philosophy and mathematics, and taught mathematics at Graz [Græcij] and Vienna. He wrote in defence of the Gregorian calendar against Sethus Calvisius [Sethum Caluiſium], where he also wrote against Scaliger's *Diatribe on the Precession of the Equinoxes*; a *Geographical Problem* on the discrepancy in the counting of days between those who sail to the New World and those who stay there; the *Centrobaryca*; and other works. He died in 1643.

Paul Hainzel [Paulus Hainztlius] [recte: Hainzelius, per the book's errata], consul of Augsburg, observed the stars from the year 1572 at Göggingen [Geggingę] near Augsburg of the Vindelici with a very large quadrant of 14 cubits. For his praises see Tycho, volume 1, from p. 352 and at p. 444.

Paulus Philosophus [Paulus Philoſophus] wrote an *Introduction to Astrology* in the 9th century of Christ.

Petosiris [Petoſiris, ſeu Petoſciris], or Petosciris, an Egyptian, treated astrological matters out of the sacred books, at the end of the 9th century of Christ.

Pierre d'Ailly [Petrus Aliacenſis], cardinal of the Holy Roman Church [S. R. E. Cardinalis] and bishop of Cambrai, chancellor of the University of Paris and teacher of Jean Gerson [Ioannis Gerſonis], wrote questions on the *Sphere* of Sacrobosco, on the reform of the calendar, and a *Concordance of Theology and Astronomy*, besides theological and ecclesiastical treatises. He took part in the Council of Constance in 1416, and urged it to repair the calendar.

Peter Apian [Petrus Apianus], of Leipzig [à Leypziga], flourished chiefly at Ingolstadt from the year 1530. He wrote a *Cosmographia*, revised and enlarged by Gemma Frisius, with observations or notes of many eclipses; an *Instrument of the Primum Mobile* [inſtrumentum primi Mobilis], with a hundred propositions or problems; and the *Opus Caesareum*, in which, with most ingenious wheels and automata, he teaches how to solve almost all astronomical problems — with an added treatise on the comets he had observed, and on the torquetum.

Pietro d'Abano [Petrus Aponus], called the Conciliator, flourished in 1317.

Pietro Catena [Petrus Catena] wrote a *Sphere* at about the same time as Giovanni Pierio Valeriano [Io. Pierius Valerianus].

Peter Crüger [Petrus Crugerus], mathematician of Danzig [Dantiſcanus], besides logarithmic tables wrote an *Astronomia Dantiscana*, which however he

did not bring to completion, as Hevelius, his own pupil, testifies on p. 167 of the *Selenographia*. He also wrote a *Uranodromus cometicus*.

Pedro Ciruelo [Petrus Ciruellus], a theologian, wrote learnedly in favour of astrology — but a sound astrology — against Pico. I have not seen him, but Caussin names him in book 3 of *De Domo Dei*.

Pierre Gassendi [Petrus Gaſſendus], canon of Digne, distinguished for his astronomical observations made at Paris, Digne, Aix [Aquis Sextijs] and Marseille, and a man of wonderful candour in style, in mind and in character, is still flourishing, and has flourished from the year 1625. In 1642 he wrote on the apparent size of the Sun low and high; on motion impressed by a mover that is itself carried [de motu impreſſo à motore tranſlato], where there is much in favour of the Earth's motion; likewise a judgement on the new stars seen around Jupiter; and two books of *Institutiones Astronomicae*, on the occasion of the chair of mathematics conferred on him at Paris.

Pierre Hérigone [Petrus Herigonius], professor of mathematics at Paris, wrote a *Cursus Mathematicus*, in whose volume 4, published in 1644, he treats of the sphere of the world and of the use of the geographical map, and in volume 5 the theory of the planets.

Pedro Nunes [Petrus Nonius] of Alcácer do Sal [Salacienſis] wrote on twilights and on the errors of Oronce Finé [Orontij]; then astronomical problems, and rules for observing maritime matters and celestial phenomena, and on the motion of a ship; and on Peuerbach's *Theoricae* [in Theoricas Purbachij], where in note 1 he says: "In our time, that is, in the year 1552 from the birth of Christ, etc.," and yet in the same notes he says he was born in 1492; so at that time he was in his 60th year.

Pietro Pitati [Petrus Pitatus] of Verona wrote an *Isagoge to the Ephemerides*, and on establishing a new calendar, addressed to Pope Paul III in 1537; to this end he had made some observations.

Pierre de la Ramée [Petrus Ramus], a pupil of Oronce Finé [Orontij Finei], published in 1569 two books of *Arithmetic* and 27 of *Geometry*, and in 1566 31 books of *Scholae Mathematicae*, in the earlier of which he treats much concerning the origin and growth of astronomy. Is this the physician whom Giuntini, in his *Astronomical Calendar*, says was born in 1532, on February 22, at $3^h\ 23^m$ after noon?

Phlegon, an eminent chronographer, a freedman of Hadrian, according to Génébrard, book 2 of the *Chronographia*, p. 117, and Volaterranus [Volaterrano] in the *Anthropologia*, book 18, col. 567.

Philipp Apian [Philippus Appianus], son of Peter Apian, declared his judgement on the star of the year 1572 in a letter, which Tycho quotes in volume 1 of the *Progymnasmata*, p. 643.

Philips van Lansbergen [PHILIPPVS LANSBERGIVS] of Ghent [Gandauenſis], in the year of the Christian era 1632 — which he thinks is truly 1635 — when he was in the 71st year of his age, published at Middelburg tables of the celestial motions accommodated to the meridian of Goes [Goeſę], with

a *Treasury of Observations* and *Theories of the Planets*, assembled by the labour of almost 44 years. He also published an *Uranometria*, *Progymnasmata* on the motion of the Sun, a work *On Triangles*, and *Commentationes* on the diurnal and annual motion. These are held in great esteem, and rest partly on the observations of others and partly on his own, and on those of Martinus Hortensius [Martini Hortenſij].

Philolaus of Croton [Philolaus Crotoniata], a pupil of Pythagoras, one of those who said the Earth moves and that all things come about by a kind of harmonic necessity, was of such renown that Plato bought his books from his kinsmen for forty Alexandrian minae, and from them transcribed the *Timaeus*; but see Laertius on Philolaus. He flourished in the year 430 before Christ.

Philosophus [Philoſophus], a man called by this as his proper name in the Suda [apud Suidam], a pupil of Plato around the year 380 before Christ, wrote on the eclipse, on the distance and size of the Sun, Moon and Earth, and on the planets.

Pytheas of Massalia [Pitheas Maſſilienſis], a cosmographer cited by Strabo, flourished under Alexander the Great around the year 320 before Christ.

Plato [PLATO Athenienſis] of Athens, who treats astronomical matters and the system of the heavens in the *Timaeus*, the *Epinomis* and others of his dialogues, was born in Olympiad 88, year 1, on day 7 of the month Thargelion — that is, in the year 428 before Christ. He died in his 81st year, in Olympiad 108, when Theophilus was archon at Athens, namely in the year 348 before Christ, as Laertius records, while reclining at a wedding feast; granted that Neanthes says he died at the age of 84. Speusippus succeeded him.

Pliny the Elder [Plinius Senior], who has much on celestial matters in book 2 of the *Natural History*, flourished under Vespasian, and perished on Vesuvius at the age of 55, in the year of Christ 80, while examining its crater too inquisitively, as Pliny the Younger relates in book 6, letter 16; [see also] Volaterranus [Valaterranus] in the *Anthropologia*, and Génébrard.

Plutarch of Chaeronea [Plutarchus Cheronenſis] shows himself not ignorant of astronomy in the little work *On the Face of the Moon*, in the books *On the Opinions of the Philosophers*, and elsewhere. He flourished from the year of Christ 70 to 104, and was the teacher of Trajan. See Eusebius, Génébrard, Volaterranus [Valaterranum] and Vigarius [Vigarium] [?].

Polemon, a geographer, a hearer of Panaetius of Rhodes, completed a description of the world, and flourished in the year 640 before Christ, according to the Suda.

Pomponius Mela, who wrote on the situation of the world, flourished in the year of Christ 47 under Claudius, and Génébrard assigns him to the first century; but the man who prefixed a preface to Pomponius doubts whether he flourished under Claudius or under Augustus.

Posidonius [Poſſidonius], a pupil of Panaetius, a mathematician according to Pliny the Elder and an astronomer, a geographer according to Strabo, observed Canopus at Rhodes. He flourished under Pompey, who did not blush to knock

at his door and to listen to him; so he lived in the year 50 or 60 before Christ. Cicero, too, in book 2 of *On the Nature of the Gods*, calls him his friend, and commends the sphere he built, which displayed the motions of all the planets.

Proclus Lycius, that is, from Lycia, surnamed Diadochus, was, as the Suda testifies, a Platonic philosopher and a pupil of the great Syrianus, and taught at Athens for a long time. He wrote commentaries on Euclid, on the sphere, on the astrolabe, and on the *Hypotyposes of Astronomy*, in book 2, chapter 23 of which he has these words: *"Taking the parallax in the Sun, since the Earth does not have at all the ratio of a centre and a point with respect to the sphere of the Sun, as Hipparchus and Ptolemy themselves held."* So he was later than Ptolemy, who flourished under Hadrian and Antoninus. And yet Stöffler [Stœflerus], on the *Sphere* of Proclus, p. 1, says that he was the teacher of Marinus of Neapolis [Marini Neapolitani], who wrote the life of Proclus under Hadrian; by this conjecture he holds that Proclus lived under Trajan — though it could still be said that he lived some few years after Ptolemy. Barozzi, however, in the preface to his scholia on Proclus on book 1 of Euclid, says that he was the teacher not only of Marinus but also of Marcus Antoninus [Marci Antonij], and was raised by him to the consulship, on the report of Spartianus. There were therefore two men named Proclus. One was older than Ptolemy, whom Giuntini, in his *Catalogue of Illustrious Mathematicians*, not wrongly places in the year of Christ 84. The other was later than Ptolemy: he wrote the *Astronomical Hypotyposes* and was given the surname Diadochus. And this, unless I am mistaken, is that Proclus the eminent mathematician who, as Zonaras relates in part 3 of the *Annals* — and from him Pierre de la Ramée in book 1 of the *Scholae Mathematicae*, and Baronius at the year of Christ 514 — burned with bronze burning-mirrors the fleet of Vitalian [Vitaliani] as it besieged Constantinople, and was the interpreter of the Emperor Anastasius's dreams; and he is the same man who, as the Suda testifies, in imitation of Porphyry the Platonist spewed out 18 *Epicheiremata* [Epicheremata] against the Christians, which were outstandingly refuted by John the Philosopher [Ioanne Philoſopho]. Biancani, in the *Chronology of the Mathematicians*, placing him within the fifth century of Christ, and Georg Henisch [Georgius Heniſchius], on the *Sphere* of Proclus, take him to be the author of the Proclan *Sphere*. Stöffler [Stoeflerus], however, on the same *Sphere*, p. 1, attributes it to the older Proclus, who flourished under Trajan, and thinks he was called Diadochus by a family surname, from a gem resembling beryl, described by Pliny the Elder in book 37, chapter 10, which gave the family its surname.

Jacob ben Machir ibn Tibbon [Profatius, ſeu Prophatius Iudæus], called Profatius or Prophatius, a Jew, observed the Sun's greatest declination as 23° 32′, 230 years after al-Zarqālī [Arzachelem] and 160 after al-Maʾmūn [Almæonem] — that is, in the year of Christ 1300 — as Copernicus relates in book 3, chapter 2, and Reinhold in the *Theoricae*, p. 238. Kues [Cuſanus] relates that he observed the equinox in 1303.

Prometheus, as Aeschylus has it in the tragedy of Prometheus, and Servius on the 7th Eclogue, first made astronomy known to the Assyrians, having acquired it on the very lofty Mount Caucasus, around the year 1590 before Christ.

Prosdocimo de' Beldomandi [Proſdocimus de Beldomando] of Padua, a little before Giovanni Battista Capuano [Io. Bapt. Capuanum], wrote commentaries on the *Sphere* of Sacrobosco, which came out in 1531 through the work of Luca Gaurico [Lucæ Gaurici].

St Prosper of Aquitaine [S. Proſper Aquitanus], bishop of Reggio [Rhegienſis], wrote an Easter cycle of 532 years, and died in the year of Christ 466.

Claudius Ptolemy [CLAVD. PTOLEMÆVS], prince of astronomers, geographers and astrologers. Whether he was of the royal stock of the Ptolemies, and an Alexandrian, is disputed. That he was is affirmed by Vincent in his *Speculum historiale*, and by Andreas Trapezuntius, son of Georgios, in the preface to his translation of the *Almagest*. Having listed the men illustrious for learning whom Alexandria produced, he adds: *"But by everyone's leave, let me say it: in the reign of Antoninus she brought forth this Ptolemy, sprung of royal stock, easily the first of all the philosophers she nourished, in letters, in talent and in virtue. When the kingdom of the Ptolemies had ended in Cleopatra under Octavian, and Egypt had been reduced to a province, he himself, a private man but of royal spirit and talent, gave himself not to sordid crafts, not to an idle life, not to retreat into solitude; but in the then most celebrated gymnasium of Alexandria, with no mean resources, he devoted himself wholly to letters — first to philosophy, then to mathematics," etc.* Tycho held the same view in the epigram he placed beneath the portrait of Ptolemy that he kept in his museum, as you have it in the *Epistolae*, p. 239. For thus he sang:

> Such were the eyes, the face, the beard, such the limbs borne by that Claudius whose name was Ptolemy. He was indeed sprung from the illustrious line of kings, where the Nile wanders through the meadows with its watering streams. Yet the Roman soldiery, raging through the whole world, did not deem him worthy of royal honour. This he bore patiently, though unwilling, and nursed the hope that he might be one whom a greater honour perhaps awaited. Nor was he disappointed in this — although the Egyptian fields, although the wealth of the Nile, he did not restore. Indeed, still a private man, he held a greater empire than Rome, and was greater than the whole world. Etc.
>
> [Sic oculos, faciem, barbam, ſic membra gerebat / CLAVDIVS is, nomen cui PTOLEMÆVS erat. / Ille quidem illuſtri Regum de ſtemmate cretus, / Nilus vbi irriguis prata pererrat aquis. / Regali tamen hunc non eſt dignatus honore / Romanus toto miles in orbe furens. / Id tulit inuitus patienter, ſpemque fouebat / Se fore, quem maior fortè maneret honos. / Nec fruſtratus in hoc, quamuis Ægyptia rura, / Quamuis Niliacas non reparauit opes. /

Quin priuatus adhuc maius, quàm Roma, gerebat / Imperium, toto maior & orbe fuit. &c.]

Luca Gaurico, however, in the letter before the *Almagest* addressed to Domenico Pallavicino [Dominicum Pallauicinum], speaks thus: *"Our Claudius Ptolemy of Pheludia [Pheludienſis], easily the prince of all the mathematicians who have been, who are, and who will be in years to come, published at Alexandria in Egypt — the city founded by Alexander the Great — the* Almagest*, that is, the work of the great construction, a truly divine work, and, I believe, the* Geography*. He ended his last day when he was in the 78th year of his age, in the year 147 of the saving Incarnation. Whether he also wrote the four books of the* Apotelesmata *and the hundred aphorisms, and whether he was one of the kings of Egypt, I would not dare to affirm."*

Cardano [Cardanus], in the proem to Ptolemy's *Quadripartitum*, calls him a native of Pelusium [Peluſienſem], called an Alexandrian because Pelusium is not far from Alexandria. Magini, however, in his commentary on Ptolemy's *Geography*, notes that Pelusium is 160 miles from Alexandria, that it was once called Eliopolis [Eliopolim], and that today it is not called Damietta [Damiatam], as Castaldo [Caſtaldus] and Ziegler [Zieglerus] think, but rather *Tenesse* [Teneſſe]; and that Ptolemy was called an Alexandrian because he lived long at Alexandria and observed there. Magini denies, moreover, that he was descended *from the ancient kings, the Ptolemies*, since he did not live in the times of the Ptolemies, and in his *Geography* he gives place-names instituted by the Roman emperors, such as Iuliopolis, Forum Tiberii, etc. But these arguments, which Magini himself calls evident, are unworthy of Magini, otherwise a man of keen judgement: for the question is not whether Ptolemy was in fact a king of Egypt, but whether he was descended from their stock.

The authority of the prince Albuguate [principis Albuguate] seems to press harder, in the book *On the Choice of Sciences and the Beauty of Words* [de ſcientiarum electione, & verborum pulchritudine], which is prefixed to the old translation of the *Almagest* published at Venice in 1515 under the direction of Peter Liechtenstein of Cologne [Petri Liechteſtein Colonienſis]. Albuguate affirms that Ptolemy was born and raised at Alexandria, that his lineage was from the land of Shem [de terra Sem] and from the province called Pheuludia, and that he was not one of the kings of Egypt who were called Ptolemies, granted that he had that name. He adds that he was moderate in stature, white in complexion, long in stride, with slender feet; marked with a red sign on the right jaw; with a thick black beard; with the front teeth exposed; with a small mouth; of good and sweet speech; strong in anger and slow to be appeased; that he was accustomed to walk about much and to ride; that he ate little and fasted much; that his breath was fragrant and his clothing neat; and that he died in the 78th year of his age. After his apophthegms, in which he depicts Ptolemy's truly royal mind and lofty wisdom, he adds that Ptolemy, invited by a certain king to a banquet, excused himself and told his friends that kings are like certain paintings, which please when viewed from afar but displease when

seen closer. From this it seems to follow that this was not the Ptolemy who foretold the empire to Otho and accompanied him into Lusitania, as Tacitus relates.

Whether, then, he was of the stock of kings and an Alexandrian by birth or not, it matters little to the glory of a man who obtained the primacy of geography and of astronomy. By his geographical labour he brought the whole world into the dominion of his mind; and by restoring astronomy he raised his head, crowned with stars, to the heavens, and his name to the ages. Suidas, however, plainly errs when he writes that this Ptolemy lived under Augustus and Mark Antony. For if he died in the year 147 of the Christian era, aged 78, he was certainly born in the year 69 or 70, when Galba and Otho reigned; and from the same fact I again infer that he is not the Ptolemy who, as Tacitus relates, foretold the empire to Otho and accompanied him into Lusitania. Ptolemy himself, moreover, in the *Almagest*, often records his observations in the time of Hadrian and Antoninus, and we have no observation of his older than the one in book 4, chapter 9, where he reports an eclipse of the Moon observed by himself in year 9 of Hadrian, that is, of Christ 125, when he was in his 56th year. And in book 7, chapter 3 of the *Almagest* he says: *"From the times of Hipparchus's observation to the reign of Antoninus, in which we observed very many advances of the non-wandering stars, about 265 years are reckoned."* He had said, moreover, that Hipparchus's last observation, near Regulus, was made in year 50 of the third Callippic period, namely 128 before Christ; subtracting these from 265 years, these Ptolemaic observations fall in the year of Christ 136 or 137. So much for Ptolemy's stock, birthplace, and the time in which he lived.

As for his books, Pierre de la Ramée, in book 1 of the *Scholae Mathematicae*, judges thus: *"How great and how celebrated a mathematician was Ptolemy! For the volumes he published on celestial matters contain a kind of library of all earlier ages and schools (as I have often testified of the books of Aristotle), but defined and distributed by a more convenient method and art. We see that he condensed the twelve books of Hipparchus, and the six of Menelaus on chords [de ſubtenſis], into five theorems. He comprises Egyptian astrology — indeed the Latin astrology brought under the empire of Caesar — in an equal compendium; and in the* Quadripartitum *he names the observations of the Chaldeans expressly. The* Music*, the* Itinerary of the Stars*, the* Planisphere *or* Analemma*, and the* Geography *are as many ornaments of a noble mind."* He could have added the little work *On Mirrors*. But there are three principal works of Ptolemy: eight books of the *Geography*; thirteen books of the [Greek: μεγάλης συντάξεως (megalēs syntaxeōs, "of the great composition")], that is, of the *Great Construction*, or *Almagest* — a word that is either compounded of the Arabic *al* and the Greek [Greek: μέγι[?]ον (megiston?, "greatest")], or from the Egyptian *Megasite* [Megaſite], and signifies "the greatest" or "the perfect", as if you were to say that greatest and perfect work. And finally, the [Greek: τετράβιβλος σύνταξις (tetrabiblos syntaxis, "four-book composition")], that is, the *Quadripartite Syntaxis*, or *Quadripartitum*, in which he treats of the *Apotelesmata*, or of the judgements of the stars; to it is

attached the book called [Greek: καρπὸν (karpon, "fruit")], that is, the *Fruit* — namely the *Centiloquium*, or hundred aphorisms, of Ptolemy.

That the Ptolemy who composed the *Almagest*, the *Geography* and the *Quadripartitum* is one and the same is gathered from Ptolemy himself. For at the beginning of the *Quadripartitum*, text 1, he says: *"There are, Syrus, two chief means by which one arrives at astronomical predictions: one, which is first in order and in power, by which we grasp the motions of the Sun, the Moon and the other stars, and their configurations with one another and with the Earth; the other, by which, from the natural property of those configurations, we consider the changes of the things subject to them."* And shortly after, in text 2, he adds: *"And the first of these has its own study, worthy in itself, even if the end is not reached by joining the other to it; and we have explained it in particular in another book, with its reasoning examined by as certain arguments as we could."* By this he indicates clearly enough that he had already treated separately the matters contained in the *Almagest*.

Again, in book 8 of the *Geography*, he says: *"But since we have shown in the Mathematical Syntaxis that the sphere of the fixed stars also moves in the order of the signs [in consequentia Mundi] with respect to the tropical and equinoctial signs, and not about the equinoctial poles but about those equidistant from the circle drawn through the zodiac,"* etc. And conversely, at the very end of the last chapter of book 2 of the *Almagest*, he says: *"With the business of the angles now completed, it would follow that we compute the distances of the illustrious cities in longitude and latitude according to the phenomena. But since this business is of chief importance in itself and is connected with the geographical method, we shall show it separately, following those who, so far as was possible, have handed down this kind of record; and we shall write down by how many degrees each of the illustrious cities is distant from the equinoctial along the meridian described through it, and by how many degrees the meridian of each city is distant on the equator, to the east or west, from the meridian drawn through Alexandria. For it is to this meridian that the times of our computations are accommodated."*

So what Ptolemy promised in this place he carried out in book 8 of the *Geography*, writing down the distances of places from Alexandria in Egypt, and in both works placing Alexandria at a pole-height of 30° 58′ — for so he has it in book 5 of the *Almagest*, chapter 13, and in book 4 of the *Geography*, chapter 13 — just as in both he puts the obliquity of the ecliptic, or the distance of the tropics from the equator, at 23° 50′; and he keeps the same method in finding the sides and angles of triangles. Nor is it an objection that in book 7 of the *Almagest*, chapter 3, he makes Rome west of Alexandria by 1^{h} 20^{m}, or 20°, while in the *Geography* he gives Alexandria a longitude from the Fortunate Isles of 60°, and Rome 36° 40′, and so makes Rome west by 23° 20′. For when he completed the *Geography*, having become more learned in this matter than his former self, and following better sources, he changed his opinion, and corrected what in the *Almagest* he had perhaps assumed from Marinus of Tyre [Marino Tyrio]. Indeed, it is gathered from book 8 of the *Geography* that he changed even this

second opinion, since there he puts an hour and a half between Rome and Alexandria, that is, 22° 30′ — unless there is a fault in these numbers.

Finally, it is no objection that Ptolemy, in book 1 of the *Geography*, chapter 8, mentions Julius Maternus [Iulij Materni]; for this is not the younger Julius Firmicus Maternus, who flourished under Constantine, and who, in the preface to book 2, in chapter 32 and elsewhere, mentions our Ptolemy. I admit, however, with Pétau in the preface to the *Uranologion* and in book 2 of the *Dissertationes*, chapters 4 and 8, that Ptolemy's *Parapegma* on the appearances of the fixed stars and their significations is twofold: one, which Pétau himself translated from the Greek, is not unworthy of Ptolemy, and is printed from p. 71 of the *Uranologion*; the other was translated by Niccolò Leonico [Nicolao Leonico], and is not Ptolemy's but a rhapsody gathered out of a miscellany of various parapegmata that do not agree with one another at all.

Lastly, on the translations of the *Almagest*. Joseph Justus Scaliger [Ioſephus Scaliger], in book 5 of *De emendatione temporum*, p. 394, asserts that he saw a very ancient translation from Greek into Arabic, in whose preface were these words: *"This book was translated by order of Maimon, king of the Arabs, who reigned in Baghdad [Baldach], by Alhazer son of Joseph son of Maire the arithmetician, and by Serigus son of Elbe, a Christian, in the year 212 of the sect of the Saracens [in Anno CCXII. ſectæ Saracenorum]."* He adds that the new moon of Muharram, the first month of the year 212 of the Saracens, fell on 827 April 2, and therefore that both al-Maʾmūn [Almamonem], or King Maimon, and this translation were older than al-Battānī [Albategnio]. Boulliau [Bullialdus] has the same in the prolegomena to the *Astronomia Philolaica*, and adds that by order of the Emperor Frederick II the *Mathematical Syntaxis* was translated from the Arabic language into Latin around the year 1230. In book 3, chapter 2, besides the Greek codex of Basel, he also cites a manuscript of the Royal Library of Paris. Five editions, moreover, circulate widely. The first is the Greek, published at Basel in 1538 with the commentaries of Theon, in which the general title is [Greek: κλ. πτολεμαίου μεγάλης συντάξεως βιβλ. ιγ. (Kl. Ptolemaiou megalēs syntaxeōs bibl. 13, "Claudius Ptolemy's Great Syntaxis, 13 books")], that is, *Claudii Ptolemaei Magnae Syntaxis libri 13*; but in the particular titles of the books it has [Greek: μαθηματικῆς συντάξεως (mathēmatikēs syntaxeōs, "of the mathematical composition")], that is, *of the Mathematical Syntaxis*, which is how Ptolemy himself names it in book 8 of the *Geography*. The second is the Latin, which came out at Venice in 1515 through the work of Peter Liechtenstein of Cologne. The third, likewise Latin, is that of Georgios Trapezountios [Georgij Trapezuntij], revised by Luca Gaurico, which came out at Venice in 1527. The fourth, of the same Trapezountios, was published at Basel in 1541 through the work of Hieronymus Gemusaeus [Hieronymi Gemuſæi]. The fifth, again of Trapezountios, was published at Tübingen by Schreckenfuchs [Schreckenfuxio] in 1551; Kepler also consulted it in the *Catalogue of the Fixed Stars* [Catalogo Affixarum], p. 114 of the Rudolphine Tables, where he says that the Alphonsines and Copernicus followed the Arabic version. Besides

these I have seen no other. Whether it is entitled the *Mathematical Construction* by antonomaſticῶς], because astronomy is the most excellent of the mathematical disciplines, or the *Great*, because it is a great — indeed the [Greek: μέγιστον (megiston, "greatest")] — work: Gemusaeus, in his dedicatory letter, holds that just as nature produced Aristotle in philosophy, so it produced Ptolemy in astronomy, *"to form a supreme man, whom it might set up as an example of all its powers, and show how far the mind of man may advance in this kind, so that it can go no further, in the method of speaking and the manner of inquiry which he was the first to perfect in this discipline."*

Pythagoras of Samos [PYTHAGORAS Samius], son of Mnesarchus [Mneſarchi], an engraver of rings, learned astrology among other things in Egypt and from the Chaldeans, and discovered music in the heavens. As Laertius testifies, he flourished in Olympiad 60, that is, in the year 540 before Christ, and was killed at the age of 80 — or, as most have it in Laertius, at 90. He also showed that Lucifer and Hesperus, which were thought to be two planets, are one and the same, namely the star of Venus, according to Pliny the Elder, book 2, chapter 8. He came to Italy in the year 245 from the founding of the City, or 509 before Christ, according to Solinus, chapter 17. He died in the year 497, after he had been at Croton for 12 years and had led the Italian school, as Eusebius has it. The people of Metapontum worshipped him as a god, as Justin says in book 20. Of the Pythagorean intervals of the stars we shall say more in their place. Plutarch, in book 2 of the *Placita*, chapter 12, says that the obliquity of the zodiac was first detected by him, and yet that Oenopides of Chios claimed this discovery for himself; but Pliny the Elder, book 2, chapter 8, attributes it to Anaximander.

Pytheas: see Pitheas.

R

Rabbi Avraham [RAbbi Abraham] wrote on the sphere in the year of Christ 1115.

Rabbi Adda, son of Ahabac [Rabbi Adda filius Ahabac], flourished at the end of Diocletian's reign and the beginning of Constantine the Great's. He arranged the Hebrew calendar and handed down rules for finding the *tekufot* [Tekuphas], or revolutions of the equinoxes — although many have preferred to follow Rabbi Shmuel [Rabbi Samuelem].

Rabbi Yitzchak [Rabbi Iſaac], an astrologer, in the eleventh century of Christ, according to Génébrard.

Rabbi Levi [Rabbi Leui], full of all the sciences and most devoted to astronomy, wrote the book *Milhamot Hashem* [Milhamot-Heſsem], that is, *Of the Defences of God* [defenſionum Dei], in the year of the Incarnation 1335. In treatise 5 of it he says that in his time Spica and Regulus held the places in the heavens that were due to them according to al-Battānī [Albategnium], as Agostino Ricci [Riccius] relates in the treatise *On the Eighth Sphere*, chapter 43.

Rabbi Moshe [Rabbi Moyſes], in the book *Mishneh Torah* [Miſnetora], that is, *of the Law Repeated*, treated of the double motion of the eighth sphere.

Raffaele Maffei of Volterra [Raphael Volaterranus], chronographer and cosmographer, flourished in the year of Christ 1495.

Redento Baranzano [Redemptus Baranzanus], of Serravalle [Serrauallenſis] in the diocese of Vercelli, a Clerk Regular of St Paul, taught physics and astrology at Annecy [Anneſij] in Savoy, and wrote an *Uranoscopia* in 1617.

Robert Grosseteste [Robertus Linconienſis], bishop of Lincoln, wrote a *Compendium of the Sphere*, published in 1531 by Luca Gaurico. He flourished under the Emperor Conrad in 1140, and was called by the surname *Grossa testa* [Groſſa teſta]; he was a most subtle theologian, as Sisto da Siena [Sixtus Senenſis] says in the *Bibliotheca*.

Rudolph Goclenius [Rodulphus Goclenius], doctor of medicine at the University of Marburg [in Academia Marpurgenſi], published in 1615 his *Urania*, with her twin daughters Astronomy and Astrology.

Rumold Mercator [Rumoldus Mercator], son of Gerard [Gerardi], flourished in 1600.

S

Solomon [SAlomon], who by wisdom divinely infused knew *the courses of the year and the dispositions of the stars*, as is said in Wisdom 7, flourished in the year 1012 before Christ.

Scipione Chiaramonti [SCIPIO CLARAMONTIVS], a knight of Cesena [Cæſenas Eques] and formerly professor of philosophy at the University of Pisa, highly expert in mathematical matters, published many excellent works. The chief of them are: *Antitycho*, for sublunary comets, 1621; *Apologia pro Antitychone*, published 1626; *De tribus novis stellis* [De tribus nouis Stellis], against Tycho and others, 1628; a second *Defensio* of the *Antitycho*, in Italian, 1633; *Supplementum Antitychonis*, on the sublunary seat of comets, 1636; *Antiphilolaus*, 1643; a *Defensio* against the attacks of Fortunio Liceti [Fortunij Liceti], 1644; and sixteen books *De Universo* [de Vniuerſo], in the same year 1644. He is still living, in this year 1651 in the 86th year of his age; for in 1572 he was seven years old, as he himself relates in the preface to his book on the new stars.

Sebastian Münster [Sebaſtianus Munſterus], condemned among the heretics of the first class, 1535; he wrote notes on Ptolemy's *Geography* and a *Cosmographia universalis* [Coſmographiam vniuerſalem].

Seneca flourished under Nero, and wrote on comets in Book 7 of the *Natural Questions* [quæſtionum naturalium]; he was put to death in the year of Christ 65.

Sextus Avienus Ruffus [Sextus Auienus Ruffus], a learned poet, a Spaniard, as some suspect according to Pietro Crinito [Petrum Crinitum], book 5. Besides Aratus's *Phaenomena*, which he rendered elegantly in Latin verse, he completed a book on the circuit of the earth in hexameters, imitating Dionysius; and in iambics he wrote *De Oris Maritimis* [On the Sea-Coasts]. Giraldi [Gyraldus], however, in dialogue 4, says that he did not so much imitate Dionysius as translate him from Greek into Latin. Crinito says he flourished under Diocletian; but Giraldi, from St Jerome [S. Hieronymo] and from the inscription of the

poem addressed to Probus, a man of consular rank, to whom Claudian wrote, proves that he flourished with Claudian under Theodosius, about the year of Christ 395. Génébrard [Genebrardus] places him under Pope Melchiades.

Sextus Empiricus, nephew of Plutarch of Chaeronea [Plutarchi Chęronenſis nepos] and disciple of Herodotus, flourished under Antoninus about the year of the Lord 135. He wrote sharply against the mathematicians, that is, the judicial astrologers [Aſtrologos Iudiciarios].

Simplicius, born in Phrygia, a distinguished Platonist and Peripatetic philosopher and an excellent commentator on Aristotle's *De caelo* [de cælo], flourished at Alexandria from the year of Christ 500 — but of Diocletian 216. Some, not distinguishing these years, assign him to the year of Christ 216 or 224. See Génébrard under Silverius [in Syluerio], and the Suda under the word *Damascius*, who was a friend of Simplicius.

Simon Marius wrote a book on the companions of Jupiter [de Iouis Comitibus], entitled *Mundus Iovialis* [Mundus Iouialis]; he flourished about the year 1610.

Simon Stevin [Simon Steuinus], of Bruges, flourished at the beginning of this century; he set out the theorics of the planets [Theoricas Planetarum] and tables of the celestial motions.

Sixtus ab Hemminga, a Frisian, had at first supported judicial astrology [Aſtrologiæ iudiciariæ] and studied it long and much; later he opposed it. He undertook to demonstrate its falsity from the nativity of Adrianus Junius [Adriani Iunij] and of Charles V [Caroli V.], under whom he flourished, and from many others, and he pronounced the art impossible and useless to mankind.

Sisto da Siena [Sixtus Senenſis], of the Order of Preachers, wrote one book of astronomical questions and one book of geographical questions on Sacred Scripture; he flourished in 1576.

C. Solinus Polyhistor wrote *De situ orbis* [de ſitu orbis]. Biancani [Blancanus] includes him in the first century of Christ; his scholiast places him a little after Vespasian; Sansovino [Sanſouinus] in his *Chronologia* assigns him to the year of Christ 114, with whom Raynaudus [?] agrees in his *Breviarium chronologicum* [breuiario Chronolog.], and Génébrard under Evaristus [in Euariſto].

SOSIGENES, an Alexandrian astronomer, was brought to Rome by C. Julius Caesar [C. Iulio Cæſare] and restored the Roman calendar, introducing a solar year of 365 days and, every fourth year, an intercalary year of 366 days; on which see Pliny the Elder [Plinium], Book 18, chapter 25. He lived long under Augustus and again gave his effort to the correction of the year. He flourished in 45 before Christ and afterwards. Macrobius, however, *Saturnalia* Book 1, chapter 14, relates that Flavius the scribe noted down the individual days and handed them to Caesar, and urged him to that restoration; on which see also Solinus chapter 3, Dio Book 43, Plutarch in the *Caesar*, and Censorinus chapter 8.

Stephanus Rosinus [Stephanus Roſinus], of Augsburg [ex Auguſta Vindelicorum], a philosopher and bachelor of Sacred Scripture at Vienna, where he was a canon, taught astronomy, and in 1500 published a table of the declination of the fixed stars, with prognostications.

Strabo, a Cappadocian and a distinguished geographer, described the world, a great part of which he had travelled through. Biancani places him within the first century of Christ. He flourished, however, not only under Tiberius but also at the end of Augustus's reign, and died in the 11th or 12th year of Tiberius, as Casaubon [Caſaubonus] has in his *Life of Strabo*; therefore before Christ he was:

Straton of Amasia [Straton Amaſenus], a philosopher, wrote seven books of *Geographica* in the first century of Christ, on the testimony of the Suda.

C. Sulpicius Gallus [C. Sulpitius Gallus], a military tribune, was the first among the Romans to predict an eclipse of the Moon, under Paulus Aemilius [Paulo Æmylio], and set out a booklet about it, in 168 before Christ.

T

Taruntius Firmanus, an astrologer and friend of Varro, flourished in 86 before Christ.

THALES of Miletus [THALES Mileſius], the first among the Greeks to predict an eclipse of the Sun, of the stock of Agenor and Cadmus, and the first of the Sages. He wrote on the solstices and equinoxes [de Solſtitijs, & Æquinoctijs]; he was the first to observe that the apparent diameter of the luminaries is the 720th part of its circle; he measured the pyramids of Egypt by their shadow. He was born in the first year of Olympiad 35, that is, 640 before Christ, and died at the age of 70, as Apollodorus has in his *Chronicles*, or 90, as Sosicrates has, or 92, since he died in Olympiad 58, as Laertius has. Callimachus, in a poem, says that he was the first to have measured out the little stars of the Wain [plauſtri ſtellulas], by which the Phoenicians steered their navigation.

Tadeáš Hájek [Thaddæus Hagecius ab Hayck], a Bohemian, wrote accurately on the new star of the year 1572; on which see Tycho, Volume 1 of the *Progymnasmata* [prog.], from p. 505.

THEBIT Ben-Chora, that is, son of Chore, preferred the sidereal year to the equinoctial. He introduced a tenth, immovable sphere, and the motion of trepidation from north to south. He observed the Sun's greatest declination [maximam declinationem] as 23° 33′ 30″, at about the same time as Almaeon [Almæon], as Jacob Christmann [Kriſtmannus] has in his commentary on al-Farghānī [in Alfraganum], chapter 6. He therefore lived in the 12th century of Christ, in which Almaeon also lived, as Génébrard also has, and our Gualterus in his *Chronicon*; and Giuntini [Iunctinus] sets him in the year 1198. But Biancani moves him forward into the 13th century of Christ, as does Clavius [Clauius] in the preface to the *Sphere*, where he places him 1140 [M C XL] years after Ptolemy, that is, in 1287 after Christ.

Theaetetus of Athens [Theætetus Athenienſis] was of great fame, especially in astronomy. He fitted the five regular bodies to the world and to the elements.

He was a contemporary and friend of Plato, who accordingly wrote a dialogue under his name.

Theodoret the Bishop [Theodoretus Epiſcopus] is counted among the astronomers by Giuntini, in the year of Christ 469.

Theodorus Gaza wrote a book in Greek on the months, and on the year, in which he showed himself not unacquainted with astronomy. He flourished about the year of the Lord 1478.

Theodorus Graminaeus [Theodorus Graminæus], professor of mathematics at Cologne, published a *Commentary* on the star of the year 1572 — but one of little astronomical worth, as Tycho judges, Volume 1, from p. 775.

Theodosius of Tripoli [Theodoſius Tripolita], in the year 52 before Christ, wrote *On Days and Nights* [de diebus, & noctibus], three books of *Spherics* [Sphæricorum], and sceptical astrological chapters [ſceptica capita Aſtrologica].

Theon of Alexandria [Theon Alexandrinus], mathematician: there were two of this name. One was a contemporary of Ptolemy and a little older; his observation of Venus, made in the 16th year of Hadrian, that is, the year of Christ 132, is adduced by Ptolemy in Book 10 of the *Almagest*, chapter 1, and from him by Copernicus, Book 5, chapter 20. The other was much later than Ptolemy: he published commentaries on Ptolemy's *Almagest* and on Aratus, was the father of Hypatia, and wrote on the rising of the Dog Star [Caniculæ] and on the small astrolabe. The Suda makes him a contemporary of Pappus. But Denis Pétau [Petauius], in the dissertation of his *Uranologion* [Vranologij], p. 96, shows that he flourished in the year of Christ 360, and Giuntini puts him in 390. Theon himself, in Book 6 on the *Almagest*, p. 334, reports an eclipse of the Sun observed by himself in the year of Nabonassar 1112, that is, of Christ 365.

Theophrastus of Lesbos [Theophraſtus Lesbius], surnamed Eresius [Eriſſius], wrote six books on astrology and succeeded Aristotle in the Lyceum, in the year 322 before Christ.

Thius of Athens [Thius Athenienſis], about the year of the Lord 500, devoted himself to observing the stars, as Boulliau [Bullialdus] relates in the prolegomena to the *Astronomia Philolaica* [Aſtronomiæ Philol.].

Thomas Digges [Thomas Diggeſeus], of Kent in England, on the occasion of the new star of the year 1572 wrote a booklet which he entitled *Alae seu Scalae Mathematicae* [alas ſcalaſque Mathematicas: Mathematical Wings and Ladders]; on which consult Tycho, Volume 1 of the *Progymnasmata*, from p. 653.

Thomas Fincke [Thomas Finkius], of Flensburg, flourished in 1583, when he published the *Geometria rotundi* with tables of sines; afterwards he observed stars and comets, as is clear from his letters, which Giovanni Antonio Magini [Maginus] cites in his *Tabulae directionum* [tabulis directionum], from p. 77, and from Tycho, Volume 2.

Timaeus of Locri [Timæus Locrus, ſeu Locrenſis], a Pythagorean, wrote on the nature of the world; from this work Plato took not only the name of his

dialogue *Timaeus* but in large part its content. Timaeus flourished when Plato was young, and Plato, at the beginning of that dialogue, affirms that he was most expert in astronomy.

TIMOCHARES, astronomer, observed the fixed stars in particular around the year 300, or 294, before Christ, as is gathered from Ptolemy, *Almagest* Book 7, chapters 2 and 3 — namely in the 36th year of the first Callippic period [primæ Calippi periodi].

Titus à Popma, a Frisian [Phryſius], wrote in 1568 tables on the *Sphere* [tabellas in Sphæram] and *Elements of Astronomy* [Elementa Aſtronomiæ].

TYCHO BRAHE, restorer of astronomy, first-born son of Otte Brahe [ex Othone Brahe], of eminent nobility in Denmark, was born in the year of restored salvation 1546 in the castle of Knudstrup [in arce Kundſtorpiana] in Scania. His astronomical life, and the sequence of his observations and works, we have gathered from his own books, but chiefly from the *Mechanica Astronomiae* [Mechanica Aſtronomiæ], from the first book of the *Epistles* [ex Epiſtolarum prima] to Moritz, Landgrave of Hesse [ad Mauritium Haſſiæ Lantgrauium], from the Appendix to Volume 1 of the *Progymnasmata*, from Kepler [Keplero] in the *Hyperaspistes*, p. 104, and in the preface to the Rudolphine Tables [ad Rudolphinas], and lastly from the Bohemian observations published by Willebrord Snellius [Villebrordo Snellio].

Tycho, then, came to Leipzig [Lipſiam] in 1560, at the age of 14, for the sake of humane letters. Having stayed there three years, with his genius urging him on to astronomy — though his tutor, who had set him to jurisprudence, opposed it — he secretly began to accustom himself to astronomical observations. He used a somewhat larger pair of compasses as a sextant, taking the distances of the stars with his eye set at the joint of the compasses, and a small globe of the stars. From these rudiments, without a master, he advanced so far that he noticed manifest errors in the Alphonsine and Prutenic calculations [in Alphonſinis, & Prutenicis Calculis], especially in 1563, when the great conjunction of Saturn and Jupiter took place in the first degrees of Leo, around the end of September; he saw that it departed by a whole month from the Alphonsine reckoning and by some days from the Prutenic table [Prutenico abaco], being then in his 17th year. In 1564, accordingly, he secretly obtained from Bartholomäus Scultetus [Bartholomæo Sculteto] a wooden astronomical radius [Radium Ligneum Aſtronomicum] made on the pattern of the radius of Gemma Frisius [Gemmæ Friſij], divided by transversal points according to the prescription of Homelius [Homelij]; and with it, on clear nights, unknown to his tutor, he took many distances of stars. He did the same at Wittenberg [Vuitebergæ] and Rostock [Roſtockij].

Afterwards, in 1569 and 1570, he stayed at Augsburg [Auguſtę Vindelicorum], where he persuaded Paul Hainzel [Paulo Hainzelio], consul for the year [Conſuli anniuerſario], to have a very large quadrant made, showing single minutes, which Tycho describes in Volume 1 of the *Progymnasmata*, p. 355, and in the *Mechanica*, p. 30. They had it set up at Göggingen [Geggingæ] on a hill

half a German mile from Augsburg, and observed the stars together. Tycho, however, was at that time also using a wooden sextant, but an imperfect one, and at the same time he was toiling at pyronomic labours [Pyronomicis laboribus]. Then, going to Herrevad [Herritzuadium] to his maternal uncle Steen Bille [Stenonem Bille], he obtained a place suitable for chemical and spagyric experiments. While he was there, in 1572 November 11, he began to take notice of the new star in Cassiopeia [Caſſiopeę]; he was using a different sextant, indeed, but he lacked instruments fit for the necessary precision, as he admits in Volume 1 of the *Progymnasmata*, p. 335.

Later he procured one instrument after another, which he carried with him through Germany so as to choose a seat suited to observations. Thus in 1575, with Italy in mind, he passed through Kassel [Caſſellis] around the Easter festival and stayed there more than a week, making some observations with Wilhelm, Landgrave of Hesse [Gulielmo Lantgrauio Haſſiæ]. Then, travelling through the northern parts of Italy, he had resolved to fix his astronomical seat at Basel [Baſileæ Rauracorum], for the healthiness of the air and its borders with Italy, France and Germany, and so as not to be drawn away from the sky again and again by his kinsmen and friends in his homeland. From there he came to Regensburg [Ratiſponam] for the Diet, at which Rudolf, son of the Emperor Maximilian [Rudolphus Maximiliani Imper. Filius], was crowned King of the Romans. From there he returned to his homeland before winter; and while he was preparing his journey to Basel, as though intent on something else, he was invited by letters and by a messenger from Frederick II [Friderico II.], King of Denmark and Norway, who offered him the island of Hven [Huennam] in the Danish Sound — which, Tycho says, may be called Scarlatina by foreigners and Venusia in Latin — and offered him funds for astronomical and pyronomic instruments and works.

Therefore in that same year 1576 he began to build the castle of Uraniborg [Vraniburgi], suited to astronomical work, and new instruments; and, having gathered others skilled in these matters, who were at least 8 or 10, he observed there over many years the fixed stars, the planets, and the comets of the years 1577, 1580, 1585, 1590 and 1593. In 1582 he determined the places of the fixed stars more accurately from the distance of Venus compared with the Sun; and in 1584, having detected refraction, he corrected the equinoxes and solstices, sending also Elias Olai [Elia Olai] to Frombork [Fruemburgum] in Prussia to examine the altitude of the pole taken by Copernicus. In 1585, when he was 40 years old, he observed the winter solstice exactly, and began to write chapter 10 of Volume 2; and in 1588 (up to which year he had extended his observations of the fixed stars) he began to write on the Sun and the Moon and to arrange their tables. In 1590 he wrote on the new star of the year 1572, and obtained a privilege [diploma] from Rudolf II that no others might print what he was permitted to print, etc. In the same year he wrote more accurately on the comet of the year 1577, and up to the year 1592 he applied himself to the treatise on the Sun, the Moon and the fixed stars. In 1593 he obtained another privilege, from

James, King of Scotland [Iacobo Rege Scotiæ], for the printing of his books, which he was printing at Uraniborg at his own expense. Further, in 1596 he published Volume 1 of the *Epistles* [tomum 1. epiſtolarum vulgauit].

Then, embittered and despairing of the expenses to be supplied by the successor of Frederick II, King of Denmark, he nevertheless meanwhile prepared part of the *Mechanica Astronomiae*, polished the catalogue of a thousand fixed stars, and began to print the second volume. So in 1597 he moved, with such instruments as he could take, from the island of Hven to Copenhagen [Hafniam], then to Rostock, and then, as the plague was raging, to Wandsbek [Vuandesburgum] in Holstein [in Holſatiam], at the invitation of Rantzau [à Ranzouio]. In 1598, summoned by the Emperor Rudolf II, he set out from Holstein for Prague but halted at Wittenberg until the plague at Prague should abate; and he completed and published the *Mechanica Astronomiae instauratae* [Mechanicam Aſtronomiæ inſtauratæ]. Then in 1599 he came to Prague, and from there to the castle of Benátky [in arcem Benaticam], granted to him by the Emperor for observing the stars; but on returning to Prague he changed house twice, and meanwhile received his larger instruments from the journey, carried by ship. While he was living in Bohemia, with Longomontanus assisting, he worked more intensively at perfecting the theory of the Moon.

To him, in 1600, in the month of February, Kepler [Keplerus] came at Benátky, invited from Styria by frequent letters from Tycho, on the occasion of the *Mysterium Cosmographicum* [Myſterij Coſmographici]; and Longomontanus was also there. An agreement having been made with Tycho, Kepler returned to Styria in June to fetch his family and his household of books; and in October of the same year, when Longomontanus had already left, Kepler was with Tycho at Prague. But, seized by a quartan fever and hindered by it until the solstice of the following year 1601, he was of no use to him; and since he had gone back to Graz [Gratium] on account of an inheritance and returned to Prague in September, he was with Tycho no more than two months.

For Tycho, in 1601, on the mornings of October 10 and 11, observed the distance of Mars from Pollux, Procyon and Regulus (which was his last observation, as it was also for Walther [vt & Vualthero]). On October 13, at a dinner, having held his urine beyond his custom while he drank too freely, and feeling a tension of the bladder, he put his health below courtesy; and when he had returned home he could not pass water. At the onset of this illness (says Snel) the Moon was in opposition with Saturn and in quartile aspect with Mars in Taurus, and Mars was in the same place that Tycho had set as his own Ascendant. With Mars thus hostile, and Venus giving no help, after five sleepless days the urine at last began to come drop by drop, with very severe torment. There followed continual sleeplessness, fever and delirium; and as his diet [ratione victus], from which he could not be restrained, aggravated the illness, he kept chanting in his delirium that saying of his, *Ne frustra vixisse videar* [Let me not seem to have lived in vain]. At last, on November 24, when

the delirium had abated, he died, having observed the stars for 38 years — but more accurately for 20 — and having set a thousand fixed stars in order.

After his death his heirs published Volumes 1 and 2 of the *Progymnasmata*; the third perished. At length, when his observations had been found in the possession of Kepler's nephew [apud nepotem Kepleri], they were handed over, by order of the Emperor Ferdinand, to Father Albert Curtz [P. Alberto Curtio] of the Society of Jesus [Societ. IESV], who is in charge of their edition. Happier indeed would Tycho have been had he gained heaven and CHRIST; for then he would truly not have lived in vain. But that he was too much inclined toward Luther, Philipp Melanchthon [Philippum Melanchthonem] and David Chytraeus [Dauidem Chytręum], pests of the human race, is shown plainly enough by what he has in Volume 1 of the *Progymnasmata*, pp. 712, 776, 777 — granting that Johannes van Heeck [Io. Heckius] of Deventer, in his disputation on the new star of the year 1604, p. 20, calls him a Calvinist: perhaps because at Prague he migrated from Luther to Calvin, or mixed both poisons for himself. Heckius was at Prague when he wrote this.

V

Valentin Naibod [Valentinus Naiboda] published in 1580 three books of *Astronomical Institutions* [Aſtronomicarum inſtitutionum]; but in 1560 at Cologne, where he taught mathematics, he published an *Enarratio elementorum astrologicorum* [enarrationem elementorum Aſtrologicorum], collected from al-Qabīṣī [Alcabitio] and other Arabs, on account of which he was listed among the condemned authors by the sacred censors.

Valens, an astrologer of Antioch, flourished under Constantine the Great, on the testimony of Zonaras.

M. Varro flourished in 86 before Christ.

Victorinus of Aquitaine [Victorinus Aquitanus], celebrated author of the Paschal Cycle [Cycli Paſchalis], and an astronomer, was called by Pope Hilary to the correction of the Roman calendar in 467.

Willebrord Snellius [Villebrordus Snellius à Royen] flourished at the beginning of this century. He wrote on the comet of the year 1618; a *Doctrina triangulorum* [doctrinam Triangulorum]; the *Eratosthenes Batavus* and the *Tiphys Batavus* [Eratoſthenem ac Typhim Batauum]. He published the Hessian and Bohemian observations, with some notes, together with the observations of Regiomontanus and Walther [Vualtheri], also in 1618. And he translated Ludolph of Cologne [Ludolphum Colonienſem] *De circulo*, with its additions, from the vernacular into Latin, and illustrated it with notes, in 1619.

Vicenç Mut [Vincentius Mutus], of Majorca [Maioricenſis], most expert in astronomy, observes the stars diligently at Majorca [Maioricæ], and wrote an excellent little work, *De Sole Alphonsino* [de Sole Alphonſino]. To him I owe a very great deal.

Witelo [VITELLIO], born of a Thuringian mother and a Polish father, is said to have flourished in 981 according to Giuntini [Iunctino], or in 984 according to Sansovino. But Friedrich Risner [Federicus Riſnerus], in the preface to

Witelo, shows, together with Erasmus Reinhold [Eraſmo Reinholdo] and Caspar Peucer [Gaſpare Peucero], that he lived in 1269, when there also lived Willem van Moerbeke [Gulielmus de Morbera], to whom Witelo dedicated his work, as penitentiary of the Supreme Pontiff. That he was a Pole, that he came to Italy and lived at Cubalum between Padua [Patauium] and Vicenza, and afterwards was at Viterbo [Viterbij], Witelo himself intimates in Book 10, theorems 42, 67 and 74.

M. Vitruvius Pollio [M. Vitruuius Pollio] wrote for Augustus ten books *De Architectura*, in the ninth of which he touched on astronomical matters. He served in the camp of Julius Caesar [in Caſtris Iulij Cęſaris] as prefect of the engines of war, as is gathered from his Book 8, chapter 4, and Book 10, chapter 16. He flourished, therefore, about the year 45 before Christ.

Václav Pantaleon Kirwitzer [Vuenceslaus Pantaleo], of the Society of Jesus, from the province of Austria, set out for China [in Sinas] with Father Nicolas Trigault [P. Nicolao Trigautio], and died at Macao [Macai] in 1626 May 22. He had written up observations of the comets of the year 1618 made by members of our Society in the East Indies [à noſtris in India Orientali].

Wolfgang Schuler [Vuolfangus Schulerus], professor of mathematics at the University of Wittenberg, treated in 1573 of the star of the year 1572; his reply to Peucer is reported by Tycho, Volume 1, p. 621.

Z

Zoroaster [ZOroaſtres], king of the Bactrians, wrote on predictions from the stars about 500 years before the Trojan War, that is, in 1990 before Christ.

End of the Chronicle [FINIS CHRONICI.]

LIBER PRIMVS DE SPHÆRA MVNDI IN COMMVNI ASTRONOMIÆ IMMO' ET COSMOGRAPHIÆ ELEMENTA, ET PRINCIPIA VNIVERSALIA COMPREHENDENS.

Book One: On the Sphere of the World in General, comprising the Elements and Universal Principles of Astronomy, and indeed of Cosmography.

Diagram. A woodcut armillary sphere, set obliquely, standing beneath the book title. The rings are drawn as bands with chequered (alternately black and white) edges. A small globe of the Earth, with land masses shown, sits at the centre. The axis runs from a short cylindrical pole-stub at the upper left to another at the lower right. The broad horizon ring crosses the sphere horizontally; the meridian ring is the outer circle; the equator, the two tropics, the two polar circles and a broad zodiac band carrying sign glyphs are set obliquely to the horizon. Labels, as printed:

- POLVS BOREAL. (upper left, beside the upper pole-stub): the North Pole
- MERIDIANVS. (along the outer ring, top): the meridian

- CIRC. AR CTICVS. (upper left, along a small circle near the north pole): the Arctic Circle
- TRO PICVS CANCRI (upper left of centre, along an oblique ring), followed by a glyph like "69", read as the sign of Cancer ♋: the Tropic of Cancer
- AEQVATOR (right of centre, along an oblique ring): the equator
- HORIZON. (along the horizontal ring, below the globe): the horizon
- AEQVAT (lower left, on the other side of the same oblique ring): the equator
- TROPICVS CAPRI COR (lower centre, along an oblique ring): the Tropic of Capricorn
- ANTA RCTICVS. (lower right, along a small circle near the south pole): the Antarctic Circle
- POLVS AVSTR. (lower right, beside the lower pole-stub): the South Pole
- Zodiac band: sign glyphs along the two visible arcs of the band. Front arc, from the top: ♋ (at the end of TROPICVS CANCRI), ♌, ♍, one sign left of the globe that cannot be made out [?], ♏, ♐, and ♑ partly hidden at the lower left. Rear arc, from the bottom: ♒, ♓, ♉. No sign is visible for Aries or Gemini.

AVCTORES QVI DE SPHAERA IN COMMVNI, Et Aſtronomiæ, vel Coſmographiæ Elementis tractarunt.

Authors Who Have Treated of the Sphere in General, and of the Elements of Astronomy or Cosmography.

The chief writers on this subject have been: Geminus, in his *Elements of Astronomy* [Elementis Aſtronomicis]; Cleomedes, *On the Circular Theory of the Heavens* [de Mundi cyclica theoria]; Alfraganus [al-Farghānī], *On the Rudiments of Astronomy* [de Rudimentis Aſtronomicis]; Meshala the Arab [Māshāʾallāh], *On the Elements and the Celestial Orbs* [de Elementis, & Orbibus Cœleſtibus]; Martianus Capella, in Book 8 of *On the Marriage of Philology* [de Nuptijs Philologiæ]; Bede [Beda], in volume 1, the treatise *On the Sphere* and *On the Constitution of the World* [de Sphæra, & de Mundi Conſtitutione]; and Proclus, in his *Sphere*, which Io. Stoeflerus [Johannes Stöffler], Erasmus Osualdus [Erasmus Oswald Schreckenfuchs] and Georgius Henischius [Georg Henisch] have elucidated with annotations or commentaries.

Ioannes de Sacrobosco [Johannes de Sacrobosco] also won the name of a classic author with his *Sphere*. It was made illustrious by the paraphrase, commentaries or questions of Petrus de Aliaco [Pierre d'Ailly], Cichus Asculanus [Cecco d'Ascoli], Io. Bapt. Capuanus [Giovanni Battista Capuano], Prosdocimus de Beldomando [Prosdocimo de' Beldomandi], Michael Scotus [Michael Scot], Iacobus Faber [Jacques Lefèvre d'Étaples], Maurus Florentinus [Mauro Fiorentino], Bartholomæus Vespuccius [Bartolomeo Vespucci],

Elias Vinetus [Élie Vinet], Ariel Biccardus [Ariel Bicard], Franciscus Iunctinus [Francesco Giuntini], and Christophorus Clauius [Christoph Clavius] of our Society. Robertus Linconiensis [Robert Grosseteste], Campanus [Campanus of Novara], Pierius Valerianus [Pierio Valeriano], Alexander Piccolomineus [Alessandro Piccolomini] and Iosephus Blancanus [Giuseppe Biancani] of our Society likewise wrote on the sphere.

On cosmography, Orontius Finæus [Oronce Finé], Petrus Apianus [Peter Apian], Gemma Frisius, Franciscus Maurolycus [Francesco Maurolico] and Franciscus Baroccius [Francesco Barozzi] wrote, and Io. Fernelius [Jean Fernel] on cosmotheory [de Coſmotheoria]. Finally, the following treat of the elements of this subject, or of astronomy: Ptolemy, in Books 1 and 2 of the *Great Construction* [Magnæ conſtructionis], which in Graeco-Arabic is called the *Almagest*, and there Theon [Theon of Alexandria] in his commentary, and Regiomontanus in the *Epitome*; Geber [Jābir ibn Aflaḥ], in Books 1 and 2 of his *Astronomy*; Nicolaus Copernicus, in Book 1 of *De revolutionibus* [Reuolutionum]; Michael Neander, in the *Elements of Spherical Doctrine* [Elementis Doctrinæ Sphæricæ]; Titus à Popma [Titus van Popma], on the sphere and the first principles of astronomy; Iosephus Langius [Joseph Lange], in the *Elementale*; Christianus Seuerinus Longomontanus, in the *Astronomia Danica*, Book 1, *Of Spherics* [Sphæricorum]; Io. Keplerus [Kepler], in the *Epitome of Copernican Astronomy* [Epitome Aſtronomiæ Copernicanæ]; Adrianus Metius [Adriaan Metius], *On Spherical Doctrine and the Use of the Globe* [de Doctrina Sphærica, & de vſu Globi]; Petrus Herigonius [Pierre Hérigone], in volume 4 of his *Course of Mathematics* [curſus Math.]; and Petrus Gaſſendus [Pierre Gassendi], in the *Institutio Astronomica* [inſtitutione Aſtronomica]. Besides these, there are the older writers reviewed at the beginning. From them, and from others who touch on these matters here and there, we have compiled this book, with the favour of God, Best and Greatest [Deo O. M.].

CAPVT I. Quid ſit Aſtronomia, & Coſmographia, & quibus Scientijs, aut Artibus indigeat.

Chapter I. What Astronomy and Cosmography Are, and What Sciences or Arts They Require.

[Margin: Aſtronomia Definitio. — Definition of astronomy.]

Astronomy is a *physico-mathematical science of the bounded quantity of the celestial bodies, a quantity that also bounds their sensible accidents*. It is subordinate to physics insofar as it considers the sensible changes of the heavens and the stars, or the variety of the sensible accidents in them — such as shape, colour, light, shadow, place, position, order, distance and motion. But it is subordinate above all to mathematics, because it does not consider these accidents precisely as natural affections, or under any other aspect, but insofar as they fall under a definite and bounded quantity, whether that quantity is continuous or discrete, and whether permanent or successive. Astronomy, moreover, is the noblest

species of the whole of mathematics, and it requires no other minds than celestial ones, or *an admirable nature*, as Plato judges *in the Epinomis*.

[Margin: Aſtrologia. — Astrology.]

[Margin: Aſtronomiæ diſcrimen. — How it differs from astronomy.]

Astrology is *the art of divining natural effects from the position and revolutions of the stars*, and so it is a certain part of practical astronomy. I said "natural effects", not events — that is, future contingents that depend on free causes as such, or on chance, or on Fortune as it stands relative to us. For a certain and evident foreknowledge of these belongs by nature to God alone, and this science of divining is truly divine. No human art of these things exists, since from mere and general inclinations determinate events follow neither always nor for the most part. Those who boast of this part of judicial astrology [Aſtrologiæ Iudiciariæ], or practise it, have therefore rightly incurred the censure of Holy Scripture and the sacred canons. Even though, as Tacitus keenly says, that breed of men is one *which will always be forbidden in the City, and always retained*, he would have said better: in the world [in Orbe]. Astronomy is therefore far broader than astrology taken strictly, and it is only through want of skill that some use these names without distinction.

[Margin: Geographia. — Geography.]

Geography, taken more narrowly, is *the art of measuring and describing the globe of the Earth, and its inhabited or habitable surface*. It is concerned with the bounded quantity of the terraqueous globe — compacted, that is, of earth and water — not only absolutely but also relatively: both with respect to its parts, situated in various ways within it and set far apart, and with respect to the regions of the sky, from which come the various properties of lights and shadows, of days and nights, and of the seasons of the year. Its parts are hydrography, which undertakes the description of seas and islands; topography, which describes single places, say one country house or village; and chorography, which describes particular regions only, say Etruria or Italy. Both of the last are content with their description without reference to the whole surface of the Earth. Histiodromy [Hiſtiodromia], moreover, which is the art of navigating by means of the magnetic compass, presupposes hydrography rather than being a part of it.

[Margin: Geogr. — Geography.]

Geography as defined above is as necessary to astronomy as a base to a column, for other reasons and above all because of the difference of longitude and latitude between the places of celestial observations, or of phenomena to be predicted.

[Margin: Coſmographia. — Cosmography.]

Cosmography is *a science compounded of astronomy and geography together*. It differs from spherics — the treatment of the celestial and elementary sphere — only in brevity and compression: what cosmography does amply and expansively, spherics does strictly and succinctly, so as to set before beginners a kind of introduction [Iſagogem] to astronomy and geography. We too take this up

in this first book of ours and in the second, and shall expound the theories of the stars [Theoricas ſyderum] in other books.

The sciences or faculties that a complete astronomy chiefly requires are, further, seven: namely arithmetic, geometry, optics, gnomonics, organics, geography and chronology [Chronica].

[Margin: Arithm[?]tica. — Arithmetic.]

Arithmetic is *the science of numbers, or of discrete quantity, partly speculative and partly practical*. The part of it at least that the astronomer needs is the one that teaches how to compose, or gather into one sum, several numbers; how to subtract, multiply and divide numbers both whole and fractional; how to find a fourth proportional number by the golden rule of proportions, or the rule of three [Regulam Trium], as they call it; and how to extract the square and cube root of a given number. But the special portion of arithmetic that is even more necessary to him is the one that belongs to logistic [Logiſticæ], which applies the rules of reckoning, subtracting, multiplying and dividing to degrees of signs, of circles and of angles, and also to days and hours, and to the minutes of degrees or of hours, that is, sixtieths and sixtieths of sixtieths. We shall give it below, in chapter 5.

[Margin: Logiſtica — Logistic.]

[Margin: Logarithmica. — Logarithmic arithmetic.]

Logarithmic arithmetic is not necessary, yet it is in the highest degree to be sought after for solving triangles, above all spherical ones, and for constructing astronomical tables by that solution. With its help the rule of three is completed by the mere addition of artificial numbers, and things are dispatched much more quickly that are otherwise accomplished — with the greatest trouble, and scarcely — through the usual tables of sines, tangents and secants by repeated multiplication and division, at a cost in time of more than four times as much, and much more with larger numbers. We shall therefore give it very briefly in the second volume of the *Almagest*, in the trigonometrical book.

[Margin: Geometri[?] — Geometry.]

Geometry is *a science partly practical and partly speculative, of magnitudes, or of continuous bounded quantity as such*. The part of it the astronomer must learn thoroughly is the one that treats the more notable properties of triangles, circles, ellipses and spheres. From practical geometry, the portion the cosmographer and the astronomer ought to know better is the one that teaches how to measure, by means of visual rays, either surfaces and distances — this is called geodesy [Geodæſia]; or heights — this is called altimetry [Altimetria], in Greek ὑψομετρία [Greek: hypsometria, "height-measurement"]; or floors — this is called ἐμβαδομετρία [Greek: embadometria, "area-measurement"]; or depths — this is named βαθεομετρία [Greek: batheometria, "depth-measurement"]. These at least must be sampled, and we shall use them in various problems, especially in the geographical book.

[Margin: Trigonmetria. [recte: Trigonometria.] — Trigonometry.]

But the part that deals with the analysis of triangles, and teaches how to solve triangles both plane and spherical, must be learned thoroughly by the astronomer, since he needs to use it constantly and very often indeed. Accordingly, from the various forms of trigonometry in circulation, I have decided to give the one that seemed to me at once the safest and the quickest, in a separate book, which will be the first of volume 2 of the *Almagest* and is entitled *Trigonometricus*.

[Margin: Optica. — Optics.]

Optics is *the science of the manner of vision, and of visibility insofar as it can come about through visual rays and through shadows bounded by rays*, whether those rays are direct and freely propagated from the object to the eye or not. If they are transmitted directly, or unreflected, through openings or slits, it is called dioptrics [Dioptrica]. If they are reflected from some surface partly transparent and partly opaque, it is called catoptrics [Catoptrica] or anacamptics [Anacamptica]. If they pass along refracted lines in a medium of differing density, it is called anaclastics [Anaclaſtica]; yet insofar as anaclastics considers rays not reflected toward the illuminating object but propagated through a transparent medium to the visual power, it is a part of dioptrics. Of these, the parts the astronomer needs are those that teach how to distinguish the true shapes, distances, positions and magnitudes of celestial phenomena from the apparent ones. We shall therefore treat that part of optics which the astronomer needs in Book 3 of volume 2 of the *Almagest*, the *Opticus*, together with much on parallaxes, refractions and shadows. In that part we shall touch on gnomonics [Gnomonicen], which deals with the shadows of gnomons; for the science that deals with shadows and their projections universally is called sciaterics [Sciaterica], from "shadow", which in Greek is σκιὰ [Greek: skia, "shadow"].

[Margin: Organica. — Organics.]

Organics, in its subject matter, is *the art of making and applying mechanical instruments suited to observing the celestial phenomena*. For whatever appears chiefly in the heavens is called in Greek φαινόμενα [Greek: phainomena, "things that appear"], and the observations themselves τήρησες [Greek: tērēseis, "observations"] [recte: τηρήσεις]. No one, however, can be a perfect instrument-maker unless he is thoroughly versed in astronomy; for when the end and the proper use of these instruments are unknown, many points of exactness in their construction must also go unrecognized. I therefore judged it worth my while to set out, in an entire book which I have named the *Organicus*, the way to construct the choicest of all the instruments that are necessary or very useful to astronomy, together with a method for handling and applying them without error, and an order for choosing [them] in observing the phenomena of the heavens. This will be Book 2 of volume 2 of the *Almagest*.

[Margin: Chronologia. — Chronology.]

Chronology is *the art of computing times and their intervals*. It has two parts. The first is the doctrine of times according to the different forms of years and months, and the calendars of the different nations, which comprises the

reckoning of the civil and the sacred computus. The second is the knowledge of the different epochs or eras — that is, of the starting points from which years are counted forward or backward — from which is derived the method of properly connecting them with one another. The astronomer cannot examine as he should the observations made by others at different times, nor derive the celestial motions from those observations for other nations, without knowing those times themselves; and not merely ordinary astronomers but some of the foremost have slipped in this matter. I have therefore thought it necessary to share with the readers of the new *Almagest*, at the end of volume 2, a book, the *Chronologicus*, which I had put together from my youth onward for other uses in sacred and profane history, with tables added that are most convenient for computing dates.

CAPVT II.

De Cœli Rotunditate, Motuque Circulari Cœlorum, aut Syderum.

On the roundness of the heavens, and the circular motion of the heavens or of the stars.

That the heavens are spherical, and that their motion and the motions of the stars manifest to us are circular, is affirmed, with the ancient astronomers, by Ptolemy in Book 1 of the *Almagest*, chapter 3; by Theon in the same place; by Regiomontanus in the *Epitome*, Book 1, conclusion 1; by Copernicus, Book 1, chapters 1 and 4; by Johannes de Sacrobosco, chapter 1, and there by Clavius, p. 76; by Barozzi, Book 1 of the *Cosmographia*, p. 11 — and who does not? It is shown in three ways, as follows.

[Margin: Argumentum 1. — Argument 1.]

I. *A priori*, from fittingness. Just as *the circle is greater than all the regular rectilinear figures isoperimetric with it, so too the sphere is greater than all the bodies isoperimetric with it* — as Theon and Clavius demonstrate in part in the places cited above, and Pappus in part. To the heavens, then, which contain all things within themselves, the most capacious figure was owed, and so the spherical one. Next, of all bodies the sphere is the most nimble for the motion of revolution, as the circle is, because it suffers less resistance from the medium: any of its parts moves into the place of the parts next to it, with no external body rushing in or giving way. And it is evident that a motion of revolution, and a circular one, befits the heavens, since it is the noblest and simplest motion and returns into itself most regularly, and so suits the noblest of inanimate bodies, the simplest, and the most regular in its motions — at least in its more evident ones. Finally, the circle and the sphere, by their capacity and by their figure, in which neither beginning nor end actually appears, in a certain way imitate the divine immensity and infinity. Therefore this sensible world, other things being equal and preserved, represents the archetypal world — that is, God Most Good and Greatest [Deus O. M.] — better by that figure; as do the other, more perfect parts of the upper world as well: the Sun, the Moon and the other stars. Granted, other bodies too, especially liquids, tend toward roundness — drops

of water, seeds as well, and the trunks of trees — and any agents that are not impeded act spherically: that is, they spread their force from one point along lines in every direction, equally distant from it; hence the space to which their force can extend is called the *sphere of activity* [Actiuitatis Sphæra]. Lastly there comes the fittingness drawn from the roundness of the lower world and of the terraqueous globe, which had to be contained by a like body and to be ruled and nourished equally by its influences — not, indeed, by absolute necessity, but on the supposition of what God and Nature are accustomed to do, namely what is best.

[Margin: Argumentum 2. circularis motus. — Argument 2, for circular motion.]

II. *A posteriori*, from the experience of the senses. For to those who watch the heavens on clear days or nights, they appear vaulted like an arch, that is, spherically concave — even though the parts nearer the horizon seem farther from us than those above the zenith, because of a deception of sight, which is accustomed to measure intervals and distances by the intervening bodies, between us and the horizontal part of the heavens. Moreover, the stars, in the daily motion from rising through the meridian toward setting, ascend little by little with uniform motion until they reach the meridian and their highest altitude; then they descend step by step with uniform motion until they set from our sight, and after a proportional time they rise again and begin to ascend. And in this motion they keep among themselves the same distance that first appeared, and so they are seen to be moved equidistantly about the Earth as about a centre, and consequently to describe circles, since an equal distance of lines from a centre is the mark of the circular form. Of the fixed stars, those which always appear to us — such as the Greater and Lesser Bear for the Greeks — describe perfect and manifest circles about one point of the heavens, which is called the pole of the world; those nearer to it are also hidden, but for a shorter time, and those farther away are hidden for a proportionally longer time, according to the ratios of the circles that they describe about the pole of the world. The projections of shadows, too, their increments and decrements, and the figures they describe with their tips, come about exactly as the circular motion of the stars that illuminate the Earth requires. Sundials [Horologia … sciaterica], too, and the instruments with which astronomers observe the altitudes of the stars, their distances and their motions, suppose that the motions of the heavens or of the stars are circular, and many of them require the figure of a whole or a partial circle in order to exhibit the celestial phenomena more nearly to the truth. In the planets' proper motion from west to east, the circular motion prevails, whether it consists of one circle or of several; and if any irregularity appears in it, it is reduced to regularity by adopting the hypothesis of motion through several circles, or through forms depending on the laws of the circle, such as ellipses.

[Margin: Argumentum 3. — Argument 3.]

III. The third argument is taken from the absurdities that would follow if the heavens were not spherical, or if all circular motion were denied to the heavens and the stars. For then the things we spoke of in argument 2 would not appear at all, and many would appear in the opposite way. In the first place, if the heavens were flat, the distances between any two fixed stars would appear unequal to the same observer at different times, or to different observers at the same time; and the stars would be nearer to some than to others, and consequently would look larger at the zenith, or at their meridian altitude, than at the horizon — whereas the contrary happens. You will understand these arguments better once you have learned the circles of the sphere.

SCHOLIA.

[Margin: Isoperimetræ figuræ quæ? — What are isoperimetric figures?]

I. *Isoperimetric figures are those contained by an equal perimeter; regular figures are those that are equilateral and equiangular in themselves. Thus, if a circle is given whose circumference is ten palms, and a triangle whose sides taken together equal ten palms, the two figures will be isoperimetric, or of equal perimeter. And an equilateral triangle — each of whose lines, for the sake of example, is one palm — is a regular figure, since it also has equal angles. That among isoperimetric and regular plane figures the circle is the most capacious, and among bodies the sphere, some argue from the fact that figures with more angles are more capacious, while the circle and the sphere exceed without limit the finite angles of a figure inscribable in them. But if the circle is compared with a regular figure inscribable in it, it will indeed be greater, since it contains that figure and something more; yet this reasoning is not universal. Neither are the demonstrations brought by Theon and Clavius, since they hold only for the sphere compared with a body in which a sphere can be inscribed, and which is contained by plane or conical surfaces. For this reason Clavius admits that one must have recourse to [no.] 70 of Pappus of Alexandria [ad 70. Pappi Alexandrini], who demonstrated this universally of every body.*

II. The spherical figure did not suit man — although he is an image of the archetypal world, and in some respects a more perfect one than the heavens — because it was not suited to the variety of the operations of the soul [animasticarum operationum], as it is to the operations of the heavens. That is why in argument 1 we say "other things being equal and preserved"; and so the objection is answered that Clavius and Barocius made against this argument from fittingness, put forward by Sacrobosco, and indeed by Manilius too, in these verses of Book 1:

> This form endures eternal, and most like the gods, which has no beginning anywhere, nor end in itself, but remains like to the whole, and is equal throughout.

III. Some, in Ptolemy, seem to have said (as above) that the stars are moved along infinite straight lines. They are easily refuted by the stars' return and revolution to the same starting point, which takes place in a finite time. Others said that the stars are extinguished at the western horizon and kindled at the eastern, and born anew,

so as to remove a perfectly circular motion and grant at most a semicircular one. But since the appearances dealt with in argument 2 occur all round the whole globe of the Earth, and what is the horizon for some is the meridian for others, the stars would have to be extinguished and rekindled at every single moment, and the same stars at that. Nor can any sound reason be given why the fixed stars that always appear are not extinguished while the rest are. Indeed, since the same fixed stars that always appear to some — as Cynosura does to the Greeks — lie hidden from others at the same time — as from the Peruvians — the same stars would have to be extinguished and not extinguished; which is absurd.

IV. The vacuum which Aristotle (De Caelo, Book 2, text 22), and Sacrobosco [Sacrobuſcus] with him, says would result if the heavens were not spherical lacks any sound reason. For it would also be avoided if the heavens had an oval figure, as Clavius notes; and the argument supposes that the side of a cube, for example, is a place deprived of the body due to it. But if the world were of cubic figure, its surface would not have to contain any other body, nor would there be in it a privation of such a body — except on the hypothesis of a sphere to be completed, which is the very point in dispute here — unless it is said, in a vicious circle, that it must be spherical because it must be spherical.

V. The absurdities dealt with in argument 3 would be avoided, and many of the appearances dealt with in argument 2 would be saved, if one could say with the Copernicans that the Earth moves; or with others, that the distance of some of the planets from the Earth is, if not infinite, at least so great that the difference in the phenomena arising from a figure circular on the one side and not circular on the other would become insensible. But it is enough for us here that the motion is circular to the senses, and that those who devise these things depart from the senses.

VI. Those who try to reduce the motions of the planets to spirals or ellipses are nonetheless compelled, in those very curves, to depend on the ratios and properties of the circle; so on this point they are not opposed to the common opinion.

VII. Lactantius (Divine Institutes, Book 3, chapter 23) and Procopius of Gaza [Procopius Gazæus] (on Genesis, chapter 1) deny the roundness of the heavens; and Saints Justin, Basil, Chrysostom and Ambrose seem to have doubted it, according to Pererius [Benito Pereira] (on Genesis, Book 2, question 3). But other Fathers stand for it, especially Saints Jerome and Augustine (De Genesi ad litteram, Book 2, chapter 9). Augustine there shows that God stretched out the heavens like a tent and a vault, according to Isaiah, chapter 40, or like a skin, according to Psalm 103 — since a skin too can be stretched spherically, as happens with inflated wineskins, bladders and bellows; and every horizon has above it a hemisphere of the heavens vaulted like an arch. Moreover, the Sun is said in Ecclesiastes 1 to return into its circles; and the divine Wisdom in Ecclesiasticus 24 says "I alone have gone round the circuit of heaven" — in Greek ἐκύκλωσα [Greek: ekyklōsa, "I encircled"], that is, "I have rounded about"; and in Proverbs 8, that it enclosed the deeps with a circuit — that is, the watery matter that is between the heavens and the Earth — or, as the Hebrew reading has it, that it drew a circle upon the face of the deep. From these Pererius teaches that the roundness of the heavens agrees wonderfully with divine Scripture.

CAPVT III.

Suppoſitiones de Terræ Figura, Situ, Magnitudine.

Suppositions on the figure, position and size of the Earth.

I. We suppose (1) that the mass of the Earth and of the water is spherical to the senses — which will be shown more conveniently in Book 2, on the elementary sphere; (2) that the Earth is, to the senses, in the middle of the world, as the centre about which the circular and more manifest motion of the heavens takes place; (3) that the Earth, relative to the heavens, especially the highest heaven, is like a point. Although Ptolemy and Copernicus demonstrate these things at the beginning of their works, and the writers on the sphere have imitated them in their first chapters, we shall show them more opportunely in the book on the elementary sphere; for then, once the circles of the sphere and many other things have been set out, the arguments for these hypotheses will be better grasped. But since we had to treat the circles of the sphere, we had first to show that the heavens are round and their motions circular, so that we should not seem to have chosen these figures arbitrarily. Nor, however, do we here set the different systems of the world before beginners, since knowing them presupposes that many other things about the planets are explained first; they will nonetheless be indicated in Book 3, where the place of the Sun is treated.

CAPVT IV.

Circuli Definitio, Proprietates inſigniores, ac Dimenſiones.

Definition of the circle; its more notable properties; and its dimensions.

[Margin: Circuli Definitio. — Definition of the circle.]

I. *A circle is a plane figure contained by a single line, to which all straight lines drawn from one point within the figure are equal to one another.* Such is the figure ABGD: all straight lines drawn from the point C to the curved line ABGD are equal to one another, as CA, CB, CG, CD, and likewise the others, infinite in number.

Diagram. A circle set into the right column beside the definition. A vertical diameter runs from B at the top to D at the bottom, crossing a horizontal diameter from A at the left to G at the right at the centre C. Below the horizontal diameter a second horizontal chord runs from K at the left to M at the right. A straight line runs from the centre up and to the left to the point F on the circumference, left of B.

- F (upper left on the circumference): point
- B (top): end of the vertical diameter
- A (left): end of the horizontal diameter
- C (centre, just right of the crossing): the centre
- G (right): end of the horizontal diameter
- K (left, below A): end of the lower chord

- M (right, below G): end of the lower chord
- D (bottom): end of the vertical diameter

II. *The circumference of a circle* — in Greek περιφέρεια [Greek: periphereia, "circumference"] — *is the curved line containing, or bounding, the circle.* It is not seldom called the circle by synecdoche; properly, however, the circle is not a line lacking breadth but a plane surface bounded by a curved line.

III. *The centre of a circle is the point from which all straight lines, any whatever, drawn to the circumference are equal to one another* — as the point C in the figure above.

IV. *The diameter of a circle is the straight line drawn from one point of the circumference, through the centre of the circle, to another point of the same circumference,* as ACG or BCD. It is called the diameter, or *dimetiens*, because it divides the circle in two, or measures it through the middle. It is also called the greatest of the chords that can be subtended in a circle by arcs of the same circle.

V. *The semidiameter of a circle, or radius, is half the diameter,* as AC or CG. In trigonometry and in tables of sines it is called the *whole sine* [Sinus totus], because it subtends a whole and entire quadrant of the circle and measures a right angle.

VI. *A quadrant of a circle is the fourth part of the circle, contained by a fourth part of the circumference and by two semidiameters that make a right angle at the centre of the same circle,* as the portion BCG of the circle.

VII. *The greater segment of a circle is a portion of the circle greater than a semicircle,* as KBM; *and the lesser segment is a portion less than a semicircle,* as KDM.

VIII. *A circle is said to be touched,* whether by a straight or by a curved line, when it is touched at a single point of the periphery; or when it is touched in such a way that the periphery is not cut, and the tangent line, if produced, cannot enter the circle.

PROPRIETATES CIRCVLI.

Properties of the circle.

The properties of the circle are most beautiful and innumerable, but candidates in astronomy need to know only a few of them. The chief of these are the following; their proof [apodixis], or demonstration, is to be sought from the authors cited below.

I. *An arc of the circumference of a circle is the measure of the angle made at the centre of the circle by the straight lines that contain the arc.* For an angle is said to be as great — of so many degrees or minutes — as is the arc of a circle described from the vertex of the angle as centre and bounded by the straight lines drawn from that centre to the circumference. Thus in the preceding figure, if from the centre C the arc FB of the circle ABGD is described, and from the same C the lines CF and CB are drawn, the measure of the angle FCB will be the arc FB; and if this arc is 40° 25′, the angle FCB will also be said to be 40° 25′. Hence a quadrant of the circle, such as BG, is the measure of the right angle

BCG, and each is 90°, since the whole periphery of the circle is divided into 360°. A semicircle such as BGD is the measure of the two right angles BCG and GCD taken together, and of 180°; for the straight line GC, falling on the straight line BD, makes with it two right angles, or angles equal to two right angles, by Euclid, *Elements* I.13. So the arc FAD is the measure of the obtuse angle FCD, which is greater than a right angle and consists of more than 90°. Finally, the whole circle is the measure of four right angles, and of 360°; for about the centre, one and the same point C, four right angles stand in the same plane, neither more nor fewer, by the corollaries to Euclid, *Elements* I.13.

II. *The arcs of several circles described from the same centre, and contained by the same straight lines drawn from that centre, are similar to one another.* Thus in the following figure the arc AB is similar to the arc MN, because both are described from the same centre C and both are intercepted by the same straight lines CMA and CNB, drawn from the same centre C. Similar, I say, not equal: that is, the greater arc has the same ratio to its whole greater circle as the lesser arc has to the lesser circle; and if one is, for example, a sixth part of its circle, or 60°, the other too is a sixth part of its circle, and 60°. Our Clavius demonstrated this in his *Sphaera*, chapter 1, p. 203 in my copy [pag. mihi 203].

Diagram. Two concentric circles set into the left column beside property II. Two straight lines run from the common centre C (its label set just below the vertex) up to the left and up to the right, cutting the inner circle at M (left) and N (right) and the outer circle at A (upper left) and B (upper right). Between M and A the line is printed broken, as two short dashes.

- A (upper left, on the outer circle): end of line CMA
- B (upper right, on the outer circle): end of line CNB
- M (left, on the inner circle, set obliquely along the line): point
- N (right, on the inner circle, set obliquely along the line): point
- C (centre): common centre

III. *A straight line touching a circle makes a right angle with the semidiameter or diameter of the circle drawn to the point of contact.* What it is to touch a circle was stated in definition 8. It is demonstrated by Euclid, *Elements* III.18.

IV. *The angle in a semicircle is a right angle.* The angle in a semicircle is the one whose vertex ends on the circumference of the circle while the lines forming it end at the extremities of the diameter. The angle in the lesser segment of a circle is greater than a right angle; in the greater segment, less than a right angle. Euclid, *Elements* III.31.

V. *In a circle the angle at the centre is double the angle formed at the circumference* — provided, that is, that both stand on the same arc of the circumference as their base. Euclid, *Elements* III.20.

VI. *In the same circle, equal straight lines ending at the circumference are equally distant from the centre;* their distance is measured along the shortest line, namely the one drawn from the centre perpendicular to them. Euclid, *Elements* III.14.

VII. *In quadrilaterals inscribed in a circle, two opposite angles are together equal to two right angles;* so the four angles taken together are equal to four right angles. Euclid, *Elements* III.22.

VIII. *The square of the tangent to a circle is equal to the rectangle one of whose sides is the diameter of the circle produced as far as*

the other end of the tangent, while the other side is equal to the external addition to that diameter. Euclid, *Elements* III.36.

IX. *The diameters of different circles are to one another as the circumferences;* and conversely, the circumferences are to one another as the diameters. Pappus of Alexandria, *Collection*, Book 11, theorem 5. *And the square of the semidiameter is half the square inscribed in the circle:* Clavius, in the lemma to proposition 17 of Book 1 of Theodosius.

X. *Circles are to one another as the squares of their diameters* — understand, as to their area. Euclid, *Elements* XII.2. So if the square erected on the diameter of one circle is three times the square erected on the diameter of another circle, the first circle too will be three times that other circle; and likewise for other ratios.

XI. *The arc whose chord is the semidiameter of the circle is a sixth part of the circumference,* from Euclid IV.15.

DIMENSIO CIRCVLI.

Measurement of the circle.

The measurement of the circle is the finding of the size of the diameter from a given circumference; or of the circumference from a given or known diameter; or of the area from a given circumference and diameter. For these, take the following selected theorems and problems, drawn from Archimedes, *On the Measurement of the Circle*; from Clavius, *Geometria practica*, Book 4; and from Ludolphus Collen [Ludolph van Ceulen], *De Circulo et Adscriptis*, Book 4.

I. *A circle is equal to a right triangle one of whose sides about the right angle is equal to the semidiameter of the circle, and the other side equal to the periphery.* The greater side containing the right angle is called the base by Archimedes (*On the Measurement of the Circle*, theorem 1), although most people call the base the line that subtends the right angle itself.

II. *The area of a circle is equal to the rectangle contained by the semidiameter of the circle and a line equal to the semicircumference.* So our Clavius, cited above, and in the *Sphaera*, p. 85.

III. *A circle has to the square of its diameter the ratio of eleven to fourteen;* so Archimedes, theorem 2, cited above.

IV. *The circumference of any circle is triple the diameter and exceeds it further by less than a seventh part of the diameter, but by more than ten seventy-firsts;* so the same Archimedes, cited above, theorem 3. Iosephus Scaliger [Joseph Justus Scaliger] tried in vain to pick at these theorems in his *Cyclometrica elementa*, and for that he was soundly beaten by many — by Vieta [François Viète], Clavius

and Rivaltus [David Rivault]. Hence it is that, with the fraction dropped, you find everywhere — in Pliny the Elder, Book 2, chapter 23, in Macrobius on the *Dream of Scipio*, and in others — that the diameter of the circle is to the periphery as 7 to 22. But a subtler ratio is the one Ptolemy found (*Almagest*, Book 6), and Viète; and subtler still the one of Ludolph van Ceulen, which he wished to have carved on his monument. Our Christophorus Griembergerus [Christoph Grienberger] examined it in his *De Triangulis* and found it true. They are as set out below.

Circuli Diameter ad Circumferentiam eſt — The diameter of the circle is to the circumference:

Authority	as (Vt)	to (Ad)
Ptolemæo — Ptolemy	10,000,000	31,416,666
Vietæ — Viète	10,000,000,000	31,415,926,535
Ludolpho, & Griembergero — Ludolph van Ceulen and Grienberger	100,000,000,000,000,000,000	314,159,265,358,979,323,846½

From these arise the following problems and rules, worked out with sufficient precision.

1. Data Circumferentia reperire Diametrum Circuli.

1. Given the circumference, to find the diameter of the circle.

[Margin: Diametri Circuli inuentio. — Finding the diameter of a circle.]

Multiply the circumference by 7 and divide the product by 22: the quotient will be a diameter slightly less than the correct one. Then multiply the circumference again by 71 and divide the product by 223: the result will be a diameter slightly greater than the correct one. Choose, therefore, the mean between these, or multiply the circumference by 100 and divide the product by 314: in this way you will obtain, in a single operation, very nearly the value you are looking for.

Probl. 2. Data Diametro Circuli reperire Circumferentiam.

Problem 2. Given the diameter of a circle, to find the circumference.

[Margin: Circumferentiæ Circuli inuentio. — Finding the circumference of a circle.]

Multiply the diameter by 22 and divide the product by 7: the result will be a circumference greater than the correct one. Then multiply the diameter by 223 and divide the product by 71: the result will be a circumference smaller than the correct one. Choose, therefore, the mean between these; or, in a single operation, multiply the diameter by 314 and divide the product by 100, for the quotient will be the circumference sought.

Probl. 3. Datis Diametro, & Circumferentia reperire Aream Circuli.

Problem 3. Given the diameter and the circumference, to find the area of the circle.

[Margin: Areæ Circuli inuentio. — Finding the area of a circle.]

Multiply a quarter of the circumference by the diameter, or half the circumference by the semidiameter of the circle; either way the result will be the area of the circle, that is, its surface in square measure. For example, if the semidiameter was 10 feet and the semicircumference roughly 31½ feet in length, the area of the circle will be roughly 315 square feet.

CAPVT V.

De Circuli diuiſione in Gradus, & Graduum, Dierum, Horarumq; in Minutias, & eorum Logiſtica.

Chapter V. On the division of the circle into degrees, and of degrees, days and hours into fractional parts, and on their logistic.

[Margin: Cur circulus diuiſus in gr. 360. — Why the circle is divided into 360°.]

I. Every circle is divided by cosmographers — indeed by all geometers — into 360 equal parts, which they call *degrees* [Gradus]. The semicircle, accordingly, is divided into 180°, the quadrant of the circle into 90°, the sextant into 60°, the octant into 45°, and the triens into 120°. The reason for this division was the number of days in a year midway between the solar year and the lunar year. The solar year is 365 days, or 366 if it is a leap year [Biſſextilis], whereas the lunar year is 354 days; and between these numbers lies this round number, 360. So it was into that many degrees that the zodiac was divided first — the circle which the Sun runs through in roughly the same number of days — then the equator [Æqnator], and finally every circle. This number also contains a most beautiful blend of six and ten, which the Pythagoreans rightly held to be the most fertile numbers: six multiplied by itself gives 36, and this multiplied by ten gives 360. And since the zodiac, from which this distribution arose, is divided into twelve months, as the Moon indicated, every other circle is likewise divided by geometers into twelve segments, which are also called signs, and each sign into 30 degrees [gtadus], or equal parts.

[Margin: Gradus ſubdiuiſio. — Subdivision of the degree.]

II. Every degree — like the day for Ptolemy, and the hour for other astronomers — is subdivided into sixty minutes [minuta], or *scrupula prima*. This is done because of the convenience of the number sixty: among the numbers made up of two figures there is none that has as many aliquot parts as sixty — that is, none that can be divided into as many of its own parts, each measuring it by repetition without a fraction. For it has 10 aliquot parts, and it is produced from six and ten multiplied together. Its half is 30 degrees, its third part 20, its quarter 15, its fifth 12, its sixth 10, its tenth 6, its twelfth 5, its fifteenth 4, its twentieth 3 and its thirtieth 2, as you can see more distinctly in this small table:

Sexagenarij Numeri Partes aliquotæ cū Valore in Gradib. — The aliquot parts of the number sixty, with their value in degrees.

Partes (Parts)	2	3	4	5	6	10	12	15	20	30
Valor (Value)	30	20	15	12	10	6	5	4	3	2

[Margin: Minuti ſubdiuiſio. — Subdivision of the minute.]

III. Every minute, or *scrupulum*, is subdivided into sixty equal small parts, which are called *secunda* (understand *scrupula*: "second" minutes); each second into 60 *tertia* [thirds]; each third into 60 *quarta* [fourths]; each fourth into 60 *quinta* [fifths]; each fifth into 60 *sexta* [sixths]; and so on to infinity, as far as one cares to subdivide into sixtieths of sixtieths. The characteristic signs, or notations, of these fractional parts come in four forms, as can be seen in the small table, or tablet [laterculus], added here. Further on, at the end of the work, I will give a table converting minutes of a day into hours, and hours into minutes of a day.

Notæ	M	S	T	Qua.	Qni.	Sex.	Sept.	Oct.	Non.	Dec.
Vel	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.
Vel	I	II	III	IV	V	VI	VII	VIII	IX	X
Vel	′	″	‴	⁗	v	vi	vii	viii	i^{x}	^{x}

Notation key: Notæ = signs; M = minutes; S = seconds; T = thirds; *Qua.* = fourths; *Qni.* = fifths; *Sex.* = sixths; *Sept.* = sevenths; *Oct.* = eighths; *Non.* = ninths; *Dec.* = tenths; *Vel* = "or".

LOGISTICA.

Logistic.

Logistic [Logiſtica] is the part of arithmetic that teaches how to add up, subtract, multiply and divide astronomical or cosmographical numbers — namely signs, degrees, days, hours and their fractional parts, or *scrupula*, and sixtieths of sixtieths. Its rules are the following.

PRÆCEPTVM I. DE ADDITIONE.

Rule I. On addition.

First, arrange the denominators of the numbers so that signs stand properly under signs, degrees under degrees (or days under days), hours under hours, minutes under minutes, and seconds under seconds. Second, begin the adding-up, or reckoning, from the right, proceeding towards the left. Third, for every sixty seconds carry one minute into the column of minutes; for every sixty minutes carry one degree, or one hour, into the column of degrees or of hours; likewise for every thirty degrees carry one sign into the column of signs; and for every twelve signs throw away the circle so made, keeping in the sum the number of signs [Signognorum], if any remainder was left after the twelves were thrown away. In the same way, for every 24 hours put down one day.

EXEMPLVM ADDITIONIS.

Example of addition.

Denominatores	Sig.	Gr.	′	″	vel Dies	Hor.	′	″
Numeri Colligendi	6	25	38	46	13	19	45	38
	8	7	42	51	2	7	15	22
		2	15	20		3	5	12
Summa	3	5	36	57	16	6	6	12

Denominatores = denominations; *Numeri Colligendi* = the numbers to be added; *Summa* = sum; Sig. = signs; Gr. = degrees; Dies = days; Hor. = hours; *vel* = "or".

You see that in the first example the sum of the seconds 46, 51 and 20, which is 117, contains 60 once, that is, one sixtieth. For that sixtieth, therefore, I mentally carry one minute into the column of minutes, and under the seconds I write only the remaining 57, which are left when 60 is taken from 117. Next, since the sum of the minutes 38, 42 and 15, with that minute arising from the seconds added, would be 96, which contains one sixtieth, I carry a unit into the column of degrees and write under the minutes the remaining 36. Third, since the sum of the degrees 25, 7 and 2, with that one unit arising from the minutes added, would be 35, and thirty degrees make one sign, I write only 5 degrees, and for the other 30 I carry one sign into the column of signs. Finally, since the sum of the signs 6 and 8, with that unit added, would be 15, in which twelve signs — that is, one whole circle — are contained once, I throw away the 12 signs and write in the sum only the remaining 3 signs. And so the useful sum, the one to be kept after the whole circles, is $3^{s}\ 5^{\circ}\ 36'\ 57''$.

[Margin: Diſcrimen ſummæ Logiſticæ, a vulgari. — The difference between the logistic sum and the common one.]

Likewise in the second example: if the sum had been reckoned not by logistic but by common arithmetic, it would be 15 days, 29 hours, 65 minutes and 72 seconds; but if the rule of logistic I have stated is observed, it is $16^{d}\ 6^{h}\ 6^{m}\ 12^{s}$.

PRÆCEP. II. DE SVBTRACTIONE.

Rule II. On subtraction.

First, write the numbers to be subtracted under numbers of the same kind — that is, seconds under seconds, minutes under minutes, degrees under degrees, and so on. Second, begin the subtraction from the right and proceed in it towards the left. Third, if the upper numbers are greater in each kind, carry out the subtraction in the usual way. But if they are smaller, so that the subtraction cannot be made from them taken by themselves, borrow one unit from the next kind to the left, resolve it into the following kind, add it, so resolved, to the number that was smaller, and from the total subtract the number you wanted to subtract. And if the signs from which the subtraction is to be made

are fewer, add to them a whole circle, that is, 12 signs, and so you will complete the subtraction.

EXEMPLVM SVBTRACTIONIS.

Example of subtraction.

	Sig.	Gr.	′	″	Sig.	Gr.	′	″
Numerus à quo	8	21	34	49	4	7	20	10
Numerus ſubtrahendus	5	6	25	10	3	20	15	40
Reſiduum	3	15	9	39	0	17	4	30

Numerus à quo = the number from which; *Numerus ſubtrahendus* = the number to be subtracted; *Reſiduum* = remainder.

In the first part of the example there is no difficulty. In the second part, however, since 40 cannot be taken from 10 seconds, I take one minute from the 20 minutes, resolve it into 60 seconds, and add it to the 10 seconds to make 70, from which I subtract 40; the remainder is 30 seconds. Next, when 15 is taken from the remaining 19 minutes, 4 minutes are left. Third, since 20 degrees cannot be subtracted from 7 degrees, I take one sign from the number of signs, resolve it into 30 degrees, and add it to the 7 degrees to make 37, from which I now subtract 20, and 17 degrees are left. Finally, since of the 4 signs, after one sign was taken from them, 3 remained, if I take 3 signs from these nothing is left; so I write a cipher, 0, under the signs. The whole remainder is thus 0^{s} 17° 4′ 30″.

[Margin: Quid tum Signa ſunt pauciora. — What to do then when the signs are fewer.]

But if 3 signs had had to be subtracted from 2 signs, I would have taken a circle of 12 signs and added it to the 2 signs, making a sum of 14 signs; and with 3 subtracted from these, 11 signs would have been left.

PRAECEP. III. DE MVLTIPLICATIONE.

Rule III. On multiplication.

Logistic multiplication has two uses in astronomy. The first is when artificial, or astronomical, numbers are to be multiplied by natural and common numbers. Each kind is then multiplied separately, and afterwards the fractional parts are reduced to degrees or hours by division by sixty, degrees to signs by division by thirty, and hours to days by division by twenty-four. The numbers to be multiplied could, however, be resolved into the lowest kind and so multiplied by natural numbers, and the product of the multiplication afterwards reduced to the earlier kinds by means of division. The second use is when both the multiplier and the multiplicand are logistic and artificial — that is, when degrees, minutes, seconds, etc. are to be multiplied in turn by degrees, minutes, seconds, etc. The operation is then most troublesome, although it can be carried out

somewhat more easily by means of the Canon of Sexagenes, or of Hexacontads. But we are very well off, in that this use is not at all necessary to the astronomer; and so it seems wiser to me not to detain candidates in this entrance-hall with trifles of this sort. Anyone who delights in them should consult Erasmus Reinoldus [Erasmus Reinhold] in the *Prutenic Tables* [Prutenicis Tabulis], from p. 5; Biancani in the *Sphaera*, book 9, chapter 13; Vincentius Renerius [Vincenzo Renieri] in the *Tabulae Mediceae*, precept 3, who gives a table of Hexacontads after p. 60; and Magini in the *Tabulae secundorum mobilium* [tabul. fecund. mob.].

EXEMPLVM MVLTIPLICATIONIS PRIORIS CASVS.

Example of multiplication of the first case.

	Sign.	Gr.	′	″
Multiplicandi	10	20	30	40
Multiplicans fit 3.	3	3	3	3
Summæ fingulæ	30	60	90	120
Summæ Reductæ	32	1	32	0
Sed abiectis circulis.	8	1	32	0

Multiplicandi = the numbers to be multiplied; *Multiplicans fit 3.* = let the multiplier be 3; *Summæ fingulæ* = the separate products; *Summæ Reductæ* = the reduced products; *Sed abiectis circulis* = but with the circles thrown away.

Let $10^{s}\ 20^{\circ}\ 30'\ 40''$ be multiplied by three. I begin from the right and multiply 40″ by 3, which gives 120″. Next I multiply 30′ by 3, which gives 90′. Third, I multiply 20° by 3, which gives 60°. Finally I multiply 10 signs by 3, which gives 30 signs. Now since 120 seconds contain exactly two sixties, that is, two minutes, if these are added to the 90 minutes they make 92′. But since this includes one sixty, that is, one degree, I add it to the 60 degrees, making 61°, and keep 32′. And since these contain two signs, or two thirties of degrees, I keep a single degree and add 2 to the 30 signs, making 32. So the sum comes out at $32^{s}\ 1^{\circ}\ 32'\ 0''$. But if the whole circles, which are contained twice in the 32 signs, are to be thrown away, then with 24 thrown away there remain $8^{s}\ 1^{\circ}\ 32'\ 0''$.

[Margin: Multiplicationis Logiſticæ altera forma. — Another form of logistic multiplication.]

Had I resolved the $10^{s}\ 20^{\circ}\ 30'\ 40''$ into the lowest kind given, namely into seconds, they would be 1153840 seconds. For 10 signs multiplied by 30 make 300 degrees; with 20° added these make 320°. Again, 320° multiplied by 60 make 19200 minutes; with 30′ added these make 19230 minutes. Finally, these multiplied by 60 make 1153800 seconds; with 40″ added they make, as I said, 1153840 seconds. If you multiply these by 3 they make 3461520 seconds. These, however, must be reduced to the usual kinds, as follows. When 3461520″ are divided by 60, the result is 57692 minutes without any fraction, and therefore

without any seconds. Next, when 57692 minutes are divided by 60, the result is 961 degrees and 32/60, that is, 32′. Finally, when 961 degrees are divided by 30, the result is 32 signs and 1/30, that is, 1 degree, and so on, as above. For the analysis of this, consult the last scholium written below.

PRAEC. IV. DE DIVISIONE.

Rule IV. On division.

Logistic division likewise has two uses. The first is when astronomical numbers are to be divided by common ones — for example, if signs, degrees and fractional parts are to be divided by three. This is done either by resolving the given astronomical numbers into the lowest kind and carrying out the division in the usual way, or by dividing each kind separately and, if any fractions are left over, adding them to the remainders of the kind immediately following. The second is when astronomical numbers are to be divided by other astronomical numbers. This is not commonly used either, and the whole of astronomy can be completed without it; so I pass it over. The curious reader may consult on it the authors named in Rule III. For the first case, here is an example.

EXEMPLVM DIVISIONIS.

Example of division.

	Sig.	Gr.	′	″
Diuidenda	10	20	30	40
Diuisor 3.	3	3	3	3
Quotiens	3⅓	6⅔	10	13⅓
Hoc est	Sig. Gr. 3 10	Gr. ′ 6 40	′ 10	″ ‴ 13 20
Ergo Quotiens Logisticè.	3^{s}	16°	50′	13″ 20‴

Diuidenda = the numbers to be divided; *Diuisor 3.* = the divisor, 3; *Quotiens* = quotient; *Hoc est* = that is; *Ergo Quotiens Logisticè* = therefore the quotient, reckoned logistically.

So, when 10 signs are divided by 3, they make 3⅓ signs, that is, 3 signs and 10 degrees. Next, when 20 degrees are divided by 3, the result is 6⅔ degrees, that is, 6° 40′. Third, when the

30 minutes are divided by 3, the result is 10 minutes. Finally, when the 40″ are divided by 3, the result is 13⅓ seconds, that is, 13″ 20‴. Reducing this quotient, therefore, to the usual logistic form, the quotient is 3^{s} 16° 50′ 13″ 20‴.

[Margin: Diuisionis alia forma — Another form of division.]

But someone may perhaps find it easier first to resolve the number to be divided into the lowest of the given kinds — in our case, into seconds. Now, as I said in the second part of the example for Rule III, 10^{s} 20° 30′ 40″ resolved into seconds are 1153840. When these are divided by 3, the quotient is 384613⅓

[printed: 384613′. & ⅓]. And when 384613″ are divided by 60, the result is 6410′ 13″. When the 6410 minutes are divided by 60, the result is 106 degrees and 50 minutes. Finally, when the 106 degrees are divided by 30, the result is 3 signs and 16 degrees. So, as above, the quotient is 3^{s} 16° 50′ 13⅓″, or 13″ 20‴.

PRAECEP. V. DE RADICE QVADRATA.

Rule V. On the square root.

If a square root is to be extracted from an astronomical number, the number must be resolved into the lowest kind given, as I taught above, and from the number so resolved the square root — or the root nearest to a square — is to be extracted by the usual rules of arithmetic.

SCHOLIVM.

Scholium.

I. Among the Greeks sixtieths [Sexagenæ] are called ἑξηκόνταδες [Greek: ἑξηκόνταδες (hexēkontades, "sixties")]; minutes [scrupula] are called λεπτὰ ἢ ἑξήκοστα [Greek: λεπτὰ ἢ ἑξήκοστα (lepta ē hexēkosta, "small parts, or sixtieths")]. If these are first parts, or minutes, they are called πρῶτα [Greek: πρῶτα (prōta, "firsts")]; if seconds, δεύτερα [Greek: δεύτερα (deutera, "seconds")]; if thirds, τριτὰ [Greek: τριτὰ (trita, "thirds")]; if fourths, τετάρτα [Greek: τετάρτα (tetarta, "fourths")]; if fifths, πεντὰ [Greek: πεντὰ (penta, "fifths")]; if sixths, ἑκτὰ [Greek: ἑκτὰ (hekta, "sixths")], and so on. Ptolemy, however, indicates in book 1 of the *Almagest*, chapters 10 and 11, that the circle was divided by Eratosthenes and Hipparchus into 83 parts.

II. The Hebrews, the Persians and formerly the Arabs, as Scaliger affirms in book 1 of *De emendatione temporum*, and as appears from the Jewish calendars, divide the hour into 1080 points [puncta], and each point into 76 moments [Momenta]. So one point equals 3 of our seconds and 20 thirds, and a moment equals 2 thirds and 48 fourths.

III. If either the whole circle of 360 degrees, or a degree, an hour or a day, is to be divided into the parts of the as [Aſſis], in the way the as, or pound [Libra], was divided by the ancient Romans into 12 ounces [vncias], or 12 equal parts, consult the following small table. It is useful to those who read Ptolemy regularly, since, as Keplerus [Kepler] noted in the Rudolphine Tables, chapter 14, Ptolemy very often used this division. Thus the sextant of the circle has 60 degrees, the sextant of an hour or of a degree has 5 minutes, the sextant of a day 4 hours, and so on.

[Margin: Diuiſio Aſſis, ſeu Libræ. — The division of the as, or pound.]

Partes Aſſis	Circuli (Gr.)	Gra. vel Hor. (M.)	Diei. (Hor.)
Vncia	30	5	2
Sextans	60	10	4
Quadrans	90	15	6

Partes Aſſis	Circuli (Gr.)	Gra. vel Hor. (M.)	Diei. (Hor.)
Triens	120	20	8
Quincunx	150	25	10
Semiſſis	180	30	12
Septunx	210	35	14
Bes	240	40	16
Dodrans	270	45	18
Dextans	300	50	20
Deunx	330	55	22
As	360	60	24

Partes Aſſis = parts of the as; *Circuli* = of the circle, in degrees (Gr.); *Gra. vel Hor.* = of a degree or an hour, in minutes (M.); *Diei* = of a day, in hours (Hor.).

IV. The analysis of a degree or an hour into fractional parts down to tenth minutes, and likewise the analysis of the circle itself into minutes down to tenths, is very useful for logistic multiplication and division, and so I give both here in the two following small tables.

Gradus vnus / Hora vna — continet	
Minuta	60
Secunda	3600
Tertia	216000
Quarta	12960000
Quinta	777600000
Sexta	46656000000
Septima	2799360000000
Octaua	167961600000000
Nona	100776960000000000
Decima	6046617600000000000

Gradus vnus / Hora vna continet = one degree, or one hour, contains: minutes, seconds, thirds, fourths, fifths, sixths, sevenths, eighths, ninths, tenths.

Circulus vnus continet	
Gradus	360
Minuta	21600
Secunda	1296000
Tertia	77760000
Quarta	4665600000
Quinta	279936000000
Sexta	16796160000000
Septima	1007769600000000
Octaua	6c4661760000000000 [recte: 60466176000000000]
Nona	362797056000000000000
Decima	21767823600000000000000

Circulus vnus continet = one circle contains: degrees, minutes, seconds, thirds, and so on to tenths.

CAPVT VI.

Sphæræ Definitio, Proprietates insigniores, & Dimensiones.

Chapter VI. The definition of the sphere, its more notable properties, and its dimensions.

I. According to Theodosius, *Sphaerica* book 1, definitions 1 and 2, a sphere [SPHAERA] is a solid body enclosed by a single surface, such that all the straight lines drawn to it from one point within the figure are equal; and that point is the centre of the sphere. Or, as Euclid says in book 11, in a causal definition: a sphere is what results when, the diameter of a semicircle remaining fixed, the semicircle is carried round until it returns to the place from which it began to be carried round. Thus, in the figure placed here, if the semicircle ABG is understood to move about the diameter ACG — which stays fixed, supported on the props AD and GF — and to be carried round in one complete revolution, it will generate the sphere ABKG, or will mark out a space equal to the sphere, whose centre will be C.

Diagram. A small woodcut set into the right column beside definition I: a circle, shaded on its right side to model a sphere, crossed by a horizontal diameter whose two ends rest on two vertical props standing on short bases, like a globe on a stand.

- B (top of the circle): the summit of the semicircle ABG
- A (left end of the diameter): end of the axis; top of the left prop
- C (centre, on the diameter): centre of the sphere
- G (right end of the diameter): end of the axis; top of the right prop
- D (foot of the left prop): base of prop AD
- K (bottom of the circle): lowest point of the sphere ABKG
- F (foot of the right prop): base of prop GF

Labels read: B, A, C, G, D, K, F. Labels not read: none.

II. The axis of the sphere, so called from ἀξίω [Greek: ἀξίω (axiō; glossed in the text as *voluo*, "I turn")], which means "I turn", is a straight line drawn through the centre of the sphere and ending on both sides at the surface of the sphere, about which line, while it stays at rest, the sphere can be turned round — in the preceding figure, the line ACG. Therefore the axis of the sphere is also a diameter of the sphere; but not every diameter of the sphere is its axis, since the sphere does not turn round every diameter, but round one only.

III. The poles of the sphere are the two points that end the axis of the sphere at its surface, and that, like the axis, are immovable — as A and G. They are named from πολέω [Greek: πολέω (poleō, "I turn")], which means "I turn", and so they are also called vertices [Vertices] and hinges [Cardines].

IV. The circuit of the sphere [Ambitus], in Greek περίμετερ [Greek: περίμετερ (perimeter, "perimeter")], is its convex surface; whereas in the circle the circuit and the circumference are the same.

PROPRIETATES SPHAERAE INSIGNIORES.

The more notable properties of the sphere.

[Margin: Triplicata proportio quid? — What is a triplicate ratio?]

I. Spheres are to one another in the triplicate ratio of their diameters: so Euclid, *Elements* book 12, proposition 18. A triplicate ratio is when a proportion of the same kind is continued as far as the fourth term. For example, between 2 and 4 there is the simple double proportion; but if it is made "as 2 to 4, so 4 to 8", the ratio between 2 and 8 will be duplicate; and if it is made again "as 4 to 8, so 8 to 16", there will be between 2 and 16 the triplicate ratio of the double proportion. Thus, if the diameter of the smaller sphere were 2 feet and that of the larger 4, the solidity of the smaller sphere will stand to the solidity of the larger as 2 to 16. Hence, when the solidity of one and the diameters of both are known, the solidity of the other is easily found.

II. The surface of any sphere is four times the great circle in the sphere: so Archimedes, *On the Sphere and Cylinder*, book 1, proposition 30.

III. The rectangle under the diameter and the circumference of a sphere is four times the great circle in the sphere [maximi in Sphæra Circuli]: from Clavius, *Sphaera*, p. 100. Therefore, by property 2, such a rectangle is equal to the convex surface of the sphere itself.

IV. The solid rectangle contained under the semidiameter of a sphere and a third part of its convex surface is equal to the whole sphere. From Clavius, *Geometria Practica*, book 4, and in the *Sphaera*, where he treats isoperimetric figures, proposition 16, or p. 100, where he calls the surface of the sphere its *Ambitus*, and its solidity or total capacity its *Area*.

V. A sphere is equal to a cylinder whose base is equal to the great circle of the sphere, and whose altitude or axis is equal to two-thirds of the sphere's diameter. Archimedes, *On the Sphere and Cylinder*, proposition 32.

VI. A cylinder has to the sphere inscribed in it a sesquialteral ratio [ſeſquialteram proportionem]: Archimedes, *On the Sphere and Cylinder*, book 1, proposition 32. It is therefore as 3 to 2. Moreover, this cylinder has a base equal to the great circle of the inscribed sphere, and an axis or altitude equal to the diameter of that same sphere.

VII. A sphere is equal to a cone whose axis or altitude equals the sphere's diameter, and whose base has a diameter twice as large as the diameter of the sphere. Archimedes, as above.

VIII. A sphere is four times a cone whose base equals the great circle of the sphere and whose altitude equals the sphere's semidiameter. Archimedes, as above.

IX. The surface of a sphere is equal to a circle having a semidiameter equal to the diameter of the sphere. This is a corollary of Archimedes, from property 2, discussed above.

X. A cube has to its inscribed sphere a ratio greater than 21 to 11, but less than 426 to 223. Clavius, from Archimedes, *Geometria Practica*, book 5, chapter 5.

XI. The square on the diameter of a great circle of the sphere has to the surface of the sphere a ratio greater than 7 to 22 and less than 71 to 223. Clavius, as above; he also shows that the said square has to the inscribed circle a ratio greater than 14 to 11, but less than 284 to 223.

XII. The rectangle contained under the diameter of a great circle in the sphere and under its periphery is equal to the convex surface of the sphere, and four times that same circle. Clavius, *Geometria Practica*, book 5, chapter 5, proposition 2.

The remaining properties of the great or non-great circles of a sphere will be reviewed presently, in the next chapter.

DIMENSIONES SPHAERAE

Dimensions of the Sphere

Probl. 1. Datis Diametro, & Circumferentia Circuli in Sphæra maximi, inueſtigare Superficiem Sphæræ conuexam.

Problem 1. Given the diameter and the circumference of a great circle in the sphere, to find the convex surface of the sphere.

[Margin: Superficiei Sphæricæ inuentio. — Finding the spherical surface.]

Multiply the circumference of the great circle by its diameter, and the total will be the surface of the sphere in square measure. Alternatively, find the area of the great circle by Problem 3 of chapter 4 and quadruple it, for you will obtain the same result. This follows from properties 2, 9 and 12 of the sphere, discussed above.

Probl. 2. Datis Semidiametro, & Superficie Sphæræ, inquirere Soliditatem Sphæræ.

Problem 2. Given the semidiameter and the surface of a sphere, to find the solidity of the sphere.

[Margin: Soliditatis Sph. inuētio. — Finding the solidity of a sphere.]

Multiply a third part of the convex surface of the sphere by the semidiameter, and you will have the solidity of the sphere, though in cubic measures. You will obtain the same result if you multiply a sixth part of the surface by the diameter of the sphere. This follows from property 4 above.

Probl. 3. Cubum inuenire ſoliditati Sphæræ datæ æqualem.

Problem 3. To find a cube equal to the solidity of a given sphere.

Find the solidity of the sphere by Problem 2, and find the cube root of that number; for it will give the side of a square on which, if a cube is raised, the cube will be equal to the sphere, or very nearly so if the cube root is not exact but approximate.

Probl. 4. Conum inuenire æqualem Sphæræ datæ.

Problem 4. To find a cone equal to a given sphere.

Let a right cone be made whose altitude is equal to the diameter of the sphere, and whose base is a circle having a semidiameter equal to that same diameter of the sphere; for it will be equal to the sphere, by property 7.

Probl. 5. Cylindrum inuenire æqualem Sphæræ datæ.

Problem 5. To find a cylinder equal to a given sphere.

Let a right cylinder be made whose base is a circle having a diameter equal to the diameter of the sphere, and whose altitude is to the diameter of the sphere as 2 to 3; and this cylinder will be equal to the solidity of the sphere, by property 5.

CAPVT VII.

De Circulis Sphæræ Naturalis, & Artificialis in Communi, eorumque Proprietatibus.

Chapter VII. On the circles of the natural and the artificial sphere in general, and on their properties.

[Margin: Sphæra Naturalis. — The natural sphere.]

The natural sphere, among cosmographers, is the celestial, the elementary, and the terrestrial or terraqueous sphere, since these were made by Nature herself. From what was said in chapter 2, and from what is to be said in the Book on the Elementary Sphere, it is assumed that the heavens, the mass of the elements bounded by the concavity of the lunar heaven, and the globe compacted of earth and water are of spherical shape.

[Margin: Sphæra Artificialis. — The artificial sphere.]

The artificial sphere is one made by art in imitation of the natural sphere. It is either solid, as with the celestial globe, on which the fixed stars are marked and which is called the Aratean sphere [Sphæra Aratæa] after Aratus, who first used or perfected it; and as with the terraqueous globe, on whose surface are drawn the peripheries of the principal circles, imitating in site and position the circles of the celestial sphere.

[Margin: Sphæra Armillaris. — The armillary sphere.]

Or else it is made of rings or armillae representing the circumferences of the circles of the natural sphere, and is called the armillary or material sphere. It is built in such a way that an eye contemplating it from outside can see its parts within, along with the circles of the secondary movables [fecundorum Mobilium] and of the planets that are usually inserted, and in such a way that it may be lighter and easier to handle. Of whatever form and workmanship, in the end, was the sphere that Archimedes enclosed in glass and that Claudian praised in that celebrated epigram:

Iupiter in paruo cum cerneret Aethera vitro,
When Jupiter saw the heavens in a small glass,

Although the image of either sphere can be projected onto a plane in many ways and represented on a plane, an art treated above all by Guidubaldus de Monte [Guidobaldo del Monte] and many others in their planispheres, it is nevertheless better at this point to set before beginners its simplest image, so that they are not frightened off at the start by the multitude and confusion of the circles; provided only that they grow used to imagining, under straight or curved lines, the circles usually signified by their diameters or circumferences, whether whole or merely sketched [adumbratis].

Although, therefore, at the beginning of this book, on p. 1, I set out a figure of the oblique sphere to be viewed with the eye turned to the east, with the divisions of the four principal circles into degrees indicated; and although it seemed right here to set out, roughly in imitation of it, another figure, but of a right sphere, with the eye however turned to the west, and with the beginning of Cancer placed in mid-heaven at C, and so the north pole of the ecliptic below the horizon at M: nevertheless, for greater simplicity and clarity, we shall use a third schema to explain the circles of the sphere, in which the eye, turned to the west, sees a right sphere, so that the north pole of the ecliptic is above the horizon at T, and the beginning of Capricorn in mid-heaven at K.

Let the second schema, then, be of an armillary sphere, but a right one, as you see in the following figure.

Diagram. Woodcut of an armillary sphere in the left column: a heavy outer ring (the meridian) enclosing crossing armillary bands, with a broad graduated band running obliquely across the figure, a small dark globe at the centre, and a horizontal ring through the centre. Labels read on the block:

- E (top)
- K (upper left of E) and C (upper right of E)
- N (upper left) and T (upper right)
- A (left end of the horizontal) and B (right end of the horizontal)
- G (above the central globe)
- F (left of the globe) and I (right of the globe)
- O (lower left) and M (lower right)
- P, Q, R (along the bottom, left to right)

I. Let the third schema, then, be as in the following figure. With centre G and at the interval of the semidiameter AG, let a circle AEBQ be described; it will represent the meridian and at the same time the solstitial colure [Colurum Solftitiorum], while its diameter AGB will represent both the horizon and the axis of the equator. Next let EGQ be drawn, equal to AGB, cutting it in two equal parts and at right angles at the centre G; for it will represent the plane of the equinoctial circle, whose axis will be AGB. The poles of the equator, which are also those of the world, will be the points A and B, namely the southern and the northern. Next let one quadrant of the circle, say AE, be divided into 90°, and from it let 23½° be taken with the compass. On the solstitial colure AEBQ, starting from point E of the equator, let an arc of the same number of degrees, 23½°, be taken, and let it be arc EK; and from point Q let another arc

equal to it be taken toward the other side, and let it be QR. Having marked the points KR, let them be joined by two parallels KR, distant from each other by 12°, or 16°, or 20°; for the small zone enclosed by them, KGR, will represent the zodiac, through the middle of which runs the ecliptic line. Through the centre G let a straight line OGT be drawn, equal to AGB, and let it cut in G, in two equal parts and at right angles, the ecliptic, that is, the middle line of the parallels KGR; for OGT will represent the axis of the ecliptic, whose poles will be O and T. These will be as far from the poles of the world as the ecliptic is from the equator, so that arcs TB and AO will always be as large as EK and QR.

[Margin: Zodiacus. — The zodiac.]

Diagram. Linear woodcut in the left column: a circle with horizontal diameter, vertical diameter and an oblique diameter through the centre, two close oblique lines running from upper left to lower right, and lines near the left and right of the circle joining points on the circumference. Labels read on the block:

- E (top), with K to its left and C to its right
- N (upper left) and T (upper right)
- A (left) and B (right)
- F (left of centre) and G (at centre)
- O (lower left)
- M (lower right)
- P, Q, R (along the bottom, left to right)

II. With this done, take arc PQ equal to arc QR, and EC equal to arc EK, and also arc AN equal to AO, and arc BM equal to TB, marking the points PC NM on the solstitial colure. Through points K and P let a line KFP be drawn, either straight or curved, representing the circle parallel to the equator EGQ; for it will show the Tropic of Capricorn.

[Margin: Tropici. — The tropics.]

A line similarly drawn through points C and R, namely CR, will represent the Tropic of Cancer. Thus point K will be the beginning of Capricorn, point R the beginning of Cancer, and point G the beginning of Aries on one side and of Libra on the other. Finally, through T and M let a straight line be drawn, or if you prefer a curved one, parallel to CR; and through N and O a line parallel to KP. For these will represent the polar circles: TM the Arctic circle, and NO itself the Antarctic circle.

[Margin: Polares circuli. — The polar circles.]

The spaces enclosed by these will represent zones. For the space enclosed within the tropics KP and CR will represent the Torrid Zone, whose breadth KEC, or PQR, will be 47°.

[Margin: Zona. — Zone.]

The space enclosed between the Tropic of Cancer CR and the Arctic circle TM will represent the North Temperate Zone, and the space enclosed between the Tropic of Capricorn KP and the Antarctic circle NO the South Temperate

Zone. The breadth of each of them, CT and KN, will be 43°. The remaining spaces, enclosed between the polar circles and the nearer poles of the world, will represent the Frigid Zones: the northern TBM etc., and the southern NAO etc. Their semidiameter, TB and NA, will be 23½°, while the diameter, TM and NO, will be 47°, which is, of course, the breadth KC of the Torrid Zone.

QVID SINT CIRCVLI IN SPHAERA

Maximi, & non Maximi; Paralleli, & non Paralleli.

What great and non-great circles, and parallel and non-parallel circles, are in a sphere.

I. Those circles are said to be in a sphere whose peripheries lie on the surface of the sphere itself. Others that can be considered within it are nevertheless not considered by cosmographers, except for the circles of the planets; but those are considered in the theorics of the planets, not here, although the chief of them surround their spheres. Further, the circles of a sphere are divided into great and non-great, or small; and into parallel and non-parallel, or inclined.

II. Great circles in a sphere are those that pass through the centre of the sphere; non-great circles are those that do not [non] pass through the centre of the sphere, by proposition 6 of book 1 of the *Sphaerics* of Theodosius of Tripoli.[5]

III. Parallel circles are those that are equally distant either from one another or from some great circle in the sphere; non-parallel circles are those that are inclined to one another and are not equally distant from one another.

IV. The poles of any circle in a sphere are the points on the surface of the sphere from which all straight lines drawn to the circumference of their circle are equal to one another, from definition 5 of book 1 of the *Sphaerics* of Theodosius. This holds true, however, also of arcs on the surface of the sphere drawn perpendicularly from the pole to the circumference, for these too are equal to one another.

V. The distance of small circles from the centre of the sphere is taken along the perpendicular, that is, the straight line drawn from the centre of the sphere to the plane of the circle, from definition 6, added by Clavius to the definitions of Theodosius in his book 1 of the *Sphaerics*.

QVOT, ET QVI SINT CIRCVLI

Maximi Sphæræ Cœleſtis, & Terreſtris.

How many and which are the great circles of the celestial and the terrestrial sphere.

[Margin: Circuli maximi. 13. — Great circles: 13.]

VI. The great circles in the celestial sphere are 13, namely: the horizon; the meridian; the equator; the ecliptic with the zodiac; the equinoctial colure; the solstitial colure; the vertical circles, or circles of altitude; the circles of

[5] the "non" before the second "transeunt" stands between the lines, not in the line of type, and looks like a later addition in ink; the line of type alone reads "non Maximi ſunt, qui tranſeunt"; the errata of the book make the same correction.

declination; the circles of latitude; the hour circles [Horarij]; the circles of position; the circles of the celestial houses; and the circles of distances. Of these the meridian, the horizon and the vertical are immovable, and the rest movable. In the artificial and armillary sphere, however, only the first six are usually set. It would be useful, though, to add one circle turning about the poles of the equator, to serve for the hour circles and the circles of declination; one turning about the poles of the ecliptic, to serve for the circles of latitude; and a third drawn through the poles of the horizon, that is, through the zenith and the nadir, a vertical one, for altitudes. For by moving these around, beginners would more easily learn the doctrine of the primum mobile and many theorems and cosmographical problems.

[Margin: Circuli n[?] Maximi. — Circles n[?] great.]

VII. The circles in the celestial sphere that are not great, or are smaller than the great circles, are 10, namely: the Tropic of Cancer; the Tropic of Capricorn; the Arctic circle; the Antarctic circle; the circles of the climates; the circles of perpetual visibility [ſemper Apparentium]; the circles of perpetual occultation [Semper Latentium]. These seven are parallel to the equator when they are distinct from it; for the equator itself, too, is one of the circles at once of perpetual visibility and of perpetual occultation. The remaining three kinds are:

circles parallel to the ecliptic; the almucantar circles [circuli Almuncatarath], or those drawn through altitudes, which some therefore do not distinguish from the circles of altitude, and these are parallel to the horizon; and the physical or sensible horizon, which is itself also parallel to the horizon simply so called, or the astronomical and rational horizon, and is one of the almucantar circles. In the armillary sphere, however, only the tropics and the polar circles are usually set.

VIII. Circles of longitude, moreover, are not distinguished from the ecliptic or from the parallels of the ecliptic, just as circles of right ascension are not in reality distinguished from the equator or from the parallels of the equator. And although among these are the tropics and the polar circles, the circles of perpetual occultation and of perpetual visibility, and those of the climates, nevertheless there are besides these innumerable other circles parallel to the equator, which can serve to determine the right ascension of stars or of points of the ecliptic, even though the equator alone suffices to measure it. Finally, the circles bounding the zodiac are in truth small circles, belonging to the parallels of the ecliptic, even though the zodiac, because of the ecliptic, is counted among the great circles.

SCHOLION.

The remaining circles that can be imagined in a sphere either belong to the circles of the planets and lie within the sphere, or are not usually considered by cosmographers, such as the parallels of the meridians and of the verticals. Along

these, as we shall show in Book 4 of Volume 2 of the *Almagest*, in the section on Histiodromia, one can travel and sail on the surface of the terraqueous globe. This kind of circle, though less often named, could be added to the small circles, at least those of the terrestrial sphere.

PROPRIETATES INSIGNIORES

Circulorum Sphæræ in Communi.

The more notable properties of the circles of a sphere in general.

I. Great circles in a sphere pass through the centre of the sphere, and conversely. Theodosius, *Sphaerics*, book 1, proposition 6.

II. Great circles in a sphere cut one another in two, that is, into two equal portions; and conversely, if they cut one another in two, they are great. Theodosius, book 1, propositions 11 and 12.

III. Great circles in a sphere are equal to one another, for they have equal diameters, by the corollary of the preceding.

IV. Of parallel circles, those equally distant from the centre of the sphere are equal to one another, and those unequally distant are unequal; and of these, those farther from the centre of the sphere are smaller. Theodosius, book 1, proposition 6.

V. In any circle in a sphere, a straight line drawn from the centre of the circle to the centre of the sphere falls perpendicularly on the circle, that is, makes right angles with the plane of the circle. Theodosius, book 1, proposition 7.

VI. A straight line drawn from the centre of the sphere through the centre of a circle placed in the sphere, if produced, falls on the poles of that circle. Theodosius, book 1, proposition 8. The Arabs and Maurolico add this converse of it: If there is a circle in a sphere, and from one of the circle's poles a straight line is drawn to the centre of the circle, it will be perpendicular to it, and when produced will pass through the other pole; I myself add: and through the centre of the sphere.

VII. A straight line drawn from one pole of a circle in a sphere perpendicularly to the plane of the circle falls on the centre of the circle, and if produced falls on the centre of the sphere and on the other pole of the same circle. Theodosius, book 1, proposition 9.

VIII. A straight line drawn through the poles of a circle in a sphere falls perpendicularly on the plane of that circle, and passes through the centre both of the sphere and of the circle. Theodosius, book 1, proposition 10.

[Margin: Corollaria. — Corollaries.]

From the said propositions V to VIII it follows that a great circle which passes through one of the poles of any circle in a sphere also passes through the other; and therefore that the two poles of any circle in a sphere are diametrically opposite, that is, that a semicircle of a great circle lies between them; and that these four points, namely the two poles of any circle in a sphere, the centre of the circle, and that of the sphere, lie on one and the same straight line, which is

also the diameter of the sphere, as Clavius gathers in his corollaries to the said propositions of Theodosius.

IX. If in a sphere a great circle cuts some circle at right angles, it will cut it in two and will pass through its poles. Theodosius, book 1, proposition 14.

X. If in a sphere a great circle cuts a non-great circle in two, it will cut it at right angles and through the poles. Theodosius, book 1, proposition 14.

XI. If in a sphere a great circle cuts some circle in the sphere so as to pass through its poles, it will cut it in two and at right angles. Theodosius, book 1, proposition 15.

Four other theorems are added here by Clavius from another version, and they are these. 1. If in a sphere a great circle passes through the poles of another great circle, the latter in turn passes through the poles of the former. 2. If in a sphere a circle cuts a circle through the poles and is great, it cuts it in two and at right angles. 3. If in a sphere a circle cuts a circle in two and at right angles, it is a great circle and cuts it through the poles. 4. If a straight line drawn from the pole of a circle in a sphere perpendicularly to the plane of that circle is equal to the semidiameter of the sphere, the circle is great. Clavius, in his scholia on Theodosius.

XII. A straight line drawn from the pole to the circumference of a great circle in a sphere is equal to the side of the square inscribed in a great circle. Theodosius, book 1, proposition 16.

XIII. If in a sphere there is a circle such that a straight line drawn from its pole to its circumference is equal to the side of the square inscribed in a great circle, that circle will itself be great. Theodosius, book 1, proposition 17.

XIV. If in a sphere a straight line drawn through the centre cuts in two another straight line in the sphere not drawn through the centre, it will cut it at right angles; and conversely, if it cuts it at right angles, it will cut it in two. Theodosius, book 1, proposition 22.

XV. In a sphere, parallel circles are described from the same poles; and conversely, if they are described from the same poles, they are parallel. Theodosius, book 2, propositions 1 and 2.

XVI. If in a sphere a great circle touches one of the circles described on the spherical surface, it will also touch another equal and parallel to it. Theodosius, book 2, proposition 6.

XVII. Any arc drawn from the pole of a great circle in a sphere to the circumference of that same circle is a quadrant of the circle, or 90°, from Regiomontanus, Clavius and others on spherical triangles; and that same arc makes right angles with the circumference both of the great circle and of a circle parallel to that great circle: by the same authors.

We shall have to return to these properties, or to the others set down by Theodosius in books 2 and 3 of the *Sphaerics* and explained there by Maurolico or by Clavius, for many of the things to be said below about the circles of the sphere in particular, if anyone wishes to know their more universal reasons.

[Margin: Proportio circuli maximi ad nō maximū. — The ratio of a great circle to a non-great one.]

The ratio of the circumference of a great circle to a non-great one is given by Clavius in the *Sphaera*, p. 384; by Magini on Ptolemy's *Geography*, book 1, chapter 20; and by us in the Geographical Book. See meanwhile Scholium 3 of chapter 16, and the table of it at the end of the work.

CAPVT VIII.

De Horizonte Rationali, & Senſibili.

Chapter VIII. On the rational and the sensible horizon.

[Margin: Horizontis ſpecies. — The kinds of horizon.]

The HORIZON, in Greek [Greek: ὁρίζων (horizōn, "bounding")], from the Greek verb [Greek: ὁρίζομαι (horizomai, "to bound")], which means "I bound" or "I limit", is the circle called *Finitor* [the Bounder], because it bounds and limits day and night, and the sight of an inhabitant on the sphere, etc. It is divided into the rational horizon, which is also called the natural and the astronomical, and the horizon simply so called. Proclus and Geminus, however, call it [Greek: λόγῳ θεοριτὸν [recte: θεωρητόν] (logō theoriton, "contemplable by reason")], contemplable by reason, since our senses do not reach it, at least not the whole of it, but find it by reasoning. It is divided, I say, into the rational and the sensible or physical, which for Proclus and Geminus is [Greek: αἰσθητὸν (aisthēton, "perceptible")], perceptible, that is, by sense; Clavius calls it apparent, and Maurolico and Neander artificial. So much for the name.

[Margin: Horizon Rationalis. — The rational horizon.]

II. The *rational horizon* [Horizon Rationalis] is a great circle of the sphere whose poles are at the inhabitant's vertex and at the point opposite the vertex. It divides the sphere into an upper and a lower hemisphere with respect to someone living on the sphere. To understand this, let C in the accompanying figure be the centre of the world and of the Earth, and BAEN, etc., the globe of the Earth; let HVRK be the heaven, or the celestial meridian; and let an inhabitant A stand on the surface of the Earth. Above his head let there be in the heaven the vertex or vertical point V, and diametrically opposite it the point K. From the points V and K let the great circle HCR be conceived as described: this will be the rational horizon. Its poles will be V, which in Arabic is called *Zenith*, and K, the pole or point that is called *Nadir*, and in Latin *Imum Cæli* [the lowest of the heaven]. If a straight line VK is drawn through these points, it will be the vertical line, or the axis of the horizon, if the horizon were imagined as movable. The horizon will divide the sphere into an upper hemisphere, which in the universe is HVRC and on the terrestrial sphere is BAEC, and into a lower one, which there is HKRC and here is BNEC. The upper is painted white and the lower black, because the Sun placed above the

horizon makes day above and in the meantime is not in the lower hemisphere, or because the upper is visible to the inhabitant A and the lower hidden.

Diagram. Woodcut inset at the right of the left column: a large outer circle with a vertical and a horizontal diameter, and a small inner circle about the centre whose lower half is solid black. Labels read on the block:

- V (top, outside the circle) and K (bottom, outside the circle)
- H (left, outside the circle) and R (right, outside the circle)
- A (on the vertical, above the inner circle)
- B (left), C (centre, just above the horizontal), E (right), along the inner circle's horizontal diameter
- N (on the vertical, below the black half of the inner circle)

[Margin: Horizon Rectus, & obliquus. — The right and the oblique horizon.]

III. The *right horizon* [Horizon Rectus] is the one that passes through the poles of the world and of the equator, as HCR does if we suppose the poles of the world to be H and R, and the equator to be represented by the line VCK. This horizon makes right angles with the equator, and so those living on it are said to live in a right sphere, whose properties are given below. The *oblique horizon* [Horizon Obliquus] is one that does not pass through the poles of the world, but has one of them raised above itself and visible to the inhabitant, and the other below and hidden; of this we shall speak when we treat of those living in an oblique sphere. See its position in the figure placed on page 1.

[Margin: Proprietates Horizōtis. — Properties of the horizon.]

IV. The chief *properties of the horizon* [Horizontis Proprietates] are these. 1. It makes right angles with the meridian. 2. It divides the upper hemisphere from the lower. 3. It is the limit from which the altitudes of the pole and of the stars are taken. 4. It determines the true rising and setting of the stars, which are said to rise when they ascend above the horizon and to set when they descend below it; but above all the Sun, and therefore. 5. In it are marked, besides the four cardinal points, which are *Septentrio, Meridies, Ortus Occaſuſque Aequinoctialis* [north, south, and the equinoctial rising and setting], four other points, namely the solstitial rising and setting at each solstice. In the figure of Chapter 7 these are RP, CK, if the circle AEBQ in that figure is supposed to be the horizon and the line AB the meridian. The point of north and of south is the one at which the meridian intersects the horizon, as in the same figure B and A. The points of equinoctial rising and setting are those at which the equator intersects the horizon, as there Q and E; and lastly the points of solstitial rising and setting are those at which the tropics intersect the horizon. 6. It determines the stay of the stars above and below it; this stay, if it is of the Sun and above, is called the artificial day; if below, the artificial night. 7. It is the circle in which the ortive and occasive amplitude of the stars is measured. This amplitude is as great as the arc of the horizon intercepted by its points at which stars can rise or set, according to their different declination and latitude; half of it is the arc of the horizon between the said points and the points at which the equator intersects it. 8. It is the circle in which are marked the regions from

which the naming of the winds is taken. 9. It shows with which degree of the ecliptic any star rises or sets, and which degree of the equator ascends or descends with a given point of the ecliptic or a star, rightly in a right sphere and obliquely in an oblique one, if that point of the ecliptic or the star is placed on the horizon according to the appropriate altitude of the pole. In this way it determines the right or oblique ascensions and descensions.

[Margin: Azimutha, & Almuncatarath. — Azimuths and almucantars.]

10. It is the circle in which *azimuths* [Azimutha] are taken; these are nothing other than arcs of the horizon intercepted between the meridian and another vertical circle in which the star is located. 11. It is the circle with respect to which the *almucantars* [Almuncatarath] are taken, namely the parallels of the horizon passing through the stars according to their different altitudes. 12. It is the plane with reference to which craftsmen determine the sensible horizon, as being parallel to the rational horizon, when they true floors to the level.

DE HORIZONTE SENSIBILI.

On the sensible horizon.

[Margin: Horizon Senſibilis. — The sensible horizon.]

V. The *sensible horizon* [Horizon Senſibilis], or physical, or artificial, is a non-great circle of the sphere, parallel to the rational horizon, which divides the segment of the sphere visible to the inhabitant from the invisible one. It is called artificial because craftsmen use it in levelling buildings, waters and instruments that are to be set perpendicular to the horizon or so as to stand equidistant from it, although by means of this horizon reference is also had to the rational horizon. In the following figure, then, let C be the centre of the Earth and of the world; FAG the globe of the Earth; HVRK the heaven or the celestial meridian; A an inhabitant on the surface of the terrestrial globe, whose zenith is V and nadir K, and whose vertical line is VAK; and HCR the rational horizon, drawn at right angles to that line. Let the straight line SAP be drawn parallel to HCR and tangent to the Earth at A. It will represent the sensible horizon of the inhabitant A, because it divides the visible segment of the heaven SVP from the remaining invisible one SKP.

[Margin: Diſcrimen Rationalis, & Senſibilis Horizōtis. — The difference between the rational and the sensible horizon.]

VI. The sensible horizon therefore differs from the rational. 1. Because it is a non-great circle. 2. Because it does not divide the sphere into two hemispheres or equal segments, but into two unequal segments, of which the upper, SVP, is smaller and the lower, SKP, larger. 3. Because all the other properties that it shares with the rational horizon it has only as regards appearance, except the first: for it makes right angles with the meridian strictly. But altitudes, risings and settings and their amplitudes, days and nights, ascensions and descensions, azimuths and almucantars, when taken from this horizon or in it, are called

apparent. For example, if HVRK is imagined as a great circle of altitude, and the Sun rises for the eye at A at the point R of the rational horizon, it nevertheless does not of itself, setting aside the refractions of rays, rise visibly for that eye, since the eye at A cannot see what lies below the horizontal line SAP if it is in no way raised above the Earth. But when the Sun has reached P it can appear and rise sensibly for the eye at A. Conversely, when it sets sensibly at the point S, it has nevertheless not yet truly set with respect to the rational horizon, until it descends below the point H.

Diagram. Woodcut inset at the right of the right column: a large circle with a vertical and a horizontal diameter and a smaller circle about the centre; a horizontal line through the top of the smaller circle runs to the large circle on both sides, a shorter horizontal line lies below it within the smaller circle, and two lines from a point on the vertical above the smaller circle pass the smaller circle on either side to the large circle at lower left and lower right, where a horizontal line joins them. Labels read on the block:

- V (top, outside the circle) and K (bottom, outside the circle)
- B and A (on the vertical, B above A)
- S (left, outside the circle) and P (right, outside the circle), at the ends of the upper horizontal
- F (left) and G (right), at the ends of the shorter horizontal
- H (left, outside the circle) and R (right, outside the circle), at the ends of the horizontal diameter
- C (below the centre of the horizontal diameter)
- M (lower left, outside the circle) and N (lower right, outside the circle)

[Margin: Proprietates Senſibilis Horizōtis. — Properties of the sensible horizon.]

VII. The specific properties of this horizon are these. 1. As I said, it separates the visible and smaller segment of the sphere from the larger and invisible one. 2. It determines the invisible portion of the upper hemisphere of the heaven, whose measure is the arc PR or HS, subtended by the Earth's semidiameter CA; so that the eye A sees almost the whole upper hemisphere, namely SVP, except of course the small part HS or PR, which is the smaller the greater the distance CR of the heaven from the Earth's centre C. 3. It is the limit of horizontal parallaxes and refractions. 4. It is the limit from which winds truly reach the inhabitant with a perceptible blast; for they are not judged able to reach him from the rational horizon. 5. It is the plane to which craftsmen directly align their levels and plumb lines.

SCHOLIA.

[Margin: An cuilibet ſuus ſit Horizon. — Whether each person has his own horizon.]

I. The question is often asked whether every inhabitant has his own horizon, distinct from the horizon of another person living on the surface of the Earth.

There is no doubt that he has, if astronomical rigour is kept, since to each person there corresponds in the heaven his own distinct vertical point or zenith. Physically, however, those people have the same horizon for whom the same point of the heaven appears to hang perpendicularly above the head, as when some fixed star appears to many people to be at the vertex of each. For its distance from the vertex of another inhabitant cannot be noted as one minute unless he moves away by about one Italian mile, etc.

[Margin: Horizon oculi à Terra eleuati quis? — What is the horizon of an eye raised above the Earth?]

II. I have not found it examined what the sensible horizon is of an eye or of an inhabitant raised above the Earth, as when the eye climbs from A to the top of a mountain B. For if you say that its horizon is SAP, or another line parallel to it and passing through B, it will not have the principal properties of the physical horizon: it does not cut off from the hemisphere the visible part from the invisible, since an eye so raised can see a large part of the heaven below that line, and indeed sometimes below the rational horizon. Let the straight visual lines BGN on one side and BFM on the other be drawn from the eye B, touching the Earth at F and G: the eye will then see more than a hemisphere, namely the portion MVN, and a star can rise for it at N before reaching the point R of the rational horizon. But if you say that it is the straight line FG, parallel to the rational horizon and drawn from contact to contact of the visual line touching the Earth, because such a horizon divides the smaller and visible segment of the terrestrial sphere, namely FAG, from the larger and unseen one, then this will be a horizon only with respect to the terrestrial sphere. If you say that the physical horizon is the lines BM and BN, or the space enclosed by them all round, it does indeed divide the part of the heaven visible to the eye B, which is MVN, from the invisible MKN, but it is not a circle described from the vertex V as from a pole. It remains, therefore, that it be the circle marked by the straight line MN. Although in the preceding figure this line touches the Earth, that is not necessary: it can cut the Earth, or neither cut nor touch it; and it can also coincide by accident with the astronomical or rational horizon HCR, as the height of the eye AB may require. It is of this horizon, then, with respect to the heaven, that Maurolico must be understood in the *Cosmographic Dialogues*, p. 36, when he says: "Indeed it will be able to view even more than a hemisphere, if it is set in so elevated a place." On the Earth, however, it will be the straight line FG, parallel to it, because this cuts off the visible segment FAG.

[Margin: Diſtantia viſus quāta? — How great is the distance of sight?]

III. One can ask here how great the distance of sight is of an eye raised above the Earth. But the solution of this question depends not only on the eye's height AB, but also on the Earth's semidiameter CA, on whose size depend the arcs AF and AG, which take in the space of the Earth visible from the eye B. Meanwhile let it suffice to know that if the eye B is 6 feet high, which is about

the stature of a man, the arc AF does not reach four Italian miles. The rest I shall say in Book 2, Chapter 10.

[Margin: Portio Cæleſtis Hemiſphærij latens. — The hidden portion of the celestial hemisphere.]

IV. It can likewise be asked how great the portion of the celestial hemisphere is that is hidden from the eye A, namely the arc PR or SH; and likewise how great the portion is that the eye raised at B sees beyond the hemisphere. But both depend on the distance of the heaven from the centre of the Earth, which is CR. Meanwhile let it suffice to know that the arc PR is as great as the horizontal parallax of the star to which the heaven in question belongs. Both will therefore be treated more fully in the Optical Book, Section 1, where parallaxes are discussed; or consult the tables of the horizontal parallax of the Sun, the Moon and the fixed stars in Books 3, 4 and 6.

CAPVT IX.

De Meridiano Circulo.

Chapter IX. On the meridian circle.

[Margin: Definitio Meridiani — Definition of the meridian]

I. The MERIDIAN circle, in Greek [Greek: μεσημβρινὸς (mesēmbrinos, "of midday")], for Ptolemy the circle of midday, or the circle that runs through the middle of the heaven, is a great circle of the sphere passing through the poles of the world and the vertex and lowest point of the inhabitant, and its poles are at the horizon's points of equinoctial rising and setting. In the figure of Chapter 7 such a circle is AEBQ, if the horizon there is AGB, the poles of the world A and B, and so the zenith E and the nadir Q. It is called the meridian because, when the centre of the Sun reaches it by the motion of the primum mobile, it becomes midday for all who are under that circle, if the Sun is above the horizon, just as it becomes midnight if the Sun is below.

[Margin: Meridiani proprietates. — Properties of the meridian.]

II. The properties and functions of the meridian are these. 1. It cuts the equator and the horizon in half and orthogonally, that is, at right angles, by property 11 of Chapter 7, since it passes through the poles of both and is a great circle. 2. It divides the sphere into an eastern and a western hemisphere; signs or stars placed in the eastern are said to ascend, and those in the western to descend, as regards the motion of the primum mobile. 3. It divides equally and in half the diurnal arc into two semidiurnal arcs and the nocturnal arc into two seminocturnal arcs; on this depends the length of the time before noon and after noon, reckoned from rising and setting. 4. It measures the greatest altitude of any star that it can have on any given horizon on a given determinate day; for this altitude is as great as the arc of the meridian between the horizon and the star's centre, not greater than a quadrant. 5. It makes midday, when the Sun's centre has reached the meridian altitude. 6. It measures the altitude of the pole in an oblique or a parallel sphere (for in a right sphere the pole is not

raised at all); for the altitude of the pole is as great as the arc of the meridian between the horizon and the visible pole of the world or of the equator. 7. By cutting the equator in half it divides the natural day into two equal parts, and so into twelve hours before noon and twelve after. 8. It is equivalent to the horizon of the right sphere, and therefore determines right ascensions, even for an oblique horizon or for those living in an oblique sphere; for the same point of the equator that rises or sets together with some point of the ecliptic in a right sphere crosses the meridian together with that point in an oblique sphere. And so astronomers, to avoid the variation of oblique ascensions, begin the natural day from noon. 9. It is therefore the limit from which astronomers count the hours and moments of the natural day, because the stars stand in the same relation to the equator on the meridian, but not on the horizon, as we shall say when we treat of the inequality of natural days. 10. It determines the beginning of geographic longitude, and together with other meridians the difference of longitude between any two places on the Earth.

SCHOLIA.

[Margin: Quot sint Meridiani — How many meridians there are]

I. The meridians worth considering in the sphere are far fewer in number than the horizons. For every inhabitant and every point of the sphere has its own horizon, but not everyone has his own meridian: many live under the same meridian, from one pole to the other. And although as many meridians could be drawn on geographic globes or maps as there are degrees of the equator, and indeed as many as there are minutes, they are usually drawn only as 24, taking in 15° of the equator each, or the time of one hour; or 36, taking in 10° each; or 72, taking in 5° each. The rest on these matters is given below, when we treat of geographic longitude and latitude.

[Margin: Lauretani Templi B. Virg. Situs. — The site of the Temple of the Blessed Virgin at Loreto.]

II. Biancani, *Sphaera*, Book 1, Chapter 4, adds that both the Temple of Solomon in former times, and now the House of the MOST BLESSED VIRGIN at Loreto, were divinely so placed that two opposite faces of each stood toward the equinoctial rising and setting, and the remaining two in the plane of the meridian circle, one to the south and the other to the north.

But because the meridian line and the altitude of the pole belong to the meridian, I have decided to speak of each separately, because of the universal and outstanding use of both in cosmography; but of the altitude of the pole and of the equator I shall speak in Chapter 12, after the exposition of the equator.

CAPVT X.

De inuentione Lineæ Meridianæ, & Declinationis Magneticæ.

Chapter X. On finding the meridian line and the magnetic declination.

From the very many methods that we shall set out, either in the Geographical Book or in the Book of General Problems, we have selected this one as the simplest and clearest for beginners.

I. On some white plane, exactly parallel to the horizon (which is done with a chorobates [Chorobatem], or with a plumb line and an exact square, or with a level), taking C as centre, describe several circles, at least three, about one finger's breadth apart. The smallest of them should have a semidiameter CD large enough to be exceeded by the noon shadow of the style to be used, which you can determine by trial on the previous day or by estimate. It is best to mark these circles not in ink, but only with a dry compass or in yellow colour. Then, at the same centre C, erect the gnomon CG, or style, normally, that is, at right angles to the horizontal plane on every side, which will be done with the help of a very exact square. With these preparations made, about two hours before noon, as roughly judged, when the Sun is beyond the hazard of sensible refractions, or very far from the horizon, and while the weather of the day stays perfectly clear, observe the moment at which the tip of the morning shadow of the style reaches the periphery of one of the described circles, and then with the help of a needle mark the point on that periphery that is indicated by the tip of the shadow. As in the preceding figure, with the style CG set up and the Sun at K, shining through the tip of the gnomon G to B, if the tip of the decreasing shadow has reached B, let the point B be marked. You will mark this more finely and clearly if the style is not longer than half a Roman foot and is not so sharply pointed that the tip of the shadow vanishes, but is very slightly blunted. After noon, too, returning to the observation in good time, observe the moment at which the afternoon shadow, as it grows, reaches the periphery of the same circle on which you marked the point before noon, and then with the needle mark another point on the same periphery; as in the figure given, when the Sun is at P and the shadow CA has reached A, let the point A be marked.

Diagram. Woodcut inset at the right of the left column: three concentric circles with a dotted vertical line through the centre; a small rayed sun stands outside the circles at upper left and another at upper right, a dotted line runs from each through a point on the vertical above the centre toward the opposite lower side, and heavy solid arms run from the centre to that upper point and to two points at lower left and lower right on the circles. Labels read on the block:

- K (upper left, beside the left sun) and P (upper right, beside the right sun)
- M (top, on the vertical, between the suns)
- G (on the vertical, at the top of the upper arm)
- C (at the centre, below the junction of the arms)
- A (lower left, at the end of the left arm) and B (lower right, at the end of the right arm)
- D (on the vertical, below C, on the innermost circle)
- S (bottom, on the vertical, outside the circles)

With these points marked, divide the arc ADB in half at D, by the corollaries to 9 of Book 1 of Euclid's *Elements*; and through the point of division D and the centre of the style C draw as straight a line as you can, either with a ruler or with a silk thread stretched and coated with colour, and let it be SM. This will be the meridian line, and it lies in the very plane of the meridian circle.

[Margin: Declinationis Magneticæ obſeruatio. — Observation of the magnetic declination.]

II. Suppose that before or afterward you divide one of those circles, or another described from the centre C, into degrees, and some of the degrees nearer the line into single minutes or into tens of minutes, and that at the centre C you place a style supporting a magnetic needle, half of which is equal to the semidiameter of the circle divided into degrees. The needle itself either finally comes to rest over the meridian line, and will show that it has no declination, or, with the end that faces north, it will decline toward the west or the east, and you will note how many degrees and minutes it declines. Mariners express declination toward the west by the verb *Maestrizzo*, from the wind called *Magister*, and toward the east by the verb *Græcisso*, from the Greek wind. But to obtain a proper declination, the magnetic needle must be very freely turning, very far from iron objects that could draw or incline it toward themselves, and very well protected from every breath of air and from any shaking of the ground or floor.

SCHOLIA.

[Margin: Probatio 1. lineæ Meridianæ. — Proof 1 of the meridian line.]

I. If before and after noon you mark several points on several circles as the tip of the shadow reaches all of them, and if, when the arc they intercept is divided in half, the same meridian line comes out from all the divisions, you will have strong evidence of a true meridian line.

[Margin: Solſtitio exactior Meridiana linea notatur. — The meridian line is marked more exactly at the solstice.]

II. If you seek the meridian line in the manner described above on the days of the solstice, it will, other things being equal, be more exact and better suited to astronomical work, because on those days the Sun over one whole day hardly varies its declination perceptibly, and therefore the morning shadow is, as far as the senses can tell, just as long as the afternoon one. But on days distant from the solstice, the Sun changes its declination within the same day and the hours of the day, and therefore the morning shadow is longer than the afternoon one as long as the Sun is in the ascending signs, that is, from the beginning of Capricorn through Aries to the beginning of Cancer; for in the descending signs it is shorter.

[Margin: Et Solſtitio probatur. — And it is proved at the solstice.]

III. If on those same solstitial days, or on others, you find by means of an exact azimuthal instrument, at an equal eastern and western azimuth, a morning

altitude of the Sun equal to the afternoon one; or if you count a time before noon equal to the time after noon, and find at the beginning of the former and the end of the latter equal altitudes of the Sun's centre or of a fixed star, you will be able both to draw a new meridian line and to test and correct one already drawn. But you will do this more surely on any clear night, if you obtain for a fixed star an equal altitude on either side together with an equal azimuth, or an equal interval of time.

[Margin: Plures Meridianæ ex vna tranſcriptæ. — Several meridian lines transcribed from one.]

IV. Once one meridian line has been found, you can mark several others on nearby horizontal planes. For with styles set up perpendicularly, as soon as the shadow of the style reaches the meridian line first found, let an assistant be at hand to mark a point at the tips of the shadows that the other styles cast on the horizontal plane; the line drawn through that point and through the centre of its own style will be a meridian line. On walls perpendicular to the horizon, however, it will be enough to fix a style in any way, to mark a point at the tip of the shadow at the moment when the tip of the shadow reaches the first, root or prototype meridian line, and to draw a straight line perpendicularly through that point: this too will be a meridian line. In either case, instead of a style one can use the thread of a plumb line once it is at rest, and at the moment of noon mark two points in its shadow and draw a straight line through them.

CAPVT XI.

De Aequatore, & Motu Primi Mobilis.

Chapter XI. On the equator and the motion of the primum mobile.

[Margin: Aequatoris Nomina. — Names of the equator.]

I. The EQUATOR is called in Greek [Greek: ἰσημερινός (isēmerinos, "of equal day")], in Latin *Aequidialis*, although the name *Aequinoctialis* has prevailed, because when the Sun is placed on it the days equal the nights over the whole world; while for those living under the equator, every day is equal to the night, in whatever point of the ecliptic the Sun stands. The ancients also called it the *Cingulum Mundi* [Belt of the World], and Ptolemy the circle of the *Aequationis diei* [equalising of the day]. Now the equator is a great circle of the sphere whose poles are the same as the poles of the world and of the daily revolution, or of the primum mobile: as in the figure of Chapter 7 the circle EGQ, described from the poles A and B. One of these is called *Australis* [Southern], from Auster, which blows from there, and *Antarcticus* [Antarctic], that is, set opposite the Arctic, and *Meridionalis* [Meridional], because from there the noon shadow is cast toward the opposite region. The other is called *Borealis* [Boreal], from Boreas, which blows from there, and *Arcticus* [Arctic], from the Bears, the constellations placed near it, for the Bear in Greek is called [Greek: ἄρκτος (arktos, "bear")]; and *Septentrionalis* [Septentrional], from the seven brighter stars of Ursa Major, which are called *Triones*, either from their wearing down

(*terendo*) the parts near the pole, or from the fact that [Greek: τρίων (triōn, "ox", as the page itself says)] means an ox, while the constellation of the Bear is like a wagon drawn round the pole at a slow, ox-like pace. No one however sees both poles at once from the surface of the Earth, unless he is raised above it and stands on the equator itself; most people see a single pole, as in the lines of Virgil, Book 1 of the *Georgics*:

This pole stands ever high above us; but that one Black Styx and the deep-dwelling shades see beneath their feet.

[Margin: Proprietates Aequatoris. — Properties of the equator.]

II. These are the properties and functions of the equator. (1) It cuts any meridian at right angles, and not merely in two equal parts; and in the right sphere it cuts the horizon at right angles, because it passes through their poles. (2) It is the measure of the daily motion, or of the primum mobile, which is common to absolutely all the stars, at least in appearance. For the constant agreement of the ages has observed that the wandering and the fixed stars alike are carried round in the space of 24^{h} from east toward west until they return to the east, and that with respect to this motion they complete equal spaces, or equal arcs, in equal times, whether on the great circle [circulus maximus] which for that reason they have also called the equator, or on a circle parallel to the equator; and so in any hour 15° of the equator or of its parallels cross the meridian or rise above the horizon, in 4^{m} of an hour one degree crosses or rises, and in one minute of an hour a quarter of a degree, namely 15′ of the equator or of a parallel. On this principle a small table has been drawn up that converts degrees of the equator into hours and fractions of hours, and conversely hours into degrees, etc., which we shall give at the end of the work. (3) The Sun, moved by this motion, produces the natural day [dies Naturalis], which the Greeks call [Greek: νυκτημέριον (nyktēmerinon, "of a night and a day")], that is, composed of a night and an artificial day [dies Artificialis]; for one complete revolution of the Sun on the equator, or on a parallel of the equator, is itself the natural or composite day. (4) It makes the artificial day equal to the night: always for those who live on the equator itself, but for everyone else only twice a year, namely on the day the Sun enters Aries, which in the Julian calendar, as reformed, is about March 21, when the vernal equinox occurs; and on the day it enters Libra, very nearly September 23, when the autumnal equinox occurs. The reason is that there, or then, while the Sun is carried from rising to setting, 180° of the equator rise, and to these twelve hours correspond. (5) By its common intersection with the horizon it marks the two cardinal points of equinoctial rising and setting. (6) It divides the sphere into two hemispheres, northern and southern; and it distinguishes northern declinations from southern, which are reckoned from it as from a boundary, although they are counted on the meridian: for the declination of a star, or of a celestial point, from the equator is as great as the arc of the meridian between the star's centre and the equator. (7) It is the measure, indeed also the subject, of right and oblique ascensions, since these are nothing other than arcs of the

equator rising together with arcs of the ecliptic, or with parallels of the ecliptic, on which stars may lie, in the right sphere or in the oblique, counted from the vernal intersection of the equator with the ecliptic, or from the beginning of Aries. (8) It is the measure of geographical longitude, which is as great as the arc of the equator intercepted between the first of the meridians and the meridian of the other place. (9) It works together with the ecliptic to determine the remaining artificial days of the year, which are as long as the number of degrees of the equator that rise above the horizon during the time the Sun is carried from rising to setting.

SCHOLIA.

[Margin: Notatio lineæ Aequinoctialis. — Marking the equinoctial line.]

I. On a horizontal plane the equinoctial line cuts the meridian line at right angles, and it is traced by the tip of a style's shadow on the equinoctial days; for on the days when the equinoxes occur, the tip of that shadow travels, to the senses, along one and the same straight line.

[Margin: Diei Solaris, & diei Primi Mobilis differentia. — The difference between the solar day and the day of the primum mobile.]

II. One day of the primum mobile, if it is not referred to the Sun's time — such is the revolution of a fixed star from the meridian back to the same meridian — is exactly 24^{h}. But the solar day is 24^{h} of the primum mobile and about 4^{m} besides, because in that much time one degree of the equator passes through the meridian, while the Sun, by its own motion toward the east, completes very nearly one degree in one day. So, when the point of the equator at which the Sun stood at yesterday's noon has revolved to the same meridian, today's noon will not occur at that same point of the equator, but at the end of one degree which, beyond the 360 degrees, must pass the meridian for the Sun to stand on the same meridian on which it stood yesterday. From this arise two tables, one for the day of the primum mobile, the other for the day of the Sun; see them at the end of the work.

CAPVT XII.

De Altitudine Poli, & Aequatoris Inuenienda.

Here too, out of the very many ways of finding the altitude of the pole [Altitudo Poli] and of the equator which we shall give either in the Geographical book or in the book of General Problems, let us choose for beginners two or three, the most evident of all. The first is by the meridian altitudes of a circumpolar star; the second by the meridian altitude of the Sun, taken with instruments; the third by the same altitude, found from the shadow of a gnomon.

[Margin: Poli Altitudo ex ſtella circumpolari. — The altitude of the pole from a circumpolar star.]

I. For the first, let the horizon be HR, the meridian HZRN, the zenith Z, the nadir N, the vertical line ZN, the equator EQ, the axis of the equator, or

of the world, AB, and the pole of the equator, which is also the pole of the world, northern at B and southern at A. On a night longer than 12^h, then, both meridian altitudes must be taken of the star nearest your pole, of the kind our people call the Polar star, though it is better called Circumpolar; such in this age is Cynosura, the last in the tail of Ursa Minor. Such nights, in this age, are those toward the end of December and the beginning of January; for in the evening as night begins, and the next morning as night ends, both meridian altitudes of that star can be observed without hindrance from twilight. So, with a quadrant or an accurate geometric square set up on the meridian line, take the meridian altitude of that star, both the greatest, when the star is at C, and the least, when it is at P; and add half the difference between the two altitudes to the least altitude, for the sum from that addition will be the very altitude of the pole on your horizon. For example, let the star's least altitude RP be exactly 40°, and the greatest RC 47°. The difference, arc CP, will then be 7°, and half the difference 3° 30′. If you add this to the least altitude of 40°, the result is the altitude of the north pole B, namely arc RB, 43° 30′; and its complement to the quadrant RZ will be arc BZ, 46° 30′.

Diagram. Woodcut inset at the right of the right column: a circle crossed by four diameters through the centre, with a star drawn on the circumference at C and at P. Labels read on the block:

- Z (top) and N (bottom)
- H (left) and R (right)
- E (upper left) and Q (lower right)
- B (upper right) and A (lower left)
- C (star, upper right, between Z and B)
- P (star, right, between B and R)

Labels not read: none. All ten labels are cited in the prose of this page.

Once the altitude of the pole is obtained, you will easily have the altitude of the equator, namely arc HE, since it is equal to the complement of the altitude of the pole, or the remainder to 90°. So in the example given, HE will be 46° 30′, while the distance of the equator from the vertex, namely arc EZ, is always equal to the altitude of the pole. You will learn this plainly on an armillary sphere: for as far as you raise the visible pole from the horizon, so far you will see the equator move away from the zenith Z, counting the degrees on the meridian.

[Margin: Poli Altitudo ex Declinatione Solis. — The altitude of the pole from the Sun's declination.]

[Margin: Tych. To. 1. pag. 79. — Tycho, vol. 1, p. 79.]

II. For the second method, let the meridian and the horizon be as above, but let the equator be AB, its axis EQ, the north pole of the world E and the south pole Q. On a clear day observe the meridian altitude of the Sun with a quadrant or an astronomical square, or with parallactic rulers, or with an astronomical ring, and you will have the seen, or apparent, altitude of the Sun. Convert this into the true altitude by adding the parallax proper to that day

and subtracting the refraction, if it is sensible, consulting the tables of solar parallaxes and refractions, either Tycho's or our own at the end of the work; and thus you will have the true meridian altitude of the Sun. Then from an ephemeris, or from astronomical tables, gather the Sun's place in the zodiac for noon of the day on which the observation was made; and with the Sun's place look up the Sun's declination in a table of solar declinations — such a table is found everywhere, but the most exact is in Clavius, *Sphaera*, from p. 264 — and if the declination is southern, add it to the true meridian altitude of the Sun; if northern, subtract it; and you will have the altitude of the equator on your horizon, whose complement to 90° will be the altitude of the pole. We too shall give an accurate table of declination at the end of the work.

For example, let the Sun be at P, its true and corrected altitude the arc of the meridian RP, 40°, and its southern declination the arc PB, 3° 30′; this, added to the altitude, makes arc RB, 43° 30′, and that therefore will be the altitude of the equator. Its complement to 99° [recte: 90°] will be the distance of the equator from the vertex, namely arc BZ, 46° 30′, and the altitude of the pole will be just as great. But if the declination were CB and the altitude RC, then with CB taken away, RB would remain, the altitude of the equator.

Diagram. Woodcut inset at the right of the left column, the same construction as the figure on the preceding page: a circle crossed by four diameters through the centre, with a star drawn on the circumference at C and at P. Labels read on the block:

- Z (top) and N (bottom)
- H (left) and R (right)
- E (upper left) and Q (lower right)
- B (upper right) and A (lower left)
- C (star, upper right, between Z and B)
- P (star, right, between B and R)

Labels not read: none. E, H, A, N and Q are not cited in the example beside the figure; E, Q and A are cited at the head of this method on the preceding page.

[Margin: Solis altitudo ex vmbra Meridiana. — The altitude of the Sun from the meridian shadow.]

III. If you want to observe the Sun's meridian altitude by the meridian shadow of a gnomon, the height of the style and the length of the meridian shadow must be known in the smallest possible parts, and in parts of the same kind, say in hundredths of one inch [vncia] of the Roman foot. Then, by trigonometry, one must find in the right-angled rectilinear triangle the angle opposite the gnomon. This is done most quickly by logarithms, if you add together the logarithm of the gnomon, or style, and the residual logarithm [Reſiduum Logarithmum] of the shadow; for the sum will give the mesologarithm [Meſologarithmum] of the desired angle, and that angle will be the seen altitude of the Sun's upper limb. If you subtract from it the Sun's apparent semidiameter, there will remain the altitude of the Sun, that is, of its centre, as apparent; and this, corrected by

adding the parallax and subtracting the refraction, will give the true altitude of the Sun, with which, together with the Sun's declination, you will obtain the altitude of the equator and of the pole, as above in the second method.

SCHOLIA.

[Margin: Stellæ idoneæ ad Poli altitud. Capiendam. — Stars suitable for taking the altitude of the pole.]

I. In the first method, other stars nearer the pole may be used, though somewhat larger ones, such as the bright star in the shoulder of Ursa Minor; and among the southern stars those of the CROSS, called *il Crozier* [?]; and of these, the ones nearer the southern pole are those in the ankle and in the left knee of the Centaur — provided that at their meridian altitude they are not near the horizon and do not undergo sensible refraction, or at least that it is established how much refraction must be subtracted from the altitude to obtain the true altitude.

II. In the second and third methods, if the true altitude of the Sun is taken at the time of the equinox, there will be no need to look up its place or its declination, for the Sun's place will be the beginning of Aries or of Libra, and its declination nil. The altitude of the equator will thus be as great as the Sun's true altitude, provided the equinox took place at the very moment of noon with respect to the meridian on which the Sun's altitude was observed. Otherwise, however many hours the equinox preceded or followed, the declination will be that many minutes of arc, and one could err by that many minutes in the altitude of the equator, and of the pole to be deduced from it.

[Margin: Altitudines Poli per Vmbras apud Priſcos fallaces. — Altitudes of the pole found by shadows among the ancients are deceptive.]

III. It was customary for the old practitioners to seek the altitudes of the pole and of the equator by the equinoctial shadows of gnomons. So in Vitruvius, book 9, chapter 8, there is the celebrated observed equinoctial shadow, in ratio to the gnomon, at Rome as 8 to 9, at Alexandria as 3 to 5, at Athens as 3 to 4, and at Rhodes as 5 to 7; and in Pliny the Elder, book 2, chapter 72, at Rome as 8 to 9 and at Ancona as 34 to 35; and in Strabo, book 2, at Carthage as 7 to 11. But the altitudes of the pole obtained this way were uncertain among them, for three reasons. First, because they did not subtract the Sun's apparent semidiameter from the altitude of the Sun's upper edge, just as if the ray passing over the tip of the style and bounding the shadow came from the centre of the Sun and not from its edges. Second, because at the time of observation they believed it was the equinox, which nevertheless had sometimes already preceded by many hours or was yet to follow. Third, because they sometimes took the day of the equinox in the civil and not the astronomical sense. There is the further point that if the style is small, an error in the parts is easily committed, and yet it disturbs the true altitude of the Sun not a little; while if it is longer, the tip of the shadow can scarcely be distinguished because of the penumbra. For

that reason I would believe there is an error in Clavius's *Sphaera*, p. 279, where he calls this way of taking the Sun's altitude more difficult and more certain [difficiliorem, & certiorem]; for I think *incertiorem* ("less certain") should be restored. But more on these things in the Geographical book.

IV. If in the third method the reversed shadow is used, namely that of a gnomon fixed into a wall perpendicular to the horizon, then the angle opposite the gnomon, subtracted from 90°, will give the seen altitude, but of the Sun's lower limb. So the Sun's apparent semidiameter must be added to it to obtain the seen altitude of the Sun's centre.

[Margin: Polaris ſtellæ acceſſus ad Polum quantus. — How far the pole star approaches the pole.]

V. If you have just one meridian altitude of the pole star, add to the least, or subtract from the greatest, this star's distance from the pole, which at the start of this year 1642 is 2° 37′ 30″, and which each year in this century and the next will diminish by 20″, as I have observed, following Tycho, by comparing meridian altitudes of various years taken by us and by others.

CAPVT XIII.

De Latitudine, & Longitudine Geographica.

What was said in Chapter 12 about the altitude of the pole, in connection with the meridian, and in Chapter 11 about the functions of the equator, gives rise to a very timely explanation of the geographical latitude and longitude of places. Without these, places can neither be marked exactly on a globe or on geographical maps, nor, once marked, be found at once.

[Margin: Latitudo Geographica quid? — What is geographical latitude?]

I. *Geographical latitude* is the distance from the equator of a place situated on the surface of the terrestrial globe, measured on that place's meridian circle. So it is exactly as great as the distance of the vertex, or zenith, from the equator; and this is as great as the altitude of the pole, from what was said in Chapter 12. Therefore geographical latitude is known at once if the altitude of the pole is known. It is called *latitude* because the part of the Earth known both formerly and now is narrower from one pole of the world to the other than from west toward east; and custom has established that in a surface bounded by a line other than a circular one, the narrower part is called the latitude [Latitudo]. Next, among astronomers the latitude of the stars is their distance from the ecliptic toward one or other of its poles; in imitation of this, then, the distance of places on Earth from the equator toward one or other pole of the world has been called latitude, although it more closely resembles the declination of the stars, which is reckoned from the celestial equator.

[Margin: Longitudo Geographica quid? — What is geographical longitude?]

II. *Geographical longitude* is the arc of the terrestrial equator intercepted between the meridian of the place and that other meridian, the first of them, which has been adopted and accepted by geographers as the beginning of all

the meridians. It is called *longitude* because the part of the Earth known along the equator and its parallels, from west toward east and conversely, is much greater than what is known from pole to pole of the world; and because the astronomical longitude of the stars is reckoned from west toward east, although it is computed on the ecliptic from the beginning of Aries; and so geographical longitude more closely resembles the right ascension of stars and signs, which is computed on the celestial equator. The first of all the meridians is the one that passes through the Fortunate Islands, and from there Ptolemy, prince of geographers, and very many others have been accustomed to count longitude toward the east, although others count from elsewhere.

III. The *difference of geographical longitude* between two places on Earth is the arc of the equator intercepted between the meridian circles of the two places. The *difference of latitude* is the difference in the altitude of the pole, whether the places lie on the same meridian or on different ones — that is, in equivalence of measure; for formally it is the difference in distance from the equator, reckoned on the meridian of each of the places.

[Margin: Modus prior Longitud. Geograph. inquirendæ. — The first way of finding geographical longitude.]

IV. The ways of finding and determining geographical longitude, or its difference, are very many, and, God willing, we shall give them in the Geographical book. They reduce, however, to two heads. The first is that of the methods which use the latitude of two places and the road distance between them, measured on a great circle of the Earth. These cannot be carried out without trigonometry, or the analysis of triangles, and without certain knowledge of the miles contained in one degree of a great circle of the Earth; so they will be better given after the Trigonometric book, in Book 4 of Volume 2, which will be the Geographical one.

[Margin: Modus poſterior. — The second way.]

The second head is that of celestial phenomena which happen and are observed at the same moment of time in two places on Earth, while their time is observed as well, down to minutes of an hour. For the difference of time, converted into parts of the equator by the method indicated in Chapter 11, property 2, and by the table named there, will show the difference of longitude between those places. The place to which the same phenomenon has appeared more hours and minutes after noon or midnight, or after sunrise or sunset, will be the more easterly. But eclipses of the Moon hold the chief place in this business.

[Margin: Exemplum 1 per Eclipſes. — Example 1, by eclipses.]

To illustrate this, in the following figure let the horizon be HR, the celestial equator HVRD, and beneath it the terrestrial equator AFB, on which there are three observers at three places A, F and B, who observe the beginning of a lunar eclipse and its time, derived chiefly from the fixed stars. Let the beginning of this eclipse occur at the point of midnight with respect to place F, which is to be the farthest of the Fortunate Islands, and let its meridian be VFD, the Moon

being placed very nearly on that meridian; with respect to this meridian let R be the point of rising and H of setting. But let observer B note the same beginning of the same eclipse at exactly the 3rd hour after midnight. This, converted into parts of the equator, will give arc VN in the sky and FB on Earth, of 45°. So the difference of longitude between places F and B will be 45°. Indeed, if F lies under the first of the meridians, from which longitude is begun, the longitude of place B itself will be 45°, and place B will be more easterly than place F by that many degrees, because R is the point of rising, and 3^h after midnight are more than none.

Diagram. Woodcut inset at the right of the left column: a large circle crossed by four diameters through the centre, with a star drawn on the circumference at each of the eight ends; a small circle about the centre; and three short strokes, each ending in a dot, rising from the small circle toward G, V and N. Labels read on the block:

- V (top) and D (bottom)
- H (left) and R (right)
- G (upper left) and K (lower right)
- N (upper right) and M (lower left)
- A (small circle, left), F (small circle, top), and B (small circle, right)

Labels not read: none. K and M are on the block and not cited in the prose of this page.

[Margin: Exemp. 2. — Example 2.]

Again, let the beginning of the same lunar eclipse occur at V at the 6th hour after sunset, the Sun being already at H; but with respect to place B let it occur at the 9th hour after sunset, the Sun for that place being at G; and at the beginning of the eclipse let the Sun have reached D, where the nadir of place F lies. For the difference of longitude will again be 3^h, namely 45°. What I have said of two places on the equator holds for other places off the equator, whether they lie on the same parallel or on different ones: for similar arcs of the parallels are intercepted between those places, that is, of as many degrees as if they were on the equator; and so the difference of the time at which the same phenomena of the sky appear to them is just as great.

[Margin: Exemp. 3. — Example 3.]

Now let the eclipse occur at place F, under the point V of the sky, at the 6th hour after midnight, but at place A, which lies under G, at the 3rd hour after midnight; and let VFD be the first of the meridians. The difference of longitude will appear to be arc GV, 45°, or 3^h, and place A more westerly. Yet because cosmographers proceed from the beginning of the meridians toward the east, and in our case consider the arc of the equator VRDG, which is the complement of arc GV to 360° and is in our case 315°, or 21^h, they therefore say that place A is more easterly than place F, and has in our case a longitude of 315°. So according to them this limitation would have to be added to the definition of geographical longitude: *Reckoned toward the east*. But on this see the Scholia.

[Margin: Vſus Longit. & Latitud. in Globo Geographico. — The use of longitude and latitude on a geographical globe.]

V. Once the longitude of a place is known, a meridian is drawn through the poles of the world, passing through the point of the equator that lies as many degrees toward the east from the beginning of the meridians as the degrees of the longitude found; and on that same meridian, according to the latitude found, the arc of distance from the equator is taken. In this way one obtains the indivisible and determinate point at which the place is to be marked on a globe or on a geographical map, or at which, if it is already marked, it can be found at once. For instance, if you read in a historian who uses the terms of cosmography that Rome is at a northern latitude of 42° and a longitude of 39°, then, counting 39° on the equator from the Fortunate Islands, if the beginning of the meridians is in them, and on the meridian passing through the end of the 39th degree counting 42°, or taking them with compasses, you will at once find the point at which the navel [vmbilicus] of Rome is or ought to be.

In this way tables of the longitude and latitude of places are compiled; of this kind we shall give at the end of the book one far more certain than those constructed so far, deduced from many eclipses.

SCHOLIA.

[Margin: Latitudo, & Longitudo Orbis olim & nũc cogniti. — The latitude and longitude of the world as known formerly and now.]

I. The known latitude of the world, formerly smaller and later greater, did not exceed, in Pliny the Elder, book 2, chapter 108, and in Ptolemy, book 1 of the *Geography*, chapter 10, 80° 19′, from the shore of the Ethiopian Ocean to the northern extreme beyond the mouths of the Tanais; or, as Ptolemy has it, from Agisymba to Thule. But in our age it is 139°, of which 81 are northern and the remaining 58 southern, for navigation has reached that far: northward by Gulielmo Barensonio Belga [Willem Barentsz], southward by Gulielmo Schouten Hollando [Willem Schouten]. On this matter see again below, Book 2, chapter 9.

The known longitude of the Earth's globe, formerly, in Pliny the Elder, book 2, chapter 108, and book 6, chapter 33, and in Ptolemy, book 1 of the *Geography*, chapter 12, and book 7, chapter 5, did not exceed a semicircle, or 180°. But in our time not a few ships' masters have circumnavigated the whole globe, following the ship *Victoria* of Ferdinandi Magellanici [Fernão de Magalhães]; and from their voyages, with the known intervals of overland journeys added, it comes about that the whole circle of 360° is known. But on this, again, Book 2, chapter 9.

[Margin: Longitudo verſus Occidẽtẽ, numerata. — Longitude counted toward the west.]

II. The longitude of places could be counted toward the east so long as it does not exceed 180°; but if it exceeds that, it would better be counted toward

the west, as it is by certain royal cosmographers, and by name by Ludouico Teisera [Luís Teixeira]. Otherwise a place which is more westerly with respect to the place of the first meridian, and in the western hemisphere, could seem more easterly because of a longitude called eastern, as in the third example of no. IV, place A with respect to place F. But if longitude is counted toward the west when it exceeds 180°, and the complement of the longitude to 360° is taken, as arc FA in the same case, the western longitude will agree with the westernness of the hemisphere in which the place lies.

[Margin: Initium Meridianorũ varium. — The beginning of the meridians varies.]

III. Disagreement among authors in determining the longitude of places does not always arise from some error in road intervals or in celestial observations, from which the difference of time, and from that the difference of longitude, has been taken; often it arises from the starting point of longitude. For some begin longitude from the Fortunate Islands, others from the Azores or the Hesperides, others from Thule, others from the Pillars of Hercules or the Strait of Gades; and among the Fortunate Islands themselves some are more westerly than others. So one must first consult the starting points, and what the place of the first meridian is. But more on this in the Geographical book.

[Margin: Solis, an Lunæ Eclipſes meliores ad Longitud. diff. — Whether eclipses of the Sun or of the Moon are better for the difference of longitude.]

IV. Kepler, in the *Optics* and in the Rudolphine Tables, prefers eclipses of the Sun for determining the difference of geographical longitude, because he thinks their beginnings and ends are observed more clearly than those of lunar eclipses, and that the calculation of the parallaxes is no obstacle, since he asserts that it comes out most exact from his tables. But Tycho, Magini and most others, fearing the perplexity of the parallaxes of the Sun and Moon, prefer lunar eclipses in this practice, and especially the beginnings of total eclipses, or the emersion from the shadow of the Earth.

CAPVT XIV.

De Ecliptica, & Zodiaco: vbi de Motu Secundi Mobilis, atque Obliquitate Eclipticæ.

On the ecliptic and the zodiac: where also on the motion of the second mobile, and on the obliquity of the ecliptic.

[Margin: Ecliptica quid? — What is the ecliptic?]

I. The ECLIPTIC is a great circle whose poles stand as far from the nearer poles of the equator as the Sun's greatest declination from the equator. The Sun's greatest declination occurs at either solstice. It is called the ecliptic because eclipses of the Sun and Moon do not happen unless the luminaries are in the plane of this circle or a little distant from it. Frequently, however, the name "ecliptic" refers rather to the line that is the circumference of this circle than to the circle itself. It is also called the Royal Road [Via Regia], because the Sun, king of the planets, always travels along it with the centre of his body, even

granting that the other planets depart from it in latitude, now to the south, now to the north. Aristotle and Geminus also call it the oblique circle, λοξὸς κύκλος [Greek: loxos kyklos, "oblique circle"], or the circle "that runs through the middle of the signs", from the obliquity it has with respect to the equator and the meridians. You can see the position and configuration of the ecliptic in the figure of Chapter 7: there the line KR, drawn through the middle of the parallels, marks the ecliptic.

[Margin: Zodiaci definitio. — Definition of the zodiac.]

II. The *zodiac* is a celestial band or zone, cut in two by the ecliptic into a northern and a southern part, and bounded by the circumferences of two circles that are not great circles. These circles stand from the ecliptic as far as the greatest latitude of the planets, of those that deviate most from the ecliptic, namely 8° or 10°. It is called the zodiac, and by Ptolemy κύκλος τῶν ζωδίων [Greek: kyklos tōn zōdiōn, "circle of the animals"], that is, *the circle of animals*; and also the Signifer, because it is divided into 12 signs named after the stars, whose configurations, by some likeness, resemble the form of men or of other animals, or even their properties in their influences. For Libra is referred to the claws of Scorpius, which grasp the scales; the Arrow to Sagittarius; and the Urn of Aquarius to Aquarius. The ecliptic and the zodiac are, moreover, frequently used for the same thing.

[Margin: Zodiaci Signa quot, & quæ. — How many signs of the zodiac there are, and which.]

III. The *signs of the zodiac* are twelve. Six of them are northern: they begin at the vernal intersection, that is, at the point at which the ecliptic intersects the equator and at which the vernal equinox occurs, and they end at the autumnal intersection, where the autumnal equinox occurs. The other six are southern: they begin at the autumnal intersection and end at the vernal. Their names, characters and qualities, and their power to stir the humours of animals in respect of predominance, you may see in order and in succession in the following table.

SEX SIGNA BOREALIA. — *The six northern signs.*

♈	♉	♊	♋	♌	♍
Aries	Taurus	Gemini	Cancer	Leo	Virgo
Κριὸς	Ταῦρος	Δίδυμοι	Κάρκινος	Λέων	Πάρθενος
Fiery [Igneum]	Earthy [Terreum]	Airy [Aëreum]	Watery [Aqueum]	Fiery [Igneum]	Earthy [Terreum]
Choleric [Cholericum]	Melancholic [Melancholicū]	Sanguine [Sanguineum]	Phlegmatic [Phlegmaticū]	Choleric [Cholericum]	Melancholic [Melancholicū]

SEX SIGNA AVSTRALIA. — *The six southern signs.*

♎	♏	♐	♑	♒	♓
Libra	Scorpius	Sagittarius	Capricornus	Aquarius	Pisces

♎	♏	♐	♑	♒	♓
Ζύγος	Σκόρπιος	Τοξότης	Αἰγόκερος	Ὑδρόχοος	Ἰχθῦς
Airy	Watery	Fiery	Earthy	Airy	Watery
[Aëreum]	[Aqueum]	[Igneum]	[Terreum]	[Aëreum]	[Aqueum]
Sanguine	Phlegmatic	Choleric	Melancholic	Sanguine	Phlegmatic
[Sanguineum]	[Phlegmaticū]	[Cholericum]	[Melancholicū]	[Sanguineum]	[Phlegmaticū]

To help the memory they are also gathered in the following couplet:

Sunt Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libraq; Scorpius, Arcitenēs, Caper, Amphora, Pisces.

[There are Aries, Taurus, Gemini, Cancer, Leo, Virgo, / and Libra, Scorpius, the Archer, the Goat, the Amphora, Pisces.]

MOTVS PROPRIVS SYDERVM ORIENTEM VERSVS.

The proper motion of the stars toward the east.

[Margin: Eclipticæ origo. — The origin of the ecliptic.]

IV. The reason for introducing the ecliptic and the zodiac into the artificial sphere, and for recognizing them in the natural and celestial sphere, was the proper motion of the stars from west toward east, which astronomers observed to take place in this oblique circle or in circles parallel to it. This motion appears most plainly in the Moon. If the Moon is seen one night on the meridian at the first hour after sunset, then when 24^{h} have passed from then she will not yet have reached the meridian on the following night; about 50^{m} more will be required, because by her proper motion she has become further east. When she reaches the meridian it will be nearly the second hour after sunset; on the third night it will be the second hour with about 40^{m}, and so on, until she appears on the meridian only at the end of the night. What I say of the meridian holds also of the horizon: if today, as the Sun sets, the full Moon rises on the horizon, tomorrow she will not rise as the Sun sets, but about an hour after sunset, and so on, later and later. Moreover, if tonight the Moon was seen in conjunction with some fixed star, on the following night at the same hour she will appear distant from that star toward the east by about 13°, and so she will continually draw away from it. This is a sign that she has moved toward the east by a proper motion, true or apparent.

On the other hand, the Moon appears to become further east each day in such a way that she now approaches the equator and now recedes from it, now to the south, now to the north, and through one semicircle of her motion she is on this side of the equator, but through the other beyond it. From both motions together, then, the one in longitude toward the east and the one in latitude toward the poles of the equator, there arises a path oblique to the equator, and from this the zodiac.

What has been said of the Moon from daily experience is evident also in the Sun, at least after some days. From the same fixed star with which he was in conjunction he recedes toward the east by nearly one degree each day, and

after three months by about 90°, so that the rising Sun appears on the horizon when that star appears on the meridian. After 6 months he will stand about 180° from it, and as he rises that star will set in nearly the opposite part of the horizon. This is proof that each day the Sun has become, truly or apparently, further east. And since by this motion he declines now to the north, now to the south, this motion, mixed from a motion in length and one in breadth, appears to take place along an oblique circle. The same motion appears in the other stars also, but it does not become evident so quickly in the superior planets, and much less in the fixed stars, since these do not complete one degree toward the east except in about 70 or 72 years, at least in these centuries.

[Margin: Duo motus contrarij — Two contrary motions]

V. How it can actually happen that one and the same star moves continually with two contrary motions, one

[Margin: an possibiles. — whether they are possible.]

diurnal and common, that of the primum mobile, along the equator or its parallels, which are described from the poles of the world, and from east to west; the other proper, that of the second mobile, and this monthly, or annual, or longer than annual, according to the greater or lesser speed of each star's proper motion, striving against the motion of the primum mobile, which is called the sweeping motion [motus Raptus], and tending from west to east: this will be discussed in Book 3. Meanwhile the imagination of beginners is usually helped by the motion of an ant that crawls slowly eastward along the zodiac of an armillary sphere, by one or more degrees of the zodiac, while you with your hands turn the whole zodiac, together with the equator, toward the west. For the present it is enough to conceive the ecliptic, and the zodiac, as described from their own poles, which stand as far from the poles of the equator as the Sun stands from the equator when he declines furthest from it at the solstices; and to conceive all the stars, whether on the ecliptic or on parallels described from the poles of the ecliptic, as moving from west toward east, while by the sweep of the primum mobile they are moved toward the west in a daily revolution of 24^{h}.

[Margin: Eclipticæ munia. — The functions of the ecliptic.]

VI. *The functions and properties of the ecliptic* are these. (1) To cut the equator in two at those two opposite points at which the equinoxes occur: the vernal when the Sun enters Aries, the autumnal when he enters Libra. (2) To cut the equator at these points obliquely, that is, at angles that are not right. The angle that the ecliptic makes with the equator subtends an arc of the colure of the solstices, which colure is one of the movable meridians, and an arc as great as the Sun's declination from the equator at the solstices, which is then at its greatest. This angle is called the *obliquity of the ecliptic*. Of precisely the same quantity, that is, of the same number of degrees, are the said angle and the obliquity of the ecliptic, the Sun's greatest declination, the distance of the tropics from the equator, and the distance of the poles of the ecliptic from the nearer poles of the equator; and according to the truer opinion these are always

23° 30′. (3) With its poles and their daily motion it describes around the poles of the world the Arctic and Antarctic circles, and so determines the frigid zones. (4) By its obliquity it determines the position of the tropics and their distance from the equator, and by means of these it divides the torrid zone from the temperate zones. (5) It is the rule of the motion of the second mobile, by which all the stars are moved from setting to rising, and which is called *motion in longitude* from the beginning of Aries. For the true proper motion of a star is the arc of the ecliptic reckoned from the beginning of Aries according to the series or succession of the signs, as far as the point at which the ecliptic is intersected by the circle of latitude passing through the centre of the star; and the line drawn from the centre of the Earth to that point of the ecliptic is called the line of true motion. (6) It is the boundary from which the latitude of the stars is measured. For the latitude of a star is the arc of a great circle drawn through the poles of the ecliptic and the centre of the star, intercepted between the ecliptic and the centre of the star; and this latitude is northern if the star stands from the ecliptic toward the north, southern if toward the south. (7) It is the cause of the inequality of days and nights in the oblique sphere, and of the alternation of the seasons everywhere, and from there of generations and corruptions, which *Aristotle* rightly attributes (*On Generation and Corruption*, book 2) to the oblique circle: understand, to the Sun and the planets travelling along it, now approaching us, now receding toward the poles. It is likewise the cause of the variety of risings and settings. And so a certain distributive justice is kept: in the same climate where there was winter with the longest nights, there is in its own time summer with the shortest nights; and so that the passage to these extremes may not be immediate, two temperate seasons, spring and autumn, come between. For these reasons God [D.O.M.], by his admirable providence, devised this oblique circle. (8) Together with the equator it is the cause of the oblique ascensions, whose variety depends chiefly on the widely varying angle of the ecliptic with the horizon. For although a whole semicircle of the ecliptic always stands above the horizon, since each is a great circle and so, by *Theodosius*, book 1, theorem 11, they bisect each other, yet they do not always cut each other at equal angles, but now at right angles, now at acute on one side and obtuse on the other. (9) It divides the celestial sphere into a northern and a southern hemisphere with respect to the latitude of the stars, as the equator does with respect to declination; and in Ptolemy, in his book *On the Analemma*, and among the writers on gnomonics, any vertical circle does the same. Hence the same star is said in three ways to be in the northern or southern hemisphere: by latitude, that is, distance from the ecliptic toward the north; or by declination, that is, distance from the equator toward the north; or by departure from some vertical circle chosen for describing the hours, again toward the north; and likewise for the southern hemisphere. So it sometimes happens that one and the same star is at the same time northern by reason of declination and southern by reason of latitude, as when it lies between the equator and the northern semicircle of the ecliptic. (10) It is a partial cause of

eclipses of the Sun at new moons and of the Moon at full moons, when the body of the Moon either is on the ecliptic itself or comes very close to it. For only then can the Moon come between the Sun and our sight, and so the Sun fail, or the shadow of the Earth come between the Moon and us, and so the Moon suffer eclipse.

SCHOLIA.

[Margin: Latitudo Zodiaci. — The latitude of the zodiac.]

I. Sacrobosco in Chapter 2 of the *Sphere*, and Clavius on that passage, give the zodiac a latitude of 12°, because most planets, and most of the time, do not recede from the ecliptic more than 6° of latitude on either side. But Regiomontanus gives the zodiac a latitude of 16°, and others otherwise; for Kepler gives Mars a departure from the ecliptic toward the north of nearly 7° or 6° 47′, and Venus a greatest digression of 10°, or, as Argolus [Andrea Argoli] has it in the *Pandosion Sphaericum*, chapter 29, 9° 3′. Therefore the whole latitude of the zodiac, according to the more recent writers, may for safety's sake be extended to 20°, so as to be the 18th part of the whole circle.

[Margin: Obliquitas Eclipticæ an varia? — Whether the obliquity of the ecliptic varies.]

II. The *obliquity of the ecliptic to the equator*, in Greek Ζωδιακοῦ λόξωσις [Greek: zōdiakou loxōsis, "obliquity of the zodiac"], was and is always the same according to Ptolemy, al-Battānī, Agostino Ricci, Kepler, Gassendi, Kircher, Renieri and ourselves, and according to us indeed 23° 30′. Many others, however, have believed it inconstant and changeable by some anomaly; more on this in Book 3.

[Margin: Duodenaria partitio Zodiaci. — The twelvefold division of the zodiac.]

III. The zodiac was divided not only into six *physical signs* [Signa Physica], by reference to the sixth part of the circle that is taken in by compasses opened to the interval of the semidiameter, as the Alphonsine astronomers and the Arabs did in their sexagesimal tables of motions, but into 12 parts. The reason was both the number of the 12 months, whether lunar or solar, and the four seasons of the year, the four elements and the four humours of animals, in which there is found a threefold degree and notable difference, namely beginning, middle and end, or highest, middle and lowest: and 4 multiplied by 3 give 12. Moreover, the number twelve has five aliquot parts, corresponding to the twelve aspects of the signs, in which they notably exert their power. For the parts of the circle 1 pertain to conjunction, 2 to opposition, 3 to the trine, 4 to the square, and 6 to the sextile aspect.

[Margin: Initium Zodiaci cur à sectione Verna? — Why the zodiac begins from the vernal intersection.]

IV. The reason why astronomers took the beginning of the zodiac and of motion in longitude from the beginning of Aries, that is, from the point of

the vernal intersection of the ecliptic with the equator, was that this beginning had to be sought from one of the four cardinal points, at which either the beginnings or the highest perfection of the seasons of the year occur. It was better, moreover, to begin from the equinoctial points than from the solstitial, because of the equality of the days and the moderate temperateness of the year. It was better, finally, to begin from the vernal equinox than from the autumnal, because the astronomers who introduced these things were in the northern hemisphere, which the Sun enters from the beginning of Aries. In this hemisphere, indeed, there are both more fixed stars in the sky and more inhabited regions, and nations better suited and more inclined to civil culture and to the study of the arts and of religion; and the Sun himself lingers nearly eight days longer there than in the southern hemisphere. Leave aside the question whether the world was created by God [D.O.M.] in spring or in autumn; on this, see our Chronological book, which is Book 5, vol. 2, of the *New Almagest*. Among southerners, however, spring comes when the Sun enters Libra, and for this reason, if those astronomers had been southerners, they could very fittingly have begun the zodiac from the beginning of Libra.

[Margin: Et cur ab Ariete? — And why from Aries?]

V. Finally, the reason for calling the twelve signs of the zodiac by the names of animals, of which above, and the beginning of the first sign the beginning of Aries, was that the dodecatemories [Dodecatemoria], that is, those twelve segments of the zodiac, at the time when astronomers in Egypt and in Greece instituted or completed this division, occupied those regions of the sky in which those stars or constellations of the 12 animals lay: occupied them, I say, either wholly, or with the greater part of themselves, or at least with their beginning. So in about the year 388 before Christ, according to my tables, the first star shining in the horn of Aries was on the colure of the equinoxes and within the zodiac, since its northern latitude does not exceed 7° 7′ 13″. And in the preceding century, or a little before, namely in the year 548, Anaximander of Miletus had flourished, the inventor among the Greeks of the ecliptic and of the solar clock, as Pliny the Elder reports (book 2, chapter 8).

[Margin: Duplex Zodiacus notandus. — The two zodiacs to be noted.]

VI. It must further be carefully noted that there are at least two zodiacs in the sky. One is invisible in itself, merely imaginary, or conceivable by reason. Astronomers commonly speak of this one, and its twelve parts are equal, each divided into 30 degrees. The other is visible, that is, filled with fixed stars and the twelve constellations [Astris], which once gave their names to the parts of the invisible zodiac. The twelve constellations of this zodiac do not occupy equal parts in the sky, nor 30°: the constellation of Aries occupies in longitude 20° 13′, but Taurus 31° 24′, and so some more, some fewer than 30°. Since, however, the fixed stars have by now advanced in longitude, that is, toward the east, by about 28° since the time mentioned above, this zodiac (the "starred" one, to speak barbarously, and visible) differs by almost whole signs from the signs of the invisible zodiac, which is immobile with respect to this second

motion; so much so that now the constellation of Aries lies, with its greatest part, under the Taurus of the invisible zodiac, and Taurus under Gemini, and so on. They therefore call the former the Rational zodiac [Zodiacum Rationalem], and that of the sphere of the primum mobile, or the immobile; the latter the Apparent or Sensible, and mobile, and that of the eighth sphere. I shall speak of it again in Book 3, on the precession of the equinoxes.

[Margin: Domus Planetarum. — The houses of the planets.]

VII. How the 12 celestial houses, which are also called δωδεκατεμόρια [Greek: dōdekatemoria, "twelfth parts"], are related to the 12 signs of the invisible or rational zodiac will be discussed below, in Chapter 34, on erecting a celestial figure. Meanwhile it is enough here to indicate which signs astrologers call the *house of exaltation* of the planets and which that of their *fall* [Casus], and likewise which the principal house and which the less principal. For example, Leo is the principal house of the Sun and Cancer that of the Moon, because the Sun in Leo produces the greatest heat, while the Moon in Cancer moistens most. Aries is the house of exaltation of the Sun, because from there the days begin to lengthen for northerners. You see then, reader, that these things do not hold among southerners: for at that time the days begin to shorten for them, and it is with the Sun placed not in Leo but in Aquarius that they have their greatest heat. But if the power of producing heat was once increased not only by the Sun's distance midway between the summer solstice and the autumnal equinox, but also by conjunction with the Heart of Leo, the Dog Star, etc., this cause at any rate is now separated from the Leo of the rational zodiac and has migrated into its Virgo, beneath which the constellation of Leo is now found. So it is no wonder if the seasons of the years have varied. Nevertheless, here is a table of these houses, as it stands among the astrologers.

Planets and their characters [Planetæ, & eorum character]	House of exaltation [Domus Exaltationis]	House of fall [Domus Casûs]	Principal house [Domus Princip.]	Less principal house [Dom. minus Princ.]
Sun [Sol] ☉	♈	♎	♌	. . .
Moon [Luna] ☾	♉	♏	♋	. . .
Mercury [Mercurius] ☿	♍	♓	♍	♊
Venus ♀	♓	♍	♉	♎
Mars ♂	♑	♋	♏	♈
Jupiter [Iupiter] ♃	♋	♑	♐	♓
Saturn [Saturnus] ♄	♎	♈	♑	♒

[Margin: Eclipticæ in Cœlo obseruādæ ratio. — The way of observing the ecliptic in the sky.]

VIII. The *indicator of the ecliptic in the sky* is the half-full or horned Moon. If you gaze at her horns and, with imagination aiding the eyes, draw a circle through both horns of the Moon, it will pass through the poles of the ecliptic, especially if the Moon has no latitude. And if both horns are on the same vertical circle, which you can observe if they coincide with the thread of a plumb line

hanging perpendicular and still, the Moon will be at the nonagesimal degree of the ecliptic, that is, in the middle of the semicircle of the ecliptic that stands above the horizon. There is also now, in the bend of the third knot of Draco, a star of the 4th magnitude nearest the pole of the zodiac, about three degrees from it, whose longitude is in the 7th degree of Leo, and which shows us the pole of the zodiac as closely as possible.

CAPVT XV.

De Coluris.

On the colures.

[Margin: Colurus quid sit? — What a colure is.]

I. COLURE, in Greek κόλουρος [Greek: kolouros, "docked, curtailed"], does not mean the erect tail of an ox, as Johannes de Sacrobosco ridiculously imagined (for which he was censured by Clavius and by Barozzi), but something imperfect and mutilated. For there are two circles of the sphere that cut each other at right angles at the poles of the world, one of which passes through the equinoctial points of the zodiac and the other through the solstitial. Although in a right sphere they appear whole within the space of 24^h, and do not deserve the name of colures, yet in an oblique sphere they never appear whole, nor uniformly, either at once or successively, as do the other perfect and movable circles, namely the equator and the zodiac, which may be seen whole within the space of 24^h; rather, some portion of them always lies hidden below the horizon. They have therefore been called mutilated and imperfect, and, by antonomasia, *colures*. For besides these there are many other great circles that share this imperfection, namely all those that pass through the poles of the world and are movable: for never do all their parts rise above the horizon in an oblique sphere.

[Margin: Colurus Aequinoctiorū quid? — What the colure of the equinoxes is.]

II. The *colure of the equinoxes* is a great circle whose poles are at the beginning of Cancer and of Capricorn on the equator. It passes through the poles of the world, that is, of the equator, and cuts the equator at right angles at the equinoctial points. In other words, its poles lie on the equator, 90° from the beginning of Aries and of Libra.

[Margin: Colurus Solstitiorū quid? — What the colure of the solstices is.]

III. The *colure of the solstices* is a great circle whose poles are at the beginning of Aries and of Libra. It passes through the poles of the world and cuts the equator and the ecliptic at right angles at the solstitial points. Hence the colures cut each other at right angles at the poles of the world, by 15 of Book 1 of *Theodosius*, since each passes through the poles of the other and through the poles of the equator.

[Margin: Proprietates Coluri Aequin. — The properties of the colure of the equinoxes.]

IV. Besides those indicated in the definition, the properties and functions of the *colure of the equinoxes* are these. (1) It cuts the ecliptic in two, as one great circle does another, but at oblique angles, since it does not pass through the poles of the ecliptic; and its obliquity to the ecliptic is as great as the complement of the obliquity of the ecliptic to the equator, the complement, I say, to 90°, that is, in our own and the truer opinion, 66° 30′. (2) It separates the signs of the ecliptic and the zodiac into six northern signs and six southern. (3) It cuts all circles parallel to the equator in two and at right angles, as can easily be shown from the *Spherics* of Theodosius. (4) It marks the meridian on which noon occurs at the moment of the equinox, and conversely on which the equinox occurs at the moment of noon; for it coincides with the meridian of the place at which these two instants or moments fall together, namely that of the true equinox and that of noon. In this way it marks the equinoxes, whose precession will be discussed below.

[Margin: Proprietates Coluri Solstitior. — The properties of the colure of the solstices.]

V. Besides those indicated above, the properties and functions of the *colure of the solstices* are these. (1) It divides the zodiac into six si- gns that ascend and six that descend.

[Margin: Signa Ascēdētia ac Descendentia quæ? — Which signs are ascending and which descending.]

For northerners the ascending signs are *Capricorn, Aquarius, Pisces, Aries, Taurus, Gemini*, because from the beginning of Capricorn to the end of Gemini the Sun approaches the north pole and, moving away from its least meridian altitude, rises higher above the horizon each day up to the greatest of the meridian altitudes; and from that point the day too, starting from its shortest, begins to grow up to the longest day. But from the beginning of Cancer to the end of Sagittarius the Sun recedes from the north pole, and the day and the Sun's meridian altitude decrease. So the six signs that descend, with respect to those who live on the northern side of the equator, are *Cancer, Leo, Virgo, Libra, Scorpio, Sagittarius*. The latter six ascend directly and descend obliquely; the former ascend obliquely and descend directly for northerners, according to what will be said below about these ascensions. Among southerners, however, everything is the opposite of this: for them the ascending signs are those that are descending for northerners, and vice versa. (2) It cuts in two at right angles not only the equator but also all its parallels; and so by this colure and by the colure of the equinoxes the equator, the parallels of the equator, and the ecliptic are cut into four quadrants, which gives the four seasons of the year. (3) It marks the meridian of the place at whose noon the solstices occur, for the colure of the solstices coincides with that meridian. For that reason, in the figure of chapter 7, we took the same circle AEBQ for the meridian and for the colure of the solstices; and this will also often have to be done in many astronomical problems.

[Margin: Solstitij Etymologia. — The etymology of "solstice".]

In this way it marks the solstices. They are so called both because the Sun, when it has reached the beginning and tropic of Cancer or of Capricorn, declines no further from the equator toward the poles of the world, but is halted within those limits and turns its course toward the equator; and because on those days the difference in the length of the days, and in the meridian altitudes of the Sun and in the shadows, is so imperceptible that the Sun seems to stand in the same parallel. (4) It carries the Sun's greatest declination, that is, the distance of the tropics from the equator, and also the distance of the pole of the ecliptic from the pole of the world; for each of these is an arc of this colure, between the equator and the tropics or between those poles, and in this way it measures those distances. In the following figure the former is the arc EC or EK, and the latter TB or NA.

SCHOLIA.

I. For one at whose noon the equinox falls, the pole of the ecliptic is at its greatest distance from the meridian: toward the west if the equinox is the vernal one, toward the east if the autumnal. But for one at whose noon a solstice occurs, the pole of the ecliptic is on the meridian and higher than the pole of the world by 23° 30′, if the solstice is the winter one for northerners; lower, if the summer one.

[Margin: Præcessio Aequinoctiorum. — The precession of the equinoxes.]

II. The *civil* precession of the equinoxes is the anticipation in time by which the true equinox comes before the day assigned to the equinox in the calendar; I shall speak of it more fittingly in Book 3, in the chapter on this matter. The *astronomical* precession of the equinoxes, on the other hand, is the recession by which the first shining star in the horn of Aries moves away from the point of the vernal equinox, by a motion of longitude toward the east. This holds whether the motion is truly a motion proper to the fixed stars, or, as others prefer, a motion of the equinoctial points themselves toward the west, on account of which the fixed stars, motionless in themselves, appear to move away from those points toward the east. On this subtlety I shall speak in Book 3.

CAPVT XVI.

De Tropicis, Circulis Polaribus, & Zonis.

On the tropics, the polar circles, and the zones.

I. TROPICS are named from the noun τροπή [Greek: tropē, "turning"], which signifies a return or conversion, because when the Sun reaches these circles it returns and bends its course toward the equator, and does not go past these limits toward the poles of the world.

[Margin: Tropicus Cancri q̄ d? — What the Tropic of Cancer is.]

II. The *Tropic of Cancer*, in Greek τρόπικος θερινὸς [Greek: tropikos therinos, "summer tropic"], that is, the summer tropic with respect to northerners,

is not a great circle. It is drawn from the poles of the world, and is therefore parallel to the equator; it stands as far from the equator as the Sun's greatest declination, or the obliquity of the ecliptic, amounts to; and it touches the ecliptic at the beginning of Cancer. Its function, besides those already indicated, is to bound the torrid zone on one side and the northern temperate zone on the other; and then to produce the summer solstice and the longest day for northerners, and the winter solstice and the shortest day for southerners. Such, in the following figure, is the circle CR, drawn from the north pole B.

[Margin: Tropicus Capricorni quid? — What the Tropic of Capricorn is.]

III. The *Tropic of Capricorn* is not a great circle. It is drawn from the poles of the world, is parallel to the equator, stands as far from the equator as the Sun's greatest declination amounts to, and touches the ecliptic at the beginning of Capricorn. Its office is to bound the torrid zone on one side and the southern temperate zone on the other; and then to produce the winter solstice and the shortest day for northerners, and the summer solstice and the longest day for southerners.

[Margin: Dies Solstitiorū quæ? — Which days are those of the solstices.]

The solstices occur when the Sun enters Cancer and Capricorn, namely about the 21st of June and of December in the corrected Julian year, that is, three days before the Nativity of St John the Baptist and of Christ the Lord. Accordingly the saints, Augustine above all, expound that saying of St John the Baptist (*Illum oportet crescere, me autem minui* ["He must increase, but I must decrease"]) as referring also to this growth and shrinking of the days, because Christ was born on the day when the days were already beginning to grow, and St John the Baptist on the day when they were beginning to shrink; for in that age the solstices occurred about the 24th or 25th of June and of December. You have a specimen of the tropics in the figure added here, in which the line CR denotes the Tropic of Cancer and KP that of Capricorn.

[Margin: Polares Circuli qui? — What the polar circles are.]

IV. The *polar circles*, according to the more common acceptation among astronomers, especially the Latin ones, are lesser circles, parallel to the equator and therefore drawn from its poles, and as far from the poles of the world as the tropics are from the equator, namely 23° 30′; in other words, circles whose circumferences are traced by the poles of the ecliptic as they are carried round the poles of the equator in a whole daily revolution. One of them is called the northern, or septentrional, or arctic, ἀπὸ τοῦ ἄρκτου [Greek: apo tou arktou, "from the Bear"], that is, from the Bear, the neighbouring constellation; it contains within it the northern frigid zone and bounds the northern temperate zone. The other is called the southern, or antarctic, that is, set opposite to the arctic; it contains within it the southern frigid zone and bounds the southern temperate zone. So in the adjoining figure the arctic circle is TM and the antarctic NO.

Diagram. A small circle set into the lower part of the right column, the text wrapped around its left side. A vertical diameter runs from E at the top to Q at

the foot, and a horizontal diameter from A at the left to B at the right, crossing at G at the centre. A double line runs from K at the upper left through G to R at the lower right. A further line runs from T at the upper right through G to O at the lower left. Curved arcs stand on the circle between the labelled points named in the text. Fourteen labels were read on the block, and no others were seen; the referents below are the ones the page's own prose assigns.

- E (top): end of the arcs EC and EK
- K (upper left): with P, the Tropic of Capricorn (KP)
- C (upper right): with R, the Tropic of Cancer (CR)
- N (left, above A): with O, the antarctic circle (NO)
- T (right, above B): with M, the arctic circle (TM)
- A (left): the south pole
- F (left of the centre, above the horizontal line): not cited in the text of this page
- G (centre): not cited in the text of this page
- B (right): the north pole
- O (left, below A): with N, the antarctic circle
- M (right, below B): with T, the arctic circle
- P (lower left): with K, the Tropic of Capricorn
- Q (foot): lower end of the vertical diameter, cited in AEBQ for the figure of chapter 7
- R (lower right): with C, the Tropic of Cancer

DE ZONIS.

On the zones.

[Margin: Zonæ quid? — What zones are.]

V. *Zones*, among cosmographers, are bands on the surface of the celestial or terrestrial sphere, but especially the ter- restrial, bounded by the tropics, or by the polar circles, or by both. There are five of them, namely the *Torrid Zone*, the *Northern Temperate Zone*, the *Southern Temperate Zone*, the *Northern Frigid Zone*, and the *Southern Frigid Zone*. Virgil describes these zones superbly in Book 1 of the *Georgics*, starting from the verse *Quinque tenent Cœlum Zonæ* ["Five zones hold the sky"]; so does Ovid in Book 1 of the *Metamorphoses*, starting from *Vtque duæ dextra Cœlum læuaque* ["And as two, on the right, the sky, and on the left"]; and Tibullus, Book 4, Elegy 1.

[Margin: Zona Torrida quæ? — What the Torrid Zone is.]

VI. The *Torrid Zone* is contained between the two tropics, and its breadth is as great as the distance of the tropics from each other, that is, double the distance of the tropics from the equator, namely 47°. Such, in the preceding figure, is the band enclosed between the arcs KC and PR; and it is cut in two by the equinoctial line. Aristotle, and Pliny the Elder (Book 2, ch. 68), judged it uninhabitable on the Earth because of the excessive heat produced by the Sun's rays, reflected more directly toward the air lying over the heads of the

inhabitants; and so it was called *Torrid*, especially since for those inhabitants the Sun passes through the zenith twice a year.

[Margin: Zona Torrida habitabilis. — The Torrid Zone is habitable.]

But in reality it is inhabited in many places. By the gentle providence of God, Best and Greatest, it is blown through by very frequent and almost daily breezes of wind, or sprinkled with rain, so that the heat is tempered; and not rarely men of white colour have been found living in it. Those live in this zone for whom the pole is not raised more than 23° 30′. For its other properties see ch. 20, no. 8.

VII. The *Temperate Zones*, so called from the moderation of heat and cold and of the length of the days, are contained as follows: the northern between the Tropic of Cancer CR and the arctic circle TM, the southern between the Tropic of Capricorn KP and the antarctic circle NO. Each of them is as broad as the complement to 90° that the torrid zone lacks, namely 43°. In the northern temperate zone live the largest part of Europe, of Asia, and of northern America. Those live in the temperate zones for whom the pole is raised no more than 66° 30′ and no less than 23° 30′.

VIII. The *Frigid Zones* are contained, one within the arctic circle TM and the north pole B, the other within the antarctic circle NO and the south pole A; although the poles, being points, can bound rather than contain. And although for those who live within these zones the pole is raised more than 66° 30′, so that they have one continuous day lasting several of our days, indeed even several months, the zones nonetheless are and are called frigid in comparison with the other zones. This is both because they also have a night no less long, made up of the nights of several months, and because the Sun's rays are reflected toward their air only very obliquely and very remotely, and the Sun is very far from the zeniths of the inhabitants; just as, if the Sun stayed always on the horizon or very near it, it would not warm us much. Yet it has been learned from Dutch and English navigators, who have penetrated into the northern frigid zone, that these zones are inhabited.

On the cause of the Sun's greater heat from reflection at less oblique angles, I shall speak in Book 3, ch. 5.

SCHOLIA.

[Margin: Polarium circul. alia notio. — Another notion of the polar circles.]

I. In Proclus, Cleomedes, Geminus, and some Greek astronomers, the polar circles are the same as the circles of perpetual visibility or of perpetual occultation [semper Apparentium, semperue latentium], treated in the next chapter below, because they are drawn from the poles of the world. But taken in this way they are not fit to bound and distinguish the five zones, since for those for whom the pole is raised 66° 30′ the tropics themselves are circles of perpetual visibility, whereas the polar circles as commonly understood are not circles of perpetual visibility except for those living under the tropics.

II. Those who live precisely under the tropics belong to the torrid zone and to the nearer temperate zone; those under the polar circles belong to the temperate and the frigid zone together, since what is in the middle shares in its extremes.

III. If anyone wants the ratio of lesser circles to great circles, let him multiply the sine of the complement of the lesser circle's declination by 360° and divide the sum by the radius; the quotient will be the number of degrees of the great circle to which the whole circumference of the lesser circle is equal. But we shall give a table for this ratio at the end of the book and in the Geographical Book, with the miles corresponding to one degree.

[Margin: Dextra, & sinistra in Mūdo quæ? — Which are the right and the left in the world.]

IV. Since Virgil and Ovid, in their description of the zones, mentioned a right and a left side of the world, Clavius (p. 310) takes the occasion to explain which side of the world is the right and which the left, and Iacobus Mazzonus [Jacopo Mazzoni] more learnedly still, in his defence of Dante, Book 1, ch. 15, and Book 3, ch. 30. The sum of the doctrine is this. Among philosophers and geographers the right is the east, because the daily motion begins from it, as in animals from the right side; or because northern geographers, when about to describe the inhabited world, face the north pole, and so the east remains on their right; and in this way they present their maps to us so that the east is on our right. Among astronomers, on the other hand, the right is the west, because they contemplate chiefly the planets and the stars of the zodiac, and turn to face south (understand this of northerners), so that for them the west is on the right. Among poets, finally, the right is the north, because it is nobler in its multitude of stars and of more civilized and more learned inhabitants, and in the Sun's longer stay in the northern signs, by about 8 days more than in the southern.

[Margin: Tropici cœlestes extra Terræ globum. — The celestial tropics lie outside the globe of the Earth.]

V. Since there is a danger that the unskilled may think that the tropics, the circles of the terrestrial sphere, lie in the same plane as the celestial tropics, and the terrestrial polar circles in the plane of the celestial polar circles, let them remember that the globe of the Earth is, in relation to the sky, like a point, and that the Earth's diameter is therefore far shorter than that part of the sky's diameter which subtends the breadth of the celestial torrid zone. From this it follows that the planes of the celestial tropics lie wholly outside the Earth. It is true that if straight lines are drawn from any points on the circumference of a celestial tropic to the Earth's centre, they will pass through the circumference of its own terrestrial tropic; and I say the same of straight lines drawn from the circumference of a celestial polar circle to the Earth's centre, for they will pass through the circumference of the terrestrial polar circle, as Clavius gathers from the last proposition of Book 6 of Euclid in his *Sphere*, p. 311, where he also adds a figure.

VI. Polybius subdivided the torrid zone into two, as Strabo reports, but he had no followers. The first divider of the zones was Parmenides; but already from the time of Thales they were distinguished by polar circles taken as circles of perpetual visibility. Posidonius, however, made them fixed, by adopting polar circles drawn from the pole of the ecliptic; but if the obliquity of the ecliptic varies, these too vary. Kepler in the *Epitome of Copernican Astronomy* thinks it not improbable that the two temperate zones once contained as much space as the three intemperate ones together, so that there should be equality between intemperateness and temperateness; and accordingly that the obliquity of the ecliptic was greater than 24°. But God did not look to these material Ideas, nor did he practise geometry in mere quantity; he had other ends. See Book 3, ch. 26, Scholium 1.

CAPVT XVII.

De Circulis semper Apparentium.

On the circles of perpetual visibility.

I. CIRCLES of perpetual visibility, that is, of stars or of points of the sky, do not exist in a right sphere, that is, for those who live on the equator. In a parallel sphere, the one in which those living under the poles of the world dwell, the equator itself is the circle of perpetual visibility for one group and of perpetual occultation for the other, just as it also serves as the horizon. So a dweller under the north pole sees perpetually all the points of the northern hemisphere, and all the stars that are within it, for as long as they are within it and keep a northern declination; but he can never see the points or stars of the southern hemisphere, except incidentally by reason of refraction. Conversely, one living under the south pole can always, on every day or night, see all the points and all the stars of the southern hemisphere, but never those of the northern, except incidentally through the refraction of the rays, which lifts the stars.

II. In an oblique sphere, however, the circles of perpetual visibility and of perpetual occultation are lesser circles, drawn from the poles of the equator, and so parallel to it, and touching the horizon. Within them are contained the points of the sky and the stars that of themselves either never set or never rise. There are as many such circles as there are elevations of the pole, and they are the larger the greater the elevation of the visible pole. By means of them one can tell which stars never descend below the horizon, or which never ascend above it, if the altitude of the pole and the declination of the stars are known.

III. The circle of perpetual visibility is equal to the circle of perpetual occultation, by 6 of Book 2 of *Theodosius*, since they are parallel and equally distant from the equator. For those living under the tropics the polar circles themselves serve as circles of perpetual visibility on one side and of occultation on the other; for those living on the polar circles, the circles of perpetual visibility and occultation are the tropics themselves.

IV. But so that you may understand this more easily, let the horizon be HR, the meridian HERQ, the equator EQ, the axis of the equator and of the world AB, the north pole of the world B, the south pole A, and the altitude of the north pole BR, equal to the depression of the south pole HA. Now through the points R and H, where the meridian cuts the horizon, let two circles SR and HL be drawn, parallel to the equator EQ and touching the horizon at R and H. SR will then be the circle of perpetual visibility for a dweller for whom the north pole is raised by as much as the arc RB. Stars on the circumference of the circle SR will, at their least meridian altitude, touch the horizon at R, but will not set; stars within this circle and the pole B will always be above the horizon. Conversely, the circle HL will be, for the same dweller, the circle of perpetual occultation. Stars placed on its circumference will, at their greatest elevation, graze the horizon at H, but will not rise; the others, contained within it and the pole A, will always be hidden below the horizon.

Diagram. A circle set into the left column, the text wrapped down its left side. A horizontal line runs from H at the left to R at the right. A long diagonal runs from E at the upper left to Q at the lower right, and a second long diagonal from B at the upper right to A at the lower left, crossing the first at the centre. Shorter lines stand parallel-looking to E–Q: S to R on the upper right, F to G above the centre, a line from K to N at the foot, and H to L at the lower left. Twelve labels were read on the block, and no others were seen; the referents below are the ones the page's own prose assigns.

- F (top, left of S): with G, the parallel FG, on which a star is supposed
- S (top): with R, the circle of perpetual visibility SR
- E (upper left): with Q, the equator EQ
- B (upper right): the north pole
- K (left, above H): the point to which the star on HL is apparently raised; the page prints "the parallel KH"
- H (left): with R, the horizon HR; with L, the circle of perpetual occultation HL
- R (right): with H, the horizon; with S, the circle SR
- G (right, below R): with F, the parallel FG
- A (lower left): the south pole
- Q (lower right): with E, the equator
- L (foot): with H, the circle HL
- N (foot, right of L): not cited in the text of this page

V. The remaining stars, contained between the equator EQ and those circles, will rise and set, and their stay above the horizon will be the longer, the greater the arc of those circles intercepted between the meridian and the horizon. Yet this arc will always be greater, and that stay longer, than the arc and the stay below the horizon, for stars contained between the equator and the circle of perpetual visibility. This is apparent on the circle FG, parallel to EQ, on which a star is supposed to be: for the arc from F to the horizon HR is greater than the one below, from the horizon to G. Conversely, for stars contained between

the equator and the circle of perpetual occultation, the arc and the stay above the horizon will be less than the arc and the stay below the horizon. Finally, if any stars are on the equator itself, the arc and the stay above will be equal to the arc and the stay below the horizon.

SCHOLIA.

[Margin: Refractio hos circulos variat. — Refraction varies these circles.]

I. What has been said so far of the perpetual visibility or occultation of stars, or of their contact with the horizon, is true of itself, setting aside the physical variation that usually arises from refractions and from the vapours of the horizon, incidentally as regards the astronomical position of the sphere. For suppose that in the preceding figure some star is on the parallel FG. In its greatest depression it would be at G, below the horizon HR, and would of itself set; but since the refraction of its rays can be so great that its image is lifted to R, and the refraction of altitude equals the arc of depression RG, it can appear at the very point R of the horizon, or even above it, if the refraction is greater. Conversely, let another star be on the parallel HL; when it has come to H, and would not of itself rise, it may yet be raised apparently to K by the agency of horizontal refraction. For it will seem to be on the parallel KH and not to be among those that are always hidden, just as the star G, raised to R, will seem to be among those that always appear.

II. I also said in number 1, "Which, and for as long as, etc." because the phrase *semper Apparentium aut Latentiū* must be understood absolutely as regards points of the sky, which do not change their declination; but as regards stars, which do change their declination, only on a hypothesis, namely that their declination is such that they remain within the circle of perpetual visibility or occultation. For in the course of time they leave those circles, and stars that previously never set or never rose begin to set or to rise, because of the changed declination.

[Margin: Modus secernēdi circulum semper Apparentium. — The way of distinguishing the circle of perpetual visibility.]

III. The rule for knowing the size of the circle of perpetual visibility, that is, how far it stands on the meridian from the pole of the world, or how far it declines from the equator, is very easy. The altitude of the pole itself gives its distance from the pole of the world, and the complement of that altitude to 90° gives its declination from the equator, which in the figure above is the arc ES. Thus for us at Bologna, where the north pole is raised 44° 29′ 30″, the circle of perpetual visibility SR stands from the pole B by the arc SB or BR, 44° 29′ 30″, and declines from the equator EQ by the arc SE, of 45° 30′ 30″.

IV. The rule for knowing stars of perpetual or non-perpetual visibility is of this kind. Join the star's northern declination to the altitude of the north pole. If the sum equals a quadrant, that is 90°, the star will touch the horizon but will not set for northerners. If the sum is greater than a quadrant, it will

be one of those that always appear above the horizon. If it is less, it will be one of those that neither always appear nor always lie hidden, but rise and set, unless refraction prevents it. If this refraction is as great as the excess of the quadrant over that sum, the star will incidentally appear on the horizon; if greater than that excess, it will be seen above it; if less, it will still lie hidden below the horizon. And say the same of southern stars and the south pole with respect to southern dwellers.

EXEMPLVM.

Example.

Let the example be Capella, whose northern declination in the year of Christ 1600 was, by my observations, 45° 29′ 35″; at the completed year 1609 it was 45° 30′ 30″; and at the completed year 1644, 45° 34′. The altitude of the pole at Bologna is 44° 29′ 30″. If you add the first declination to this, the sum is 89° 59′ 5″, less than a quadrant. So at that time Capella was, for us, one of the stars that rise and set of themselves. But since the quadrant exceeds that sum by 55″, and the horizontal refraction of the fixed stars is, by Tycho's reckoning, 30′, it was incidentally always visible above the horizon. Now add the second declination to the same altitude of the pole: the sum becomes equal to a quadrant. So in 1609 Capella, at its lowest depression, should have touched the horizon at R, but incidentally, because of refraction, it appeared about 30′ higher. Finally add the third declination, and the sum is 90° 3′ 30″, greater, that is, than a quadrant by 3′ 30″. Therefore in 1644 Capella was already, not only incidentally but of itself, one of those that always appeared above the horizon; and then, at its lowest altitude, it should have been 3′ 30″ higher, but because of refraction 33′ 30″. And it will be always visible for many future centuries, and will appear the higher at its lowest altitude, the greater its northern declination becomes, which in this century at least, and almost in the next, has grown each year by 6″.

V. The rule for knowing the stars that always lie hidden is of this kind. Add the star's southern declination to the altitude of the north pole. If the sum equals a quadrant, the star will touch the horizon but will not of itself rise; if the sum is greater, it will always lie hidden; if less, it will be among those that rise and set. If you are a southern dweller, use the altitude of the south pole but the northern declination, that is, stars declining toward the north, and do the rest as above.

VI. From what has been said you will understand many passages of the poets, and the reason why Virgil, for example, says:

Arctos Oceani metuentes æquore tingi. ["The Bears, fearing to be dipped in the water of Ocean."]

For he is speaking of Ursa Major and Ursa Minor, which for the Greeks and Latin inhabitants never set at that time, just as they do not set even now. Likewise why Ovid said:

Magna minorq; feræ, quarum regit altera Graias; Altera Sydonias, vtraque sicca, rates. ["Great and lesser beasts, of which one guides the Greek ships, the other the Sidonian, and both of them dry."]

For neither of the Bears set for the Greeks, and so either was fit, at any hour of the night, for steering a course at sea. But for the Sidonians and all the Phoenicians, Ursa Major set, and only Ursa Minor stood always above the horizon.

CAPVT XVIII.

De Climatibus, & eorum Parallelis.

[Margin: Clima q̄ d? — What a climate is.]

I. CLIMATE [Clima], in Greek κλίμα [Greek: klima, "ladder" or "step", as the page goes on to gloss it], that is, a ladder or the rungs of a ladder, is a small zone on the surface of the sphere, especially the terrestrial sphere, enclosed by two circles parallel to the equator, or by the equator and one of its parallels. Its breadth, and its difference from the next climate, are as great as competent judges reckon a notable difference between them, in the length of the longest artificial day and in the temperature of the soil or the air. If this difference is taken uniformly in time, so that each climate is distinguished from the next by a difference of half an hour in the longest day of the year, it makes the breadth of the climates ever narrower and narrower toward the poles, as can be seen in the adjoining figure. In it the horizon is ABDE, the equator AGD and the meridian BGE, while the remaining lines indicate the parallels within which the climates are contained. The reason is that for an equal difference in the day, the smaller the difference required in the altitude of the pole, the greater the altitude of the pole itself, as is clear from the theory and the problems of the primum mobile. This is the origin of the name "climates": for if climates are drawn in this way on maps or geographical globes, they will represent ladders by which one climbs from the equator toward the poles, to a greater and greater altitude; and perspective artists draw the more remote rungs of a ladder at a smaller interval from their neighbours than the rungs nearer the eye.

Diagram. A circle set into the lower part of the left column, the text wrapped down its left side. Horizontal lines cross it at intervals, which were not measured. Labels read on the block: five. No others were seen. The referents below are the ones the page's own prose assigns.

- B (top): on the horizon ABDE and the meridian BGE
- A (left): on the horizon ABDE and the equator AGD
- G (centre, on a horizontal line): on the equator AGD and the meridian BGE
- D (right): on the horizon ABDE and the equator AGD
- E (foot): on the horizon ABDE and the meridian BGE

[Margin: Climatum Paralleli. — The parallels of the climates.]

II. *Parallels of the climates*: some bound the climates, giving a beginning to one and an end to another; others are drawn through the middle of a climate. Through the middle, I mean, in proportion to half the difference of the longest day by which one climate differs from the next. For they ought not, as the inexperienced suppose, to be drawn through the middle of the place or space, so as to divide the climate in two. So if the difference of one climate from another is taken from the half hour by which the longest day of one inhabitant exceeds the longest day of another, the parallel through the middle of a climate must be drawn through that part of the climate in which there is a difference of one quarter [of an hour] in the longest day from the day of the parallel bounding the climate. In this way, between two neighbouring parallels drawn through the middles of climates, the difference will be half an hour.

III. *Anticlimate* [Anticlima] is the opposite climate, whose breadth and distance from the equator toward the other pole, and whose longest day of the year, are equal, though not on the same day of the year.

[Margin: Climatum denominatio. — The naming of the climates.]

IV. The *naming* of climates is usually taken from some notable place on the Earth through which the parallel through the middle of the climate passes: so in tables of climates you will note the *parallel through Rome*, the *parallel through Byzantium*, and so on. Usually added are the altitude of the pole, the length of the longest day, the equinoctial and solstitial shadows of gnomons at noon, and the number of miles corresponding to one degree; these belong either to each parallel or at least to the parallels through the middles of the climates. You will see this in our tables of climates, which we shall present more fittingly in the Geographical Book. For it is there that the controversy so far pursued over the number and proportion of the climates, which different people determine differently, and over how many miles correspond to one degree, will have to be settled, and the whole table reformed, for just reasons. Meanwhile see the tables in Clavius's *Sphere*, p. 429; those of Biancani and of Cluverius [Philipp Clüver] in the *Introduction to Geography*; of Langius [?] in the *Elementale Geographiae* [Elementali Geogr.], p. 492; of Barozzi in the *Cosmography*, Book 3, from p. 212; of Hérigone, volume 4, p. 90; of Stöffler on Proclus, p. 30.

CAPVT XIX.

De Triplici Sphæræ Positione, & de Diuersitate Dierum, ac Noctium in illa.

I. The POSITION of the sphere is considered according to the situation of the equator relative to the horizon. Either the equator cuts the horizon orthogonally, that is, at right angles, and from this arises the *right sphere* [Sphæra Recta]; or at oblique angles, and from this the *oblique sphere* [Sphæra Obliqua]; or it does not cut it but coincides with the horizon, so that the parallels of the equator are also parallels of the horizon, and from this comes the *parallel sphere* [Sphæra Parallela]. Look at their diagrams in order in the three following figures: in

the first of them the equator CD cuts the horizon AB orthogonally, etc.; in the second it cuts it obliquely; in the third AB is at once equator and horizon.

Diagram. The first of three circles set in a row across both columns. A horizontal diameter runs from A to B, and a vertical line from C to D. Further vertical lines stand on either side of CD. Eight labels were read on the block, and no others were seen. Which of the vertical lines ends at which letter was read at strip scale and is hedged.

- E, C, F (top, left to right): C on the equator CD; E on the tropic EG and F on the tropic FH, as the prose on this page assigns
- A (left), B (right): the horizon AB
- G, D, H (foot, left to right): D on the equator CD; G and H the lower ends of the tropics EG and FH

Diagram. The second circle of the row, standing over the gutter. A horizontal line runs from H at the left to R at the right. A long diagonal runs from B at the upper right to A at the lower left. A band of parallel lines slants from the upper left to the lower right. The text on the next page assigns all these letters to this figure. Labels read on the block, eighteen in all: H and C together at the upper left, B at the upper right; E, L, K descending the left side; a second H at the left end of the horizontal line, with O just inside it; D and F on the horizontal line; G and R at its right end; N, I, Q, M descending the right side; P and A at the foot. No others were seen. ⚠ H stands twice on the block, and both are needed by the prose (horizon HR, meridian HCRP; parallel HI). The small letters D, F and G were read at strip scale and are hedged.

Diagram. The third circle of the row. A vertical line runs from C at the top to D at the foot, and horizontal lines cross the circle, of which AB is the one through the centre. Eight labels were read on the block, and no others were seen. No line was distinguished on the block as a separate ecliptic FH; line end-points were read at strip scale and are hedged.

- C (top), D (foot): the axis of the world CD
- A (left), B (right): at once equator and horizon AB
- E (upper left), H (upper right), F (lower left), G (lower right): the ends of horizontal lines; the prose on the next page names FH as the ecliptic

[Margin: Sphæra Recta quæ? — What the right sphere is.]

II. The right sphere, then, belongs to those for whom the equator cuts the horizon at right angles, and its properties are these. 1. For them the poles of the world lie on the horizon, while the equator passes through the zenith and the nadir, as the Sun also does on the days of the equinox, since it is then on the equator. 2. All days are equal to the nights, of themselves and setting aside that small portion of the day which refraction adds, when it makes the Sun rise about three or four minutes of time earlier, and set as many later, than it should. The cause of this equality appears in the first figure, in which the horizon is AB, the equator CD and the tropics EG and FH; of these, as of all the parallels along which the Sun travels, the arcs above the horizon are equal to the arcs below the horizon. 3. The shadows, especially the noon shadows, of

gnomons set upright on horizontal planes point south as long as the Sun is in the northern signs, but north when it is in the southern signs. 4. All the stars without exception rise and set for such an inhabitant, stay above the horizon for 12^h, and lie hidden below it for as many. In this sphere are the Island of St Thomas, the middle of Taprobane, and many other places.

[Margin: Sphæra Obliqua. — The oblique sphere.]

III. The oblique sphere belongs to those for whom the equator cuts the horizon at oblique angles, that is, obtuse toward the visible pole and acute toward the other pole. So in the second figure, in which the horizon is HR, the meridian HCRP, the equator EQ and its axis AB; the depressed south pole of the world is A and the elevated north pole is E [recte: B]; the tropics are CN for Cancer and KP for Capricorn; and the rest are parallels of the equator, which the Sun describes by its daily motion when it is at the beginning of the signs.

The properties of this sphere are these. 1. It has one pole always elevated and the other always depressed below the horizon. 2. If an inhabitant is between the equator and a tropic, the Sun passes over his head twice; those outside them never have the Sun at the zenith. 3. All days, except the equinoctial ones, are of themselves unequal to the nights: for northerners they are longer than the nights as long as the Sun is in the northern signs, and shorter than the nights as long as it is in the southern signs. Conversely, for southerners the day exceeds the night when the Sun is in the southern signs, and is shorter than the night when the Sun is in the northern signs. The cause of this inequality is the unequal arcs of the parallels of the equator. Let the Sun be on the tropic of Cancer CN: the semidiurnal arc CG, which the Sun traverses from its rising at G to the meridian at C, is greater than the seminocturnal arc GN, which is below the horizon. So too with the Sun placed at the beginning of Gemini or Leo, as on the parallel HI, the semidiurnal arc HF is greater than the seminocturnal FI. But if the Sun is on the tropic of Capricorn KP, the semidiurnal arc KO is less than the seminocturnal OP; and with the Sun at the beginning of Sagittarius or Aquarius, that is, on the parallel LM, the semidiurnal arc LD is less than the seminocturnal DM; and likewise for the other parallels. All this will become clearer if you turn a material sphere and, placing on the horizon the point of the ecliptic where the Sun is, count the degrees of the equator that rise in the time the Sun takes to reach the meridian, and convert them into times, as was said in Chapter 12, no. 2. For besides this inequality you will also learn the size of the semidiurnal arc with the pole elevated to any altitude you please. 4. For those outside the torrid zone, the shadows of gnomons always point toward the visible, or elevated, pole; for those inside the torrid zone, they point sometimes toward one pole and sometimes toward the other. The Sun never reaches the zenith of the first group, but it reaches that of the second twice a year and passes over their heads. 5. There are some stars, or at least points of the sky, that always appear to them, and some that are always hidden.

[Margin: Sphæra Parallela. — The parallel sphere.]

IV. The parallel sphere belongs only to those two inhabitants who are directly under the poles of the world, as in the third figure, in which horizon and equator together are AB; the meridian ACBD; the axis of the world CD; the ecliptic FH; and the rest are parallels of the equator and of the horizon alike. Its properties are these. 1. For them the poles of the world are at the zenith and the nadir, and the axis of the world is the same as the vertical line. 2. One living under the north pole C has a single day of six months, as long as the Sun is in the northern signs. The Sun then describes parallels around the horizon and never sets for him from the beginning of Aries to the beginning of Libra, and during that time the inhabitant under the south pole D has perpetual night. Conversely, when the Sun runs through the southern signs, the inhabitant under the south pole has perpetual day for about six months, and the other meanwhile a night of six months, that is, from the beginning of Libra to the beginning of Aries. 3. The shadows of gnomons describe with their tips a circle or a helix, because the Sun goes around them on every side in the space of 24^{h}. Yet by the force of refraction the Sun rises for these people before it reaches the equator.

V. Clavius, however, on p. 23 of the *Sphere*, thinks that according to Johannes de Sacrobosco's mind those living under the poles of the world dwell in the oblique sphere, insofar as dwelling in the right sphere does not apply to them. But Sacrobosco does not seem to have made an exhaustive division of the position of the sphere, since he left out the parallel sphere. Common to the oblique and parallel spheres is this: the day for those living toward or under one pole is as long as the night for those living toward the other pole and having an equal altitude of the pole; and for the same inhabitant the day is as long as the night was or will be when the Sun was or will be at the opposite point of the ecliptic. So if with the Sun at the beginning of Leo the day is of 15^{h}, the night will be of as many hours when the Sun is at the beginning of Aquarius. From this appears the admirable compensation and distribution of times made by the infallible Providence of God, Best and Greatest [D.O.M.].

But on the variety of artificial days in these spheres, see what we shall say more fittingly below, in Chapter 26.

CAPVT XX.

Quid sint Antipodes, Antœci, Periœci, Antiscij, Amphiscij, Heteroscij, Periscij: & de Vmbris Gnomonum; earumque diuerso situ, ac figura.

I. So that you may grasp the notions of these names more quickly, in the following diagram or description the horizon is HR and the meridian HARB; beneath it is the meridian of the terrestrial globe KPOM, and the equator AB, and the parallels KM and PO, equally distant from the equator. On these let there be four inhabitants, two in the upper hemisphere, K and P, and two in the lower, M and O. With this laid down:

Diagram. A large circle in the right column, with a smaller circle, the terrestrial globe, inside it at the centre. Four small human figures stand on the

inner circle, feet toward the centre, at K and P above and at M and O below. A horizontal line runs from H to R, a vertical line from A to B, and two diagonals cross at the centre, running from C at the upper left and D at the upper right toward F and E at the lower right and lower left. Twelve labels were read on the block, and no others were seen. The diagonals run from C to F and from D to E. Inside the inner circle two short vertical lines run from K to M and from P to O.

- A (top), B (foot): the printed text calls AB the equator and includes A and B in the meridian HARB
- H (left), R (right): the horizon HR
- C (upper left), D (upper right), E (lower left), F (lower right): not cited in the text on this page
- K (upper left of the inner circle), P (upper right): the two inhabitants of the upper hemisphere
- M (lower left of the inner circle), O (lower right): the two inhabitants of the lower hemisphere

[Margin: Antipodes. — Antipodes.]

II. *Antipodes* of an inhabitant on the Earth's surface are those who live in the place diametrically opposite on the Earth, and have the soles of their feet set against the soles of his. That is why they are called in Greek ἀντίποδες [Greek: antipodes, "with feet opposite"], which you might render in Latin as *Contrapedes*. Such, in the figure above, is the inhabitant M compared with the inhabitant P, and the inhabitant O with K; and in turn P is the antipode of M, and K of O. So they have all their geographical properties entirely opposite. The nadir of one is the zenith of the other; the moment of noon for one is that of midnight for the other; when the day is longest for one, the night is longest for the other, and the day for one is as long as the night for the other; the deepest winter of one is the height of summer of the other; the altitude of the north pole for one is as great as the altitude of the south pole for the other; when the Sun rises for one it sets for the other, and when it sets it rises; and the stars that always appear to one are always hidden from the other. Yet they agree in the size of the altitude of the pole and in having the identical horizon, which is one and the same for both, being described from the same vertical points. They are also called *Antichthones* by Pliny the Elder, Book 16, ch. 22, and *Antigenæ* by Albertus Magnus.

[Margin: Antœci. — Antoeci.]

III. *Antoeci* [Antœci], in Greek ἀντοίκοι [Greek: antoikoi, "those dwelling opposite"], in Latin *Contraccolæ* (for οἶκος [Greek: oikos, "house"] is a house or dwelling), are those who live on the opposite and equal parallel, and so one equally distant from the equator toward the other pole; and in the strict sense of this name, they are those who are also on the same meridian, and for whom noon occurs at the same moment, as K is with respect to P, and M with respect to O. In the broad sense, however, they are all who live on the antiparallel just mentioned, and in this way the antipodes too are included under this name, so

that every antipode is an antoecus, but not the reverse. An antoecus has the opposite equinox and solstice: what is the autumnal for the one is the vernal for the other, and what is the winter solstice for the one is the summer for the other, and vice versa. Likewise the day for one is always as long as the night for the other.

[Margin: Periœci. — Perioeci.]

IV. *Perioeci* [Periœci], in Greek περίοικοι [Greek: perioikoi, "those dwelling around"], in Latin *Circumcolæ*, are those who live on the same parallel and have the same altitude of the same pole, though under a different meridian, as those who live on the parallel PO. They have everything in common in the seasons of the year, in the length of days and nights, and in the position of shadows, but they differ in the reckoning of the hours and moments of the day. Some would have a perioecus, taken strictly, be one who lives at the diametrically opposite point of the same parallel, as O with respect to P, because a whole semicircle of the parallel must be travelled round to reach him; and for him it is midnight when it is noon for the other.

[Margin: Antiscij. — Antiscii.]

V. *Antiscii* [Antiscij], that is, *Contraumbres*, so called from shadow, which in Greek is σκιά [Greek: skia, "shadow"], are those who have shadows turned in the opposite direction. In this way, those in the southern frigid and temperate zones are antiscii with respect to those living in the northern frigid and temperate. But not all who live beyond the equator are antiscii on any given day with respect to those living on this side of the equator; they are so only on certain days. In this way that part of Arabia which lies further south and within the torrid zone is antiscian to Italy. Arabs migrating there to bring help to Pompey were astonished at their shadows, which in their own region they had found to point to the left, toward the south, and afterwards in Latium to point toward the north, which for the poets is the right-hand part of the world, as was said in Chapter 16, Scholium 4. Hence the line of Lucan:

Ignotum vobis Arabes venistis in orbem; Vmbras mirati nemorum non ire sinistras.

["You Arabs came into a world unknown to you, astonished that the shadows of the groves did not fall to the left."]

[Margin: Periscij. — Periscii.]

VI. *Periscii* [Periscij], that is, *Circumbres*, are those whose right shadows go round in a circle and describe with their tip what is almost the circumference of a perfect circle; from this carrying-round of the shadow they are called περίοικοι [recte: περίσκιοι] [Greek: periskioi, "shadowed all round"]. Such are those who live in the parallel sphere, that is, under the poles of the world.

[Margin: Heteroscij. — Heteroscii.]

VII. *Heteroscii* [Heteroscij] are those who have only one kind of shadow, as those who live within the temperate zones: for northerners within the temperate zone shadows extend only toward the north, and for southerners only toward the south.

[Margin: Amphiscij. — Amphiscii.]

VIII. *Amphiscii* [Amphiscij] are those of two shadows, that is, whose shadows are alternately southern and northern, according as they have the Sun now to the south and now to the north of the point overhead. Such are all who live within the torrid zone. Yet when the Sun is at their zenith, gnomons cast no right shadow at noon, and for this reason Pliny the Elder calls them *Ascii* [Ascij], that is, lacking shadows, which happens to them twice a year, as it does once to those who live under the tropics. From this comes Lucan's phrase about Syene, which lies under the tropic of Cancer: *Vmbras nusquam flectente Syene* ["with Syene nowhere bending its shadows"], which Strabo, Cleomedes and Pliny the Elder also affirm. Moreover, those within the torrid zone have two summers and two winters. But those who live in the northern part of the torrid zone have a colder winter with the Sun in Capricorn than in Cancer, and those in the southern part of the torrid zone have a colder winter with the Sun placed in Cancer. They have summer when the Sun is overhead. So for those living under the equator the equinoxes turn into summers, and in this respect they share in the solstitial altitude, that is, the highest. For this reason Lucan calls the equator the *circle of the high solstice*, in these verses:

Deprensum est hunc esse locum, quo circulus alti Solstitij medium signorum percutit orbem. ["It was found that this is the place where the circle of the high solstice strikes the middle of the circle of the signs."]

That is, it cuts the zodiac in two. For the Sun cannot be higher, and also produce greater heat (which are the chief properties of the summer solstice), than when it stands at an altitude of 90° and passes overhead; granted that Gassendi and others have understood by the name "high solstice" the summer solstice, as distinct from the winter one, in which the Sun is lower.

Hence those living within the torrid zone are said to have four solstices, two high and two low. For when the Sun is at their zenith, which happens twice a year, they have the height of summer and the greatest altitude of the Sun above the horizon. But when the Sun is at the beginning of Cancer or of Capricorn, they have two winters, and the Sun then has the least meridian altitude that it can have toward one of the poles. Granted, the etymology of "solstice" may not always hold true for them, and the Sun does not stand still in the manner we described in Chapter 15, no. 5.

SCHOLIA.

[Margin: Antipodas qui negarint. — Who denied the antipodes.]

I. Lactantius (Book 3 of the *Divine Institutes*, ch. 24), St Augustine (Book 16 of the *City of God*, ch. 9), Lucretius (Book 1) and certain other ancient theologians denied that there are antipodes, because they were said to be in another world. It was thought absurd that there should be people not redeemed by CHRIST, since it is commonly held that CHRIST came only to this world of ours and not to other worlds. And because Bishop Virgilius [Virgil of Salzburg] was thought to have spoken in this sense when he asserted that there are antipodes,

Pope Zachary, at the urging of St Boniface, Bishop of Mainz, ordered Virgilius to be suspended from sacred functions if he asserted the antipodes in such a way as to assert several worlds outside this one. This is plain from Zachary's letter, found in Baronius [Cesare Baronio], written to Utilo [Odilo], Duke of Bavaria, which M. Velserus [Markus Welser] also weighs learnedly in Book 5 of the *Rerum Boicarum*. So Zachary did not condemn all who asserted the antipodes, nor did he err on a question of law or of cosmographical history. If he erred, the error was on a question of fact, though not even on that, since he passed a hypothetical sentence, not an absolute one. Antipodes can, however, be said to be in another world in the sense in which the Indians and Americans are said to be in a new world, and Columbus to have discovered a new world, namely new parts of this world, previously unknown to us. But whether someone who asserted that there are human inhabitants on the Moon or on the other planets, and yet added that they belong to this world and that CHRIST died for them too, would deserve any censure other than that of rashness or novelty is not a matter to dispute here. Meanwhile, for retaining the antipodes, consult Cleomedes, *De mundo*, Book 1; Strabo, *Geography*, Book 1; Pomponius Mela, Book 1; Solinus, ch. 66; Macrobius, Book 2 on the *Dream of Scipio*; Martianus Capella, Book 6; Manilius, Book 1, ch. 4; Albertus Magnus, the book *De natura locorum*, dist. 1, ch. 10, and Book 2 of the *Meteora*, tr. 2, ch. 11; Stöffler on Proclus, p. 50.

II. The unlearned, however, think there are no antipodes, because they fear they would fall down. But they do not see that in standing or walking these people press and tend toward the same centre of heavy things, which is at the centre of the Earth, and that the same centre is downward for them and for us. What is the nadir for us is the zenith for our antipodes, and they can no more fall upward to their zenith than we can to ours, for that would be to ascend, not to descend. But O happy fall, if it should befall them and us and everyone, God willing, to fall into Heaven! Against the fantasy of these people see, I beg you, Pliny the Elder, Book 2, ch. 65, and Book 16, ch. 22, arguing it beautifully.

III. It can nonetheless be said that some part of the Earth's surface actually lacks antipodes, because on the opposite side there is no inhabited land, or there are only the waters of the sea, and fish that are *Apodes* [footless] rather than antipodes. In this way, to someone looking round an artificial terrestrial globe, almost all of Italy will appear to lack antipodes, unless perhaps sailors are sailing opposite it at the time.

[Margin: Vmbrarū linea figura diuerſa — The line of the shadows, of differing shape.]

IV. Although the tip of the shadow of a gnomon set upright on a horizontal plane describes an almost circular line for those living under the poles, which is why they are also called periscii, for others, living in the torrid zone and in the temperate zones, it describes a straight line on the day of the equinox, and on the other days a hyperbolic, parabolic or elliptical line. The writers on gnomonics demonstrate this from the *Conics* of Apollonius, and Maurolico

teaches it briefly in Dialogue 2, in these words: "The plane on which the shadow is cast either cuts the parallel or does not. If it cuts it, then the extremity of the shadow describes a hyperbola in the plane. If it does not cut it, then it either touches the parallel or does not. If it touches it, then the top of the shadow describes a parabola in the plane. If it does not touch it, then it either is equidistant from the parallel or is not. If it is equidistant, the shadow describes a circle in the plane; if not equidistant, an ellipse." By the term "plane" he means the whole circle of the horizon. Thus every horizon in which the pole rises less than 66° 30′ has, outside the equinoctial days, a hyperbolic shadow: for such a horizon cuts the parallels on which the Sun stands. But for those living beneath the Arctic or Antarctic circle, that is, those for whom the pole is raised 66° 30′, the shadow is parabolic on their summer solstitial day, because their tropic then touches the horizon; on the other days they have a hyperbolic shadow. Finally, those for whom the pole rises higher than 66° 30′ have at times hyperbolic shadows, at times parabolic and at times elliptical; but if it rises 90°, circular ones.

V. On the ratio of the equinoctial and the solstitial shadow to the gnomon, it will be more fitting to speak in the Geographical Book.

CAPVT XXI.

De Alijs Sphæræ Circulis Capite 7. nominatis.

On the other circles of the sphere named in Chapter 7.

[Margin: Almincantarath. — Almucantar.]

I. ALMVNCATARATH, commonly Almincantarath, circles, so called by an Arabic name, are circles parallel to the horizon, and thus described from the poles of the horizon and drawn through the altitudes of stars or of celestial points. So in the figure added here, let the horizon be HOR and the meridian HVRN, and let a star be at S. Through it let the circle ASL be drawn, parallel to the horizon HOR and described from its pole, the zenith V: this will be an almucantar circle.

Diagram. A circle set into the left column under the opening of Chapter XXI, the text wrapped down its left side. Curved meridians run from top to foot, with a straight vertical between them; horizontal lines cross the circle at intervals, not counted against the prose. A six-pointed star stands at S. Labels read on the block: ten. No others were seen. The referents below are the ones the page's own prose assigns.

- V (top): the zenith and vertex
- A (upper left): on the parallel ASL
- S (upper left, beside the star): the star, on the parallel ASL
- L (upper right): on the parallel ASL
- H (left): on the horizon HOR and the meridian HVRN
- R (right): on the horizon HOR and the meridian HVRN

- Z (left of centre, below the horizontal line HR): on the circle of altitude VZNMV
- O (centre, below the horizontal line HR): on the horizon HOR and the vertical VON
- M (right of centre, below the horizontal line HR): on the circle of altitude VZNMV
- N (foot): the nadir

[Margin: Altitudinis Circulus. — Circle of altitude.]

II. The *circle of altitude* [Altitudinis Circulus], by another name the *vertical* [Verticalis], is a great circle of the sphere drawn through the vertex and the lowest point, that is, through the inhabitant's zenith and nadir, with its poles on the horizon. By 13 and 15 of Book 1 of Theodosius it therefore cuts the horizon at right angles. It is called the circle of altitude because on it is measured the altitude of a star or of any other object visible on the sphere; this altitude is as great as the arc of the vertical circle intercepted between the object and the horizon. So in the figure just given, if a star is at S, and the circle VZNMV is drawn through it, the vertex V and the nadir N, this will be the circle of altitude, and the altitude of the star S will be the arc ZS, while its complement to 90°, the arc SV, will be the star's distance from the vertex. When, however, a star is considered below the horizon, as if it were in the quadrant ZN, the circle is called the circle of depth [Profunditatis] or of immersion [Demersionis]. There are as many verticals as there are points on the horizon. Chief among them are the meridian (for every meridian is a vertical, although not every vertical circle is a meridian) and the *prime vertical* [Verticalis Primarius], namely the one that passes through the points of equinoctial rising and setting, as VON does. Finally, a common vertical is one that passes through the vertices of several places.

III. The *circle of right ascension* [Ascensionis Rectæ circulus] is the same as the equator, or the circle of declination, of which more shortly.

[Margin: Azimuthalis Circulus. — Azimuthal circle.]

IV. The *azimuthal circle* [Azimuthalis Circulus] is the same as the rational horizon, if it is taken as the measure between the meridian and the other vertical circles; otherwise the Arabs call the vertical circles azimuths [Azimutha].

[Margin: Declinationis Circulus. — Circle of declination.]

V. The *circle of declination* [Declinationis Circulus] is a great circle of the sphere passing through the poles of the world and having its own poles on the equator, and therefore cutting the equator at right angles, by 13 and 15 of Book 1 of Theodosius. It is so called because on it are taken the declinations of celestial points or of stars, that is, their distances from the equator: for the declination, say of a star, is as great as the arc of this circle intercepted between the equator and the star's centre. So in the following figure, let the horizon be HGR, the meridian HERQ and the equator EOQ; let the poles of the equator, or of the world, be A the southern and B the northern; and let the circle drawn through the poles of the world and through the star's centre be AOBIA, for

this will be a circle of declination. So if a star is at O or at I, it will have no declination; but if it is at S, on the parallel CN, its northern declination will be the arc OS, and the complement of the declination the arc SB. But if the star is at M, or if the declination of the parallel KP is sought, the southern declination of either will be the arc MO, and the complement of the declination the arc MA. Similarly, if the star were on the horizon, as at G or at F, the northern declination would be the arc FI, and the southern GO.

Diagram. A circle set into the right column, the text wrapped down its left side. A horizontal line, two near-vertical lines, an arc from A to B through the centre region and oblique lines cross it; six-pointed stars stand beside S, O, M, G, I and F. Labels read on the block: seventeen, one of them undecided. No others were seen. Referents are those the page's prose assigns; line end-points were not traced.

- K (upper left): on the parallel KP
- E (top): on the meridian HERQ and the equator EOQ
- C (top, right of E): on the parallel CN
- B (upper right): the northern pole
- S (upper centre, beside a star): the star at northern declination, on the parallel CN
- O (upper centre, beside a star): on the equator EOQ and the circle AOBIA; set small and not cleanly distinct from c on the scan
- M (left of centre, beside a star): the star at southern declination
- H (left): on the horizon HGR and the meridian HERQ
- R (right): on the horizon HGR and the meridian HERQ
- G (left of centre, beside a star): on the horizon HGR
- a small letter at the centre, a turned capital D: not cited in the prose of this paragraph; a page below (Chapter XXII, para. XIV) cites a point D on this figure, and that citation has not been used to settle the letter
- F (right of centre, beside a star): on the horizon
- A (lower left): the southern pole
- I (lower centre, beside a star): on the circle AOBIA
- P (foot): on the parallel KP
- Q (foot, right of P): on the meridian HERQ and the equator EOQ
- N (lower right): on the parallel CN

Gather from the definition that any meridian is a circle of declination, but not conversely; and the same goes for the colures. And because right ascension, discussed below, ends at the point where the equator is cut by a circle of declination, that circle is called the circle of right ascension.

[Margin: Circuli Domorum. — Circles of the houses.]

VI. The *circles of the celestial houses* [Domorum Cœlestium Circuli] are great circles of the sphere drawn through the common intersections of the meridian and the horizon, and dividing into twelve equal parts: either the equator, following the rational way of Avraham ibn Ezra and of Regiomontanus; or the prime vertical, following the way of Campanus and Gazulus; or the semidiurnal

and seminocturnal arcs separately, and by means of them the equator, following the way of al-Qabīṣī and of Johannes de Saxonia; or the equator into 12 parts corresponding to as many temporal hours, or to the intersections of the hour circles, following the way of Ptolemy. On this see below, in the chapter on the celestial theme. Some, however, prefer to draw these circles through the poles of the equator, others through the poles of the zodiac, and in that case they reject the meridian and use another circle.

[Margin: Horarij circuli. — Hour circles.]

VII. *Hour circles* [Horarij circuli] are great circles of the sphere whose poles lie on the equator, drawn through the poles of the equator and through points of the equator that intercept 15° each, that is, the single hourly intervals. All hour circles are therefore in fact circles of declination, but not conversely. For an example of them see the following figure, in which the horizon is HR, the meridian HQBRA, the equator EQ, the poles of the equator, or of the world, B and A, and then the remaining hour circles. The meridian itself is the circle of hour 12, both from noon and from midnight, and so for the remaining 10; for each of them serves for two opposite hours, as for the first after noon and the first after midnight. From this is distinct the circle of the eleventh hour after noon or midnight, although in the figure, to avoid multiplicity, they seem to coincide. When, however, the 24 hours are unequal, or begin from rising or setting, they are drawn otherwise.

Diagram. A circle set into the right column, the text wrapped down its left side. A horizontal line HR crosses it, and a sheaf of curved hour circles converges from A at lower left to B at upper right. A straight line runs from Q at the top to E at the foot, with hour numerals set slantwise along it on both sides. Labels read on the block: six letters, and the numerals below. The referents are the ones the page's prose assigns.

- Q (top): on the meridian and the equator EQ
- B (upper right): a pole of the equator or world
- H (left): on the horizon HR
- R (right): on the horizon HR
- A (lower left): a pole of the equator or world
- E (foot): on the equator EQ
- Numerals, upper half of the line: 12, 11, 10, 9, 8, 7 running down from the top on its left side, and 1, 2, 3, 4, 5, 6 running down on its right side; the sequences were read at the scale of the page and not checked sort by sort
- Numerals, lower half of the line: 7, 8, 9, 10, 11, 12 running down on its right side; on its left side 5, 4, 3, 2, 1 were made out, and a sort at the head of that run could not be settled [?]

[Margin: Latitudinis Circulus. — Circle of latitude.]

VIII. The *circle of latitude* [Latitudinis Circulus] is a great circle of the sphere whose poles lie on the ecliptic, drawn through the poles of the ecliptic and so cutting it at right angles. It is called the circle of latitude because on it the latitude of the stars, that is, their distance from the ecliptic, is measured and

taken: for the latitude of a star is as great as the arc of this circle intercepted between the ecliptic and the star's centre. So in the following figure, let the horizon be HR and the meridian and colure of the solstices HZRQ, the ecliptic ZC, the equator EQ, and the poles of the ecliptic G the southern and P the northern. The circle GIPLG drawn through them will be a circle of latitude. If a star is at I, it will have no latitude; if at K, its northern latitude will be the arc IK and its complement the arc KP; but if at F or at L, its southern latitude will be, for example, the arc FI, and the complement of the latitude the arc FG or LG. From what has been said you will gather that the colures and the meridian can sometimes be circles of latitude, since they can pass at once through the centre of a star and through the poles of the ecliptic.

Diagram. A circle at the head of the left column, the text wrapped down its left side. A horizontal line, an ellipse-like arc and oblique lines cross it; six-pointed stars stand at K, at L, and at a point left of centre near I. Labels read on the block: fourteen. Letters at left of centre are faint on the scan. Referents are those the page's prose assigns; line end-points were not traced.

- Z (top): on the meridian HZRQ and the ecliptic ZC
- E (upper left): on the equator EQ
- B (upper right): not cited in this paragraph
- P (upper right): the northern pole of the ecliptic
- I (upper centre): on the circle GIPLG
- K (right of centre, beside a star): the star at northern latitude
- F (left of centre, below a star; faint): the star at southern latitude
- H (left; faint): on the horizon HR and the meridian HZRQ
- R (right): on the horizon HR and the meridian HZRQ
- G (lower left): the southern pole of the ecliptic
- L (lower centre, beside a star): on the circle GIPLG
- A (lower left, outside the rim): not cited in this paragraph
- C (foot, right of centre): on the ecliptic ZC
- Q (lower right): on the meridian HZRQ and the equator EQ

[Margin: Longitudinis Circulus. — Circle of longitude.]

IX. The *circle of longitude* [Longitudinis Circulus] is taken by some for the ecliptic, because the motion in longitude is counted along it; by others, however, for the circle of latitude, inasmuch as that same circle determines the longitude of a point or star at the place where it cuts the ecliptic, according to what will be said below in Chapter 22, in the definitions.

[Margin: Positionis Circulus. — Circle of position.]

X. The *circle of position* [Positionis Circulus] is a great circle of the sphere passing through the common intersections of the horizon and the meridian, and through a star or a place on the surface of the sphere that lies under a meridian different from the meridian of that star or place with respect to which its position is being considered. It is therefore a kind of movable horizon. So in the following figure, with the meridian HVR etc., the horizon HAR and the star or place P, the great circle HPR drawn through P, passing through the

points H and R at which the horizon and the meridian cut each other, is the circle of position that the star or place P has with respect to the point lying under the vertex V. The poles of this circle lie on some other horizon. When the quadrant of the vertical circle VA is drawn through P, the *angle of position* [Angulus Positionis] HPV or RPV arises.

Diagram. A circle in the left column, the text wrapped down its left side. A horizontal line runs across it from H to R, an arc rises from H through P to R, and a line descends from V through P to A. Labels read on the block: five. No others were seen.

- V (top): the vertex
- P (above centre): the star or place
- H (left): on the horizon HAR, the meridian and the circle HPR
- A (centre, below the horizontal line): on the horizon HAR and the quadrant VA
- R (right): on the horizon HAR, the meridian and the circle HPR

Besides these circles there are many others: namely the parallels to the equator, which the stars describe by the diurnal motion of the primum mobile, and which are described from the poles of the equator; likewise the parallels to the ecliptic, also described from its poles, which the stars describe by their motion in longitude; and the parallels to the meridians, which we will show in the Geographical Book, in the section on histiodromy, can be described by natural motion on the surface of the land or sea. Finally, there is the circle of the distance of the stars, which is a great circle and passes through the centres of two stars.

CAPVT XXII.

In quo Definitiones Arcuum, & Angulorum insignium ad Circulos Sphæræ pertinentium, nec non ipsorum Circulorum ordine Alphabetico.

In which are definitions of the notable arcs and angles pertaining to the circles of the sphere, and of the circles themselves, in alphabetical order.

[Margin: Altitudo syderis qu? — What the altitude of a star is.]

I. The ALTITUDE of a star [Altitudo Syderis], or of a point visible on the sphere, is the arc of a great circle drawn through the vertex, intercepted between the star or that point and the horizon. Its remainder to 90°, that is, to the quadrant, is called the *complement of the altitude* [Complementum Altitudinis]. This is the same as the star's distance from the vertex, and it is the arc of the vertical circle intercepted between the vertex and the star's centre. If the vertical is the meridian, it is called the *meridian altitude* [Altitudo Meridiana], and on that day it is the greatest. See the figure of Chapter 21, no. 2. The altitude is *true* [Vera] if the star's true place is considered, and *visible or apparent* [Visa seu apparens] if its place is seen elsewhere because of parallax or refraction.

[Margin: Almincatarath. — Almucantar.]

II. The *almucantar* [Almincatarath] is for some the altitude of a star itself; for others, a circle parallel to the horizon, drawn through a star that stands high above the horizon. On this see Chapter 21, no. 1.

[Margin: Amplitudo Ortiua. — Ortive amplitude.]

III. The *ortive amplitude* [Amplitudo Ortiua] of a star or celestial point is the arc of the horizon between its most northerly and its most southerly rising: the true rising if the amplitude is true, the apparent if it is apparent. So the Sun's ortive amplitude, the true one, is the arc of the horizon comprehended between the tropics.

[Margin: Amplitudo Occidua. — Occiduous amplitude.]

IV. The *occiduous amplitude* [Amplitudo Occidua] of a star etc. is the arc of the horizon between the most northerly and the most southerly setting of the star etc.: the true setting if the true amplitude is considered, the apparent if the apparent. The amplitude of the other planets is greater than the Sun's ortive and occiduous amplitude by as much as their greatest declination doubled.

[Margin: Angulus Sphæralis. — Spherical angle.]

V. The *spherical angle* [Angulus Sphæralis, seu Sphæricus], taken strictly, is an angle made on the surface of a sphere by the meeting of two arcs that are portions of a great circle of the sphere; or it is the inclination of those two arcs. Taken broadly, it is the inclination or meeting of any two arcs of spherical circles.

[Margin: Angulus Eclipticæ & Meridiani. — Angle of the ecliptic and the meridian.]

VI. The *angle of the ecliptic and the meridian* [Angulus Eclipticæ, & Meridiani] is the spherical angle made by an arc of the ecliptic and an arc of the meridian. At the solstitial points it is a right angle; at the others it is oblique. But once it is known, there are also known both the other angle vertically opposite it, because that is equal to it, and the other that follows next to it, because that is its complement to two right angles, that is, to 180°. Further, such angles at points of the ecliptic equally distant from the equinoctial points are equal to one another; so to construct the table of the angles of the ecliptic and the meridian, which we will give in its place, it is enough to build it for one quadrant of the ecliptic.

[Margin: Angulus Eclipticæ, & Horizōtis. — Angle of the ecliptic and the horizon.]

VII. The *angle of the ecliptic and the horizon* [Angulus Eclipticæ, & Horizontis] is the spherical angle that the portion of the ecliptic standing above the horizon makes with the horizon. Once this angle is known, the one next to it is also known, since it is its complement to 180°. It is also called the angle of the *east* [Orientis] or of the *ascendant* [Ascendentis], meaning the ascendant point of the ecliptic, because it is generally observed in the eastern part of the horizon; although there corresponds to it on the opposite side an equal angle in the west, where the point of the ecliptic diametrically opposite the ascendant point is then setting.

[Margin: Anguli aliorū Circulorum. — Angles of other circles.]

VIII. The *angle of any two circles* [Angulus duorum quorumuis circulorum] is the one made by any two arcs of any two circles, especially great circles. Of this kind are the angle of the equator and the meridian, which is always a right angle; of the equator and the horizon, which in a right sphere is right and in an oblique sphere oblique, and as great as the altitude of the equator, speaking of the acute angle; the angle of the equator and the circle of declination, which is always right; of the equator and the circle of latitude; of the ecliptic and the equator, and this one is 23° 30′; of the ecliptic and the circle of latitude, and this one is always right; of the ecliptic and the circle of declination; likewise the angle of the ecliptic and the vertical; and also of the circles of declination and latitude; of the circles of declination and the vertical; of latitude and the vertical; likewise of the circles of declination and the horizon; of the circles of latitude and the horizon; and of the vertical circle and the horizon, which is always right; and so on for the other comparisons of circles, whether the centres of stars or other points of the sphere are considered in those angles.

[Margin: Ascensio syderis, & Descensio. — Ascension of a star, and descension.]

IX. The *ascension of a star* [Ascensio Syderis] or of a point of the ecliptic is the arc of the equator counted from the vernal section, that is, from the beginning of Aries, toward the east, up to that point of the equator which rises above the horizon together with that star or point of the ecliptic by the motion of the primum mobile. Its *descension* [Descensio] is the arc of the equator counted from the beginning of Aries toward the east, up to that point of the equator which sets below the horizon with that star or point. Thus the simultaneous co-rising or co-setting of parts of the equator with some star is called its ascension or descension, because of the connection it has with the motion of the primum mobile, of which the equator is the measure. For example, if at Rome, at the moment when 3° of Leo rises, degree 106 and minute 40 of the equator rises with it, counted from the vernal section toward the east, that degree and that minute of the equator are called the ascension of 3° of Leo, because they end the arc of the equator that has been ascending from the rising of the beginning of Aries up to the moment when 3° of Leo rises.

[Margin: Ascensionis Recta duplex notio. — The twofold notion of right ascension.]

X. The *right ascension* [Ascensio Recta] of a star or of a point of the ecliptic, and the *descension*, taken as opposed to oblique ascension, in the way commonly used in astronomical tables bearing this title, is the ascension or descension that occurs in a right sphere, because there the equator makes right angles with the horizon, with whatever star or point of the ecliptic it may rise. In the same way *oblique ascension and descension* [Ascensio, & Descensio Obliqua] is that which occurs in an oblique sphere, because of the obliquity of the angles that the equator has there with the horizon, which is indeed very variable. The right ascension of points of the ecliptic rising above a right horizon is as great as their

transit across the meridian in any horizon whatever; that is, as great as the arc of the equator counted from the beginning of Aries toward the east, up to that point of the equator which crosses the meridian, or Midheaven [Medium Cæli], at the moment when that point of the ecliptic crosses the same meridian. The reason is that any meridian is the horizon of someone living in a right sphere. Hence it has come about that astronomers begin the time of the primum mobile from noon rather than from rising or from setting, so that an equal time would correspond for every sphere. But because the stars move toward the east by their own motion, in the time that elapses between rising and transit across the Midheaven the arc of the equator varies somewhat, and the arc that ascends and the arc that crosses the meridian are not strictly the same.

[Margin: Ascensionis Recta altera notio. — The other notion of right ascension.]

XII [recte: XI]. *Right ascension taken as slow*, as it is taken by Pliny the Elder (Book 2, 19), by Manilius and by the ancients, and likewise descension: that is, comparatively, not with respect to the angles of the equator with the horizon but with respect to the arc of the ecliptic counted from the beginning of Aries toward the east up to the point of the ecliptic rising or setting with the point of the equator. It occurs when the arc of the equator is greater than the said arc of the ecliptic, for more time is required; and then that point of the ecliptic, and the whole preceding arc of the ecliptic, is said *to ascend rightly* [rectè ascendere], that is, to ascend more rightly or more slowly. Say the same of a star having the same longitude as that point of the ecliptic which ascends or descends rightly. Conversely, *oblique ascension and descension* taken as less slow is when the arc of the equator ascending or descending with a point of the ecliptic, or with a star having the same longitude, is smaller than the said arc of the ecliptic. For then it ascends or descends more quickly. See the rules to be given separately in the next chapter.

XII. The *right ascension of the Midheaven* [Ascensio Recta Medij Cæli] is the arc of the equator counted from the beginning of Aries toward the east, up to the point of the equator that crosses the Midheaven, or meridian, at any given moment of the day; whether it is considered absolutely, as is often done, or with a point of the ecliptic or a star then crossing the meridian. For brevity, astronomers usually indicate the Midheaven with the letters MC. What the mediation of the heaven [Mediatio Cæli] is, with respect to the stars, I will say below.

[Margin: Horoscopus. — Horoscope.]

XIII. The *ascendant* [Ascendens], or *horoscope* [Horoscopus], is the point of the ecliptic rising at some determined moment of the natural day, say the moment at which an infant is conceived or born. It is so named from two Greek nouns: ὥρα [Greek: hōra, "hour"], which means hour, and σκόπος [Greek: skopos, "target"], which means the target on which one must take aim. For the whole condition of future time is believed to depend on that point; and therefore that moment and point of the ecliptic must be set up as

the chief target at which astrological consideration is to be directed, and must be established before everything else.

[Margin: Ascensionalis Differentia. — Ascensional difference.]

XIV. The *ascensional difference* [Ascensionalis differentia] of a point of the ecliptic or of a star is the arc of the equator intercepted between the point of the equator co-rising with that point of the ecliptic or star and the circle of declination drawn through that point of the ecliptic or through the star's centre. Because this arc is always as great as the difference between right and oblique ascension, some usually define it by saying that it is the difference between the right and the oblique ascension of the point or star. So once tables of ascensional difference have been made, tables of oblique ascensions are easily constructed, as we will teach in its place. To assist the imagination, look at the figure of Chapter 21, no. 5, in which let a star be at F, rising at a point of the horizon, and let the circle of declination drawn through that point be BFIA, etc. For the arc of the equator DI will be the ascensional difference of the star F, and the point co-rising with it will be the point D of the equator.

[Margin: Azimutha quid sint? — What azimuths are.]

XV. *Azimuth*, and with a Latin declension *Azimuthum*, is an Arabic noun signifying the arc of the horizon intercepted between the meridian and the point of the horizon at which a star or point of the ecliptic stands; or through which point of the horizon there passes that vertical circle on which the star or point of the ecliptic stands. If this arc of the horizon is eastern it makes an eastern azimuth; if western, a western azimuth. The complement of the azimuth, which some confuse with the azimuth, is the remaining arc of the horizon needed to complete the quadrant, that is, the arc from there to the point of the prime vertical. So in the first figure of Chapter 21, if a star is at Z or at S, on a point of the vertical passing through Z, the azimuth of that star will be the arc HZ, and the complement of the azimuth the arc ZO.

Colure: see Chapter 15. *Climate*: see Chapter 17.

[Margin: Cōplementum arcus quid? — What the complement of an arc is.]

XVI. The *complement of an arc* or of an angle [Complementum Arcus, vel Anguli] is the remaining arc needed to complete the quadrant, that is, the fourth part of the circle: in other words, what is required to reach 90°. For example, if a latitude, or an arc of latitude, is 30° 20′, its complement will be 59° 40′; for the sum of these makes up the quadrant of the circle, which comprehends a right angle. The complement is obtained at once if the given arc or angle is subtracted from 90°.

XVII. A point of the heaven is said to be *culminating* [Culminans], or to *culminate* [Culminare], as a star also is, that crosses the meridian, or at the time when it crosses it, especially if at the same time it crosses through the zenith.

XVIII. The *declination* [Declinatio] of a star or of a celestial point is the arc of a great circle drawn through the poles of the equator, intercepted between the equator and the centre of that star, or that point.

XIX. The *circle of declination* is a great circle of the sphere having its poles on the equator, and drawn through the poles of the same equator and through the centre of the star, or the point, whose declination is being considered. See Chapter 21, no. 5.

XX. *Descension*, right or oblique: see what was said above, nos. 9, 10 and 11.

XXI. *Direction* [Directio], or the *directory arc* [Directorius arcus], is the arc of the equator between two right ascensions, or two oblique ones, one of the promissor, the other of the significator; that is, of the celestial point that promises or signifies something in the future, say the death of the native.

XXII. The *distance of the poles* [Distantia Polorum], namely of the pole of the equator from the pole of the ecliptic, is the arc of the colure of the solstices intercepted between the pole of the equator and the nearer pole of the ecliptic. It is as great as the obliquity of the ecliptic, or as the Sun's greatest declination. For me, always 23° 30′.

XXIII. The *distance of the tropics* [Distantia Tropicorum] is the arc of the meridian intercepted between the tropics; for me, always exactly 47°.

XXIV. The *distance of the stars from one another* [Distantia syderum inter se] is the arc of a great circle on the sphere, drawn through the centres of two stars at once, intercepted between those two stars. It is true if the true place of the stars is considered; visible or apparent if the visible place is considered, which differs from the true one because of parallax or refraction.

XXV. *Dodecatemorion*, in Greek δωδεκατημόριον [Greek: dōdekatēmorion, "twelfth part"], is a twelfth part: usually of the zodiac, but among some writers sometimes of the equator; or it is one of the 12 celestial houses.

XXVI. *Hour circle*: see Chapter 21, no. 7.

XXVII. *Horizon*: rational, astronomical, natural; or sensible, physical and artificial. See Chapter 8.

XXVIII. *Horoscope*: see *Ascendant*.

XXIX. The *latitude of a star* [Latitudo syderis] is the arc of a great circle drawn through the poles of the ecliptic, intercepted between the ecliptic and the star's centre. It is true if the star's true place is considered, and apparent if its apparent place is considered.

XXX. *Circle of latitude* [Latitudinis circulus]: see Chapter 21, no. 8.

XXXI. *Geographical latitude* [Latitudo Geographica]: see Chapter 13.

XXXII. The *longitude* [Longitudo] of a star or of a point of the ecliptic is the arc of the ecliptic counted from the beginning of Aries toward the east as far as the circle of latitude passing through the star's centre, or as far as the great circle drawn through the poles of the ecliptic and the star's centre. Thus in the figure of Chapter 21, no. 8, if a star is at K and the beginning of Aries at Z, and through K is drawn the circle of latitude PKIG, cutting the ecliptic at I, the longitude of the star K will be the arc of the ecliptic ZI. It is true with respect to the true place, and visible if the visible place lies elsewhere because of parallax or refraction.

XXXIII. The *circle of longitude* [Longitudinis Circulus] is the same as the circle of latitude, since it performs a double office: that of measuring latitude and that of terminating longitude.

XXXIV. *Geographical longitude* [Longitudo Geographica]: see Chapter 13.

XXXV. The *mediation of the heaven* [Mediatio Cæli] is the point of the ecliptic that crosses the meridian together with some star; for some writers, however, it is the same as right ascension.

XXXVI. The *nonagesimal degree of the ecliptic* [Nonagesimus gradus Eclipticæ] is the degree or point of the ecliptic 90° distant from the rising point of the ecliptic. So, once the nonagesimal is known, if 90° are added to it, the rising point of the ecliptic becomes known; and if the rising point of the ecliptic is already known, subtract 90° from it and the nonagesimal of the ecliptic will become known. Note, moreover, that the vertical circle passing through the nonagesimal of the ecliptic is also a circle of latitude.

XXXVII. The *obliquity of the ecliptic* [Obliquitas Eclipticæ] is the angle made by the ecliptic and the equator at the equinoctial points. It is as great as the Sun's greatest declination, and for me it is always 23° 30′.

XXXVIII. *Polar circle* [Polaris Circulus]: see Chapter 16, no. 4.

XXXIX. The *pole of the horizon* [Polus Horizontis] is the same as the vertical point or its lowest point, that is, the zenith and the nadir.

XL. *Circle of position* [Positionis circulus]: see Chapter 21, no. 10.

XLI. The *depth of a star* [Profunditas syderis] is the arc of a vertical circle intercepted between the horizon and the centre of a star placed below the horizon.

XLII. *Circle of those always visible* [Semper Apparentium Circulus]: see Chapter 17.

XLIII. *Vertical circle* [Verticalis Circulus]: see Chapter 21, no. 2.

XLIV. The *zenith* is the vertical point, to which the diametrically opposite point is the nadir.

XLV. *Zone* [Zona]: see Chapter 16, no. 5.

CAPVT XXIII.

Regulæ Selectę de Ascensionibus Signorum, & Punctorum Eclipticæ.

Select rules on the ascensions of the signs and of the points of the ecliptic.

In Chapter 22, nos. 10 and 11, we set out what right ascension and right descension are, and we promised select rules about them, which we now bring out.

I. Rule. *In the right sphere*, Gemini, Cancer, Sagittarius and Capricorn, taken singly, ascend and descend rightly, that is, slowly; the other eight signs ascend and descend obliquely, that is, quickly. The reason is that in the right sphere more than 30 degrees rise with the four signs named, namely 32° 12′, and fewer with the others, as you will learn from the little table below, taken from the complete table of right ascensions.

Ascension and descension of the signs in the right sphere				Degrees and minutes of ascension and descension
♈ Aries	♍ Virgo	♎ Libra	♓ Pisces	27° 54′
♉ Taurus	♌ Leo	♏ Scorpio	♒ Aquarius	29° 54′
♊ Gemini	♋ Cancer	♐ Sagittarius	♑ Capricorn	32° 12′
Quadrant of the ecliptic I	Quadrant of the ecliptic II	Quadrant of the ecliptic III	Quadrant of the ecliptic IV	90° 0′, sum

II. Rule. *In the right sphere*, any quadrant of the ecliptic ascends or descends neither slowly nor quickly, that is, neither rightly nor obliquely in this sense, since 90° of the equator, or a quadrant of the equator, ascend or descend with it.

III. Rule. *In the right sphere*, any two arcs of the ecliptic that are equal and opposite, or equally distant from the prior equinox or solstice, have equal ascensions and descensions, taken singly. Thus the ascension of Taurus equals that of Leo, because they are equally distant from the point of the summer solstice, as you can gather as a sample from the preceding little table. Consequently, once the right ascensions of one quadrant of the ecliptic have been worked out by trigonometry, the ascensions of the remaining signs for the remaining three quadrants easily become known.

IV. Rule. *In the right sphere*, the descension of a sign or of a point of the ecliptic equals its ascension, because descension on one right horizon is ascension on the other right horizon, that of the antipodes.

[Margin: Signa Rectæ & Obliquæ Ascensionis. — Signs of right and of oblique ascension.]

V. Rule. *In the oblique sphere*, among northern peoples, Cancer and the five signs following it ascend rightly, that is, slowly, but descend obliquely; the other six signs ascend obliquely for them and descend rightly. Among southern peoples, however, Capricorn and the five signs succeeding it ascend rightly and descend obliquely, and the other six ascend obliquely for them and descend rightly. This assumes that they rise and set; for if the pole is elevated beyond 66° 30′, certain signs neither ascend nor descend for northern and southern peoples. So those verses of Manilius hold for the oblique sphere, but among northern peoples and on this side of the Arctic circle:

> They go upright, they fall aslant, from the star of Cancer until
> Chiron ends; but the other signs are born prone, and go down on
> a straight path.

[Recta meant, Obliqua cadunt à sydere Cancri / Donec finitur Chiron; sed cœtera signa / Nascuntur prono; descendunt tramite recto.]

Let this stand here as your evidence of these things, from the fuller tables of oblique ascensions, for three altitudes of the north pole.

Ascension of the signs taken separately in the northern oblique sphere.

Altitude of the pole		30°	45°	60°
♈ Aries	♎ Libra	21° 9′	16° 10′	7° 16′
♉ Taurus	♏ Scorpio	24° 22′	20° 3′	10° 56′
♊ Gemini	♐ Sagittarius	29° 55′	28° 1′	22° 56′
♋ Cancer	♑ Capricorn	34° 29′	36° 23′	41° 28′
♌ Leo	♒ Aquarius	35° 26′	39° 45′	48° 52′
♍ Virgo	♓ Pisces	34° 39′	39° 38′	48° 32′
Sum of the semicircle		180° 0′	180° 0′	180° 0′

6

VI. Rule. *In the oblique sphere*, the whole northern semicircle of the signs and the whole southern, among northern and southern peoples alike, ascend and descend in a middling manner, since neither more nor fewer than 180 degrees of the equator ascend or descend.

VII. Rule. *In the oblique sphere*, any two equal arcs of the ecliptic that are equally distant from the nearer equinoctial point have equal ascensions, taken separately from the others and compared with each other. See the little table of Rule 5.

VIII. Rule. *In the oblique sphere*, any two arcs of the ecliptic that are equal and opposite have ascensions, taken together, equal to the ascensions of the same arcs made in the right sphere. For example, at an altitude of the pole of 45°, the ascensions of Aries and Libra, opposite signs, taken together come to 55° 48′, as you will learn from the little table of Rule 5. But if from the little table of the first rule you add up the right ascensions of Aries and Libra, the sum will be exactly 55° 48′.

From this rule and the preceding one there arises a remarkable short cut. It is enough, for any altitude of the pole, to gather the ascensions of one quadrant of the ecliptic; for from these, and from the ascensions of the same quadrant in the right sphere, you will gather the ascensions of the remaining three quadrants in the oblique sphere. To construct tables of oblique ascensions for all altitudes of the pole, moreover, there suffice

5985 analyses of triangles, which would otherwise have to be four times as many. You will obtain the same thing more easily, however, through the ascensional differences, as Clavius teaches in the *Sphaera*, p. 337, and as we do in the Problems of the primum mobile.

IX. Rule. *In the oblique sphere*, signs or arcs of the ecliptic that ascend rightly, that is, slowly, descend obliquely, that is, quickly.

X. Rule. *In every sphere*, right or oblique, the descension of any sign or arc equals the ascension of the opposite sign or arc. So tables of descensions are

[6]The second column of signs is printed in this order, Libra at the top and Pisces at the foot. Rule VII below makes signs equally distant from the nearer equinox equal, and the sum of 55° 48′ for Aries and Libra at altitude 45° in Rule VIII is reached from the first and last rows of the table, so the text uses the signs of this column in the reverse order.

not necessary, since descension can be gathered sufficiently and easily from the tables of ascensions.

XI. Rule. *In every sphere*, right or oblique, the ascension and descension of the same sign or arc, taken together, are equal to the ascension and descension, taken together, of the opposite sign or arc. This in fact follows from Rule 10.

XII. Rule. *In the oblique sphere*, signs that ascend rightly among northern peoples ascend obliquely for southern peoples, and those that ascend obliquely for northern peoples ascend rightly for southern peoples, and so on.

SCHOLION.

All the preceding rules are proved both from the Problems of the primum mobile, by inquiring *a posteriori* through the analysis of triangles into the arcs of ascensions and descensions from their own data; and from the revolution of the armillary sphere, by comparing the degrees of the equator that rise together or set together with the degrees of the ecliptic, and seeing whether they are more or fewer.

Those verses of Lucan, Book 1 (*Non obliqua meant*, etc.), are moreover to be understood of the right sphere, and to be read in the order that our Clavius brings out from Petrus Iacobus Hispanus [?] in the *Sphaera*, p. 325.

CAPVT XXIV.

De Discrimine Dierum Naturalium à Diebus Artificialibus, & Ciuilibus.

On the difference between natural days and artificial and civil days.

[Margin: Diei definitio. — Definition of the day.]

I. The name *day* is equivocal, though the name *night* is not equally so. For sometimes it is taken for the whole day, compounded with that part of itself which is called night. So in Genesis 1, in the Seventy translators, a single day made from evening and morning is called ἡμέρα μιά [Greek: hēmera mia, "one day"], and the second day ἡμέρα δεύτερα [Greek: hēmera deutera, "second day"]. Among most Greeks, however, it is distinguished by a compound name from νύξ [Greek: nyx], which means night, and ἡμέρα [Greek: hēmera], which means day; and it is called either, as a noun, νυχθήμερος [Greek: nychthēmeros, "night-and-day"], or, as an adjective, νυχθημερινὸς [Greek: nychthēmerinos, "of a night and a day"], a name also found in St Paul, 2 Corinthians. The day taken in this way, then, is the time in which the centre of the Sun, by the motion of the primum mobile, or from east toward west, revolves from a meridian back to the same meridian, or from a horizon back to the same horizon, in one whole revolution.

II. Sometimes, however, the day is taken for the simple day, not compounded with the part that is night, or as it is distinguished from night. In this way Genesis 1 says that God, Best and Greatest [DEVS O. M.], divided the light from the darkness and called the one *Day* and the other *Night*. The day so taken is usually defined as the Sun's delay above the horizon, and the night as

its delay below the horizon: not because it delays, that is, does not move, but because it delays there its setting, here its rising. The day is better defined by saying that it is *the time in which the Sun moves from its rising above the horizon until its setting below the same horizon*; and the night, *the time in which the Sun moves from its setting below the horizon until its rising above the same horizon*.

III. It is now disputed by what name, among the Latins, the compound day is to be distinguished from the simple. No one, however, so far as I know, has called the day compounded with the night *artificial*; all call it either *natural*, or *civil*, or *legitimate*. But the simple day, contrasted with the night, some call natural and others artificial.

IV. For the simple day is called *natural*, and the compound day *civil*, by Censorinus, *De die natali*, Chapter 10, and by Gellius, Pliny the Elder, Macrobius, Giraldi, Vinet, Barozzi, Origanus, Goclenius, Boulliau and our own Tirinus; and Origanus adds that there is no artificial day except the one that art makes by lighting lamps to overcome the darkness of night. Isidore, however, calls *legitimate* what others call civil, and it is so called because law, in fixing days, and civil custom, in counting the days of magistracies, contracts and other civil acts, use compound and whole days, so long as they do not expressly distinguish the day from the night, as it is distinguished in Matthew 4: *When he had fasted forty days and forty nights*. They call the day distinguished from the night natural because the motion of the Sun from its rising to its setting does not come from art or from civil institution: nature itself distinguishes light from darkness, to say nothing of God, the author of nature. Moreover the etymology of *dies* is from *dio*, which means open and manifest; so that to be *sub dio* is to be in an open place, exposed to the light of the Sun, and *interdiu* means by day. The connection of this name with the simple day therefore seems more natural.

V. On the other hand, the day compounded with the night is called *natural*, and the simple day *artificial*, by very many, both of the theologians on Genesis Chapter 1, such as Abulensis [Alonso Tostado], Cornelius à Lapide and others, and of the astronomers, such as Regiomontanus, Reinhold, Stöffler, Finé, Sacrobosco, Neander, Maurolico, Clavius, Magini, Tycho, Longomontanus, Kepler, Biancani, Lansbergen and several others, in their tables of the equation of natural days. Their reason is that nature seeks the whole day and intends a complete circulation; whereas they call the simple day artificial because it serves artisans, or because the diversity of such days is produced only by the supreme artifice of God, Best and Greatest [DEI O.M.], and is learned by the manifold use of the artificial sphere.

Although the authors of no. 4 seem older and more elegant, we are nevertheless compelled to follow the authors of no. 5, so as not to seem to speak against the torrent of astronomers. So from here on we shall call *natural days* those that also include the night, and *artificial days* those distinguished from the night.

SCHOLIA.

I. In the frigid zones, the natural day according to the authors of no. 5 would not only be made up of several months of the year, but for those living under the pole it would coincide with the year itself, since there one artificial night lasts six months and one day consists of the other six months.

II. Both the natural day and the artificial day can be taken either as true or as apparent. The true is the one produced by the Sun's true motion with respect to the centre of the Earth; the apparent is the one produced by the motion apparent to us on the surface of the Earth, both because of parallaxes and because of refractions, of which below.

[Margin: Discrimen Diei Solaris à Die Primi Mobilis. — The difference between the solar day and the day of the primum mobile.]

III. Again, the day can be divided into the day of the primum mobile and the day of the second mobile [Secundi Mobilis], that is, the solar day. The former is one whole revolution of the equator; the latter is one whole revolution of the Sun to the same meridian or horizon from which it began to revolve. Besides a whole revolution of the equator, this requires as large a part of a second revolution of the equator as corresponds to the Sun's own motion in longitude, which on average is usually about 1°, that is, 4^m of time. Therefore, if one observes the time in which one conspicuous point of the heaven, but a fixed one, or one moved by no motion other than the diurnal, revolves from a meridian back to the same meridian, and compares it with the revolution of the Sun from a meridian back to the same meridian, the solar day will be found longer than the day of the primum mobile by very nearly 4^m. We have found this by experience more than once, with incredible patience and subtlety, counting both times by means of the vibrations of a pendulum, about which more in the *Liber Organicus* [Libro Organico]. For the former revolution we used the transit of a fixed star through the same meridian from one night to the following night, because the motion of the fixed stars toward the east is imperceptible in one day and is to be counted as nothing in this matter. Astronomers, however, let alone ordinary people, measure the motions of the stars by the solar day and its parts. See what was said in Chapter 12, Second Scholium, and what will be said in Book 3, Chapter 30.

CAPVT XXV.

De Inæqualitate Dierum Naturalium.

On the inequality of natural days.

Although natural days, that is, days compounded of daylight and the darkness of night, are commonly thought to be all equal, whether they are compared with other days of the same year or with days of different years, and although sundials themselves do not make their inequality sufficiently evident, astronomical subtlety has nevertheless detected it. Though this calls for deeper investigation, and is to be examined by us, God willing, in the questions on the primum

mobile, it nevertheless had to be indicated briefly for candidates in astronomy. But it is more conveniently deferred to the end of the Book on the Sun, which is the 3rd; see Chapter 30 there.

[Margin: Inæqualitatis Dier. Natural. Causæ. — Causes of the inequality of natural days.]

The causes are commonly three: the unequal course of the Sun in the zodiac; the inequality of right ascensions for equal arcs of the ecliptic; and the motion of the Sun's apogee.

CAPVT XXVI.

De Inæqualitate Dierum Artificialium.

On the inequality of artificial days.

The inequality of artificial days has two causes. One is common to them and to natural days: for since the artificial day is a part of the natural day, and the natural day is unequal both as a whole and in each of its parts, the artificial day cannot but share in its inequality, which I indicated in the preceding chapter can be made up of three causes, or even of four. The other cause of inequality is proper to artificial days, and it arises from four heads.

[Margin: Inæqualitatis Dier. Artific. Causæ. — Causes of the inequality of artificial days.]

I. The first head is the *horizontal parallax of the Sun* [Parallaxis Horizontalis Solis]. Because of it the Sun's centre, when it really reaches the rational horizon and rises with respect to the centre of the Earth, has not yet reached the sensible horizon of an eye placed on the surface of the Earth, if the eye is not raised at all. But if the eye is raised, whether to the top of a tower or to that of a mountain, it will be able to see the Sun rising even though the Sun is still below the rational horizon. Hence it comes about that even in the right sphere, in which the artificial day in itself is always equal to the night, the day can accidentally, by reason of parallax and of the diversity of the sensible horizon, be less than 12^h if the eye is not raised at all and there is no refraction (of which shortly), or more than 12^h if it is raised sufficiently. On the diversity of the sensible horizon, it has been discussed from Chapter 8, no. 5; on parallaxes I shall speak below, in Chapter 35.

II. The second head is the *horizontal refraction of the Sun* [Refractio Horizontalis Solis], which makes any star appear higher than it is, whereas parallax, on the contrary, depresses it in appearance. Refraction is far greater than parallax: the Sun's parallax does not exceed 3½′, while the Sun's horizontal refraction is about 34′, and with the parallax, which diminishes it, taken away, it is at least 30′. So even in the right sphere the Sun, not yet really risen, can be seen as risen, and when it has already set, can be seen as not yet set; and on both counts the equinoctial day can accidentally be of 12^h and nearly 8^m, and in the parallel or quasi-parallel sphere of more days than it would be without refraction.

III. The third head is the differing obliquity of the horizon, arising from the differing altitude of the pole and of the equator. Because of it, even if the Sun remained always on the same parallel of the equator, the day on one oblique horizon would still equal no day on the other oblique horizons: either because the semidiurnal arc of that parallel would be unequal, owing to the unequal section made by the horizon, or because in the frigid zones, if at times the horizon did not cut the Sun's parallel, it would yet touch it or be unequally distant from it. All this you will learn from Theodosius, *On Days and Nights*, and from figure 2 of Chapter 19 and what was said there in no. 5, or better from the armillary sphere, if, with the Sun placed on one parallel and on the horizon, you count the degrees of the equator up to the Sun's revolution to the meridian, at one altitude of the pole, and then at others and others. This cause, then, operates in the oblique sphere alone.

IV. The fourth head is the obliquity of the Sun's course along the ecliptic. Through it the Sun is placed each day on different parallels, from one tropic to the other, and so on parallels unequally cut by the same horizon or unequally distant from it. Hence it comes about that no days of the first half-yearly course, from the beginning of Cancer to the beginning of Capricorn, are equal to one another on the same horizon, just as no days of the second half-year, from Capricorn to Cancer, are equal to one another. This cause too, moreover, holds only in the oblique sphere.

Setting aside the first and second causes for now, I shall give from the 3rd and 4th certain rules, for a more distinct knowledge of the equality and inequality of artificial days. You will learn that they are true by use of the armillary sphere, or of the table of semidiurnal arcs (on which consult the index of tables at the end of this volume), or from the 2 books of Theodosius of Tripoli *On Days and Nights*.

[Margin: Regula diuersitatis Dierum. — Rule of the diversity of days.]

I. Rule. *In the right sphere*, any artificial days of the same year are in themselves physically equal, both to one another and to their nights, even if mathematically some slight inequality lies hidden in them, arising from the unequal motion of the Sun or from refractions and parallaxes.

II. Rule. *In the parallel sphere*, as the Sun enters Aries, one day begins for northern peoples and one night for southern, which will last 186½ natural days; and the night ends for northern peoples and the day for southern, which lasted 178½ natural days. As the Sun enters Libra, on the other hand, the day begins for southern peoples, and for northern peoples *non vna* [recte: nox vna], one night, which will last 178½ natural days; and the night ends for southern peoples and the day for northern, which lasted 186½ natural days, in these centuries at any rate. So not strictly, but in a rough and broad way, an equinox then occurs for them. On their twilights see the Scholium of Chapter 31.

III. Rule. *In the oblique sphere*, as the Sun enters Aries and Libra, the days on any horizon are physically equal to the nights, that is, of 12^{h}, and consequently equinoxes occur everywhere.

IV. Rule. *In the oblique sphere*, as the Sun enters Cancer, northern peoples have the longest day of the year and the shortest night, and southern peoples the longest night and the shortest day; and the longest becomes so much the longer, and the shortest so much the shorter, as the former peoples are more northerly and the latter more southerly. As the Sun enters Capricorn, on the other hand, southern peoples have the longest day, which is longer for those farther south, and the shortest night, which is shorter for those farther south; while northern peoples have the longest night and the shortest day, the former longer and the latter shorter for those farther north.

V. Rule. *In the oblique sphere*, the day begins to grow and the night to shrink for northern peoples from the Sun's entry into Capricorn, and for southern peoples the day to shrink and the night to grow, and so continuously until the Sun's entry into Cancer. From then the day begins to grow and the night to shrink for southern peoples, and for northern peoples the day to shrink and the night to grow, until the Sun's entry into Capricorn.

VI. Rule. *In the oblique sphere*, as long as the Sun is in the northern signs, the days of northern inhabitants are longer than their nights, and those of southern inhabitants shorter. Conversely, when the Sun is in the southern signs, the days of southern inhabitants are longer than their nights, and those of northern inhabitants shorter.

VII. Rule. *In the oblique sphere*, as long as the Sun is in the northern signs, the day, for northern and southern peoples alike, is the greater the farther they are from the south pole; but when the Sun is in the southern signs, the day, for both, is the greater the farther they are from the north pole.

VIII. Rule. *In the oblique sphere*, any two days of the same horizon, and any two nights, are equal to one another on which the Sun is at degrees of the ecliptic equally distant from the same solstitial point. For example, the Sun at the beginning of Gemini and of Leo makes two equal days, say May 21 and July 23; at Rome it makes them of 15^{h} 48^{m}, because in both places of the ecliptic it is equally distant from the beginning of Cancer, namely 30°, or from the beginning of Capricorn, namely 150°. In the same way, on any other horizon those two days are equal to one another, even though they are not equal to the other days of the year on that same horizon, or to the same days on different horizons. I said *from the same solstitial point* because, although the Sun at the beginning of Leo and at the beginning of Aquarius, for example, is equally distant from the nearer solstice, it is not equally distant from the same solstice: at the beginning of Leo it is 30° from the beginning of Cancer, and at the beginning of Aquarius it is 150° from the beginning of Cancer. And so those two days are not equal to one another, just as the days on which it is at the beginning of Gemini and of Sagittarius are not.

IX. Rule. *In the oblique sphere*, any two days are equal to the future or past nights on the same horizon, as nights are to days, on which the Sun will be, or was, in the other semicircle of the ecliptic, at a degree of it equally distant from the equator. For example, at Rome the day on which the Sun is at the

beginning of Leo is equal to the night that occurred at Rome when the Sun was at the beginning of Aquarius; and the night at the beginning of Leo is equal to the day that occurred there at the beginning of Aquarius. Say the same of the beginning of Gemini compared with the beginning of Sagittarius.

X. Rule. *In the oblique sphere*, any day of northern peoples is equal to the night, in the same natural day, of equally southern peoples, and the night of the former to the day of the latter; just as the day of southern peoples is equal to the night, and their night to the day, of equally northern peoples: that is, of those whose distance from the equator, each toward his own pole, is equal. For example, if for one person the altitude of the south pole and for another the altitude of the north pole is 48° in each case, then if one has a day of 15^h and a night of 9^h, the other will have a night of 15^h and a day of 9^h.

XI. Rule. *In the oblique sphere*, any two days belonging to different natural days among northern peoples are equal to days of equally southern peoples on which the Sun will be, or was, in the other semicircle of the ecliptic, and at a degree of it equally distant from the equator. For example, if for one person the altitude of the north pole and for another that of the south pole is 48°, the day of the one, made by the Sun placed at the beginning of Leo, is equal to the day made, or to be made, for the other at the beginning of Aquarius. Say the same of two of their days, made or to be made, for one at the beginning of Gemini and for the other at the beginning of Sagittarius; and so of similar cases.

XII. Rule. *In the oblique sphere*, outside the cases stated, no artificial days of the same year are equal to one another, and no nights to one another, whether on the same horizon or on different ones.

SCHOLIA.

[Margin: Solis mora in semicirculo Boreali. — The Sun's stay in the northern semicircle.]

I. What I said in Rule 2 was said for the sake of a round number. For if you keep the obliquity of the ecliptic at 23° 30′, and the Sun's apogee and eccentricity as Clavius has them, the Sun spends in the northern signs 187 natural days 6^h 39^m, and in the southern signs 177 days 23^h 21^m. But if you follow the Tychonic obliquity and the rest, it spends in the northern signs 186 days 18^h 24^m 23^s, and in the southern signs 178 days 11^h 24^m 23^s. So the difference between these comes from the different eccentricity of the Sun and obliquity of the ecliptic.

II. In the same Rule 2 I added *in these centuries*, because in them the Sun's apogee is in the northern semicircle of the ecliptic, and the Sun therefore stays more days in that semicircle than in the southern. But if the apogee once was, or ever will be, in the southern semicircle, then the Sun will likewise stay longer in the southern semicircle than in the northern. So if in the year of Christ 1600 the Sun's mean apogee was at Cancer 6° 40′, and the Sun's apogee moves in the order of the signs by very nearly 1′ each year, it follows that it was at the

beginning of Aries in the year 4140 before Christ and will be at the beginning of Libra in the year of Christ 6660; and accordingly that before that year 4140 and after the year 6660 the Sun has stayed, or will stay, longer among southern peoples than among northern. Kepler, however, on p. 42 of the Rudolphine Tables, puts it at the beginning of Aries in the year 3993 before Christ, July 24, on account of other astronomical agreements, because of which he also limited the motion of the solar apogee so that it would fall in that year. On this we speak in the Chronological Book, where the age of the world is treated, and below in Book 3, Chapter 24.

III. The artificial day, no differently from the natural day, can accidentally seem longer or shorter because of a journey toward the west or the east; on this see below, Chapter 28, Scholium 4.

CAPVT XXVII.

De Inuenienda quantitate Semidiurna, & Seminocturna; cognitis Altitudine Poli, & gradu Eclipticæ, in quo Sol versatur.

On finding the semidiurnal and seminocturnal quantity, given the altitude of the pole and the degree of the ecliptic in which the Sun is.

I. The altitude of the pole is known either from the table which we mention in the index of tables at the end of this volume, or from globes or the more correct geographical maps, or from one's own observation or that of others, according to the method given in Chapter 11.

II. The Sun's place at noon on any given day is known either from ephemerides, or from astronomical calculation, or from observing the Sun's declination from the equator and then using the tables of declination. More roughly, it is known from the days of the Sun's entry into the signs of the zodiac, by adding as many degrees of that sign as the assigned day is days distant from the day of entry into that sign. For the entry into the signs of the zodiac the following little table is enough for beginners, using the days of the Gregorian calendar with respect to the meridian of Rome. A leap year of Christ, moreover, is every fourth year of Christ, except the years 1700, 1800 and 1900, in accordance with what will be said in the Chronicle Book. So, when the years of Christ are divided by 4: if nothing is left, the year is a leap year; if 1, 2 or 3 is left in the numerator of the fraction, the year will be the first, second or third after the leap year. A leap year, moreover, is the same as the fourth after a leap year. With this laid down, for these centuries let there be:

Days of the Sun's entry into the signs of the zodiac, in the years after the nearest leap year.

Signs	Months	Year 1	2	3	4
♈ Aries	March	20	20	21	20
♉ Taurus	April	20	20	20	19
♊ Gemini	May	21	21	21	20

Signs	Months	Year 1	2	3	4
♋ Cancer	June	21	21	22	21
♌ Leo	July	23	23	23	22
♍ Virgo	August	23	23	23	23
♎ Libra	September	23	23	23	23
♏ Scorpio	October	23	23	24	23
♐ Sagittarius	November	22	22	22	22
♑ Capricorn	December	21	21	22	21
♒ Aquarius	January	19	20	20	20
♓ Pisces	February	18	18	18	19

III. The first way of finding the semidiurnal quantity of the artificial day is by means of an armillary sphere, or a geographical or star globe, on which the meridian, the equator and the ecliptic are divided into single degrees. For, first, set the pole raised above the horizon according to the altitude of the pole of the place in question, and set on the horizon the degree of the ecliptic in which the Sun is on that day; and with some visible mark, or at least from memory, note the point of the equator, or at any rate the degree, which is then on the horizon. After this turn the sphere or globe toward the west until the Sun, or the degree of the ecliptic in which the Sun is, comes under the meridian, and count how many degrees of the equator have meanwhile ascended above the horizon. Convert these into hours and minutes in proportion, using the little table of Chapter 12, no. 2, and you will have the semidiurnal time of that day for the given altitude of the pole. If you subtract this from 12^h, you will have the seminocturnal time. For example, at Rome, where the altitude of the pole is 42°, let the year be 1650, the Jubilee year, namely the second after a leap year, and the day the 15th of August, on which, by the preceding little table, the Sun will be at Leo 23°. If you raise the pole that is on the meridian of the sphere 42° above the horizon, and set the degree Leo 23° on the horizon, you will see that the degree of the equator on the horizon is 132½°, counted from the beginning of Aries. When the globe or sphere has been turned until the degree Leo 23° is under the meridian, you will note that the degree of the equator on the horizon is 235½°. So 103° have ascended, to which correspond $6^h\ 52^m$. Therefore on that day at Rome the semidiurnal arc is 103°, or $6^h\ 52^m$, and the seminocturnal time is $5^h\ 8^m$.

Where the pole is raised 66½°, the longest day is of 24^h. But where the pole is raised more than 66½°, the arc of the ecliptic that never sets must be carefully noted: for as many degrees as it has, nearly so many natural days will the continuous day have.

IV. The second way is by the tables of oblique ascensions constructed for a given altitude of the pole. From them one gathers the oblique ascension of the degree of the ecliptic in which the Sun is on the given day, and the oblique ascension of the point diametrically opposite to it, or 180° away. The former is subtracted from the latter, and the diurnal arc remains; half of it is

the semidiurnal arc, to be converted into time as above. Let the example be the same as above. At Rome the oblique ascension of Leo 23°, in which the Sun is on July 15 [recte: August], is 132° 30′, whereas the oblique ascension of Aquarius 23°, which is opposite it, is 338° 12′. When the ascension of the degree in which the Sun is has been taken from this, 205° 42′ remain, half of which is 102° 51′, or in round figures 103°, namely about 6^{h} 52^{m}. If the subtraction could not be made, then, so that it can be made, add 360° to the smaller number.

V. The third way is by the ascensional difference defined and explained in Chapter 21, no. 12. For, as Copernicus shows in Book 2, Chapter 7, the ascensional difference is the same as the difference by which the semidiurnal arc exceeds a quadrant of the equator or falls short of it. Therefore for northern peoples when the Sun is in the northern signs, or for southern peoples when it is in the southern signs, the ascensional difference is to be added to 90°, and the semidiurnal arc will result. But when the Sun is in the southern signs it is to be subtracted among northern peoples, or, when it is in the northern signs, subtracted by southern peoples, and the semidiurnal arc will be left.

When the altitude of the pole is greater than 66½°, subtract the altitude of the pole from 90°, and there will remain the declination of the beginning of the arc of what is always visible. Look up this declination in the body of the table of declinations [arealiter], and in the left or right margin you will find the degree of the sign that is the beginning of the arc of what is always visible. From it count the degrees as far as the nearest solstitial point, and double them. Then from the tables of the Sun's motion look up the days and hours in which the Sun completes the degrees of that doubled arc, or at any rate take as many days as there are degrees, and you will have how many natural days the continuous day contains on that horizon. But this second way is not so exact.

VI. The fourth way is by trigonometry, on which see the problems of the primum mobile.

CAPVT XXVIII.

De diuersis Dierum Naturalium Initijs, vnde Horarum quasi species quatuor; & de mutua illarum Conuersione.

On the different beginnings of natural days, from which come, as it were, four kinds of hours; and on their conversion into one another.

I. The same day, begun by different peoples from four chief points of the natural day, as from the hinges of the hours, has produced as many kinds, as it were, or denominations of hours: namely Babylonian hours, counted from sunrise; Italian hours, from sunset; astronomical hours, from noon; and finally European hours, which comprise 12^{h} from midnight and as many others from noon.

[Margin: Initiū Diei variū apud diuersos. — The beginning of the day varies among different peoples.]

II. The Babylonians, Persians, Syrians and Damascenes, with most Eastern peoples, used to begin the day from sunrise; as also, today, do the people of the Balearic Islands and of Nuremberg.

III. The Hebrews began the day from sunset, thinking that night, or evening, preceded light on their horizon, from Genesis 1. So did the Athenians, and so today do the Austrians, Bohemians, Marcomanni, Poles, Silesians, Chinese and Cathayans, but above all, today, the Italians: hence the name *Italian hours*.

IV. The Umbrians, the Arabs and the greatest part of the astronomers started the day from noon: hence *astronomical hours*. So Ptolemy, Peuerbach, the Alphonsines, Regiomontanus, Tycho, Longomontanus, Kepler, Lansbergen, Boulliau, Magini, Biancani and very many others; and rightly, for in this way one avoids the inequality that spills over into the day from the obliquity of ascensions and descensions and from the horizontal vapours at rising and setting; and the moment of noon is in itself conspicuous and of the most evident mark.

V. The Egyptians of old, however, and the Romans and the Mysians began the day from midnight; and among astronomers, Hipparchus, Copernicus, Reinhold, Pétau and Mulerius [Nicolaus Mulerius]. The Roman Church too retains this in its obligations of fasts and of the canonical hours, and in their limits.

VI. But the Spanish, the Portuguese, the French, the Belgians, the English, and a good part of Germany and indeed of Europe count 12^h from noon and as many from midnight: hence *European hours*.

This is gathered from Pliny the Elder, Book 2, Chapter 77; Censorinus, Chapter 10; Macrobius, *Saturnalia*, Book 1, Chapter 3; Isidore, *Origines*, Book 5, Chapter 28; Io. Rosinus [Johannes Rosinus], *Antiquitates Romanae*, Book 4, Chapter 3; Giraldi, *De annis* etc., p. 133; Clavius on the *Sphere*, p. 279; and Origanus, volume 1, p. 95.

Conuersio Horarum in Horas.

The conversion of hours into hours.

VII. Once the semidiurnal time is known from its own table, or from elsewhere, according to what was said in Chapter 27, if you subtract it from 12^h the seminocturnal time will remain. Each of them, doubled, will give the whole: the former the whole day, the latter the whole night, or night-time. In the following rules, moreover, when a subtraction cannot be made, the full sum of 24^h is added to the smaller number, and so the subtraction is made. And when, finally, the sum produced by the prescribed addition exceeds 24, then, 24 being discarded, the remaining hours are kept. With this said in advance:

Babylonicæ Horæ Conuertuntur.

Babylonian hours are converted.

Into Italian hours from the preceding sunset, thus. Add the nocturnal quantity to the Babylonian hours. If, however, the sum exceeds 24, what remains after 24 is discarded will be Italian hours from the following sunset.

Into astronomical hours, from the noon preceding the sunrise, thus. Add to the Babylonian hours the nocturnal and the semidiurnal quantity together. But if the sum exceeds 24, what remains after 24 is discarded is counted from the noon following the sunrise. If, however, the Babylonian hours exceed the semidiurnal quantity, subtract it from the Babylonian hours, and astronomical hours from the following noon will remain.

Into European hours from the preceding midnight, thus. Add the seminocturnal time to the Babylonian hours. But if the sum exceeds 12, they will be European hours from the following noon; and if it exceeds 24, they will be hours from the following midnight, discarding in the former case 12, in the latter 24.

Italicæ Horæ Conuertuntur.

Italian hours are converted.

Into astronomical hours, thus. Add the semidiurnal quantity to the Italian hours, and if the sum does not exceed 24, keep it; if it exceeds, discard 24, and the remainder will be hours from the preceding noon.

Into European hours, thus. Add the semidiurnal quantity to the Italian hours, and if the sum does not exceed 12, they will be European hours after the preceding noon; if it exceeds 12, then with 12 discarded the remainder will be European hours after the preceding midnight.

Into Babylonian hours, thus. Add the diurnal quanti- ty; and if the sum does not exceed 24, they will be hours from the preceding sunrise. If it does exceed it, they will be hours from a sunrise that does indeed precede, but with respect to the sunset from which the Italian hours were counted, it will be the following one.

Astronomicæ Horæ Conuertuntur.

Astronomical hours are converted.

Into European hours, thus. If they do not exceed 12, they coincide with European hours counted from noon. If they exceed 12, then with 12 discarded there remain European hours from the midnight that followed the noon from which the astronomical hours were counted.

Into Babylonian hours, thus. Add the semidiurnal time to the astronomical hours; and if the sum does not exceed 24, they will be Babylonian hours from the sunrise preceding the noon from which you counted the astronomical hours. If they exceed it, then with 24 discarded there will remain Babylonian hours, but from the sunrise following that noon.

Into Italian hours, thus. Subtract the semidiurnal time from the astronomical hours, if it is less than they are, and there will remain Italian hours from the sunset following the noon from which the astronomical hours were counted. But if the semidiurnal time is equal to or greater than the astronomical hours, add 24 to them, and when the semidiurnal time has been subtracted from the

sum, there will remain Italian hours from the sunset preceding the noon from which the astronomical hours were reckoned.

Europæ à Media Nocte Vertuntur.

European hours from midnight are converted.

Into astronomical hours, thus. Add 12^h to the European hours.

Into Babylonian hours, thus. Subtract the seminocturnal time from the European hours, if you can, and you will have Babylonian hours from the sunrise following the midnight from which you were counting the European hours. If you cannot, add 24^h to the European hours and from the sum subtract the seminocturnal time; for there will remain Babylonian hours, but from the sunrise preceding that midnight.

Into Italian hours, thus. Add the seminocturnal quantity to the European hours.

SCHOLIA.

I. Where it is the custom to count hours not from the true sunset but from the civil or artificial sunset, namely half an hour after the true sunset (and this because of the evening twilight, or evening dawn, into which the day is prolonged for the benefit of labourers and artisans), account must be taken of that half-hour. Subtracted from solar Italian hours it will give civil Italian hours, and added to the civil it will give the solar.

[Margin: Europæarū Horarum laus. — In praise of European hours.]

II. The reason for dividing the natural day in two, into 12^h from noon and 12^h from midnight, was the greater convenience of counting them on striking clocks [horisonis horologijs]. Because of this, in the end, those clocks strike only six hours at a time, with as many strokes, since the common people themselves otherwise easily distinguish whether it is six simply or six doubled: for if they hear six strokes at noon, they nevertheless declare it hour 12 from midnight. Moreover, European hours are better suited to civil and ecclesiastical use than Italian hours (forgive me, Italians) or Babylonian: both because they are counted from more fixed and certain points of the day, and because the hour of noon and of midnight is always counted by the same number of hours, being always the twelfth. Consequently business and offices tied to certain hours from midnight or from noon take place throughout the year always at the same hour, that is, at the same number of hours. For example, if a midday meal or a sermon is customarily held at hour 2 before noon, or hour 10 after midnight, there will be no need to change the hour and repeatedly warn the people of the change; it will be settled that these things are to be done always at hour 10. And on one person, the keeper of the public clock, falls the task of regulating the striking clock so that, by inspection of the meridian line, hour 12 is struck at the moment of noon. Those who use Italian or Babylonian hours certainly lack this convenience. For, to make this clear by a single example, at

Rome that hour 2 before noon is hour 16 Italian on equinoctial days, but hour 14½ Italian on the day of the summer solstice, and $17^{h}\ 30^{m}$ on the day of the winter solstice, in Italian reckoning and taking solar hours into account; for in civil reckoning, according to what was said in Scholium 1, the former will be 14 and the latter 17. There are some things, however, which even among those who use European hours cannot take place at the same hour throughout the year: for example, the recitation of Matins of the Roman Breviary, which by privilege may be done as soon as the evening time has begun, that is, as soon as half of the semidiurnal time, counted from noon, has passed; for then the Sun is nearer to setting than to noon, and therefore the evening time is already approaching. So although this office can be begun on the equinoctial day immediately after hour 3 from noon, at Rome it cannot be begun on the day of the summer solstice until $3^{h}\ 43^{m}$ from noon have elapsed, whereas on the day of the winter solstice it can be begun when $2^{h}\ 15^{m}$ from noon have elapsed.

III. Those who are western can be so many hours more western than we are that they count one day fewer than we do; and conversely easterners can be so far east that they count one day more than we do in the same calendar. For suppose a place more western than Rome by 195° of the equator, or 13^{h}, according to what was said in Chapters 12 and 13; such, nearly, is Isabella, one of the Solomon Islands, or Quivira, the city of the kingdom of Quivira. And suppose Easter is celebrated at Rome on March 22, so that the Saturday of Holy Week ends at sunset of the 21st, and the following morning begins at hour 12 Italian of March 22. Then in Isabella or Quivira it will be hour 23 Italian, but of March 21, and so still the Saturday and a time of fasting. And so of similar cases.

IV. Besides, some people can be so much more western or more eastern than others that while the one counts European hours from noon the other is already counting European hours from midnight, and indeed with a disagreement of one day in the number of days of the year. As in the same example of Scholium 3: for the morning hour of Easter, or hour 12 Italian, will for the Romans be hour 6 after midnight of March 22, but for the people of Quivira hour 5 after noon of March 21.

[Margin: Numerus dierum minor eūti ad Ortum. — The number of days is smaller for one going east.][7]

V. Those travelling westward, and measuring time with the usual clocks of 24^{h}, can in the end fall one day short in the number and naming of the days of the same calendar; and conversely those going eastward can count one day more than they otherwise should. The first actually happened to the companions of Ferdinandus Magellanicus [Fernão de Magalhães (Magellan)], who, setting sail from Seville on 1519 August 10, surveyed the whole world by a westward voyage and returned to Seville on 1522 September 7, as the people

[7]as printed; the text beside it gives the smaller count to those travelling west.

of Seville counted it, whereas those shipmasters believed it was September 6, as Pigafetta [Antonio Pigafetta] relates in his history of that voyage, and Ramusius [Giovanni Battista Ramusio] from him.

The cause of this error is that those sailing westward follow the Sun as though it were fleeing, and therefore their day is prolonged every day, so that in the end, when those additions to the day are collected, one whole day is found distributed and, as it were, dispersed among all the other preceding days. For suppose a voyage or journey begun from the island of São Tomé [Insula S. Thomæ], which is on the equator, on January 1 at noon itself, and sailing on the equator westward for 24^{h}, covering 15° (which I say for the sake of clarity, not from practice). So when 24^{h} have elapsed on the striking clock, on the solar clock there will still remain one hour before noon, because the meridian you have reached is one hour farther west than the island of São Tomé. An unskilled shipmaster will therefore think that the striking clock needs correcting, and will think it has run fast by one hour; whereas he ought to say in the log of the voyage: *On the second day we arrived at such-and-such a place, at hour 24 after the noon that occurred on the island of São Tomé, but at that place only at hour 23.* Proceeding in this way, the whole equator would be completed and one would return to the island of São Tomé at the end of day 24, with respect to the meridian on which the island of São Tomé lies; and yet the shipmasters, having followed the Sun, would count the day as only the 23rd. The contrary would happen, for the contrary reason, to those sailing in this way to the east, for in the end they would count one day more, namely the 25th.

Our own Molina [Luis de Molina] treated this problem at the end of the work on the six days, and Biancani in his *Sphaera* at the end of Book 7, proposing the case of two voyagers, one going west and the other east, who meet and disagree by two whole days in the number of days. But many other problems arise from this: whether voyagers of this kind would be obliged to a fast, or a feast day, or the intercalation of the leap day, etc.; or whether they could follow the number and order of days according to the reckoning they made by following solar clocks. It is not fitting for us to digress to these matters here, if the brevity of the introduction [Isagoges] we have undertaken and the end we have set ourselves are to be kept.

CAPVT XXIX.

De Horis Inæqualibus, seu Temporalibus, & earum Commutatione in Horas Aequales.

On unequal or temporal hours, and their conversion into equal hours.

I. Among astronomers, some hours are *equal*: in Greek [Greek: ἰσημεριναὶ (isēmerinai, "equinoctial")], and in Latin you might say *aequidiales* or, as others do, *aequinoctiales*. They are so called because they are the twelfth part of the natural day, and so each is equal to any other; just as on an equinoctial day any night hour is in itself equal to any day hour. It is these we have been speaking of so far, in Chapters 27 and 28. Others are *unequal*, in Greek [Greek:

καιρικαὶ (kairikai, "seasonal")], that is, changeable with the time; and for that reason they are called in Latin *temporales*, or, as Sacrobosco and Giuntini prefer, *naturales*, although they are the twelfth part of the artificial day or night, whose inequality gives rise to the unequal hours; and this by a threefold inequality. The first arises from the difference of oblique horizons, because of which the solstitial day, for example, is shorter at Rome than at Kraków, and so the twelfth part of the Kraków day is greater than the twelfth part of the same day at Rome. The second comes from the difference of the parallels the Sun runs through, with respect to the oblique sphere, because of which the twelfth part of the day of the summer solstice at Rome is longer than the twelfth part of the winter-solstice day, likewise at Rome. The third, finally, arises from comparing a non-equinoctial day with the night of the same natural day and the same horizon, because of which, among northern peoples, the twelfth part of the day is longer than the twelfth part of the night when the Sun is in the northern signs, and shorter when it is in the southern signs. The opposite of this happens among those who live in the south. But the alternation of these inequalities can be judged well enough from what was said about the inequality of artificial days in Chapter 26. So although the hours of the artificial day are equal to the daytime hours of the same natural day and on the same horizon, outside the equinoxes they are nevertheless unequal: to the night hours of the same natural day and the same horizon; to the daytime hours of different natural days, on which the Sun runs through unequal parallels; and to the daytime hours of the same natural day but on different horizons.

[Margin: Conuersio Horarū inæqualium in æquales. — Conversion of unequal hours into equal hours.]

II. Further, daytime temporal hours are counted from sunrise, and night hours from sunset. Daytime hours are converted into equal Babylonian hours by multiplying the hours and minutes of the daytime by the temporal hours and minutes, and dividing the sum by 12. Night temporal hours are converted into equal Italian hours by multiplying the length of the night by the temporal hours, and dividing the resulting sum by 12. *For example*, with the Sun placed at 12° of Cancer, the daytime is 15^{h}. Let temporal hour 10 be given. The 15 hours multiplied by it make 150, which divided by 12 give 12½. So at that moment at Rome temporal hour 10 is hour 12½ from sunrise, but an equal hour. If you add to it the night's length of 9^{h}, the Italian hour will be 21½; if instead you subtract the semidiurnal $7½^{h}$, the astronomical hour will be 5.

Another example. On the same day at Rome let the temporal night hour be 6. Since the night at Rome is then 9^{h}, multiply them by 6, which makes 54; and these divided by 12 give 4½ equal Italian hours. If you add to them the semidiurnal time of $7½^{h}$, the astronomical hour will be 12.

SCHOLIA.

I. *Ancient authors, speaking of unequal hours, call the long daytime hours summer or solstitial hours, and the short ones winter or hibernal hours. To the same hours belongs that saying of* CHRIST, *John 2:* "Are there not twelve hours of the day?" *and the celebrated epigram of Martial, Book 4, Chapter 7, which begins:* "The first and second hour hold those who come to pay their morning calls" [Prima salutantes, atq; altera continet hora.] *Finally, the astrologers use the same hours in assigning the hours over which the planets rule, and they therefore call them* planetary*; of these in the next chapter.*

[Margin: Quatuor Horæ diei partes. — The four Hours, parts of the day.]

II. *The Romans, from about the 300th year after the founding of the City, and the Hebrews and most Orientals, used to divide the artificial day into four equal parts. The* First [Prima] *began at sunrise and lasted to the moment at which three temporal hours were completed; then the signal was given that the First had elapsed and the Third was beginning. The second part was called the* Third [Tertia]*, because it began at the end of three temporal hours, and it lasted to the end of six temporal hours; when these were completed the signal was given that the Third was finished and the Sixth was beginning, which was at midday. The third part, then, was called the* Sixth [Sexta]*, because it began at the end of 6 temporal hours and lasted through three unequal hours, that is, to the end of 9 temporal hours. When these were finished the signal of the Ninth was given, and from there began the fourth part of the day, called from its beginning the* Ninth [Nona] *and from its end* Vespers [Vespera].

[Margin: Et quatuor Vigiliæ. — And the four watches.]

In the same way the night was divided into four equal parts, or military watches, to each of which fell three temporal hours. The First Watch began at sunset and ended when three temporal night hours were completed; from there began the Second Watch, and it lasted until midnight, etc. But for more on these, see St Jerome on Psalm 89; Baronio, Year 34, no. 163; Mazzonus [Jacopo Mazzoni] on Dante, Book 1, Chapter 16; and Fuluius Vrsinus [Fulvio Orsini] in the Appendix to Ciacconus [Pedro Chacón].

CAPVT XXX.

De Horis Planetarijs, & Planetarum Characteribus.

On planetary hours and the characters of the planets.

I. The characters of the planets are these: of the Sun ☉; of the Moon ☾; of Mercury ☿, which is the sign of the caduceus, that is, of a staff entwined by two snakes; of Venus ♀, which is the sign of a mirror with a handle made in the form of a cross; of Mars ♂, which shows a shield-boss with an arrow; of Jupiter ♃, which stands for [Greek: Ζεῦς (Zeus)], that is, Jupiter; and of Saturn ♄, which is the sign of the sickle with which Saturn, that is, Time, mows down all things.

II. The hours over which the individual planets rule are the unequal hours discussed in Chapter 29; or, according to the subtler astrologers, they are those

12 parts in which 15° of the zodiac rise at a time. These are certainly unequal hours, since the halves of six signs rise in unequal times.

[Margin: Horæ Planetariæ, & Hebdomadicorū dierum ordo. — The order of the planetary hours and of the days of the week.]

III. By astrological observation, the order of dominion over the hours and the days of the week begins from the Sun, which is the strongest and the swiftest in acting, and to it is assigned the first hour of the first weekday [prima feria]. From the Sun the descent runs through the planets below the Sun; when these are done one climbs to Saturn, and from him returns through Jupiter and Mars to the Sun. With the 12 unequal hours of the day distributed in this way, Saturn will rule the 12th hour of the first weekday, Jupiter the first hour of the night, and Mercury the 12th hour of the night. The Moon will therefore rule the first hour of the second weekday, and that is why the second weekday is called the day of the Moon, as the first is called the day of the Sun. If you continue in the same order, Mars will rule the first hour of the third weekday, Mercury the first of the fourth, Jupiter the first of the fifth, Venus the first of the sixth, and Saturn the first of the seventh. This is the first cause of the order the pagans kept in assigning the names of the planets to the days of the week. But this order supposes, following the ancient system, that the planets stand so that Saturn is in the highest place, then Jupiter, then Mars, with the Sun below him, Venus below the Sun, Mercury below Venus, and the Moon last of all; whereas it has been discovered that Mars sometimes descends below the Sun, that Mercury and Venus are sometimes carried above the Sun, and finally that Mercury is nearer the Sun than Venus is, as will become clear from what is to be shown in Book 3, Chapter 6, and in Book 9, where the system of the world is treated more fully. Thus there wavers the foundation of this distribution. For it, nevertheless, take the two following little tables.

Daytime hours [Horæ Diurnæ.]	Weekday [Feriæ.] 1	2	3	4	5	6	7
1	☉	☾	♂	☿	♃	♀	♄
2	♀	♄	☉	☾	♂	☿	♃
3	☿	♃	♀	♄	☉	☾	♂
4	☾	♂	☿	♃	♀	♄	☉
5	♄	☉	☾	♂	☿	♃	♀
6	♃	♀	♄	☉	☾	♂	☿
7	♂	☿	♃	♀	♄	☉	☾
8	☉	☾	♂	☿	♃	♀	♄
9	♀	♄	☉	☾	♂	☿	♃
10	☿	♃	♀	♄	☉	☾	♂
11	☾	♂	☿	♃	♀	♄	☉
12	♄	☉	☾	♂	☿	♃	♀

Night hours [Horæ Nocturnæ.]	Weekday [Feriæ.] 1	2	3	4	5	6	7
1	♃	♀	♄	☉	☾	♂	☿
2	♂	☿	♃	♀	♄	☉	☾
3	☉	☾	♂	☿	♃	♀	♄
4	♀	♄	☉	☾	♂	☿	♃
5	☿	♃	♀	♄	☉	☾	♂
6	☾	♂	☿	♃	♀	♄	☉
7	♄	☉	☾	♂	☿	♃	♀
8	♃	♀	♄	☉	☾	♂	☿

IV. Another cause of the weekly distribution just described is the aspect nearest to opposition, following seven isosceles triangles whose bases are the sides of a heptagon inscribed in a circle, the circle being divided into seven equal parts and these distributed among the individual planets, beginning from the Moon and proceeding to the right. For this purpose let there be the following circle, with a heptagon inscribed in it; on each of the heptagon's sides let seven isosceles triangles be erected, inscribed in the same circle; and finally at the vertices of the triangles let the characters of the seven planets be placed, beginning from the Moon and proceeding to the right to Mercury, then to Venus, the Sun, etc.

Diagram. A circle with seven points on its circumference, joined by straight chords that form a seven-pointed star; chords joining neighbouring points are also drawn, giving the inscribed heptagon. A planetary sign stands outside the circle at each point. A repaired tear runs down just outside the circle on the right, clear of the signs; the ring of the sign for Venus is printed incomplete.

- Top: ☾ (crescent)
- Upper right: ☿
- Right: ♀ (the ring of the sign is broken by the tear)
- Lower right: ☉ (a ring with a central dot)
- Lower left: ♂
- Left: ♃
- Upper left: ♄

For you will see that the Sun ☉ has opposite it on the right the Moon ☾, and on the left Saturn ♄; and so the first day after the day of the Sun is dedicated to the Moon, while the day of Saturn came before it. When, therefore, you have gone along a straight line from the Sun to the Moon, you will see that ♂ stands opposite the Moon on the right, so the day of Mars follows the day of the Moon. And when you are at the apex of Mars, you will see that Mercury ☿ stands opposite it on the right, so the day of Mercury follows the day of Mars; and likewise for the rest.

But all this, even if it does not lack some plausibility, nevertheless appears to contain much made up at will, and who does not know that it could have been invented otherwise? The harmonic reason handed down by Dio [Cassius Dio] is discussed learnedly by Bettini in *Apiarium* 10, *Progymnasma* 1, Proposition 4. But the diatessaron, the diapente and the 7 intervals of this kind depend on the distances of the stars; and in fixing these GOD had in view a harmony not of the ears but of the intellect, and proportions directed to an end other than sound or the sweetness of sound. It is in vain, then, that we look in the heavens for harmonies other than these.

CAPVT XXXI.

De Crepusculis.

On twilight.

[Margin: Crepusculi Definitio. — Definition of twilight.]

I. Twilight [crepusculum] is an appendix of the artificial day: it is the time between the apparent rising or setting of the Sun and the beginning or end of the solar light reflected to the Earth's surface from the exhalations of the atmosphere. It is called *crepusculum* either from the crackling [crepitus] that the vapours shut in the pores of wood give out, rarefied by the heat of the approaching Sun; or rather from *crepundia*, that is, the first beginnings of a doubtful and uncertain light. This agrees with Censorinus, *De die natali*, Chapter 10, who says: "Uncertain things are called *creperae*, and it is uncertain whether that time belongs to night or to day." If the twilight is morning twilight, it is called *Aurora*, from the golden light [aurea lux] or from the increase of dew [roris], and in Italian *Alba*, from the vapours whitening around the horizon. Four things are usually inquired into at this point: the beginning of morning twilight or the end of evening twilight in a given region and at a given time of year, on which its duration depends; then the Sun's depth below the horizon when morning twilight begins or evening twilight ends; and finally the altitude of the exhalations from which the Sun's direct or refracted light is reflected to the Earth.

[Margin: Modus obseruãdi Crepusculum. — The method of observing twilight.]

II. As to the beginning and end of twilight, each is observed by taking, with the help of a quadrant or a geometrical square, the altitude of some fixed star at the moment when, on a clear night, the illumination of the vaporous exhalations first appears around the eastern horizon, or ceases to appear around the western. For by the problems of the primum mobile, from the star's declination and right ascension together with the altitude of the pole and the Sun's place, one gathers what hour it is, and from that the interval of time before the Sun's rising or since its setting, and thus the duration of twilight. Granted, that moment is doubtful, and that illumination does not become perceptible at once; and so, from the varying temperature both of the year and of the region, different

observers gather a different time and duration, and on that the Sun's varying depth and the altitude of the exhalations depend in part. There is, however, another cause, not so much physical as astronomical, that varies the duration of twilight: namely, the straightness or obliquity of the Sun's ascension or descension. In the right sphere and on equinoctial days, because the Sun rises and sets straight, twilight is at its shortest, other things being equal. If the arc of depth at which twilight begins is, as most writers set it, 18°, those degrees rise in one equinoctial hour and 12^{m}, and twilight there lasts just that long. But in the oblique sphere twilight is longer, and the longer the more oblique the horizon, that is, the greater the altitude of the pole. At the same altitude of the pole, it is generally longer the farther the Sun declines from the equator toward the tropics, and longer still if the declination is toward the visible pole of the world. So the longest twilight occurs at the summer solstice, yet not the longest at the winter solstice. In the parallel sphere, as long as it is night, twilight, if not continuous, nevertheless lasts as morning twilight for more than a month and a half, and as evening twilight for more than another month and a half, while the Sun meanwhile stays below a subhorizontal depth of 18° or 20°. From the differing obliquity of the horizon, then, and the variety of the parallels in which the Sun moves, there arises the astronomical diversity of twilight. And so it happens that evening twilight sometimes and in some places runs on into morning twilight, and that the whole night is not sheer night but twilight, as happens at the summer solstice and on some of the nights nearest it, for those at whose place the pole is raised above 48½°. And although in the common Problems we are going to teach the method of investigating the duration of twilight geometrically, you will nevertheless be able to find it with the help of an armillary sphere, if, at the given altitude of the pole and with the Sun's place in the zodiac given, you set that point of the zodiac 18° below the horizon, or at whatever other depth you think more probable, counted on a vertical circle or with compasses set straight and perpendicularly between that point and the horizon. For when you have noted the point of the equator that is then on the horizon, turned the sphere, counted the degrees of the equator that rise until the point of the zodiac occupied by the Sun has reached the horizon, and converted them into time, you will have the duration of twilight, unless a difference in the air, arising from the condition of the region, stands in the way. For Father Iosephus Acosta [José de Acosta] reports that on the coast of Chile twilight is very short, and that within one quarter of an hour clear day comes out of sheer night.

[Margin: Profūditas Solis Crepusculina. — The Sun's depth at twilight.]

III. The Sun's depth below the horizon on a vertical circle, at the beginning of morning twilight or the end of evening twilight, is investigated from the time of the duration converted into an arc of the equator, and from the complement of the altitude of the pole and the Sun's declination, by the problems treated in the common Problems of the primum mobile and the second mobile, as I shall indicate in Scholium 2. But it comes out differently, because of the physical

causes indicated above. In the same way the altitude of the exhalations depends not only on the varying depth of the Sun but also on the varying quantity assumed for the Earth's semidiameter, and indeed also on the varying opinion about the cause of twilight. For Scultetus, following Cardano, *De subtilitate*, Book 4, thought that the exhalations that reflect the light of twilight to us are above our zenith; and so, using a ray reflected perpendicularly from there to us, he deduced an insane altitude for the exhalations. But who has ever seen the light of twilight above his own zenith, when it girds the horizon by only a few degrees? Nearly all the rest estimate this reflection as coming from exhalations and fumes raised about 40 or 50 thousand paces, but from the Sun's rays striking those exhalations directly. Gassendi, however, holds that that altitude can be less, because that first uncertain light can come from the Sun's ray not directly but by reflection from the lower parts of the atmosphere, so that it is reflected a second or a third time. For my part, with Kepler, and before I had read it in him, I thought and still think that this light is produced from a ray of the Sun first refracted in the surface of the atmosphere and then reflected to us from the exhalations. On this supposition the distance of these exhalations will have to be investigated geometrically by us in a far different way, and with a different figure from the one commonly used, in the Book on Optics, where the effects of refractions will be discussed more subtly. Kepler, however, adds that part of this light comes from the ethereal air spread around closest to the Sun.

[Margin: Auctores qui de Crepuscul aut altitudine Vaporum, &c. — Authors on twilight or on the altitude of vapours, etc.]

In the meantime, however, the chief expositors of twilight may be consulted: namely Ibn al-Haytham and Witelo, Book 10, Proposition 60; Nonius, Book 2, on observation, from p. 82, and in an entire book on twilight; Clavius on the *Sphere*, from p. 131, and in a short work on twilight; Magini, *Primum Mobile*, Book 11, Problem 30; Gemma Frisius in the supplement to the *Astrolabe*; Barozzi in the *Cosmographia*, p. 189; Biancani in the *Sphaera*, Book 6, Chapter 5, together with Book 10, Chapter 15; Tycho, *Progymnasmata*, volume 1, pp. 95 and 733; Scultetus, Book 2 of the *Phaenomena*, Chapter 10; Cardano, *De subtilitate*, Book 4; Rothmann in Tycho's *Letters*, for the year 1588, February 21 and 24; Simon Stevin in the *Cosmographia* of the atmosphere; Abraham Roggembach [?] in Tanner, Question 7 on *De caelo*; the Coimbra commentators, *De caelo*, Book 3, Chapter 5, Question 2; Longomontanus in the *Astronomia Danica*, Book 2 of the *Spherics*, Chapter 11; Kepler in the *Epitome of Copernican Astronomy*, pp. 73, 308 and 369, and also Part 5; Gassendi in the *Institutio astronomica*, Book 1, Chapter 18; Cabeo, *Meteorologica*, Book 1, Question 15, Book 2; Froidmont in the *Meteora*, Book 6, Chapter 4, Article 2; Gloriosi, *De cometis*, Book 2, Chapter 2. Of these, Nonius and Biancani give a table of twilights suited to nearly every elevation of the pole, which, for the reasons indicated, we judge must be reformed in the Book on Optics. Here, however, it seems good to report the opinions of others, and to show beginners, for civil use, a specimen of the table of Nonius and Biancani. The part of that table for the Sun entering the signs,

then, is of this kind, with the Sun's depth set at 18° or 19°. In it, t. n. means that twilight lasts the whole night, or is all-night; d. c. means continuous day; d. p. means pure day; and n. p. means pure night.

SCHOLIA

I. [Margin: Praxis inuestigandi Altitudinē exhalationum. — The procedure for finding the altitude of the exhalations.] Given the depth of the Sun below the horizon at the beginning of morning twilight or the end of evening twilight, the altitude of the exhalations is easily found, provided twilight is assumed to be the offspring of pure reflection and the Earth's semidiameter is known. The procedure, briefly, is this. From the arc of the Sun's depth subtract 15′, which is the portion by which the Sun, being larger than the Earth, illuminates more than a quadrant of the terrestrial hemisphere on one side. For half of the remaining arc, look up the secant in the tables of secants. Multiply it by the Earth's semidiameter and divide the product by the radius of the tables, or whole sine; you will then have that same secant known in paces or miles, whichever the Earth's semidiameter was known in. From this, therefore, subtract the Earth's semidiameter, and what remains is the excess of the secant, known in the same measures: this is the altitude of the exhalations itself, if it comes from pure reflection from there to us.

For example, the depth of the Sun at the end of evening twilight, at the time of the equinox, observed by me with Father Francesco Maria Grimaldi with the greatest attention and care, was found to be 20° 30′. Taking away 15′, the remainder is 20° 15′. Half of this is 10° 7½′, whose secant is 101582, of the parts of which the radius is 100000. Now the Earth's semidiameter has been found by me to be 5000 ancient Italian miles. The secant 101582 multiplied by this gives 507910000; dividing this by the radius, 100000, leaves 5079 1/10. Taking away, then, the 5000 miles of the terrestrial semidiameter, the altitude of the exhalations remaining is 79 1/10 miles.

II. [Margin: Profūditas Solis Crepusculina, qua Methodo inuestigetur. — The Sun's twilight depth, and by what method it is found.] The depth itself, however, is found from the given altitude of the pole, the observed duration of

[8] In this copy a later hand has written in ink over the table. It has struck through the word for "half an hour" in the Cardano row and written a figure above it; written over the Longomontanus altitude and its fraction; and struck through what stands before "288" in the next Cardano row.

twilight and the Sun's declination, by this method. Add together the semidiurnal arc and the duration of twilight converted into degrees of the equator, subtract the sum from 180°, and call the remainder the argument of the depth. The residual of the second logarithm corresponding to the argument of the depth, added to the mesologarithm of the complement of the altitude of the equator, will then give the mesologarithm of the first arc. Subtract this arc from the complement of the Sun's declination if the Sun is in the southern signs, or from the sum of the declination and 90° if in the northern, and you will have the second arc. Then add together the second logarithm of the complement of the altitude of the pole, the residual second logarithm of the first arc just found, and the second logarithm of the second arc; for the sum will give the second logarithm of the arc to be subtracted from 90°, so as to leave the depth of the Sun that was sought. I am speaking, however, with northerners, and with those who know, or wish to learn, the most expeditious analysis of triangles by logarithms. I shall illustrate this precept with a diagram and with examples in the Optical Book, or in the Book of Common Problems, or in both. Meanwhile, enjoy this indication of mine, such as it is, and do not let twilight observed on a mountain summit, rather than on a plain concentric with the sea and equally distant from the centre, trouble you in the meantime.

III. The altitude of the exhalations and fumes that become the torches of twilight, which is the subject here, is one thing. The altitude of the moister vapours, which fly less high without the wings of the exhalations, is another. Another again is the altitude of the clouds, which are denser vapours and also rise less high than exhalations or thin vapours. And another, finally, is the altitude of the refracting air, that is, the air capable of producing sensible refractions of the celestial rays, which is likewise thought to be much lower, and about which more in the Optical Book.

[Margin: Vespertinū Crepusculū Matutino prolixius. — Evening twilight is longer than morning twilight.] Moreover, the duration of evening twilight, and the depth of the Sun deduced from it, are not the same as those of morning twilight, but greater, as I gather from my own observations with reliable confidence. The cause is that the exhalations, warmed and rarefied during the day, rise higher, but afterwards, around the middle of the night, being cooled, become lower and lower for the following twilight. This is also the physical cause why, in summer twilight, the duration is greater, and so are the depth of the Sun and the altitude of the vapours derived from it. For at Bologna, at a pole altitude of 44° 29½′, I have observed that on the equinoctial days twilight lasts $1^h\ 47^m$ in the morning, but 2^h in the evening; summer morning twilight, around the solstice, $3^h\ 40^m$, for the evening twilight occupies almost the whole half-night; and winter morning twilight $1^h\ 50^m$, for the evening twilight I have not yet been able to observe. Tycho is therefore wrong when, in the *Letters*, p. 139, from observations made in 1589 February 10 and 15, he declares universally that the Sun's twilight depth does not exceed 17°.

IV. [Margin: Hora faciēdi Sacrū Opportunitate Crepusculi. — The hour for saying Mass, by the opportunity of twilight.] Those who by privilege may celebrate the Sacrifice of the Mass immediately from dawn and the beginning of twilight may, if the twilight lasts all night, perform the Sacrifice immediately after midnight. Nor is this surprising, since those whose night is no longer than one hour may say Mass immediately after midnight, and this is not too early.

But what is permitted in this regard to those living in the parallel sphere, for whom twilight lasts up to a month and a half on either side, before one equinox and after the other, is not for this place to determine.

CAPVT XXXII.

De Ortu, & Occaſu Syderum, & de Arcu Viſionis, occaſione Ortus Occaſuſq; Heliaci.

On the Rising and Setting of the Stars, and on the Arc of Vision, on the occasion of Heliacal Rising and Setting.

I. Of the twenty-four configurations, or relations, of the stars to the Sun that Ptolemy lists in *Almagest*, Book 8, Chapter 4, the chief are their rising and setting. Each of these is divided into the astronomical and the poetical. The astronomical is the right or oblique ascent or descent of a star, whether the Sun is then rising or setting, or is on the meridian, or elsewhere. The poetical is so called, not because astronomers do not concern themselves with it too, but because it alone is what poets have spoken of ever since Hesiod, when they marked out for us in verse, by the risings of the stars, the calendars and the seasons favourable to agriculture or navigation, or things of that kind. This poetical rising and setting is referred to the Sun rising or setting, and is subdivided into cosmical, acronychal and heliacal; or into true morning, true evening, and apparent, which is itself subdivided into apparent morning and apparent evening.

True morning rising and setting has been called cosmical, or mundane, because at the Sun's rising the adornment of the world and the face of Nature are renewed. True evening has been called acronychal, with a letter discarded by ectlipsis, when it ought to be called acronychal [Acronyctus], from ἀπὸ τοῦ ἄκρου [Greek: apo tou akrou, "from the extreme"], that is, from the first limit and point, and νυκτός [Greek: nyktos, "of night"], that is, of night; because it occurs accurately and exactly at once, and "punctually", as they commonly say, at the very beginning of the night and the true setting of the Sun; even though the less skilled, with Sacrobosco, call it chronical, or temporal. Apparent rising or setting has been called heliacal from ἀπὸ τοῦ ἡλίου [Greek: apo tou hēliou, "from the Sun"], that is, from the Sun, because the star, though it does not then truly ascend or descend at the horizon, nevertheless begins either to be freed from the neighbouring rays of the Sun or to be hidden by them, and so appears to rise or set.

So that we need not be repeatedly compelled to repeat and compound the Greek words, it is enough to have indicated the simple words first. Thus rising is called here not so much ἀνατολὴ [Greek: anatolē, "rising, east"], which means rising in the sense of the east [Oriens], as ἐπιτολὴ [Greek: epitolē, "rising" of a star]; setting, δύσις [Greek: dysis, "setting"]; morning or cosmical, ἑώα [Greek: heōa, "of the dawn"] or κοσμικὴ [Greek: kosmikē, "cosmical"]; evening or acronychal, ἑσπερία [Greek: hesperia, "of the evening"] or ἀκρονυκτὴ [Greek: akronyktē, "acronychal"]; if it is true, it is called ἀληθινὴ [Greek: alēthinē, "true"]; if apparent or heliacal, it is called φαινομένη [Greek: phainomenē, "apparent"] or ἡλιακὴ [Greek: hēliakē, "heliacal"]. Therefore, by compounding, the true morning rising will be called ἐπιτολὴ ἑώα ἀληθινὴ, and so on for the rest. Now let us explain these kinds one by one.

II. [Margin: Ortus Cosmicus. — Cosmical rising.] True morning rising, or cosmical rising, is the ascent of a star above the eastern horizon at the moment when the Sun rises from the same place, whether it is seen by us or not, because of the nearness of the Sun. This kind of rising belongs to all the stars in general, that is, to planets and fixed stars, unless they are among those that always lie hidden below the horizon or always revolve above it. So in the first of the figures below, in which, with the Sun rising at E, the stars I and L likewise ascend above the eastern horizon AEC.

III. [Margin: Occasus Cosmicus. — Cosmical setting.] True morning setting, or cosmical setting, is the descent of a star below the western horizon at the moment when the Sun rises on the eastern horizon, whether that star is then seen, or a little before, or not. This kind belongs to every kind of star, and to every star that can descend below the horizon and be 180° from the Sun. In the same first figure, for example, are the stars FRG, which descend below the horizon ARC with the Sun rising at the point E of the horizon AEC. And so it does not belong to Venus, which does not depart from the Sun by more than 48°, nor to Mercury, which does not depart by more than 28°.

Diagram. Woodcut, numbered I above the circle, of a sphere divided by two curved horizons running from A at the left to C at the right. The word COSMICI stands above the circle, with B at the top inside the rim and D below the rim at the bottom. The upper horizon arches through three stars labelled F, R and G. A small dark globe sits at the centre on a straight line from A to C, between the two arcs; the lower horizon arches beneath it; the part of the sphere below it is heavily shaded and holds a rayed Sun with a face at E, on that arc, with stars labelled I and L on either side. Labels read:

- I (above the circle): figure number
- COSMICI (above the rim): "cosmical"
- A (left), C (right): ends of the horizons
- B (top, inside the rim), D (below the rim)
- HORIZ. OCCID. (along the upper arc): "western horizon"
- F, R, G (beneath the stars on the upper arc)
- HORIZ. ORIEN. (along the lower arc): "eastern horizon"

• I, E, L (stars and Sun on the lower arc)

Labels not read: none. Letters cited in the prose as AEC, FRG and ARC are all on the block; R and E stand on the two arcs.

IV. [Margin: Ortus Acronyctus. — Acronychal rising.] True evening rising, or acronychal rising, is the ascent of a star above the eastern horizon at the moment when the Sun truly sets, that is, descends below the western horizon. In the second figure below, for example, the stars IKL, if they ascend above the horizon AKC with the Sun setting at E. This kind of rising belongs only to those stars that can be so opposed to the Sun as to stand 180° from it. And so it does not belong to Mercury, which cannot depart from the Sun in the zodiac by more than 28°, nor to Venus, which cannot by more than 48°. But it is not unsuited to the other stars.

V. [Margin: Occasus Acronyctus. — Acronychal setting.] True evening setting, or acronychal setting, is the descent of a star below the western horizon at the moment when the Sun also descends below it and sets. In the second figure, for example, if with the Sun setting at E the stars F and G slip below the horizon AFC. This kind belongs to all kinds of stars, and indeed to any individual star that can descend below the horizon.

VI. [Margin: Ortus Heliacus Matutinus. — Heliacal morning rising.] Apparent or heliacal morning rising is the first appearance of a star on the eastern horizon shortly before the Sun's rising, the star having until then been unable to be seen under the Sun's rays, because of the glare of the too-near Sun. In the third figure below, for example, if, as the Sun E approaches and its rising is imminent, the star F has so emerged from its glare, under which it lay hidden, that it can be seen on the horizon AFC, unless the thickness of the horizontal vapours happens to obstruct it. This kind of rising belongs to all stars that are, or can be, slower than the Sun in apparent motion in longitude, because the Sun, by its proper motion toward the east, can leave them behind it toward the west; and so it belongs to all except the Moon. Moreover, on the following days the star will appear farther and farther from the Sun, as at G:

Diagram. Woodcut, numbered II above the circle, standing at the head of the left column and built like Figure I, but with the Sun on the upper horizon. The word ACRONYCTI stands above the rim. Two curved horizons run from A at the left to C at the right. A rayed Sun with a face stands on the upper arc under the letter E, with a star on each side; F and G stand below those stars. The lower arc has three stars beneath it, with I, K and L above them. A small dark globe sits at the centre on a straight line from A to C. The part of the sphere below the lower arc is heavily shaded. Labels read:

• II (above the circle): figure number
• ACRONYCTI (above the rim): ”acronychal”
• B (top, inside the rim), D (below the rim)
• A (left), C (right)
• E (above the Sun on the upper arc)
• HORIZ. OCCID. (along the upper arc): ”western horizon”

- F, G (below the stars on the upper arc)
- HORIZ. ORIEN. (along the lower arc): "eastern horizon"
- I, K, L (above the stars on the lower arc)

Labels not read: none.

Diagram. Woodcut, numbered III above the circle, standing at the head of the right column. The word HELIACI stands above the rim. Two curves descend from B at the top: one to the left, through the stars at G and F to the rayed Sun beside E, on the lower arc; the other to the right, through the stars at L and I to a second rayed Sun beside H, on the upper arc. A small dark globe sits at the centre on a straight line from A to C, and the part of the sphere below the lower arc is heavily shaded. Labels read:

- III (above the circle): figure number
- HELIACI (above the rim): "heliacal"
- B (top, inside the rim), D (below the rim)
- A (left), C (right)
- HORI. OCCID. (along the upper arc): "western horizon"
- L, I (beside the stars on the right-hand curve), H (beside the Sun on the upper arc)
- G, F (beside the stars on the left-hand curve), E (beside the Sun on the lower arc)

Labels not read: none. No label stands along the lower arc in this figure. The prose's "AFC" and "AIC" are not lettered as such; A, C, F and I are all on the block.

VII. [Margin: Ortus Heliacus Vespertinus. — Heliacal evening rising.] Apparent or heliacal evening rising is the first appearance of a star on the western horizon shortly after the Sun's setting, the star having until then lain hidden under the Sun's rays because of its glare, too great and too near. In the third figure, for example, if, with the Sun set and sunk below the point H, the star I begins to appear on the western horizon AIC, as far as the vapours of the horizon allow, the Sun's glare no longer preventing it. This kind belongs to all stars that can be faster than the Sun in apparent motion in longitude toward the east. It therefore belongs to the Moon, whose first phase after the new moon is noticed in the evening; and likewise to Venus and Mercury after a conjunction with the Sun completed at the apogee of the epicycle, and after descent from the apogee; and Venus is then called Hesperus, or Vesperugo. But it does not belong to the fixed stars or the three superior planets.

VIII. [Margin: Occasus Heliacus Matutinus. — Heliacal morning setting.] Apparent or heliacal morning setting is the first hiding of a star on the eastern horizon under the rays of the Sun, which is near and about to rise shortly afterwards. In the third figure, for example, if the star G, which until then was seen on the horizon before sunrise, has overtaken the Sun E, or has come closer to it because of the star's faster motion in longitude, and no longer appears, the glare of the nearby Sun prevailing and overwhelming the star's rays. This kind belongs to all stars that can be faster than the Sun: thus to the Moon, whose last

phase before the new moon is noted in the morning; and also to Venus, which is then called Lucifer, or Phosphoros, and to Mercury, when they approach the apogee of the epicycle; but not to the fixed stars, nor to the three superior planets.

IX. [Margin: Occasus Heliacus Vespertinus. — Heliacal evening setting.] Apparent or heliacal evening setting is the first hiding of a star on the western horizon under the rays of the Sun, which has set shortly before. In the third figure, for example, if the star L, which the day before appeared on the horizon AIC shortly after sunset, does not appear the next day because of the Sun's approach to it. This kind belongs only to stars that can be slower than the Sun's proper motion in longitude, and thus to all except the Moon; and in the case of Venus and Mercury, only after the first station, as they descend toward the perigee of the epicycle.

X. To help the memory, I have composed for these kinds this octastich, such as it is, which shows which risings or settings belong to which stars.

True risings in the morning and true settings in the evening every star undergoes in its own seasons. Neither true settings in the morning nor risings in the evening has God granted to Venus or to Mercury. Both heliacal rising in the morning and heliacal setting in the evening the Moon alone, among the stars of heaven, lacks. Heliacal settings in the morning and risings in the evening only the Moon, Venus and Mercury possess.

But if this does not help, look at the following table [laterculum].

		Belongs	Does not belong
TRUE	Morning or cosmical rising; evening or acronychal setting	☾ ☿ ♀ ♂ ♃ ♄ ✶	
	Morning or cosmical setting; evening or acronychal rising	☾ ♂ ♃ ♄ ✶	☿ ♀
APPARENT or HELIACAL	Morning rising; evening setting	☿ ♀ ♂ ♃ ♄ ✶	☾
	Morning setting; evening rising	☾ ☿ ♀	♂ ♃ ♄ ✶

XI. Some other rules about the rising and setting of the stars are commonly given here: for example, that stars with northern latitude first rise cosmically with the Sun, then heliacally, then culminate with it, and finally set with the Sun heliacally and afterwards acronychally, while the contrary happens to stars that have southern latitude, or as long as they have it. It is also usual to add examples, either those found in the poets or others. But these require a fuller knowledge of the celestial motions and of the stars, and so I reserve them for the Book on the Fixed Stars, which will be the 6th of this first Volume, or else for Book 4 of Volume 3 of the *New Almagest*.

[Margin: Auctores qui de Ortu, & Occasu Syderum. — Authors on the rising and setting of the stars.] In the meantime I shall point out the chief authors who can be read through on such risings and settings. They are: Autolycus, on the

rising and setting of the fixed stars, with the notes of Giuseppe Auria; Geminus in the *Elements of Astronomy*, Chapters 11 and 16, where there is a catalogue of risings with a Greek calendar; Aratus of Soli in the *Phaenomena* and *Prognostica*, with Cicero, Rufius Festus Avienus and Germanicus Caesar as translators; Achilles Tatius in the *Isagoge* to the *Phaenomena* of Aratus; Hipparchus, but the Bithynian, Book 3 on the *Phaenomena* of Aratus and Eudoxus, with Pétau as translator; the book of Eratosthenes on the *Phaenomena*, with the same translator; Ptolemy in the book *On the Apparitions and Significations of the Fixed Stars*, with an Egyptian calendar, and also *Almagest*, Book 8, Chapter 4, and there Theon and Regiomontanus in the *Epitome*, from Proposition 3; Ovid in the *Fasti* and Virgil in the *Georgics*, with the scholiasts; an old calendar compiled from Ovid's *Fasti*, Columella, Book 11, Chapter 12, and Pliny the Elder, Book 18, from Chapter 26 to 30, which Pétau has in the *Uranologion*; Julius Firmicus, Book 2, Chapter 81; Johannes Stöffler on the *Sphere* of Proclus, from p. 32; Copernicus, Book 2, Chapter 13; Reinhold in the *Directions*, from Precept 34 to 37; Johannes Stadius in the *Canon of the Celestial Motions*, from Chapter 6 to the end, with an ancient calendar and a catalogue of the rising of the stars; Maurolico in Dialogue 3 of the *Cosmographia*, p. 99; Clavius on the *Astrolabe*, p. 655, and on the *Sphere* of Sacrobosco, p. 315; Barozzi in the *Cosmographia*, Book 3, Chapter 1; Biancani in the *Sphaera*, Part 3, Chapter 3, or Book 17, Chapter 10; Giovanni Antonio Magini in the *Directions*, from Canon 17 to 22, and in the *Primum Mobile*, Book 10, Problems 2 and 3, and in the *Theoricae Planetarum*, Book 2, from Chapter 14, and in Canon 98 of the *Second Mobiles*, and in the *Introduction to the Ephemerides*, Part 4, from Chapter 3, with a catalogue of the rising and setting of the stars; Origanus, Volume 1 of the *Ephemerides*, Part 2, Chapter 8, with catalogues; Longomontanus in the *Astronomia Danica*, Book 2 of the *Sphaerica*, Chapter 4, with a catalogue of the stars rising, setting and crossing the mid-heaven, for a pole elevation of 56° and for the year 1630; Johannes Kepler in the *Epitome of Copernican Astronomy*, Book 3, from p. 364 to 399, and Book 5; Dionysius Petavius [Denis Pétau], S.J., in the *Uranologion*, Book 1, and Book 2 from Chapter 8, and Book 7, Chapter 1; Franciscus Montebrunus [Francesco Montebruni] at the end of his latest *Ephemerides*, with a catalogue; Cavalieri in the *Centuria*, Problems 21 and 44; Pierre Gassendi in the *Institutio Astronomica*, Book 1, Chapter 20.

DE ARCV FVLSIONIS, SEV VISIONIS.

On the Arc of Shining, or of Vision.

XII. [Margin: Quid sit arcus Fulsionis. — What the arc of shining is.] The arc of vision [Arcus Visionis], or arc of shining [Arcus Fulsionis], of the stars is the arc of a vertical circle, intercepted between the horizon and the centre of the Sun, that is required for a star to be visible to us despite the Sun's glare. It is therefore the arc on passing which a star rises heliacally; within it the star lies hidden, and on first entering it the star sets heliacally. This arc is not constant,

however, even with respect to the same star. For it varies (1) as the star's latitude and declination vary; (2) as the rectitude of ascension or descension varies, that is, their slowness, and their obliquity, that is, their speed; and (3) as the distance of the planets from the Earth varies. Nevertheless Ptolemy in *Almagest*, Book 13, Chapter 7, and with him Regiomontanus in the same place in the *Epitome*, Propositions 22 and 23, Magini in the *Directions*, Canon 20, and in the *Theoricae Planetarum*, Book 2, Chapter 15, and Kepler in the *Epitome of Astronomy*, p. 369, lay down this arc [Greek: ὁλοσχερᾶς [recte: ὁλοσχερῶς] (holoscherōs, "in general terms, roughly")], as coming very close to the common phenomena, from an ancient observation of the Chaldeans. And it is as follows.

Arcus Visionis Stellarum, seu Profunditas Solis sub Horizonte Requisita ad Stellarum Apparitionem.

The arc of vision of the stars, or the depth of the Sun below the horizon required for the appearance of the stars.

For the planets	Arc	For fixed stars of magnitude	Arc
☿	10° 0′	1	12°
♀	5° 0′	2	13°
♂	11° 30′	3	14°
♃	10° 0′	4	15°
♄	11° 0′	5	16°
		6	17°

Nothing is said here about the Moon, because this arc, necessary for its appearance, is markedly variable, according to the Moon's differing speed and for other causes to be touched on in Book 4. The arcs given above, moreover, apply to stars assumed to be in the ecliptic itself, and were deduced by Ptolemy from arcs of vision observed in Syria by the Chaldeans when the planets were at the beginning of Cancer, near the Sun. For at that time they judged the air to be purer and the vapours of the horizon less harmful to the shining of the stars, and at that time the inclination of the zodiac to the horizon is moderate. So at that time, because of latitude, they found that Saturn rose heliacally in the morning when it was 14° from the Sun in longitude, Jupiter at 12° 45′ and Mars at 14° 30′; but that Venus rose heliacally in the evening at a distance of 5° 40′, and Mercury at 11° 30′. From this distance Ptolemy, by the analysis of triangles, gathered the arc of shining stated above. But more on these matters once the latitude of the planets has been determined.

SCHOLION.

I. [Margin: Ortus, & Occasus notatu faciliores. — Risings and settings easier to notice.] The heliacal rising would better be called an emersion or *phasis* than a rising, as Kepler too notes; and the heliacal setting would better be called [Greek: κρύφις [recte: κρύψις] (krypsis, "concealment")], that is, concealment [occultatio], or [Greek: ἀφανισμὸς (aphanismos, "disappearance")], that is,

disappearance [disparentia], than a setting. Moreover, since the night has two [Greek: ἄκρα (akra, "extremes")], that is, extremes, its beginning and its end, Ptolemy seems to call *acronycti* those stars that shine all night, both rising in the evening as the Sun goes down and setting in the morning as it rises. Chiefly, however, attention is paid to the beginning of night, since they shine all night and can be observed; whereas once the Sun has risen they can scarcely be observed after a quarter [quadrantem]. Again, the morning rising, the true one with the Sun, and the true evening setting with the Sun, cannot be observed, and are not useful for distinguishing the seasons for farming, for medical treatment or for navigation. The better ones, therefore, are the heliacal risings and settings, and after them also the true evening risings and morning settings. And if Pliny the Elder and others mark out the seasons by invisible risings and settings of the stars, perhaps they do so in order to point to hidden and astrological causes of the weather, as the same Kepler observes. But the heliacal risings and settings themselves, and the others, vary somewhat because of parallaxes and refractions, and far more because of the vapours of the horizon, on account of which stars seem to rise later on the eastern horizon and to set earlier on the western than they otherwise should. This gave some people the occasion for differing opinions on the times of these risings and settings, as Pétau notes from Wendelen in the dissertations of the *Uranologion*, p. 99. Certainly stars are very rarely and with great difficulty discerned on the horizon itself, and one must wait until they are raised a little above the horizon.

CAPVT XXXIII.

De Aſpectibus, & Radiationibus Syderum mutuis.

On the Mutual Aspects and Radiations of the Stars.

I. [Margin: Aspectuum numerus. — The number of the aspects.] Mutual aspects, and the radiations of signs or stars, are relations of one to another at a determinate distance at which they are fit to bring something about together. They are commonly counted as five and are attributed to signs and to stars placed within the zodiac, but they are extended to other stars as well. Their characteristic marks, names and the distances required for them are given in the order written below.

			Gr.
☌	Conjunction [Coniunctio]	[Greek: σύνοδος (synodos, "meeting")]	0°
⚹	Sextile [Sextilis]	[Greek: ἑξάγωνος (hexagōnos, "hexagon")]	60°
□	Square [Quadratus]	[Greek: τετράγωνος (tetragōnos, "square")]	90°
△	Trine [Trinus]	[Greek: τρίγωνος (trigōnos, "triangle")]	120°
☍	Opposition [Oppositio]	[Greek: διάμετρος (diametros, "diameter")]	180°

Conjunction and opposition, and indeed all the aspects, are also called [Greek: συζυγίαι (syzygiai, "yokings")], that is, conjugations [coniugationes]. So if two stars are no distance apart in the zodiac, they are said to be conjoined, even

if the heaven of one is separated by a long interval from the heaven of the other, as the Moon from the Sun at new moon. But if they are 60° apart, they are said to regard each other in sextile aspect, and the arc of their distance subtends a chord that is the side of a hexagon, or six-angled figure, inscribable in a circle; by 15 of Book 4 of Euclid that side is a sixth part of the circle, and so the aspect is called sextile, or *sextans*. If they are 90° apart, or a quadrant of the circle, the aspect is square, because the arc of distance subtends a chord that is the side of a square inscribable in a circle. But if they are 120° apart, the aspect is trine, because they are a third [Trientem] apart; or triangular and trigon, because the arc of their distance subtends a chord that is the side of a trigon inscribable in a circle, that is, of an equilateral triangle. And I say the same of the signs of the zodiac. So if, by 15 of Book 4 of Euclid, you inscribe a hexagon in the circle of the zodiac, and by 6 a square, and by 2 of the same an equilateral triangle, you will have figures representing these aspects and radiations, as appears in the following diagram.

[Margin: Figura Aspectuum. — Figure of the aspects.] In it Cancer ♋, Virgo ♍, Scorpio ♏, Capricorn ♑, Pisces ♓ and Taurus ♉ each regard the one nearest to it among these in sextile aspect; but Cancer ♋, Libra ♎, Capricorn ♑ and Aries ♈, in tetragonal aspect, form a square with their rays; and finally Cancer ♋, Scorpio ♏ and Pisces ♓, in trine aspect, form a trigon, or equilateral triangle.

Diagram. Woodcut set into the left column, the text running down its left side: a single circle with the twelve signs of the zodiac outside the rim and straight lines drawn between points on the rim, forming a hexagon, a square and an equilateral triangle that all share the vertex at the top. Labels read, clockwise from the top:

- ♋ (top)
- ♊ (upper right)
- ♉ (upper right, at a vertex)
- ♈ (right, at a vertex)
- ♓ (lower right, at a vertex)
- ♒ (lower right)
- ♑ (bottom, at a vertex)
- ♐ (lower left)
- ♏ (lower left, at a vertex)
- ♎ (left, at a vertex)
- ♍ (upper left, at a vertex)
- ♌ (upper left)

Labels not read: none. The block carries no point-letters and no figure number.

II. The reason for this number was both the observation of the effects and influences that signs or stars produce on sublunary bodies in the positions just named, and the division of the zodiac into harmonic intervals with the integrity of the signs preserved in the dividing. Thus to opposition corresponds

the diapason, because of the double ratio that the whole circle of 12 signs has to the 6 signs by which opposite signs or stars are apart. To trine aspect corresponds the diapente, because of the hemiolic, or sesquialter, ratio between the 6 signs of distance assigned to opposition and the 4 assigned to trine aspect. To square corresponds the diatessaron, because of the sesquitertian, or epitritic, ratio between the 4 signs assigned to trine aspect and the 3 assigned to square. Finally, to sextile corresponds a lesser diapente, because of the two signs of distance attributed to this aspect; for between 2 and the 3 assigned to the next aspect there is a hemiolic ratio, but the interval is smaller than that of 6 and 4 signs. The dodecagon, and the distance of one sign, have been left out because of the weakness of their powers; and the octagon, whose side subtends 45°, and the decagon, whose side subtends 36°, because they divide the circle with damage to the integrity of the signs. On this number of aspects see, if you wish, Ptolemy, Book 1 of *On the Judgments of the Stars*, Chapter 12, and Book 3 of the *Harmonics*, Chapter 8; Julius Firmicus, Book 2, Chapter 29; the *Introduction to Astrology* of Abū Maʿshar, Book 6, Chapter 8; Reinhold on the *Theoricae* of Peuerbach, from p. 179; Maurolico in the *Cosmographia*, p. 46; Magini in the *Directions of the Primum Mobile*, Canon 59; Kepler in the *Harmonice*, Book 4, Chapter 6, in the dissertation on the *Sidereus Nuncius*, in the *Ephemerides*, p. 33, and in the book *On the New Star and the Fiery Trigon*, from Chapter 9, who treats these matters most learnedly. [Margin: Aspectuum Numerus auctus à Recentioribus. — The number of the aspects increased by the moderns.] There, however, he admits among the aspects the decile biquintile aspect, which requires 144°, or two fifths of the circle, and the quintile, which requires 72°, and the semisextile, which requires 30°. And in the same author Fabricius admits the quincunx, 150°; and Mästlin admits, besides the quintile and biquintile, also the semiquintile, 36°, and the sesquiquintile, 108°, and the semisquare, 45°, and the sesquisquare, or *sesquadrum*, 135°. For lower nature is said to be stirred by these aspects. But the most celebrated aspects of all are the Great or Greatest Conjunctions of the superior planets, and their intervals, determined by the trine aspect of the signs of the zodiac, which are called triplicities.

III. [Margin: Triplicitates, seu Trigona Magnarũ Coniunctionũ. — Triplicities, or the trigons of the Great Conjunctions.] The triplicity, or trigon aspect, observable in the recurring Great Conjunctions of Saturn and Jupiter, is divided according to the nature of the 4 elements. The fiery trigon, or fiery triplicity, ends with its angles at the fiery signs, namely Aries, Leo and Sagittarius; the airy at the airy signs, Gemini, Libra and Aquarius; the watery at the watery signs, Cancer, Scorpio and Pisces; and the earthy at the earthy signs, Taurus, Virgo and Capricorn. The conjunction of Saturn and Jupiter takes place every 20th year in the signs of one class, and after every 200 years they pass into three other signs, and in about 800 years they complete all the triplicities with their meetings. Thus in the year of Christ 1583, 1643 and 1703 they have been and will be conjoined in Aries; in the year 1603, 1663 and 1723 in Sagittarius; and

in the year 1623, 1683 and 1743 in Leo. But in the year 1783, the passage to the watery signs having been made beforehand, it will take place in Pisces, etc., as the following figure shows after a fashion. The Greatest Conjunctions of the three superior planets, Saturn, Jupiter and Mars, require more years; this is not the place to treat of them, since there is a controversy over whether true conjunctions are to be considered, or mean ones, that is, according to the mean motions, and from what tables, or how, they are to be computed exactly. See on these matters, if you wish, Kepler in the book *On the New Star and the Fiery Trigon*; Aboassar, or Albumasar [Abū Maʿshar], *On the Great Conjunctions*; Bortholomæus Spina [?] and Io. Goclenius [?] on the same; Valentinus Naiboda [Valentin Naibod], Differentia 4; Origanus, Volume 1 of the *Ephemerides*, Part 3, Section 2, Chapter 1.

Diagram. Woodcut at the head of the right column, below the citations: a circle within a ring divided into twelve compartments, each holding one sign. Inside the inner circle are three bundles of lines running between three regions of the rim, so forming a set of nearly coincident triangles with their vertices near Aries at the top, Leo at the lower left, and Sagittarius at the right. Dotted lines run from the vertices to groups of years, each group set radially, so that the groups at the top and at the right read rotated or inverted. Labels read:

- ♈ (top, left of the head), ♓ (top right), ♒ (upper right), ♑ (right), ♐ (right), ♏ (lower right), ♎ (bottom), ♍ (bottom left), ♌ (lower left), ♋ (left), ♊ (upper left), ♉ (upper left)
- 1583, 1643, 1703, 1763 (near the top vertex, set sideways)
- 1603, 1663, 1723 (near the right vertex, inverted)
- 1623, 1683, 743 (near the lower-left vertex)

Labels not read: the third year of the lower-left group shows only "743" on the scan; no leading figure is visible, and the 1743 of the prose is not supplied to it. The block carries no point-letters and no figure number.

SCHOLIA.

I. [Margin: Reductio Aspectuũ. — The reduction of aspects.] When stars, because of latitude, do not attain the exact distance required for some aspect, one must find the time and the place at which the exact radiation suited to such an aspect will occur. How this is to be done is not agreed among everyone. On this reduction see Regiomontanus in the *Directions*, Problem 31; Magini in the *Directions of the Primum Mobile*, Canon 31; and Kepler in the *Ephemerides*, p. 37.

II. The question is often asked whether the aspect of the planets is to be considered between the bodies of the planets themselves, so that one planet then acts more strongly on another, or rather in their common radiation upon these lower things, through a triangle whose vertex is in the sublunary things and whose base is in the chord subtending the arc of distance required for

aspects distinct from the synod and opposition. On this question see Kepler in the *Fiery Trigon*, Chapter 9, arguing on this matter against Plotinus and Pico.

CAPVT XXXIV.

De Domorum Cœleſtium Diuiſione, & Erectione Thematis Cœleſtis.

On the Division of the Celestial Houses and the Erection of a Celestial Theme.

I. [Margin: Domus Cœlestes quid & quot. — What the celestial houses are, and how many.] The celestial houses, in Greek [Greek: δοδεκατημόρια [recte: δωδεκατημόρια] (dōdekatēmoria, "twelfth-parts")], are twelve segments of the zodiac, divided by the horizon, the meridian and four other great circles of the sphere, whether circles of position or of declination, according to the various systems astrologers have followed. For Avraham ibn Ezra and Regiomontanus use circles of position, which divide the equator into twelve equal parts but the ecliptic into as many parts that are not all equal; this is called the rational method [modus Rationalis], and is used by most of the more recent astrologers. Al-Qabīṣī, however, and his commentator Johannes de Saxonia use circles of declination, which divide the equator into unequal parts, namely the semidiurnal arc into three equal parts and the seminocturnal into three unequal ones; this method appears to have been Ptolemy's, inasmuch as he used hour circles, which divide the equator into 12 parts corresponding to two temporal hours each. But Campanus and Gazulus used circles of position, drawn through the sections of the prime vertical divided into 12 equal parts; for where circles of this kind cut the ecliptic, there are the cusps of the houses, that is, the beginning of one house and the end of another. These methods, with their practice, are carefully taught by Giovanni Antonio Magini in the *Directions of the Primum Mobile*, from Canon 23.

II. [Margin: Thema Cœleste quid. — What a celestial theme is.] A celestial theme [Thema cœleste] is nothing other than a figure representing, for any given moment of time, the position of the heavens, that is, the constitution of the twelve celestial houses. For example, if someone wants to know, at the moment when a certain person was born or when an equinox occurs, which point of the ecliptic was, or is, ascending on the horizon, and which at mid-heaven; and likewise for the other boundaries of the houses. To represent these things it is usual to use either a circle or the diagram below, in the middle of which are written the year, the month and the hour, with the minute after noon, for which the theme is ordered to be erected.

[Margin: Figura Thematis Cœlestis. — Figure of a celestial theme.] The first house begins from the eastern horizon, and its whole twelfth-part [dodecatemorion] lies below the horizon. It is called the Ascendant, because by the motion of the primum mobile its beginning is rising at the moment for which the theme has been constructed. For the names and order of the rest, look at the following little table; but beware of the errors condemned by papal

decrees, where the talk is of signifying future contingents. This, too, someone has enclosed in these little verses:

Diagram. Woodcut set into the right column, the text running down its left side: an outer square containing an inner square, the space between them divided by diagonal rules into twelve triangles, each numbered. The numbers run anticlockwise from the left. Labels read:

- 1 (left), 2 (lower left), 3 (bottom left), 4 (bottom centre), 5 (bottom right), 6 (lower right), 7 (right), 8 (upper right), 9 (top right), 10 (top centre), 11 (top left), 12 (upper left)
- An / M. / H.P.m. (three lines in the inner square)

Labels not read: none. The block carries no figure number.

Vita, Lucrum, Fratres, Genitor, Natiq. Valetud: Vxor, Mors, Pietas, & Munia, Amici, Inimici.

Life, Gain, Brothers, Father, and Children, Health; Wife, Death, Piety, and Duties, Friends, Enemies.

[Margin: Vanitatis Astrologicæ speculum. — A mirror of astrological vanity.]

Order of the houses [Domorum Ordo.]	Names of the houses [NOMINA DOMORVM.]			Significations [Significata]
1	Cardine of the East [Cardo Orientis]	[Greek: ὡρόσκοπος ἀνατολὴ (hōroskopos anatolē, "horoscope, rising")]	Horoscope, Ascendant [Horoscopus, Ascendens]	Life [Vita]
2	First succedent [Succedens prima]	[Greek: ἀναφορὰ (anaphora, "ascent")]	Lower gate [Inferna porta]	Hope, gain [Spes lucrum]
3	First cadent [Cadens prima]	[Greek: δεὰ [recte: θεά] (thea, "goddess")]	Goddess [Dea]	Brothers [Fratres]
4	Cardine of the lowest heaven [Cardo Imi Cœli]	[Greek: ὑπόγειον (hypogeion, "underground")]	Angle of the Earth [Angulus terræ]	Parents [Parentes]
5	Second succedent [Succedens secunda]	[Greek: ἀγατὴ τύχη [recte: ἀγαθὴ τύχη] (agathē tychē, "good fortune")]	Good fortune [Bona fortuna]	Children [Liberi]
6	Second cadent [Cadens secunda]	[Greek: κακὴ τύχη (kakē tychē, "bad fortune")]	Bad fortune [Mala fortuna]	Health [Valetudo]
7	Cardine of the West [Cardo Occidentis]	[Greek: δύσις (dysis, "setting")]	Setting [Occasus]	Spouse [Coniux]
8	Third succedent [Succedens tertia]	[Greek: ἐπικαταφορὰ (epikataphora, "descent")]	Upper gate [Superna porta]	Death [Mors]
9	Third cadent [Cadens tertia]	[Greek: θέος (theos, "god")]	God [Deus]	Religion [Religio]
10	Cardine of the mid-heaven [Cardo Medij Cœli]	[Greek: μεσουβάνημα [recte: μεσουράνημα] (mesouranēma, "mid-heaven")]	Mid-heaven [Medium Cœli]	Kingdom, offices [Regnum, Officia]

Order of the houses [Domorum Ordo.]	Names of the houses [NOMINA DOMORVM.]			Significations [Significata]
11	Fourth succedent [Succedens quarta]	[Greek: ἀγαθοδαίμων (agathodaimōn, "good daemon")]	Good daemon [Bonus dæmon]	Benefactions, friends [Benefacta, Amici]
12	Fourth cadent [Cadens Quarta]	[Greek: κακοδαίμον (kakodaimon, "bad daemon")]	Bad daemon [Malus dæmon]	Prison, enemies [Carcer, Inimici.]

III. Further, once the cusps of the houses have been found, that is, the degree and minute of the ecliptic at their beginning, that degree and minute are written in, with the character of the sign. And once the places of the planets at the same moment have been found, the character of the planet is written in, with the degree and minute of the sign in which it is found. This is done, however, so that if the cusp, or beginning of the domicile, has more degrees of that sign than the planet, the planet is then written before the cusp; but if fewer, it is written after, according, that is, to the succession in the zodiac.

The method of finding the cusps of the houses for a given time is taught by many writers on ephemerides in their introductions, or *Isagoges*, to the ephemerides, but especially by Magini, Stadius, Origanus and Argolus [Andrea Argoli]; let anyone who takes pleasure in these things consult them.

CAPVT XXXV.

De Parallaxibus.

On Parallaxes.

I. [Margin: Parallaxis notio & Definitio. — The notion and definition of parallax.] Parallax, in Greek [Greek: παράλλαξις (parallaxis, "parallax")], from the verb [Greek: παραλλάσσω (parallassō, "to stray")], which means to stray from a place or to vary a place, is a variation of view [diuersitas aspectûs] arising from the different situation of the place from which some phenomenon is observed. It can be defined as the difference between the true place of a phenomenon, observable from the centre of the Earth, and its apparent place, that is, its place as seen from the surface of the Earth. Its species are many, but the first and, as it were, the root of all the others is vertical parallax [Parallaxis Verticalis], or parallax of altitude. By virtue of it the same star or comet, at the same distance from the centre of the Earth and observed from the surface of the Earth, seems farther from the zenith and less high above the horizon than if it were observed from the centre of the Earth; and it appears the more depressed the greater its true distance from the vertex is, so that the parallax is greatest when the phenomenon is on the horizon. Moreover, at an equal altitude above the horizon, that phenomenon has the greater parallax which is nearer to the centre of the Earth. To make this easier to understand:

Diagram. Woodcut in the right column, below the table: a semicircle on a horizontal base line, with two smaller concentric semicircles and a small innermost one about the point A at the centre of the base. A vertical line rises from A to the top of the outer arc, and a second horizontal line crosses the figure above the base, from the outer arc on the left to the outer arc on the right. Straight lines radiate from A and from the point on the vertical where the upper horizontal crosses it, out to the outer arc on both sides. Labels read:

- V (top of the outer arc)
- D, E, and a third letter to the right of E (upper right, outside the outer arc)
- Q, T, X (upper left, outside the outer arc)
- G (upper right, on the second arc), C (on the inner arc)
- I (upper left), D (upper left, to the right of I)
- B (on the vertical, above the upper horizontal line)
- O (left end of the upper horizontal), N (its right end), M (above N), K (above M)
- L (right, on the inner arc), S (right, on the second arc)
- H (left end of the base), R (right end), A (centre of the base, below the line)
- Z (on the base, left of A), Y (on the base, right of A), I (below the base line, under Y)

Labels not read: the third letter to the right of E, which is [?] on the scan. Two letters on the block read as D, one at the upper right and one at the upper left; both are listed as seen. Every letter the prose below cites stands on the block; Q, T, X, E, M and the upper-right D are on the block but not cited in what is printed on this page.

II. In the following figure let the upper hemisphere of the Earth be ZBY, and the semicircle of the vertical circle HVR, passing through the vertex V of the inhabitant or observer B. Let a straight vertical line be drawn from the zenith V to the centre of the world and of the Earth, A, and let it be AV; at right angles to it let the rational horizon HAR and the sensible horizon [Horizon Sensibilis] OBN be drawn. From the centre A let two other semicircles be drawn, one for the heaven of the Moon, which is to be LCD, etc., the other for the heaven of the Sun, SGI; that is, for their vertical circle, which lies below the same vertical of the highest heaven and passes through the vertex of the observer B. Now let the centre of the Moon, L, first appear on the sensible horizon, and through the centre of the Moon let the straight line ALK be drawn from the centre of the Earth, A, as far as the highest heaven. With this laid down it is clear that the Moon L, which seen from the centre A would appear, and would be, raised above both horizons and distant from the vertex V by the arc VK, which is less than a quadrant, will nevertheless, seen from the surface of the Earth at B, appear on the physical horizon and distant from the vertex V by the whole right angle VBN, that is, by a full quadrant of the circle. Its true place, with respect to the centre of the world, will be the point K of the highest heaven;

the line of its true place, ALK; and its true distance from the vertex, the arc VK, which the angle VAK measures. But its seen place will be the point N; the line of its seen place, BLN; and its seen distance from the vertex, VN. Pa- rallax, then — the horizontal parallax [Parallaxis Horizontalis] in this case — will be both the arc KN, inasmuch as it is the difference between the true and the seen distance of the Moon from the vertex, and also the angle KLN: not because the arc KN has been described from that angle as from a centre, but because that angle is as large as the angle ALB, set vertically opposite to it, by the 15th of Book I of Euclid's *Elements*; and the angle ALB is as large as the horizontal parallax, as I shall show in Scholium 3.

III. Next let the centre of the Sun appear at S, a point of the sensible horizon. For, seen from B, it will seem to be on the horizon itself and to be distant from the vertex V by a whole quadrant; but if it were seen from A, it would be raised above the horizon. So its seen place in the highest heaven will be N, but its true place M; the line of its seen place, BSN, and of its true place, ASM; its seen distance from the vertex, VN, but its true distance, VM; and the difference between the true and the seen place, the arc MN. And so this will be the Sun's horizontal parallax: certainly less than the lunar one, because the distance of the Moon L from the Earth's centre A, which is AL, is less than AS, the Sun's distance from the same centre A; and therefore the arc and parallax MN is only a part of the whole lunar parallax KN.

IV. Now let the Sun I and the Moon D appear at the same altitude to the eye at B, seen so that the centres of both bodies are on the same line of the seen place, BX, and the apparent place of both beneath the highest heaven is the point X; and let the lines of the true place be drawn from the Earth's centre A through the centres of the luminaries. Of these, the straight line ADQ, through the Moon's centre D, will show the Moon's true place at Q, and the lunar parallax will be the arc XQ, as large as the angle XDQ. The straight line AIT, on the other hand, through the Sun's centre I, will show the Sun's true place at T, and the solar parallax will be the arc XD [recte: XT], less than the lunar parallax, as being a part of the whole.

V. Now let the Sun G and the Moon C be at the same true altitude, so that the line of the true place, D, is one and the same and passes through the centres of both, namely the line AD. Through these centres let two straight lines of the seen place be drawn from B: the line BCF, drawn through the Moon's centre C, will indicate the Moon's seen place at F and the lunar parallax DF; while the line BGE, through the Sun's centre G, will show the Sun's seen place at E and the solar parallax DE, less than the lunar parallax DF, as a part is less than the whole.

VI. Finally let the bodies be at the greatest altitude and appear at the vertex V; for whether they are seen from A or from B, the straight line of the true place, AV, and that of the seen place, BV, will coincide, and so there will be no parallax. These are the four cases of vertical parallax, that is, parallax observed in a vertical circle. With respect to the vertex it is called parallax of distance

from the vertex; with respect to the horizon it is called *parallax of altitude*, or in altitude. Concerning this species of parallax the following propositions are to be committed to memory. Although they can be demonstrated, they have been accepted by astronomers as certain axioms of a kind, and they can be demonstrated with very little trouble.

[Margin: Regula Parallaxium. — Rule of parallaxes.]

1. *A star situated at the vertex has no parallax.*
2. *A star placed on the horizon has the greatest parallax.*
3. *Of one and the same star, having the same distance from the Earth's centre, the parallax is greater at a greater distance from the vertex than at a lesser.*
4. *Of any two stars whatever, standing at the same true altitude, the parallax of the one that is less distant from the Earth's centre is the greater.*
5. *Of any two stars whatever, appearing at the same seen altitude, the parallax of the one that is less distant from the Earth's centre is the greater.*

SCHOLIA.

I. *The species of parallax are very many, according to the many species of situation in which objects, viewed from different places, can appear; but the chief ones in astronomy are the parallaxes of altitude, of depth, of distance, of longitude, of latitude, of right ascension, and of declination. More about these in our Optical book, in the Section on Parallaxes.*

II. *In no. 6 a fifth case could have been added: namely, when a star is on the rational horizon but appears below it. It has been passed over, however, because with the eye placed at B this cannot happen, since the eye cannot see what is below the sensible horizon unless it is raised above B. It remains, then, either that the star appears on the sensible horizon, and is then truly above it; or that it both is and appears at the vertex at once; or that two stars are at the same true altitude and differ in the seen altitude; or that they appear at the same seen altitude and disagree in the true.*

III. [Margin: Anguli Parallactici demonstratio. — Demonstration of the parallactic angle.] *It was said at no. 2 that the angle made at the centre of the star by the line of the true place and the line of the seen place is the measure of parallax; the angle ALB is of this kind. This is easily shown. For it is the angle by which the true distance from the vertex is exceeded by the seen distance. In that example the seen distance is the angle VBL, which together with the angle LBA makes two right angles, by the 13th of Book I of Euclid's* Elements. *The measure of the true distance, namely of the arc VK, is the angle VAK, that is, BAL, since the arc VK is described from the angle's point A as from a centre; and this angle, together with the angles ABL and ALB, is equal to two right angles, by the 32nd of Book I of* Euclid. *So, taking away the common angle ABL, there remains the angle VBL of the seen distance, equal to the angle BAL of the true distance and the angle ALB taken together. Therefore the angle ALB is the one by which the true distance from the vertex is exceeded by the seen distance. Similarly, in the triangle ACB, the angle at C is the measure of parallax, because it is the one by which the true distance, that is, the angle BAC, is exceeded by*

the seen distance VBF. For the angle ABC is the common complement to two right angles, both of those at B, by the 13th of Book I of Euclid, *and of those in the triangle ABC, by the 32nd of the same Book I. Taking away, then, the common angle ABC, there remains the angle VBC of the seen distance, equal to the angle BAC of the true distance and the angle ACB taken together. Therefore the angle ACB is the one by which the true distance is exceeded by the seen distance.*

IV. *The seen distance from the vertex either becomes known through instruments with which altitudes are taken from B, or is inferred from a given true distance from the vertex, whether by trigonometry or by tables made for this use, which I have in the end thought it better to keep back for the end of the book.*

CAPVT XXXVI.

De Refractionibus.

On Refractions.

I. [Margin: Refractionis notio ac Definitio. — The notion and definition of refraction.] REFRACTION, in Greek [Greek: ἀνάκλασις (anaklasis, "refraction"; literally "a bending back")], is the bent propagation of a direct ray, occurring at the common surface of two transparent media [diaphana] of different density. For by varied and long experiment it has been discovered that the rays of a luminous body and of any visible object whatever, falling on something opaque, are reflected back towards their origin, with the angle of reflection equal to the angle of incidence; but that, falling on something transparent yet of a density different from the medium through which they had so far been propagated, they do not go straight on along the same straight line, but are as it were broken and bent, that is, propagated along another straight line, though they do not return towards their origin; and that if the medium on which they newly fall is denser, they are broken towards the perpendicular, but if rarer, they are refracted away, departing or diverging from the perpendicular.

II. There are as many species of refraction of celestial rays in the air as there are of parallax, but for beginners it will be enough to have pointed out the primary species, from which the others spring: namely *vertical refraction* [Refractio Verticalis], or refraction of altitude, which must be used very frequently in astronomy, so that the true altitude of the stars may be distinguished from the apparent one, altered by the force of refraction. In the following diagram, then, let there be the quadrant COG of a vertical circle, described from the Earth's centre A, and beneath it the quadrant TB of a great circle of the Earth; and from the same centre of the Earth, A, let the spherical surface of the denser vapours be described, of which DRE is a quadrant: denser, I mean, than the air enclosed between DE and GOC. Let ABG be the rational horizon and TRO the physical horizon. Now let the star, as regards its true place or true altitude, be at S, and let its ray SR fall on R, a point of the surface of the denser vapours; to that point

Diagram. Woodcut set into the right column, the text running down its left side: a quadrant with its right angle at A at the lower left, the vertical side rising from A to C and the horizontal side running from A through B and E to G; the outer arc runs from C to G. Within it a heavily inked arc runs from D, on the vertical side, to E on the base; a lighter arc runs from T to B. Near the crossing of the heavy arc stands R: a horizontal line runs from T through R to the outer arc at O, a line runs from L through R, a line runs from A through R, and a line runs from R to the outer arc at S. Labels read:

- C (top of the vertical side)
- D, L, T (down the vertical side, in that order)
- A (the corner, lower left)
- B, E, G (along the base, left to right)
- R (on the heavy arc)
- O, S (on the outer arc at the right, O above S)

Labels not read: none.

let the perpendicular AR be drawn from the centre A. So the ray SR will not go straight to L, as it would if the medium were of the same density, but will be refracted towards the perpendicular RA. Let us now suppose it to be refracted to T. Then, since the eye sees an object along a straight line, and in the position in which it is represented by that straight line which immediately affects the sensory organ, the object will appear to it to be on the line TRO, or at the point O; and so it will appear on the horizon, even though it is in fact below the horizon. Conversely, if the object or luminous body were at T, and the direct ray were TR, here, on leaving the denser medium, it would be refracted from the perpendicular AR, departing from R towards S. In the first case the *ray of incidence* would be SR, the *ray of refraction*, or refracted ray, RT, and the *angle of refraction* LRT; in the second case the *ray of incidence* would be TR, the *refracted ray* RS, and the *angle of refraction* ORS.

Diagram. Woodcut set into the left column at the head of the page, the text running down its left side: the same construction as on the preceding page, a quadrant with its right angle at A, an outer arc from C to G, a heavily inked arc from D to E, a lighter arc from T to B, and lines through R from T to O, from L, from A, and from R to S. Labels read:

- C (top of the vertical side)
- D, L, T (down the vertical side, in that order)
- A (the corner, lower left)
- B, E, G (along the base, left to right)
- R (on the heavy arc)
- O, S (on the outer arc at the right, O above S)

Labels not read: none.

III. From what has been said it is now established that the effect of refraction is altogether contrary to the effect of parallax. For parallax represents a star or similar phenomenon as less high than it really is, whereas refraction represents it as higher: what is at S, for instance, it represents at O. This is also seen

in a coin placed at the bottom of water, in a stick seen broken, and in other things submerged under water, which because of refraction appear higher, and are seen also by those by whom they could not otherwise be seen. There are very many things, moreover, both worth knowing and necessary for the accomplished astronomer, about the refractions of stars and comets, and we shall speak of them at length in the Optical book. Meanwhile let the following propositions, accepted by all as axioms, be enough for the beginner whom we are instructing.

[Margin: Regula [?] Refractionū. — Rule [?] of refractions.]

1. *A star situated at the vertex has no refraction of altitude.*
2. *A star placed on the horizon has the greatest refraction.*
3. *Of one and the same star, retaining the same distance from the Earth's centre, the refraction is greater at a greater distance from the vertex than at a lesser; so much so that at about 45° refraction is scarcely perceptible, while near the horizon it grows with a headlong increase.*
4. *Between the refractions of two stars having the same true altitude above the horizon, that one is the greater which belongs to the star less distant from the Earth's centre, and this of itself.*

For Kepler admits that the fact that Tycho's little table shows refractions of the Moon very slightly smaller than the refractions of the Sun arose from a fallacious observation, though one honestly reported.

As for the tables of refractions, I judged it wiser to put them off to the end of the book, with the remaining astronomical tables.

SCHOLIA.

I. *Besides* the refraction of altitude there is the refraction of depth, of longitude, of latitude, of right ascension, of declination, and of distance *between two stars; these arise from the refraction of altitude or of depth. More on these in the Optical book, in the Section on Refractions, where more exact tables of refractions will also be presented.*

II. *When a true place or a true altitude is compared with the place or altitude seen by the force of refraction, this is understood with parallaxes set aside, or with the seen place and altitude already corrected and reduced to the true by the addition of parallax. So if some star has at once both a parallax of altitude, because of which it appears lower, and a refraction because of which it appears higher, than it really is, then to get the true altitude the parallax must be added to the seen altitude, and from the altitude thus corrected the refraction must be subtracted. But if the true altitude is to be converted into the seen, the parallax will have to be subtracted from it, and the refraction added to the remainder.*

III. *Although refraction differs from reflection chiefly in these respects, that the direct propagation of a ray is impeded in refraction by the density of the transparent medium, but in reflection by opacity, and that a reflected ray turns back towards its origin, whereas a refracted ray does not, this is nevertheless to be understood of*

simple transparency and density taken separately. For if some transparency of a denser medium is mixed with some opacity in a certain respect, reflection and refraction can occur together. Further, there is no contradiction in a ray's being first reflected and then refracted, or first refracted and then reflected. Those who treat of the rainbow or of twilights ought to have considered this, since they exclude refraction on the ground that the sight of the rainbow and of twilight's light comes about through rays reflected to our eye. But against these, below, in the Optical book.

LIBRI PRIMI FINIS.

End of the First Book.

LIBER SECVNDVS DE SPHÆRA ELEMENTARI AC PRÆCIPVÈ DE GLOBO TERRAQVEO.

Book Two: On the Elementary Sphere, and Chiefly on the Terraqueous Globe.

CAPVT I.

De Terræ simul, & Aquæ figura.

On the Figure of Earth and Water Together.

I. [Margin: Opiniones de Figura Terræ. — Opinions on the figure of the Earth.] This terraqueous element in which we live, that is, the one composed of earth and water, *Anaximander* judged to be like a column; *Leucippus*, like a cylinder or a war drum; *Cleanthes*, like a cone or a top; *Heraclitus*, like a bowl [Scaphio]; *Democritus*, like a hollow disc; *Anaximenes* and *Empedocles*, like a flat table; while *Xenophanes of Colophon* held that it rests on a root infinite downwards. So report, in part, Aristotle, *De caelo* Book 2 from text 76, in part Plutarch, *De placitis philosophorum* Book 3, chap. 10, and Laertius in their lives. But that this mass is, to the senses, spherical was first demonstrated by *Parmenides of Elea*, on the testimony of Aristotle; then by *Thales of Miletus*, who added that the Earth floats on the waters; and they were followed by the Stoics, and by the Peripatetics with their Aristotle, above. Among the cosmographers, the same roundness is shown by *Ptolemy*, *Almagest* Book 1, chap. 4, and *Theon* there, and *Regiomontanus* in the *Epitome*, concl. 2; *Cleomedes*, *De Mundo*, p. 376 in my copy; *al-Farghānī*, difference 3 [different. 3]; *Martianus Capella*, Book 6; *Copernicus*, Book 1, chaps. 2 and 3; *Fernel*, *Cosmotheoria* Book 1; *Maurolico*, *Cosmographia*, dialogue 1, p. 7; *Clavius* in the *Sphere*, pp. 3, 117 and 197; *Barozzi*, *Cosmographia* Book 1, p. 22; *Biancani* in the *Sphere*, part 3, tract. 3, chap. 4; and the interpreters of Aristotle, *De caelo* Book 2 from text 104; *Argoli* in the *Pandosion Sphaericum*, chap. 5; and *Kepler* in the *Epitome of Copernican Astronomy*, from p. 17.

II. [Margin: Argumentum 1. Rotunditatis Terræ. — Argument 1 for the roundness of the Earth.] The first argument is from the common name *orb of the earth* [Orbis terræ], which the Vulgate version of Psalms 23 and 92 uses, and which Pliny the Elder also touched on, Book 2, chap. 64, saying: *"We certainly call it the orb of the earth, and we admit that a globe is enclosed by poles; for the form*

of a perfect orb does not exist with such height of mountains and such flatness of plains, but it is one whose curves, if the ends of the lines are taken in by a circuit, would make the figure of a perfect orb." The height of the mountains, however, is not so great that, compared with the Earth's diameter, it can perceptibly impede its globosity; for its diameter is 10348 ancient Italian miles, while the height of the mountains is far below 50 miles, as will be clear on both points from our Geographical book. Some liken its roundness to the shell of eggs or of an orange, whose convexity is not spoiled by the modest unevenness of the pores, which stand for valleys, and of the little bumps, which stand for mountains.

III. [Margin: Argum. 2. Rotunditatis Terræ. — Argument 2 for the roundness of the Earth.] The second argument, a priori, is from the nature of earth and water, which by their very nature seek a spherical figure, because of the equal impetus with which their homogeneous parts tend to the same centre of heavy things, so that they stand at equal distances from it. And so, if the Earth, reduced to physical atoms without any glue of moisture to hold it together, were allowed to move to its own place, all its grains of sand would rush down to the common centre of heavy things, in the way that the parts of water flow together from higher places, until the parts of the surface were equidistant from the centre; and thus they would make up a spherical heap. For the equidistance of the surface from the centre is the property and the proof of a sphere, from what was said in Book 1, chap. 6.

As for the parts of water, all of them, and indeed of all liquids, that they form themselves into a spherical surface if allowed to move naturally until they settle and come to rest is so certain by experiment that it needs no demonstration. Archimedes nevertheless demonstrated this very thing in Book 1 of *On Things Carried in Water* [de his, quæ vehuntur in aquis], in that proposition 2: *"The surface of every fluid that has settled and stays at rest is spherical, and the centre of this sphere is the same as the centre of the Earth."* This can readily be understood in another way, as follows. Let the centre of the Earth be C, the hemisphere of the Earth APB, and two heaps of water MV and KN. For they will flow together towards P, as the lower-lying place, and will not settle until, the surface RGS having been formed, the parts of the watery surface stand at equal distances from the centre C. That they do not settle as long as some are further from the centre of heavy things is plain from daily experience; and that there is no greater reason why some should stand further from it than the rest is established from their homogeneous fluidity.

Diagram. Woodcut set into the right column, the text running down its left side: a semicircle on the base AB with its centre C marked below the base, and a higher arc over it. A straight line runs across the top from M at the left to N at the right, and straight lines run from M and from N down to C. Labels read:

- G (above the top of the higher arc)
- M (left end of the upper line), N (its right end)
- P (below the upper line, at the crown of the semicircle)

- R, V (at the left; V italic, inside the figure)
- S, K (at the right; K inside the figure)
- A, C, B (along the base, left to right)

Labels not read: none.

IV. [Margin: Argum. 3. Rotunditatis Terræ. — Argument 3 for the roundness of the Earth.] The roundness of the Earth together with the sea is gathered from the approach of ships and their withdrawal from shores, or from the sight of towers seen first near and then far off. For

Diagram. Woodcut across the right column: an oval globe with a winding coastline drawn on it, and straight lines radiating from the point P within it towards its upper rim. A straight line runs above the globe from F at the left through A to E at the right. On the upper rim stand small drawn objects: at the upper left two tall narrow pointed ones, one rising from the rim near H to a point beyond K, the other lying from the rim near G with its point at F; at the upper right one with a pennant, by D and B; and at the right another with a pennant, by C, its top towards E. Labels read:

- F (far left), K, A, D, E (far right), along the upper line from left to right
- H (below K), G (below H, on the left rim)
- B (below D), C (on the right rim, below E)
- P (within the globe)
- T (at the foot of the globe)

Labels not read: none.

the eye on the shore at A sees the whole height of the mast and the bottom of a ship setting sail from the shore; then, as the ship withdraws, it sees only the upper parts, and the lower parts, DB, are hidden; and finally the whole ship with its mast CE sinks, for that eye, below the sensible horizon AE. Pliny the Elder too notes this, Book 2, chap. 65. In the same way the eye A, which of the tower KH, equally tall, sees a part of it, yet sees nothing at all of the tower FG, which is just as tall. This is evidence that ships travel over the convex surface of the waters and that their masts stand perpendicular to the water, the line of direction DB and EC tending toward the same centre P — the point toward which the plumb lines of towers and of all buildings also tend. And these things have by now been observed on every sea and on every shore.

Diagram. Set in the left column below the paragraph above. A large circle (the meridian) carries eight letters on or just outside it, each at a small star; inside it, at the centre, a small circle (the terrestrial globe) with three little figures or balls on spokes above it. Straight lines through the common centre join V to D, N to M and H to R; a fourth runs from K through the centre toward G and stops just short of it. The three balls stand on the upper radii, one each on the lines to G, V and N.

- V (top of the outer circle): the zenith star of the argument below
- N (upper right, outer circle)
- R (right, outer circle)
- K (lower right, outer circle)

- D (bottom, outer circle)
- M (lower left, outer circle)
- H (left, outer circle)
- G (upper left, outer circle)
- A (left, on the inner circle's upper arc, beside the ball on the line to G)
- F (top centre of the inner circle, beside the ball on the line to V)
- B (right, on the inner circle's upper arc, below the ball on the line to N)

V Wherever one goes from north toward south along the same meridian, different stars keep coming into view. The southern stars rise higher and higher above the horizon while the northern stars sink lower and lower until at last they are hidden. And the increments of elevation on the one side and of depression on the other keep the proportion that the difference between those stars requires, as measured on the circumference of a circle. So people sailing from Holland or England, or from Portugal, toward the Hesperides and further south see the meridian altitude of the stars of both Bears grow less and less, until, once placed under the equator, they see the Pole Star either grazing the horizon or already hidden beneath its vapors. Conversely, they see the four stars of the Southern Cross, which they had not seen this side of the Torrid Zone, or see them more elevated where before they were less so.

[Margin: Argument 4 for the roundness of the Earth.]

You have a specimen of this experience in the figure above, in which the globe of the Earth is AFB and the meridian is HVRD. An inhabitant at A beneath this meridian sees the star G at his zenith. If he travels toward the south pole R, as far as F, he will now see that star at a distance from his vertex V by the whole arc VG. And if he goes on further under the same meridian to B, he will see the star G at a distance from his vertex by the whole quadrant NG, and now on the horizon GK. Other stars, which stood at a distance from the vertex, he will see at the vertex: the star V when he is at F, and the star N when he is at B. Others, finally, which he did not see while he was at A — such as the star R and K — he will see when he comes to F or B. And this happens not on some one meridian but on all meridians. It is therefore a sign that the Earth is spherical from south to north, since if it departed perceptibly from this figure these things would not appear in this way. This will be evident to anyone who draws the various figures, invented by the ancient natural philosophers, that we listed in number I.

IV [recte: VI] The risings and settings of the stars appear later to those further west, and so do eclipses. Thus for people who are 15° further west, the Sun sets one hour later [than for those to the east of them], and the beginning of the same lunar eclipse occurs one hour later — exactly as the Earth's spherical form requires. Shipmasters sailing around the whole globe from east to west have by now experienced this. This terraqueous mass is therefore spherical all around, and not merely in the direction of the poles of the world.

[Margin: Argument 5 for the roundness of the Earth.]

VII In addition, in every lunar eclipse, anywhere on land or sea, it has been observed that the Earth's shadow — by which, as we here assume, the Moon is darkened — imitates a circular disk. This is a sign that the body casting such a shadow onto the face of the Moon is round. It has rightly been called, then, the *orb of the Earth* [Orbis Terræ]. For figures supporting this argument, see Book 5, on eclipses.

[Margin: Argument 6 for the roundness of the Earth.]

VIII Finally, for those who inhabit the higher parts of the Earth the Sun rises sooner and sets later than for those living low down, and from more elevated places an ever wider prospect of plains and sea opens up. We would by no means experience this if the Earth were flat in the manner of a disk or a table, or of a cubic surface, etc.

[Margin: Argument 7 for the roundness of the Earth.]

SCHOLIA.

I Pliny the Elder (Book 2, Chapter 64) does not deny that the Earth is globular if its circuit is taken through the mountain tops. He held, however, that the mountains on its surface are much higher than Dicaearchus had said. Dicaearchus, having measured Pelion, the highest mountain of Thessaly, and found that its perpendicular height did not exceed 1250 paces, had concluded: "That height is nothing — in proportion, that is, to the whole roundness of the Earth." But Pliny the Elder raises two objections against him, namely "so great a loftiness of mountains, so great a flatness of plains," and adds: "To me this conjecture seems uncertain, since I am not unaware that certain peaks of the Alps rise over a long stretch, no shorter than fifty thousand paces." Pliny therefore thinks it follows from the ascent of the Alps of at least 50 miles that they stand perpendicularly much more than 1250 paces high. This is perfectly true, considering how steep their ascent is in places, as I shall say in the *Geographical Book*. But even if we granted that the Alps are 50,000 paces high, that height, compared with the Earth's circumference of 32512 old Italian miles, would not stand against the roundness Dicaearchus asserted, nor against the phenomena discussed above. I shall touch on opinions about the height of mountains below, in this Book, Chapter 11.

[Margin: Whether the height of mountains stands against the roundness of the Earth.]

II As for the flatness of plains and the level of the sea, a twofold deception of sight is hidden here. Opticians teach one of them when they show, with Ibn al-Haytham (Book 3), that the more distant points of a pavement appear to us more elevated because they are seen by a higher ray; hence the curvature of the sea appears flat, while the flatness of plains appears raised toward the horizon, so much so that the land seems hollow in the manner of a bowl, as Heraclitus said. Maurolico touches on the other in Dialogue 1 of the *Cosmographia*, as follows: "What you survey of land and sea, standing on this hill, is so tiny compared with the whole magnitude that you cannot gauge any curvature in it; just as if you cut from a large circle, of a thousand paces more or less, a circumference two

or three feet long, you would see no bending in it." I myself have tested this on a circumference, with a small nail tied to a rope of fifty feet and carried around: a foot-long part of the circumference had a barely perceptible curvature and looked nearly like a straight line. The whole semicircumference was 157 feet. And yet the proportion of 1 foot to 157 is far greater than that of 70 miles to the 16256 miles contained in the semicircumference of the Earth's upper hemisphere. Now 70 miles of sea cannot be seen unless the lookout or mountain is 600 paces high perpendicularly, as will be shown in Chapter 10 and in the *Geographical Book*, where visual distance is treated; and someone standing on the shore itself sees no more of the sea than 3 miles, or at most 4. What wonder, then, my dear Pliny, if so tiny a portion seems flat to him, for the two causes stated?

[Margin: Why the sea and the plains look flat.]

III As for what Francesco Patrizi [Franciscus Patritius] brings forward in Books 25 and 26 of the *Pancosmia* against Archimedes, Aristotle, Clavius and other defenders of the roundness of Earth and water, it shows so great an ignorance of geometry [ageometriam] that one is reluctant to report it, let alone refute it. Still, I shall point out one or two of his errors. For this, look at the figure set beside number 3 of this Chapter 1. He says, then, that if water lies on the plane MPN it does not flow together to the lowest place, and that the parts M and N are not higher than the point P physically, granted they are so mathematically. He adds that as he withdrew from the town of Comacchio the bottoms of the houses gradually disappeared, and that at length, after ten miles covered on that lagoon, the tower of the principal church, 72 feet high, vanished entirely. And yet the bottom of the lagoon did not exceed two feet, whereas, he says, it should have been 72 feet deep if the tower had to be hidden because of the swelling and roundness of the water.

[Margin: Patrizi's mistaken opinion against the roundness of the Earth.]

But you are hallucinating, my dear Patrizi. Look at figure 2, at number 4 of this Chapter, and let the tower FG in it be 72 feet high, and let the distance FA from the eye A be 10 miles, or 50000 feet. The entire tower below its apex F will be hidden from the eye A, even if it has not sunk at all below the surface of earth or water, as trigonometry will teach you from the true semidiameter of the Earth PG, if you are versed in it. You, however, supposed that the tower FG stands perpendicular to the horizontal line FA. But if that were so, you would have had to be sunk down to 72 feet. Yet you did not descend in that way, and neither do others sailing, from whose view towers standing on the shore — the Lanterna, say, or the Pharos of Genoa — at length pass out of sight;

they are therefore hidden for no other reason than the curved surface of the sea.

IV. But Patrizi presses us with two further experiments in Book 26. He relates that in the year 1562, when he was about to sail to Cyprus and the ship was still moored at the Venetian shore, a mountain of Liburnia overlooking Assuero, two hundred thousand paces from Venice, was seen in the morning; but once the Sun had risen it was no longer seen, while he sailed toward it.

And in the year 1574, when he was sailing beyond Toulon [Tolonem] in the Tyrrhenian Sea, the mountains of Corsica and almost the whole island were sighted, although it is more than 300 thousand paces away. And he concludes: "If over so great a space the surface of the sea had been swollen, it would have taken from our sight either the whole mountain or the greatest part of it." But another would infer more plausibly that those mountains are 12 thousand paces high perpendicularly and the mountain of Liburnia nearly six thousand, since the former could be seen from the surface of the sea at an interval of 300 miles and the latter at 200 — were it not that refraction stands in the way. According to Snel and Kircher, refraction raises the appearances of things, especially near the horizon, and above all for those sailing toward the sunrise; and when refraction ceases, many things lie hidden beneath the physical horizon which by its force appeared above it. But there is more on this in the Optical book.

CAPVT II.

Terram esse Centrum Mundi, & in Centro Cœli supremi Stelliferi, saltem quoad sensum.

That the Earth Is the Centre of the World, and at the Centre of the Highest Starry Heaven, at Least to the Senses.

I. [Margin: Opiniones de Terræ loco in Mundo. — Opinions on the Earth's place in the world.] This is the view not only of the Peripatetics, with *Aristotle*, *De caelo* Book 1 from text 96, and *Pliny the Elder*, Book 2, chap. 69; and of the cosmographers, with *Ptolemy*, *Almagest* Book 1, chap. 5; *al-Farghānī*, difference 4; *Johannes de Sacrobosco* in the *Sphere*, chap. 1, and *Clavius* there, p. 135; *Maurolico*, *Cosmographia*, dialogue 1, p. 9; *Biancani* in the *Sphere*, Book 4, chap. 1; and *Barozzi*, *Cosmographia* Book 1, p. 29. It is also the view of the *Pythagoreans* and *Copernicans*. Although they place the Sun at the centre of the world and say that the Earth moves around it in the orb in which the others hold that the Sun moves — the orb they call the annual orb [Orbem Annuum], from the yearly revolution in the zodiac of the Earth and not of the Sun — they nevertheless admit that the distance of the fixed stars from the Earth is so great, and that not only the globe of the Earth but the annual orb itself is so small, that compared with the distance of the Aplanes, or eighth sphere, it has an imperceptible ratio to it. All phenomena therefore appear to us, to the senses, just as if the Earth were in the middle of the world, so that it can be called the centre of the world in a physical or loose sense, granted that for them it is no such thing in astronomical rigor, the Sun being that centre. Setting sacred authority aside, the arguments by which it is customarily proved that the Earth is in the middle of the world in fact show nothing else than that the Earth is, to the senses, in the middle of the world with respect to the highest starry heaven, as we shall soon see, or that it lies between the Sun on the one hand and the Moon and the three superior planets on the other, when these are

in opposition to the Sun, as the Moon is at full moons. For this is the sum of the arguments.

II. [Margin: Arg. 1. pro Terra in cētro Mundi. — Argument 1 for the Earth at the centre of the world.] First, if the Earth were not in the middle of the world, the horizons of all the inhabitants of the Earth would not cut it in two together with the heaven. Nor would six of the twelve signs of the starry zodiac be seen above the horizon, nor half the heaven. Nor, of two stars diametrically opposite — as the southern eye of Taurus and the heart of Scorpius nearly are — would one be seen on the eastern horizon when the other is on the western horizon. Instead, some would see much more than half the heaven and others a much smaller part, etc., which is contrary to the experience of every age. To make this easier to grasp, let the Earth first be BC, let the centre of the Earth and of the universe be C, let the highest heaven of visible things be HMR etc., and let the rational horizon be HCR and the sensible horizon ABD. In this way the eye B will see half the heaven, if not HMR, at least AMD; and of two stars diametrically or almost diametrically opposite, such as H and R or A and D, when one rises at H or at A, the other will be seen to set at R or at D.

Diagram. Woodcut in the right column near the head of the page: a large circle with four parallel horizontal chords, and two small circles inside it on its vertical centre line, the upper about O and the lower about C. The chord from E to L runs through the top of the upper small circle at N; the chord from F to G runs through the upper small circle's centre O; the chord from A to D runs through the top of the lower small circle at B; the chord from H to R runs through the lower small circle's centre C. Labels read, none unread:

- M (top, above the large circle)
- N (above the upper small circle)
- E (upper left) and L (upper right), ends of the first chord
- F (left) and G (right), ends of the second chord
- O (inside the upper small circle)
- B (above the lower small circle)
- A (left) and D (right), ends of the third chord
- H (left) and R (right), ends of the fourth chord
- C (inside the lower small circle)

Let the Earth next be at O. Its rational horizon will then be FOG and its physical horizon ENL. The horizon, therefore, would not cut the heaven in two, nor would it any longer be a great circle [circulus Maximus] in the sphere of the world, as is commonly supposed. Nor would the eye N see half the heaven, but only the portion EML. Nor would it see two stars 180° apart, such as H and R, opposed to each other on its horizon.

III. [Margin: Arg. 2. pro Terra in cētro Mundi. — Argument 2 for the Earth at the centre of the world.] Fixed stars on the equator or very near it are observed on clear nights to move successively by the diurnal motion, from their rising above the horizon to their setting, in such a way that they are above the horizon for 12 equinoctial hours, when the nights are at least 12 hours long.

This would not happen if the Earth were not, to the senses, in the middle of the universe but were at O. For a star ascending from E would hurry to its setting, through M, at L much sooner than in a space of 12 hours; nor in the meantime would half the equator, HMR, ascend, but a far smaller arc of it, namely EML.

IV. [Margin: Arg. 3. pro Terra in cētro Mundi. — Argument 3 for the Earth at the centre of the world.] The same stars, seen on the same clear night on the horizon, appear either equal to themselves when they have come to the meridian, or rather, because of the vapors of the horizon, larger. This is a sign that they are, to the senses, equally distant from the Earth, and the Earth from them. If you are concerned about the vapors of the horizon, look at the same star — the Fidicula of the Lyre [Lyræ fidiculam], say, or Arcturus — on different meridians, for you will see it of the same magnitude everywhere. But if the Earth were perceptibly nearer the heaven on one side than on the other, say at O, the same star on the meridian, say at M, would appear much larger than at the point E or L of the horizon; for what is nearer appears larger.

By the same reasoning, the distances of the fixed stars from one another would not appear, as they do in fact appear to us, always the same and equal to themselves. For example, I have always observed the distance of Arcturus from Regulus to be 59° 49′, whether near the horizon or far from it, and everyone anywhere will always observe the same. But if the Earth were not physically in the middle of the universe, any two of the fixed stars would appear more distant from each other near their meridian altitude than near the horizon to those who were nearer their zenith than their nadir, as to the inhabitant N. Conversely, to those living in the opposite hemisphere, who were further from their zenith than from their nadir, they would appear more distant near the horizon than near the meridian. For the same distance between two visible things appears greater at a smaller distance from the eye and less at a greater one; and modest refraction near the horizon would not account for so great a difference.

V. [Margin: Arg. 4. pro Terra in cētro Mundi. — Argument 4 for the Earth at the centre of the world.] If the Earth were outside the middle of the universe, that is, outside the plane and axis of the equator, it would be either on the axis or off the axis of the equator. If it were on the axis of the world and of the equator, perceptibly nearer one of its poles than the other, and outside the zodiac, no horizon would cut the zodiac into two equal parts except the right horizon; and so outside the right sphere there would be no equinox anywhere. But then the inhabitant of the right sphere would not be on the equator, and those nearer the pole would have a day always shorter than the night. If, on the other hand, it were within the zodiac and on some parallel that the Sun runs through, the equinox in an oblique sphere would occur on the day on which the Sun runs through that parallel, and not on the days on which it now occurs. And if the Earth were in the plane of the Tropic of Cancer, the equinox would occur on the day on which the Sun, now coming closest to the north pole, makes the solstice:

nor on the equinoctial day would the shadow of a gnomon set up perpendicular to the horizon constantly trace with its tip one and the same straight line. These results run against the established experience of astronomers, as Clavius shows in the *Sphere*, from p. 139, with many figures added. In place of them, look at the figure of the armillary sphere placed at the beginning of the Book, and imagine the Earth in the positions just stated.

But if the Earth were in the plane of the equator but not on its axis, there would be no equinox in the right sphere except on the one horizon that passed through the centre of the world. In the oblique sphere, either there would be no equinox, or it would not fall midway in place and time between the winter and summer solstices; nor would the excess of the longest day over 12 hours equal the shortfall of the shortest day. Finally, if the Earth were located neither on the axis nor in the plane of the equator, we would run into all the absurdities just stated, which conflict with the plainest experience.

VI. [Margin: Arg. 5. pro Terra in cētro Mundi. — Argument 5 for the Earth at the centre of the world.] Since the Earth is the heaviest of all things, it tends simply downward. If it were placed outside the middle, whether whole or cut into parts, it would naturally tend as a whole, as its parts also do, downward and to the centre of the universe, so as to stand equally distant from the place that is, and is called, up, namely the highest heaven. For there would be no greater reason why it should come nearer to one part of the heaven than to another; indeed, there is reason for the opposite, so that it may share equally in the influences and benefits of the heaven. The place naturally due to the Earth is therefore the middle of the world and the centre of the universe. So everyone rightly says and acknowledges that the Earth is in the lowest place of the world, and most true is that saying sanctioned in Holy Scripture, Proverbs 25: *"The heaven above, and the Earth below."* The Copernicans, however, evade this argument.

SCHOLIA.

I. We are not here dealing with the Pythagoreans and Copernicans, who set the Sun motionless at the centre of the world and have the Earth revolve around the Sun in the Ptolemaic orb of the Sun. For to understand their hypothesis and the answers to their arguments is not a matter for a novice but for a more accomplished astronomer. These things are therefore to be treated by us in Book 9, where the systems and hypotheses of all astronomers are discussed, and also in the small work on this subject that we have in hand, entitled *Apology for the Sacred Censure, Passed by the Holy Congregation of Cardinals, against Those Who Assert the Annual and Daily Motion of the Earth* [Apologia sacræ censuræ contra Assertores motus Telluris annui, & diurni, latæ à S. Congregatione Cardinalium].

II. [Margin: Quantam Cœli portionem Terra nostro visui intercludat. — How large a portion of the heaven the Earth shuts off from our sight.] We do

not always see exactly half the heaven. One reason is the vapors of the horizon, which by their opacity obstruct the sight of the fixed stars in it. Another is the position of the spectator, who sometimes is not raised at all above the surface of the Earth and so cannot see what lies below the sensible horizon. This horizon is not a great circle of the sphere [Circulus Sphæræ maximus], but cuts it into a smaller segment, which we see, and a larger, which is hidden from us. Yet if he is raised some paces onto a hill or a tower or a similar lookout, he can see even more than half the heaven. And if he is not raised, that portion of the heaven AH or DR which the Earth's semidiameter takes from us is nevertheless very small and imperceptible. For it is exactly as large as the horizontal parallax of the fixed stars, which in everyone's opinion is imperceptible, and the smaller the further those stars are from the Earth. For this, look at the following little table [laterculum].

In it I have passed over the opinion of the Copernicans, because they do not agree on the distance of the fixed stars from the Earth. Some set it at a minimum of 7850000 semidiameters of the Earth; others with Lansbergen extend it to 41958000 semidiameters; others with Kepler stop at 34077067 semidiameters, or with Hortensius at 10300190. It is certain among them, however, that the said parallax, and the portion of the hemisphere hidden from us, are much smaller than among the Tychonians or Ptolemaics. Against these, Mario Bettini did not hesitate to put the distance of the fixed stars at only 2290 semidiameters of the Earth, on account of certain harmonic intervals; and from that distance follows a sensible parallax, namely 1½′. But there is more on these matters in the Optical book, where parallaxes are treated, and in the Book on the fixed stars.

Distance of the fixed stars from the Earth	In semidiameters of the Earth	Horizontal parallax of the fixed stars ″	‴
Ptolemy and al-Battānī	19000	11	0
al-Farghānī	20110	10	0
Tycho	14000	14	44

III. [Margin: Argum. ab Eclipsibus pro situ Terræ quanti valeant. — What the arguments from eclipses are worth for the position of the Earth.] The reader may perhaps wonder that I have left out the argument from lunar eclipses, which Regiomontanus, Maurolico, Biancani and Clavius — the most brilliant lights of astronomy, that is — use to show that the Earth is situated in the middle of the universe. For they say that if the Earth were not in the middle of the world, lunar eclipses would not always occur in diametrical opposition to the Sun, but sometimes when the Sun and Moon are far fewer than 180° apart in the zodiac, as is shown in the first figure of this scholium. For although with the Earth placed in the middle at A, the Moon L would be eclipsed by the shadow AV, in opposition to the Sun S, yet with the Earth placed outside the centre of the world, as at I, the Moon P would be eclipsed by the Earth's shadow IB, while less than a semicircle of the zodiac from the Sun.

Diagram. Woodcut set into the right column, the text running down its left side: two concentric circles, with a small circle at the right overlapping the outer circle and carrying S within it. From that small circle two long narrow cones run leftward, one through a dark globe in the upper part of the inner circle and out past the outer circle to B, the other through a dark globe in the lower part of the inner circle and out past the outer circle to V. Labels read:

- B (upper left, outside the outer circle, at the point of the upper cone)
- P (top of the inner circle, on the upper cone)
- a small drawn Moon just below P, on the upper cone (a dark disc with a crescent rim)
- I (right of the upper dark globe)
- A (below the lower dark globe)
- V (left, outside the outer circle, at the point of the lower cone)
- L (just right of V, below the lower cone)
- a small drawn Moon just right of L, on the lower cone (a dark disc with a crescent rim)
- S (inside the small circle at the right)

On the other hand, they say, if it is granted, even for two eclipses, that the Moon is in diametrical opposition to the Sun, as astronomical observation and calculation require, it follows necessarily that the Earth is on both of those diameters. And since all diameters of the world intersect at the centre of the world, it must be that the Earth is in the middle of the world. They explain this by the second figure here, in which the Sun in its heaven and the Moon in its own are diametrically opposite in two eclipses, and the diameters intersect at the point C.

Diagram. Woodcut set into the right column, the text running down its left side: two circles one within the other, the inner about the point C. Two straight lines cross at C. At the upper ends of the two lines stand two rayed suns, upper left and upper right, on the upper part of the circles; at the lower ends stand two dark crescent moons, lower left and lower right, on the inner circle. One label read, none unread:

- C (at the crossing of the two lines)

This argument seems to have greater force in horizontal eclipses of the Moon, that is, when the Moon is eclipsed while rising as the Sun sets, or while setting as the Sun rises. Pliny the Elder reports such an eclipse in Book 2, chap. 13, and Mästlin one seen by himself, in Kepler's *Astronomia Optica*; and such, with respect to the horizon of Rome, will be the eclipse of 1668 May 25. So Argoli raises a triumphal song there against Copernicus, believing he has established from this that the Earth, and not the Sun, is at the very centre of the world. Nor did Clavius, in the *Sphere*, pp. 137 and 143, recognize the paralogism; but like good Homer he nodded here.

[Margin: Argoli, & Clauij argum. claudicans. — The limping argument of Argoli and Clavius.]

These authors, however, reason falsely, or at any rate equivocate, from the diameter of the heaven of the luminaries to the diameter of the world. For from the said eclipses it is established only that the Earth comes between the Sun and the Moon, that these three bodies are on the same straight line, and that the Moon is then beneath the part of the ecliptic opposite to the part beneath which the Sun is. All of this can be true even if the Sun were at the centre of the world and the Earth outside it — not only where Copernicus places it, but much further from the centre of the world — provided that the Earth's shadow reached the Moon and the Earth were between the Sun and the Moon, as we shall show in its place. This argument therefore limps on one leg, and does not prove the more important part of the desired conclusion.

CAPVT III.

De Terræ Immobilitate. — On the Immobility of the Earth.

I. [Margin: Motus Terræ quot? — How many motions has the Earth?] Four motions of the Earth are commonly debated. The first belongs to its parts and is called, by a single name made up of two words, an *earthquake* [Terræmotus]. It occurs when an exhalation enclosed in the bowels of the earth and ignited seeks to rarefy and expand; having no room sufficient for itself, it seeks room with great and very swift force through the hollows of the earth, and so shakes parts of the earth and the foundations of buildings until it finds an exit through a vent. In the same proportional way an exhalation ignited within clouds produces thunder while seeking an exit. We are not speaking here, however, of this motion of the earth, but of the motion of the whole Earth.

II. [Margin: Trepidatio Terræ an vlla. — Whether there is any trepidation of the Earth.] The second is the motion of *trepidation* [Trepidationis], whose proponents were *Marsilius* [Marsilius of Inghen], on Book 8 of the *Physics*, tract. 1; *Maior* [John Mair], on Book 2, dist. 24, quaest. 12; *Johannes de Saxonia*, on *De caelo* 2, quaest. 10; *Vasquez* [Gabriel Vázquez], on the *Prima Secundae*, disp. 83, chap. 3; *Scheiner*, in the *Disquisitiones Mathematicae*, no. 15; and *Cottunius* [Ioannis Kottounios], on Book 1 of the *Meteorologica*, lect. 17. For they say that the Earth's centre of gravity must coincide exactly with the centre of the Universe. Since the centre of gravity within the Earth is perpetually changing, because of the collapses and landslips of mountains, diggings of the ground on one side and heapings-up on the other, new buildings, etc., the Earth too, they say, nods this way and that with a perpetual but imperceptible wobbling.

The contrary opinion, however, conforms better to that stability of the Earth which the sacred writings teach, especially Psalm 104: *You who founded the earth upon its stability; it shall not be inclined for ever and ever* [Qui fundasti terram super stabilitatem suam, non inclinabitur in sæculum sæculi], and which the theologians teach in *Raynaudus* [Théophile Raynaud], *Theologia naturalis*, dist. 4, quaest. 3, art. 3. These, with St Gregory (*Moralia* 2, chap. 15) and St Thomas (*De Malo*, quaest. 16, art. 10), say that not even the angels themselves

can naturally move the earth the least bit from its place. And so, finally, do the ancients, who for that reason called the Earth *Vesta*, because it stands by its own force, according to that line of Ovid:

The Earth stands by its own force; from standing by force it is called Vesta [Stat vi Terra sua, vi stando Vesta vocatur.]

The reason is this. The mass of the Earth, with all its weight, exceeds any weight shifted about on its surface by far more than any weight immovable by the motive power of one man, or even of several, exceeds that power. And it is established that there are weights which no human force, no lever and no machine can budge. Therefore neither can weights placed on top of the Earth budge it, even if they were Olympus, Pelion and Ossa. If you say that it moves of itself so as to stand in equilibrium, the case is the contrary. Any weight that is usually added to the Earth on one side has a smaller proportion to exciting its motion than the wing of a fly, or the lightest speck of dust, added to one of two scale-pans that rest in equilibrium with ten equal pounds on each side; especially since, for motion upwards or downwards, the resistance of all the air surrounding the opposite hemisphere has to be overcome. For Cleomedes (*De Mundo*, Book 1) and Seneca (*Naturales Quaestiones*, Book 4, quaest. 11) rightly said that the Earth is to the mountains as a huge ball to a hair [ingentem pilam ad pilum]; whether you say with Simon Stevin (*Statics* [Statices], Book 3) that the weight of the Earth is 2,000,000,400,000,000,000,000,000 pounds, or with *Forerius* [Lorenz Forer], in the *Viridarium disputationum philosophicarum*, on impulse and the centre of gravity, part. 47, that it is 899,564,914,285,714,283,714,285½ pounds. So, just as not any and every effort of ours is enough to move any and every weight, so not any and every heaviness is enough to shift the Earth from its equilibrium, whatever that celebrated boast Archimedes made to Hiero, more magnificent than true:

Tell me where I may stand, and I shall move Heaven and Earth [Dic vbi consistam, & Cœlum Terramq. mouebo.]

For the better theologians judge that this has not been granted by God even to the angels.

III. The third motion is that of daily revolution, which is called the motion of *rotation* [Vertiginis], by which in the space of 24 hours the Earth is said to move about its centre and axis from west to east — [Margin: Vertigo Terræ circa suum cētrum an asseri possit. — Whether a rotation of the Earth about its centre can be asserted.] said so by Plato, *Hicetas* of Syracuse, *Ecphantus* the Pythagorean and *Heraclides* of Pontus, and afterwards by the Copernicans and the Semi-Copernicans. To the second class belong *Gulielmus Gilbertus* [William Gilbert], *Longomontanus*, *Mulerius*, *Origanus* and *Argoli*. For so as not to admit in the stars two continuous and contrary motions, one common and daily from east to west, the other proper from west to east, and so as not to grant the fixed stars an incredible speed, they say that it is the Earth itself which, together with the atmosphere, indeed with almost the whole elementary region, moves towards the east. It therefore goes to meet the stars, and these

seem to move towards the west, though they move by no other motion than towards the east: just as, to people being carried in a boat towards one quarter of the world, the shores and banks seem to move and to recede towards the opposite quarter, although in fact they stand still. And they press on us that line of Virgil, *Aeneid* 3:

We sail forth from harbour, and lands and cities recede [Prouehimur portu, terræq. vrbesq. recedunt.]

But this opinion, when asserted absolutely and not merely hypothetically, was condemned by the Sacred Congregation of Cardinals appointed by Pope Paul V for the Index of Prohibited Books, on 1616 March 5; and again, by order of Urban VIII, by the same Congregation, on 1633 June 22, where it is judged *at the least erroneous in Faith* [Ad minus erronea in Fide]. For in the sacred writings the daily motion is attributed not to the Earth but to the Sun: thus Ecclesiastes 1, *The Sun rises and sets, and returns to its place, and there being reborn*, etc. [Oritur Sol, & occidit, & ad locum suum reuertitur, ibiq. renascens &c.]; and Joshua held it back from this motion (Chapter 10); and very often the Sun is said to have risen, as in Genesis 15 and 19, Judges 19, etc.; and by this motion the Sun went backward on the dial of Ahaz (Ecclesiasticus 48 and Isaiah 38). Nor is there any necessity to depart from the literal sense of Holy Scripture, since the opponents themselves admit that, given the daily motion of the stars, all the phenomena of astronomy are saved in full rigour; and that contrariety of two motions can be produced by a spiral motion, or by the daily motion alone, as we shall show in its place. The said Congregation further calls this opinion *Absurd and false in Philosophy* [Absurda, & falsa in Philosophia]; and rightly. For it was introduced without any necessity, against the common evidence of the senses, to which it is physically evident that the stars move from east to west and that the Earth does not so move, even granting that this is not mathematically evident; nor is it established from any other source that the sense is to be corrected, as it is established in some other cases.

IV. [Margin: Translationis motus an Terræ tribui possit. — Whether a motion of translation can be attributed to the Earth.] The fourth motion of the Earth is that of *translation* [Translationis], which is called the *annual* [Annuus]. By it, with the Sun standing still in the centre of the Universe, the Earth's centre is said to move through that orb in which, according to Ptolemy, the Sun moves with an annual motion of 365 days and about 6 hours; so that the retrogradations and stations of the planets are apparent, not real, and many other astronomical matters are handled better on this hypothesis than if the Earth stood still and the Sun were said to move in the annual orb. So thought long ago, about the annual as well as the daily motion of the Earth, *Philolaus* the Pythagorean and *Aristarchus of Samos*, as is reported of them by Aristotle (*De caelo* 2, text 72), Plutarch (*De Placitis* 3, chap. 13), Laertius in their lives, and Archimedes in the *Sand-Reckoner* [Arenario]. The same was asserted later, not merely hypothetically but absolutely, by Nikolaus von Kues, Nicolaus Copernicus in his *De revolutionibus*, both in the preface and in Book 1, Chapters 8, 10 and 11;

Ioachimus Rheticus [Georg Joachim Rheticus], *Michael Mästlin*, *Schickard*, *Kepler*, *Rothmann*, *Cœlius Calcagninus* [Celio Calcagnini], *Didacus Astunica* [Diego de Zúñiga], *Paulus Antonius Foscarinus* [Paolo Antonio Foscarini], *Galileo*, *Simon Stevin*, *Philips and Jacob van Lansbergen*, *Pierre Hérigone* and *Ismaël Boulliau*. For Gassendi, out of reverence for the decrees of the Sacred Congregation, at the end of Letter 2 *De motu impresso à motore translato* at last acquiesced in the immobility of the Earth.

But this opinion was condemned far more strongly by the same Sacred Congregation, cited above, in whose censure it is called *Absurd and false in Philosophy, and, as regards the immobility of the Sun, formally heretical, as being expressly contrary to Sacred Scripture; but as regards the motion of the Earth, at the least erroneous in Faith* [Absurda, & falsa in Phylosophia, & quoad Solis immobilitatem, formaliter hæretica, vtpote expressè contraria Sacræ Scripturæ; quoad motum verò Terræ, ad minus erronea in Fide]. For not only is the Earth called stable, immobile, etc. in the Sacred Writings (Paralipomenon 16, Psalms 92 and 104, and Ecclesiastes 1), but also, and above all, the Sun is expressly asserted to move with an annual motion, Ecclesiastes 1: *It circles through the south and bends towards the north*, etc. [Gyrat per Meridiem, & flectitur ad Aquilonem &c.] This motion too is against the physical evidence of the senses; nor does any reason compel us to depart either from this evidence or from the literal sense of the Sacred Scriptures. And so in vain are examples heaped up from Holy Scripture in which sense and imagination have to be corrected and in which one must grant that Scripture speaks figuratively, or to suit the grasp of the common people. In those examples, if they hold good, the deception of the senses is already evident from another source: from other, more manifest sensations, or from evident reasoning and necessary, apodictic arguments. Neither of these is found in our case, since the Copernicans admit that all the phenomena of the heavens can be saved on either hypothesis, that of the Earth standing still and the Sun moved, or that of the Earth moved and the Sun and fixed stars standing still. But these matters must be discussed more forcefully and more fully in Book 9.

V. [Margin: Motus Terræ annuus sed Declinationis. — An annual motion of the Earth, but one of declination.] The fifth motion of the Earth, ascribed to it by Copernicus, is the annual motion of *declination* [Declinationis], by which the axis of the terrestrial equator moves in the precedent direction [in præcedentia], contrary to the annual motion of the centre, which takes place in the consequent direction of the signs [in consequentia Signorum]. Its purpose is to account for the Sun's apparent motion obliquely from south to north. Because this motion is a little swifter than the motion of the Earth's centre, it causes the equinoctial and solstitial points to appear to recede in the precedent direction, towards the west; so their motion is called the *precession of the equinoxes*, and by this motion Copernicus accounts for the apparent motion of the fixed stars towards the east. Although the Sacred Congregation of Cardinals issues no express decree on this motion, it nevertheless seems tacitly to have condemned it, since it is no

less repugnant to Holy Scripture than the annual motion of the Earth's centre. For the divine writings attribute the motion of declination too to the Sun, in Ecclesiastes 1, where it is said of it: *It circles through the south and bends towards the north*, etc. [Gyrat per Meridiem & flectitur ad Aquilonem &c.]

VI. [Margin: Motus Librationis duplicis Copernicæ. — The motion of Copernican double libration.] The sixth motion of the Earth is one of double *libration* [Librationis], to account for the anomaly of the precession of the equinoxes and of the obliquity of the ecliptic. Of this and of the preceding one we shall speak more opportunely in Book 3, Chapters 27, 28 and 29, where we shall also speak of the motion of the Earth upwards and downwards, by which it is not the Sun that becomes apogean or perigean, but rather the Earth that becomes aphelial and perihelial [Aphelia & Periphelia]. The slowest motion of the Earth, substituted by *Andrea Cæsalpino* [Andrea Cesalpino] (*Quaestiones Peripateticae*, Book 3, quaest. 4) in place of the proper motion of the fixed stars towards the east, is the one indicated by Copernicus in Book 1, Chapter 11, and it reduces to the Copernican motion of the precession of the equinoxes, although Cesalpino extends its period to 30000 years.

SCHOLIA.

I. [Margin: Argumenta contra motum Terræ quāti valeant. — What the arguments against the motion of the Earth are worth.] Many physical and astronomical arguments are commonly heaped up against the Copernican motion of the Earth, both daily and annual. Even men otherwise skilled in philosophy and astronomy judge them to be apodictic, or wholly demonstrative, yet on inspection they are not so. But it is not for everyone to search out thoroughly the depth of the Copernican hypothesis, and so I have put off the exposition and discussion of these arguments to the end of this work and to a separate book on this subject. I wish only that beginners [tyrones] be warned of three things. The Copernicans attribute that motion, both daily and annual, to all bodies of the atmosphere as a common one, apart from their own motion upwards, downwards and animate [animasticum]. They place the centre of heavy bodies in the centre of the atmosphere, not in the centre of the Universe. And they hold the fixed stars to be at so great a distance from the Earth that the Earth, by its annual motion, experiences no perceptible diversity of aspect. With these points laid down and properly understood, a great many of the arguments hurled against them collapse. And were it not that sacred authority and the evidence of the senses deter us from that opinion, no mathematical arguments have so far been devised, as far as I at least know, that ought to have moved us away from it. I think, however, that with God's help I shall in due time bring forward one or two arguments which, from the phenomena given in astronomy by the Copernicans themselves, will convict their opinion of falsity, in part at least.

II. [Margin: Congregationis Cardinalium auctoritas. — The authority of the Congregation of Cardinals.] The Sacred Congregation of Cardinals, taken apart from the Supreme Pontiff, does not make propositions matters of Faith, even if it defines them to be of Faith or their opposites to be heretical. Hence, since no definition on this matter has yet come forth from the Supreme Pontiff, or from a Council directed or approved by him, it is not yet of Faith that the Sun moves and the Earth stands still, by force of the decree of that Congregation taken precisely; but at most, and only, by force of Sacred Scripture, for those to whom it is morally evident that God so revealed. All we Catholics, however, are bound by the virtue both of prudence and of obedience to hold what that Congregation has decreed, and at least not to teach the opposite absolutely. But I have dealt expressly with this theological subtlety in my Treatise on Faith, where I discuss the Rules of Faith. From this, however, you will understand how Marin Mersenne, who denies that the opinion of Copernicus has been condemned as heresy, can be reconciled with *Iusto Lipsio* [Justus Lipsius], Melchior Inchofer and *Georgio Polacco* [Giorgio Polacco], who say that its opposite is of Faith; which, however, Gassendi denies in the letter mentioned above and at the end of Book 3 of the *Institutio Astronomica*.

CAPVT IV.

Terræ Centrum esse Centrum Commune Omnium Corporum Grauium: Vbi selecta quædam Corollaria ad illud Centrum spectantia. — That the centre of the Earth is the common centre of all heavy bodies; with certain selected corollaries concerning that centre.

I. [Margin: Centrum grauitatis & centrum molis. — Centre of gravity and centre of mass.] The centre of gravity is not of its own kind the same as the centre of figure, or of magnitude. For the centre of magnitude is *that point around which parts of equal magnitude stand on all sides*. The centre of gravity, by contrast, is *a point placed within a body, such that if the heavy body is conceived as hung from it, it rests while it is carried and keeps the position it had from the start, and is not turned about in the carrying itself*. So Pappus of Alexandria defined it (*Mathematical Collections*, Book 8); or, as Federico Commandino says at the start of his book *De centro gravitatis*, it is *a point within a body around which parts of equal moments stand on all sides*. For if a plane is drawn through such a centre, cutting the figure in any way whatever, it will always divide it into parts of equal weight. *Moment* [Momentum] here means the force and power to move downwards, which in inanimate bodies is nothing other than gravity. The *line of direction* [directionis], or *diameter of gravity* [Grauitatis diameter], is a straight line perpendicular to the horizon, drawn through the centre of gravity.

Now in homogeneous bodies, that is, those with wholly similar parts, the centre of gravity is the same as the centre of figure and of magnitude. This is shown more clearly in regular figures: thus in the circle and in the sphere, and in all rectilinear or plane figures with equal sides that can be inscribed

in or circumscribed about a circle or a sphere, the centre of gravity and of magnitude is the same, if they are homogeneous; as when a sphere or a cube is made entirely of the same gold, or lead. In heterogeneous bodies, on the other hand, the centre of gravity is often one thing and that of magnitude another. For if you make a sphere with one hemisphere of wax and the other of lead, the centre of gravity will lie outside the centre of figure and within the lead segment.

II. [Margin: Idem centrum grauit. & molis in Terra. — The centre of gravity and of mass is the same in the Earth.] In the sphere of the terraqueous globe, then, the centre of gravity and the centre of magnitude are judged to be the same, at least physically and to the senses. For although the globe is interspersed with waters and mixed with heterogeneous parts near its surface, these have an imperceptible proportion to the remaining homogeneous mass of the Earth, and are unfit to weigh it down towards one side, as we said in Chapter 3, no. 2, and as will be confirmed by what is to be said below about the depth of the sea and the mass of the waters compared with the Earth. Moreover, as is gathered from the natural history of those who have travelled round almost the whole globe, God, Best and Greatest [DEVS O. M.], has so arranged the mountains and seas around the Earth that the moments around its centre are equal on all sides; whether or not, for that very reason, certain seas are higher, as Cabeo asserts of the Tyrrhenian Sea (*Meteorologica*, Book 1, p. 55), and as others assert of the Red Sea and the Northern Sea [Mari Nortico] with respect to the Ocean *del Sur*. Finally, if the centre of gravity in the Earth were perceptibly distant from the centre of magnitude, plumb lines let down freely above the surface of plains or of the sea would surely show this somewhere, for they would lean to one side rather than the other. Since this has nowhere appeared so far, it would be quite without grounds to suppose that these two centres in the terrestrial sphere stand perceptibly apart from each other.

III. [Margin: Centrum Terræ est centrū omnium grauium. — The centre of the Earth is the centre of all heavy bodies.] From this the question is now easily solved, whether the centre of the terrestrial globe is that common centre towards which all heavy things tend of themselves by an innate appetite, and from which light things withdraw, along straight and shortest lines, unless they are hindered or forced to descend towards it, or ascend from it, by a longer and oblique path. It must indeed be affirmed. For everywhere on land and sea the weights of plumb lines, let down through the air or through still water, descend along that straight line which makes equal angles on either side with the surface of the terraqueous globe, or right angles with a straight line or horizontal plane touching the convex surface of the said sphere; and so along that straight line which, produced either actually or in imagination, continues the Earth's semidiameter and falls on its centre. This is so true that a straight line making equal angles on either side with another has acquired from it the name of *perpendicular line* [Lineæ perpendicularis]. And this becomes more manifest both in waters, whose surface, when still, is also convex-spherical,

for on it the equality of the angles produced on all sides by the thread of a plumb line is apparent, and in drops of water falling straight onto the sand of a shore. For why do they not flee from that sand, which by its dryness will consume them, or at least preserve them less well? Or why do they not turn aside by an oblique path to the nearby sea? Surely because the gravity placed in them, as parts inclined to the good of the whole, prevails, and moves them towards the one common centre of all heavy things, which is in the very middle [meditullio] of the Earth. Finally, we see the masts of ships, the walls of buildings, the trunks of trees, the stalks of grain, the pyramids of flames and the little rods of smoke keeping of themselves, violent motion aside, a position perpendicular to the terrestrial globe in their motion upwards or downwards, or in their rest, wherever in the end they may be. Granted, the smallness of two neighbouring walls, compared with the depth of the Earth, is so slight that they seem parallel and not about to meet perpendicularly at the centre of the earth.

From this there now follow some corollaries worthy of note, from which I shall point out those I judge more worthy of cosmographers and more useful to them.

COROLLARIA

Ex Centro Grauitatis, & Magnitudinis Terræ. — From the centre of gravity and of magnitude of the Earth.

I. The imagination of those must be corrected who think that their antipodes, if there are any, will fall into the opposite part of the heavens. For they do not fall; with gravity inclining them towards the same centre of the Earth, they stand perpendicularly on the earth's surface, no differently from us. Read, please, against such people Pliny the Elder (Book 2, Chapter 65), and what I said in Book 1, Chapter 20.

II. [Margin: Tellus qua vi in medio Mundi pēdeat. — By what force the Earth hangs in the middle of the world.] Likewise to be corrected is the imagination of those who have difficulty grasping how the Earth, unless it rests on a very deep and infinite root below, as Xenophanes imagined, can stand immobile. For if, with God, Best and Greatest, so arranging the element of earth and water, all its parts stand on all sides around the same centre and are in equilibrium, there is no reason why this mass, however great, should be carried elsewhere. But how will they be able to grasp why the whole world stands around the one centre of the Universe, and does not drift this way and that in the divine immensity, which coexists with infinite imaginary spaces, not to say equals them? Let them listen to Manilius, Book 1, Chapter 2:

Nor should the nature of the hanging Earth seem a marvel to you, since the world itself hangs and sets its footsteps on no ground [Nec verò tibi natura admiranda videri / Pendentis Terræ debet; cum pendeat ipse / Mundus, & in nullo ponat vestigia fundo.]

And that line of Ovid, *Metamorphoses* 1:

Balanced by its own weights, it stays motionless [Ponderibus librata suis immobilis hæret.]

Against these people Pliny the Elder too, Book 2, Chapter 65, is to be read.

III. If the Earth were divided into two hemispheres, and only one of them remained, such as the hemisphere AB, on the horizontal plane ACB a single man could stand perpendicularly, at C, while the others would naturally hang inclined more or less to the horizon, according as they were more or less distant from the centre C, or from the point C, terminating the line in which the centre of gravity of the earth would be: for then the common centre of heavy things would not be C, but another point within the earth's hemisphere. But if that centre remained at C, the man B, at the extremity of the horizon, could not stand perpendicularly above the horizon, but would lie down; although he could not even lie there, but would rush downwards towards C. Again, trees, buildings, the stalks of crops, etc., outside C would be inclined.

Diagram. A hemisphere with its flat side upward and shaded curvature below, set into the right column beside the text of no. III. A small human figure stands upright at the middle of the flat top; a second figure at the right end of the flat top leans over or falls.

- A (upper left, at the left end of the flat side)
- C (centre of the flat side, under the standing figure)
- B (upper right, above the leaning figure at the right end of the flat side)

IV. If there were a straight line, or a plain, touching the earth at a single point and produced notably far, such as HPR, touching the Earth's globe PC at the point P, men placed on that plane and distant from the point of contact P, as A and B are, would not stand upright on it, but inclined, as the line of direction AC or BC would require, drawn through their centre of gravity and produced to the centre of the Earth C. And if a heavy sphere were set on the same plane far from the point of contact P, as at H, it would not rest there, but would rush down to the point P, so as to be as close as possible to the centre C. The plains and pavements on which we stand upright, however, although they seem straight and flat, are nevertheless convex, though imperceptibly, for the reasons given in Chapter 1 of this Book, Scholium 2; or if they are flat, our inclination to them is imperceptible.

Diagram. A circle (the Earth) with a straight line tangent at its top, set into the right column beside the text of no. IV. Lines run from the centre of the circle out to figures on the tangent line. Two small figures lean on the right part of the line; a ball or figure stands on its left part.

- P (inside the circle, just below the point of tangency)
- C (lower part of the circle, the centre)
- A (above the tangent, right of P, beside the first leaning figure)
- B (above the tangent, far right, beside the second leaning figure)
- R (right end of the tangent line)

- Not resolved: a small stroke at the extreme left end of the tangent line. The text cites H at that end of the line; no H was read on the block at this magnification.

V. [Margin: Turres inclinatæ nec cadentes. — Towers that lean yet do not fall.] Men standing on the ground on one foot or two, whether leaning or pushed or pulled by another in wrestling, will stay standing for just as long as the line of direction drawn from their centre of gravity to the centre of the Earth falls within their soles; but if it falls outside, they too will fall. The same happens with trees and with towers, in which the root or foundation serves as the sole. From this arose that device of architecture by which a leaning tower, such as the Garisenda Tower at Bologna, does not fall; and that tower of Cologne, leaning so far that men climb over its sloping back. The reason they do not fall is that the line of direction falls within the foundations, as the line EBC or GD would in the attached diagram. So it greatly helps for the foundations to widen downwards with an oblique increase, so that the line of direction, falling outside the projecting part of the tower ABRE, should nevertheless not fall outside the foundations, but should strike within them, even if only slightly, and not be like the line GD. It is also advantageous for the tower, especially in its upper part, to be hollow and empty of stones, and for the rest to be solid, so that the greater part of the weight may the more surely lie in the foundations and in the portion of the tower joined to them, and thus the line of direction may fall within the foundations. An architect will easily determine this, having weighed with due skill the weights of the stones, lime and mortar of both parts: if the weight of the part FDBEA is a thousand, and of the part EBRE 400, he will safely declare that the line of direction will stay within the foundations.

Diagram. A leaning tower drawn as an oblique parallelogram rising to the upper right from a wider, flared base, set into the right column beside the text of no. V. Two dotted verticals descend from the top edge to the base.

- E (top edge, left)
- G (top edge, centre)
- R (top edge, right)
- K (on the right side of the tower, where the dotted vertical from G crosses it)
- A (left, at the junction of the upper tower and the base)
- B (inside the base, on the dotted vertical from E)
- F (bottom left corner)
- C, D (bottom edge, right, at the feet of the two dotted verticals)

VI. The reason why on stairs, or on the slopes of mountains, although they are longer than the planes beneath them, no more men can stand than on the base, is that they must stand perpendicularly on the surface of the earth; and so ascent by steps whose treads are parallel to the horizon is more convenient. Thus in the figure placed here, although the slope of the staircase AK is longer than the base AB, yet if the base AB holds only three men standing and occupying

with their soles the three spaces AC, CD and DB, no more than three will stand on the slope AK either, occupying, in a position upright to the horizon, steps equal to the spaces of the base, such as EI, FL and GK.

Diagram. Three rising rectangular steps over a horizontal base, with a diagonal line drawn from the lower left to the upper right corner, set into the right column beside the text of no. VI.

- A, C, D, B (along the base, left to right)
- E (left, at the top of the first step)
- F (above the second step)
- G (top of the third step, left)
- K (top of the third step, right)
- I (at the upper right of the first step, on the diagonal)
- L (at the upper right of the second step, on the diagonal)

VII. If a single staircase were to be made occupying a whole quadrant of the Earth, by which one had to ascend by equal steps, but with their angles ending on the periphery; for instance from one Pole of the Earth, as far as the Equator, as if in the quadrant ACB a staircase were to be made from A, through D and E, as far as C. The fewer the steps were, and the longer the interval separating them from one another, the more obtuse the angles at which they would meet, and the more they would be raised out of parallel with the horizon; and men leaping up them could stand only at their middle and their end: as FN in the middle of the step AD, GM in the middle of the step DE, and KL in the middle of the step EC. For there the lines of direction, produced straight, would fall on the Earth's centre B, as you see in the lines FNB, GMB and KLB. So too at D, the end of the first step and the beginning of the second, the line BD would coincide with the line of direction, and so one could stand at D. Moreover, from A to N we would experience a descent, and from N to D an ascent; from D to M a descent again, and from M to E an ascent; and D and E would be, as it were, the summits of mountains.

Diagram. A quadrant of the Earth with its centre at the lower right, set into the left column beside the opening lines of the page. Straight chords run along the arc from the lower left to the top right, forming the steps of the staircase, and lines run from the points on them down to the centre, one of them dotted.

- A (lower left)
- B (lower right, the centre)
- C (top right)
- D (left, on the arc)
- F (left, beside N; blurred, close to E in form)
- N (just inside the arc, near F)
- G (upper left, at the end of a line running beyond the arc from B)
- M (on the line from G to B)
- E (on the arc at the top, between G and K)
- K (at the top, above the arc)
- L (on the line from K to B)

Suppose, however, that one staircase were to be made of steps with right angles, each step being one foot wide. Since the Earth's semidiameter AB contains 25870000 feet, that is, 5174 miles, according to what will be said in Chapter 7, the same number of steps would have to be built, but inconvenient ones, each one foot high, since all of them taken together would have to equal the perpendicular height of the staircase CB, which is as great as AB. So it would be better to make it of half-foot steps, 51740000 of them.

VIII. [Margin: Error multorū in Altimetria Montiū ac Turrium. — The error of many in the altimetry of mountains and towers.] Those are gravely mistaken who measure the heights of towers and mountains by altimetry, from the angle of altitude and from a considerable distance between the foot of the mountains and the eye of the measurer. They use a right-angled rectilinear triangle, supposing that of the sides about the right angle in that triangle one is this distance and the other is the very height of the tower or mountain, whereas this side is far from the perpendicular line running to the Earth's centre, along which, nevertheless, the height in question must be reckoned.

For in the next figure let there be the quadrant of the Earth ABC, in which the height of the mountain is PKM, perpendicular and making equal angles on either side at P; and let it be continued in a straight line with the Earth's semidiameter PA. Now almost all the geometers I have read, in order to investigate the height of a mountain from a station at C, take with a geometrical quadrant DEF, or some other similar instrument, through the sight CE, the angle ECF, sighting the summit of the mountain M along the visual line CEM. The arc EF gives this angle. Next they find the distance CK from the eye C to the foot of the mountain, in miles, leagues or stadia; and having constructed from it the triangle CKG, right-angled at K, they gather from the angle C and the distance CK the height KG, which they think to be the very height of the mountain, exactly as if the visual line had ended at G, when in fact it ends at M. But the true height of the mountain is PM itself, far greater than GK. Further, CK is not necessarily a perfect plane; it is often curved, and has to be tested with a level. And often the place of the station C is higher than that curved surface of the Earth which is concentric with the convexity of the sea. Yet you will find that *Oronce Finé*, *Magini*, *Clavius* and *Biancani* did not recognise this false construction. *Cabeo* did recognise it in his *Meteora*, but he too went wrong in the remedy he applied, as I shall show in the Geographical book, in the section on the Height of Mountains, where, God granting, I shall teach how the practice of these geometers is to be corrected.

Diagram. A quadrant of the Earth with its centre at the lower left, set into the left column beside no. VIII. A mountain rises from the arc at the upper right, with the sight lines drawn to it from the station at the upper left and a small quadrant of the instrument at that station.

- A (lower left, the centre)
- B (lower right)
- C (upper left, the station)

- D (above C)
- E (on the small arc, upper left)
- F (on the small arc, below E)
- G (upper right, on the line above K)
- M (upper right, the summit)
- K (right, below G)
- P (on the arc, on the line from A to M)

IX. [Margin: Error aliquorum in Fluminum libramēto. — An error of some people on the gradient of rivers.] Those are equally mistaken who think that the beds of rivers running down from far away into the sea lie in one continuous plane of bottom, and that rivers are borne along a single straight track. If this were true, those rivers would not only be unnavigable, but would rush into the sea with a huge crash and a whirl of waters and a headlong course, and the height of the fall and of the source would be monstrous. Let the proof of this be the Nile, in the following diagram, in which ABC is a quadrant of the Earth's globe, the supposed bed of the Nile is the straight line AM, the source of the Nile in the Mountains of the Moon is M, and the perpendicular height of the spring M

is FM, continued with the Earth's semidiameter FC. Now let the Nile run down from its source to the Canopic mouth A, through, if not 54 degrees, as *Froidmont* will have it in his *Meteora*, then at least 44°, as is gathered from more recent geographical maps; and let these degrees on the Earth's great circle be the arc AF. Then the secant CM, from the tables of sines, would be 13902 of the parts of which the semidiameter CF is 10000. Therefore if the Earth's semidiameter CF is, as I shall show in Chapter 7, 5174 ancient Italian miles, CM would be 7197 48/100 miles; and so, with CF taken away, the height of the Mountains of the Moon, indeed of the source of the Nile, FM, would remain at 2023 48/100 miles. From so great a height, I ask, in how great a plunge would the Nile rush down? For a river whose fall is 6 feet higher in every thousand paces is navigated at the greatest peril; and if it is 2 paces high, it is unnavigable? Yet that is how the summit of the Nile would be raised, since the Nile runs through more than 3000000 paces. Besides, from the mouth A the source M could be seen, and much more the summit of the mountain M, which is contrary to experience. Rivers therefore repeatedly change their bed, and glide, for example, from D to L along a straight or nearly straight line DL, then from L to K, and from K at last to A, describing a line that is nearly a conchoid.

Diagram. A quadrant of the Earth with its centre at the lower left, set into the right column beside the opening of the page. The straight line AM runs horizontally along the top from A to M, outside the arc; lines run from the centre up to the points on the arc, and a broken course runs along the arc.

- A (top left)
- M (top right, at the end of the line from A)
- K (on the top line, near the middle)

- C (lower left, the centre)
- B (lower right)
- D (right, beyond the arc)
- L (right of K, under the top line)
- G (under the top line, left of K; this letter is not cited in the text around the figure)
- I (mid-figure, on one of the radii; not cited in the text around the figure)
- [?] (lower, on the arc, where the text's F should stand; the letter has a stem and a top bar running only to the right, with no middle arm visible: an F whose middle arm has not printed, or a Γ-shaped sort)

X. Here too belongs the fallacy by which some water engineers [Hydragogi] measure the gradient of water badly with levelling instruments. For this purpose let the hemisphere of the Earth be AIB, with its centre C. If from D, through a levelling sight, you look at a visible mark N, and from N, through the sight ER, parallel to the horizon and making right angles with the perpendicular NC, you look at a second mark F, that mark will be much higher than D, the place of the first station, as is clear when the perpendicular CDF is drawn. So if you thought that F was as high as N, and therefore that, with a channel made from N to G, a point a few feet lower than F itself, the water would flow from N to G, you would be badly deceived. Therefore, as our own *Cabeo* also advises in his *Meteora*, Book 2, text 6, question 3, one must place oneself at about the midpoint between the two places or marks D and N whose level is in doubt, as at IM, and through the sight at M look once at the mark D and again at the mark N. For then, if the channel is made from N to a place below D, the water will be able to flow by reason of the slope.

Diagram. A semicircle standing on a base, set into the right column beside no. X, with a line of sight running through the top of the semicircle from E through N, and straight and dotted lines rising to the upper right.

- A (base, left)
- C (base, centre)
- B (base, right)
- I (inside the semicircle, above C)
- E (left, at the lower end of the sight line)
- N (left, above the semicircle)
- R (right of N)
- M (at the top of the semicircle)
- D (right, at the semicircle)
- G (upper right)
- F (top right)

XI. Finally, Scheiner's problem [Ploblema] must be examined, in the *Disquisitiones Mathematicae*, no. 15. [Margin: Scheineri de motu perpetuo hypothesis. — Scheiner's hypothesis on perpetual motion.] For he says that perpetual motion will result if about the centre of the Universe C there is attached a heavy gnomon, at one end of which is the weight G, while the other end of the

gnomon, pierced at C, turns on the axle ACB, supported by the little columns AH and BN. For the weight G, outweighing the rest of the gnomon, will move from G towards P and so describe the circle GPL, and in perpetual motion, since there is no reason why, once moved, it should stop moving. This is confirmed by experience in statics, where a gnomon set up on a floor so that its shorter part is perpendicular to the horizon and its longer and heavier part parallel to the horizon falls over because of the overbalance. But that most acute investigator of the Sun is deceived. For, as Father Francesco Maria Grimaldi argued at once on seeing this figure, that gnomon falls because by its fall it comes nearer to the centre of all heavy things; but the weight G would not fall, because it could not come nearer to the common centre C. Indeed it would not move perpetually even if pushed, but would come to rest when the external impulse died away.

Diagram. A circle with a horizontal axle through its centre, set into the right column beside no. XI. An L-shaped gnomon rises from the centre and carries a large black ball on the circumference at the right of the top. Two small columns stand under the ends of the axle.

- L (top of the circle)
- G (at the ball, upper right)
- D (at the angle of the gnomon)
- A (left end of the axle)
- C (centre)
- B (right end of the axle)
- H (foot of the left column)
- N (foot of the right column)
- P (bottom of the circle)

The letter D is on the figure and is not cited in the text around it.

XII. Yet a perpetual bridge could be made in the air around the Earth, resting on no columns or piers, as Biancani points out in Book 4 of his *Sphaera*: for example, if in the following figure, around the Earth MN and its great circle, say the Equator or some meridian, a bridge were made over the whole circuit on columns of equal height NB, MA, etc., of equal size everywhere and of homogeneous material, as is shown here by the larger circle AB, etc. For with the columns NB and MA removed, it would still stand, because of its equal distance from the centre of heavy things C and the homogeneity of its parts, which balance one another about that centre.

Diagram. Two concentric circles, the outer one broken at the upper left, set into the left column beside the end of no. XII. Two short radial lines run from the centre through the inner circle to the outer.

- A (upper left, outside the outer circle)
- B (upper right, outside the outer circle)
- M (on the left radial line)
- N (on the right radial line)
- C (the centre)

CAPVT V.

In which there is a timely digression on gravitation and on the natural motion of the elements and of mixed bodies [Mistorum] away from or towards the centre of the Universe; and on bodies floating in a liquid.

I. [Margin: Grauitas in specie & Grauitas in indiuiduo. — Gravity in species and gravity in the individual.] I say, first, that a body is *specifically heavier* [Grauius in specie] when it is heavier than another having an equal solid mass or size, as a lead cube one palm across is heavier than a wax cube one palm across. A body is *individually heavier* [Grauius in indiuiduo] when it is absolutely heavier than another, whether it has an equal or an unequal mass, though this is better discerned in an unequal mass, as a pound of feathers is heavier than an ounce of lead.

II. [Margin: Grauiorum ac Leuiorū mutuus motus. — The mutual motion of heavier and lighter bodies.] I say, second, that the elements and the mixed bodies made from them, when placed outside their own place and with the obstacle removed, naturally ascend upward or descend downward by the force of gravity, and not by the force of rarefaction or of preventing a vacuum. I say also that they move not only relative to the common centre of heavy things but also relative to one another, so as to keep their order among themselves: that is, so that the heavier is under the lighter and the lighter stands above the heavier, and the former is less distant and the latter more distant from the Earth's centre, observing a kind of distributive justice. For a wineskin full of air, placed under water on the bottom and released, rises and pushes our hand upward, no less than water is carried down to the bottom; indeed, it shoots a little stick laid on its back upward, above the surface of the water. Nor is there more reason why the heavier should only descend than why the lighter should not ascend.

III. I say, third, that according to the common opinion and system of the Peripatetics and the Ptolemaics, that common centre to which or from which heavy and light things are carried is the centre not only of the Earth but of the whole World, as was proved in Chapter 4. In the opinion and system of the Pythagoreans and the Copernicans, however, it is indeed the centre of the Earth and of the atmosphere, or of the whole elementary sphere, but not, in strict cosmographical terms, of the whole World and of the celestial sphere, since in such a system the centre of the World is the Sun, and the Earth's centre is distant from it by many hundreds of terrestrial semidiameters.

IV. [Margin: Aer aliquid grauitatis habet — Air has some gravity] I say, fourth, that water and our air have some lightness mixed with their gravity, so that by the force of the former they ascend, in order to be above what is heavier than they, and by the force of the latter they descend. Hence inflated playing-balls, well blown up with compressed air, weigh more than when slack, even without any fine flour and wine poured in, as you will detect with a precise balance. Indeed, I myself weighed an ox bladder that when slack was

of 4 scruples and 4 grains, and when inflated was of 4 scruples 6 grains; so the air added by the inflation weighed 2 grains.

V. [Margin: Elementa in suis locis non grauitant. — The elements do not gravitate in their own places.] I say, fifth, that the elements in their own places do not actually gravitate, and that upper homogeneous parts do not press on lower ones. Otherwise slender plants that grow upright from the bottom of waters would be seen bent towards the bottom by the force of the mass of water, and light feathers and awns of grain bent by the whole mass of the surrounding air; and divers swimming under water would feel this gravitation to their great harm. Hence we do not feel a bucket full of water and submerged under well-water to weigh anything except as much as the weight of the bucket itself exceeds an equal amount of water, and we do not feel at all the weight of the water enclosed in the bucket. If, however, the lower parts once begin to move, and access is given for a descent beneath a body lighter than they are, as happens when a pipe is opened at the bottom of casks, then certainly the upper parts move downward. And the motion of all of them together, in the manner of one moving body, is the swifter the greater the mass, and so the more that element or mixed body is heavier than its parts taken separately, as individuals, and than the body below which it is carried, in species. From this some have wrongly deduced that the parts of water or of dust are universally pressed by those above them, and that the elements gravitate in their proper places as long as they are far from the Earth's centre.

VI. [Margin: Cur quædam supernatēt in Aqua, &c. — Why some things float on water, etc.] I say, sixth, with *Archimedes* in the book *De his, quæ vehuntur, aut insident in humido* [On Floating Bodies], and with *Galileo*, *Tartalea* [Niccolò Tartaglia], *Ghetaldo* [Marin Getaldić] and others who have elucidated Archimedes' little work, that the reason why some things float on water or in air is that they are specifically lighter than the body on which they float: that is, because their mass is lighter by its nature than an equal mass of water or of air. And the reason why they descend, and do not float whole, is that they are specifically heavier. Hence a sphere of lead, which cannot float on water, can float on water like a boat if it is beaten out into a very thin plate or leaf and a wide vessel is made from it, because the body made of lead and enclosed air is, in so great a mass, lighter than a mass of water equal to the mass of lead and air together. Hence a ship laden with goods floats for as long as its mass, with the air and the goods it contains, is lighter than an equal mass of water. Nor does it matter for this whether the depth of the water is great or small: even if below the submerged part of the keel there were a depth of only an inch, it would still support the ship in question. Hence ice in water and clouds in air float, even setting aside exhalations levitating upward, because the mass of that aggregate of ice and the enclosed air by whose force it swells, or of vapour and purer air, is lighter than an equal mass of water or of denser and thicker air. This weakens the argument of *Pliny the Elder*, Book 36, Chapter 9, who from the load of ships assigns to the Tiber as great a depth of water as to the Nile.

VII. [Margin: Cur leuissima in Aere supernatent. — Why the lightest things float in air.] I say, seventh, that the reason why some things that are specifically heavier do not descend, such as flakes of gold or specks of dust in air, is not that their shape is in itself less suited to breaking through the medium, as Aristotle thought, granted that shape may help a motion once begun to go more easily and swiftly; it is that, when the shape is changed, a little vessel is made, within which the enclosed air makes up a body with them whose whole mass is lighter than the mass of air on which they float. In the same way a needle, which sinks when set on water by its point, floats if it is laid on the water lightly with its length parallel to the horizon, because within the margins of the water the air clinging to the needle forms a body with it that is lighter than a mass of water equal to the mass of the needle and of the air enclosed within those margins. So if two cones of wax equal in all respects are made, and the vertex of one and the base of the other are set on water, the former will not for that reason penetrate to the bottom because it is sharp, nor will the latter fail to penetrate because its base is blunt and unsuited to dividing the medium; both will float, as you see in the following figure, with MN marking the surface of the water, and in the cones K and L, because their mass is lighter than an equal mass of water.

VIII. [Margin: Cur quædā plus, quædā minùs demergātur. — Why some things are submerged more, some less.] From this one can now catch the scent of the reason why some things descend with their whole mass to the bottom of the water, some float entire, some are wholly submerged below the surface of the water and descend no further, and some, finally, are submerged below the surface of the water by a greater or lesser part of themselves, with the remaining part standing out of the water. For this, take these selected propositions from Book 1 of Archimedes' *De his, quæ vehuntur in aquis* [On Floating Bodies], which stand in him in this order.

Proposition 3 of Archimedes: Solid magnitudes which, having an equal mass, are as heavy as the liquid, when let down into the liquid will be submerged so that nothing of them stands out of the liquid's surface; yet they will not be carried further downward. Archimedes proves this there, as he does the following ones; and the case of this one you may see exemplified in the following figure, in which the water is ABCD, its surface AB, and beneath it the solid F, as heavy as a mass of water as great as the mass of the solid F itself.

4. Any solid magnitude lighter than the liquid, when let down into the liquid, will not be wholly submerged; some part of it will stand out of the liquid's surface. Let the solid E be an example of this.

5. Any solid magnitude lighter than the liquid, when let down into the liquid, will be submerged until a mass of the liquid as great as that of the submerged part has the same gravity as the whole magnitude. Let the solid E be an example, if you understand a mass of water equal to its submerged part to be of the same weight as the whole mass of the solid E.

6. Solid magnitudes lighter than the liquid, when forced into the liquid, are carried upward with as much force as the liquid having a mass equal to that magnitude is heavier than the magnitude itself.

7. Solid magnitudes heavier than the liquid, when let down into the liquid, will be carried downward until they descend; and they will be lighter in the liquid by as much as is the gravity of liquid having a mass equal to that magnitude. Let the solid G be an example.

Diagram. Set into the left column beside proposition 7. Above, a rectangular tank of water holding three solids: one standing partly out of the surface at the left, one at the surface in the middle, and one lower down at the right. Below, a horizontal line with an inverted cone at the left and an upright cone at the right, both crossing it.

- A (left, at the surface of the tank)
- B (right, at the surface of the tank)
- C (lower left corner of the tank)
- D (lower right corner of the tank)
- E (on the left solid, above the surface)
- F (above the middle solid)
- G (on the right solid)
- M (left end of the lower line)
- N (right end of the lower line)
- K (over the inverted cone)
- L (beside the upright cone)

And Book 2, proposition 1: *If some magnitude lighter than the liquid is let down into the liquid, it will have in gravity the same ratio to liquid of equal mass as the submerged part of the magnitude has to the whole magnitude.*

IX. [Margin: Ingenium ponderādi res in Aqua. — A clever way of weighing things in water.] From what Archimedes has demonstrated, it follows that the weight of different liquids can be known by means of a single body whose weight you know beforehand. For if you have a cube, say of lead, weighing one pound in air, and this when submerged in water is found to be of eight ounces, and in wine of six ounces, you will conclude that the water is to that wine in gravity as 4 to 6. In these operations, however, it is best to hang the things to be weighed by horsehairs, since these are as heavy as an equal mass of water; otherwise the cord and its own weight must be taken into account. This way of weighing things in water was used by *Tartaglia*, by *Villalpandus* [Juan Bautista Villalpando] on Ezekiel, by *Getaldić* in his *Promotus Archimedes*, and by ourselves after them. From these sources take the following tables. In the first of them, if a vessel full of oil weighs 9 pounds, the same vessel full of wine will weigh 10 pounds, and full of tin 75 pounds, and so for the rest. *Getaldić* also adds the weight of various spheres of the same mass, namely of gold, lead, etc., and their mass at equal weight; consult him on this.

	Villalpando. Pounds [Libræ.]	*Ghetaldo* Pounds [Libræ.]
Oil	9	1
Wax		1 5/121
Wine	10	1 4/55
Water	10	1 1/11
Honey	15	1 32/55
Tin	75	8 4/55
Iron	80 37/97	8 8/11
Bronze [Aes]	91	9 9/11
Silver	104	11 3/11
Lead	116 1/2	12 6/11
Quicksilver	150	14 62/77
Gold	187 1/2	20 8/11

X. [Margin: Maria quædā cur inscrutabilis fundi. — Why some seas have an unsearchable bottom.] From what has been said there also follows what has been indicated by *Leone Baptista Alberto* [Leon Battista Alberti] and by *Cabeo* in his *Meteora*: namely, that the sea can be so deep that no sounding-line [bolide] one could procure can measure it, even if rope is not lacking. This happens, that is, if the weight of the given lead or iron, together with the rope, is less than a mass of water equal to the mass of the rope and the lead together. For then the rope will not be drawn down perpendicularly by the rope [a fune], but will drift this way and that and float in waves. But these authors do not teach the method of investigating how much lead is to be hung on a given rope so that you may be sure the rope will be drawn straight and perpendicularly down by it. I, however, will teach this practice by one example.

In the second part of the following figure, let the surface of the sea be MR and the sounding-line EGK, whose rope EG is 1000 feet long; and let the weight of the lead GK be sought that is suited to keep the rope EG in the straight position of a perpendicular line under water. Take a ten-foot rope of the same kind and thickness as EG, thoroughly soak it with sea water and weigh it; and let it be, for example, 3 pounds. To it hang the lead GK, weighing 2 1/2 pounds in air, but weighing only 2 pounds when weighed in sea water, so that the difference is half a pound; and let the sum of the weights in air be 5 1/2 pounds. Having noted these on a slip of paper, let the whole ten-foot rope EG, with that lead GK, down below the surface of the sea water MR, and weigh both together with a steelyard; and let their weight together be, for example, 1 pound. Subtracting the weight of 1 pound from their combined weight outside the water, then, 4 1/2 pounds remain: so that depth of water whose mass equals the mass of the whole sounding-line EGK has this weight. And when the half pound, which was the difference between the weight of the lead and the weight of the rope, is taken from the 4 1/2 pounds, 4 pounds remain, which belong to a depth of water equal to the rope EG alone. Let this number be called the argument of the depth of the water. With this argument you will settle the rest of the problem as follows. Multiply by the said argument,

in our case by 4, the number of feet of the given rope, which was 1000, and the result is 4000; dividing this by 10 leaves 400. Say then: if 10 feet of such a rope weigh 3 pounds, a rope of 1000 feet weighs 300 pounds. When these are taken from the 400 pounds, there remain 100 pounds of lead to be hung on the rope of a thousand feet so that it is drawn straight down. Otherwise, if the weight of the lead is less, and the sea deeper than a thousand feet, the rope will drift obliquely, and the depth of the sea cannot be explored with such a sounding-line.

Diagram. Two apparatuses side by side, set into the right column beside the worked example. At the left, a large speckled ball with a short bar and a slanting hook below it. At the right, a horizontal line crossed by a vertical rope, with a pointed lead weight hanging from the rope's lower end. The numerals on the rope and beside the weight give their weights in the example.

- D (above the ball)
- A (left end of the bar)
- C (under the ball, small letter)
- B (right end of the bar)
- F (lower end of the hook)
- M (left end of the horizontal line)
- E (at the crossing of the rope and the line)
- R (right end of the horizontal line)
- 3 (beside the rope)
- G (at the top of the weight)
- 2 1/2 (beside the weight)
- K (at the point of the weight)

XI. [Margin: Leon.Bapt. Alberti fallax modus metiēdi fūdū Maris. — Leon Battista Alberti's fallacious method of measuring the bottom of the sea.] For the other method, which *Alberti* teaches, of exploring the depth of the sea without a sounding-line is most fallacious. As he directs, and *Biancani* after him in the *Sphaera*, Book 5, Chapter 4, a lead hook ABF, of which the longer part is BF, is to be hung from the little loop C on a small ball of oak gall or cork D, and let down to the bottom of the sea, and at the same moment the clepsydra is to be turned. For as soon as that lead strikes the bottom of the sea, the hook will tip back and come out of the loop C, and so the gall or cork will return upward to the surface of the water. When it has returned, the clepsydra is to be stopped and the time measured. Then let the depth of that sea be explored with a sounding-line, and let it be, for example, 300 feet, and that time 10^{m}. Therefore, he says, if a hook of the same weight, and the cork, are let down into another, unknown sea, and the time of descent and ascent together is counted, its depth can be known without a sounding-line: for as 10^{m} are to 300 feet, so this second time is to the depth sought.

However, as *Cabeo* points out in the *Meteora*, Book 2, text 6, question 15, Alberti wrongly supposes that the ratio of depth to depth is the same as that of the one time to the other, and that the waters of the sea are everywhere of the same

thickness and density. But heavy and light things ascend or descend in their natural motion faster and faster towards the end, and so non-uniformly. This takes place, as I shall show elsewhere from our own most certain experiment, made before we had read Galileo on this matter, according to the arithmetical increase of the continually odd numbers. One must therefore find the square number of each time; for whatever proportion there is between these squares, the same will hold between the depth previously known and the one being sought. This assumes, however, that other things are equal in the quality, agitation, etc. of the sea water.

XII. The increase of velocity by which heavy things are carried downward and light things upward in natural motion along a straight line, faster and faster towards the end, will be explained by us more opportunely at the end of this book, in Chapter 21.

CAPVT VI.

That the Earth is like a point with respect to the heavens, although with respect to ourselves it is very large.

I. That this terrestrial globe is very large with respect to ourselves is evident from two things. First, the greatest part of its surface is the part that all the many men and animals do not occupy with their bodies, whether standing or lying down. Second, although the walls of houses are in fact built to the perpendicular, they are not parallel, since the lines of the perpendiculars, if produced, would meet at the centre of the Earth; and yet to the senses they appear parallel, because of the great distance from the centre of the Earth. But if the Earth were small, and the distance of its surface from the centre moderate, the straight lines of the perpendiculars would appear inclined towards one another, in the direction of the centre.

II. [Margin: Argumenta paruitatis Terræ collatæ cum Cœlo. — Arguments for the smallness of the Earth compared with the heavens.] Nevertheless, that this same globe is like a point and exceedingly small with respect to the heavens, especially the highest heaven, is the common assertion of the wise. So say *Aristotle*, *De caelo*, Book 2, text 110; *Ptolemy*, *Almagest*, Book 2, Chapter 6; *Regiomontanus*, in the same place, Conclusion 4; *Copernicus*, Book 1, Chapter 6; *Johannes de Sacrobosco*, in Chapter 1 of the *Sphere*, and *Clavius* on that place, from p. 143; *Maurolico*, Dialogue 1 of the *Cosmographia*, p. 11; *al-Farghānī*, Differences 4 and 22; *Barozzi*, Book 1 of the *Cosmographia*, p. 30.

The arguments for this smallness are almost the same as those for its position at the centre of the universe, on which see Chapter 2. For everywhere on land and sea a whole hemisphere of the heavens is seen, and half of the starry zodiac. And of any two stars diametrically opposed, that is, 180° distant from one another, when one is seen on the eastern horizon the other is seen by us on the western horizon, whether they are fixed stars, as roughly the Heart of the Scorpion and the Eye of the Bull, or wandering ones, as the Sun and the

Moon at full moon. And the same stars, whether viewed on the horizon or on the meridian, appear to us of the same magnitude, and keeping the same distance from the other fixed stars. And stars situated on the ecliptic [recte: the equator, per the book's errata, which correct *Ecliptica* to *Æquatore*], or near it, remain above the horizon for 12 equinoctial hours.

All this would be false if the globe of the Earth were very large in comparison with the heaven of the Sun, let alone the heaven of the non-wandering stars, as one may see in the following figure. In it, if the Earth is small, like A, and the heaven is HZR, the hemisphere HZR can be seen by us, or at least LZM; nor can its portion LH or MR, which lies between the rational horizon HR and the sensible horizon LM, and which is withdrawn from us by the Earth's semidiameter, be noticeable. But if the Earth is imagined as large as the circle BC represents, the sensible horizon would be PBQ, and our eye at B would see of the heavens and the zodiac only PZQ; and stars at Z would appear to us much larger, as being nearer, than at P or at Q, etc.

Diagram. Set into the left column at the right of the text. Three concentric circles: a large outer circle, a middle circle, and a small circle at the centre. Three parallel horizontal lines cross the figure: an upper line touching the top of the middle circle and running out to the outer circle, a second line a little above the centre, and a third through the centre, cutting the small circle.

- Z (top, above the outer circle)
- B (top of the middle circle, on the upper line)
- P (upper line, left end)
- Q (upper line, right end)
- L (second line, left end)
- M (second line, right end)
- H (third line, left end)
- R (third line, right end)
- A (below the small central circle)
- C (bottom, between the middle circle and the outer circle)

III. [Margin: Arg. alia eiusdē paruitatis. — Other arguments for the same smallness.] Astronomical instruments used on the surface of the Earth, and sundials drawn on that surface, show us the motions and positions of the stars just as if their centres, or the tips of their gnomons, were at the centre of the Earth; and on that supposition no sensible error is found. Nor is the variation of view noticeable, except with respect to the Moon, of which shortly. It is therefore a sign that the whole Earth is like a point with respect to the heavens, since it makes no difference whether the observations just mentioned are made on its surface or at its centre.

But if the Earth were very large with respect to the highest heaven, there would also be a great difference between them, and a great variation of view, that is, a great parallax. Nor would the horizontal parallax of the Moon itself be less than 2°, as it now is; nor that of the Sun less than 4′; nor that of the fixed stars less than ½′, as they have been found up to now by all astronomers. For

the horizontal parallax of any star is as great as the arc of the heavens themselves intercepted between the two horizons, namely the rational and the sensible; on this arc see Chapter 2, Scholium 2. Therefore, if the Earth were BC, that parallax would be as great as the arc HP or RQ, and hence of many degrees.

IV. The rays of the Sun reaching the Earth, propagated from the same point of the Sun, are parallel to the senses, as I shall show in Book 3, Chapter 10. And for that reason the meridian shadows of two gnomons set up on the same meridian line are, to the senses, equal on the same day; which would not happen if the Earth were very large with respect to the heaven of the Sun, and therefore close to it. But the very distance of the stars, of which in its proper place, compared with the distance of the Earth's surface from its centre, of which likewise in its proper place, that is, the semidiameter of the heaven compared with the Earth's semidiameter, shows the smallness of this sphere compared with the celestial sphere. And it refutes those who would dare to say that it is by the force of horizontal refraction that a hemisphere is seen by us, and that with this removed a very small portion of the heavens would be seen.

SCHOLIA.

I. On this cosmographical truth is founded that moral and high-minded exclamation [Epiphonesis] of Seneca, found in the preface to the *Natural Questions*: "Is this that point which is divided among so many nations by iron and fire? O how ridiculous are the boundaries of mortals! It is this point on which you sail, on which you make war, on which you dispose kingdoms!" But what is small for a giant is a vast plain for an ant, and the lion's hide that barely covered Hercules could hold many Pygmies. Add here a similar closing exclamation [Epiphonema] of Maurolico, from Scholium 4 below.

II. [Margin: Clauij opinio de mole Terræ, & Cœli. — Clavius's opinion on the bulk of the Earth and of the heavens.] How great a portion of the highest heaven the Earth's semidiameter takes from us out of the hemisphere, that is, how great the horizontal parallax of the fixed stars is according to the opinion of certain authors, we have already said in Chapter 2, Scholium 2. But how great the whole Earth is with respect to the heavens cannot be defined unless the diameters of both are determined. For the sake of argument, however, *Clavius*, on p. 147 of the *Sphere*, following what he himself takes to be the common opinion of astronomers, assumes that the diameter of the firmament, as far as its concave surface, contains 22612½ diameters of the Earth. And since spheres are to one another in the triplicate ratio of their diameters, by proposition 18 of Book 12 of Euclid, he concludes that the solidity of the Earth and sea together is to the solidity of the heaven placed within the concavity of the firmament as 1 to 11562340095703⅛; which is insensible, and like a point, with respect to so vast a number.

But, with Clavius's leave, the comparison that cosmographers intend when they say that the Earth is like a point concerns the diameter or semidiameter; for it is this that makes the variation of view in the phenomena great or small.

Granted, from the smallness of the bulk the smallness of the diameter may be inferred.

III. [Margin: Alfragani argumentum. — Al-Farghānī's argument.] *Al-Farghānī*'s argument from the stronger case [à fortiori], in which he says that many of the fixed stars are larger than the whole Earth and yet are like points of light with respect to the firmament, so that the Earth is much more like a point with respect to the firmament, is indeed excellent, especially if the stars are viewed through the telescope and stripped of that hair of rays that makes them look larger; for they then appear as shining points. But it presupposes a great distance of the stars from the Earth, known and proved from elsewhere; otherwise opponents would say that the stars appear so tiny because they are in fact so tiny, and smaller than the Earth.

IV. [Margin: Quanta Tellus visa ex Cœlis? — How large would the Earth look seen from the heavens?] *Cleomedes*, Book I of the *Cyclical Theory*, says that the Earth viewed from the Sun appears like a point, but from the fixed stars does not appear at all. And *Maurolico* also asks, in Dialogue I of the *Cosmographia*, p. II, how large the Earth would appear if it were viewed from each of the heavens of the planets or of the fixed stars. He could have answered briefly: of as many minutes as the horizontal parallax of those stars, doubled, contains; and that parallax is inferred from the distance of the stars. Nevertheless, assuming the distances of Ptolemy or of al-Farghānī, so as to explain the matter by some perceptible and more familiar comparison, he answers in these words, certainly worthy to be copied out here:

"Placed in the heaven of the Moon, you would see the Earth three times as wide as the Moon is seen from here, and somewhat more. From the orb of the Sun, you would see it twice as wide as Venus appears here. Being in the sphere of Mars, you would say the Earth was equal to a small star, provided it shone. And finally, from the starry heaven you would not easily gauge it by sight, so small would it show itself. I think that, stupefied there, you would say: Goodness! How can it happen that so great a mass, so great a magnitude, looks so tiny? Or how can that little body, or rather that point, hold so many castles, so many estates, so many cities, so many provinces, so many islands, so many mountains, so many forests, so many valleys, so many rivers, so many lakes, so many seas?" And, what is the height of wonder, he adds: "Are there so many envies there? Are so many desires, so many malices, so many frauds practised?" And in these and other words you would laugh at the folly of men.

Yet by the trickery of the demon, who dared to display all the kingdoms of the world and their glory from a very high mountain even to Christ the Lord himself, these things seem greater than can befit the greatness of the human soul. Would that we might ascend that holy mount Zion, on which, according to the prophecy of Isaiah, chapter 33, "the eyes of the just will see the King in his beauty, they will behold the land from afar"; that is, they will look down on it as nothing, if here too they have looked down on it in comparison with heaven.

I now add the words of Pliny the Elder from Book 2, Chapter 68, truly fine ones, on the same argument: "These so many portions of the Earth, or rather, as more have handed down, this point of the universe (for the Earth is nothing else in the universe), this is the material of our glory, this its seat. Here we hold honours, here we wield power, here we covet wealth, here the human race is in tumult, here we renew wars, even civil ones, and by mutual slaughter we make the Earth roomier. And to pass over the public furies of nations, as for this Earth, on which we drive out those who border us and by stealth dig our neighbour's turf on to our own soil, so that he who has marked out his fields most widely and driven his neighbours beyond their bounds, what fraction of the lands does he enjoy? Or when he has extended them to the measure of his greed, what portion of them does he obtain in the end, once dead?"

Finally, to this purpose belongs what Scipio the Elder impresses on the Younger, for despising the glory that is sought from the little men of so small an Earth, as Cicero has it in that truly golden *Dream of Scipio*.

V. Since, however, Maurolico assumed certain distances of the planets that perhaps not everyone concedes, here is how you may learn how large the Earth would appear if it were viewed from this or that distance of a star, that distance being known in semidiameters of the Earth. Look up in our logarithmic tables, or in those of others, the residual of the logarithm of the given distance, and you will have the mesologarithm of the angle under whose double the Earth would be seen. Or else divide the radius by the given distance, and the quotient will be the tangent of the angle under whose double the Earth will be seen.

But if you want to know at what distance the Earth would appear under this or that angle, take half of that angle and look up the secant of its complement to 90°; divide this by the radius, and the quotient will give the distance sought. As a specimen of this, see the following small table; another like it is to be seen in Book 3, Chapter 9, Scholium 4. The use of the following table is this: if the distance of the fixed stars is 20627 semidiameters of the Earth, the Earth viewed from there would measure 20″; and conversely, if it had to be viewed under an angle of 20, the distance would have to be 20627 semidiameters; and so on for the rest.

Angle under which the Earth would be seen	Distance from which the Earth would be seen under the said angle (semidiameters of the Earth)
0′ 20″	20627
0′ 40″	10313
1′ 0″	6876
1′ 20″	5194
1′ 40″	4125
2′ 0″	3438
4′ 0″	1719
6′ 0″	1146
115′ 0″	60

CAPVT VII.

On the absolute magnitude of the Earth, and first on the measures of intervals.

I. [Margin: Mensuræ interuallorum. — Measures of intervals.] Before the threefold magnitude of the Earth is presented, a few points on the measures of intervals must be drawn here from the fuller treatment of them that we give in the *Geographical Book*, section 1. From it we assume that the Italian mile consists of 1000 geometrical paces; the pace of five feet; the foot of four palms; the palm of four common digits in breadth; and finally the digit of four grains of our native barley in breadth; while the cubit is 6 palms, that is, a foot and a half.

Further, from the same source I assume that the Italian stadium was equal to the Olympic or Herculean stadium, and was an eighth part of a mile; or, what comes to the same thing, that it consisted of 600 Herculean feet, but of 625 common Roman feet, or 125 paces. The Greek stadium, however, varied, but more commonly was of 120 Herculean paces, as is gathered from *Pliny the Elder*, Book 2, Chapter 23; *Strabo*, Book 7; *Columella*, Book 5, Chapter 1; *Gellius*, Book 1, Chapter 1; *Polybius*, Book 3; *Censorinus*, Chapter 11; *Martianus Capella*, Book 6, the chapter on the circuit of the Earth; *Isidore*, Book 15 of the *Origins*, Chapter 16; and *Hero the Mechanic*. On the other stadia, miles and leagues we must say much in section 1 of the *Geographical Book*.

II. [Margin: Pes Romanus quinā eligendus. — Which Roman foot is to be chosen.] I likewise assume that, of the many ancient Roman feet of which the paces and Italian miles consisted, we should choose the one in use under Augustus and Vespasian. This is, first, because the Roman consuls and emperors used it when they measured the Roman world through their surveyors, as *Polybius* and *Strabo*, cited above, indicate; and these measures still appear in the *Antonine Itinerary*, corrected by our own *Andreas Schott*. And second, because its measure was kept on the Capitol, from which was taken the height of the twin metal congius still preserved today in the Farnese palace at Rome. This congius was examined by *Poetus* [Luca Peto], the jurist [I. C.], who compared the foot cut on it with several other very ancient bronze Roman feet dug out of the ruins; then our own *Villalpandus* [Juan Bautista Villalpando] and *Grienberger* measured it most carefully, copying the measure of the Roman foot from it.

Poetus has shown us this congius and foot in his book *De antiquis mensuris*, and Villalpando in volume 3 on Ezekiel, part 2, Book 3, Chapter 25. *Marino Ghetaldi* approved and chose that measure in his *Archimedes promotus*; and it is the very one that Grienberger left on a sheet at Rome, which sheet Father *Athanasius Kircher* generously shared with me.

Further, that foot which *Willebrord Snellius* chose in his *Eratosthenes Batavus*, and before him *Budaeus* [Guillaume Budé], *Porcius* [?], *Philander* [Guillaume Philandrier] and *Ermolao Barbaro*, was taken from the Colotian and Statilian marble, as they themselves admit. But it is the foot of the architects, who flourished long after Vespasian, as Poetus points out; and it is to the Villalpandian

foot, as it stands in Snel, as 56 to 54. Snel preferred it, however, because it is equal to the Leiden and Rhineland foot, and to the foot used by the Roman architects in building the fortress of the Catti.

Finally, the more recent Bolognese foot, from the common and authentic measure, which we used in measuring the Earth, is to the ancient Roman foot, that is, the corrected Villalpandian, as 5 to 4, or, more finely, as 1495 to 1200. The true length of the half-foot of the ancient Roman foot just mentioned is as much as you see in the following figure R; and that of the recent Bolognese foot, as much as in figure S.

Diagram. Two long horizontal double-ruled bars at the foot of the page, running across both columns below the text and the table, each with a vertical stroke at both ends and cross-ticks along its length. Each is a printed half-foot, to be read off at its full printed length, so the printed length is the content of the figure. Each bar is divided by five cross-ticks into six equal parts. The lower bar, S, is the longer, beginning further to the left and ending further to the right than R; on the leaf its right end rises with the curve of the page.

- R (left end of the upper bar)
- S (left end of the lower bar)

R: The corrected ancient Roman half-foot.

S: The more recent Bolognese half-foot.

I said "to the corrected Villalpandian" because, as the Dutch printers have observed, and Snel following them, the lengths of lines printed from copper plates become shorter once the sheets, wetted beforehand, have dried, and fall short of their prototype by a sixtieth part of themselves; and each time books are printed again, this defect increases. Taking this into account, Snel corrected and enlarged the Statilian and Colotian foot, copied from the first printing of Philander. But I found at Bologna that sheets, although firmer, when worked under a rotating cylindrical press, do not shrink and contract in the same way after they dry, but only by a fiftieth part of themselves in length. Now it was in this way, from bronze plates, that the Villalpandian congius was published, along with the measure of the Roman foot in his work. We have therefore corrected that measure by adding a 49th part. The Samian and Alexandrian foot, and so too the stadium, was to the common Roman and Greek foot as 6 to 5, as *Hero* of Alexandria the Mechanic testifies, and Snel agrees, Book 2 of the *Eratosthenes*, Chapter 2.

III. [Margin: Modus tutior transmittēdi mēsuras ad exteros, & posteros. — A safer method of transmitting measures to foreigners and to posterity.] But there is another method, more difficult indeed yet safer, of transmitting these measures to foreigners and to posterity, to whom the prototype itself cannot be shown: namely, through measures of liquids. So Villalpando says that if a cubic vessel is made holding precisely 10 pounds of purified cistern water, the height of that cube will be equal to the Roman half-foot taken from the congius of Vespasian. But Snel, Book 2, Chapter 5 of the *Eratosthenes Batavus*, because he uses a larger and less ancient foot, says that a cube equal to the Roman half-foot

contains 125½ ounces of purified water. The present-day Bolognese foot, as I have said, is to the ancient Roman foot, and mile to mile, as 5 to 4. And the Leiden or Rhineland foot, taken from Snel's book and corrected as he himself wishes, is to the corrected Roman foot of Villalpando as 25 to 24, and to the Bolognese as 5 to 6.

IV. [Margin: Duplex modus metiendi Telluris globum. — Two ways of measuring the globe of the Earth.] With these points set out in advance, there are several ways of investigating the magnitude of the terraqueous globe, which we shall present and weigh in the *Geographical Book*; but all come down to two heads. The first contains various ways of investigating the diameter or semidiameter of the Earth, however hidden it may be from our eyes. This kind is presented by *Maurolico*, *Grienberger*, *Bettini* and *Cabeo*. Once the diameter is known, the circumference and the rest of the Earth's magnitude are easily deduced, from what was said in Book 1, Chapters 4 and 6, on the dimensions of the circle and the sphere. But among these ways the most evident and most expeditious is the one that very recently occurred to Father *Paolo Casati* of our Society, and it is as follows.

[Margin: Modus P. P. Casati. — The method of Father P. Casati.] Let there be a tower situated on the seashore, of the kind that is the Lantern of Genoa, and let it be AB, of known height. From its top let the surface of the sea, calm and still, be viewed along the line of sight BD, touching the water, which is concentric with the Earth, at the furthest visible point D. For this tangent, by proposition 18 of Book 3 of *Euclid*, will make with the Earth's semidiameter CD a right angle, namely CDB. While the point D is being viewed from B, let the angle ABD be taken with a dioptra and an exact instrument. And let the straight line AE be understood, perpendicular to AB itself, touching the globe of the Earth at A, and produced to E, until it runs into the secant CE, drawn through the viewed point D; for it will cut the tangent BD at F, and there will arise the triangle ABF, right-angled at A. In this the side AF and the base BF can be found, since there are already known, besides the right angle A, the angle ABF and the height of the tower AD [recte: AB].

Now FB [recte: FD, per the book's errata] is equal to AF itself. For since they belong to the same angle ACD, the tangents BD and AE are equal to each other, and the secants CB and CE to each other. Therefore, when the semidiameters CA and CD are taken away, the excesses of the secants, AB and DE, remain equal to each other. And the angles A and D are right, and the angles at F are vertical and therefore equal by proposition 15 of Book 1, and by proposition 32 of Book 1, B and E are equal complements of two right angles. Hence by proposition 26 of Book 1, FD will be equal to AF itself, which is known. Therefore the whole tangent BD will be known, in parts of which AB was known, since it consists of the known parts BP [recte: BF] and FD. Therefore in the triangle CDB, right-angled at D, with the angle B and the side BD known, the Earth's semidiameter CD will be known by the analysis of

triangles; and when this is doubled, the diameter AG, in parts of the known height AB.

Diagram. Set into the left column at the right of the text. A circle with a vertical line running from a point above it, down through the top of the circle and the centre, to the bottom of the circle. From the upper point a line descends to the right to a point on the circle; a horizontal line runs from the top of the circle to the right, beyond the circle; and a line from the centre runs up to the right through the point on the circle to meet the end of the horizontal line.

- B (top, above the circle)
- A (top of the circle, left of the vertical line)
- F (on the horizontal line, where the descending line crosses it)
- E (right end of the horizontal line)
- D (on the circle, upper right)
- C (centre, left of the vertical line)
- G (bottom of the circle)

V. The second head comprises several ways of investigating how many miles, stadia or leagues are included in a given and known arc of a great circle of the Earth, such as the meridian or any vertical circle. For from this it at once becomes known how many such measures the whole great circle contains; and from this the diameter and the remaining dimensions become known, according to what was said in Book 1, Chapters 4 and 6. Those who have used a method of this kind are *Eratosthenes*, *Posidonius*, *Ptolemy*, *Almæon* [?] with many Arabs, *Fernelius* [Jean Fernel], *Mazzoni*, *Kepler*, and ourselves with Father *Francesco Maria Grimaldi*.

But the methods of others, since they need examination and some of them correction, we reserve for the *Geographical Book*; and for just reasons we present in this place only the one that Father Grimaldi and I, in joint study, not only devised but carried into practice with all the circumspection possible.

[Margin: Modus P. Fr. Mariæ Grimaldi, & Noster. — The method of Father Francesco Maria Grimaldi and our own.] It has two parts. The first lies in investigating the arc of a vertical circle between the tower of the great church of Modena, called the tower of San Geminiano, and the country house that our College of Bologna has on Monte Serra near Paderno [Paternum], where the observation was undertaken during the general vacation, because of the suitability of the place. The second part contains a way of measuring geometrically the paces and miles lying between the tower and that house.

VI. For the first part, let the horizon of Monte Serra be HR, and its meridian HPR, and the north pole B, and the vertex or zenith of that mountain P, and the meridian of the tower of Modena BMH, etc., in which the zenith of the tower is M. Let the altitude of the pole on Monte Serra be BR, 44° 27′, as it has more than once been taken there by us with large quadrants on the occasion of other observations; and so its complement PB is 45° 33′. Likewise, let the altitude of the pole at Modena, taken in repeated observations near the tower

just mentioned by Father Francesco Maria Grimaldi, and precisely established, be 44° 37′; and so its complement BM is 45° 23′.

Diagram. Set into the right column at the right of the text. A circle representing the sphere, with two lines across it from H on the left to R on the right: an upper one on which A stands, and below it the edge of the hatched lower part. From the top point a curved line descends through two points to a point on the horizon; another curved line rises from the left end of the horizon to the upper right point of the circle; and a third curve runs from the lower of the two interior points to the same upper right point.

- P (top of the circle)
- M (inside the circle, upper, where the curves from P and H meet)
- B (upper right on the circle)
- L (inside the circle, lower, on the curve from P)
- A (on the horizon)
- H (left end of the horizon)
- R (right end of the horizon)

Now let there be understood, in a window of our house, a triangle suspended from three threads, in such a way that, with one of them descending perpendicularly by means of a plumb-line hung from it and at rest, the whole triangle would show exactly the plane of the vertical circle PA, the two other threads being directed towards the middle of the tower of Modena. So Father Grimaldi waited, in 1645, at the end of September, with this thread triangle made ready by day and duly directed towards the tower of Modena, for the bright star of Lyra, descending from the meridian, to pass through the plane of the vertical PA. And at once, with a quadrant set up beforehand as was proper, he took its altitude AL, which was 20° 17′, and its distance from the vertex was 69° 43′. At that time the northern declination of this star was, according to Tycho, 38° 29′ 36″; but from our own observations of the fixed stars, carried out with incredible labour, as will be clear from volume 2 of the *New Almagest*, it was 38° 30′. So the complement of the declination of the bright star of Lyra, L, was 51° 30′.

With these points laid down, in the triangle PLB the three sides are given; and so, by proposition 4 of our *Oblique-Angled Spherical Triangles*, the angle PLB is found to be 48° 42′. Then in the triangle BML, with the angle MLB found, which is the same as PLB, and with the sides given as above, BL, the complement of the declination of Lyra, and BM, the complement of the altitude of the pole at the tower of Modena, by proposition 6 of the same *Triangles* the side ML was found to be 69° 25′ 25″. When this was subtracted from the complement of the altitude of Lyra, LP, which was 69° 43′, the arc PM came out at 0° 17′ 35″, lying between the tower of Modena and the house just mentioned, on the vertical circle passing through the vertices of both.

VII. For the second part of the problem, let the tower of Modena be M, and our house on Monte Serra be P. And let the tower at Bologna called the Asinelli be A, and the gate of San Felice with its turret be F, and let the church

and monastery of San Luca be L, on the hill called Custodia, where the most sacred image of the MOST BLESSED VIRGIN stands, painted by St Luke and celebrated at Bologna for its miracles and solemn benefactions; and finally let B, beside the bank of the river Reno, be a certain column or four-sided pier, once the post of some gate. For these stations were chosen by Father Grimaldi as highly suited to this operation.

Diagram. Set in the left column, interrupting the sentence above. A survey network of straight lines. From M at the far left, three long lines run to A, L and P. A stands at the upper right and P at the lower right, joined by a nearly vertical line. F and B lie between M and A, near A; F is joined to A, to B and to L; B is joined to L; L is joined to A and to P.

- M (far left)
- F (upper middle, just below the line MA)
- A (upper right)
- B (middle, left of L)
- L (middle, below F)
- P (lower right)

Then, with a twisted cord stretched straight and supported, the interval FB was measured, so as to have some large side for measuring the remaining triangles more exactly. The angles were taken at the said stations with the help of a geometrical quadrant, and through repeated trigonometry the necessary sides were worked out, until the side MP in the triangle MAP was found: that is, the distance between the tower of Modena and our house on Monte Serra, corresponding to the arc found above. The side BF having thus been found mechanically to be 1088⅖ Bologna paces, the rest of this analysis went as can be seen briefly in the following synopsis. It sets out the order and number of the triangles, the angles both observed and geometrically derived, and the sides of the triangles, with the Bologna paces reduced to ancient Roman ones according to the proportion we stated in no. II to hold between them. Here, then, is the synopsis of this procedure.

Order of the triangles	Angles observed, or derived geometrically: the angles		Value	Sides found trigonometrically, except BF, which was investigated mechanically	Bologna paces	Ancient Roman paces
I.	BFL	Obs.	70° 8′	BF	1088 ⅖	1523
	FBL	Obs.	71° 59′			
	BLF	Coll.	37° 53′	FL	1685 ⅗	2354
II.	LFA	Obs.	116° 9′	FL	1685 ⅗	2354
	LAF	Obs.	43° 16′	FA	864 ⅗	1080
	ALF	Coll.	20° 35′	AL	2204	2755
III.	MLA	Obs.	124° 37′	AL	2204	2755
	MAL	Obs.	50° 17′			
	AML	Coll.	5° 6′	MA	20404	25505
IV.	MAP	Obs.	102° 24	MA	20404	25505
	APM	Obs.	70° 14′			
	AMP	Coll.	7° 22′	AP	2780	3475

Order of the triangles	Angles observed, or derived geometrically: the angles		Value	Sides found trigonometrically, except BF, which was investigated mechanically	Bologna paces	Ancient Roman paces
V.	MAP	Obs.	102° 24′	AP	2780	3475
	APM	Obs.	70° 14′		.	
	AMP	Coll.	7° 22′	MP	21P76 [recte: 21176]	26470

The angles MAP and APM could indeed have been taken, and this operation dispatched with the single triangle APM, if the lie of the land had allowed us to measure the interval AP; but the unevenness of the little valleys and hills did not allow it. It was therefore necessary to use a level plain stretching evenly from the gate F to the pier B, and, sighting the other points mentioned from there, to work out the distance MP, which alone we needed. But Snel needed far more triangles, and his method is much more complicated than ours, as is clear from his *Eratosthenes Batavus*.

[Margin: Nota insignis veritatis, huius mensuræ. — A remarkable mark of the truth of this measure.] [Margin: Distantia inter Turrim Bononiensem & Mutinensē. — The distance between the tower of Bologna and that of Modena.] Two things especially worth noting concur in the measure of the interval MP. For the Roman foot of Villalpando, or Vespasian's foot, corrected as is right from typographical observation, stands to our own Bologna foot as 1200 to 1495, that is, very nearly as 4 to 5. Therefore the distance MA between the tower of Modena and that of Bologna, which Father Grimaldi found to be 20404 Bologna paces without any thought of the Antonine Itinerary, when reduced to paces composed of ancient Roman Vespasianic feet, had to be 25505 paces. And in the most ancient Antonine Itinerary, 25 thousand paces are set down three times between Bologna and Modena, whether because only whole miles are recorded there, or because the distance from the towers to the gates, or to other termini which the Roman surveyors had in view, makes up the difference of half a mile.

Conversely, if the proportion of the ancient Roman foot to that of Bologna is inferred from the distance between these places, taking whole miles, then since that distance is 25 miles in the Antonine Itinerary, and 20 Bologna miles as found by Father Grimaldi and then verified by us, the proportion turns out to be exactly the same as was found from the simple comparison of the two feet, namely as 4 to 5. Amid such darkness and diversity in the ancient measures and distances, I have so far been able to find nothing more evident than this mark of truth among the writers who have laboured in this dust.

VIII. With this foundation laid, then, as a most solid one, the first part of the problem must be joined to the second. So if between the tower of Modena and the summit of Monte Serra, where the house of our College stands, there is an arc of a vertical circle of 17′ 35″, and if in this interval there are 21176 Bologna paces, of which there are 20404 between the tower of Modena and

that of Bologna, then in one degree of a great circle of the Earth, such as a vertical circle is, there are certainly 72256 paces. And if these are converted as 4 to 5, there are in one such degree 90320 Roman paces, measured by the ancient Vespasianic foot. From this measure many of the more accurate ones do not depart very far; on these see the end of Table 1 below, and more in the Geographical Book.

Further, by multiplying 1° by 360 we have the circumference of the whole terraqueous globe, and from it the diameter and its remaining magnitudes, by the rules given in Book 1, Chapters 4 and 6. These measures, finally, are the ones written below.

[Margin: Magnitudo Globi Terraquei trina, immo quina. — The size of the terraqueous globe, threefold, indeed fivefold.] For ease, however, in many if not all of the problems that depend on this, we shall be able to use a semidiameter of the Earth of 4000 Bologna miles, and of 5000 ancient Roman miles. But if, when other stars have been used, something in this measure should have to be changed, we shall not be ashamed to declare it frankly in the Geographical Book.

Meanwhile the distance between the said towers, the altitudes of the pole, and the declination of the bright star of Lyra are most evidently established for us; nor is there reason to doubt about the altitude of Lyra. Even so, we wish to repeat it, to call other stars into counsel, and, God willing, to put into practice other new methods that we have devised for this measurement of the Earth. On another occasion, however, when we supposed the altitude of the pole at Modena, as taken, to be 44° 40′, we deduced from the remaining data above a semidiameter of the Earth of 3897 ancient miles; but it was not evident to us, and from that so great a difference arose.

Measure of the Earth's globe	Italian miles of Bologna, of the year 1645	Ancient Roman Italian miles, in use under Augustus and Vespasian
1 degree of a great circle	72 ¼	90 8/25
Semidiameter of the Earth	4139	5174
Diameter of the Earth	8278	10348
Circumference of a great circle	26010	32512
Area of a great circle	Square miles. 53827695	84108544
Convex surface	Square miles. 215310780	336434176
Solid content of Earth and water together	Cubic miles. 296457106140	580236807150

SCHOLIA.

I. [Margin: Auctores de Quantitate Terræ tractantes. — Authors who treat of the size of the Earth.] The diversity in the size of the terrestrial globe, as great as it is among the authors, arises not only from the different method applied, and from the unequal care taken by different people, but also from the diversity of the measures with which they measured the intervals. If these were brought

back to one better-known measure, the diversity would perhaps not be as great as it appears at first sight. So judge, with Lucillo Filalteo [Philalthæus] wrongly protesting, Pedro Nunes, Book 2 of *De observat.*, Chapter 18, and *De Crepusculis*, Proposition 18; Francesco Maurolico, Dialogue 3 of the *Cosmographia*; Jacopo Mazzoni, in the *Defensio Dantis*, Book 1, Chapter 77; Clavius, on the *Sphere*, Chapter 1, pp. 198 and 211; and the Coimbra commentators [Conimbricenses] on *De caelo* 2, Chapter 14, Question 1. Giuntini, it is true, in his *Sphere*, p. 223, thinks that this came about from the differing swelling of the Earth, measured in different places by different people; and Biancani, in his *Sphere*, Book 4, Treatise 3, Chapter 5, thinks that the Earth has constantly diminished through the wash of the waters, and that its measure has been found ever smaller and smaller, which, however, is false.

The authors just mentioned report various opinions on the size of the terrestrial globe. So too do Aristotle, *De caelo* 2, from the antepenultimate text; Lucillo Filalteo in the same place; Cleomedes, *De Mundo*; Pliny the Elder, Book 2, Chapters 108 and 109; Martianus Capella, Book 6, Chapter 4, and Book 8, p. 192; Finé, Book 5 of the *Cosmographia*, Chapter 4; Fernel, Book 1 of the *Cosmotheoria*, Chapter 1; Daniel Santbech, Problems 15 and 144; Magini, Johannes Werner and Petrus Bercius [Petrus Bertius], in their commentaries on Book 1 of Ptolemy's *Geography*; Francesco Barozzi, Book 1 of the *Cosmographia*, p. 40; Caspar Peucer, in the little work on the measurement of the Earth; Kepler, in the *Epitome of Astronomy*, p. 28; Willebrord Snel, in the *Eratosthenes Batavus*; Mario Bettini, *Apiarium* 2, from p. 78, and *Apiarium* 8, Progymnasma 2, Proposition 3; and Kircher, in the *Ars Magna*, Book 9.

The single opinion of Eratosthenes, on the other hand, is reported by Vitruvius, Book 1, Chapter 6; Strabo, Book 2 of the *Geography*; Censorinus, *De Die Natali*, Chapter 11; and Macrobius, Book 1 on the *Dream of Scipio*. That of Almæon [?] and the Arabs is reported by al-Farghānī, Difference 8, and Ibn al-Haytham, in the little book *De Crepusculis*. Archimedes gives his own in the *Sand-Reckoner*; Ptolemy his own and that of Marinus of Tyre, *Geography*, Book 1, Chapters 7 and 11, and Book 7, Chapter 5; al-Battānī his own, Chapter 6; Tycho his own, *Progymnasmata*, vol. 1, pp. 97 and 733. So also Longomontanus, in the *Astronomia Danica*, Book 2 of the Spherics, Chapter 11; Kepler, in the Rudolphine Tables, Chapter 16, in the *Astronomia Optica*, pp. 115 and 129, and in the *Epitome of Astronomy*, p. 31; William Gilbert, Book 6, Chapter 3; Adriaan Metius, *De Usu Globi*; Stöffler, on the *Sphere* of Proclus, p. 76, and on the *Astrolabe*, Proposition 34; Peter Apian, Part 1 of the *Cosmographia*, Chapter 12; Georg Henisch, on the *Sphere* of Proclus, p. 117; Gemma Frisius, Book 1 of *De Principiis Astronomiae*, Chapter 20; Cornelius Gemma, Chapter 87 of the *Astrolabe*; Mästlin, in the Appendix to Kepler's *Prodromus*; Pierre Gassendi, in the *Institutio Astronomica*, Book 2, Chapter 13; and Mersenne, in the preface to the *Cosmographia Astronomica*.

Lastly, the opinion of the navigators and more recent cosmographers on this matter is adduced by Petrus de Medina [Pedro de Medina], Book 3 of the

Ars Navigatoria, Chapter 7; Nunes, *De observ.*, Book 2, pp. 17 and 27; Gerardus Mercator and Willem Blaeu, at the beginning of the *Novus Atlas*; Clüver, Chapter 7 of the *Introductio ad Geographiam*; Bertius, in the *Tabulae Contractae*, p. 40; Hérigone, vol. 4 of the *Cursus Mathematicus*, p. 164; Bernardinus Ginnarus [Bernardino Ginnaro], Part 1 of *Xaverius Orientalis*, Book 1, Chapter 5; and Ramusio, vol. 1 of the *Navigations*, p. 116, where the opinion of the Portuguese is reported, and p. 374, where that of the Castilians, and in the Voyage of the Dutch to Novaya Zemlya, Part 3, where that of the Dutch. From these, take the following for the present.

II. [Margin: Eratosthenis, & Hipparchi mēsura. — The measure of Eratosthenes and Hipparchus.] Eratosthenes found 694 4/9 stadia in one degree of a great circle of the Earth, and 250000 in the whole circle, as Cleomedes and Strabo report. But if, attracted by a round number, you give 700 stadia to one degree, there are 252000 in the circle; and for that reason this is the number reported by Vitruvius, Macrobius, Censorinus, Capella, Sacrobosco, Clavius, Magini, and indeed Pliny the Elder, who adds that by Roman reckoning these make 31500 miles.

But Eratosthenes erred. Misusing the gnomon of the scaphe, and treating the Sun's rays from different points of the Sun as though they were parallel, he thought that between Alexandria and Syene there were 7° 12′ and 5000 stadia, whereas from the data he himself gives 7° 26′ or 28′ should be put back, as I shall show in Book 3, Chapter 27, no. 7. Therefore he should have put at most 670 stadia in one degree; indeed, since Syene and Alexandria do not lie exactly under the same meridian, he should have put very nearly 600 stadia. If these were Olympic or Roman, they give 75 miles. But if they were Alexandrian stadia, as is more probable, they give 90 ancient Roman miles.

Hipparchus, according to Pliny the Elder, added 25000 stadia to Eratosthenes' figure in the whole circle; therefore 69 stadia to one degree, that is, nearly 9 miles, or, if you follow the Alexandrian reckoning, 10. So with Eratosthenes and Hipparchus corrected, there are 90 or 100 ancient miles in one degree. But more on these points in the Geographical Book, where also on the error of [Margin: Possidonij error. — The error of Posidonius.] Posidonius, who thought there were 5000 stadia and 7° 20′ between Rhodes and Alexandria, when there are only 4° 48′; and on [Margin: Archimedis opinio. — The opinion of Archimedes.] Archimedes, who in the *Sand-Reckoner* affirms that the circuit of the Earth is 300000 stadia.

III. [Margin: Ptolemæi, Albategnij, & Regiomontani opinio. — The opinion of Ptolemy, al-Battānī and Regiomontanus.] Ptolemy, with Marinus of Tyre, gives 500 stadia to one degree. If they had been Roman, these would be 62½ miles. Finé, Barozzi, Filalteo and Giuntini subscribe to this opinion, Giuntini, however, wrongly attributing it to al-Farghānī. But how much more probable it is that the Alexandrian cosmographer used the Alexandrian stadium! For Ptolemy, therefore, one degree has 74 ancient miles, though these are too few. Al-Battānī comes closer to the truth, giving it 85 miles, and nearer to him is

Regiomontanus, giving 80 miles. The cause of the error for Marinus of Tyre and Ptolemy was that they cut the journeys reported by navigators by a third on account of their obliquity, as is clear from Ptolemy, *Geography*, Book 1, Chapters 10 and 12; and I shall show in the Geographical Book that this is too much.

IV. [Margin: Arabum genuina opinio. — The genuine opinion of the Arabs.] Almæon [?], King of the Arabs, as al-Farghānī reports, or rather Alammon [?], as Kircher reads in Abū al-Fidāʾ the geographer, called together a number of wise geometers and ordered them, in the plains of Fingar [?], along the straight route of the Red Sea, to find out how many miles there are in one degree of a meridian circle; and 53⅔ [recte: 56⅔, per the book's errata; corrected by hand to 56⅔ in this copy] miles were found, each of which, however, consists of 4000 cubits, as al-Farghānī says. To this opinion, as the most probable, have adhered Ibn al-Haytham, Thābit ibn Qurra, Ismaël Abilfedea, or Abulfeda [Abū al-Fidāʾ], Abomadus [?] and the rest of the Arabs, as well as Maurolico and Campanus.

Now if you use the Roman cubit, which consisted of a foot and a half, the Arabic mile consisted of 1200 paces. Therefore 5[?]⅔ [the second figure is under an ink blot, with a 6 written over it by hand; the book's errata give 56⅔ for a misprinted 53⅔ in this line] miles are 68 miles, as Fernel, Maurolico and Kepler rightly calculate, although most report those miles indiscriminately as 53⅔ [recte: 56⅔, per the book's errata; corrected by hand to 56⅔ in this copy]. But if the Arabs used the Babylonian cubit, or the ancient Hebrew one, which contained 1 9/12 Roman feet, or the Alexandrian foot, there would be 80 or 81 Roman miles in one degree. Whether Fernel, who drew his opinion of 68 miles from his own experiment, though a very slippery one, as we shall show in the Geographical Book, accommodated it to the numbers of the Arabs, I would not dare to say.

V. [Margin: Iacob. Mazzoni Methodus. — The method of Jacopo Mazzoni.] Jacopo Mazzoni, very ingeniously indeed, starts from the 300 stadia which, on the testimony of Pausanias, Cleomedes and Pliny the Elder, are occupied by the space lacking a meridian shadow of gnomons on the day of the summer solstice at Syene, Cyrene and other places situated under the Tropic of Cancer; and he supposes, from Posidonius, that the apparent diameter of the Sun at that time is the 750th part of the solar heaven in length, that is, 28′ 48″; and he infers 625 stadia in one degree of a great circle of the Earth. But if the diameter of the Sun at apogee is then 30′, 600 stadia in one degree are deduced from this; and if these were Alexandrian stadia, as I shall show to be more probable in the Geographical Book, they make 90 ancient Roman miles, exactly like the corrected measure of Eratosthenes. For it was Eratosthenes too who measured that space under the Tropic.

VI. [Margin: Villebrordi Snellij sententia. — The opinion of Willebrord Snellius.] Willebrord Snel carried out this geometry with incredible labour and industry, as can be seen in his *Eratosthenes Batavus*. In the end he found in one

degree of a great circle of the Earth 68⅖ miles, measured by the foot of Leiden and the Rhineland, which he thought to be the ancient Roman foot. In fact, however, it is the Herculean foot and the greater Greek foot, which Roman architects began to use when the Empire had already been divided, or its seat transferred to Greece. However that may be, I am certain from the data given by Snel himself that the Leiden foot stands to the Roman Vespasianic foot as 25 to 24; and so from his own thesis at least 71 Vespasianic miles are deduced. But his method was too intricate and was composed of too many operations, so that a very small error in each could have produced this sensible and great difference from what we found.

[Margin: Et Gassendi verior. — And that of Gassendi, truer.] Gassendi, who says he is almost certain that 73 Italian miles are contained in one terrestrial degree, is speaking of modern Italian miles. This is as near to the truth as possible, if the talk is of miles such as are used in this district of Bologna. For the diversity of miles within Italy itself is incredible, as I shall show in the Geographical Book.

VII. [Margin: Nauclerorum verior sententia. — The truer opinion of the navigators.] The navigators, as Petrus Medinensis [Pedro de Medina], Nunes and Cornelius Gemma report, give one degree 17½ leagues, each of which, as Pedro de Medina explains, consists of 4 modern Italian miles. In addition, sea-leagues are assigned 4 modern Italian miles by Aloysius Cadamustus [Alvise Cadamosto] in Ramusio, vol. 1, p. 98; by Vasquius Gama [Vasco da Gama], p. 120; by Petrus Aluarus [Pedro Álvares], p. 122; by Simon Maiolus [Simone Maiolo], who was very experienced in voyages to the Canaries, in the tenth Canicular Colloquy; by Io. Gonzales de Mendoza [Juan González de Mendoza], in the index of his *History of China*; and by Fathers Lucena [João de Lucena] and Tursellinus [Orazio Torsellino], in the life of St Francis Xavier. Therefore 17½ leagues make 70 miles of this kind; and if these are equated with Bologna miles, they give 87½ ancient Roman ones. Anyone who prudently weighs the voyages and journeys in Ramusio, Theodorum Bry [Theodor de Bry] and others will see that this is closest to the truth.

To mention just one example, of a very well known and much-travelled voyage: from the port of Sanlúcar, or that of Seville, to the island of Tenerife, a route usually covered on a nearly straight course with following winds, there are 12° on most of the more recent globes. Navigators commonly estimate this route at about a thousand miles, or 250 leagues, although Fernão de Magalhães, as Antonio Pigafetta and Odoardus Barbosa [Duarte Barbosa] state, is said to have traversed it in the year 1519, covering 960 miles. But let these be chosen, so that we may compensate for the obliquity of the route, and let 960 be divided by 12. Here, for one degree there result 70 miles[9]. Nowhere, however, have I been able to read of 53 Italian miles being given to one degree by the navigators, although Clavius affirms it, and following him Biancani, Ginnaro, Bertius and

[9]960 divided by 12 is 80; the page prints 70, and its table below also gives 70 for the recent navigators.

Bettini. But if any have affirmed it, either they were rather inexperienced, or they spoke of longer miles, such as the English ones, for example, which stand to the Italian as 14 to 10, as you will see in the tables and scales of Willem Blaeu, who in the tables of Spain too gives one degree 17 leagues throughout.

VIII. [Margin: Germanorū de Germanicis Milliaribus opinio. — The opinion of the Germans on German miles.] There remain some German geographers or astronomers. Of these, Longomontanus and Mästlin assign 15 German miles to one terrestrial degree; while Peter Apian, Gemma Frisius, Stöffler on the *Astrolabe*, Mercator, Metius, Blaeu, Kepler in the *Epitome of Astronomy* and Georg Henisch assign 15 German and at the same time 60 modern Italian miles, and with these Magini, Hérigone and Clüver agree. But Tycho, and Stöffler on Proclus, assign 15 German and 65 Italian miles. Kepler, however, later says in the Rudolphine Tables, Chapter 16, that the common German mile is two hours' journey for an unencumbered walker, and that there are 15 of these in one degree of a great circle of the Earth. But I, who am not the most robust of men, have more than once easily covered nearly 3 Bologna miles in one hour, and of the smaller kind, such as the ancient Roman miles were, a full 3. Therefore, on Kepler's view, there are 90 ancient Italian miles in one degree. Indeed, in the same place he deduces from Strabo that 800 stadia are due to one degree, that is, 100 ancient Italian miles.

IX. [Margin: Dionysiodori figmentū non omnino vanū. — The fiction of Dionysiodorus, not altogether empty.] Lastly there is Dionysiodorus, famous for his geometrical knowledge. As Pliny the Elder reports in Book 2, Chapter 109, he left in his tomb a letter written in his own name to those above, in which he affirmed that he had reached from the tomb the lowest place of the Earth, that is, the centre, and that it was forty-two thousand stadia to there. Therefore the whole diameter of the Earth, on his opinion, is 84000 stadia, the circumference 264000, and one degree 733⅓ stadia, and so 88 56/100 Italian miles.

This is what Pliny the Elder calls the greatest example of Greek vanity, since Dionysiodorus wanted to attest his geometrical reasoning by an experiment after his death. Yet if you look at the measure, it belongs not to vanity but to truth. For it comes close to the measure that we ourselves have tested among the living, and it agrees with that of Eratosthenes, and nearly with that of Hipparchus, Strabo and the more recent navigators, and likewise with Mazzoni, once corrected. [Margin: Dionysiodori & Dātis iter ad centrū Terræ fictum. — The fictitious journey of Dionysiodorus and Dante to the centre of the Earth.] Mazzoni too, examining the journey of Dante to the underworld, poetically invented, inquires how great the semidiameter of the Earth is, and most ingeniously uses the rays of the Sun, meeting at the centre of the Earth. For where neither Dionysiodorus nor Dante reached, the rays of the Sun are nevertheless supposed, by a more solid fiction, to penetrate, if they are understood as produced straight through gnomons that lack a shadow. Now

follow two tables containing the opinions on the size of the Earth, first corrected, then uncorrected.

Opinions on the size of the Earth, probably corrected or accepted in the preceding Scholia. Authors corrected in the Scholia.	1 degree of a great circle of the Earth: recent Italian miles of Bologna	1 degree of a great circle of the Earth: ancient Roman Vespasianic miles
Dionysiodorus, from Scholium 9.	71	88 56/100
Archimedes, as it stands.	81	104
Eratosthenes, from Scholium 2.	72	90
Hipparchus, from Scholium 2.	80	100
Strabo, from Scholium 8.	80	100
Ptolemy, from Scholium 3, at least. But another correction is needed, as I indicate there.	59	74
Almæon [?] and the Arabs, from Scholium 4.	65	81
Jacopo Mazzoni, from Scholium 5.	72	90
Willebrord Snel, from Scholium 6.	57	71
Pierre Gassendi, from Scholium 6.	73	91 ¼
The more recent navigators, and those named in Scholium 7.	70	87 ½
Some German cosmographers, from Scholium 8.	60	75
Tycho and Stöffler, from Scholium 8.	65	81
Kepler finally, from Scholium 8.	72	90
Or with Strabo.	80	100
Ourselves, as above, for the present, with the fractions thrown away.	72	90

Here we have added either the recent Italian miles from the ancient Roman ones, or those from these, taking the Bologna miles as average modern Italian miles, between those of Piedmont, which are larger, and others, which are smaller.

CAPVT VIII.

Some corollaries that can be deduced from the size of the Earth are indicated.

[Margin: Time required to circumnavigate the globe of the Earth.]

I First, it is clear from what has been said that what Aristotle contends at the end of *De caelo* 2 holds: the Earth is small with respect to the heaven, and large indeed with respect to human beings, yet not so large that it cannot be travelled around in a few years. And in fact Magellan's ship, as is clear from the narrative of Antonio Pigafetta, who sailed in her, circumnavigated the whole globe in three years, covering 57840 miles on an extremely winding route, or 14460 leagues, to each of which Pigafetta gives 3 miles[10]. And yet they were held up for many months in ports and by dead calms. Now, if it were possible to sail on a straight course 180 Italian miles a day, that is, 2°, then the whole circle could be completed in 180 days, or 6 months. On foot, if you covered 3 miles each hour, you would then complete one degree in 30^{h}, and the whole circumference of the Earth in 450 days.

[Margin: Alexander the Great's couriers.]

But if Anistius and Philonides, Alexander the Great's couriers, covered 1200 stadia a day, or 150 miles, on the testimony of Solinus, Chapter 6, then running in this way they would run around the Earth in 216 days. But woe to their lungs, woe to their chests, woe to their spleens, woe to their legs and soles!

[10] 14460 leagues at 3 miles is 43380 miles; the page prints 3, and its total of 57840 answers to 4.

[Margin: The ingenuity of the Persian kings.]

II If some king wished to learn something as quickly as possible from his antipode, 180° distant, or to announce something to him, then with torches stationed around the semicircle of the Earth, in the manner of the Persian kings and the emperors of Constantinople, or with watchtowers, or with guards shouting in succession and saying, for example, *The King N. is dead*, this could certainly be done within 270^{h}, or 11¼ natural days. For as Cleomedes relates in Book 2 of the *Cyclica Theoria*, and Caelius Rhodiginus [Lodovico Ricchieri] in Book 18, Chapter 8 of the *Antiquae Lectiones*, the king of the Persians, while staying at Susa, received messages from Athens in this way within 48^{h}, although those cities are only 32° apart.

III If Phaëthon had really driven the chariot of the Sun around the Earth at the speed with which the Sun now moves in its daily motion, then, taking the semidiameter of the solar heaven, according to Ptolemy, as 1220 semidiameters of the Earth, and so the circumference of the solar heaven as 7668 semidiameters of the Earth, that is, 38340000 ancient Italian miles, which the Sun runs through in 24^{h}, he would have completed the 32512 miles in the circumference of the Earth in 1^{m} 13^{s}; and so within a single natural day he could have flown around the Earth a great many times.

IV If a shaft were dug right down to the centre of the Earth, a stone let down through the air enclosed in the shaft would reach the centre by natural motion within 25^{m} of time, provided it weighed at least one pound. For in the treatise on the speed of the natural motion of the elements, which we will discuss at the end of this Book 2, Chapter 21, we have shown that a ball of chalk of 8 ounces would cover nearly 4000 miles within 18^{m}, let alone 20^{m}. But the Earth's semidiameter contains about 5000 ancient miles. Yet the stone would swing past the centre, up and down, like a pendulum, as Galileo thinks in the second dialogue on the system of the world, and would finally come to rest at the centre of the Earth.

V If the surface of the Earth's uncovered land is about as great as that of the waters, and if the whole Earth were levelled, or its mountains and valleys were reduced to one convex surface, and each person were allowed one square pace, so that they could stand and lie down, then one square mile would hold 1000000 people. Therefore the Earth's surface, not counting the waters, would hold 168217088000000 people, since half of the terrestrial surface is

168217088 square miles. But whether people descended from Adam, had they not died, would fill this number cannot easily be determined.

VI What Archimedes shows in *The Sand-Reckoner* about the number of the sand, which is not altogether innumerable, and, following him, Clavius in the *Sphere*, p. 218, supposes an Earth's diameter no greater than 10000 miles. But he does not determine the true diameter there. Clavius, however, taking that quantity for convenience, shows that in the whole world, within the concave of the firmament, there would not be grains of sand whose number would exceed unity with 51 zeros, and so that this number can be written, which some denied

in Archimedes' time. But let it be enough to have played at these matters, or played a prelude to them for others.

VII As for a table converting degrees, both of the equator and of the parallels, into miles, or miles into degrees, look for it in the Geographical Book.

CAPVT IX.

On the extent of the Earth known formerly and now.

[Margin: How much of the globe has been navigated so far?]

I Pliny the Elder deals with ancient voyages in Book 2, Chapter 67, with the inhabited portion of the Earth in Chapter 68, and with the measure of the known globe in Chapter 108. So too do Ptolemy, in Book 1 of the *Geography*, Chapters 10 and 11, and Book 7, Chapter 5; Strabo, Books 1 and 2; and Martianus Capella, Book 6; but each for his own age.

[Margin: Distinguished navigators.]

In our own time, not only did the ship of Fernão de Magalhães, called *Victoria* from the conquest of the whole ocean, set sail from Seville on 1519 August 10 and, having circumnavigated the globe westward, return to Seville on 1522 September 7, having covered 14460 sea leagues, though by a winding route, as Antonio Pigafetta relates in his account of this voyage, in Ramusio; but after her Gulielmus Scouthen [Willem Schouten] and others surveyed the whole globe along its longitude. For Thomas Candysh [Thomas Cavendish], an English nobleman aged 28, set sail from England on 1586 July 21 and, having circumnavigated the globe, returned to England on 1588 September 5. But before him Franciscus Dracus [Francis Drake], a noble knight, leaving England on 1577 December 13 [Idibus Decēbris], returned to his native country after going around the globe on 1580 September 28 [4.Kal.Octobris], when he was 43 years old.

II As for latitude, the same Schouten, a Hollander, reached Cape Horn, which is at 58° south latitude. Another man, Gulielmus Barensonius [Willem Barentsz], a Netherlander, reached 81° north latitude. Together these make up 139° of latitude; and 41° are lacking to the semicircle between the poles of the world, or of the Earth. If anyone wishes to know the longitude and latitude of the globe as formerly known, here is a small table for you, with the degrees of the equator or meridian reduced to ancient Italian miles, according to our opinion in Chapter 7; multiplied by 8, these will give stadia.

KNOWN LATITUDE OF THE GLOBE OF THE EARTH.	Lati-tude.	Ancient Italian miles.
For Hipparchus, in Strabo, Book 1, from Meroë to the Borysthenes.	42° 28′	1822
For Eratosthenes, in Strabo, Book 2, from the equator toward the north.	70° 20′	6600
For Pliny the Elder, from the shore of the Ethiopian Ocean to beyond the mouths of the Tanais.	80° 20′	7230
For Isidorus, in Pliny the Elder, from the Ethiopian Ocean to Thule.	80° 31′	7246
For Martianus Capella, from the Ethiopian Ocean to beyond the mouths of the Tanais.	89° 24′	8046

KNOWN LATITUDE OF THE GLOBE OF THE EARTH.	Lati-tude.	Ancient Italian miles.
For Marinus of Tyre, in Ptolemy, from the Tropic of Capricorn to Thule.	87° 0′	7830
For Ptolemy himself, from Agysimba to Thule; 79° 26′, but in round figures.	80° 0′	7200
Now, from 58° south to 81° north.	139° 0′	12510

KNOWN LONGITUDE OF THE GLOBE OF THE EARTH.	Longi-tude.	Ancient Italian miles.
For Eratosthenes, in Strabo, Book 2, from the farthest part of Spain to India.	128° 42′	11583
For Artemidorus, in Pliny the Elder, from Gades to the Ganges.	127° 45′	11497
For Isidorus, in Pliny the Elder, from Gades to the eastern mouth of the Ganges.	144° 24′	12960
For Pliny the Elder himself, from India to Gades.	126° 10′	11355
For Martianus Capella, from the longitude of Africa and of Asia together.	148° 30′	13365
For Marinus of Tyre, in Ptolemy, from the Fortunate Isles to the Seres.	225° 0′	20250
For Ptolemy, correcting Marinus, from the Fortunate Isles to the Seres.	177° 15′	15952
For Ptolemy himself, from the meridian of the Fortunate Isles to the Serican meridian, on the equator.	180° 0′	17200
For on the parallel of Thule, at 63° north altitude.	180°	7300
Of Rhodes, at 36° north altitude.	180°	13100
Of Syene, at 23° 50′ north altitude.	180°	14400
Of Agisymba, at 16° 26′ south altitude.	180°	15460
In our time, the whole circumference.	360°	32400

CAPVT X.

On the distance of sight, or the amplitude of the sensible horizon: where also on the altitude of an object visible on Earth, and on the levelling of waters.

I Many things worth knowing depend on exact knowledge of the Earth's semidiameter. Among them are the four indicated in the title of the chapter, which belong to the same inquiry; chiefly the distance of sight [Distantia visus], to which human sight extends on the surface of the Earth or of the sea, or the portion of the convex surface of the terraqueous globe that it can see, which others call the amplitude of the sensible horizon [Amplitudo Horizontis sensibilis]. Once this has been found, the remaining things mentioned in the title will at once be known, as I will soon show. Moreover, the distance of sight can be taken either as simple, that is, looking toward one part of the world, say the east; or as composite, looking toward both opposite parts, say the east and then, with the eye turned round, the west.

[Margin: Opinions on the distance of sight.]

II I find the opinions on the distance of sight, collected with the greatest care, to be strongly at odds. For:

For Eratosthenes, in Clavius's *Sphere*, p. 297, the simple distance of sight is 352 stadia, or 44 Italian miles.

For Proclus, in the *Sphere*, the simple distance is 250 miles, unless you read in him 100 stadia, namely [Greek: δισχιλίων (dischiliōn, "of two thousand")]; for then it would be 12½ miles.

For Macrobius, *On the Dream of Scipio*, Book 1, the simple distance is 180 stadia, or 22½ miles.

For Albertus Magnus, in Clavius, the distance of sight, I believe the composite one, is 125 miles.

For Clavius, *Sphere*, p. 297, and Barozzi in the *Cosmographia*, the simple distance of sight is 62½ miles, because Ptolemy assigns that many miles to one degree of the terrestrial equator; as if it were certain that a person sees one degree of a great circle of the Earth, whatever his stature and height, which is nevertheless false.

For Goclenius, in *Urania*, that same distance is 20 Italian miles.

For Mario Bettini, *Apiarium* 2, Progymnasma 3, Proposition 7, the average distance of sight is 280 stadia, or 35 miles.

But for Kepler, in Book 1 of the *Astronomia Copernicana*, p. 23; Giordano Bruno, p. 283; Denis Pétau, Book 7 of the *Uranologion*, in the *Variae Dissertationes*, Chapter 10; Pierre Hérigone, vol. 4 of the *Cursus Mathematicus*; and Niccolò Cabeo, in the *Meteora*, it is relative to the height of the eye. If human stature is 1⅕ paces and a person stands on the seashore, according to them he cannot see more than, as nearly as possible, 3½ Italian miles. But if he were 12 paces high, he would see 9 Italian miles toward one side; if 131 paces high, 30 miles; if 524 paces, 60 miles; if 4721 paces, 180 miles. For Kepler there assumes that the Earth's semidiameter contains 3440 Italian miles, and 860 German. Finally, Geminus, in the *Elements of Astronomy*, Chapter 4, said that the diameter of the sensible horizon, as FG in the following figure, does not exceed 200 stadia, or 25 miles, and the semidiameter, or the distance of sight, 100 stadia, or 12½ miles.

[Margin: The error of the geometers about the distance of sight.]

But the opinion of Kepler, Bruno, Pétau, Hérigone and Cabeo is true: namely, that this distance depends on differences of stature and of the height of the eye; and I add, on differences in the size of the Earth's semidiameter. And it is a wonder that so many other geometers, and of such great ability, have been so mistaken in this that they defined this distance absolutely.

Diagram. Set in the left column, interrupting the sentence that follows between "in se-" and "quenti". A large circle with a smaller circle inside it, the two sharing one centre, C. A vertical diameter runs from V at the top of the large circle to K at its foot, through B, A and C. Four horizontal lines cross it: SP, touching the small circle at its top, A; FG, a little below; HR, through C; and MN, at the foot of the small circle. From B two straight lines descend, through F to M and through G to N, so that BMN stands as a triangle around the small circle.

- V (top of the large circle)
- K (foot of the large circle)

- B (on the vertical, between V and A)
- A (on the vertical, at the top of the small circle)
- S (left end of the upper horizontal)
- P (right end of the upper horizontal)
- F (left, on the small circle)
- G (right, on the small circle)
- H (left end of the horizontal through the centre)
- R (right end of the horizontal through the centre)
- C (centre)
- M (lower left, on the large circle)
- N (lower right, on the large circle)

Labels read: all thirteen above. Labels not read: none.

For in the following diagram let FAG be the Earth, whose rational horizon is HCR, and whose sensible horizon is FG with respect to the eye at B, but SP if the eye is at A, a point of the Earth's surface concentric with the surface of the water. For it will see nothing except what is nearest the eye, and it will not see anything of the convexity of the terraqueous globe below the line SAP. But because the eye of a standing person is raised about as much as a person's stature, say AB, it sees something of the convexity of this globe: as much, that is, as the visual line tangent to this globe takes in, namely on this side the arc AF, bounded by the tangent BF, and on that side the arc AG, bounded by the tangent BG. But if AB is not a mere human stature, but includes the height of a mountain or a tower, etc., a far wider space of land or sea all around can be seen; and all the wider, the greater the height AB of the eye, or, at an equal height, the shorter the Earth's semidiameter assumed. Granted, with respect to the heaven an eye at B may see more than a hemisphere, namely the arc MVN. Since, therefore, ordinary human stature is about 5 feet, or one pace, then if the Earth's semidiameter is 3440 Italian miles, Kepler, and with him Pétau, Hérigone and Cabeo, rightly state that a person placed on the seashore cannot see, of the convex surface of the sea, toward one region, more than 3½ miles, and that sight cannot reach even to 4. But if with us you take the Earth's semidiameter as 5000 ancient Roman miles, he will see only 3 miles, as will be clear from the analysis of the triangle, of which presently.

[Margin: Problem of finding the distance of sight.]

So, in order that, given the height of the eye B above the surface at A and the Earth's semidiameter CA, the arc AG can be known, which, converted into miles, gives the distance of sight, let there be a second, simpler figure, in which the Earth's hemisphere is HAR, the rational horizon HCR, and BAC the perpendicular to it, erected from the Earth's centre C. On this the eye is at B, and its height AB is given, which, joined with the Earth's semidiameter AC, likewise given, will give the whole BC.

Diagram. Set at the right of the right column, with the text beside it running short. A semicircle HAR on the base HCR, with C at the middle of the base. A vertical rises from C through A, at the top of the arc, to B above

it. A horizontal chord joins F and G, both on the arc, crossing the vertical. A straight line runs from B down to G, and another from C up to G.

- B (top of the vertical, above the arc)
- A (on the vertical, at the top of the arc)
- F (left, on the arc)
- G (right, on the arc)
- H (left end of the base)
- C (middle of the base)
- R (right end of the base)

Labels read: all seven above. Labels not read: none.

Now let the visual line be drawn from the eye B, touching the Earth or the sea at G, and let this be BG; and to the point of contact G let the straight line CG be drawn from the centre C. For by Euclid III.18 it will make a right angle with the tangent at the point G, and the triangle CGB will be right-angled at G. In this triangle, since the base BC is given, as I said, and the Earth's semidiameter CG, the angle BCG, which measures the arc AG, can then be found by 11 of our Right-Angled Plane Triangles; and this arc, converted into miles according to the opinion chosen on the miles in one degree of a great circle of the Earth, will show the distance to which sight extends toward one side.

But if, conversely, this distance is given, and the arc AG, that is, the angle BCG, together with the Earth's semidiameter CG, and the height AB of the eye is sought, the base CB must be sought by 3 of our Right-Angled Triangles; and when the semidiameter CA has been subtracted, the height of the eye B will be known; or, if the eye were at G, looking at the top B of a mountain, a tower or the like, the height AB of the mountain, tower, etc. will be known, in the same kind of measure in which the Earth's semidiameter CG was given.

[Margin: Abridgement of the problem.]

Therefore, in the first case, make: as the base CB is to the radius of the tables, so the given side CG, or the Earth's semidiameter, is to the sine of the angle CBG, whose complement to 90° will be the angle BCG, that is, the arc AG. Or join together the residual of the logarithm of the base CB with the logarithm of the side CG; and, with unity removed from the left, the result will be the logarithm of the angle CBG, whose complement to 90° is the angle BCG.

In the second case, make: as the radius is to the given semidiameter CG, so the secant of the angle BCG, that is, of the given arc AG, is to the base CB; if you subtract the Earth's semidiameter CA from this, the known height AB will remain. But when the arc AG is less than 1°, or 90 ancient miles, it is expedient first to reduce the Earth's semidiameter CG to paces, or rather to feet, since a pace consists of five feet; and if the arc is less than one mile, the same semidiameter must be reduced to inches, of which 12 make one foot, so that the operation for the levelling of waters [libramento aquarum], discussed below, may be safer and finer. And the secant of the angle BCG, or of the given arc AG, must be multiplied by the semidiameter so resolved, and the

product divided by the radius, or whole sine [Sinum Totum]. For the quotient will give the base CB in the parts into which CG was resolved, and when CG, that is, CA, is subtracted from the whole CB, the height AB will be known.

EXEMPLVM.

[Margin: Example of the second case.]

Let the eye be at G, say in the bottom of a ship, and let it see the summit B of a mountain at a distance of 4°, the distance from which navigators commonly see Mount Pico, which is on the island of Tenerife, one of the Canaries; and let the Earth's semidiameter CG be, according to our opinion, 5000 ancient Italian miles. Now the secant CB of the arc AG of 4° is 10024419 parts, which, multiplied by 5000, makes 50122095000. When this sum is divided by the radius 10000000, there remain for the base CB 5012 miles and in addition 2095/10000, that is, 209½ paces. Therefore, with the 5000 miles, or CA, subtracted, there remains the height AB of the mountain, 12 ancient Italian miles and 209½ paces; and with this set down in turn, the arc AG, or the distance of sight, of 4° would be found by the first part of the problem. By this device the following small table was constructed by us, with 2^{h} of labour.

The distance of sight and of an object, one of the two being placed on the surface of the terraqueous globe, at the extreme visible or visual limit, and the other raised above that surface, the Earth's semidiameter being taken as 5000 ancient Roman miles.

Height of the eye, or of the object, AB: Paces	Feet	Inches	Distance of sight and of the object, or arc AG: Deg., Min.	Anc. Ital. miles	Paces
0	0	2 1/3	0° 0½′	0	750
0	1	0	0° 1′	1	500
1	0	0	0° 2′	3	0
2	0	0	0° 3′	4	500
3	2	6	0° 4′	6	0
5	2	6	0° 5′	7	500
7	2	6	0° 6′	9	0
10	2	6	0° 7′	10	500
13	2	6	0° 8′	12	0
17	0	0	0° 9′	13	500
21	0	0	0° 10′	15	0
30	2	6	0° 12′	18	0
41	2	6	0° 14′	21	0
54	0	0	0° 16′	24	0
68	2	6	0° 18′	27	0
84	2	6	0° 20′	30	0
126	0	0	0° 25′	37	500
190	2	6	0° 30′	45	0

☉ 1210			89° 57′ 10″	8095	
7000			89° 59′ 30″	8098	
✶ or ☉ 14000			89° 59′ 45″	8099	

[Margin: The distance of 14000 semidiameters is that of the Sun according to Wendelen, but of the fixed stars according to Tycho.]

SCHOLIA

And the use of the preceding table.

[Margin: To find the distance of sight, given the height of the observer.]

I Given the height of the eye, either by itself or placed on the summit of a mountain or tower, as AB in the preceding figure, and with that height looked up in the first column of the table, you will find the distance, or arc of sight, expressed in minutes or degrees in the second column, and in ancient Italian miles in the third column. For example, if the height is one pace, the eye can see from it an arc of 2′, or 3 miles. But if the exact height is not in the table, use the proportional part between the greater and the lesser. Thus, the height of the Lantern of Genoa is 480 geometrical feet down to the foot of the crag, or 96 paces; in the first column of the table the next lower number is 84 paces, to which correspond 20′, or 30 miles, while the next higher is 126, to which correspond 25′, or 37½ miles. You will therefore infer that a distance of sight of nearly 22′, or 33 miles, corresponds to the height of 96 paces. The operation

will, however, be more accurate if you work according to the rule and the example given before the table.

[Margin: The height of an object, given the distance, with the eye not raised.]

II If the eye is not raised above the Earth, and you wish to know how great the height of the object must be from the given distance of the visible thing, look up the distance in the second or in the third column, and opposite it you will find the required height in the first column. For example, if the eye is on the northernmost shore of the island of Corsica, which may be supposed to be 3° distant from one of the Alps, say from Mount Vesulus [Monte Viso], you will find in the first column that a height of 6 miles and 850 paces is required. But if no such mountain is seen from there, either the assumed distance is false, or intervening mountains stand in the way, or Mount Vesulus is not so high.

[Margin: The distance of sight between an object and an eye, both raised.]

III But if both the eye and the object are raised, and you seek the greatest distance from which the object's summit can be seen, look up separately the distances corresponding to each height and add them together. For example, if a ship's mast is given as 27½ feet high, that is, 5 paces 2½ feet, a distance of sight of 5′, or 7½ miles, corresponds to it. But if the Lantern of Genoa is 96 paces high, then from what was said in no. 1, 22′, or 33 miles, correspond to it. Therefore, by combining these, the distance within which the summit of the Lantern will begin to be seen from the summit of the mast, or the summit of the mast from the summit of the Lantern, and beyond which they will vanish from the eyes, will be 27′, or 40½ miles. But an eye one pace high will not see the ship's mast beyond 10½ miles.

IV Given the distance of a sluice-head [Incilis] or spring from which water is to be led through a single straight channel to a place on a surface of the Earth concentric with the sea (river mouths are of this kind), you will find in the first column its fall [libramentum], that is, the perpendicular height that the sluice-head or spring must have. Otherwise the water will either not run down from there to the intended place, or will do so only by a curved path or through several straight channels not set in a direct line, as was said in Chap. 4, no. 9. From this you will learn that Leon Battista Alberti in his *Architecture*, and others, came as close as possible to the truth when they said that if a straight channel or conduit is a thousand paces long, the height of the sluice-head or spring must be at least 9 inches, but that for the water to flow from there more securely to the desired place, a fall of one foot is required.

CAPVT XI.

On the height of mountains.

[Margin: Opinions on the height of mountains.]

I We said in Chap. 1 of this Book, with Dicaearchus and most cosmographers, that the height of mountains is no obstacle to the physical roundness of the Earth.

But because Pliny the Elder judged that height to be greater than Dicaearchus did, and therefore held a somewhat different view of the Earth's roundness, as we said there in Scholium 1, it is useful to know how great the maximum height of mountains is, especially since some parallax of altitude or depth of the stars, visible even below the rational horizon, ultimately depends on it. But these matters involve many points that are indeed worth knowing, yet rather subtle and not sufficiently examined so far; and therefore we defer a full treatment of them to a complete section on the subject, to be given in the Geographical Book. From it we shall sample a few things here, so as not to send candidates in cosmography away altogether hungry.

II The ancient geometers, then, assigned to no mountains a height greater than 4 Italian miles, though most assigned only 10 or 15 stadia, or 1250 or 1875 paces. I believe because they measured them by a method that I have shown to be fallacious in Chap. 4, Corollary 8, and in Book 10, sect. 4, probl. 32. [Margin: The height of mountains.] Thus Dicaearchus, in Pliny the Elder, Book 2, Chap. 65, and in Geminus, *Elements of Astronomy*, Chap. 14, found Pelion to be 10 stadia high, Satabyrium 14 and Cyllene 15, that is, in paces, Pelion 1250, Satabyrium 1680 and Cyllene 1875. [Margin: Of Pelion, Satabyrium, Cyllene. Of Olympus.] Likewise, as Plutarch has it in the *Aemilius*, Xenagoras measured Olympus at 10 19/125 stadia, or 1269 paces. But in Strabo, Book 11, the Rock of Sisimitres was found to be 15 stadia, or 1875 paces, high, and that of the Sogdians 30 stadia, or 3750 paces. Ibn al-Haytham, and Pererius [Benet Perera] on Genesis, Book 12, Disp. 9, allowed the highest mountains 4 miles. Boterus [Giovanni Botero] in his *Report on the Sea*, Scorcia [?] in *On the Nile*, Book 1, Chap. 2, and Biancani in his *Sphere*, Part 3, Treatise 3, Chap. 5, believe that no mountain is higher than one and a half Italian miles, because no sea is deeper either; since God, in the opinion of St Damascene, *On the Faith*, Book 2, Chaps. 9 and 10, and of Philoponus on Book 2 of *On Generation*, t. 37, made the mountains out of the hollow of the sea. As if some mountain higher than the deepest sea could not have been heaped up from the earth of several hollows, just as many bricks are dug out of clay pits, and from them are built structures far higher than the depth of the pits! Besides, in some places the sea is much deeper than one and a half miles, as I shall say in Chap. 14. Cleomedes, too, thought that the height of neither mountains nor sea exceeds 15 stadia; indeed Plutarch, cited above, not even 10. Kepler, in *Astronomia Optica*, pp. 129 and 135, and in the *Epitome of Copernican Astronomy*, Book 1, p. 26, allowed the loftiest mountains half a German mile, or 2 Italian miles, the same amount he also allowed to the air suited to refractions. Furnerius [Georges Fournier], *Hydrography*, Book 19, Chap. 8, denies that any mountain is 7358 paces high.

[Margin: Of Pico, Etna, Lilybaeum.]

But Willebrord Snel, in *Eratosthenes Batavus*, Book 2, from Chap. 17, shows that Mount Pico of Tenerife, one of the Fortunate Islands, is 10, or at least 8, thousand paces in perpendicular height, Etna 4 thousand paces, and the promontory of Lilybaeum a single mile. Fromondus [Libert Froidmont] in

Meteora, Book 1, Chap. 2, Pétau in the *Uranologion*, Book 7, Chap. 10, and Cabeo on Book 1 of the *Meteorologica*, t. 63, q. 2, subscribe to this. But in Book 10, sect. 4, probl. 30, and sect. 6, probl. 50, I shall demonstrate that Pico is 10 Italian miles high, and Etna 5 8/10, even if refractions assist its being seen from afar.

[Margin: The height of the Caucasus.]

On the Caucasus, it is astonishing how Jacopo Mazzoni, in *The Comparison of Plato and Aristotle*, sects. 3 and 4, Chap. 5, Biancani, on the mathematical passages of Aristotle, at Book 1 of the *Meteorologica*, no. 48, and Cabeo on Book 1 of the *Meteorologica*, t. 63, q. 2, twist themselves, because Aristotle was not sufficiently understood, or because inquiry into deeper astronomy and geometry was neglected. Mazzoni, for his part, infers from the data given by Aristotle a perpendicular height of the Caucasus of 78 miles, but from Magini he reports 276 miles. Biancani gives 270, or 78, or 52, all of which, however, he considers absurd. Cabeo concedes the Caucasus 15 miles at most. But from the data given by Aristotle, fully and plainly understood, I shall demonstrate in Book 10, sect. 4, probl. 30 and 36, that the Caucasus must be granted a height of 58 Italian miles, if no account is taken of refractions; but if account is taken of them, I shall show in Book 10, sect. 6, probl. 50, that the Caucasus is 51 Italian miles high.

[Margin: The height of Mount Athos.]

As for Mount Athos, if what Pliny the Elder, Solinus, Plutarch and others consistently report about its shadow is true, I shall show most evidently in Book 10, sect. 4, probl. 35, that it is 28 Italian miles high. Those skilled in deeper geometry have approved these demonstrations.

[Margin: Mount Casius of Seleucia.]

III. There remain other mountains of no common height, treated in my Geographical Book. For Mount Casius formerly saw the Sun from its summit from the fourth watch of the night, on the testimony of Pomponius Mela, Book 1, Chap. 49, Solinus, Chap. 37, Pliny the Elder, Book 5, Chap. 22, and Ammianus Marcellinus, Book 22; and from this I deduced a height of at least 20 miles. [Margin: Ida.] On the summit of Ida too, a mountain of Phrygia, the Sun shone long before it did on those at the mountain's foot, as Solinus reports, at Chap. 16, and Diodorus Siculus, Book 17. [Margin: Haemus.] Haemus, a mountain of Thrace, was climbed for 6 thousand paces, as Pliny the Elder, Book 4, Chap. 11, and Solinus, Chap. 15, relate, and it was asserted to Philip, King of Macedon, that the Graian Alps could be seen from its peak. [Margin: The Alps.] The Italian Alps rise over a stretch of no less than 50 miles and are climbed in scarcely 5 days, as Polybius, Books 3 and 4, Strabo, Book 4, and Pliny the Elder, Book 2, Chap. 65, say; but for Polybius the ascent and descent comprise 1200 stadia, or 150 miles, from which I estimated a height of 10 or 12 miles. And yet several Peruvian mountains, compared with these Alps, seem like very tall buildings set beside low huts, as José de Acosta affirms, *Historia Indica*, Book 3, Chap. 9. [Margin: The mountains of America.] And the mountains of Beragua

[Veragua] in the province of Paria in America have an ascent of 50 miles, on the testimony of Peter Martyr [Pietro Martire d'Anghiera] in Ramusio, vol. 3, p. 15. [Margin: Mount Atlas.] Pomponius Mela, Book 3, toward the end, Capella, Book 6, the chapter on Africa, and Pliny the Elder, Book 5, Chap. 22, tell marvels of Atlas, a mountain of Mauretania, which on account of its height is sung of as rising to the confines of the Moon and holding up the sky. Pliny the Elder adds that the Consul Suetonius Paulinus reached its summit only at the tenth camp, that is, by a military march of ten days, from which a height of 15 miles and more is inferred, even with the windings taken into account. [Margin: Stolp. The highest of the Riphaeans.] The highest of the Riphaean mountains, called Stolp by the Tartars, that is, the column of the world, can scarcely be climbed in 17 days [recte: scandi], as Sigismund von Herberstein asserts, in Ramusio, vol. 1, p. 169; from which I showed in my Geographical Book that it must be granted a minimum height of 25 miles. [Margin: The mountains of Norway.] The higher mountains of Norway are climbed in no more than four days, on the testimony of Olaus [Olaus Magnus], Book 2, Chap. 2; from this Simone Maioli, in Colloquy 6 of the *Dog Days*, infers a journey of 40 miles, but that is too short; from this I deduced a height greater than 6 miles. [Margin: The Mountains of the Moon.] The Mountains of the Moon, from whose lake rise huge rivers, the Nile, the Niger and the Zaire, which traverse in their course almost the whole length or breadth of Africa and discharge into the sea: from the sure rules on the fall of rivers, to be set out in Chap. 13, I have established for these a height no less than 12 or 15 miles. [Margin: The mountains of Chile.] Father Alonso de Ovalle has recently told me, in speech and in writing, in Chap. 5 of his *Chilean Report*, of the remarkable height of the mountains of Chile, and has affirmed that their ascent takes no less than four days. I am therefore certain that mountains or hills, however high, which we look up at as they extend from the Apennine, are to the very high mountains that Sacred Scripture calls *Mountains of God* as low plants are to very tall pines or oaks.

[Margin: A twofold objection is met.]

But if there are any to whom so great a height would, so to speak, bring on dizziness, let them, I ask, first examine our foundations, and then, if they can, overturn them. As for the fear of violating the Earth's roundness, which moves some, let them know that this Cybele is of such vast stature that not only towers, but not even mountains of 50 miles, set around her head a crown unfitting to it; on this see the appendix to Chap. 1 of this Book. But how preposterous it is to wish to estimate the height of mountains, in some places geometrically evident, from the height of the regions of the air, which is varied and uncertain and to be distinguished not absolutely but relatively to the mountains themselves, I shall show in the Appendix to Chap. 19 of this Book, where mountains that raise their heads above the clouds are treated.

CAPVT XII.

On the diminution of mountains, and on the change in the roundness of the Earth, of shores, etc., and on the argument from this for a finite duration of the world.

Above all, we have three arguments for a perpetual change in the roundness of the Earth and for the decrease of mountains: 1. in the mountains themselves; 2. in the plains; 3. in the shores of the sea.

[Margin: The diminution of mountains.]

I. As to the first: that saying of Job 14 is certain from experience: *By flooding the Earth is little by little consumed.* For rain waters, river waters, and those of torrents and melted snows gnaw away the sides of mountains; so that the foundations of houses on mountains are seen laid bare, or the houses themselves hang from the highest banks of the mountains, about to fall at any moment, or half-ruined. Hence the foundations of the Capitol at Rome are now visible, and others discussed by Georgius Agricola, *De subterraneis*, Book 3, Chap. 1. Moreover, these same mountains are everywhere bored through and undermined by the hidden tunnels of insidious waters, until they give way and great masses of earth slide down, which the Italians call *Labinas*, from their sliding [a labendo]. These have sometimes been so great as to drag entire villages and towns with them into the grave. This happened within our memory to the village of Piuro, within the borders of the Swiss, the Clavena river being blocked as a result; and to others in Pliny the Elder, Book 2, Chap. 91.

[Margin: The increase of the Earth's plains.]

II. By contrast, plains lying below mountains grow from time to time from the mountains' sand and clods, carried down by the force of waters or of carts, to whose wheels they cling; so that the Earth's roundness, which decreases at the summit of the mountains, increases at their feet and in the fields. And therefore ancient buildings that once stood wholly exposed now lie hidden below the pavement, wholly or in great part; and the higher the piled-up earth has shod them in buskins, the greater the proof of their antiquity. Who does not know that ancient Rome must now be sought beneath Rome; that the Arch of Septimius has now become an underground bridge; and that one descends into the Pantheon, into which one formerly climbed by many steps? Or what architect is unaware that this skin of earth heaped on top is what the common people call *Cōmotam* [gloss: "moved" or "disturbed" ground], and is by no means fit to bear the foundations of houses? From this, finally, you may see the ancient windows and door-leaves blocked up at Modena, Ravenna, Benevento and other more ancient cities.

[Margin: Changes of shores.]

III. From the same flooding, and from banks gradually brought together toward the sea, and from earth thrust out by rivers and torrents, inasmuch as the waters' tribute does not suffice, shores grow, and not only valleys but estuaries of the sea, and seas, are filled up. And those exchanges of Earth and Sea take place which Aristotle treats in Book 1 of the *Meteorologica*, Pliny the Elder in

Book 2 from Chap. 85 to Chap. 102, Strabo in Book 12, Polybius in Book 4, and Bercius [?] in Book 1 of the *Geography*. For the part of Egypt called the Delta is a gift of the Nile, and a great part of the territory of Ferrara is a gift of the Eridanus [Po] and the Rhenus [Reno], because they consist of sand and clods carried down by these rivers. The Ammonian marsh and that of Maeotis, on the other hand, were formerly much deeper and could bear larger ships than afterwards, when mud had been brought into them, on the testimony of Aristotle. But at the very shores of the sea five noteworthy things result from this. First, the shores themselves are extended, and cities formerly on the shore are now many stadia distant from the sea. Indeed, where Guelders now is, there was formerly sea; and already in Pliny the Elder's time the sea had receded from the port of Ambracia by 10 miles, from Athens by 5, and now from Padua by 25, from Barcelona by 30, from Ravenna by 6. And there was formerly sea above Memphis as far as the mountains of the Ethiopians, and around Ilium and all Teuthrania, where there are now plains thanks to the Maeander.

Second, islands have been joined to the mainland and, as it were, glued to it, by earth carried in by rivers and torrents or by the collapse of promontories. Thus Pliny the Elder, Chap. 89, Book 2, relates that Antissa was joined to Lesbos, Zephyrium to Halicarnassus, Ethusa to Myndus, Dromiscos and Perne to Miletus, and Narthecusa to the promontory of Parthenium; indeed, that Hybanda, once an island of Ionia, afterwards stood 200 stadia from the sea, within the mainland; that Syrites, in the interior of Ephesus, and Derasidae and Siphonia, in that of Magnesia, which were formerly islands, are inland; and finally that Epidaurus and Oricum have ceased to be islands. To this refers that oracle in Ovid, *Metamorphoses* 15:

The time will come when one day the Pyramus, with its rapid waters, will reach sacred Cyprus by its heaped-up shore.

[Tempus erit, rapidis olim cùm Pyramus vndis, / In sacram veniet congesto littore Cyprum.]

That is, to that Cyprus which, formerly joined to the mainland of Syria, was afterwards torn from the mainland by the force of an earthquake or of the sea; just as Sicily was torn from Italy, Euboea from Boeotia, Atalante and Macris from Euboea, Besbycus from Bithynia, and Leucosia from the promontory of the Sirens, on the testimony of Pliny the Elder, Book 2, Chap. 88.

[Margin: New islands, or islands swallowed up.]

Third, by a hidden addition of earth, with nature working at this under the waters of the sea, new islands arise, which were formerly like hidden hills or mounds of the waters; or certainly they emerge when the sea is thrust elsewhere. Of this kind were the Echinades, heaped up by the river Achelous, and others, of which Pliny the Elder treats, Book 2, Chaps. 86 and 87.

Fourth, the sea having swollen and risen from the soil brought into it, the Venetian, Baltic, Dutch and Prussian estuaries have been filled up; and the sea, overflowing from there, has either swallowed certain islands or peninsulas, or looms over them and threatens them, as Pliny the Elder relates, Book 2, Chaps.

90 and 92, and the geographers here and there concerning Zeeland and certain neighbouring places.

Fifth and last, when earth has been mixed with the roots of trees and with papyri, rushes, seaweeds and other longer and aquatic plants, and thus heaped up, certain great masses form, yet lighter than water and therefore floating. The people of Ferrara, in their valleys, call these *Cuoras*, as if *Coria* [hides]; poets and historians, on the other hand, call them floating islands in the sea; Pliny the Elder treats them, Book 2, Chap. 95. Unless you should say that they are carried here and there resting on the backs of whales, or that they waver and sway, rather than float, from the nearby tremor of volcanoes, or by the force of subterranean fires.

[Margin: An argument against the eternity of the world.]

IV. Therefore, from these frequent exchanges, Biancani, in Book 4 of the *Sphere*, Chap. 4, and on the mathematical passages of Aristotle, p. 103, concludes that the Earth neither has been from eternity with this shape, nor will naturally last for eternity. And he judges it necessary that, with earth brought into it, the sea has at length overflowed, or will wholly overflow, and has overwhelmed or will overwhelm the whole face of the Earth, if the world is from eternity or will be for eternity. But Bartholomaeus Mastrius [Bartolomeo Mastri] and Bonaventura Bellutus [Bonaventura Belluto], *De caelo*, Disp. 4, q. 4, art. 6, teach that this is by no means necessary, because by the force of winds or of cold lands can be heaped up elsewhere, or turn to stone, or new hills be produced. And Simon Stevinus [Simon Stevin], Book 2 of the *Geography*, says that lands, from the decrease of mountains, are levelled in such a way that on one side they rise evenly and on the other hold in the waters; and that it is not necessary for all the earth of the mountains to slide down into the hollows of the sea, but that part of it is spread over the terrestrial surface, so that it never becomes everywhere lower than the sea. Finally Cabeo too, on Book 1 of the *Meteorologica*, text 72, q. 1, infers from this perennial diminution of the mountains that the world has not been from eternity in the way in which it now is; but about a future eternity, nothing. [Margin: Alfonso Pandolfi on the end of the world.] You can see more against Biancani's argument in the most illustrious and reverend Alfonsus Pandulfus [Alfonso Pandolfi], in the treatise *On the End of the World*, which began to be printed this year, 1648, here in Bologna.

CAPVT XIII.

Some select matters for cosmographers: on springs and rivers, and their origin, measure, velocity, overflow, etc.

I. From mountains to springs, from these to rivers, and through these to the seas, the passage is easy for us. But it is not part of our plan to treat fully here what natural philosophers, or hydraulic engineers [Hydragogi], and the measurers and levellers of waters teach about these. Still, a few things must

be pointed out that savour of mathematics and that, if unknown, could lead cosmographers into shameful errors.

DE ORIGINE FONTIVM ET FLVMINVM.

On the origin of springs and rivers.

[Margin: Opinions on the origin of springs.]

All Catholics must indeed accept that saying of Ecclesiastes 1, not as a popular proverb but as an utterance of divine Wisdom: *All rivers enter the sea, and the sea does not overflow: to the place from which [?] the rivers go out they return, to flow again.* But as to how this happens, there are three heads of opinion. For some teach that it happens by local motion alone; others, by a new production of waters from clouds raised from the sea; others, by a new production of waters in the subterranean caverns of the Earth and by a hidden rain, with vapours raised from Tartarus, which communicates with the sea.

[Margin: 1st opinion.]

II. Saints Basil (Homily 4 on the *Hexaemeron*), Jerome (on Chap. 1 of Ecclesiastes), Damascene (*On the Faith* 2, Chap. 9), Isidore (*Origines* 3, Chap. 20) and Philo (*De mundi opificio*), and Hugo Victor. [Hugh of St Victor] (on Chap. 2 of Genesis), Maioli (Colloquy 11 of the *Dog Days*) and the Coimbra commentators [Conimbricenses] (on Book 1 of the *Meteorologica*, at text 62), seem to attribute this solely to local motion, and that perpetual. Add to these Albertus Magnus, who in Book 2 of the *Meteorologica*, tr. 2, Chap. 11, says that vaporous air in caverns of the Earth draws waters upward; I believe, when it is cooled at night or in winter, condenses and occupies a smaller place, in the way that we see air enclosed in thermoscopes and in oblong glass phials condense and, to prevent there being a vacuum, draw water upward. Add St Thomas, in 2, dist. 14, q. 1, and Zanardus [Michele Zanardi] on Book 1 of the *Meteorologica*, who attribute this to the stars, which by a hidden power draw waters upward for the benefit of plants and animals. Add Scaliger [Julius Caesar Scaliger], *Exercitationes* 46, and Geraldinus [?] on Book 1 of the *Meteorologica*, who attribute this to the thicker and heavier water of the sea, which compresses and propels the subterranean waters, made lighter by percolation itself, and drives them to burst out through narrower channels, as through the goose-neck of phials, above the level of the sea. This would be helped if in some place the sea were higher than the spring. Add finally Seneca, *Natural Questions* 7, Chap. 25, who thinks that, just as the upper part of animals draws blood upward, so the upper parts of the Earth draw waters upward, lest they crack from excessive dryness; in much the way that a sponge or a filter draws water upward by its absorbent dryness. Unless here you prefer to take refuge in a Machine and in Intelligences, which maintain this perpetual motion by their impulse or traction.

[Margin: 2. Opinion.]

III. Molina [Luis de Molina], disput. 11 on the work of the six days, has recourse to external rain, which, coming mostly from clouds that arose from

the sea, is supposed to penetrate the earth and produce springs. But it has been observed that rainwater does not penetrate the earth beyond 12 or 15 feet, and much less the rocky mountains of Peru, Chile and the like, under which, however, there are deep sources of springs. Certainly from the beginning, as is said in Genesis 2, "The Lord had not yet rained upon the earth", and yet "A spring rose from the earth, watering the whole surface of the earth."

[Margin: 3. Opinion.]

IV. Others, finally, attribute it to an internal rain and a perpetual dripping of waters. So Aristotle, Book 1 of the *Meteorologica*, from text 63 on, and the Peripatetics there, the Parisians, Kottounios and Cabeo. For that there is under the earth an Abyss of waters, or Tartarus, is handed down not only by Plato in the *Timaeus* and the *Phaedo*, Seneca, *Natural Questions* 3, Chap. 11, Pliny the Elder, Book 2, Chap. 103, Contarenus [Gasparo Contarini], 2 *De elementis*, Virgil, *Georgics* 4, and Fracastorius [Girolamo Fracastoro] in his *Siphyllis*; Sacred Scripture also hints at it, in Genesis 2 and 49, Psalm 134, Proverbs 8 and Ecclesiasticus 24. Those waters, then, on this view, are raised into vapours by the force of subterranean fires; these vapours, cooled in a colder region of the Earth, are turned into drops, which at length run down through higher passages to the mouths of springs. For we see, in the digging of wells, the earth sweating out these drops like a sponge, and in vaulted mountain caverns drops trickling from above, so much so that in one of them I counted more than 300 drops, which were filling the little cistern of a single spring.

V. Yet physico-mathematics [Physicomathesis] could hardly endorse this opinion, if there is brought to calculation on the one hand the water that any river discharges into the sea daily, and on the other the multitude of all the rivers, torrents, streams, springs and lakes that contribute their waters to one and the same river through very many branches. The Eridanus [Po], near its mouths, is about two perches, or 4 paces, deep in the middle, and less deep near the banks; but let it be 15 feet, or 3 paces, all round, and let it be a thousand paces wide there, and cover six miles in one hour. From this it follows that every hour it discharges into the Adriatic 18000000 cubic paces of water, and every day 432000000. Grant now that 60 rivers flow directly into the Eridanus, as Pliny the Elder affirms; of these the Mincius [Mincio] flows from Lake Benacus [Garda], the Oleum [Oglio] from Iseo, the Adda from the lake of Como, and the Ticinus [Ticino] from Verbanus [Maggiore]. How many myriads of drops, then, do you suppose serve for producing and maintaining even one of these lakes? What of so many other rivers and streams flowing together into one of those 60? Take the Athesis [Adige] alone, which flows directly into the sea: let it take in 50, partly rivers, partly streams, before it reaches Trent, and afterwards about as many again, as I myself counted on the chorographic maps of Trent, Verona and Ferrara. All this considered, 432000000 drops would have to labour for the Eridanus alone, each of which, by frequent dripping, would produce one cubic pace of water every day. Now let there be 5 cubic drops in one inch of a foot, reckoned by length; a cubic pace will therefore

require 8100000000 drops. One drop will not make up this number even if it falls at every second of the hour, for at the end of one day there will be only 86400 such drops. But here, for this matter, I only indicate the method, which is to be set out fully in the Geographical Book.

DE MENSVRA AQVARVM.

[Margin: Caution in the measuring of water to be diverted.]

VI. As to the measure of waters to be diverted into meadows, gardens and other similar uses, it is not enough to look at the width of the mouth or opening, and to obtain, say, an obol of water, or to write it into a contract. One must attend to the greater or lesser velocity of the water, arising from brooks, small veins, rains, melted snows, the rarefaction and condensation of enclosed air, winds and so on, but chiefly from the slope. And so at the least the same inclination of the pipe must be written into the agreement; the greater it is, the greater the supply of water it furnishes. As to the measure of the water that rivers carry into the sea, one must attend not to the number of mouths, which are often hardly to be distinguished from the sea's estuaries, but to the trunk of the river before it is dispersed into those mouths; there its width and depth are to be measured. That depth is always smaller near the sea, and it is not uniform but shaped like a shell, and smaller near the banks. Finally the velocity too must be attended to, of which I shall speak at no. 8. On the measuring of depth enough has been said in Chap. 5, Coroll. 10.

DE LIBRAMENTO CANALIVM ET FLVMINVM.

[Margin: Fall of streams and rivers to be led off.]

VII. Fall [libramentum], in this context, is the height at one end, above the convex surface of the Earth, of the horizontal line along which the water descends, and its depression at the other, whether that line is a portion of the sensible horizon or equidistant from it. In a word, it is the slope or inclination of the straight channel along which water-engineers [Hydragogi], for the sake of easier excavation, lead waters over some thousands of feet or paces, although longer rivers do not run down the same straight channel throughout, but along one channel after another, as I said in Chap. 4, Corollary 9. The question is how great the height of the place must be from which water is to be led to a given distance. But one height is sufficient for the water not to stagnate but at least to flow slowly, another for it to run, another for it to run rapidly; hence the differing opinions of the authors. For the water to run, and for the irrigation to be done swiftly and securely, Vitruvius, Book 8, Chap. 7, requires 5 feet of height for every thousand feet of distance, since he says: "And let the bed of the channel have a graded fall, of not less than half a foot per hundred feet." From this I conjecture that in that passage of Palladius, "If it comes over level ground, let the structure slope gradually by a foot and a half between every sixty or hundred feet, so that it can have the force to run", one should read half a foot. For how could it be "gradually" if it were a foot and a half, and in a

thousand feet there were 15 feet, or 3 paces, and in a thousand paces the height were 15 paces? That would be an intolerable rapidity, or rather a precipice of water. But let us hear Leon Battista Alberti, Book 10 of the *Architecture*, and in his stead Daniel Barbarus [Daniele Barbaro] on Book 8 of Vitruvius, Chap. 6: "Geometers, moreover, say that if a straight line touches the globe of the Earth and is extended for a thousand paces, the interval between that line and the circumference and globe of the Earth does not exceed ten digits. So it has come about that, if anyone wishes to lead water in a furrow, the water does not move in each thousand unless at a level a whole foot lower than the place from which the furrow first began to be made. This place is called the *Incile* by jurists, from that first incision made for the leading of water. But if the place declines six feet in a thousand paces, the course of the water will be rapid, so as to be inconvenient and dangerous for ships." For although a height of 10 inches, which the physical horizon has after one mile according to what was said in Chap. 10, no. 6, may seem to suffice for descent, nevertheless, lest the water stagnate and stick because of the fibres and roughness of the channel and the very sluggishness and viscosity of the liquid, a whole foot at the least is required. Hence Kepler in the *Astronomia Optica*, p. 135, said that Vitruvius requires in aqueducts a fall of the two-hundredth part of the space run, that is, half a foot per hundred feet; but he adds: "There is no doubt that so great a height would be ruinous to those sailing. Therefore, if you assign a hundred miles to the windings of the Albis [Elbe], much less than half a German mile will go to the elevation of the Norican land from which it rises and flows into the Ocean, because it flows gently and stagnates." And Froidmont, Book 5 of the *Meteorologica*, Chap. 3, following Daniele Barbaro, said: "The swifter rivers decline toward the centre of the Earth by three, four, five or more feet per mile; but if by six feet, the course is so rapid and torrential that it becomes inconvenient for steering ships in it." Cardanus [Girolamo Cardano], however, in Book 1 of *De rerum varietate*, Chap. 6, says that for diverting canals a height of 8 inches per thousand feet suffices. Therefore, if a river is slow and stagnant, of the kind the Elbe is in Germany and the Arar [Saône] in France, its fall per thousand paces of channel will be much less than five paces, which are the two-hundredth part of a thousand; but if it is so rapid as to be wholly unnavigable and intolerant of ships, its fall per Italian mile will be higher than the two-hundredth part of a mile, that is, more than 5 paces or 25 feet, according to Vitruvius and Kepler; but according to Daniele Barbaro and Froidmont it will be higher than 9 feet, unless Barbaro meant to write a thousand feet in place of a thousand paces. In that way he would be better reconciled with the others, and on that supposition Froidmont, who follows him word for word, would have to be emended. For why do Vitruvius and Palladius require at the minimum 5 feet, or one pace, per thousand feet, unless because the water flows too gently and slowly if the height is less? But if the height stays within 5 paces after a thousand paces, the river will not be unnavigable. We can therefore establish by probable conjecture at least six degrees of the height of the fall,

corresponding to six degrees of velocity of navigable rivers, as we have set out in the following little table. It can happen, however, that the same river shares in several of the velocities listed below, or even in all of them, since, as I said, rivers do not always run along the same channel, or one of the same fall. Thus our Eridanus is unnavigable above Roccelum [?], navigable above the Ticinus and very swift, swift at Cremona and Mantua, and at Ferrara and beyond of moderate velocity; and there is no doubt that the same happens proportionally with the others. For the levelling of waters, moreover, and for finding the height sufficient for the water's outflow, see what we advised in Chap. 4, Coroll. 10.

Degrees of velocity of navigable rivers. Degree.	Height of the fall after each thousand paces of channel. Paces.
Unnavigable	7 8 or more
1 Navigable with danger	6
2 Navigable, very swift	5
3 Navigable, swift	4
4 Navigable, moderate	3
5 Navigable, slow	2
6 Navigable, very slow	1

DE VELOCITATE AQVARVM.

[Margin: Method of measuring the velocity of waters.]

VIII. We have now, then, slid down to the velocity of waters running naturally along sloping channels. Benedictus Castellus [Benedetto Castelli] teaches how to measure it by counting the time in which a gall-nut or a wooden ball, floating on a river or canal, covers a fixed distance. But this method is deceptive. Lighter things, such as cork, straw and gall-nuts, do not take up as much impetus as heavier things, and they are more easily retarded by the cross-current of the waves and by eddies; hence it can happen that the water itself covers twice as long a distance in the same time as that ball. Then again, the lower parts of a river move more slowly than the upper, and near the banks more slowly than in the middle of the channel. So Cabeo, Book 1 of the *Meteorologica*, from text 60, p. 336, suggests another method, carried out with a pole that has a weight hung on it below, so that in its course it is kept by the weight in a perpendicular position, with gourds tied around the pole at the top, which do not allow it to sink down entirely. For if the time is counted in which the gourds cover a fixed distance, he thinks that a more certain pronouncement can be made about the velocity of the water. But here too, because of the resistance, and an unequal one at that, of the lower weight and of the gourds, the water is carried faster than that pole. I should therefore think it better either to tinge the water with so much blood or ink that it keeps the colour in its course, and to count the time in which the coloured water reaches a fixed distance; or, in canals or pipes previously dry, to count the time from when the water begins to flow from an opened stopcock [epistomium]

or opening and runs through a fixed interval; or, for navigation on rivers, to rely on the tradition and experience of the riverside dwellers or shipmasters, who know very well how many miles are usually made in such a stretch of such a river in each hour or day. The rest concerning the velocity of rivers can be reduced to these 5 points worthy of note. The first is that rivers are much swifter near their springs, and mostly unnavigable, than in the middle stretch or near their mouths and outlets. Hence millers place their mills far from the mouths. So the Nile as far as the island of Meroë is unnavigable, and so rapid that it was called the Eagle; so the Danube above Vienna, the Po above the Ticinus, and the Rhône above Avignon are much swifter than afterwards. In the Po, at the Ticinus, about 10 miles are usually made each hour, so that the banks seem to fly; and in the Danube above Vienna in some places 10, in others 12; whereas in the Po, from Francolino to Loredum [Loreo], only 6 or 7 miles are usually covered in one hour. Secondly, the cause of the greater slowness near the mouths is twofold: one is the lesser height of the fall, the other the greater width of the channel. Because of these the banks too are less high there. And so in the Po, for 10 miles near the sea, a height of embankments of 6 feet is enough, but above Ferrara it requires higher banks, of 12 or 15 feet, and above Mantua up to 20; otherwise it readily overflows on the arrival of new waters, unless somewhere far from the sea it is wider, which rarely happens. So rivers compensate for depth with width, and they move more slowly where they are wider, not faster, as Castelli thought, deceived by the smallness of the embankments. For he thought that the embankments were made lower there because the water, passing straight through at greater velocity, does not have sufficient time to overflow towards the sides. Thirdly, the cause why water is the slower the wider the channel is, and again the swifter the narrower the channel or place through which it passes, as when it is forced to pass between the piers and arches of bridges or through narrow enclosures, is this: there the oncoming water is spread out from a straight course into an oblique one, and the quantity of water that holds the straight course is smaller, since a good part of it diverges to the sides. In the second case the cause is that just as much water comes on from behind, and all that water which was being carried dispersed, in a course mixed of straight and oblique, must pass in a straight course; therefore the water must yield place to it so much the sooner. Hence, if water was passing through a channel 100 paces wide in one hour, it will afterwards pass through a channel 50 paces wide in half an hour. In this matter Castelli was likewise deceived; against him, Cabeo, 1 *Meteorologica*, text 60. Fourthly, if two rivers flow down from the same fall and source, one by a straight and very short course, without windings and meanders, the other by an oblique course and through windings, the one that descends more directly is, other things being equal, the swifter. For at an equal interval, or distance from the source, the one carried more directly descends to a lower place, and the inclination of its channel is greater. For example, after the first thousand paces, from a place 100 paces high it descends to a place 80 paces high; but a winding

river, from a place 100 paces high, after a thousand paces of channel does not descend to a place less high than 90 paces. Hence it is that rivers arising from mountains near the sea, like some of those of Peru and Chile, because they have no windings and reach the sea by a very short route, are almost wholly unnavigable; and that, at equal velocity, a more winding river gives evidence of a greater height at its source. In estimating that height it is not enough to consider how many degrees of a great circle it covers on Earth, as some do in the case of the Nile; one must attend to the miles it makes in its oblique course, and weigh one by one the velocity it has in the separate stretches of straight channel. [Margin: Velocity of rivers.] Fifthly and finally, from the history and narration of many, whom I consider it an offence not to believe, I gather that the most rapid rivers, in which, going downstream without sails and oars, 12 miles are made each hour, are the most rapid of the navigable ones, and can indeed be navigated, but not without some danger, and that great attention is needed lest the ship, driven crosswise, strike somewhere. Of this kind in some places are the Danube, the Tigris and the Rhône. After these, rivers are held most rapid without such danger when 10 thousand paces are made each hour, as in the Po above the Ticinus, where the banks seem to fly away behind one; and rapid, when 8 miles. Conversely, they are held slowest when in one hour, without oars and sails, only 2 thousand paces are made, as near the mouths of the Elbe and the Saône; less slow, with 4 thousand paces. A river, therefore, or that part of a river, will be of velocity midway between these in which 5 or 6 thousand paces are covered each hour, as in the Po after Ferrara as far as Loredum. And these things are to be understood of the ordinary course, one not urged on by an extraordinary quantity of water from rains or melted snows, or by winds driving from behind. From this it is permissible, with a balancing that is certainly probable, to compose from these degrees and from the table of no. 7 this second table.

Degree of velocity.	Height of the fall.	Thousands of paces in 1 hour.
	Per thousand paces.	
* Unnavigable	Paces 7. 8. or more	more than 12
1 Navigable with danger	Paces 6	12
2 Navigable, very swift	Paces 5	10
3 Navigable, swift	Paces 4	8
4 Navigable, moderate	Paces 3	6
5 Navigable, slow	Paces 2	4
6 Navigable, very slow	Paces 1	2

DE INTVMESCENTIA, ET EXVNDANTIA FLVMINVM.

[Margin: Swelling and overflow of rivers: from what cause?]

IX. The adequate cause of the swelling of rivers, on account of which they overflow above their embankments into the fields, is not the wind blowing against the mouths, driving the waters back and raising them only as much as

the velocity of the course is retarded, as Benedetto Castelli, with some Roman architects and water-measurers [Hydrometræ], supposed. For that reason it is not a sufficient remedy, for avoiding the floods of the Tiber, the Po and similar rivers, to excavate other mouths not exposed to the wind. For it is impossible for those mouths to meet these two conditions: to be as near the old mouths as is required by the time for the driven-back waters to burst out there through the new channels, and not to be exposed to the same wind, since the same wind occupies nearly the whole stretch of that shore which could hold those mouths. The chief cause, moreover, is new water arriving from rains or melted snows, in such quantity and with such speed that it exceeds what is discharged into the sea in the same time; and if a wind is added that retards its course at the mouths, this concurs accidentally in the flood and the swelling. Therefore either an outlet for the water must be opened by new channels above the place for which a flood is feared, and closed with gates that can be opened when the river swells; or the embankments must be raised only as much as experts judge necessary from the swelling of many years, though always raised more far from the mouths than near them, because there the channel is usually narrower and is filled sooner by the extraordinary water. You will see more on this in our Cabeo, on 1 *Meteorologica*, from text 60, through 9 questions.

CAPVT XIV.

On the threefold dimension of the sea, and the comparison of the bulk of the terrestrial waters with the bulk of the Earth, and their equilibrium.

[Margin: Is the surface of the sea or of the land the greater?]

I. Leaving aside the waters that are above the heavens and those hidden in the abysses of the Earth, since they do not fall within our sight and measurement, there remains a twofold question about the waters that we can see and measure: one about breadth together with length, that is, about the surface; the other about depth. That the land surface is greater than the known surface of the sea is affirmed by the author of Book 4 of Esdras, Chap. 6, though he is apocryphal, who asserts that of the surface of the terraqueous globe a seventh part is water and that the remaining six were granted by God to the land to be inhabited and sown; by Salianus [Jacques Salian], vol. 1 of the *Annals*, at the third day of the world; by Alexander Piccolomineus [Alessandro Piccolomini] in his treatise on this matter; by Io. Baptista Benedictus [Giovanni Battista Benedetti] in his apology for Piccolomini; and by Io. Boterus [Giovanni Botero] in his relation on the sea, who adds that there are probably more stars in the northern hemisphere for this reason, that they may keep in its original dryness the greater part of the uncovered land, which lies in the northern hemisphere. On the contrary, that the surface of all the waters extends more widely than that of the land is the view of Copernicus, Book 1, Chap. 3; Bodinus [Jean Bodin]; Froidmont, Book 5 of the *Meteorologica*, Chap. 1; Cabeo in the same place, text 10, quest. 1; and Antonius Berga [Antonio Berga] in his discourse on this matter

against Piccolomini. Finally, on the more recent geographical maps they seem to Biancani, Book 5 of the *Sphere*, Chap. 4, physically equal, especially if lakes, pools, marshes and rivers are added. Certainly so great a difference does not appear between these surfaces that a longer controversy should be started over it; nor are geographical maps so certain with regard to regions not yet fully discovered that we are compelled to acquiesce in them.

[Margin: Opinions on the depth of the sea.]

II. The depth of the sea, says Scaliger, *Exercitationes* 38, rarely exceeds 80 paces, very rarely 100. And Benedetti, in his letter to Horatius Mutus [?], reports that the greatest depth does not exceed 500 paces, from the account of the shipmasters D. Franciscus Lopez [?] and Rodericus Gusmanus [?]. But Botero too, in the relation on the sea, Scorcia [?] on the Nile, Kottounios on Book 1 of the *Meteorologica*, lect. 17, and Biancani, Book 5 of the *Sphere*, Chap. 4, say that it is rarely found to reach one mile, never to go beyond a mile and a half, and mostly to be below 500 paces. Finally Caesar, having sent explorers through the Mediterranean, the Tyrrhenian and the neighbouring seas, did not find it greater than 15 stadia, that is, 1875 paces; hence that saying of Pliny the Elder, Book 2, Chap. 102: "Palianus [?] reports the deepest sea to be of fifteen stadia."

III. Others, however, hold a deeper view of the sea. Cabeo, Book 1 of the *Meteorologica*, text 20, q. 1, though he says that most frequently it does not exceed 60 or 100 paces, admits that in some places it reaches two or three miles; and Georgius Reisch [Gregor Reisch], Book 7 of the *Margarita Philosophica*, tr. 1, Chap. 44, says that in some places it is of 4 miles. Pliny the Elder, Book 6, Chap. 22, and Solinus, Chap. 54, say that not far from the island of Taprobane there are some channels of the sea "so deep that no anchors settle or have been able to reach the bottom." And Olaus Magnus, Book 2, Chap. 10, relates that near Ulma in Sweden an abyss was found, measurable by no ropes; and that in the ocean of Norway the depth is in some places so great that it could not be reached even by ropes as great as the largest ships could be loaded with, a very heavy mass of lead or iron being added. And our own José de Acosta, Book 3 of the *Indian History*, last chapter, Antonius Pigafetta [Antonio Pigafetta] in his voyages in Ramusio, and Froidmont in the *Meteorologica*, Book 5, Chap. 1, affirm that in some places in the Pacific Sea neither the Castilians nor the Hollanders could find bottom with a sounding-lead, however great. For this reason Maiolo, in the *Dog Days*, Colloquy 10, concludes that the sea is in some places of unsearchable depth. But this could have happened because the bulk of the whole lead was by then lighter than an equal bulk of water; in that case the line of the lead is not stretched straight down but floats obliquely. For see what we said about the method of measuring the depth of the sea in Chap. 5, Coroll. 10. We can, however, plausibly believe that the sea is in some places as deep as 10 miles and more, if we admit mountains so high, and that the sum of their height and the sea's is so great, according to what was said in Chap. 11, even if ships rarely or hardly ever stand above those inverted mountains of

water, and on the perpendicular of those watery peaks, while they explore the bottom with the lead.

IV. Now, if we give the whole sea the depth of one Italian mile, so that excess may compensate defect, and the surface of the sea is taken to be as great as that of the uncovered land, the cubic miles of the sea will not be more than 168217088. But if we give it 500 paces everywhere, they will not be more than 84108544, since the whole surface of the terraqueous globe, from what was said in Chap. 7, no. 8, is 336434176 square miles. Therefore the bulk of this water would be to the bulk of the Earth, on the first hypothesis, about as 168 to 580237, and on the second as 84 to 580237, since the bulk of the terraqueous globe, from what was said in the same place, is 580236807150 cubic miles. So, as regards this part of the element of water, there is no doubt that the bulk of water is much smaller than that of the Earth.

V. But whether, when the water that lies hidden in the receptacles of the Earth is reckoned in, or that which existed from the beginning of the world, before God

Almighty divided the waters from the waters and transferred part of them into heaven, as is found in Genesis 1, in Psalm 148 and in the Song of the Three Young Men; and this is the opinion of so many Fathers that, on the testimony of Delrio [Martín del Río], they carry the force of a single Council, though one not yet confirmed on this point by the Supreme Pontiff, so far as I know: whether, I say, when these are reckoned in, the bulk of the element of water is greater than that of Earth, was once a celebrated controversy. On one side stood Alessandro Piccolomini and his apologist Giovanni Battista Benedetti, who together with Copernicus, Book 1, Chap. 3, fought fiercely for the Earth's excess, and whom Biancani, Book 4 of the *Sphere*, Chap. 4, and Cabeo, Book 1 of the *Meteorologica*, text 11, quest. 1, have endorsed; on the other stood Antonio Berga, in his dissertation on this matter, contending for the water. [Margin: The bulk of the waters compared with the bulk of the Earth.] I judge the question to be unknown to us, and manifest to God Almighty alone and to his Intelligences. For I hear the Lord rebuking in Job 38: "Have you entered the depths of the sea, and walked in the furthest reaches of the Abyss?" I hear Ecclesiasticus, Chap. 1: "The height of heaven, and the breadth of the earth, and the depth of the Abyss, who has measured?"

The arguments of Piccolomini and Berga, moreover, are too merely dialectical [topica] for us to be obliged to lean to either side because of them. Piccolomini's arguments for the most part hold of the uncovered part of the water: as when he says that land is the containing place and water what is placed and contained; that the rays of the Sun and Moon, reaching the bottom of the sea, are the cause of the tides; that vapours of no immense bulk are drawn up from the sea, and so on. Berga's arguments, on the other hand, either rest on gratuitous assertions, as when he says that the whole Earth is like a sponge full of water, and that the bulk of the sponge is smaller than the water enclosed in it, for that is guessing; or they prove too much, as when he concludes the excess

of water from the greater number and bulk of fish than of land animals. For this would prove that the air, which he himself admits to be greater than land and water, is smaller by as much as birds are smaller than whales and elephants; and indeed that the water of the known sea alone is greater than the bulk of the Earth, because only in that water can the fish known to us live, although about this part of the water he holds the same view as Piccolomini. He adds that for the equilibrium of Earth and water, which have the same centre of gravity, it was necessary that water, being lighter than earth, should make up its defect of weight by an excess of bulk: as though water were in one pan of a balance and earth in the other, and as though this equilibrium could not come about if water, although smaller, were suitably arranged around the Earth's centre with that equilibrium preserved. Water's greater affinity with air, in place, in transparency and in moisture, the air being supposed far greater than earth, would at most hold for the whole elementary water created at the beginning. Yet it does not hold, both because liquid things on earth are not greater than dry things for the reason that they are akin to water, if water is supposed greater; and because it is very uncertain whether air, as distinct from the ethereal and celestial aura, is greater than earth, as I shall say below. Finally, Aristotle, 1 *Meteorologica*, text 12, did not say absolutely that a lower element is exceeded by the higher in a tenfold proportion, nor did he teach absolutely, 2 *On Generation*, text 37, that from one cube of earth, if it is rarefied, ten cubes of water come to be; he was arguing against Empedocles, for the sake of a fictitious example. Nor did God in fact make water out of rarefied earth.

[Margin: Is the equilibrium of the seas certain?]

VI. There remains the last controversy, on the equilibrium of the sea with itself and with the Earth. For from what Archimedes demonstrated about the consistency of waters and of every liquid, Biancani, Book 5 of the *Sphere*, Chap. 3, thinks: "All seas are necessarily of exactly equal height, and their surface is equidistant from the centre of the world, because if one were higher than another, it would flow into the lower. It is therefore plain that the counsellors of Sesostris, King of Egypt, were deluded when they dissuaded him from cutting the Egyptian Isthmus, saying that the Red Sea was higher than our Mediterranean sea and that it would accordingly come about that it would submerge all Greece and part of Asia." But notwithstanding these things, St Ambrose, Book 3 of the *Hexameron*, Chap. 2, where he relates that Sesostris and Darius the Mede had the same plan, and Froidmont, Book 5 of the *Meteorologica*, admit that the Red Sea is 3 cubits higher than the Egyptian shore. And Cabeo, Book 1 of the *Meteorologica*, p. 55, contends that the Ligurian Sea is higher than the Adriatic, because he has found by experience that from the pass of the Apennines they call the *Bocchetta* as far as Genoa the slope is, to the senses, as great as from that pass as far as the Ticinus, and that from the Ticinus to the Adriatic shore there still remains the whole of that slope down which the Po runs into the sea. To these is added the Corinthian Sea, which toward the east is believed to be higher than the western one; and this is evident from the

levelling of that Isthmus and from observation at its ends. Two of our Fathers Procurators have affirmed the same thing to me about the Ocean *del Nort* at the port of *Nombre de Dios*, that is, of the Name of God, compared with the Ocean *del Zur* at the port of *Panamà*: for to one looking from the highest mountains along the breadth of that Isthmus which joins the Americas, the Northern Ocean appears higher than the Southern.

Cabeo answers the argument taken from the equilibrium of the waters by saying that this equilibrium must follow if one considers the particular inclination of the waters, by force of which they demand to be equidistant from the centre in the parts of their surface; but not if one considers the inclination toward the good of the Universe, because of which those parts of the sea that lie diametrically opposite the heavier parts of the earth, in the opposite hemisphere, must be higher than the others. But it is not apparent how the land opposite the Ligurian Sea is heavier, since it is plain from the globe and from terrestrial maps that it is covered by the Ethiopic Ocean, at 43° of southern altitude and the neighbouring degrees. I would therefore judge rather that this equilibrium is impeded, both by the course of the sea toward the west, unless this course itself presupposes a slope, and by the variations of the tide, whose reciprocal alternations do not give sufficient time for this equilibrium to be completed. For it is established that in the channels and straits of the sea, the Sicilian, the English and so on, the water goes along one shore and carries ships with it toward the east, and along the other toward the west. Father Grassus [?] observed this very thing in the Tiber, on account of eddies twisting the water back toward the higher part, so that in the same river, with the current, one ship was carried downstream toward Ostia and another toward the Milvian Bridge. What if winds, blowing more frequently in the opposite direction, impede the balancing?

CAPVT XV.

On the Motions of the Sea.

[Margin: First motion of the sea, in longitude.]

I. The motion of the sea imitates the threefold motion of the celestial bodies, in longitude, latitude and depth. First, it moves from east to west. For ship-masters have observed that the voyage from Palestine to Spain, from England to Ireland, from Goa toward the Cape of Good Hope, from Spain toward America, and from the Strait of Magellan across the Pacific Sea to the Moluccas, is completed much more quickly than in the contrary direction, heading east, even when no adverse winds stand in the way and following winds are not lacking. The whole Atlantic and Ethiopic Sea does indeed run toward America; but this course is more evident in the straits and channels themselves, as between Africa and the island of St Lawrence [S. Laurentij insulam], where on account of the multitude of shipwrecks those Current [*Currentes*] waters are called the Valley of Jehoshaphat [*Vallis Iosaphat*]; and in the Gulf of Mexico at the island

called the Dragon's Mouth [*Os Draconis*]; and near Gadalupa [Guadeloupe] and the port of Cartagena and of Santa Marta: so much so that ships cannot struggle against it even with a helping wind, barely complete one whole mile in a day, and have the lead of the sounding-line swept away toward the west. Willebrord Snel adds, in his *Tiphys Batavus*, Book 2, Prop. 8, that between Brazil and Angola this motion of the sea is carried from April 20 to July 20 toward the north-west [Zephyroboream], but from October 20 to January 20 toward the south-west [Austrozephyrum].

I should be inclined to believe that the cause of this motion is the attraction of vapours made by the Sun as it moves with its diurnal motion, placed now in the northern signs, now in the southern; for it is fitting that the air should be moved by their motion, and hence perennial breezes and winds too blow rather toward the west. It is difficult to attribute this to rivers, since many great rivers run toward the east, such as the Maragnon, the Aureliana, the Canada, the Danube and the Yanson, and many to the south or the north. Nor does the diurnal motion of the heavens sweep our air along with it, as Contarenus [Gasparo Contarini] and the Coimbra commentators [Conimbricenses] think, since the whole heaven does not move, nor do feathers or threads suspended in the air indicate this to us.

[Margin: Second motion of the sea, in latitude.]

II. The second motion is from north to south; on it see Aristotle, Book 2 of the *Meteorologica*, Chap. 1, and St Thomas there, and Albertus, tr. 3, Chap. 6. For the Maeotian marsh runs down through the Thracian Bosphorus into the Propontis with such force that it suffices to turn mills, and ships can barely struggle against it. The Propontis in turn rolls down through the Hellespont into the Aegean, whether because of the force of the rivers that break out into the Euxine, as Aristotle thinks, or for some other cause. The Gothic Sea too flows toward France. Granted, those 4 channels [Euripi] near the Arctic pole are said to be carried very rapidly toward the same pole.

[Margin: Third motion of the sea, in height, or the tide of the sea.]

III. The third motion of the sea is flux and reflux, commonly called the tide of the sea [*Aestus Maris*]; because of its swelling upward and subsiding downward, it can be reduced to a motion of height and depth. For Galileo dared in vain to deny this swelling, manifest as it is to so many. Equally in vain does anyone gird himself to investigate the cause of this reciprocating tide who has not first thoroughly learned its history; for its variety is astonishing, both in the quantity of the tide and in the time of its alternations, as I shall presently indicate in brief, going round the shores of the sea in order.

The tides of *Europe* are as follows. In the Adriatic gulf the tide was once so great, on the testimony of Procopius, Book 1 of the *Gothic War*, that it very rapidly occupied many thousands of paces; now it occupies 2 miles of the Venetian shore at most. In the Caspian and in the Tyrrhenian Sea there is no tide, nor in all the rest of the Mediterranean on the shores of Europe, apart from some around Marseille and in the Euripus. Beyond the Mediterranean

a great tide occurs around the western shores of Spain and France. The river Baetis indeed feels it as far as Seville; there, however, on the testimony of Pliny the Elder, was a well that decreased as the tide rose and rose as the tide fell. The Tagus undergoes the tide for 20 leagues, and the Garonne as far as Bordeaux; and the same tide, at its greatest, is experienced by the shores of Flanders, up to 9 miles, and of Holland, Norway and England. The Thames receives the tide for up to 60 miles, and it then rises above 14 royal cubits. Formerly, however, on the testimony of Pliny the Elder, Book 2, Chap. 97, the British tide swelled to 80 cubits; and in the district of Lindisfarne, as Bede asserts in his life of St Cuthbert [S. Gutberti], it became an island twice a day at the approach of the sea, and at its retreat turned back into mainland. Between Norway and Denmark the tide is barely felt, on the testimony of Barthol[?] [recte: Bartolinus, per the book's errata, which correct *Bartholomæo* to *Bartolino*; in this copy the end of the printed name is struck through in ink and the type cannot be read] the Dane.

The shores of *Africa* on the Mediterranean experience a great tide, but those of the Atlantic, on this side of the Tropic of Cancer, almost none. Beyond the Tropic, at Guinea, it is so strong that 3 anchors barely suffice to hold ships against it. It is great too from there as far as the island of St Thomas and around the shores of Ethiopia, and so great in the Red Sea, or Arabian Gulf, that it has given the impious a handle for saying that Moses waited for the reflux of the sea and crossed it dry-shod by no other miracle.

The shores of *Asia* facing the Indian Ocean surge with a frenzied flux and reflux, as Q. Curtius relates, Book 9. At the shores of Cambay it is so rapid that in 2 hours it occupies 30 leagues, and the inhabitants barely escape the deluge unless they are called back by the sound of a cymbal from others keeping watch on higher ground. It is great too in the Gangetic Gulf, in the Erythraean Sea and in the Chinese Sea, so much so that the river Yansù surges daily as far as Nanking [Nanchinum], although at Pachinum [Peking] it is felt only at full and new moons, as Nicolaus Trigautius [Nicolas Trigault] relates.

The shores of *America* near the Baccalaos have a slight tide, and at Cuba and Mexico one barely perceptible; but in the Strait of Magellan, on the testimony of Acosta and of Father Alfonso Ovalle [P. Alfonso Oualio], who told me of it, the tides of the two seas meet each other, with a manifest swelling on both sides. The shores of Paria and of Peru also experience a great tide; at Panama it occupies 2 leagues. The rest of the northern coast of America, except the Vermilion Sea and California, suffers no tide from the Ocean, as Petrus Bercius [Petrus Bertius] relates. The river Maragnon retains saltiness for up to 100 leagues, says Argoli in the *Pandosion*, which is an argument that the Ocean surges nearly that far up it.

[Margin: Periods and alternations of the tide of the sea.]

IV. The alternations of time and the periods of the tides are some monthly, some daily, and some as it were yearly, half-yearly or quarterly. In many places the tide is greater in winter than in summer, and greater at the equinoxes than

at the solstices, though it is great around the rising of the Dog Star; and it is greater at full moon, which is why sailors call it living water [aquam viuam], than at new moon or after the quadratures. Hence that Venetian proverb: *Dalli otto alli noue, l'acqua no se moue; dalli ventuno alli ventidue, la non và ne in sù ne in Zue* [from the eighth to the ninth, the water does not move; from the twenty-first to the twenty-second, it goes neither up nor down]. Yet at Pachinum the tide rises only at new moon, and at the mouths of the Indus likewise it rises at new moon, on the testimony of Bertius; while on the Ethiopian coast and around Calicut it rises at full moon and falls at new moon, as Godignus [Nicolau Godinho] relates, *De rebus Abissinorum*, Book 1, Chap. 11. In most seas, however, there is twice a day a flux and twice a reflux; and in the Adriatic, Belgian, Dutch, English, Portuguese, Pacific and Gangetic seas it flows for 6 hours and ebbs for each following 6. But in the Atlantic Ocean and at the mouths of the Garonne it swells for 7 hours and subsides for 5. Conversely, at the mouths of the river Niger and at the shores of Guinea and of the Erythraean Sea, it rises for 4 hours and falls for 8. At the shore of Cambay it flows very rapidly for 2 hours and ebbs for 2. Where the flux lasts 6 hours and the reflux 6, the flux begins as the Moon ascends above the horizon, the reflux as it crosses the meridian, the flux as the Moon sets, and the reflux as it reaches the lowest point of the heavens.

So much for the history. On the causes, see what I shall indicate in the Scholia, and what we shall add at Book 4, Chap. 1, Scholium 4.

SCHOLIA.

[Margin: Authors who wrote on the motions of the sea.]

I. On the motions of the sea, and especially on the tide, one may consult Aristotle, Book 2 of the *Meteorologica*, text 6, and there Albertus Magnus [Alb. M.], tr. 3, Chap. 6; Froidmont, Book 5; the Coimbra commentators, tr. 8; Zanardus [?], quest. 30 and 31; and Cabeo, Book 2, from quest. 5 to 12 of text 6. Then Pliny the Elder, Book 2, Chap. 97, and Book 3, Chap. 1; Plutarch, Book 3 of *De Placitis Philosophorum*, Chap. 17; Mela, Book 3, Chap. 1; Gemma Frisius in the *Astrolabium*, Chap. 91; Faber [?], theorem 99; Fidelis Daniel [?], Book 1 of *De Providentia*, Chap. 91; Pandulfus Sfondratus [Pandolfo Sfondrati], in his excellent treatise on the cause of the tide of the sea; Io. Taisnerus [Jean Taisnier] and Hieronymus Borrus [Girolamo Borri], in the book on the flux and reflux of the sea; Scaliger, *Exercitatio* 52; José de Acosta, Book 3 of the *Historia Indica*, Chap. 14; Ramusio, vol. 3 of the *Navigations*, Book 2, Chap. 10; Botero, in the *Relation on the Sea*; Simone Maioli, in the *Dog Days*, colloquy 10; Biancani, on the mathematical passages of Aristotle, p. 196, or on the book *De Mundo ad Alexandrum*, Chap. 3, and in the *Sphere*, Book 5, Chap. 2; Laurentius Corvinus [?], Book 11 of the *Geography*; Galileo, in the *Dialogues*, from p. 410; Johannes Kepler, in the commentary on Mars, p. 3 of the introduction, and in the *Ephemerides*, p. 24; Bertius, in the *Tabulae contractae*, Book 1; Simon Stevin, Book 6 of the *Geography*; Levinus [Levinus Lemnius], *De occultis naturae*

miraculis; Ficinus [Marsilio Ficino], Ennead 2, on Plotinus, Book 3, Chap. 6; Pierre Hérigone, vol. 4 of the *Cursus Mathematicus*, p. 412; Antonius Maria de Rheita [Antonín Maria Šírek], in the *Oculus Enoch et Eliae*, Book 4, Chap. 3; Willebrord Snel, in the *Tiphys Batavus*, Book 2, Prop. 8; Argoli, Chap. 10 of the *Pandosion Sphaericum*; Rogerius Baccon [Roger Bacon], Chap. 5 of *De speculis*; Renatus des Cartes [Descartes], Part 4 of the *Principia Philosophiae*, no. 49.

[Margin: The cause of the tide of the sea not yet clearly known.]

II. "But as yet no schools," says Maiolo, "have sufficiently unravelled this question, and Scaliger was ready to call Cardano a god, though in bombast and half as a pagan, if he had brought forward a sufficient cause of the reciprocating tide of the sea." About the simple flow there seems to be less difficulty. For St Augustine says, Book 1 of *De Mirabilibus Sacrae Scripturae*, Chap. 7: "We are permitted to consider the flooding swellings of the sea, but we are deprived of understanding of it as it recedes." And in Book 7 of the *City of God*, Chap. 22, he says that 2 goddesses were consecrated by the Romans for this reason: Venilia, or Malina, for the approach of the sea, which the Italians call *Maream*, and Salacia, or Lidona, for its withdrawal from the shore to the open sea. This alternating motion, moreover, the Greeks call [Greek: πλημμυρίδα (plēmmyrida, "flood-tide")].

III. The Stoics attribute the cause of this tide to the soul of the terrestrial globe, breathing in and out through the cavities of the sea as if through nostrils; Apollonius of Tyana, to spirits panting under the Ocean; Timaeus, in Plato, to rivers rushing from the mountains of the Celts into the Atlantic; Buccaferreus [Lodovico Boccadiferro] and Io. Picus [?], to a sea-bed sloping more or less; Sfondrati, to the motions of the sea discussed in nos. 1 and 2, and to the various whirlpools and regurgitations arising from them. Seleucus, Galileo and some Aristarchus or other, recently revived out of France, attribute it to the agitation of the Earth, carried around the annual orb together with the diurnal motion and that of libration; because of the mixing of these the water, as in a vessel driven round in a circle, is pushed and shaken to one side and repelled to the other at fixed periods. I myself at one time, when I was younger, attributed it to motions arising from subterranean rivers and from the Abyss's eddies, or to an ebullition produced by subterranean fires, or to the alternating dominion of the 7 planets through the temporal hours, assigning them a great part of this cause; but afterwards I hesitated.

IV. The greatest part, however, attribute it to the motions and influences of the Moon and Sun: so Aristotle, Pliny the Elder, Strabo, Heraclitus, St Thomas, Scotus, Albertus Magnus, Ficino, Contarini, Bacon, Zanardus, Gul. Gilbertus [William Gilbert], Fidelis Daniel, the Coimbra commentators, Biancani, Stevin, Botero, Kepler, Rheita, Froidmont and Cabeo. But of these, Kepler with Gilbert, Zanardus and the Coimbra commentators attribute it to a magnetic attraction of the Moon, drawing the waters to itself; Contarini and Faber to occult influences of the Moon; Aristotle and Heraclitus to blasts excited under

the waters by the heat of the luminaries, and to the ebullition that results, especially on account of the heat reflected from the Moon at full moons. Rheita attributes it to a rarefaction produced in the air by the Moon, because of which the compressed waters of the sea swell against the shores, and to a condensation as the air cools, because of which the water, following the contracted air lest a vacuum occur, flows back. Cabeo, who has examined the opinions of others most diligently of all, attributes it to an occult faculty of the Moon, which excites the sulphurous and nitrous spirits at the bottom of the sea and stirs them in nearly the same manner as it moves the catarrhs and humours of animals, even when it is at new moon and placed below the horizon.

V. Although in some places the tide rises for 6 hours and falls for 6, nevertheless, because the Moon advances daily toward the east by about 13° and rises later each day by about 48^m, the beginnings and ends of these motions change daily by nearly one hour. This very time, however, varies with the varying latitude of the Moon, the obliquity of the ascensions, and other anomalies in the Moon. Simon Stevin adds that the highest tide occurs when the Moon is in the nonagesimal degree of the ecliptic, rather than on the meridian and in the degree opposite to it; and that sometimes the tide takes place in $8^h\ 5^m$ but the reflux in $3^h\ 55^m$. But let us conclude these Scholia with those verses of Lucan, Book 1:

> Whether, moved by the second star, the wave of wandering Tethys surges at the lunar hours; whether flame-bearing Titan, to draw up the waters that feed him, raises the Ocean and lifts its billows to the stars: inquire, you whom the labour of the world torments. But for me, whatever cause you are that moves such frequent passages, as the gods have willed, lie hidden ever.

CAPVT XVI.

On Navigation: Some Things Pointed Out to Beginners in Cosmography.

[Margin: Authors on nautical matters.]

I. It is not part of our plan to hand down the art of navigating in this place, nor to pursue everything treated by Bayfius [Lazare de Baïf] in *De re navali*; by Petrus Medinensis [Pedro de Medina] in 6 books *De re nautica*; by Nonius [Pedro Nunes] in his twofold problem on the art of navigating, and in nearly the whole of Book 2 of *De Observatione*, with an annotation on Aristotle's mechanical problem on the motion of a ship, in which certain points have been corrected by Giovanni Battista Benedetti, *Epistolae*, p. 214, where there is also something on the nautical armilla; by Willebrord Snel in his *Tiphys Batavus*; by Gemma Frisius in the appendix to Apian's *Cosmographia*; by Simon Stevin and Pierre Hérigone on *Histiodromia*; by Adrianus Metius [Adriaan Metius], Book 5 of the *Doctrina sphaerica*, from Chap. 4; by Morisetus [Claude-Barthélemy Morisot] in the *Orbis maritimus*; by Dominus de Varuich [?]; by Georgius Fournierus [Georges Fournier] of the Society of Jesus in his *Hydrographie*; and

by Marin Mersenne, Book 2 of *De Histiodromia* and Book 2 of the *Mechanica*. For these things are treated more fully in our Geographical book, which is the fourth of vol. 2 of the New Almagest. And so I have chosen to point out here only very little for beginners, so that they may not be wholly ignorant of what seems from this subject to pertain to Cosmography.

DE NAVIBVS ET EARVM PARTIBVS.

II. Fournier, Book 1 of the *Hydrographie*, gives an excellent account of the structure of ships; and the names of the parts are given both by him and by Morisot, Book 2 of the *Orbis maritimus*, from Pollux, Athenaeus, Baïf and others. Now the mast of a ship is called [Greek: ἱστὸς (histos, "mast")], from which comes *Histiodromia*, that is, the art of navigating. The heel of this mast is called by Macrobius, Book 5 of the *Saturnalia*, *Pterna*, its middle part *Trachelon*, and its summit *Carchesium*; the seat of the mast is the *Edolion*, and the cross-timber from which the sails hang is the *Antenna*, whose horns, as Virgil puts it in *Aeneid* 3, are also called *Ceruchi*, and in Greek [Greek: ἀκροκεραία (akrokeraia, "yard-tip")], the yards themselves being [Greek: κεραία (keraia, "yard")]. Isidore, Book 19 of the *Etymologies*, Chap. 3, gives 5 kinds of sail: namely the *Acation*, the largest sail, in the middle of the ship; the *Epidromon*, of the second size, at the stern, in Italian, if I am not mistaken, *il Trinchetto*; then the *Dolo*, the smallest, fixed at the prow, and the *Artemo*, for steering the ship; and the *Siparum*, which is added when the force of the wind flags. But the *Mendicum*, which is placed at the prow, as Sextus Pompeius would have it, hardly differs from the *Epidromon*.

[Margin: Ranks of rowers.]

III. There were formerly 3 differences among rowers. Some, the *Thalamitae*, were placed in the highest rank and therefore needed longer oars; others, the *Zygitae*, in the middle; others, called *Thranitae*, rowed in the lowest, as Snel holds with the scholiast of Aristophanes. For otherwise Pollux, Chap. 9 of the *Onomasticon*, Baïf in *De re navali*, and Philander [Guillaume Philandrier] on Book 10 of Vitruvius, Chap. 8, place the [Greek: θαλαμίτας (thalamitas, "Thalamites")] in the prow, the [Greek: ζυγίτας (zygitas, "Zygites")] on the sides of the ship, and the [Greek: θρανίτας (thranitas, "Thranites")] in the stern.

[Margin: Distinctions of ships by oars or rowers.]

Hence the differences of ships were taken either from the number of oars or from the ranks of rowers. Those named from the number ended in [Greek: ορος (-oros, "-oared")] if they had at least 20 oars: so [Greek: εἰκόσορος (eikosoros, "twenty-oared")], one consisting of 20, and [Greek: τριακόντορος (triakontoros, "thirty-oared")], one consisting of 30 oars. If they had fewer than 20, they were distinguished by the thole-pins [Scalmis] or pegs on which the oars are supported: hence [Greek: ναῦς τρίσκαλμος (naus triskalmos, "ship of three thole-pins")], a ship with 3 thole-pins, and [Greek: δεκάσκαλμος (dekaskalmos, "of ten thole-pins")], one with 10, and so on. From the line of oars, or rank of rowers, a ship was called [Greek: μονοήρις (monoēris, "single-ranked")] if it was propelled by a single rank of oars, [Greek: διήρις (diēris,

"two-ranked")] if it was a bireme, that is, of a double rank of oars, and [Greek: τριήρις (triēris, "three-ranked")] if it was a trireme, or consisted of a triple rank, and likewise with the others.

[Margin: Remarkable ships of Hiero and Ptolemy.]

Among these the most celebrated was the ship described by Athenaeus, Book 1, Chap. 10, and called the *Moschion*, which could not be launched into the sea except with the screw of Archimedes. It consisted of 20 ranks of oars, and was first called the *Syracusia*, and later, when Hiero sent it to Ptolemy, the *Alexandrina*. But more remarkable still was another, of Ptolemy Philopator, which on the testimony of Callixenus consisted of 40 ranks of rowers and was 280 cubits long, 38 wide and 48 high. The stern decks stood 53 cubits from the sea. The oars of the *Thranitae* were of 38 cubits, with lead added at the handle of the oar, and with a fellow rower; the rowers were 4000, and on each side 50 rowers; the interscalmia, or intervals of the thole-pins, were of 7 feet; the ship's servants 400; the marines 3000; there were 2 prows, 2 sterns and 7 rams; and finally stores of provisions sufficient for 50 triremes. See also another ship of the same Ptolemy in Athenaeus, Book 1, Chap. 9, and one of Demetrius in Plutarch.

[Margin: Estimate of ships by more recent authors.]

IV. More recent authors, however, estimate the capacity of ships from the burden they can carry. So a ship's tun [dolium] is of 2000 pounds; few ships carry 2000 tuns, very few 3000. A naval tun of 2000 pounds, says Mersenne, is reckoned to have 28 cubic feet; if you fill it with water, of which a cubic foot is 72 pounds, the water will be of 2016 pounds. A ship, however, is not said to be of so many tuns with respect to the water that it can hold from the bottom to the deck, but with respect to the water it can carry without inconvenience to navigation, which is commonly reckoned to be half of that water. Otherwise, as great as the weight the ship has in air, so great is the weight it has when borne on the water: so that if a ship is of 6000000 pounds, it can strictly be loaded with 6000000 pounds, but not without inconvenience, whereas with 3000000 pounds it certainly can without inconvenience. To judge the proportion of other ships from the measure of one, take a ship of 300 tuns. Its keel should be about 73 feet, its height 10 feet. Its anchor, whose shank is triple each of the 3 arms, should be about one-thousandth of the weight of the ship, so that no storm can dislodge it, but its cable twice as heavy. A storm, however, that tosses ships of 300 or 600 tuns barely moves a ship of 2000 tuns. [Margin: The ship Corona and the Fortune of Denmark.] See in Fournier, Book 1, Chap. 31, the ship called the *Corona*, of 1500 tuns, 200 feet long but 120 in the keel, with capacity for 72 guns; its mast is as great as the keel; its sails are of 600 ells; its anchor cable is 2 feet in girth and of 14300 pounds; the anchor itself, without axle or cylinder and nails, is of 4855 pounds; the weight of the ship is 4000000 pounds; the awning [tentorium] is worth 14000 gold pieces. Famous too is the ship called the *Fortune of Denmark* [*Daniæ Fortuna*], with 200 guns mounted; its mast with its extensions is of 216 feet, but without them 85. The largest ships of

the Ocean, moreover, the Spanish carracks, require yards so large that they can hardly be raised by 200 men. Finally the sounding-lead [Bolis] is pyramidal in shape, and if it is of lead and of 36 pounds it requires a rope of 24 pounds. There are, however, those who for a bottom of 1200 feet require a lead of 60 pounds, while others are content with 20.

DE REMIGIO.

V. Aristotle, in Question 5 of the *Mechanics* — which have been elucidated by Alessandro Piccolomini, by Biancani on the mathematical passages of Aristotle, no. 246, by Nonius at the end of Book 2 of *De Observatione*, and by Mersenne in the *Synopsis of Geometry*, Book 2, *Mechanics* — recognises three kinds of lever [Vectis]. The first is when the hypomoclion, that is, the fulcrum [fulcimentum], is between the weight and the moving power; the second when the weight is between the fulcrum and the power; the third when the motive power itself is between the weight and the fulcrum. So Aristotle and Piccolomini reduce the oar to a lever of the first kind, so that the sea is the weight and the ship the fulcrum. But Nonius, Biancani and Mersenne reduce it to a lever of the second kind, so that the sea is the fulcrum, the ship's hinges [cardines] the weight, and the helmsman with the rudder the moving power, turning the ship to the right while moving the sea to the left, and conversely, and by a small motion of the stern causing a large motion in the prow. For if the tiller [temo] were at the prow, the force of the water striking the side of the prow would turn the ship round, and the prow would become the stern. Since, however, Aristotle assumes that the blade of the oar always moves back whenever the vessel moves forward, and asks why the ship advances more than the half-blade [semi-palmula], Nonius, in the place just cited, therefore demonstrates the following propositions, worth knowing.

[Margin: Nonius's propositions on rowing.]

1. *If rowers can move a vessel, the handle of the oar always runs through a greater distance than the vessel.*
2. *If the handle of the oar, by its own motion, and the vessel run through equal distances, it will be impossible for the blade to move; it will instead stay unmoved, as if a centre.*
3. *If the handle of the oar, by its own motion, has covered twice the distance the vessel has, the vessel will be carried forward by as much as the blade has moved back; and conversely, if the ship moves by as much as the blade moves back, the motion of the handle is twice as great.*
4. *If the vessel runs through less distance than the handle of the oar, but more than half, it will be advanced more than the blade moves back; but if less than half, it will be carried forward less.*
5. *If the vessel moves faster than the handle, the blade will move forward and will never move back, and it will run through the distance by which the vessel's motion exceeds the motion of the handle.*

Hence it comes about that the distance the blade runs through and that of the vessel, taken together, equal the distance of the handle, when the handle moves more than the vessel; from which you may correct Aristotle's errors [sphalmata] on this point.

DE VELIFICATIONE, Mensura itineris Maritimi, & Velocitate Nauium.

On Sailing, the Measure of a Sea Journey, and the Speed of Ships.

[Margin: The mast of a ship reduced to a lever.]

VI. The mast with its yard and sails is reduced to a lever of the first kind, because the ship is the weight, the heel [Pterna] at the foot of the mast is the fulcrum, and the masthead [Carchesium] is the head of the lever, while the wind is the moving power. So Mersenne judges, with Aristotle, Question 6 of the *Mechanics*; and therefore, he holds, the taller the mast, the faster the ship moves. But Vitruvius, Book 10, Chap. 8, and Biancani on that Question 6, think that the weight is the ship with respect to that part by which the mast stands up from the ship, and that the fulcrum is in the bottom of the ship; otherwise the ship, resisting the wind, would overturn, and with the stern raised the prow would go under. This amounts to saying that the mast with its yard is a lever of the second kind. The remaining matters concerning sailing presuppose what is to be said about winds, the magnetic compass [Pyxis Magnetica], the sea chart and loxodromes, on which see below.

[Margin: Measure of a sea journey.]

VII. Measuring a sea journey far from the shore is difficult. An old instrument is found in Vitruvius, Book 10, Chap. 14. It consists of a wheel with projecting paddles, driven by the water, so that the revolutions of the wheel are completed; and by means of another wheel or a toothed cylinder, which moves a drum [timpanum] and by its sound alerts the counter, the revolutions of the wheel can be counted. For if the circumference of the wheel is known, for example three paces, and 3000 revolutions have been made in one hour, 9000 paces will have been covered. Others, however, hang from a cord of known length a cylinder, or some small beam or small wooden boat, and throw it off the stern. As the ship moves, the cord, suspended from a small cylinder that turns on pivots at the slightest touch, unwinds. So when the whole has run out, and the time meanwhile has been found by some clock, it will be established how many paces the ship has covered under the same steadiness of wind.

[Margin: Speed of ships.]

VIII. The speed of ships using the wind alone, moreover, is as various and uncertain as the winds, the weights of the ships, and the density of the waters or the resistance of running waters. In the Mediterranean, where the winds are closer to their source because the shores are near, sometimes about 500 Italian miles are completed within 24 hours, the number reckoned from Messina to Naples, and thus 20 miles and more in one hour; but for the most part the speed is far less. So too in the Ocean, where the winds, more even and further from land, blow more sluggishly, and ships of far greater bulk and weight have to

be driven. Thus the three Japanese envoys sent to Gregory XIII thought they had sailed very fast when, around the island of St Helena, they covered 180 or 200 miles a day; so too the companions of Fernão de Magalhães in the Pacific Ocean. A voyage there is judged fast if 150, 130 or at least 120 miles are run in a day; slow if, leaving aside calms or waves of the sea running against the ship, only 60 or 50 miles are covered in one natural day. On the speed of rivers, moreover, see what we said in Chap. 13. And so much on these matters, for such learning as it may give.

DE ARTE NAVIGANDI SVB AQVIS.

IX. Mortals have dared this too; whether with happy or unhappy success is not yet clear. The art of this navigation is briefly taught by Marin Mersenne in Book 2 of *De arte navigandi* and in Book 4 of the *Harmonica*, p. 368. There he also commends Ioannes Barrieus [?], an outstanding diver and the inventor of the art of breathing under water for 6 hours or more; whereas with other divers, on whose heads is placed a cask or leather bell of about 8 cubic feet, breathing fails beyond a quarter of an hour, the air being by then tainted. Within an hour we need 360 breaths, each of which lasts 10^{s}, and breathing cannot be put off longer without discomfort. But on these things see Mersenne: for I have no time to set them out, and it is enough to have pointed out the sources, to be tasted and drunk more fully elsewhere.

CAPVT XVII.

On the Winds and Anemography.

I. The number, naming and distribution of the winds are given in many places: in the commentators on Aristotle, Book 2 of the *Meteorologica*, Chap. 6; in Seneca, Book 5 of the *Natural Questions*, Chap. 16; Varro, Book 3 of *De re rustica*; Vitruvius, Book 1, Chap. 6; Vegetius, Book 4, Chap. 38; Pliny the Elder, Book 2, Chap. 47, and Book 18, Chap. 34; Aulus Gellius, Book 2, Chap. 12; Peter Apian and Gemma Frisius, Part 1 of the *Cosmographia*, Chap. 15; Stöffler, Part 2 of the *Astrolabe*, prop. 44; Oronce Finé, Book 5, Chap. 6 of the *Cosmographia*; Maurolico, Dialogue 2 of the *Cosmographia*; Barozzi, Book 2 of the *Cosmographia*; Egnazio Danti in the *Anemographia*; Daniel Santbechius [Daniel Santbech], proposition 155; Kepler in the *Epitome of Astronomy*, p. 191; Gassendi in the *Institutio Astronomica*, Book 1; Petrus Bertius in the tables *contractae*, p. 19; Pierre Hérigone, vol. 4 of the *Cursus Mathematicus*, p. 166; Gulielmus Blaeu [Willem Blaeu], vol. 1 of the *New Atlas*, Chap. 9; Philibertus Monetus [Philibert Monet] in the *Parallel of the French Language with the Latin*, under the word *Ventus*; and Metius, Book 5 of the *Doctrina sphaerica*, Chap. 4. The first observer of the winds is said to have been Aeolus, King of Sicily, as Strabo and Pliny the Elder have it; but others afterwards observed more winds, as physics, agriculture and seafaring advanced.

[Margin: 4 winds.]

II. Aeolus and Homer set four cardinal winds, which are:

1. *Solanus*, blowing from the equinoctial rising. It was once called *Eurus*, because it flows from the rising, and *Apeliotes* from the Sun, which in Greek is [Greek: ἥλιος (hēlios, "sun")]. In Italian, *Levante*.
2. *Favonius*, blowing from the equinoctial setting; also called *Zephyrus*, from its bringing life, which is [Greek: ζωὴ (zōē, "life")], as if *Zoipheros*. In Italian, *Ponente*.
3. *Septentrio*, blowing from the northern pole, or rather from that intersection of the horizon and the meridian to which this pole is nearer. It was once called *Boreas*, from a stormy sound, which in Greek is [Greek: βοὴ (boē, "shout, sound")], and *Aparctias* from Arctos, that is, the star the Bear. In Italian, *Tramontana*.
4. *Auster*, or *Notus*, diametrically opposite *Septentrio*; [Greek: ἀπὸ τῆς νοτίδος (apo tēs notidos, "from moisture")], that is, from clouds or from humidity. In Italian, *Ostro*. Ovid describes these excellently in Book 1 of the *Metamorphoses*, from the verse:

   Eurus withdrew to the Dawn and the Nabataean kingdoms. [*Eurus ad Auroram, Nabathæaq. regna recessit.*]

[Margin: 8 winds.]

III. Andronicus Cyrrhestes, on the testimony of Vitruvius, set eight winds, which he also marked out at Athens on an octagonal marble tower, with images and with a rotating bronze Triton that was to point out with a rod the wind that was blowing. Their names and order are as follows.

1. *Solanus*, or *Subsolanus*, blowing from the equinoctial rising.
2. *Eurus*, or *Vulturnus*, from the winter rising.
3. *Auster*, from the south, or *Notus*.
4. *Africus*, from the winter setting.
5. *Favonius*, or *Zephyrus*, from the equinoctial setting.
6. *Caurus*, or in contracted form *Corus*, from the setting at the summer solstice.
7. *Septentrio*, from the Arctic Pole.
8. *Aquilo*, or *Boreas*, from the rising at the summer solstice.

[Margin: 12 winds.]

IV. Philosophers, ship-masters and cosmographers afterwards recognised twelve winds, in Varro, Manilius and Pliny the Elder; granted that Aristotle names only eleven and yet recognised 12, on the testimony of Olympiodorus, for he set none opposite *Aquilo*, or *Meses*. Manilius indicates these in Book 1, from the verse:

The sphere of the sky is marked out into four parts. [*Quatuor in partes Cœli describitur orbis.*]

Their names and order are as follows.

1. *Subsolanus*, blowing from the equinoctial rising.
2. *Eurus*, or *Vulturnus*, from the winter rising; distant from *Subsolanus* 23½°.
3. *Euroauster*, *Euronotus*, *Phœnicias*, from the eastern intersection of the horizon with the Antarctic Circle; distant from *Auster* 23½°.

4. *Auster*, from the south.
5. *Austroafricus*, or *Libonotus*, from the western intersection of the horizon with the Antarctic Circle; distant from *Auster* 23½°.
6. *Africus*, or *Libs*, from the winter setting; distant from *Favonius* 23½°.
7. *Favonius*, from the equinoctial setting.
8. *Caurus*, or *Argestes*, from the summer setting; distant from *Favonius* 23½°.
9. *Circius*, named from the whirling of the clouds, blows from the western intersection of the horizon and the Arctic Circle. It is also called *Thrascias*, not from harrying Thrace, as Barozzi thinks, but from breaking the shadows of the clouds; for [Greek: θραύω (thrauō, "I break")] means "I break" and [Greek: σκιά (skia, "shadow")] "shadow". It is distant from *Septentrio* 23½°.
10. *Septentrio*, from the Arctic pole.
11. *Boreas*, or *Aquilo*, or in Aristotle *Meses*, from the eastern intersection of the horizon and the Arctic Circle; distant from *Septentrio* 23½°.
12. *Hellespontius*, or *Cæcias*, from Cæcia, a river of the Hellespont; blowing from the summer rising and distant from *Subsolanus* 23½°.

[Margin: 24 winds of Vitruvius.]

V. Vitruvius, in his second distribution, sets twenty-four winds, placing the twelve already mentioned differently, as can be seen in the following order. In it, disregarding the solstitial points, he divides the horizon into 24 equal parts, giving each 15°. With this interval established, they can easily be compared with the winds of Varro and Pliny the Elder, which stood 23½° from the four nearest cardinal points: as great, that is, as the distance of the tropics from the Equator, and of the polar circles from the poles of the world. Let the order and nomenclature of the Vitruvian winds, then, which differ in places from the Varronian and Plinian, be as in the following table. On it I note in advance that *Ornithias* is so called because it stirs birds to fly; *Etesiæ* from the year, which in Greek is [Greek: ἔτος (etos, "year")], because they blow at fixed times of the year; *Gallicus*, because it raged in Narbonese Gaul; and *Carbas* from [Greek: καυρόω (kauroō, glossed "I disturb" on the page)] "I disturb" and [Greek: βοὴ (boē)] "sound", as Maurolico conjectures. But it is surprising how Vitruvius placed *Argestes* and *Cæcias* across the Equator, when Varro and Pliny the Elder better located them on this side, since the latter takes its name from Cæcia, a river of the Hellespont. And he differs greatly from them in many other things too, as we shall soon see.

VENTI EX VITRVVIO.

The Winds according to Vitruvius.

Order	Names	Distance from the cardinal points
1	*SOLANVS*, from the equinoctial rising	0°
2	*Ornithias*	15° from Solanus

Diagram. Caption: "Diagram of the Winds according to Barozzi." A circle in the right-hand column with numbered dots round its circumference, running clockwise from point 1 at the right-hand end of the Equator. One vertical diameter crosses five horizontal lines, each label being divided by the vertical: the Arctic chord at the top, the Tropic of Cancer, the Equator, the Tropic of Capricorn and the Antarctic chord at the bottom.

- Interior, top: "Ar | ct"
- Interior, upper line: "Trop | ♋"
- Interior, middle line: "Aequ | ator"
- Interior, lower line: "Trop | ♑"
- Interior, bottom: "Anta | rct."
- Circumference, clockwise from the right end of the Equator: 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18 [?], 19, 20, 21, 22, 21 [recte: 23], 24, 25, 26, 27, 28, 29, 30, [?], 32.

[Margin: 32 winds.]

VI. Finally, from as far back as the time of Charlemagne, cosmographers and ship-masters have used thirty-two winds. Barozzi, in his *Cosmographia*, places them so that, following the distribution of the ancients, he assigns twelve of them to the cardinal points of the horizon and to the solstitial points and those of the polar circles, and the others to the remaining points, which divide the intermediate intervals equally; as can be seen in the figure on the preceding page. But most writers, imitating Vitruvius in this respect, divide the horizon into 32 equal parts, giving each interval between the winds 11¼°. Of these,

besides the four cardinal winds, others standing equally on either side of them have been called Lateral or Collateral: namely *Scirocco*, *Garbino*, *Maestro* and *Greco*, to use the Italian words. But after Flavius Melfitanus [?] painted these winds on the rose of the nautical compass, they were called rhumbs [Rhumbi] from the shape, whose point marks the region of the wind on the horizon, as can be seen in the following diagram, which comes after the 3 tables that follow.

TAB. I ORDO, & NOMINA VENTORUM ANTIQUA, RECENTIBUS PROXIMO SITU RESPONDENTIA.

Table I. The Order and Ancient Names of the Winds, Corresponding to the Modern Ones by Nearest Position.

Order of the winds	Greek names	Latin or Graeco-Latin names	Distance from the preceding cardinal wind, by the division of the horizon: Varro and Pliny the Elder	Vitruvius	The moderns
1	Απηλιώτης.	*Apeliotes*, *Solanus*, *Subsolanus*, formerly *Eurus*.	From Solanus. Deg.	Deg.	Deg.
2	Υπεύρος.	*Hypeurus* or *Hypereurus*, in Vitruvius roughly *Ornithias*.		15°	11¼°
3	Εύρος.	*Eurus*, *Vulturnus*, very nearly in Varro and Pliny the Elder.	23½°		22½°
4	Μεσεύρος.	*Meseurus*; in Vitruvius nearer to *Cæcias*.		30°	33¾°
5	Νοτοαπηλιώτης.	*Notapeliotes*, in Vitruvius *Eurus*.		45°	45° 0
6	Υποφοινίκιος.	*Hypophœnicias*, nearer to Vitruvius's *Vulturnus*.		60°	56¼°
7	Φοινίκιας.	*Phœnicias*, in Varro and Pliny the Elder roughly *Euroauster*.	66½°		67½°
8	Μεσοφοινίκιος.	*Mesophœnicias*, *Mesophœnix*, nearer to Vitruvius's *Euronotus*.		75°	78¾°
9	Νότος.	*Notus*, *Auster*, blowing from the south.	From Auster.	0°	0°
10	Υπολιβόνοτος.	*Hypolibonotus*, *Leuconotus*, nearer to Vitruvius's *Altanus*.		15°	11¼°
11	Λιβόνοτος.	*Libonotus*, *Austroafricus*, very nearly in Varro and Pliny the Elder.	23½°		22½°
12	Μεσολιβόνοτος.	*Mesolibonotus*, nearer to Vitruvius's *Libonotus*.		30°	33¾°
13	Νοτοζέφυρος.	*Notozephyrus*, in Vitruvius *Africus*.		45°	45°
14	Υπολίψ.	*Hypolibs*, nearer to Vitruvius's *Subvesperus*.		60°	56¼°
15	Λίψ.	*Libs* and *Africus*, very nearly in Varro and Pliny the Elder.	66½°		67½°
16	Μεσολίψ.	*Mesolibs*, nearer to Vitruvius's *Argestes*.		75°	78¾°
17	Ζέφυρος.	*Zephyrus*, *Favonius*.	From Favonius.	0°	0°

Order of the winds	Greek names	Latin or Graeco-Latin names	Distance from the preceding cardinal wind, by the division of the horizon: Varro and Pliny the Elder	Vitruvius	The moderns
18	Ὑπαργέστης.	*Hypargestes*, *Hypocorus*, in Vitruvius *Etesiæ*.		15°	11¼°
19	Ἀργέστης, Καύρος.	*Argestes*, *Caurus*, very nearly in Varro and Pliny the Elder.	23½°		22½°
20	Μεσαργέστης.	*Mesargestes*, *Mesocorus*, nearer to Vitruvius's *Circius*.		30°	33¾°
21	Ἀρκτοζέφυρος.	*Arctozephyrus*, in Vitruvius *Caurus*, now *Magister*.		45°	45°
22	Ὑποκίρκης.	*Hypocircius*, *Hypothrascias*, nearer to Vitruvius's *Corus*.		60°	56¼°
23	Κίρκιος, Θρασκίας.	*Circius*, *Trascias*, very nearly in Varro and Pliny the Elder.	66½°		67½°
24	Μεσοκίρκης.	*Mesocircius*, *Mesothrascias*, nearer to Vitruvius's *Thrascias*.		75°	78¾°
25	Ἀπαρκτίας.	*Septentrio*, *Aparctias*, formerly *Boreas* and *Aquilo*.	From Septentrio.	0°	0°
26	Ὑπερβορέας.	*Hyperboreas*, nearer to Vitruvius's *Gallicus*.		15°	11¼°
27	Βορέας.	*Boreas* and *Aquilo* and *Meses*, very nearly in Aristotle, Varro and Pliny the Elder.	23½°		22½°
28	Μεσοβορέας.	*Mesoboreas*, *Mesaquilo*, nearer to Vitruvius's *Supernas*.		30°	33¾°
29	Ἀρκταπηλιώτης.	*Arctapeliotes*, in Vitruvius *Aquilo*; now *Græcus*.		45°	45°
30	Ὑποκαικίας.	*Hypocæcias*, nearer to Vitruvius's *Boreas*.		60°	56¼°
31	Καικίας.	*Cæcias*, *Hellespontius*, very nearly in Varro and Pliny the Elder.	66½°		67½°
32	Μεσοκαικίας.	*Mesocæcias*, in Vitruvius roughly *Carbas*.		75°	78¾°

Diagram. A full-width woodcut compass rose of 32 pointed rays, shaded along one side, inside a numbered ring. At the centre a small circle is quartered

by two crossed lines; within it a vertical arrow with a small square at its midpoint points north, and a small trefoil ornament stands at the arrow's foot. The northern ray carries a fleur-de-lis at its tip. The cardinal names are set in capitals outside the ring, and the 32 rim figures, set radially, run clockwise from the east.

- Top, outside the ring: SEPTENTRIO [north]
- Right, outside the ring: ORIENS [east]
- Bottom, outside the ring: MERIDIES [south]
- Left, outside the ring: OCCIDENS [west]
- Rim figures: 1 at the east, then 2–8 down the south-eastern quadrant, 9 at the south, 10–16 up the south-western quadrant, 17 at the west, 18–24 up the north-western quadrant, 25 at the north, 26–32 down the north-eastern quadrant. All 32 are legible.

From the first table above it is clear out of what affinity of places and names there has arisen among the moderns such great licence, or confusion, in the nomenclature of these 32 winds. As a favour to the learned, I have decided to give a specimen of it in the 2nd table, drawn not from all authors but from the principal ones, keeping the same order of the winds as regards the numbers, but setting down the names according to other writers. I admit, however, that the wind called *Hypeurus*, because it lies under *Eurus*, can on another reckoning be called *Hypereurus*, that is, *Supereurus*, and indeed *Meseurus*, that is, midway between *Eurus* and *Solanus*; and so with similar cases.

VII Finally, modern shipmasters subdivided each of the rhumbs of the winds, or the intervals between rhumbs, into 4 parts, assigning to each 2° 48′ 45″. In line with this division, when they assigned to the quarters of the rhumbs their inclination from the meridian line drawn from Auster to Septentrio, or from *Sur* to *Nort*, they considered the four quadrants of the horizon separately. They began the order of the rhumbs and quarters not from the equinoctial rising but from Auster, counting from there 7 rhumbs towards the east and another 7 rhumbs towards the west; likewise from Septentrio 7 towards the west and 7 towards the east. For this distribution, look at the following figure with its small table, in which the division of one quadrant is to be applied to the others. The table's last column gives the winds to which, in the order of the 32 winds used until now and begun from the equinoctial rising, the same inclination from the meridian applies.

Diagram. A small circular woodcut at the foot of the left column: three concentric rings crossed by a vertical and a horizontal diameter, with radial lines dividing the space between the outer rings. In the central circle a vertical arrow points north. The outermost band carries the rhumb numbers, counted in each quadrant from the vertical diameter towards the horizontal one.

- Top, outside the ring: Nort
- Right, outside the ring: Est (a blot lies over the last letter)
- Bottom, outside the ring: Sur
- Left, outside the ring: Vee[?]

- Rim figures, north-eastern quadrant: 1.2.3.4.5.6.7 clockwise from Nort
- Rim figures, south-eastern quadrant: 7.6.5.4.3.2.1 clockwise from Est
- Rim figures, south-western quadrant: 1.2.3.4.5.6.7 clockwise from Sur
- Rim figures, north-western quadrant: 7.6.5.4.3.2.1 clockwise from the left-hand label

SCHOLIA.

[Margin: On the *Etesiæ*.] I. The *Etesiæ* do not seem to belong among the ordinary and general winds, either because they blow only at one fixed part of the year, or because they have no fixed seat. For in Spain and in Asia they blow from the east; in Pontus from Aquilo; elsewhere from elsewhere. Pliny the Elder and Strabo themselves grant that they blow from quarters other than Aquilo and the west, namely from the east too, and from the south. Again,

all winds that blow infallibly at a fixed season of the year, especially if they are wholesome and moderately cooling, can, by extending the Greek word, be called *Etesiæ*, or adjectivally *Venti Etesii*, that is, annual winds, from "year", which in Greek is [Greek: ἔτος (etos, "year")]. In this way, for Strabo, the wind *Eurus*, which blows from the Iberian coast into the Sea of the Sardinians at a fixed season of the year, is Etesian. Moreover, those *Aquilones* that precede the *Etesiæ* are called *Prodromi Etesiorum* [forerunners of the Etesiæ]. There were also formerly *Etesiæ* of 40 days after the Dog Star, called the Canicular *Aquilones*.

[Margin: What is *Ornithias?*] *Ornithias* too, that is, "of the birds", or the enticer of birds to flight or to breeding, could have been a name for *Zephyrus*, since it is the harbinger of the birds' brood; just as the same *Zephyrus* has been called *Chelidonias*, because it rouses and entices swallows when it blows in spring.

[Margin: Provincial winds.] II. Besides the general winds there are many other provincial winds, particular to some one region. Such are *Iapyx*, which blows in Calabria towards Greece; *Olympias*, which blows from Mount Olympus; *Sciron*, from the Scironian rocks; *Corinna*, which harasses Flaminia and the district of Bologna; *Catogis*, which harasses Pamphylia, and *Atabulus*, Apulia; and the Peruvian winds, called by the Spanish *della Cordigliera*, most delightful breezes to breathe, but a most immediate plague, since once breathed they kill living creatures on the spot. Furthermore, the winds that stir up storms in whirlwinds are called *Typhones*, and those that, shut up in clouds, suck waters upward are called *Scyphones*; those that blow back from the sea towards the shore are called *Tropæi*; and finally those suited to sailing farther from the shore, because of their continuous and long-sustained tenor of blowing, are called *Apogei*, and those otherwise, *Perigei*.

[Margin: The sphere of the winds.] III. If the winds blew along straight lines only, as their gusts are drawn for us by painters, one and the same wind could extend only as far as the sight itself reaches, looking all round the horizon from the place the winds blow from. Therefore, if we suppose that no winds blow from a higher region of the air than the highest mountains, and that no mountains are perpendicularly higher than 20,000 paces, the same wind will not extend beyond 460,000 paces towards one side, as is clear from what was said about the distance of sight in chapter 10 of this book. But if the mountains, and the height of the second region of the air, discussed below in chapter 19, are much less, the dominion of the same wind will be much smaller. If, however, the winds blow along curved lines, whether parabolic, hyperbolic, elliptical, circular or irregular, or if one wind is sown and propagated from another, the argument does not hold. On the force of the winds, and on the speed of navigation achieved by winds alone, I said a little at ch. 16, no. 4; more will be said in the Geographical Book.

CAPVT XVIII.

Some Matters Pointed Out for Beginners on the Declination of the Magnetic Needle, the Compass Box or Nautical Compass, the Marine Chart, Histiodromy and Loxodromies.

I. Very many writers have rightly extolled the praises and properties of the magnet stone, or Heraclean stone. For the magnet is a kind of little Earth, or in Greek [Greek: μικρογὴ (mikrogē, "little earth")], which can be called a sort of microcosm: in its motions and its turnings towards the regions of the world there is a kind of exemplar of the Copernican Earth, if that motion could be granted to the Earth, and certain sympathetic motions of the planets themselves are indicated in them; and they offer a splendid specimen of the other sympathies that exist in all of nature, and finally a compendium of natural magic. [Margin: The power of the magnet.] But there is no time to linger over these things, nor is it fitting for us to do so. [Margin: When was it applied to navigation?] If you wish, consult on them Pliny the Elder, book 36, chapter 16; William Gilbert, on magnetic philosophy; Georgius Agricola [Georg Agricola], book 5 of *De fossilibus*; Niccolò Cabeo in the *Philosophia Magnetica*; Athanasius Kircher in the *Magnes*; Bernardus Cæsius [Bernardo Cesi], *De Mineralibus*, book 4, part 1, chapter 6; Scaliger, *Exercitation* 131; Renatus des Cartes [Descartes], *Principles of Philosophy*, part 4, no. 145.

Some have doubted whether the magnet's power of turning itself to the poles, and of communicating this to steel, was known in antiquity. Giraldi, Calcagninus [Celio Calcagnini] and Leuinus [?] affirm it, on account of those lines of Plautus in the *Menecho*: *Cape versoriam* ["Take the *versoria*"]. Others commonly deny it, with Cabeo, book 1, chapter 6, and Pineda [Juan de Pineda], *De rebus Salomonis*, book 4, chapter 15. For they say Solomon was ignorant of it, at least in practice, so that the Jews should not be dispersed by navigating, and the origin of the Messiah might be more certain, and so that it might be reserved for the promulgators of the Gospel. Therefore the ancients, as Strabo, Pliny the Elder and Martianus Capella relate, steered by Cynosura, like the Phoenicians and Sidonians, or by Ursa Major, like the Greeks, or by birds, like those who sailed to Taprobane.

The first to mention the property of facing the north with one of its faces and the south with the other was Albertus Magnus, about the year 1245, and Vincentius Bellovacensis [Vincent of Beauvais], who calls the north *Zoron* and the south *Afron*. The one who first observed this turning in the magnet was Petrus Peregrinus [Pierre de Maricourt]. But the one who observed it in the magnetic needle, and who invented the nautical compass, was either Io. Goias, or Giras, of Amalfi, in 1302, as Blondus [Flavio Biondo] and Ortelius, tab. 6, relate, or Flavius of Amalfi at the same time, as Gilbert asserts. Some, however, think the inventor was older, as reported in Kircher, book 2, part 6, chapter 1. At p. 189 of the same author, read the method of rubbing a needle on a magnet so that it keeps a stable verticity; for it is well established that the

verticity is easily destroyed if the faces are interchanged in the rubbing, or if iron implements are close by, drawing the needle towards them.

[Margin: Magnetic declination.] II. The declination of the magnetic needle from the meridian line, in Greek [Greek: καλιβόκλισις (kaliboklisis, "inclination of the steel")], is the angle made by the meridian line and the magnetic needle, which has the centre of its motion on the meridian line. If it declines towards the east it is said to *Græcissare*; if towards the west, to *Magistrissare*; if to neither side, then it is [Greek: καλιβόδειξις (kalibodeixis, "pointing of the steel")]. On the island of Corui [Corvo], on Flores and Maij [Maio], at Messina by Charybdis, at Malta, at Vienna in Austria; at the Island of the Trinity, at the mouth of the river *Cantani* [?], in the Terzeræ or Tertiariæ Islands, and those of Boni aspectûs [Boa Vista]; at Cape *dellas Agullias* near the Cape of Good Hope, and near Constantinople it does not decline at all. In other places it declines, as you will learn from the small table to be set at the end of this chapter. The cause of declination is the greater or lesser abundance, or the nearness, of magnetic mines. That is why the declination is so enormous near the Arabian Gulf and Ilua [Elba], and in the Davis Strait: namely because magnet is dug out there. As for the other causes that Cabeo adduces, in book 1, chapter 7, we struck them out long ago in our *Philosophy*, since the greater tract of uncovered land does not always lie in the part towards which the magnetic needle tends, and so the declination cannot be attributed to that land.

[Margin: The nautical compass.] III. The nautical compass [*Compassus nauticus*] is a box in whose base lies a circle representing the horizon, divided into 32 rhumbs for as many winds; from these rhumbs is made the figure called the *Rosa Ventorum* [rose of the winds]. At the centre of this horizon a pin stands perpendicularly upright, carrying a pointer, or magnetic needle, which is also called a *versorium* from its verticity. The whole box, though, can be called a *versorium*, because it too is suspended from two or three rings crossing one another, so that whatever agitation of the ship occurs, its horizon remains parallel to the true horizon. A turning vane or pennant is usually added above, whose position shows the wind blowing from the opposite side.

[Margin: The marine chart.] IV. The *Charta Marina*, or nautical or hydrographic chart, is a chart on which the surface of land and sea is drawn, with places according to their proper geographical latitude and longitude. In very many places, where the wind is apt to change, images of the rose of the winds are added, of the kind seen in the second figure of the preceding chapter. That chart is very imperfect which has parallel meridians; better is the one in which the meridians meet at the poles of the world, and the lines drawn from the rhumbs of the winds to different places are curved and helicoid; of this kind the best charts were drawn by Gherardus Mercator [Gerard Mercator], Edouardus Vuricht [Edward Wright], Robertus Hues [Robert Hues], Iansonius [?], and other more recent makers, on new globes or maps.

[Margin: What is loxodromy?] V. Loxodromy is the oblique course that a ship holds when it follows the guidance of the magnet. For one can indeed sail

along the same circle, whether a great circle on the sphere or a lesser one; and if the voyage is continued along the circumference of the same great circle, it is shorter, safer and less costly. Yet that demands more ingenuity, and the analysis of very many spherical triangles, or a great mass of tables. Ship-captains have therefore chosen an easier method of navigating. It consists in following the same inclination of the rhumb on one meridian after another for as long as the same wind blows, though with that inclination corrected according to the declination of the magnetic needle, known beforehand; and in steering the ship by means of the rudder so that it follows the line marked out by the rhumb, either from the start of the voyage or chosen later. It follows necessarily that the line the ship's keel describes is curved and imitates the form of a helix. But more on these matters in the Geographical Book.

[Margin: What is histiodromy?] VI. Histiodromy is the art of navigating, so called from the ship's mast, which in Greek is called [Greek: ἱστὸς (histos, "mast")]. It has two principal parts. One is that of conjecturing, from the nautical chart, from the measure of the sea journey completed and from the latitude of places, where you are, and hence which rhumb and which wind are to be used next, so as to reach the desired place by the shortest or the most convenient navigation. The other consists in continually steering the ship along the appropriate rhumb, whether this is done by loxodromy or by orthodromy. But for more on this art see Pedro Nunes, in a twofold problem and in almost the whole of Book 2 of *De observatione*; Pedro de Medina, in six books on the art of navigation, addressed to Philip, King of Spain; Bartholomæus Crescentius [Bartolomeo Crescenzio] in his *Nautica Mediterranea*; Willebrord Snel in his *Tiphys Batavus*; Adriaan Metius in his art of navigation; Simon Stevin in *Imenereutice*; Father Georges Fournier of the Society of Jesus, in a French volume on this subject; Father Marin Mersenne in his *Histiodromia*; and Pierre Hérigone in the *Histiodromia* found in volume 4 of his *Cursus Mathematicus*, where there are also many tables for this purpose, together with fuller tables of magnetic declination taken from Io. Teliero [?]. We too shall give notable theorems and problems of histiodromy in the Geographical Book, in a section on this subject, where we shall set out a fuller table of magnetic declinations. For now the following small table will suffice, for the sake of some learning.

The Eastern Declination of the Magnetic Needle.

Place	Declination
Aleppo in Syria	3° 0′
Alexandria in Egypt	5° 45′
Amsterdam	9° 30′
Bologna in Italy	3° 30′
At the Cape of Good Hope	2° 30′
Ceylon	15° 30′
Cochin	17° 0′
Cologne	5° 0′
Crete, in its eastern part	15° 0′

Place	Declination
In Davis Strait	50° 0′
Ferrara	5° 50′
Florence	3° 30′
Ghent	1° 40′
Genoa	5° 58′
On the island of Elba, at Portoferraio [Iluæ insulæ in portu ferreo]	20° 0′
Ingolstadt	4° 30′
London, formerly	11° 16′
but now	4° 3′
Leuven	9° 0′
Lyon in France	4° 30′
Macau, on the borders of the Chinese	1° 30′
Madrid	5° 0′
Mantua	0° 30′
Marseille	2° 40′
Milan	2° 30′
Mainz	6° 7′
Eastern Declination.	
Narsinga [Narsingæ]	12° 0′
Nuremberg	8° 0′
The island of Palma in the Canaries	6° 10′
Palermo	6° 0′
Parma	6° 0′
Plemuda in England [Plemudæ in Anglia]	3° 24′
Prague	5° 30′
Rome, now	2° 45′
Between the islands of Tristan and Trinidad	19° 0′
Venice	5° 0′
Vilnius	3° 40′
Near Nova Zembla	17° 0′

Western Declination.

Place	Declination
Antwerp	9° 0′
In the Canary Islands	1° 0′
On the island of Frisland	28° 0′
Goa	17° 0′
Loreto [Laureti]	4° 0′
On the island of St Lawrence	25° 0′
Mozambique	12° 0′
Naples	0° 30′
Opposite the Arabian Gulf	16° 0′

Another, longer table is in our Geographical Book.

[Margin: Anomaly of magnetic declination.] VII. Some hold that magnetic declinations vary at one and the same place on the Earth. Among them is Marin

Mersenne, in his art of navigating, in the tract *De Magnete*. For he relates that at London it was observed by the Englishman Burrosius [William Borough], in the year 1580, as 11° 15′; but at the same place by Gontero [Edmund Gunter], in the year 1622, as 6° 13′; and by Gellibrando [Henry Gellibrand], in the year 1634, as 4° 6′. He adds that at Paris in the year 1644 it is 3°, whereas 30 years before it was 8°; and finally that at Aix it was recently observed by Gassendi as 5°, whereas long before the same man had found it to be 9°. Hence, he says, if it is observed for at least 50 years, the period of this reciprocation can be found. But I should like to be certain whether, while observing, they avoided iron implements, stones akin in nature to iron, and other things that usually draw the needle to themselves. Certainly, if it were true that the needle used to decline 6° in Italy, as Biancani relates in book 1 of the *Sphere*, chapter 4, then, since I found after almost 30 years that it declines 3° 20′, this difference does not seem one to be disregarded, so that timepieces and navigation may be handled and practised more correctly.

CAPVT XIX.

On the Height of the Regions of the Air, of Clouds, of Rainbows, and of the Whole Elementary Sphere.

I. The height of the air in which sensible refractions occur is, for Tycho (volume 1 of the *Progymnasmata*, p. 95), as great as that of the exhalations which, by reflecting the rays of the Sun about to rise, produce twilight; that is, 52 Italian miles, as he himself thinks. Longomontanus subscribes to this in the *Astronomia Danica*, book 2 of the *Spherics*, problem 2, not distinguishing vapours from exhalations, and from the greatest height of the vapours measuring the quantity of the refractive transparent medium, which for him is 56⅓ Italian miles. But Kepler, in the *Epitome of Copernican Astronomy*, p. 69, and in the *Astronomia Optica*, pp. 117, 129 and 135, distinguishes exhalations, smokes rising high and twilight torches from the vapid, thick air, which differs from water only by degrees of gravity. For this air alone, he says, is suited to sensible refractions of the rays of the stars, but it does not rise above the Earth beyond two Italian miles: as if, indeed, on mountains of so slight a height the stars could be observed unrefracted. For my part, I would believe that the air in which clouds can dwell, and in which rains, snows and hails can form, is suited to refractions; that it is indeed less high than 52 miles, but in some places higher than 2 Italian miles, as I shall presently say of both.

[Margin: The height of the regions of the air.] II. The height of the highest region of the air is therefore as great as that of the exhalations, which are hot and dry. For this is how the highest region is distinguished from the middle one by Aristotle (book 1 of the *Meteora*, summa 1, chapter 4), by Kottounios on that place (lecture 18), by Cabeo (text 15, question 2, and text 46, question 11), by Froidmont (book 1 of the *Meteora*, chapter 1; book 3; and book 5, chapter 5) and by other commentators: in the former they place exhalations

and fiery impressions, in the latter vapours and watery impressions. But on the height of the exhalations that produce twilight, opinions differ according to the differences of the air and the quantity assumed for the Earth's semidiameter in investigating this height. I have already reported them in Book 1, chapter 31, on twilight; transfer them here from there.

III. On the height of the middle region and of the clouds, opinion is no less divided. Aristotle, in the place cited, and Kottounios think it as great as the greatest height of the mountains, just as the lowest region ends at the summits of moderate mountains, as far as the rays of the Sun reflected from the Earth reach. And yet there is no less controversy over the greatest height of the mountains; granted that it may be more probable that they do not exceed 20 or 25 [recte: 40 or 50, per the book's errata; the printed figures, unreadable under the ink in this copy, are given as the errata quote them] Italian miles[11] in perpendicular height. But not a few think that sunlight reflected from the Earth reaches as far as the Moon and produces on it that secondary light which is seen at ecliptic new moons, as I shall say when treating of the lunar light. To measure the height of the lowest region of the air from this is therefore a task of uncertain hazard. Posidonius holds that *the height in which cloud-masses, winds and clouds arise is not less than four hundred stadia*, as Pliny the Elder has it, book 2, chapter 23. For the reading from old copies is not forty but four hundred, in Pedro Nunes, *De crepusculis*, proposition 18; in Tadeáš Hájek, in his book on the new star of the year 1572, p. 119; and with him in Tycho, above; and 400 stadia are 50 Italian miles. Yet Pliny the Elder adds in the same place: *Many, however, have reported that clouds rise to a height of nine hundred stadia. These things are unascertained and inextricable.* But Albertus Magnus in the *Meteora* grants 15 miles, unless one should read stadia. Froidmont, in the *Meteora*, book 1, chapter 1, and book 5, chapter 5, teaches that extraordinary exhalations can rise as far as the Moon, as comets make clear, but ordinary ones to 52 Italian miles; while the thicker vapours do not exceed 8 miles, and clouds and snows do not exceed 4 Italian miles. Cardano, on the contrary, in book 17 of *De subtilitate*, denies that clouds are raised beyond two thousand paces, which Kepler, cited in no. 1, thinks of the refractive air; and he says that the denser clouds, heavy with rain, scarcely rise to 500 paces. Kepler adds that on sea coasts they do not exceed an Italian mile. Father N., Rector of the College of the Society of Jesus at Metz, asserted to me in the year 1646 that many clouds had been brought to measurement by him, and that none had been found higher than five thousand paces. Finally Father Cabeo, in book 1 of the *Meteora*, text 15, question 2, and text 46, question 11, rightly teaches that the measure of the height of the clouds and of the middle region is not everywhere the same. For some clouds full of sulphurous and nitrous exhalations are carried higher; and in some places the middle region can be higher than the one that is highest elsewhere, especially

[11] in this copy the 4 of 40 and the whole of 50 are written over in ink by a later hand; the printed figures beneath them cannot be read.

if vapours are raised from mountain lakes. Let there be, however, a synopsis of the opinions in the following small table.

Height of the Middle Region of the Air, or	*Height of the Clouds.* Italian miles
Cardano, *if thick clouds*	½
If thin	2
Froidmont, *if the clouds are thin*	8
If thick, as also snows	4
Kepler	1 or 2
Father N., Rector at Metz	5
Albertus Magnus	15
Posidonius	50
Others, in Pliny the Elder	112½
For Pliny the Elder himself uncertain; for Cabeo and for me, variable	

[Margin: First method of measuring the height of clouds.] IV. But if anyone nevertheless wishes to measure the height of clouds, even if he cannot determine their greatest height from that, here is a threefold problem for you. First, let N be the edge of a stationary cloud, and let its altitude be observed with a quadrant or a geometric square, at the same moment, by two observers, one stationed at A and the other at B, or, if possible, at D. In this way the angle NAC will be known, and either NBC or NDA.

Diagram. A small woodcut set into the right column: a horizontal base line with a cloud drawn above its left and central part, its right end at the apex point. Four straight lines descend from the point at the cloud's edge to points on the base line, the third of them vertical.

- N (top, at the cloud's edge): the observed edge of the cloud
- A (base, far left): first observer
- B (base, left of centre): second observer
- C (base, right of centre): foot of the vertical line
- D (base, far right): alternative station of the second observer

In the first case, then, since the angle NBC is given, the angle NBA is also given, because it is its complement to two right angles, by proposition 13 of the first book of Euclid's *Elements*. Measure, then, the terrestrial interval AB in paces; and so in the triangle NAB the angles NAB and NBA, and the side AB adjacent to them, will be known. Therefore, by rule 8 of our oblique rectilinear triangles, the side AN will not remain hidden. Then, with the perpendicular NC drawn in imagination, making the right angle NCA, in the triangle NCA, right-angled, you will find from the known angle A and the hypotenuse AN the perpendicular height of the cloud NC, by rule 1 of the right-angled triangles. But if the angle at D was observed, measure the interval AD, and from it and the angles A and D find the side AN, and with that, as above, the height NC. In this way I, with Father Francesco Maria Grimaldi, found a white cloud 2177 paces high.

The second method, from Simon Stevin, is as follows. Let DK be the shadow of the cloud, with one observer at D observing the boundary of the shadow, and another at K; and with a third at the physical midpoint I, meanwhile taking the angle EIG with the help of a radius or a sextant, by sighting the extremes of the cloud, E and G. [Margin: Another method.]

Diagram. A woodcut set into the right column: a cloud drawn as a shaded lens across the top, with a straight line through it from E to G. Lines run from E and G down to a point L at the foot, and a vertical line runs from the cloud to L. Lines also run from E and G to a central point on the vertical line, and at that level a shadow is drawn as a small horizontal ellipse crossing the two lines to L.

- E (top left): one extreme of the cloud
- F (top centre, inside the cloud): foot of the vertical on EG
- G (top right): the other extreme of the cloud
- D (left of the small ellipse): one boundary of the shadow
- I (centre of the small ellipse): the third observer
- K (right of the small ellipse): the other boundary of the shadow
- L (foot): meeting point of the Sun's extreme rays

So, having drawn the Sun's extreme rays EL and GL, and given the angle ELG, which subtends the apparent diameter of the Sun, and having drawn EG, the diameter of the cloud, and the perpendicular LF to it, the half-angles of those angles will be known; and accordingly GLF, the apparent semidiameter of the Sun, and GIF from the observation. Once the shadow's semidiameter IK has been measured in paces or feet or perches, then in the triangle KIL, right-angled at I, the side IK and the opposite angle L will be known. Therefore, by rule 6 of our right-angled triangles, the side LI becomes known. Then in the triangle LIG, in which are given the angle L, the side LI, and the angle LIG, made up of the right angle LIK and the complement of the observed angle GIF to a right angle, which is the angle GIK, you will find, by rule 8 of our oblique-angled triangles, the side IG. With this as a base, finally, and with the observed angle FIG, in the triangle FIG, right-angled at F, you will find, by rule 10 of the right-angled triangles, the distance of the cloud FI, and by rule 1 the true semidiameter of the cloud FG.

But if you had investigated LK, then as LK is to LI, so is LG to LF, by proposition 4 of Book 6. So, with LI subtracted, the height IF will be known.

Froidmont teaches a third method, and Cabeo explains and completes it (book 1 of the *Meteora*, text 44, question 11): by means of the time between lightning and thunder, counted by the swings of a pendulum, if you have first observed the time between a gun's flash from the ignited powder and the hearing of its report. This method is very slippery and exposed to great error, unless it is carried out with the utmost and scarcely attainable subtlety; and so it is enough to have indicated it here.

V. The height of the rainbow, moreover, is very small and does not exceed a thousand paces, because its apex is not higher than about 45°. If it is 45°,

a right-angled isosceles triangle results, one side of which is the height of the rainbow and the other the distance of the plane of the rainbow from the measurer's eye. That distance does not usually exceed a thousand paces, if you prudently note the place on which the arc of the rainbow rests, as I have noted more than once; and I have also often found that angle to be less than 45°, as I shall say in Scholium 4.

SCHOLIA.

I. Mario Bettini, in *Apiarium* 8, progymnasma 8, proposition 3, thinks that the height of the refractive air can be demonstrated from the quantity of the refractions alone, known in degrees or minutes. Accordingly, taking from Tycho the Sun's greatest refraction of 34′, and setting the Earth's semidiameter at 3035 5/11 Italian miles, he concludes that the height of this air is only 151 paces. But I shall show the fault of this reasoning in the Optical Book, where refractions are treated. Meanwhile, it is certain enough that on mountains much higher than 151 paces, for instance on Mount Paterno and the like, refractions of the stars are perceived; although Kepler, in the *Epitome of Copernican Astronomy*, p. 72, says that on the highest mountains refraction is sometimes almost nil, especially in winter, when the air is low and less vapid. But he adds that both on mountains and in coastal places it is sometimes prodigious.

II. On Cardano's error about the greatest height of the exhalations of twilight I have said enough in Book 1, Chapter 31, where I also indicated why I have deferred my own opinion on this height to the Optical Book, although I have many observations of the Sun's depth at the beginning or the end of twilight. That Abraham Roggembach [?], in Tanner, question 7 on *De caelo*, and Cardano, book 4 of *De subtilitate*, with twilight set at only half an hour, say the height of the exhalations is 772 miles, comes from the same blunder: namely, that they think the reflected ray of twilight falls perpendicularly above our zenith.

III. From what has been said you see that the quantity of the air as distinct from the fire, and of the fire as distinct from the ethereal and celestial substance, is uncertain. For it is more probable that below the Moon there is something of the ethereal breeze, and that the bounds of the heaven do not end precisely where the body of the Moon at perigee descends to. Tycho teaches at length, in his letters to Christoph Rothmann, that the upper air and the fluid substance of the heaven can be of different species, even if they agree in transparency, fluidity and rarity; and it is not for this place to treat these matters fully. The reader will therefore pardon us if we do not dare to define the quantity of the atmosphere, although Biancani, in book 7 of his *Sphere*, has defined the elementary sphere by the height of the Moon at perigee, namely, following Tycho, by 52 semidiameters of the Earth; and has accordingly set its volume to the volume of the Earth alone as 321992320 to 2290, and the volume of the air (its height being set at 43 miles) to the volume of the Earth as 86 to 2290.

IV. Maurolico asserts that the height of the inner and more vivid rainbow is 45°, and that of the outer 56°. Yet Descartes, as found in his own *Meteora*, chapter 8, observed that the former does not exceed 41° 47′, and the latter 51° 37′. They are speaking, however, of the height taken not from the line of the sensible horizon, which does not always meet the centre of the rainbow, but of the height from the centre of the rainbow itself, and of the angle made at the spectator's eye by two lines, one of which goes to the apse or summit of the rainbow and the other to the centre; and this second line, prolonged straight, goes to the centre of the Sun.

Diagram. A woodcut set across the right column. At the left a rayed Sun with a letter in its disc. A horizontal line runs from the left through a central point to the right, and a straight line from the Sun's centre descends through that central point to the lower right. From the central point a further line rises to the top of a rainbow, drawn as two concentric dashed arcs; a line from the top of the rainbow falls to the lower line, crossing the horizontal. The arcs reach down past the horizontal on both sides.

- S (left, in the Sun's disc, cut in reverse): the Sun
- H (far left, on the horizontal): the horizon
- O (centre, at the junction of the lines): the eye
- R (right of centre, on the horizontal): the horizon
- I (on the horizontal, where the line from the top falls across it): foot of the height from the horizon
- E (far right, at the end of the horizontal): where the rainbow's arcs cross the horizon; RE is the distance between the horns in the table below
- B (top of the arcs): the summit of the rainbow
- C (below the horizontal, on the left arcs): not named in the text
- A (on the lower line): the centre of the rainbow
- D [?] (lower right, at the foot of the arcs, on the lower line): not named in the text

Therefore, the higher the Sun is above the horizon, the lower the centre of the rainbow lies below it, and no straight visual line can be drawn to that centre from our eye unless the Sun is very near the horizon, or we are on a high mountain, or a very deep valley lies between the horns of the rainbow, as can be seen in the figure added here. In it let HOR be the physical horizon; let A be the centre of the rainbow, O the eye and S the Sun, set on the same straight line SOA; let AB be the height of the rainbow from its centre, or its semidiameter, which the angle BOA measures; but let BI be the height from the horizon, which the angle BOI measures, taken with a quadrant or a geometric square. These angles are sometimes found to differ, either because of a less accurate observation, since the altitude of the Sun and that of the rainbow were not taken at the same moment, or from differences in the dewy cloud. The visible altitude of the Sun's centre S, that is, the angle SOH, which by proposition 15 of Euclid's first book equals the vertical angle IOA, must, together with the observed angle BOI, make up the angle BOA. I should like to add here some

observations of Father Francesco Maria Grimaldi and of our own, such as they are, and taken in haste; although I intend, now that I have read Descartes's book, to undertake others more accurate, if God wills. And once, from Mount Paterno, we saw a rainbow in the valleys that was more than semicircular. [Margin: A rainbow greater than a semicircle, against Aristotle, *Meteora* 3, summa 2, chapter 4.]

OUR OBSERVATIONS

Year	Month	Day	Visible Altitude of the Sun, Angle SOH	Altitude of the Rainbow from the Horizon, Angle BOI	Altitude of the Rainbow from its Centre, BOA
1643	August	9, evening	16° 10′	24° 40′	40° 50′
	September	8, evening	28° 40′	12° 32′	41° 12′
1644	May	31, evening	11° 4′	30° 4′	41° 8′
Distance of the horns RE 81° 40′; the colour at the top red, in the middle yellow, at the bottom green; and after 10^{m} a rainbow of inverted colours was added; and then the distance RE, observed with a hemicycle, was seen to be 103°. And the altitude:			9° 50′	40° 30′	50° 20′
1647	June	2, morning	4° 0′	38° 0′	42° 0′
	July	4, evening	28° 40′	12° 32′	41° 12′
	August	3, evening	4° 0′	37° 0′	41° 0′

But on the rainbow, more can be found in Witelo, book 10, from proposition 63 onwards; Maurolico, at the end of book 3 of the *Diaphana*; Biancani, on the mathematical passages of Aristotle, book 3 of the *Meteora*, from no. 162 to no. 182; Froidmont, book 6 of the *Meteora*, chapter 1; Cabeo, book 3 of the *Meteora*; Descartes, in the *Meteora*, chapter 8; the Coimbra commentators and Kottounios on book 3 of the *Meteora*; and many more in them.

CAPVT XX.

On the Oscillations of the Pendulum [Perpendiculum], Suitable for Measuring Other Motions and Times, Both in the Elements and in Mixed Bodies and in the Heavenly Bodies.

[Margin: The occasion for investigating the oscillations of the pendulum.] I. When I was publicly teaching philosophy at Parma, I wanted to test by what increase of speed heavy bodies descend faster and faster toward the end of their fall, and I saw that this required a very fine measure of time, down to

almost its smallest perceptible particles. An occasion for this measurement at last offered itself when Father Niccolò Cabeo asked me by letter to test whether two pendulums, equal in weight and in length, and released from a limit equally distant from the perpendicular toward the same quarter, would continually travel together toward the same sides in both directions. For it was then that I began to suspect that any oscillations of one and the same pendulum are equal in time to any others; and this I afterwards learned thoroughly through repeated and more accurate experiments. For at that time neither Galileo's dialogues on the system of the world, where the same thing is affirmed in Dialogue 2, nor the short work of D. Io. Baptista Baliani [Giovanni Battista Baliani] on the natural motion of solids had yet reached my hands: I read the former only two years later, and the latter only ten years later. But neither in them nor in others did I find a way or measure for determining time by oscillations of this kind. I shall therefore set out what I tested to the point of satiety, by myself and with the help of my colleagues, together with selections from Galileo and Baliani. To do this the more readily:

Diagram. A pendulum and its mounting, set in the left column. At the top a horizontal bar runs from A at the left to B at the right, with three screws or clasps drawn on it. Below the bar hang two plates forming a frame; a small axle or cylinder lies across the frame, and a chain hangs from its middle down to a large shaded sphere. A dotted vertical line drops from the left plate to the left end of the sphere's horizontal diameter. A dotted arc runs from S at the upper left, through two marked points, down to the sphere, and rises on the other side through two more marked points to T at the upper right.

- A (left end of the bar): the iron bar AB
- B (right end of the bar): the iron bar AB
- D (on the bar, left): clasp or screw
- H (on the bar, between D and F, above the left plate): head of the plate HE
- F (on the bar, right of H): clasp or screw
- G (on the bar, right of F): clasp or screw
- L (left of the left plate, at the height of the axle): end of the axle LM
- E (on the left plate): hole in the plate
- K (on the right plate, above the axle): head of the plate KI
- I (on the right plate, at the height of the axle): hole in the plate
- M (right of the right plate): end of the axle LM
- S (upper left, end of the arc): limit of the swing
- Y (on the arc, left): marked point; the prose on the next page names Y as a point of the third and fourth arcs
- Q (on the arc, left, below the last): marked point, not named in the prose on this page
- T (upper right, end of the arc): limit of the swing
- X (on the arc, right, below T): marked point; the prose names X as a point on the return toward T

- Z (on the arc, right, below X): marked point, not named in the prose on this page
- N (top of the sphere): where the chain joins it
- P (left end of the sphere's diameter): end of the diameter
- O (centre of the sphere): centre
- Q (right end of the sphere's diameter): end of the diameter
- R (below the sphere): foot of the sphere

II. In the present diagram let AB be an iron bar, fixed to some beam or support that is wholly immovable and trembles as little as possible, by means of the clasps or screws D, F, G. To this bar let there be attached or soldered, on either side, two quite thick plates of iron or steel, equal, equidistant and set perpendicular to the horizon, such as HE and KI, pierced at E and I. And let a small cylinder C be made, with an axle LM projecting from it and passed through the holes E, I, so that by means of it the pendulum is held in its motion between the plates HL and KI, and so always travels in the plane of the same vertical SOT and cannot wander off sideways. Let the length of the axle LM be as great as the diameter of the sphere POQ, and let it be parallel to the horizon, so that with a thread or rule LP one can know very exactly OC, the height of the pendulum, to be taken from the centre of the sphere to C, the centre of the cylinder set on the axle, and parallel to LP itself. Let the sphere NPRQ be made of metal and not exceed two pounds, lest with too great a weight the axle of the cylinder become less suited to equality of the motions toward the end, and be worn down too much by long use. Let this sphere be hung from C by a small chain CN, made of very small rings or links, but as strong as the weight of the sphere requires, so that they cannot break or stretch. For if you use a cord of thread, or of bristles, or of small cithara strings, it eventually stretches under the force of the weight and of the sphere's motion, and the measure of the height CN varies, although it must be constant. If, on the other hand, you use a metal wire or a slender rod, the pendulum comes to rest after very few oscillations and is unsuited to measuring a rather long time. It is useful, moreover, to know exactly not only the height CO, with LP taken from the pole L and the extremity P of the diameter, but also, by an accurate balance, the weight both of the sphere NR by itself and of the small chain CN.

[Margin: How the pendulum is to be handled.] III. With this pendulum [pendulo seu perpendiculo], or a very similar one, thus prepared, or, which is more advisable, with several of different heights, let the sphere be grasped by hand and, with the small chain extended, drawn upward through the plane of the vertical equidistant from the plates E, I, so that by the force of the motion its centre O describes the circumference SOT; and let it be released from T freely, with no impulse imparted from outside. It will then move along the arc SOT, nodding and oscillating alternately half upward and half downward, receding from the perpendicular line CO and returning to it, until, the impetus it had conceived at T or at S being spent, it at last comes to rest on that line. And if, when it is approaching rest and describing tiny arcs, it is gently grasped by

hand a little before it reaches the perpendicular, at once drawn upward through the same plane, and immediately released, with no perceptible delay between grasping it and completing the pull, its motion can be continued even for a whole day, so that this motion is suited to counting time exactly. But that takes remarkable dexterity and much prior practice. It should not be raised from O toward T or S through an arc OT or OS that reaches a quadrant of the circle; indeed, it is more advisable not to exceed a half-quadrant. And if its motion is to be continued, one should not wait for the pendulum to be close to rest, but repeat its elevations a good while earlier, so that it describes larger arcs. The definitions, further, or notions of the terms that must be known beforehand, are these.

[Margin: Definitions concerning the pendulum.] The *pendulum* is a weight suspended from some height in such a way that it can be moved from its rest without resistance; such is the sphere NR, suspended from C.

The *perpendicular of the pendulum* is the straight line standing at right angles to the horizon, on which the pendulum naturally comes to rest, as in our case COR.

The *centre of the natural motion* of the pendulum is the point about which the centre of the pendulum moves circularly, or along arcs of a circle: such as the point C.

The *height of the pendulum*, or its *length*, is the distance of the centre of gravity of the pendulum itself from the centre of its natural motion: such as the straight line CO.

The *vibrations of the pendulum* are its oscillations, or oscillatory motions, to one side and the other of its perpendicular, made by natural motion. For the sphere, raised to T, while by the force of gravity it strives to go downward along the shortest line it can, seems to be drawn by the chain CN through the plane TOS; and although this motion may seem violent for the sphere NR taken by itself, yet it is not violent for the whole pendulum taken as a complete unit, since each single ring of the chain moves naturally by its own weight, and the whole pendulum together tends to the perpendicular line, so that on it the pendulum may stand as little distant as possible from the common centre of heavy bodies, which is connatural to it.

A *simple vibration* of the pendulum is one single oscillation of it from a terminus a quo, the same in kind, to the terminus ad quem opposite in kind; such as the motion made along the arc TOS, from the terminus T to the terminus S.

A *compound vibration* is an oscillation mixed of approach and withdrawal, or a reciprocal motion from a terminus a quo, the same in kind, to the terminus the same in kind; such as the motion from T to S together with the return from S, toward T, to X.

A *semivibration* is the motion by which the pendulum recedes from the perpendicular as from a terminus a quo, or returns to it as to a terminus ad quem; of this kind is the motion made from O to T, or from T to O. With these

laid down, let there be *selected propositions, confirmed by our own most certain experiments: some of them are asserted by Galileo and D. Io. Baptista Baliani, and the first by Wendelen.*

[Margin: Galileo, Dialogue 2, on the system of the world. Baliani, on the natural motion of solids. Wendelen, in the *Eclipses*, p. 25.]

PROPOSITIO I.

Any simple vibration of one and the same pendulum is equal to the senses to any other simple vibration, and any compound vibration to any other compound one, in the time of its motion taken in itself: that is, it lasts an equal time, or in Greek [Greek: ἰσοχρονῆ (isochronē, "equal in time")].

[Margin: First experiment.] IV. For make yourself a short sand-glass of powdered tin, running, say, for half a quarter of an hour, or 10^{m}, so that there is less tedium at the start of the experiments. Let it have two clepsydras or bulbs, marked with some sign, say one with the letter A and the other with B. At the same moment of time at which you release the pendulum from the limit T, turn over bulb A, in which the powder has stood; and by yourself, or with a companion, count the simple vibrations, or the compound ones if you prefer, until all the powder has run out, and write their number on a slip of paper. It is useful to throw one pebble into a small vessel prepared for the purpose for every ten or every twenty vibrations, so that the imagination is not confused in counting while the eye attends to the reciprocal motions of the pendulum. Better still, have a witness and companion who also counts the vibrations silently. When the powder has run down into bulb B, turn the glass over so that the powder runs back into bulb A, but do not count the vibrations meanwhile. When all the powder has run down into bulb A, if the pendulum's motion continues, wait for it at some limit, say at Z, and at once turn the glass over and count the vibrations as above. For if you carry all this out exactly, you will find that an equal number of vibrations answers to those equal times. And you will find the same if the pendulum has already come to rest and you raise it again. But it will make for greater certainty if the second time you release the pendulum from a different limit: for example, if the first time you released it from T, release it the second time from X. I said the same bulb A should be used because, owing to the difference in their interior shape and the differing edges of the hole on either side, the time of one is rarely equal to the time of the other. If, however, you have not been so careful, there may be a difference of one or another vibration between the vibrations of the first and of the second time.

[Margin: Second experiment.] V. Second, set up in the plane of the meridian two threads suspended from the same point above, one of which stands perpendicular to the horizon and to the meridian line marked on it; for with that line it will form a triangle of thread that marks out, exactly to the senses, the plane of the meridian circle. Then wait until the centre of some fixed star is in the plane of that meridian. This is shown by the two threads, one covering the

other and both covering that centre, with the unmoving eye directing its gaze along those threads. At once let a companion be on hand to begin counting vibrations until another fixed star, notably distant from the first, reaches the same plane of the meridian with its centre, and let the number of vibrations be set aside. On the following night, with the pendulum released from a different limit, in whatever way, let the vibrations be counted again, from the transit of the same first star to the transit of the same second star across the same meridian. For if everything has been done exactly, and the pendulum has travelled in the same plane of its own, you will detect either no disparity in the number of vibrations or a negligible one. Thus, when we wished to weigh whether the pendulum customarily used for measuring astronomical times had suffered any perceptible change through wear of the axle and of the holes E, I, or from some other source, we counted on three nights, namely May 19 and 28 and June 2, with Fathers Francesco Maria Grimaldi and Franciscus Zenus [?], very practised in this matter, as witnesses and helpers, the vibrations from the transit of Spica to the transit of Arcturus across the same meridian. Twice we found 3212 simple vibrations and once 3214, using our custom of throwing single pebbles into a vessel after every thirty compound vibrations. But if the vibrations of one and the same pendulum took perceptibly unequal times, there could not fail to be a great difference in their number, showing itself plainly at least after many vibrations. Yet it nowhere shows itself. Therefore they are equal in time to the senses, in themselves, and leaving aside accidental causes, as when the wind blows from the opposite direction, or something else out of the ordinary speeds up or slows down the pendulum. Wendelen adds that if the pendulum is raised beyond 40° or 45° its vibrations are of longer duration, and likewise longer when the Sun is at apogee; on this matter see below, proposition 15.

PROPOSITIO II.

The earlier vibrations of one and the same pendulum are swifter than the later ones, by a difference that is uniformly difformly unequal.

For they are completed in equal times, as was shown in proposition 1, and yet they traverse unequal spaces, as is established by evident experiment. And if the arc of the first vibration was TS, the arc of the second will be smaller, as SX; that of the third smaller still, as XY; that of the fourth YZ; and that of the fifth ZΦ. Yet the difference is greater between the two earlier ones than between the two later ones: so that if the difference of the first two is the arc XT, the difference of the two later ones will be the arc ZX, smaller than the arc XT; and toward the end it is so small that equal arcs seem to be described in equal times by the centre O.

PROPOSITIO III. IV. V. VI. & VII.

III. Of two pendulums equal in all respects except height, the one of greater height completes a smaller number of vibrations within an equal time, but its whole motion persists for a longer time.

IV. Of two pendulums equal in every way except height, the one of lesser height completes its single vibrations, and its whole motion, more quickly, other things being equal.

From this, Galileo judges, it comes about that, while the upper rings of the chain by which the pendulum is hung, being less distant from the centre of motion C, strive to bring themselves to rest more quickly than the lower and more distant ones, they gradually weaken the pendulum's impetus; and that this is the reason why a motion which, with the air's resistance excluded, would perhaps be perpetual, at last ceases.

V. Of two pendulums equal in everything except heaviness, the heavier persists longer in motion, and within an equal time performs a greater number of vibrations.

VI. Of two pendulums equal in all other respects, the one that is slightly heavier, but notably greater in bulk, completes fewer vibrations in an equal time than the other.

I would believe the cause to be the resistance of the greater amount of air to be broken through by the greater bulk.

VII. Of two pendulums equal in other respects, but with one exceeding in individual heaviness and the other in bulk, the lighter comes to rest sooner and completes fewer vibrations in an equal time.

Propositions 5, 6 and 7 are against Baliani, who, if the height of the pendulums is equal, their vibrations are, he thinks, of equal duration. But I cannot disbelieve my own eyes.

PROPOSITIO VIII.

Of two pendulums equal in everything except height, the lesser height is to the greater as the square of the vibrations of the greater height is to the square of the vibrations of the lesser height, performed within an equal time; and conversely.

So it is according to Galileo, Baliani and many experiments of our own. In other words, the heights of pendulums of different height are to one another as the squares of the times. For let there be two spheres of lead, of one ounce each, one at a height of one foot and the other of two feet; and let the vibrations of the one-foot pendulum be counted, nearly 85, for meanwhile the vibrations of the two-foot pendulum will be counted as 60. Now the square of the number 60, namely 3600, is twice as great as the square of the number of nearly 85, which is 7200, just as the two-foot height is twice as great as the one-foot. The slight small difference in the numbers of the squares arises from our not being able to discern parts of a single vibration; so if you count 85 whole vibrations, their square will be 7225, which is a little more than double 3600. Now if the vibrations of a three-foot pendulum are 60, a pendulum of one-foot height will meanwhile complete very nearly 104; and the square of these, 10816, is very nearly triple the square 3600, and so on. From this arise two notable problems.

PROPOSITIO IX. Et Problema I.

Given two pendulums wholly equal but of different height, and given the vibrations of each, counted separately in an equal time, and the height of one, to find the height of the other.

Multiply each number of vibrations by itself, and you will have the squares of the vibrations. Then multiply the square of the vibrations of the known height by the known height itself, and divide the sum this produces by the square of the vibrations of the unknown height. The quotient will give the unknown height.

PROPOSITIO X. Et Problema II.

Given two pendulums wholly equal but of different height, known in each, and given the number of vibrations of one, to find the number of vibrations of the other.

Multiply the square of the number of the given vibrations by the height of the pendulum whose vibrations are given, and divide the sum this produces by the height of the other pendulum. The quotient will show you a number whose square root will give the number of vibrations.

PROPOSITIO XI. Et Problema III.

To find the time of the primum mobile, or of the solar day, that corresponds not only to the whole motion of a given pendulum but also to its single simple and compound vibrations; and from this, further, to count times exactly by its vibrations.

[Margin: Finding a pendulum for measuring times.] If the time corresponding to all the vibrations, or at least to many taken together, can be established, there is no doubt that from it, by the golden rule of proportions, the time corresponding to each one can be derived. For example, if to 3600 vibrations there corresponds one hour, that is, 60^{m}, then certainly to 60 vibrations there will correspond one minute of time, and to each single vibration one second of the seconds of time, by Proposition 1. Now this can be found in many ways, but chiefly in four, which I shall explain better by example than by a longer precept.

[Margin: First method.] First, I had observed that a pendulum of about one pound, 3 ancient Roman feet and 4 inches [vncias] high, was such that to one simple vibration of it there corresponded one second of time, and to 60 vibrations one minute; for with a sand-glass of one quarter of an hour I had many times counted about 900 of its vibrations, that is, sometimes a little more and sometimes a little fewer, because of the variability to which clocks of this kind are subject. So, to come closer to a more exact measure, once an astronomical and horizontal dial had been made, I and Father Francesco Maria Grimaldi counted, from the third hour before noon to the third after noon, 21706 simple vibrations. Now in six solar hours there are contained six hours of the primum mobile and one further minute, according to what will be said in Book 3, Chapter 30, or 21660^{s}. Therefore one simple vibration of that pendulum contained somewhat less time than one second, and it seemed

that the pendulum's height should be increased, so that, according to what was said in Proposition 3, it would complete fewer vibrations within the same time. But since the arrival of the shadow at the hour lines cannot be discerned so exactly that we need not fear an error of some seconds, I set this method aside and turned to others.

[Margin: Second method.] Second, then, we used a pendulum whose height was 3 ancient Roman feet and 4 inches, with a sphere of iron of 8 ounces and its small chain of 3 3/5 ounces; and we arranged 9 colleagues, well instructed for the purpose, nearly all of whom now publicly teach philosophy, theology or mathematics, to relieve one another after about half an hour of counting. In 1642, from noon on April 2 to noon on April 3, we kept up the counting of the simple vibrations. Their number, from the pebbles thrown into a vessel for each sixty vibrations, was found to be 1466 sixties and 38 vibrations besides. But the day of the primum mobile contains its 1440^{m}, and the day of the Sun 1444^{m} of the primum mobile. Such a pendulum, therefore, in one day of the primum mobile, completes 1462 sixties of vibrations and 38 vibrations more, whereas it should complete only 1440 if a single simple vibration of it corresponded to one second. I therefore added one ring to the small chain, so that the number of vibrations would turn out smaller and come closer, with its single vibrations, to the seconds of the primum mobile.

[Margin: Third method.] Third, then, we used the pendulum of the second method, but now 3 ancient Roman feet, 4 inches and 20/100 of one inch high. But having observed the transit of the Tail of Leo across the meridian by means of the triangle of threads described above at marginal number 5, on the night following May 12, we counted with the same colleagues, from the transit of this star through the M. C. to its next transit on the night following May 13, 1449 sixties of simple vibrations and 58 vibrations besides. So they exceeded the day of the primum mobile by very nearly 10 of its minutes; and by that proportion I made myself a small table of equation. But so that this difference should not be attributed to the variation that can arise in keeping the pendulum's motion going, and so that I should not, by imposing so much tedium in counting through a whole natural day on myself and my colleagues, abuse my own health and their endurance, I chose a fourth method. Keeping the earlier pendulum, I used another, whose height I first tested against that pendulum by trial, to see how great it should very nearly be to satisfy my wishes.

[Margin: Fourth method.] Fourth, then, I used a pendulum whose height is 3 ancient Roman feet, 2 inches and 67/100 of one inch; with a sphere of solid brass of 20 1/2 ounces, and a brass chain of 174 rings, whose weight is 3 2/5 ounces. With this pendulum, from the transit of Spica across the meridian to the transit of Arcturus across the same meridian, we counted in 1645, on three distinct nights with the observation repeated, namely on May 19 and 28 and June 2. Using Fathers Francesco Maria Grimaldi and Zenus, we found that we had counted 3212 simple vibrations twice and 3214 once. In that year the southern declination of Spica, as observed by us, was 9° 15′ 28″, that of

Arcturus, northern, 21° 5′ 22″, and the distance, taken repeatedly with sextants, 33° 22′. Therefore, by the problems of the primum mobile treated in Book 10, the difference of right ascension between Spica and Arcturus, computed on the equator, was 13° 18′. To this there corresponds, in time of the primum mobile, 53^{m} 12^{s} [Horaria Minuta 53′. 12″.]; or, reducing to seconds alone, 3192^{s}. Therefore, if 53^{m} 32^{s} of the already mentioned pendulum, that is, 3212 simple vibrations, are worth 3192^{s} of the primum mobile, then certainly 60^{m} of the pendulum, that is, 3600^{s}, are worth 59^{m} $37½^{s}$ of the primum mobile, or at least 59^{m} 36^{s}. So one simple vibration of it is worth 59‴ 36⁗ of the primum mobile. This is how the small table of equation for time [tabella Æquatoria temporis] was made. I show the reader a specimen of it, so that he may see from it how we have used other similar ones in counting times of the primum mobile. To understand it, remember that we are accustomed to use single pebbles or grains of bean for every sixty simple vibrations.

Pendulum 3 ancient Roman feet, 2 67/100 inches high, whose total weight, brass sphere with chain, is 23 11/12 ounces.

PROPOSITIO XII. Problema IV.

To find a pendulum one simple vibration of which is equal to one second of time of the primum mobile.

[Margin: A pendulum that exactly represents the times of the primum mobile by its motions.] Let a pendulum be made whose brass sphere weighs 20 1/2 ounces, with a brass chain of 174 rings, whose weight is 3 2/5 ounces, and whose height is 3 ancient Roman feet, 3 and 27/100 inches. That is, reducing the height to hundredths of an inch, let it be 3927 hundredths. For by Proposition 9 and Problem 1, the heights of two equal pendulums are to each other as the squares of the vibrations. Now a pendulum 3867 hundredths of an inch high, with its 60 vibrations or its 3600‴, equals 3576‴ of the primum mobile, by what was said in Proposition 11. Therefore, if the square of the number 3600, which is 12960000, is multiplied by the height of 3867 hundredths, the result will be 50116320000. Divided by the square of the 3576‴, which is 12787776, this leaves 3927 hundredths of an inch, that is, 3 feet, 3 27/010 [recte: 27/100] inches.

PROPOSITIO XIII. Problema V.

To derive various pendulums from one, for a finer measure of time.

[Margin: Pendulum for a time of 15‴.] Let a pendulum be made whose height is 9 and 76/100 inches of the ancient Roman foot, and let the small brass sphere, with its small chain, weigh 18 1/3 drachms. For by testing it against the pendulum treated in Propositions 11 and 12, I found that this one completes 180 of its compound vibrations while that longer pendulum completes 180 simple vibrations, which by the foregoing small table are worth 179^{s} 48‴. Therefore this pendulum represents 30‴ by its simple vibration, very nearly one second by its compound vibration, and 15‴ by its half-vibration.

[Margin: Pendulum for the swiftest motions.] Let another pendulum likewise be made, whose height is 1 15/100 inches of the ancient Roman foot, the foot on which see our chapter 7. Let its small brass sphere weigh 4 drachms, but let it hang by a thread from the centre of motion, for its weight is not so great, nor its use so frequent, that the thread could be perceptibly stretched. This pendulum completes 360 of its simple vibrations in the time in which the pendulum immediately preceding completes 60 compound vibrations, that is, 60^{s} of time or 3600‴. So by its single vibration it is equal to 10‴ of the primum mobile. We used a pendulum of this kind to measure the natural motion of heavy bodies. But in counting its vibrations, since they are extremely quick, one must raise one finger of the closed hand after each ten of them and be very attentive; or rather, for greater evidence, one must use two equal pendulums of this sort and have two counters, each noting his number separately, so that it is clear at the end of the operation whether they agree or not. Here, then, are small tables for the two pendulums just described, for adding up their times. Although the weight noted in them is not kept exactly and scrupulously, the same time will still be obtained, provided that the length of the pendulum from its centre to the centre of motion is exactly the same, and that no rather stiff iron wires are used (otherwise the pendulum's motion ceases too soon), but twisted threads, or rather small chains woven of the smallest loops.

Pendulum of 18 drachms, of a height of 9 76/100 inches.

PROPOSITIO XIV. Et Problema VI.

Given the weight of a pendulum, to find the height at which one simple vibration of it is completed in one minute of time, or one hour, or one natural day. Provided that its chain does not break, etc.

[Margin: Height of the oscillation of a minute, of an hour and of a day.] I said "provided that its chain does not break, etc." because the excessive length of the chain could either slow the motion too much, or, by the excessive weight of so many rings taken together, overcome the strength of the upper rings and, by loosening them, be broken off. We therefore cannot be certain of this effect at insane heights. Yet speaking in itself, and considering the precise difference of height, Proposition 9 holds. Supposing it, let us take the pendulum of Proposition 12, namely the one that is of 20 1/2 ounces, and with its chain of almost 24 ounces, or 2 pounds. If its height is 3 feet, 3 27/100 inches, and one simple vibration of it is completed in one second of time, as was said in Proposition 12, then by Proposition 9, if nothing else intervenes, at a height of 2356 paces one vibration of it will last one minute of time; at a height of 8,482,320 paces, one hour; and at a height of 4,885,816,320 paces, one natural day. And so, for one simple oscillation of it to last one day, the height of such a pendulum would have to be about 1000 semidiameters of the Earth.

PROPOSITIO XV. Problema VII.

To measure astronomical times more exactly with a pendulum than with any other clock.

We have very often used the pendulum treated in Propositions 11 and 12, with colleagues highly practised in this and most trustworthy, to measure the intervals of time between the transits of fixed stars across the meridian, and so the differences of right ascensions; and to measure the duration of eclipses, and the intervals between the transit of other planets and of some fixed star across the meridian. For from the practice described in Proposition 11, method 4, we were certain that within one or two hours no error greater than 5^s of time could be committed. Moreover, we used the pendulum a dodrans high [dodrantalis altitudinis], treated in Proposition 13, to count the time in which the whole disc of the Sun emerged from a clear horizon, and in which the disc of the Sun and of the Moon, on the equator or outside it, passed across the meridian, both by direct view and by view reflected into the base of the cone of light, received on a white tablet; and so to measure the apparent diameters of the luminaries, and for many other astronomical times, as will be recounted in their proper places.

[Margin: Langren, Mersenne, Wendelen and Kircher measured times with the pendulum.] I was glad, moreover, when some years later I heard that pendulum oscillations had been adopted by other astronomers: namely by Michael Florent van Langren, as I learned from a letter he himself sent to me; by Govaert Wendelen, as is evident from his *Eclipses* and his *Idea of the Atlantic Tables* [Idea tabularum Atlanticarū], p. 25; by Father Athanasius Kircher, as is clear from his *Magnes* [Magnete], p. 450; and by Mersenne and others. But it

is not established that all were equally accurate in determining the measures of the pendulum. For, so that one vibration should be equal to one second of time, Mersenne, according to Wendelen, requires a weight of 8 ounces and a cord of 3 feet, but Parisian feet; Kircher, according to the same author, a thread of 3½ feet, with no weight added. Wendelen nearly agrees with this, saying: "With a suspension of 42 Roman feet, I obtained oscillatory swings of an iron weight of 52 pounds numbering at most 543 per hour; and that is on a fair par with this reckoning of three and a half feet." He then adds: "And my friend Langennus [recte: Langrenus, per the book's errata] too, having long since undertaken to measure times with iron rods [Rhopalis ferreis] of different lengths and weights, has laboured over many other things and over the diameter of the Sun as well, and most successfully indeed." He does not show, however, how what he appends after those words can be true: "Although it is not true that all oscillations of the same suspension are of equal duration, it is true that in winter, that is, with the Sun at perigee, more are made in one hour than in summer, or with the Sun at apogee, etc." [Margin: Whether oscillations vary with the motion of the Earth?] Unless perhaps he thinks that because of the motion of the Earth they are quickened by the rapid diurnal motion on account of the approach to the Sun, and slowed in the recession from it; a view that, as we shall show in Book 3, chapter 30, also pleased Kepler, Longomontanus and Boulliau. Wendelen concedes, however, that "if the pendulum is drawn out on either side beyond its line of plumb to 10°, it completes a very great number of oscillations, isochronous for a very long time, that is, of equal duration, and equal to every sense." For us, however, who do not admit the motion of the Earth, that difference of oscillations between the Earth at aphelion and at perihelion vanishes altogether; nor does it please Mersenne, in Book 4 of the *Harmonia*, p. 369.

[Margin: Comparison of the pendulum with other clocks.] I said, moreover, that we can measure times more exactly with a pendulum than with any clock. For water clocks and the clepsydras used by the ancients, on which see Cleomedes, Book 2 of the *Cyclical Theory*, Proclus in the *Astronomical Hypotyposes*, chapter 3, and Martianus Capella, Book 8 of *On the Marriage of Philology*; and sand-glasses, on which see David Rivault [Dauid Riualtus] on the *Sand-Reckoner* of Archimedes; and mercury clocks [Hydrargyrologia], on which see Tycho, volume 1 of the *Progymnasmata*, p. 149; and *horisonia* [Horiſonia] [?], on which see the same author in the same place; and *scaphia* [Scaphia], on which see Macrobius, Book 1 on the *Dream of Scipio*, chapter 20; and all sundials [Sciaterica]: none of these are measures so exact for measuring a whole hour and its parts, whether because of their uniformly difform motion or because of the uncertain arrival of the shadow at the hour lines, as we shall say in Book 3, chapter 9, method 4, which it is useful to read beforehand at this point.

[Margin: The speed of the pulses of the human artery.] The beats of the human artery, composed of systole and diastole, which some have thought

suitable for a finer measure of time, are subject to many anomalies because of the different constitutions of different people and the same person's different ages, states of health, disturbances of mind, bodily movements, or sleep, etc. Granted that Cardano, in *De proportionibus*, Book 5, Propositions 58 and 218, says that a healthy person's artery beats 4000 times in one hour; and Kepler, in the *Epitome of Astronomy*, p. 278, that in a robust person of mature age and melancholic constitution, or one growing old, a single pulse of the artery is perceived in each second of time, with no distinction of systole or diastole; yet that this slowness is rare, and that commonly 70 beats are counted in one minute, but in the choleric and in women 80, so that commonly there are about 4000 in one hour. Wendelen speaks of 4200 beats of his own artery in one hour, quite often tested. But while very many members of our Society counted their pulses and I counted the time with the pendulum of Proposition 13, I detected a difference within one minute of time, from 50 pulses to 85, in most, however, about 60 or 65 or 70 pulses. But let us now apply the pendulum to measuring the speed of heavy bodies.

CAPVT XXI.

On the speed of heavy bodies descending in natural motion, and the proportion of the increment of their speed.

I had not yet seen Galileo's Dialogue 2 on the system of the world, nor Baliani's little work on the natural motion of heavy solids and liquids, when I was already trying, by means of the motions of the pendulum, to find out in what proportion of speed heavy bodies descending naturally moved faster and faster toward the end. I shall therefore briefly and in perfect good faith set out what I found by experiment, and in what I agree with them, or am compelled to dissent from them.

PROPOSITIO I.

Of two bodies of equal bulk, the heavier descends in natural motion from the same limit to the same limit more quickly than the lighter.

[Margin: Two bodies equally large but not equally heavy do not descend with equal speed.] For twelve globes were made of solid clay, of 20 ounces, and as many others of compressed paper, coated with a shell of clay, equal in bulk to the former but of 10 ounces. They were released two at a time from the tower of the Asinelli at Bologna at the very same moment, that is, one of ten ounces and the other of twenty. The heavier struck the ground of the pavement below while the lighter was still about 15 feet from the same pavement. And with two counters employed, using the smallest pendulum, treated in chapter 20, Proposition 13, the lighter globe struck the pavement later by about three vibrations, that is, by about 30‴. This was confirmed by repeating the experiment twelve times. Neither Galileo nor Baliani denies this proposition, but they say that the interval both of space and of time between the fall of the lighter and that of the heavier is small, because they tested it at a height of only

50 or 100 feet. [Margin: Height of the tower of the Asinelli.] But the tower of the Asinelli is 312 ancient Roman feet high, as we measured it with Father Grimaldi, and it is very well suited to such experiments, since it does not taper to a peak like a pyramid or a cone, but rises four-sided between nearly parallel plane surfaces right up to the top. The distance, however, from the cornice [coronide] to the pavement of the scaffolding [parapegmatis pauimentum], the distance from which the globes were released, is 280 feet. Present at these and the following experiments as witnesses and helpers, though not always all together, were Fathers Stephanus Ghisonus [?], Camillus Rodengus [?], Iacobus Maria Pallauicinus [?], Vincentius Maria Grimaldus [Vincenzo Maria Grimaldi], Francesco Maria Grimaldi and Zenus; Georgius Cassianus [?], and others.

PROPOSITIO II.

Of two bodies of the same species, but of unequal bulk and weight, the heavier descends in natural motion from the same limit to the same limit more quickly than the lighter.

For on 1645 August 4 we released from the tower of the Asinelli a great many chalk globes, in pairs together, one of 4 ounces and the other of 8, the experiments being repeated fifteen times; and we always observed that the heavier struck the pavement while the lighter was still 4 feet or a little more from it. When other globes were used, the distance of the lighter ones from the pavement, at the moment when the heavier ones struck it, was as great as you see in the table below.

Two globes of the same bulk released together from the same height	Globe that descended more quickly	Feet by which the lighter globe stood off from the pavement
Wax, of 6 7/8 ounces; and wood, of 4 6/8 ounces	Wax	15
Wax, of 1 5/8 ounces; and iron, of 11 7/8 ounces	Iron	30
Chalk, of 9 ounces; and wood, of 2 1/2 ounces	Chalk	20
Lead, of 2 1/2 ounces; chalk, of 2 ounces	Lead	25
Lead, of 2 1/2 ounces; wood, of 2 1/2 ounces	Lead	40
Wax, of 15 ounces; and chalk, of 20 ounces	Chalk	[recte: 12, per the book's errata; the printed cell is empty, and 12 is written by hand on the leaf in brown ink in this copy]

Let those semi-empirics, whoever they are, now go and boast, dropping pebbles from a small height and seeing a tiny interval between their impact, or striking of the pavement, that all bodies released from equal height onto the same pavement reach it in the same time to the senses.

PROPOSITIO III.

Of two bodies of unequal gravity, the proportion in descent and speed is not the same as in gravity.

[Margin: Aristotle's error on the motion of heavy bodies.] This is against Aristotle, who is deservedly refuted above all by Galileo in Dialogue 2 on the system of the world and by Baliani, cited above, and by our experiments adduced for Propositions 2 and 3. For if Aristotle's position were true, then in the time in which the globe of 20 ounces completed a space of 280 feet, the globe of 10 ounces should have completed only 140, and should have been as many further feet from the pavement, whereas it was only 15 feet away. The other, lighter globes, moreover, were never distant from that pavement in the proportion by which they were exceeded in gravity, even though all were released from the same distance of 280 feet, as is clear from the table of Proposition 2.

PROPOSITIO IV.

Heavy bodies in natural descent along a perpendicular line move faster and faster toward the end, with that increment of speed which obtains among the evenly odd numbers counted from unity; or such that the spaces traversed in given times are to each other as the squares of the times; or such that the spaces traversed have to each other the duplicate proportion of that which the times have in which those spaces were measured.

The whole assertion is that of Galileo, cited above, and of Baliani, and it has quite often been proved by our experiments. The evenly odd numbers from unity are said to be these: 1, 3, 5, 7, 9, 11, 13, 15, etc. Thus if in the first quarter of an hour some heavy body has completed 1 stadium, in the second quarter it will complete 3, and in the third 5 stadia, and so on for the rest of its progress. To test this, Father Fr. M. Grimaldi and I prepared a great many chalk globes of the same bulk, each of 8 ounces, which we released from different towers or buildings, from windows or little windows better suited to taking measurements; and we used, first of all, the towers of Bologna, namely that of the Asinelli, which is 312 Roman feet high, and San Pietro, 208 feet high, and San Petronio, 200 feet high, and San Giacomo, 189 feet high, and San Francesco, 150 feet high, although we did not use their entire height, but the height that was suited to the above-mentioned proportion. Moreover, to learn more finely the time in which the released globes reached the pavement, we employed two of the smallest pendulums, treated in chapter 20, Proposition 13, in the second place, namely those of which one simple vibration is worth 10‴ of the primum mobile. Among many experiments, however, so as not to grow too long-winded, I set before my reader in the following small table the two given below, the most carefully selected and the most certain of all.

Experiments	Simple vibrations of the pendulum	Time corresponding to the vibrations	Distance completed by the chalk globe of 8 ounces at the end of the time (Roman feet)	Distance therefore completed separately in each of the equal times (Roman feet)	Ratio of the increase of speed, expressed in simple numbers (evenly odd numbers)
	5	$0^{s}\ 50'''$	10	10	1
	10	$1^{s}\ 40'''$	40	30	3
I	15	$2^{s}\ 30'''$	90	50	5
	20	$3^{s}\ 20'''$	160	70	7
	25	$4^{s}\ 10'''$	250	90	9
	6	$1^{s}\ 0'''$	15	15	1
	12	$2^{s}\ 0'''$	60	45	3
II	18	$3^{s}\ 0'''$	135	75	5
	24	$4^{s}\ 0'''$	240	105	7
	about 26	4^{s} about $20'''$	280		

In the first experiment, then, the operation having been repeated several times, we observed that from a height of 10 feet the above-mentioned globe reached the pavement in only five vibrations of the above-mentioned pendulum. We then tried out the height that a globe equal to it would cover in 10 vibrations, and we found that it was 40 feet, and so with the rest. In the second experiment, however, we took the height as given and explored the times themselves. For having found the height of 15 feet that the globe had covered in 6 vibrations, we concluded that, if the above-mentioned proportion were true, 60 feet ought to be covered at the end of 12 vibrations. Having therefore sought out a height of 60 feet that was convenient for the practice, we acknowledged this to be true, and so with the others. We could not, however, find the height due to 30 vibrations, which would have been suitable for the rest of the progression.

You now see that in the first experiment, as the distance 10 is to 40, so the square of 5 vibrations, which is 25, is to the square of 10 vibrations, which is 100; and in the second experiment, as the distance 15 is to the distance 60, so the square of 6 vibrations, which is 36, is to the square of 12 vibrations, which is 144; and so with similar cases.

COROLLARIA.

[Margin: The blunder of Simplicius and Arriaga.] I. Those therefore are wrong by the whole heaven and all the elements who, taking their occasion from Simplicius, *De caelo*, Book 1, text 88, together with our own Arriaga [Rodrigo de Arriaga], *On Generation*, disputation 4, section 5, either deny or call into doubt the ever greater increase in the speed of heavy bodies toward the end, which others commonly admit along with Aristotle, *Physics* 5, text 76, and *De caelo*, Book 1, text 88, and Question 19 of the *Mechanics*. Nor is it an objection that smoke does not rise faster at the end, as bubbles do out of water. For it is hindered by the cold air around it and by the air's constant agitations, by which it is dispersed; and the vaporous part of the smoke is deserted by the drier

exhalations flying out of its cloud. Likewise it is no objection that a leather ball falling from on high does not break a vessel which is broken by a stone released from a lesser height. For it is not the impetus acquired on the way alone that concurs in breaking a vessel, but also hardness, density, etc. Nor in these cases are the other things assumed to be equal.

[Margin: The cause of the ever faster motion.] II. It is probable that the cause of the ever faster motion of heavy or light bodies toward the end is the intensification of the impetus produced by their heaviness or lightness at every moment in which they are away from the term of their natural rest. For it is not fitting that they should lose the impetus once produced, and if it were not increased, they would remain too long in a violent place. More on this matter at some time [olim] in our *Physics*.

III. If a chalk globe of 8 ounces covers 15 feet, or 3 paces, in a single second of time, as is clear from our second experiment, then by the proportion treated in Proposition 4, if nothing else intervened to hinder or vary the motion, such as heat produced by friction and dissolving the globe, or the differing rarity of the air or aether, it would cover 10800 paces in 60 seconds, that is, in 1 minute. For as the square of 1 second, which is 1, is to the square of 60 seconds, which is 3600, so are 3 paces to 10800 paces. In one hour, however, that is, in 60 minutes, it would complete 38880000 paces. For as the square of 1 is to the square of 60 minutes, which is 3600, so are 10800 paces to 38880000. And in two hours it would complete 155520000 paces altogether. For as the square of 1 hour is to the square of 2 hours, which is 4, so are 38880000 paces to 155520000 paces. Finally, in 48 hours, or 2 days, it would complete 89579520000 paces altogether. For as the square of 1 hour is to the square of 48 hours, which is 2304, so are 38880000 paces to 89579520000 paces. But there are 5000000 paces in the Earth's semidiameter, according to what was said in chapter 8. Therefore, dividing the above-mentioned paces by this figure, we shall have the semidiameters of the Earth set down below.

	In the time	Completes ancient Roman paces	Or semidiameters of the Earth
A chalk globe of 8 ounces, of itself, and if nothing else happens, and the space is of the same density as our air.	$0^h\ 0^m\ 1^s$	3	
	$0^h\ 1^m\ 0^s$	10800	
	$1^h\ 0^m\ 0^s$	38880000	7 39/50
	$2^h\ 0^m\ 0^s$	155520000	31
	$3^h\ 0^m\ 0^s$	349920000	70 ☾
	$48^h\ 0^m\ 0$	89579520000	17916, with a star symbol

[Margin: The time in which a heavy body would descend from the Moon or from the firmament to the Earth.] IV. Those people therefore err through the greatest ignorance who, to exalt marvellously the distance of the stars from the Earth, say that a millstone [mola molendini] would hardly reach the Earth

from the firmament after many years. From this, too, the opinion that Galileo reports in Dialogue 2 on the System of the World began to be suspect to me, namely that a cannonball would not reach the Earth from the Moon except in 6 hours; and indeed the opinion of Galileo himself too, who asserts from his own experiment that a cannonball of one hundred pounds covers one hundred cubits, or 150 feet, in five seconds of a minute of an hour, and so will cover 276480 miles in 4 hours. This distance is greater than the lunar distance taken as 56 semidiameters of the Earth, with the Earth's semidiameter at 3500 miles, as he himself assumes; for then the Moon's distance is 196000 Italian miles. But to me a chalk globe of 8 ounces, and one far lighter than that cannon globe, completes 240 paces in 4 seconds of an hour. That cannonball therefore covers many more; but Galileo will have erred in assigning a time of the primum mobile to pendulums, or at any rate let his followers show by what method he attached this time to them. Nevertheless, consistently with his own hypothesis, he says that that cannonball would reach the Earth from the Moon, that is, would cover 196000 miles, or 56 semidiameters of the Earth, in 3^{h} 22^{m} 4^{s}. But for me a chalk globe of 8 ounces would complete 349920 miles in three hours, and would measure out the lunar distance in a little more than two hours. And if for Tycho the firmament is not more than 14000 terrestrial semidiameters from the Earth, the same globe would run through this distance within two days, since for me it will finish nearly 18000 semidiameters of the Earth.

PROPOSITIO V.

[Margin: The wonderful proportion between the straight and the circular motion of heavy bodies.] *Just as the different heights of the same pendulum are to one another as the squares of the times or of the vibrations, in circular motion, so the distances covered by the same weight in natural straight motion are to one another as the squares of the times.*

This is evident from what was said in Proposition 8 of chapter 20 and Proposition 4 of this chapter, taken together. Nor is there any other difference, except that in the motion of pendulums there are, within an equal time, more vibrations of the less high pendulum, whereas in the straight motion of heavy bodies descending from a greater height more times are included. Yet that proportion is admirable, and for so many centuries it was unknown to mortals.

SCHOLIA.

I. If anyone wants more on the motion of heavy solids inclined in various ways upon a plane, let him consult Book 3 of D. Giovanni Battista Baliani's On the Motion of Heavy Solids *[de motu grauium solidorum], which is followed by Book 4, on the motion of heavy liquids, Book 5, on the sections of channels, and Book 6, on the openings of a vessel. For we are not permitted to digress further in weighing the motions of this elementary sphere; we are already being swept off to contemplate the heavens, and now, even now, the Sun with its radiance is seizing us toward itself.*

[Margin: A new reciprocation of the pendulum.] *II. In 1643 there appeared a Letter of Pierre Gassendi to Gabriel Naudé, in whose postscript he treats of a twofold reciprocation of pendulums each day, like the tide of the sea, observed by Alexander Calignonus [?] of the Dauphiné. This man hung a pendulum from a height of 30 feet, with the length of its thread enclosed in a tube so that it should not feel the agitations of the air, and with a conspicuous little point fixed to the lead below. Under this point, while it was at rest, he placed another little point fixed in a cube. And he saw that the pendulum's little point diverged from the point of the cube, for six hours at a time toward the north and for six toward the south, not without a bending from north into east and from south into west; and that the limit of the excursion toward the south was reached at noon and again at midnight. And he measured these digressions, which I know have not yet been published. From this he himself and Gassendi infer, first, that the Earth nods and that this reciprocation arises from the Earth's motion, just as, in Galileo's opinion, the tide of the sea arises from that motion, because of the unequal speed of the diurnal and annual motion; but that the ebb and flow of the sea does not take place from east to west and back, as Galileo holds, but as it happens in pendulums. Second, he infers that the altitude of a star taken at midnight is not the same as that taken at the sixth hour, because of the nodding of the pendulum, and that therefore both altitudes of the Pole Star are to be taken at the sixth hour of the morning and of the evening. Gassendi points out many other things worthy of his sagacity, but things as nodding as the solidity of this experiment itself nods.*

III. For I, with Father Francesco Maria Grimaldi, using a very long pendulum protected from the agitation of the air, etc., hung from a room subject to no tremors, found by experience that after it came to rest it was never moved from the perpendicular line for a whole day, although we visited it every half-hour. And from another quarter I think myself certain, from what is to be said in Book 9 on the systems, that the Earth does not move. Moreover, as our own Fournier reports in his Hydrographie*, between Norway and Canada there are masses of ice which in springtime float from north toward south, and which never, as they would have to because of a like motion, come back toward the north. Nor does the flow between Brazil and Africa, which comes from the east, become a reflow toward the east; nor do ships there, going from Brazil to Africa, feel any resistance from this motion. So Gassendi himself objects to himself, or rather to Calignonus. The cause of a nodding pendulum, then, where it does nod, must be sought elsewhere.*

APPENDIX Ad Librum II.

The Reverend Father Georges Fournier, of the Society of Jesus, recently published a book in French in which he treats hydrography with deep and solid learning. It contains many things with which I would most gladly have enriched this book of mine, if the volume of it, which he had most generously sent me from France in the flourishing days of Father Iacobus Dinettus [Jacques Dinet], had reached my hands in good time. But by what shipwreck or other mishap I do not know: did it perish, or did it put in elsewhere? At last another

copy of it, bought by one of our men, was shared with me, when the last page of this book was already about to go to press. So in this narrow compass of time I wanted at least to point out to the reader the books and chapters in which he treats the things I dealt with above. The rest, which concern navigation or the restoration of geography, I shall review in my Geographical Book.

From the Hydrographie *of Father Fournier.*

Book 1. On the structure and parts of ships.

Book 2, chapter 9. On certain very notable towers built on the seashore, which they call Pharoi.

Book 9. On the ebb and flow of the sea, where there is much against Galileo.

Book 11. On the variation of magnetic declination, and indeed under the same meridian, chapter 12.

Book 15. On winds.

Book 18, chapter 9. On the equilibrium of the sea, where he maintains that one sea is not higher than another.

Book 18, chapter 13. On the way of exploring the depths of seas.

Book 19, chapter 8. On the distance of vision, or the extent of the sensible horizon.

FINIS LIBRI SECVNDI.

LIBER TERTIVS DE SOLE.

CAPVT I.

On the Names, Substance and Encomia of the Sun.

[Margin: The names of the Sun.] I. The Sun [Sol] is so called in Latin because it is alone [Solus] and unique in the world, always shining and imparting day to some. In Hebrew it is *Chammah*, from heat; in Greek *Phoebus*, because it is [Greek: Φῶς Τοῦ βίου (phōs tou biou, "light of life")], that is, the light of life, and [Greek: Ηλιος (hēlios, "sun")]; and it is distinguished by many other names among the Egyptians and the Greeks. For the same is *Osiris* and *Horus* and *Titan* and *Apollo*, father and sower, that is, of the celestial harmony and of music, and also of medicinal plants, and so of medicine itself; and, if we believe Virgil, of wine and the vine, and therefore the same as *Liber*, from that passage of *Georgics* 2:

> *You, O brightest lights of the world, who lead the year gliding through the sky, Liber and nurturing Ceres.*

[Margin: The encomia of the Sun.] II. The encomia of the Sun, for their part, Pliny the Elder touches on in a few words, Book 2, chapter 6, saying: *The Sun is carried in the middle of the wandering stars, most ample in magnitude and power, ruler not only of the seasons and the lands but also of the stars themselves and of the heaven.* What he adds, however, must be cured with Catholic salt. For he says: *It is fitting to believe, weighing its works, that this is the soul of the whole world, or more plainly its mind; that this is the chief government and divine power of nature.*

This supplies light to things and takes away darkness; this conceals the other stars; this tempers the changes of the seasons and the year, always reborn, according to the need of nature; this dispels the gloom of the sky and also clears the clouds of the human mind; this lends its light to the other stars as well; splendid, outstanding, seeing all things, hearing all things too. Indeed, as Philostratus records, the Gymnosophists among the Indians used to contemplate it standing for the whole day with unaverted eye, and the 365 priests of the Egyptians observed the annual course of the Sun in the city of Heliopolis: so great was the care among them for this star that cares for all things. And rightly is the Sun everywhere called the torch of the seasons, the eye of the world, the heart of the heaven, the choragus of the stars, the governor of sensible nature, the fountain of light, the theatre of appearance [theatrum ſpeciei], the parent of colours, the lamp of gladness, the inextinguishable furnace of life-giving heat, the most brilliant trace of Divinity, and truly a splendid argument for divine providence. But all these proclamations are surpassed by what divine scripture brings forth about this coryphaeus of the planets, namely Psalm 18: *In the Sun he has set his tabernacle*, etc.; and Ecclesiasticus 42: *The Sun, giving light, has looked upon all things, and full of the glory of the Lord is his work*; and chapter 43: *The Sun in its appearance announcing at its going forth, a wonderful vessel, the work of the Most High; at noon it burns up the earth, and in the presence of its heat who can endure? Keeping a furnace in works of heat, the Sun threefold burning up the mountains, breathing out fiery rays, and shining with its rays it blinds the eyes. Great is the Lord who made it, and at his words it has hastened its journey.* Lastly, the mantle of the Queen of the stars is sought in the Apocalypse from nowhere other than the Sun, and a crown for the name of Jesus from nowhere other than its rays; nor did Christ himself set out a clearer summary of the divine beneficence toward us than when he said of God: *Who makes his sun rise upon the good and the bad.*

[Margin: The substance of the Sun.] III. The *substance* of the Sun, however very bright it is, is most obscure to us, and therefore disputed. For the Peripatetics, with Aristotle, *De caelo*, Book 2, chapter 7, flatly deny that the stars are of elementary matter, and so not fiery either, but say that they possess a certain fifth substance; and that the Sun is hot not in act but only in virtue, because it produces heat in lower things, whether by light alone or also by motion and friction of the air. And Pererius [Benet Perera] adds, on Genesis, Book 2, question 10, that if the Sun were fiery, fire would be perpetually moved in a violent motion, namely a circular one, whereas the motion natural to fire is both straight and upward; likewise, that all things would have burned up long ago, or that it would long since have exhausted the vapours of the whole Ocean; although Aristotle, Book 2 of the *Meteorologica*, judges childish and unworthy of a philosopher the opinion of those who said that the Sun feeds on moistures drawn up on high.

[Margin: The Sun seems fiery to many.] These things notwithstanding, that the Sun's substance is fiery is an opinion neither new nor yet antiquated. For *Anaxagoras* thought it a glowing stone; *Zeno* of Citium, according to Laertius,

Book 7, the purest fire, taking in from the sea the nourishment of an intelligible, that is, of a very subtle, vapour; *Democritus* and *Metrodorus* a glowing mass; *Anaximander* a portion of fire appearing from an opening in a great wheel full of fire; *Xenophanes* a clot of little fires collected from vaporous breaths; *Epicurus* a pumice or sponge set alight with fire; *Plato* said it was compacted from a great quantity of fire; the *Stoics*, according to Plutarch, Book 2 of the *Placita*, chapter 20, and *Seneca*, Book 7 of the *Natural Questions*, a conflagration endowed with mind. Nor is the Sun called [Greek: Φῶς πυρὸς εἶδος (phōs pyros eidos, "light, a form of fire")] in the *Timaeus* alone; it is also called by the Atlantians, on the evidence of Diodorus Siculus, Book 3, [Greek: πῦρ ἱερὸς ἐν [?] οὐρανῷ (pyr hieros en ouranōi, "sacred fire in heaven")], sacred fire in heaven. And in *Aristotle*, *De caelo*, Book 2, chapter 13, *Pythagoras*, placing the Sun at the centre of the universe, said that fire is at the middle of the world, and called it the guard of Jupiter. That all the stars are fiery, however, the Egyptians thought as well as the Stoics, and that from this would come at last the ecpyrosis of the world, or its conflagration; on this matter Cicero says much in Book 2 of *On the Nature of the Gods*. Sacred Scripture favours this opinion, saying of the Sun: *Keeping a furnace in works of heat*, Ecclesiasticus 43. That line of the Church's hymn favours it: *On the fourth day, who, establishing the flaming wheel of the Sun*, and again: *Now the fiery Sun withdraws*. The Hebrew name *Schemer* or *Schumah*, which means *there fire*, favours it. Finally, very many Fathers favour it, whom our own *Scheiner*, Book 4 of the *Rosa Ursina*, and *Antonius Maria de Rheita* [Antonín Maria Šírek of Rheita], in *Oculus Enoch et Eliae*, Book 4, chapter 2, gather and follow; among whom *Cyril*, in catechesis 9, stated in a beautiful antithesis *a watery heaven, and in it a fiery Sun*. Of the same opinion are *Kepler* in the Paralipomena to Witelo, p. 224, *Boulliau*, Book 1 of the *Astronomia Philolaica*, chapter 7, and *Athanasius Kircher*, Book 1 of the *Ars Magna Lucis et Umbrae*, chapter 1, who call the Sun a fiery sphere, concreted from an ethereal flux, and similar to casting furnaces, or to bronze liquefied and surging in their vats, with black soots mixed in. The larger telescopes certainly show it to us as such, as a kind of ignited ocean of flames, rough and surging with waves and whirlpools. See, however, what I shall say in Book 4, chapter 2, number 2, and in Book 9.

[Margin: Whether the Sun is animate?] IV. *Origen*, moreover, Book 1 of the *Peri Archon*, judged that the Sun and all the stars are *animate*, and indeed with a rational soul, so that they were capable of virtue, vice and redemption. This is erroneous in faith, as *St Bonaventure* points out on 2, distinction 14. For Origen was condemned on this very point by the Second Synod of Constantinople, as *St Jerome* reports in the letter to Pammachius, and *Nicephorus*, Book 17, chapter 128. Nor does the Lateran Council, in the chapter *Firmiter*, acknowledge any intellectual creature other than the angelic and the human. *Pliny the Elder* too, Book 2, chapter 8, attributes a mind to the Sun; but *Achillinus* [Alessandro Achillini], Book 3 of *On the Orbs*, and *Niphus* [Agostino Nifo], *On the Substance of the Orb*, teach that the Sun has an Intelligence in place of a soul, and *Caietanus*

[Thomas Cajetan] thinks that those words of Psalm 135, *Who made the heavens in understanding*, can be taken of an intellective soul of the heavens, and that this is the power of the heavens often expressed in Sacred Scripture. On this matter, according to Aristotle's meaning, *St Thomas*, *Contra Gentes*, Book 2, chapter 70; *Aureolus* [Pierre Auriol], as reported by Capreolus [Jean Capréolus], on 2; *Scotus*, in the same place, distinction 14, question 1, saying: *If the stars are not animate, this has been believed rather than demonstrated.* A soul lower than the intellective, however, was attributed to the stars (that is, one either sentient or vegetative or at least formative), and one that moves itself and others to the Sun, by, besides the Pythagoreans, Platonists and Stoics, *Simplicius*, *De caelo*, Book 1, comment 50; *Avicenna*, *Metaphysics* 9, chapter 2; *Scaynus* [Antonio Scaino], in his *Miscellanies*, chapter 16; *Mirandulanus* [?], *Monomachia* 19, section 2; *Philalthaeus* [Lucillo Filalteo], *De caelo* 2, text 13; and *Kepler*, in his *Mars*, Part 3, chapter 33. That this can be sustained as probable is affirmed by *Ferrariensis* [Francesco Silvestri], *Contra Gentes*, Book 2, chapter 70, and *Martinengus* [?], volume 2 on Genesis, p. 883.

On the contrary, many interpreters of Aristotle, on *Physics* 8 and *Metaphysics* 12, deny any soul whatever to the Sun and to all the stars. For Aristotelian Intelligences, they say, are forms assisting these bodies, not informing them; and there is no differentiation of organs, or any animastic effect [animasticum effectum], from which a soul in them could be inferred. So too *St Thomas*, First Part, question 70, article 3; and, as reported by Pererius, Book 2 on Genesis, question 7, Saints *Basil*, *Cyril of Alexandria*, *Damascene*, *Jerome* and *Ambrose*, although *St Augustine*, according to the same author, was in doubt on this matter. Yet to some, Aristotle seems to have attributed to the heavens, besides the assisting Intelligence, a kind of material soul; but this is not worth discussing here.

CAPVT II.

De Solis Qualitatibus, Lumine præsertim ac Figura Rotunda, & quandoq. Elliptica. [On the Qualities of the Sun, Especially Its Light and Its Round and Sometimes Elliptical Shape.]

The principal QUALITIES of the Sun seem to be *Light, Heat, Colour, Density, Opacity, Motive Force, Productive Force* and *Shape*. About these, much remains for natural philosophers to point out, and little for us, as astronomers.

[Margin: Light comes from the Sun, and is greatest in the Sun.] I LIGHT, which we see in the Sun, is not from the Sun itself but kindled by the fixed stars, said *Leucippus*, according to Laertius, Book 9; or by the Element of Fire, said *Philolaus* and *Empedocles*. But all the most distinguished lights among philosophers and astronomers acknowledge the Sun itself as the source of cosmic light. [Margin: For the opinion of Philolaus and Empedocles see below, number 5.] And not only do all the planets and the Moon, Venus and Mercury in particular, receive their primary light from the Sun, but also the comets

above the Moon and the new stars, as *Giordano Bruno* holds, with many others, in his book *De immenso et innumerabilibus*; and indeed so do the non-wandering stars, according to *Scheiner*, p. 71 of his *Disquisitiones Mathematicae*. Bruno, on the contrary, thinks that the fixed stars are Suns, wholly luminous of themselves and through themselves, and innumerable and infinite besides. But *Kepler*, in his *Dissertatio cum Nuncio Sidereo* of Galileo, does not hesitate to affirm: *The body of this Sun of ours is brighter by an inestimable measure than all the fixed stars together.* This is because the fixed stars, taken together, pour so dim a light into the most open places of the universe, whereas the Sun, through a single tiny opening in a window, lights a room so well that small letters can be read through by that light, which the whole light of the fixed stars does not achieve. To me, however, it does not seem improbable that, if as many fixed stars were to come together into one globe as would equal the bulk of the Sun, and were no less distant from the Earth than the Sun is, their gathered force, made nearer, would light the lands as much as the Sun does now; and, conversely, that a particle torn off the Sun, of the size at which Sirius or the Bright Star of Lyra now appears, would not greatly exceed the light of these stars. And *Descartes*, Part 3 of his *Philosophy*, number 9, holds the fixed stars to be neither smaller nor less bright than the Sun. As for whether all that light which was made by God on the first day of the world was on day 4 imparted to the Sun alone, or distributed among all the stars, or whether in its place another light flowed from the stars, let the interpreters see to that on chapter 1 of Genesis.

[Margin: The colours of the Sun.] II No COLOUR among the real colours is necessarily asserted of the Sun; for the phenomena it is enough to have the colour the Schools call intentional [intentionalem], which varies with the varying mixture of light and opacity, both in the body of the Sun itself and outside it, because of the vapours of the horizon or various clouds. For this is why it appears to us now glowing white, now crimson, now golden, now flame-blue, and sometimes pale, ashen or rust-coloured.

[Margin: The heat of the Sun.] III HEAT is asserted or denied of the Sun by almost the same arguments as a fiery substance is; on these, chapter 1, number 3, above. For it is not enough that heat is produced by the Sun in sublunary things for it to be called hot itself, in act and formally, and not merely in virtue and power. By what means the Sun produces heat in sublunary things, though this is not part of our plan, will be touched on below in chapter 5, in the discussion of parallelism and the Sun's illumination.

[Margin: The density of the Sun.] IV The DENSITY of the Sun, according to *Kepler*, *Astronomia Optica*, chapter 6, is so great that there is as much matter in the Sun alone as in all the rest of the ethereal air of the universe. For he says that so great a density is required by its heat-producing force, so sharp and reaching so far. That is why, he says, coals burn more than flame, and white-hot iron more than a coal: namely because of density, or a greater multitude of parts in the same space. This author adds that the water from which *Moses* indicates the heavens were made was thinned in the expanse of the aether as much as it

was condensed in the Sun, so that the body whose force had to permeate the whole aether should contain within itself as much matter as is contained in the entire aether. But this argument is very much a dialectical one [topicum]; for there is not as much matter in the heart of animals as in all the rest of the body, even though its force spreads to the whole body.

[Margin: The opacity of the Sun.] V. Some OPACITY certainly appears in the Sun, since it bounds our sight and we cannot see through it to what lies behind it, whereas we do see across the flame of our own fire, which is certainly endowed with some opacity. [Margin: But with diaphaneity.] Yet that the Sun is not wholly opaque, but, like very dense crystal, so diaphanous that our sight makes its way into the depth of the solar body and rays reach us not from the surface alone but also from the centre of the Sun, was affirmed by some of the Pythagoreans and by Empedocles. For so *Plutarch* relates, *On the Opinions of the Philosophers*, Book 2, chapter 20: *Philolaus the Pythagorean said that this disc is glassy, receiving the reflected brightness of the cosmic fire and turning the light back towards us; so that the Sun seems to be a fire in the heaven which scatters light to us as if by the reflection of a mirror; and this we call the Sun, as if the image of an image.* Plutarch goes on and says: *Empedocles makes two Suns: one, which is the primordial fire in one hemisphere of the world, placed opposite the reverberation of its own splendour; the other in the other hemisphere, which is the reflected brightness of the first, cast from the roundness of the Earth onto the crystalline Sun, with the motion of the fiery Element; and, to say it in one word, that the Sun is the reflected brightness of the fire that is around the Earth.*

But in *Astronomia Optica*, p. 223, *Kepler* teaches that the Sun was made from water condensed to the highest degree and purified, and is therefore so transparent that rays reach from its centre to the surface, and, refracted at the surface into the rarer aether, reach us from the aether; and that the interior of the Sun is thus seen by us through refracted rays. This is perhaps why the interior of the Sun looks blue to us, although its limb appears yellow: the opacity of so great a depth presents that apparent colour, as happens in the deeper parts of a crystal suffused with light. Near the horizon, moreover, it is seen, with the help of a spyglass [tubospicilli], to be like glass melted in furnaces.

[Margin: The force moving the Sun.] VI. The MOTIVE FORCE by which the Sun is carried around, whether by a motion of spin about its own centre or by one of translation around the Earth: since it does not come from an informing soul, as I consider more probable from what was said in chapter 1, number 4, it remains that it comes from something extrinsic, and very probably from some Intelligence. *Ecclesiastes*, chapter 1, seems to have indicated this Intelligence under the name of Spirit, when it says: *The Sun rises and sets, and returns to its place; and, being reborn there, it circles through the South and bends toward the North: surveying all things round about, it goes on*

Spirit. I am aware, however, that *St Jerome* and some interpreters understand something else by the name of Spirit in this passage. But this question about the motive force of the stars or the heavens is a general one, to be put off to

Book 9, on Systems and Hypotheses. Meanwhile I would have you advised that, if the Sun moves actively and from an intrinsic source, it moves for the good of the other planets and of sublunary things in such a way that it still moves for its own good: not only because it receives in turn from the planets a varied mixture of influences, but also because its own good is to exert and show its force, and to discharge the office to which God destined it, according to that line of the Psalm: *By your ordinance the Day continues, for all things serve you.* But if it is said to be moved from outside by an Intelligence, this motion will still not be perpetually violent for the Sun, because it suits the Sun's passive potency, which demands such a motion; and it does not tend to the Sun's destruction, but to making its perfection manifest without harm to it, and to spreading that perfection into so great a variety of effects. Nor do Intelligences need an animal power to move the stars, whatever *Kepler* may say in Book 4 of the *Epitome of Astronomy*, p. 508.

[Margin: The magnetic force of the Sun.] VII The MAGNETIC FORCE, of drawing the planets to itself by that part in which they are friendly and sympathetic, and of driving them away by that in which they are hostile and antipathetic, is attributed to the Sun by *Kepler*, *Astronomia Optica*, chapter 6, and in the *Commentaries on Mars*, Part 3, chapters 33 and 34. For he says that the Earth and the other planets are seized by the Sun, through its light, as if by a hand; and that while they are attracted and driven away, or while they themselves resist less or more by their agility or their inertia, they are at last turned into a circuit by the Sun, which is spun about the centre of its body; and that therefore those more distant from the Sun move more slowly, and the same planets most slowly when they are aphelion [Aphelij], that is, farthest from the Sun, and most swiftly when they are perihelion [Perihelij], or nearest the Sun. He had also indicated this in Book 4 of the *Epitome of Copernican Astronomy*, Part 3, question 5, saying: *For carrying the planets around towards the East, the Sun has in place of hands the power of its body, sent out in the straight lines of its rays into the whole extent of the world.* But this very motive force, he says, comes from the corporeal soul of the Sun, which is the former of forms in sublunary things, much as the formative faculty of the foetus is in the womb of living creatures. *Boulliau*, on the contrary, *Astronomia Philolaica*, Book 1, chapter 12, and Book 4 of his *Philolaus*, chapter 2, holds that all the planets move from an intrinsic source, because they move of necessity; an argument that is by no means necessary. *Kepler* adds, in the *Epitome*, p. 586, that these fibres pass from sign to sign by the motion that is otherwise attributed to the Sun's apogee, and he shuts the Earth within a crust. Of this fiction, elsewhere.

[Margin: The shape of the Sun.] VIII The SHAPE of the Sun appears round to us when it is raised far from the horizon; and most, with the Stoics, did indeed judge the Sun to be spherical, according to *Plutarch*, *Placita*, Book 2, chapters 20 and 22; where, however, he reports that it seemed flat to *Philolaus* and *Anaximenes*, in the manner of a disc or a circular table, and to *Heraclitus* like a bowl [Scaphij]. *Biancani*, nevertheless, *Sphaera*, Book 10, chapter 11, thinks

that all its phenomena are saved if the Sun is said to be hemispherical. But the spots, narrower at the Sun's limb and wider in its middle, give a probable argument that it is spherical and moves by a spin about its own centre. Add the nobility of the spherical shape, which suits the noblest of the stars, spreading its rays equally in every direction into the upper and lower world.

[Margin: Why the Sun appears flat?] IX Yet the Sun appears flat because of its huge distance. For according to *Euclid*, *Optics*, theorem 25, and *Ibn al-Haytham*, Book 3, proposition 25, *a sphere viewed from afar appears as a circle*, because sight cannot distinguish the greater distance of the edges from us from the lesser distance of the parts in its middle; and so we judge all its visible points to be equally distant from us and therefore to make up a flat surface. And because of the same distance we cannot certainly distinguish the angles of the stars, if perhaps they are hexagonal, or many-angled, or spherico-angular, as *Giordano Bruno* thinks they are. For not even a flame appears pyramidal when it is very distant, since according to *Ibn al-Haytham*, Book 3, propositions 25 and 59, *a many-sided figure seen from a great interval appears without angles, and circular.* [Margin: The roughness of the Sun.] Certainly the Sun, viewed through the larger telescopes, seems to have a rippled and gently uneven surface, as *Scheiner* acknowledged in the *Rosa Ursina*, p. 604, although he had earlier, in the *Disquisitiones Mathematicae*, p. 31, attributed that unevenness, seen especially when the Sun is viewed near the horizon, to vapours of the horizon raised shortly after its rising; while *Athanasius Kircher*, Book 1 of the *Ars Magna*, Part 1, chapter 1, attributes it to the eruption and whirlpools of flames flashing out perpetually from the Sun. But let the Sun at least be for us as round as the globe of the Earth, namely physically, and in such a way that a moderate unevenness of surface does its roundness no more harm than the mountains and valleys of the Earth, or the little valleys and little hills on the surface of an orange,

Diagram. A hatched oval, wider than it is tall, in the right column: the appearance of the Sun grazing the physical horizon, as the text below describes it. A dotted horizontal line AB and a dotted vertical line through C cross at the centre.

- A (left end of the horizontal dotted line): label only
- B (right end of the horizontal dotted line): label only
- C (top, at the head of the vertical dotted line): label only
- K (top edge, left of C): label only
- L (top edge, right of C): label only
- D (just right of the crossing of the dotted lines): label only
- G (lower part, beside the vertical dotted line): label only

Diagram. Directly below the first figure, a second hatched oval, nearly circular and slightly wider than tall: the appearance of the Sun a few degrees above the horizon, as the text below describes it. No lines drawn in it.

- H (centre): label only

[Margin: The elliptical Sun.] X Now, on the very horizon and near the horizon, at rising as well as at setting, the shape of the Sun appears egg-shaped

and as if elliptical; but in such a way that the higher it is raised above the horizon, the more and the sooner that ellipse is reduced to a circular shape, as can be seen in the two figures here. In the first of these, AB, is shown the appearance of the Sun grazing the physical horizon with its lower limb; in the second, H, the appearance of the Sun standing a few degrees above the horizon. This appearance [Emphasis] is not a mere mockery of the eyes, or a deception arising from the humours of the eye and from the contraction of the pupil in height and its dilation in breadth. Nor does it come from the glass of the telescope, since this phase is seen both with the naked eye and on a white tablet, or on walls facing the rising or setting Sun, and this solar ellipse [Ellipsis hæc Helliaca] is the greater the thicker the vapours of the horizon are. Nor is it in the Sun itself, since far from the horizon the Sun appears circular. It is therefore in the image, or likeness, of the Sun formed in the vapours of the horizon, and in its appearance transmitted to the eyes through refracted rays, as our own *Scheiner* learnedly teaches in the little book entitled *Sol Ellipticus*, and, following him, *Bettini*, *Apiaria* 8, *Progymnasma* 4, proposition 3. This is confirmed by the signs and properties of refraction, which in this phenomenon is greater in the part nearer the horizon, and there takes a steep and sudden increase. This phenomenon is therefore an offspring of refraction, born in the atmosphere. We shall give its causes more subtly in our book on optics; for the moment it is enough to have indicated the chief ones.

[Margin: The cause of the Sun's ellipse.] XI Since, therefore, the rays of the Sun fall from the purer air onto the denser spherical surface of the atmosphere, which is concentric with the Earth, some of them perpendicularly and without any refraction, others obliquely, though from the same point of the Sun (of which kind are those that reach our eye, placed outside the centre of this atmosphere), and more obliquely those fall that flow from the lower point of the Sun, say G, than those from the upper, say C. They are therefore refracted towards the perpendicular, in the surface of a vertical plane, say CG, as the common law of refractions requires; and the ray, inclined towards the centre of the atmosphere and of the Earth, is carried higher towards the sky, and also shows us the part of the Sun it flowed from in a higher position. And the refraction upward, whether in the circle of altitude or in the vertical CG, is the greater the more oblique the ray's incidence on the surface of the atmosphere. Therefore the lower limb of the Sun, G, appears higher than the upper, C, and so the diameter of altitude, which is CG, is contracted. But at points A and B this refraction takes place according to altitude in such a way that another slight refraction does indeed follow from it, by which the distance AB is diminished; but this is insensible, and so the Sun's diameter in the transverse length AB is not sensibly contracted. Since, then, the diameter CG is contracted and the diameter AB is not sensibly contracted, the Sun appears to us as an oblong spheroid, and as an ellipse or ellipsoid ACBG. Again, because point G is refracted upward more than point D, and D more than C, the semidiameter of altitude GD comes to appear more contracted than the semidiameter DC, and

this ellipse appears blunter at G than at C. And what has been said of point C relative to G is to be understood proportionally of any point of the Sun relative to lower points, say of points K and L: namely, that they are refracted upward less than the lower points, those nearer the horizon. But if it were refracted equally, the Sun would appear round to us; or if the refractions, as it rises from the horizon, were of the same measure, it would look elliptical to us all day. But because they diminish, this ellipse at length becomes smaller, as in H, and finally vanishes into a circular disc. When the Sun is about to set, however, it is seen first as in H, and while it sets a larger and more oblong ellipse appears, as in ADB. You will see something similar in the flame of a candle if you tilt a curved glass lens placed between it and your eye, so that the lower rays strike it more obliquely than the upper ones.

SCHOLIA.

[Margin: The first observer of the elliptical Sun.] *I Since the elliptical Sun is seen every day at rising and at setting, when the sky at the horizon is clear, it is astonishing that the older writers on optics either did not notice this phenomenon or wrote nothing about it; indeed, Ibn al-Haytham, Book 7, proposition 55, and Witelo, Book 10, proposition 54, declared universally that the stars appear round on the horizon. Yet Strabo, Book 3, seems to have indicated it, when he reports from the opinion of Posidonius:* because of moist vapours the broken line of sight takes in broader images of the Sun and the Moon when rising or setting. *But to Scheiner, to whom, as the prerogative of observing the solar spots, so too the task of bringing this elliptical falling-short of a perfect circle to measurement through observations had been reserved by divine gift.*

[Margin: The difference between the diameters of the elliptical Sun.] *II Since, from Tycho,* Progymnasmata, *Book 1, chapter 1, and his table, which we shall give at the end of the work, the Sun's refraction at the horizon is 34′, such will be the refraction of point G. But when the Sun is half a degree high, that is 30′, which is very nearly the Sun's apparent diameter at apogee, at noon, and so when the whole Sun stands clear of the horizon and G touches the horizon, then, I say, its refraction by Tycho's reckoning is 29′. Therefore the limb G is raised 5′ more than the limb C, and the difference of the diameter GC at the horizon from the diameter of the Sun placed far from the horizon can be at most 5′ or 6′. But the diameter of the transverse length ADB, because of the refraction that diminishes distances, does not reach 1″. For Kepler, in* Astronomia Optica, *p. 130, and we in our book on optics have demonstrated that if two stars on the horizon, or two bright points A and B, were 90° apart, their distance would not be diminished by the force of refraction in altitude by a full 18″; if they are 45° apart, it is not diminished by 10″; and finally, if they are 5° apart, it is not diminished by one whole second. Now the extremes of the Sun, A and B, are not 5° apart, but only half a degree. What wonder, then, if it appears sensibly contracted along the diameter of altitude CG, but not along the length AB? But what if, because of another kind and cause of refraction, the Sun's diameter AB appears greater on the*

horizon than at noon, while the diameter CG is not equally greater? On this part of the phenomenon, however, more when we treat of the apparent diameters of the Luminaries, especially in our book on optics.

[Margin: When and where the solar ellipse vanishes.] *III Although the Sun and the Moon undergo sensible refraction up to 45° of altitude from the horizon, the difference of refraction of the points G and C becomes insensible around an altitude of 18° or 20° according to Scheiner, or at least 25° by Tycho's reckoning. For the difference between the Sun's two diameters lasts somewhat longer from the Tychonic table than from the observations of Scheiner and from ours; for we too have often measured both diameters of this ellipse on a white tablet. But we have weighed both his observations and ours, and will show them to you in the book on optics, volume 2 of the* New Almagest. [Margin: The affinity of the solar ellipse with twilight.] *Meanwhile the Sun's morning ellipse seems to fail at the same altitude as the depth at which evening twilight fails, and its evening ellipse to begin at the same altitude as the depth of the Sun below the horizon at which morning twilight begins, namely around 18° or 20° in both cases. But in the parallel sphere, since the Sun circles the horizon more closely for whole continuous days, it must be seen as elliptical for many weeks and months on end.*

CAPVT III.

De Solis Maculis, & Faculis. [On the Spots and Faculae of the Sun.]

I For 55 centuries and more the Sun had rolled on for the world, with the fame of its whiteness and of its ever undefiled splendour intact. For the eclipses imputed to the Sun are eclipses not of the Sun, which is not deprived of light, but of our eyes, which are cheated of the Sun's light by the interposition of the Moon. But what the living eye of mortals in its simplicity had not suspected, it dared to detect, with its eye doubled, so to speak, and with the fragile transparency of glass lenses, dead ones though they are, taken on within a tube: blemishes in the face of light, *Spots in the Sun*. (For that is what those celestial corpuscles near and around the Sun are called, blackish on the part of them visible to us.) It detected also certain small areas brighter than the rest of the Sun's surface, and flame-vomiting, which they have called *Faculae*; of this kind, in the following figure, are the Spots F, G, D and the Faculae K. For semi-transparent corpuscles, which transmit some of the Sun's light, they have called Shadows rather than spots; although, from our Society, *Carolus Malapertius* [Charles Malapert] has called all these corpuscles the Austrian Stars.

[Margin: Who was the first discoverer of these spots, Scheiner or others?] And in the past, indeed, *Adelmus* noted one spot in the Sun and *Auen Rodan* [?] two, at different times, but they took them for Mercury, as I shall say in Scholium 2. But after these, the first who noticed them and distinguished them from every other known star was Father *Christoph Scheiner* of the Society of Jesus. In 1611 May, at Ingolstadt, on the occasion of investigating the Sun's apparent diameter with the help of the telescope, he noticed these corpuscles

and pointed them out in person to Fathers *Iacobus Gretserus* [Jacob Gretser] and *Adamus Tannerus* [Adam Tanner], and by letter to *Angelo Lynceo* [?] and *M. Velsero* [Markus Welser], as he himself shows in the *Rosa Ursina*, from chapter 1 to chapter 6. But because Father *Theodorus Busaeus* [Theodor Busaeus], then Provincial, did not want the novelty of this phenomenon to be published by him at once, his name had to be suppressed for the time being; and the three letters to Markus Welser on this subject bore in front of them the feigned name of a painter, namely *Apelles behind the picture*, secretly listening to the judgements of others, so that the man who had rather timidly painted for us the genuine face of Apollo, that is, one stained or dark in places, might be called Apelles and yet stay hidden. Welser's letters, spread into Germany and Italy, roused *Galileo* above all to observe these spots and to write back to Welser his judgement on them, weighing in as many letters the sayings of Apelles behind the picture. Nor indeed does any observation of these spots older than 1612 survive in Galileo, although *Kepler* in his *Ephemerides* affirms that they were observed in 1611 by the son of *David Fabricius*. [Margin: The praise of Scheiner.] This at least is certainly agreed: that *Scheiner* once again these spots and the solar faculae observed at Rome for several years, in the presence at times of very learned and very distinguished men, who visited this Apelles, no longer in hiding, and marvelled at the Sun painting on the cleanest paper by means of its own ray and of the images [speciebus] conveyed through the telescope. Father *Nicolao Zucchio* [Niccolò Zucchi] urged him to repeat his [Greek: τηρήσεις (tērēseis, "observations")], and the bitterness of the objections sometimes drove the good old man to tears; yet he carried this through with such diligence, shrewdness and circumspection that he bore with the Sun through more than two thousand observations, and handed down to posterity the position, place, shapes, sizes, risings, perishings, revolutions and periods of the spots so splendidly that, by making better observations a thing to despair of, he has conquered others, himself and the Sun. Nor did *Descartes*, in part 3, number 35, of the Principles of his new Philosophy, undeservedly pronounce: *nothing more diligent could be wished for in this field*. [Margin: Other observers of the spots, or writers on them.] Granted that the same spots have been observed and expounded to us by *Galileo* in his book on the Sun's spots; by *Malapert* in his *Austrian Stars*; by *Biancani* in the *Sphaera*, Book 10, chapter 21; by *Chiaramonti* in the *Anti-Tycho*, part 4, chapter 22; and by many others, of whom in number 9. And granted that certain things about these spots are touched on by *Tanner*, *De caelo*, part 1, disputation 6, question 3; *Martinus Hortensius* in the Dissertation with Gassendi on Mercury seen under the Sun; *Kepler* in the *Ephemerides* from p. 17 to p. 20, and after the *Sidereus Nuncius*; *Io. Cottunius* [Ioannis Kottounios], Book 1 of the *Meteorologica*, lecture 31; *Auersa* [Raffaele Aversa], question 34, section 9; *Mastrius* [Bartolomeo Mastri], *De caelo*, disputation 2, question 2, article 3, from number 91; *Argoli* in the *Pandosion Sphaericum*, chapter 44; *Boulliau*, Book 1 of the *Astronomia Philolaica*, chapter 8; and *Šírek* in the *Radius Sidereomysticus*, Book 4, chapter 2, from member 4 to 7.

From these, and from some observations of our own made long ago at Parma with Biancani and others, we have thought it right to select these few points.

[Margin: Method of observing the Sun's spots.] II The Sun's spots are observed either by direct sight, but with the Sun shaded by thin vapours, clouds, silk veils of rather open weave, or coloured glasses; or by reflection, from a plane mirror that throws the Sun's image on to paper about 20 feet away; or by receiving the Sun's image, through a tiny hole or through the lenses of a telescope, on very clean paper parallel to the hole or lenses and more than 4 palms from them, with the room moderately darkened all round. The best part of the day for this is the one in which the Sun stands at the 90th degree of the ecliptic counted from the horizon. If you use only two lenses and do not add a third to erect the images, they will appear in an inverted position: those on the right on the left part of the paper, the upper ones in the lower part, and so on. [Margin: The reality of this phenomenon.] Now since the spots have been observed by all these methods at the same hour of the same day, and found in the same position and with the same shape and size, it is clear that they are not bubbles or knots in the glass, nor fleeting little clouds of the air, nor mere tricks of the eyes, but a real phenomenon, and one that persists for some days.

Diagram. In the left column: a circle representing the Sun's disc, crossed by two parallel horizontal lines, an upper one between F and D and a lower one, the diameter, between A and C. Dark irregular spots lie scattered over the disc, and hatched spots lie on the limb at F and D; four star-shaped, flame-like figures stand two above and two below the lower line, each beside a K.

- K (upper left, beside a star-shaped figure)
- G (upper centre, above a large dark spot on the upper line)
- K (upper right, beside a star-shaped figure)
- F (outside the circle, left, at the upper line)
- D (outside the circle, right, at the upper line)
- A (outside the circle, left, at the lower line)
- C (outside the circle, right, at the lower line)
- B (centre, just below the lower line)
- K (lower right of centre, beside a star-shaped figure)
- K (lower left, below a star-shaped figure)
- M (lower centre)
- M (lower right of centre)

[Margin: Colours of the spots.] III The colour of the spots, such as D, F, G, M, is black or dark blue; that of the shadows, blackish; that of the faculae K, K, a brilliant white or yellow. The faculae seem to be either brighter small areas of the Sun, or little flames suddenly breathed out from it, or, if you listen to Šírek [Rheitensem], the Sun's light thrown back from the more remote spots on to the spots nearer the Sun. Many of the spots look blacker near the Sun's limbs, if they merge with others as at D and F, than in the middle at G, where, being semi-transparent, they are faintly lit by the Sun; though not so much that they are not darker than the Moon's usual spots and than some clouds,

since in the solar eclipse of 1612 May 29 they looked blacker than the parts of the Moon penetrated by the Sun, and are seen here and there through the rarer clouds themselves. So, at least, *Scheiner*. *Galileo*, however, maintains that near the limbs they are less black, because the segments of them lit by the Sun are uncovered to us and their backs are seen confusedly and at a narrower angle, although the obliquity of the line of sight at which they are seen near the limbs could make them look darker to us, in the way that panes of glass seen with their surface tilted look darker than when they are viewed straight on. He adds that the spots, on the side on which the Sun lights them, are brighter than the brighter parts of the Moon at full Moon, because the spots do not appear less clear and bright than the field around the Sun; yet in that field Venus is not seen, because of the excessive glare of the neighbouring Sun, nor would the bright parts of the Moon themselves be seen. Therefore, if the spots are brighter than the Moon and Venus, how much more so than the darker parts of the Moon! But I flatly deny that the spots are as bright as the atmosphere, or field of aether, immediately surrounding the Sun.

[Margin: Shape of the spots.] IV The *shape* of the spots usually appears irregular, and very unstable in one and the same spot, so that hardly any appears on the following day such as it was seen the day before. Near the limbs, as at D and F, they contract and become oblong; but near the middle of the Sun, as at G or M, they appear broader but less long, other things being equal. And again, near the limbs, several spots that had appeared scattered and separated from one another in the middle of the Sun's disc seem to come together into nearly one spot. This is a strong argument either that the spots move around the Sun's globe, or that the Sun turns by rotation about its own centre and carries such corpuscles around with it, and that therefore, near the Sun's edges, they grow thin individually but become closer to the others in appearance.

[Margin: Number of the spots.] V The *number* of the spots is variable and uncertain. At times, however, 50, and at times 33, have been distinctly counted at the same moment; but sometimes one or another, and sometimes none, and then the weather was, other things being equal, hotter and drier. Thus in 1618, when the Beam and the Comet shone, no spot was observed, says *Argoli* in the *Pandosion Sphaericum*, chapter 44. Nor in 1632, from July 12 or 19 to September 15, a time of remarkable drought, could [poſuit] [recte: potuit] any spot be detected on the Sun, at Rome by *Grienberger*, at Mazzorbo [Mazorbi] by *Argoli*, or at Cesena or Pisa by others, as *Chiaramonti* and *Argoli*, cited above, attest. Moreover *Fortunius Licetus* [Fortunio Liceti], in Book 6 of *De novis astris et cometis*, says that it was often observed at Padua by *Vincentio Fridiano* [?] that in clear and rather dry weather no spots of the Sun, or fewer, appear; and *Šírek* [Antonius Maria Reithensis] says the same, Book 4, chapter 2, member 9, of the year 1642, adding that in June it was cold because of the multitude of the spots. [Margin: Hence the uncertainty of astrology.] Let the astrologers go now and, since these contributory causes [concausis] of meteorological changes were unknown before this time, acknowledge the uncertainty of their predictions.

[Margin: Size of the spots.] VI The apparent *size* of the spots is likewise variable and unstable. *Scheiner*, in *Apelles behind the picture*, p. 14, sets Venus equal to the middling spots and, as he himself judges of Venus, at 3′; and, p. 25, he sets the largest of the spots, observed at the beginning of January 1612, equal to Venus and greater than Mercury. In my observation notes I have met with none larger than a tenth part of the Sun's apparent diameter. *Biancani*, however, says that a certain spot occupied a fifth part of the Sun's diameter and was therefore equal to the whole Earth, since the Earth's diameter is a 5½th part of the Sun's diameter. *Galileo*, for his part, likens the rather large spots to Asia and Africa together with the Mediterranean. *Chiaramonti* attacks this in the *Anti-Tycho*, chapter 23, denying that, even if a spot were as large as the Earth, it could, placed near the Sun, cast a shadow that would reach our eyes, or indeed one whose apex would descend below the heaven of the Sun. That is true of a shadow simply so called, but not of a penumbra, which, while it lacks some direct rays, is still lit by certain other rays. *Scheiner*, again, in the *Rosa Ursina*, acknowledges some spots to be to the Sun's diameter as 10, as 50, as 100 to 2000; some to be larger than Africa, not a few larger than the Moon, and certain compound ones equal to the entire surface of the Earth.

[Margin: Duration of the spots.] VII The *duration* of the spots seems less constant than that of certain small areas and faculae. Some, arising suddenly in the middle of the Sun's disc, and others arising elsewhere, vanish shortly afterwards; some last 1, 2, 3, 10, 15, 20, 30 days; very few, 40. Some return the same after a period of about 27 days. Under the Sun, moreover, these linger longer on the diameter ABC itself than far from the centre, for example in the paral- lel FGD. As for rising and perishing, not only apparent and optical but also real and physical, they are granted to some spots by *Scheiner*, *Galileo* and *Biancani*.

[Margin: In which direction do the spots move?] VIII. The apparent motion of the spots, or the rotation of the Sun carrying the spots around, is like that of Mercury and Venus around the Sun. In the upper part of the epicycle, on the arc of direct motion, in which they linger longer, these planets move from west towards east, but in the lower part towards the west. That is why *Galileo* says, absolutely, that the spots, which move so as to complete a period in 27 or 28 days and return, move towards the east; whereas *Scheiner*, attending to the motion visible to us, had said that they move towards the west, since they are then below the Sun. For in the morning, as the Sun rises, the spots ascend from the lower parts of the Sun, but in the evening they descend to the lower parts of the Sun. [Margin: And when the motion is rectilinear, when curvilinear.] Now those that appear in the winter season travel from the southern rising to the northern setting, and those in the summer from the northern rising to the southern setting. Their paths are similar, and pass from rectilinear into curvilinear. For from Sagittarius into Taurus inclusive, with the lower pole of the solar axis turned towards the Earth, the path of the spots appears curved upwards on the Sun's disc; but from Gemini into Scorpio, with the same pole

turning away from the Earth, their path appears curved downwards. At the intermediate times, about the beginning of December and of June, it looks rectilinear. [Margin: The apparent inequality of the motion.] This motion is uniform in itself but apparently unequal: it looks slower near the Sun's limbs than far from them, and is fastest in the middle of the solar disc, exactly as the motion of corpuscles adhering to a sphere turning uniformly about its own centre requires. This rather confirms that the Sun's body is spherical and carries the spots around by its rotation. From this inequality around the Sun it comes about that, although no spots have properly been seen ever to go backwards, a certain direct motion, a certain retrograde motion with respect to the Sun's centre, and a certain station can nevertheless be granted to them. [Margin: The speed of the spots.] *Scheiner* adds that the speed of the spots that remain under the Sun's disc for 14½ or 15 days is so great that in one natural day they cover 5693 miles on a great circle of the Sun; but this depends on the distance and size of the Sun that he himself assumes, which is not the same among all authors. [Margin: The Sun's axis is mobile.] The whole motion, of 27 days or a little more, he calls monthly, and he says that it takes place around an axis of the Sun that is not immobile but mobile with a slow, annual motion. By this motion the Sun's axis is inclined and its poles move in such a way that the southern pole of the axis around which the monthly motion takes place rises for us about the beginning of December, and the northern then sets, whereas about the beginning of June the southern is hidden and the northern rises; and from this inclination of the axis of the solar body to the ecliptic arises the curved path of the spots. But many matters of subtler inquiry about the motion of these spots, and about the poles and the axis on which that motion takes place, we deliberately reserve for chapter 12 of the ninth book and of its fourth Section. For from this motion *Galileo* draws one of his strongest arguments for the annual motion of the Earth, to be set out in that Section, and so we shall digress on this motion there at the proper time.

[Margin: The distance of the spots from the Earth.] IX. The *place* of the spots, or their *distance from the Earth*, is commonly judged to be above Mercury at perigee, and there is now no one who does not grant that they are either on the Sun's surface or as if contiguous with it, because no parallax from the Sun has been observed in them, let alone one smaller than Mercury's. Rather, on the same day the same spots have been observed in the same part of the Sun, with a motion uniformly proportional to the motion of the Sun and far slower than the motion of Mercury, however remote from one another on the Earth the observers were, as appears from the figures and from the history of the observations. [Margin: The agreement of the observers.] Thus, indeed, they were observed at Ingolstadt by *Scheiner* and *Cysatus* [Johann Baptist Cysat]; at Padua and Florence by *Vincentius Fridianus* [?] and *Galileo*; at Rome, again, by *Scheiner*, *Grienberger*, *Paulus Guldinus* [Paul Guldin] and *Niccolò Zucchi*; at Parma by *Biancani*; at Douai by *Malapert*; in the Low Countries by *Martinus Hortensius*; at Brussels by *Daniel Antoninus* [Daniele Antonini]; at Coimbra by

Gulielmus Velij [?]; in the East Indies by *Gaspar Ruess*. Notwithstanding this, *Chiaramonti* and *Kottounios*, both devoted to the Peripatos, the latter to his own Stagira, maintain that all the spots are below the heaven of the Moon, so as not to admit alterations in the heaven. [Margin: Chiaramonti's weak argument.] *Chiaramonti*, indeed, adduces a few observations of the year 1626, between August 25 and 29, in which some spots were noted by different observers in different parts of the Sun within a few hours, and from this he argues for a large parallax. But those observations ought not to outweigh so many others that are more certain, and those spots were not of the kind that last the whole day but of the kind that rise and perish shortly afterwards, others rising in another part of the solar disc; and accordingly the different place on the Sun did not belong to the same spot. [Margin: And Kottounios's against the place of the spots in the heaven.] *Kottounios*, for his part, heaps together spurious spots, of which I shall speak in Scholium 1, compacted from little globes of cloud; for he says that these are meteorological impressions of the air, and that therefore in moister seasons more and larger spots appear on the Sun. But if the Sun's genuine spots, when more numerous or larger, are not the effect but the cause of colder and moister weather, because they intercept the Sun's rays, Kottounios's argument will turn out frigid.

[Margin: Opinions on the substance of the spots.] X. The *substance* of the spots, then, if they are indeed above the Moon and very near the Sun, seems celestial rather than elementary, and offers vast material for disputing about novelties in the heaven, on which we say more in Books 8 and 9. Here, therefore, I think it enough to indicate the chief opinions. *Raphaël Auersa* thinks that, by a power of celestial causes hidden from us, some parts of the heaven are made more opaque than others, and that the heaven therefore appears sprinkled with spots. But *Malapert*, *Mastrius* and *Šírek* judge that they are perpetual stars lit by the Sun, opaque satellites of the Sun surrounding it, and of irregular shape because of their varied concurrence and their motion through different epicycles; for it is less awkward, they say, to posit this irregularity in the heaven than rising and perishing. The faculae, says *Šírek* [Rheitēſis], are the Sun's light reflected on to the spots nearer the Sun from the more remote spots. By contrast, *Galileo*, *Kepler*, *Boulliau*, and at length, though once of the contrary opinion, *Scheiner* and *Biancani* deny that they are stars, because they are neither round nor of regular shape, and are very like the most inconstant clouds; and because many of them, arising in the very middle of the Sun, vanish before they have reached the edges, or, appearing suddenly in the middle, are extinguished at once. Hence they are generated anew and perish, and are nothing other than soots or vapours boiling up out of the furnace of the solar globe, and some of them, kindled, flash in the manner of faculae. So these men make a Vulcan out of Phoebus. But how do so many remain so long that they move around the Sun, by their own motion or the Sun's, for about 27 days? Is this the nature of soots and of solar little clouds, lasting out from a more compact matter that has

grown upon the Sun? But I would rather withdraw into the shade of silence than speak of the Sun in things unascertained and unworthy of it.

SCHOLIA.

[Margin: A spurious spot on the Sun, and darkness.] I. *It is known from the historians that spurious spots have more than once appeared under the Sun, from globules of denser vapours and clouds. Hence* Cleomedes, *Book 2 of the* Cyclica Theoria, *says:* The Sun very often appears spotted to us, and around it there are as it were cloudy coils, which are nevertheless almost infinite stadia away from it, and yet seem to us to be around it. *But these are of the class of meteors, and a large parallax could be noted in them by different observers at the same time. Hence that passage on which* Plutarch, *in the* Caesar: Now the blinding of the Sun's radiance: for through that whole year its orb came up pale and without brilliance, and sent out a weak and thin heat. *To this, surely,* Virgil *looked back,* Georgics 2, *hinting at a long and spurious half-eclipse of the Sun in these verses:*

He also pitied Rome when Caesar was put out, When he covered his shining head with dark rust, And the impious ages feared an eternal night.

Zonaras also relates, in the Irene, *that because of these clouds gathered beneath it the Sun did not shine for 17 days; and that in* Justinian's *time, for the greater part of the year, though the sky was clear, the Sun lay hidden beneath them, scarcely rivalling the light of the Moon, as* Patritius [Francesco Patrizi] *reports, Book 19 of the* Pancosmia. *But see* Maiolo, *in the* Dies Caniculares, *in the conversation on the Sun. Some of these portents, however, could be referred to an extraordinary accumulation of genuine spots contiguous with the Sun; but not the blood-red colours on the Sun, of which* Génébrard *speaks in the* Chronicle, *years 1547, 1585 and 1592, and others elsewhere.*

[Margin: A spot taken for Mercury.] II. *A certain spot of the Sun was at one time believed to be Mercury. For in the* Annales Francici *published by* P. Pithœo [Pierre Pithou], Adelmus *the Benedictine, in the Life of* Charlemagne, *in the year 807.*

of CHRIST *says:* The star of Mercury, on March 17 [16.Kal. Aprilis], was seen on the Sun as a small black spot, though a little above the middle centre of that star; it was seen by us in this way for eight days, but when it first entered or left could not be noted, because clouds prevented it. *Kepler, in chapter 8 of the* Astronomia Optica, *p. 306, had altered these words, putting in place of "eight days" the adverb "eight times", and in place of the year 807 the year 808. For he believed that in 808, on March 17, Mercury was conjoined with the Sun at perigee, because of its small latitude, supposing the nodes of Mercury's orbit with the ecliptic to be at the end of Aries and of Libra; and yet that it could not have lingered under the Sun for eight whole days, since Mercury is so swift at perigee that it can scarcely be under the Sun for 7 hours. Two years later, at the end of the* Dissertatio cum Nuncio Sidereo *of* Galileo, *he confirmed this view from* Amoino [Aimoin], Bede, Eginardo [Einhard], Vincentio Bellouacensi [Vincent of Beauvais], Polydoro

Virgilio [Polidoro Virgili] *and* Sabellico [Marcantonio Sabellico], *who speak of a spot seen under the Sun in the time of* Charlemagne. [Margin: Kepler's candid palinode.] *But when, in 1612, he had been informed about the solar spots, he denied that what Adelmus speaks of was Mercury, and asserted that it was a spot, just like the one that* Kepler *himself had seen on the Sun in 1607 May 28, thinking it to be Mercury. He also acknowledged that Mercury's nodes are at 13° of Taurus, not at the end of Aries, as is plain from his letters to* Galileo *and from the* Ephemerides, *pp. 17 and 18. For Mercury's latitude on that day, May 28, had been greater than the Sun's semidiameter. Moreover* Galileo, *On the Sun's Spots, p. 54;* Scheiner *in the* Rosa Ursina; Gassendi *in the Life of* Claudij Fabricij [Nicolas-Claude Fabri de Peiresc]; *and* Boulliau, *Book 1 of the* Astronomia Philolaica, *chapter 8, deny that Mercury could have been seen under the Sun for 8 days, since it can scarcely remain under it for 7 hours, and sometimes gets clear of the Sun's disc in 4 hours. To this class, moreover, seem to belong those two spots that their observer* Auen Rodan [?] *took for Mercury, as* Picus Mirandulanus [Giovanni Pico della Mirandola] *reports,* Against the Astrologers; *or* Averroes, *in* Copernicus, *Book 1, chapter 10, who says that at the time of a conjunction of Mercury with the Sun he saw something blackish on the Sun.*

[Margin: Mercury could be taken for a spot by the inexperienced.] III. *Yet the latitude of Mercury at perigee is sometimes so small that it is less than the Sun's semidiameter, and Mercury can therefore be seen under the Sun, whatever may be said by* Ptolemy *and* Copernicus, *and with them* Fernel, *Book 1 of the* Cosmotheoria [Coſmoth.], *chapter 7, in the Scholia, who deny that it and Venus can, because of their excessive latitude, be seen under the Sun at conjunctions, or be interposed between the Sun and our sight.* Kepler *had predicted that this phenomenon would occur in 1631 on November 7, but, mistrusting the calculation of the Rudolphine Tables, he had rather timidly advised astronomers to direct their eyes to the heaven at that time.* [Margin: Pierre Gassendi's good fortune in observing Mercury under the Sun.] *Accordingly* Pierre Gassendi, *in that year 1631, on November 7, at Paris, with a telescope made ready, observed Mercury in the morning. It painted itself on the paper with its own small shade, showing an apparent diameter of not more than 23″ or 20″, whereas it was previously believed to be 2′ or 3′. It left the western edge of the Sun, he says, at* $10^h\ 28^m$ *after midnight, and reached a northern latitude of 6′ 20″, as* Gassendi *himself reports in the* Institutio Astronomica, *Book 2, chapter 14. He had not observed the beginning, because it had begun with the Sun still below the horizon; but the beginning of the observation was at* 9^h *after midnight, and* Gassendi *gathered from the Rudolphine Tables that the true conjunction of Mercury with the Sun was at Paris at* $7^h\ 58^m$ *after midnight, with the Sun placed at Scorpio 14° 36′ and Mercury's northern latitude not exceeding 4′ 30″. So relates his very close friend* Boulliau, *Book 10 of the* Astronomia Philolaica, *chapter 5, who also deservedly dedicated the whole of that Book 10 to* Gassendi, *as one who had deserved so well of Mercury by this and other observations.* [Margin: Boulliau's vote for Gassendi.] Boulliau, *indeed, adds from his own tables that in that synod Mercury was at 14° 37′ 42″, and that when it left the Sun it had a latitude of 6′ 20″; and in chapter 7 he gathers*

that Mercury's northern node was at Scorpio 13° 20′ 52″. [Margin: And that of Martinus Hortensius.] *There is also extant a most learned dissertation of* Martinus Hortensius *with* Gassendi, *published at Leiden in 1633, in which he confirms from its motion that this Gassendian phenomenon was Mercury, not a spot; since there is no spot at such a distance from the Sun's centre that travels in one day beyond a thirteenth part of the solar diameter, and those that stay around the Sun's limbs scarcely traverse in one day a 26th or 30th part of the solar diameter, as those practised in observations of the solar spots know; whereas this corpuscle was under the Sun for very few hours.* Hortensius, *however, having first corrected the polar altitude of Paris, says that the conjunction of Mercury with the Sun took place at Scorpio 14° 34′ 30″, with a northern latitude of ☿ of 5′, and indeed at 7^h 43^m after midnight; that the beginning of the ingress was at 4^h 58^m, the end at 10^h 28^m, and Mercury's stay under the Sun 5^h 30^m; and finally that the northern node was at Scorpio 14° 54′ 43″. But, he says, from the Rudolphine Tables this conjunction ought to have been at Paris at 0^h 47^m after noon on November 7, and so those tables differ from the observation by 5^h 4^m, by 14′ 24″ in the motion of longitude, and by 35″ in latitude;* [Margin: Comparison of the Rudolphine Tables with other tables in the motion of ☿.] *yet they are closer to the truth than the Ptolemaic tables, which differ from this observation by 4° 25′, the Copernican by 5°, the Danish by 7° 13′ and the Lansbergian by 1° 21′.*

CAPVT IV.

De Motu Vertiginis Solis, occasione Macularum: Vbi & de Vertigine aliorum Planetarum, & de Tremore Solis. [On the Motion of Rotation of the Sun, Occasioned by the Spots: Where Also on the Rotation of the Other Planets, and on the Tremor of the Sun.]

[Margin: Those who assert the Sun's rotation.] I The rotation [Vertiginem] of the Sun about the centre of its body, indicated by *Plato* in the *Timaeus*, has at last been recognised by our own and the preceding century, and it has been asserted above all by *Kepler* in the *Commentaries on Mars*, part 3, chapter 34; *Scheiner* in the *Rosa Ursina*; *Galileo*, *On the Sun's Spots*, pp. 32 and 49; *Boulliau*, Book 1 of the *Astronomia Philolaica*, chapter 12; and *Šírek*, Book 4 of the *Radius Sidereomysticus*, chapter 2, member 3. Now *Kepler* grants that this rotation takes 24 hours, if the Earth's daily motion is supposed to come from the magnetic force of the Sun, which drives it around by the Sun's own rotation; but that it takes 3 days, if the same proportion is supposed between the periodic motion of Mercury, which is of 88 days, and the motion of the Sun, as holds between the semidiameter of Mercury's orbit and the diameter of the solar body, which is nearly thirtyfold. This, however, is playing in the heaven without any foundation in phenomena appearing on Earth.

II. *Galileo*, *Scheiner* and *Boulliau*, for their part, hold that this rotation is nearly monthly, that is, of 27, 28 or 29 days, and they gather this from the apparent motion of the spots, which, unless they perish sooner, move under the Sun's disc from one edge to the other in 13½, 14 or 14½ days, lie hidden for as many

days behind the Sun's back, and, having completed the period of their circuit around the Sun, return. [Margin: The ground for asserting this rotation.] This motion appears just such as the rotation of the Sun's sphere about its centre demands, if the spots are supposed to move with its motion. For it appears faster in the middle than near the limbs, and greater on the Sun's diameter than on parallels to the diameter. Furthermore, a motion so constant and regular in so many spots is more fittingly attributed to one body carrying them around than either to a fluid medium around the Sun or to so many epicycles, multiplied in vain, on which each of them would be carried around the Sun. Granted, *Galileo* adds that if they did move in this way, the result would still be that because of their nearness they would communicate this motion to the Sun, which is spherical and resists nothing, and is indeed inclined to circular motion. *Gassendi* judged that the great circle of the solar body, along which, and along whose parallels, this rotation takes place, is so inclined to the ecliptic that the apparent motion of the spots seems to describe straight lines at the equinoxes and curved lines away from the equinoxes. [Margin: Disagreement between Scheiner and Galileo, and Šírek.] *Scheiner*, on the contrary, says that they describe straight lines near the solstices and curved lines at the equinoxes and elsewhere, and that this arises from a certain other annual motion besides the monthly one, by which the poles of the monthly motion move gradually with their axis. *Šírek* [Rheitensis], for his part, denies the Sun a monthly motion of rotation and assigns it to the spots, as being stars, he says, distinct from the Sun. But he grants the Sun an annual rotation of 365 days, from which it comes about that in summer it heats more also for this reason, that it turns its brighter and hotter part towards us.

[Margin: The rotation of the other planets.] III. On this occasion *Šírek* [Rheitensis], in the place cited above, adds that the other planets, the Moon excepted, move with a motion of rotation about the centre of their bodies, but that the Moon slowly oscil- lates; and that, just as the Sun rises 365 times within the annual revolution of its rotation, which is completed in $365^{d}\ 5^{h}\ 48^{m}$, so the other planets are moved 365 times within one revolution of their own periodic motion. And accordingly that a rotation, Jupiter's for example, is obtained by making the proportion: as 365 is to 24^{h}, so 4330^{d}, in which Jupiter's motion of nearly 12 years is completed, is to $284¾^{h}$, or $11^{d}\ 20¾^{h}$. On this foundation, so arbitrary, not to say flimsy, he has built for us the following little table. So easy is it,

Rotation of the Planets, from Šírek [*Vertigo Planetarum, ex Rheitenſi.*]

Planet	Rotation
♄	$29^{d}\ 12^{h}\ 38^{m}$
♃	$11^{d}\ 20^{h}\ 45^{m}$
♂	$1^{d}\ 21^{h}\ 6^{m}$
☉	$365^{d}\ 5^{h}\ 48^{m}$
♀	$0^{d}\ 14^{h}\ 45^{m}$

Planet	Rotation
☿	$0^{d}\ 5^{h}\ 45^{m}$

for those whose wit itches to devise novelties, to invent motions in the heavens from the tiniest spark of analogy. That is a giddiness [vertigo] or an itch of the mind rather than of the stars. What we ourselves have observed in the belts of Jupiter that bears on the rotation of Jupiter we shall say when we treat of Jupiter. The oscillations of the Moon, from Wendelen, and its twin libration, from van Langren and Boulliau, will be dealt with in Book 4.

[Margin: The rotation of the Moon is uncertain.] As for the rotation of the Moon, Gassendi has no doubt about it in his *Institutio Astronomica*, book 2, where he treats of the phases of the Moon. For he says that the Moon always turns the same spots toward the Earth, and yet that according to all authors it moves on an epicycle about the centre of the epicycle carried by the eccentric. On that supposition the front part at apogee ought to become the rear part at perigee; but, he says, these things are reconciled if one posits a motion of rotation by which as much of the lunar globe is turned back as is turned away by the motion of the epicycle. But not everyone uses an epicycle in the theory of the Moon. Magini in particular, in the preface to his *Theorica* of the Moon, professes to preserve this constant position of the spots toward us by an eccentric alone, whose centre, however, is carried round by the circumference of a small circle, as we shall explain in Book 4, chapter 9. Meanwhile, just as the monthly variation of the solar spots seems to indicate a solar rotation, so the monthly invariability of the lunar spots seems to indicate the Moon's immunity from any motion of rotation.

IV. That trembling of the Sun, more evident when it is rising than when it is setting, and indeed more evident shortly after its rising, and a certain jumping, with a torn and as it were serrated limb, appear as they do because of vapours heated by the Sun and running across it with an irregular upward ascent. So Bettini teaches, in *Apiary* 8, Prog. 4, prop. 4, together with Scheiner in the *Disquisitiones Mathematicae*, nos. 30 and 34, and before them Tycho, vol. 1, p. 403. For from this comes also a large part of the cause of the twinkling of the stars; and Witelo, book 10, prop. 55, thought no differently. I myself have often seen a long little cloud of narrow breadth lying across the middle of the Sun's disc after its rising and ascending at an equal pace with it, so that the body of the Sun, because of the ever-changing discharge of its rays, seemed to roll over as a whole in a vertical plane with a very rapid rotation, by an utter deception of the eyes.

[Margin: The Easter dance of the Sun.] Because around the vernal equinox more vapours accompany the rising Sun with this jumping, and around that equinox we celebrate Easter, the common people attribute an Easter dance to the Sun, as Tycho notes in the place cited.

CAPVT V.

De Illuminatione, & Calefactione Solis: vbi de Figura Radij Solaris, & de Parallelismo Radiorum. [On the Illumination and Heating of the Sun: Where Also on the Shape of the Solar Ray, and on the Parallelism of Rays.]

I. Setting aside the physical controversies over the cause of the heat produced in sublunary things by the motion of the Sun, a cause that the friction of the heavens certainly no longer supports in this age, when the heaven of the planets has been found not to be solid; and taking as given the common principles from the opticians' store, namely that from any point of a luminous body rays are propagated in all directions to any point of the illuminable subject, provided that an opaque body does not intervene; that they are propagated along straight physical lines; and that a ray falling perpendicularly on an opaque body is reflected back on itself, whereas one falling obliquely is reflected elsewhere, and always in such a way that the angle of reflection is equal to the angle of incidence: on these terms it will not be difficult to give the evident cause of the excess of the noon and summer heat produced by the rays of the Sun over the heat of other hours and seasons. For the cause indicated in the preceding chapter, from the absence of spots or from the rotation of the Sun turning its hotter part toward us, is either not constant or rests on an uncertain hypothesis.

Diagram. A semicircle standing on its diameter, the horizon BAC, with the arc BMC representing part of the meridian. From the centre A straight lines rise to the arc: to M at the top, to L and N on either side of it, and to F, D and E low on the left. Lines of the same fan run to O and P, stopping short of the arc on either side of M, and to G, H and K on the right, also stopping short of the arc. A small arc joins L and N below M, and another joins F and E to the right of D, marking the Sun's disc at each position.

- L, M, N (top of the arc, left to right): the Sun's limb, centre and limb at the zenith
- O, P (inside the arc, left and right of M): ends of the reflected rays
- F, D, E (left side of the arc, top to bottom): the Sun's limb, centre and limb at the lower position
- G, H, K (inside the arc on the right, top to bottom): ends of the reflected rays
- B, A, C (along the diameter, left to right): the ends of the horizon and its centre

[Margin: The cause of noon and summer heat.] II. Let BAC be the horizon and BMC a portion of the meridian, on which let M be the zenith, and there the centre of the Sun, whose perpendicular ray MA shines on A, as happens on equinoctial days at noon above those who live on the equator. For that ray will be reflected from A, an opaque point of the Earth, back on itself toward M, will become stronger as a result, and will excite greater heat with greater light in the stretch of air AM. Now let the extreme rays of the Sun be LA and NA, making an angle LAN as great as the Sun's apparent diameter LN. For

the incidence of the ray LA will be the angle LAB, of 89° and about 45′, since all it lacks of the right angle MAB is the angle MAL, subtending the apparent semidiameter of the Sun, which is approximately 15′. Therefore the angle of reflection equal to it will be NAC, and so the ray LA will be reflected into the ray NA, toward N, increasing its light and heat, and in turn the ray NA will be reflected from A into L, increasing the light and heat of the ray LA. In this way any two rays of the Sun setting out from points equally distant on either side of the middle M will make each other stronger by mutual reflection, and more so near the point A, because the action in them decreases in a uniformly difform manner [vniformiter difformiter] the further one goes from A, the origin of the reflection. An inhabitant of A will therefore at that noon feel an intolerable heat above and around him, because of the air heated by the direct rays of the Sun and by the reflected rays, with a reflection so close that there is none that does not coincide with some other direct ray. And if the Sun is not at the zenith, but a little beyond or short of it, some rays reflected elsewhere, although they do not run into the direct rays, will still come so close to the direct ones that by an almost joint action they strongly heat the surrounding air: as if the ray LA should be reflected to P, or the ray NA to O.

III. Now let the Sun be far from the zenith or vertex M at its meridian altitude, and let it be at D, distant from M, for example, 60°. Its central ray DA, falling on A with an angle of incidence DAB of 30°, will be reflected to H; and the reflected ray AH, with an angle of reflection HAC likewise of 30°, will be distant from the direct ray DA by the whole angle DAH of 120°. The incidence of the extreme ray EA will be EAB, of 29° and about 45′, and the reflection KAC of the reflected ray AK will be as great; the ray AK will therefore be distant from the ray EA by 120° 30′. Finally, the incidence of the other extreme ray FA will be the angle FAB, of 30° 15′, and the angle of reflection GAC of the reflected ray AG likewise 30° 15′; the ray AG will therefore be distant from its direct ray FA by 119° 30′. Because of so great a divergence and separation of the reflected rays from the direct ones, arising from the obliquity of incidence of the direct rays, they will not be able to intensify one another or assist one another by nearby action. This, then, is the chief cause why the Sun, in summer and especially at the solstice, produces at noon far greater heat on the Earth than at midwinter: because it comes closest to our vertex, and the less oblique incidence of its rays makes the reflected rays nearer to the direct ones. On the same day, moreover, the heat of the noon Sun is greater than that of the rising or setting Sun, for the same cause, namely that the Sun when higher shines on the Earth with less oblique rays.

[Margin: Other causes of greater heat.] IV. Two other joint causes are added, however: one from refrac- tion, which is less when the Sun is higher, so that the rays are less weakened; the other from the Sun's stay above the horizon, which is longer on summer days than on midwinter days. Note meanwhile, reader, how much the shape of the walls, valleys and mountains from which the Sun's rays are reflected to some place contributes to increasing the heat.

For if the places from which the reflection occurs are concave, and much more if they are parabolically or elliptically concave, and the place receiving the reflected rays lies at the other focus [vmbilico] of the ellipse or at the focus of the parabola, a far greater heat results, because of the gathering of the reflected rays at one and the same point. This is established from the properties of the parabola and the ellipse, on which we write in our book on optics, and others, now together with Apollonius, in the conic sections or on the parabolic mirror.

[Margin: Why and when the shape of the solar ray is round.] V. When the rays of the Sun enter through a window or a round opening directly facing the Sun, and end at a wall or a board parallel to the opening, an image [species] of the solar ray also appears, and it is circular. There is no doubt that the roundness of the Sun and of the opening, and the straightness of the plane receiving perpendicularly the cone of the Sun's rays and its base, come together to produce this shape. But when the opening is polygonal, say quadrangular or triangular, and yet a more distant wall parallel to the plane of the opening receives a round or circular image of the Sun, the round shape of the Sun does not suffice as the explanation. For if the opening is fairly large and quadrangular, and near the wall, a quadrangular image of the Sun is painted on the wall. The cause, therefore, is that on a distant wall several bright quadrangular bases are painted about the same centre, about which they are so disposed that their outer angles lie on the circumference of the same circle, but their tips can hardly be discerned because of the weakness of the light that has travelled further, and its smallness from the tiny opening. So, those angles being blunted, a shape that is in reality polygonal appears to the senses circular, as we explain more fully in our *Optics*. Meanwhile one may consult Aristotle in the *Problems*, Problem 5, Section 15, and Biancani on that passage, no. 345, and in his *Sphaera*, book 10, chapter 18; Witelo, book 2, prop. 39; Petsanus [John Pecham] in the common *Perspectiva*, prop. 5; Kepler in the *Astronomia Optica*, chapter 1, prop. 6; and Hérigone, vol. 5, in the *Optica*, prop. 20.

[Margin: The parallelism of the rays of the Sun.] VI. It remains to explain the parallelism of the rays of the Sun. For mathematicians commonly suppose, with Ptolemy in the *Analemma* and Proclus in the *Hypotyposes* of astronomy, that rays, but rays setting out from the same point of the Sun, reach the Earth sensibly parallel; and this is demonstrated by Pedro Nunes, book 2 of *De observatione*, chapter 18; Witelo, book 2, prop. 35; Willebrord Snel, book 1 of the *Eratosthenes Batavus*, chapter 9; and Bonaventura Cavalieri, chapter 24 of the *Burning Mirror* [Speculi Vstorij]. It could moreover be argued a fortiori: two neighbouring walls built to the perpendicular are sensibly parallel, even though in mathematical rigour they converge and, if produced as far as the centre of the Earth, would meet there, as plumb lines would too. How much more, then, will two rays of the Sun setting out from the same point toward the Earth be sensibly parallel, since on the Earth they are much more distant from the Sun than two walls are from the centre of the Earth, as is supposed here from what will be said below in chapter 7. But it is better demonstrated

by a double method, not only for the rays of the Sun but also for those of the Moon or of an even nearer luminous body, given that its distance is so great that the extent of the illuminated subject bears an insensible proportion to it.

Diagram. At the top a shallow curved line, concave upward, represents the surface of the Sun, with the point S at its middle. Below it is the Earth as a semicircle on the diameter ATC with centre T. From S straight lines descend to the semicircle: one through N to P, one through I to B, one to T, and one to R at the left end of the arc near A. A short line runs from P to T. A horizontal line joins N and I; below it an arc and a straight line both join P and B, which stand on the semicircle. A separate line drops from the upper curve straight to B; K stands just to the right of the top of that line.

- G (left on the upper curve), S (middle, above the curve), K (under the curve, right of S), L (right on the upper curve)
- N, I (on the two descending lines, at the ends of the horizontal line, left and right)
- B (right, on the semicircle), P (left, on the semicircle), R (left, at the end of the line from S), A, T, C (along the diameter, left to right)

[Margin: First proof of the parallelism of the rays of the Sun.] VII. First, with Witelo and Nonius, let ABC be the hemisphere of the Earth, whose centre is T and horizon ATC, and on its surface let two gnomons PN and BI be erected perpendicularly, which are supposed to bear no sensible proportion to the distance ST or SP of the Sun from the Earth. From the same point S of the solar surface GL let two rays fall on the said gnomons, SNP on one side and SIB on the other, and let there be drawn to the feet of the gnomons the straight line PB, and to their tips the straight line NI, parallel to PB. The triangle SPB will then be cut proportionally by the straight line NI, by Euclid VI.2, and as SP is to SN, so will PB be to NI. But SP is not sensibly greater than SN, because the proportion of PN to SP is taken to be sensibly nil. Therefore neither will PB be sensibly greater than NI, and hence PB and NI will be parallel and at the same time sensibly equal. Therefore, by Euclid I.33, the straight lines PN and BI, which join on the same sides the straight lines PB and NI, parallel and sensibly equal, will also be equal to each other and sensibly parallel, and so the rays falling on the gnomons PN and BI will be sensibly parallel.

[Margin: Second proof of the same parallelism.] VIII. Second, with Snel, in the same figure let one ray of the Sun be SR, touching the Earth at R and making there, by Euclid III.18, a right angle with the Earth's semidiameter RT, and let another ray from the same point be ST. Let the distance of the star from the Earth be given, and let it be as great as the ray ST; and let us now take the Ptolemaic distance of the Sun, of 1210 semidiameters. For in the triangle SRT, right-angled at R, there will be given RT and the base ST, of 1210 parts of which RT is one, and so the side RT. Therefore by no. 7 of our *Plane Right Triangles* the angle RTS will be found to be 89° 57′ 9″ 35‴, and so falling short of a right angle by only 2′ 50″ 25‴. The angles STR and SRT will therefore be sensibly equal and right, and so by Euclid I.28 the rays ST and RT will be

sensibly parallel, however far apart they stand on the Earth, by almost a whole quadrant of the Earth's circumference. How much more so, then, the rays ST and SP, which are less distant from each other? And so, as Snel concludes, if two places P and B were as far apart as Alexandria in Egypt and Syene, namely 7½°, the angle would fall short of a right angle by no more than 22″ and 36‴.

[Margin: The parallelism of the rays of the ☾.] IX. Now let the Moon be at S and its distance from the Earth ST at least 49 semidiameters, of which TR is one; then by the same rule 7 the angle STR will be 89° 51′ 12″. But let two of its rays SP and SB be supposed to fall on points of the Earth distant by only one terrestrial degree PB, or 90 miles, of which there are 245000 in the Moon's distance SP, since the Earth's semidiameter holds, in our opinion, 5000 ancient Italian miles, and let us put the Moon's distance SP at no less than 49 semidiameters of the Earth. On these suppositions, in the isosceles triangle SPB, with SP and SB given, each of 245000 miles, and PB of 90, either angle at the base, namely SBP or SPB, will be 89° 59′ 22″, and so sensibly right, and by Euclid I.28 SP and SB will be parallel. Cavalieri, moreover, has shown above that if the luminous body S is one mile distant from B or P, and BP is only 10 cubits, as is BI too, IN will be shorter than the straight line BP by one small part of the 3783036 equal parts of which BP consists, and so NP and IB will be sensibly equidistant.

[Margin: The parallelism of rays falling on a lens, a telescope or the pupil from the same point.] X. But so that we may gather some universal benefit from this, we suppose two rays to be sensibly parallel when each falls so nearly perpendicularly that the angle they make falls short of a right angle by no more than 3″. On this supposition we shall inquire by the preceding problem, according to the given distance of the extremes on which the rays shine, namely either on the human pupil, whose diameter PB is taken as 40 parts, of which an inch of the Roman foot is 100, or on the glass lens of a telescope or on a burning mirror, whose diameter PB is two feet, or finally on a space PB of 100 miles, how great a distance SP or SB suffices and is required for the physical parallelism of the rays SP and SB to be preserved, and for the angles SPB and SBP each to be 89° 59′ 57″. To this I reply that there suffices and is required a distance of the luminous point S of 230 paces from such a pupil; of 14 Italian miles from such a lens; and from extremes of the Earth 100 miles apart, a distance of 200000 Italian miles, that is, 50 semidiameters of the Earth, which is about the distance of the Moon at perigee. Safely[12], then, the rays of the higher stars, but rays setting out from the same point, fall sensibly parallel on the Earth.

[Margin: The pseudo-parallelism of rays from different points of the Sun, in certain authors.] For if they come from different points, say from G and L, they do not reach the Earth parallel, as Eratosthenes falsely assumed. On his fallacy there is more from us in Book 3, chapter 27, no. 7, and meanwhile see Snel

[12] the page prints *Secutè*; read as *Securè*

and Nonius above, by whom Pliny the Elder, Giorgio Valla, Ziegler and, in part, Witelo, book 2, prop. 39, are censured for this same pseudo-parallelism.

SCHOLION.

[Margin: A cold and witless cause of summer heat.] The chief and regular cause of greater heat in summer is not, as some have suspected, a greater velocity of the Sun or its greater nearness to the Earth, since at that time the Sun is rather much slower than at midwinter, and by its proper motion completes each day no more than about 57′, whereas around midwinter it completes nearly 61′, and on the meridian the daily motion appears slower. Moreover, once the Sun's apogee [Apogeitate] is admitted, the Sun around the beginning of Cancer will for so many centuries now have been more distant from the centre of the Earth than around the beginning of Capricorn, where it lies at perigee. Nor is it only in summer that the Sun is joined with hotter stars, say with Mars or Regulus; it is joined with some of them in winter too. Nor again is the cause an annual rotation of the Sun turning its hotter part toward the Earth. For whether this rotation is lengthwise, to the east or the west, or breadthwise, to the north or the south, it will not be able to turn its hotter part toward us northerners in such a way that the southerners do not for the most part face the same part; and so it would make summer at the same time for our Antoeci and Antipodes, which is contrary to experience. For it is established, from the Father Procurator of the Province of Chile, which extends to the Strait of Magellan, that it is deepest winter there when the Sun at the beginning of Cancer makes the height of summer for us. The chief cause, then, is the one I set out in no. 1.

CAPVT VI.

De Solis ac Terræ Loco in Mundo, Qua occasione Proponuntur Insigniora Mundi Systemata, & Appēdix de Terræ multiplici motu iuxta Copernici Hypothesim. [On the Place of the Sun and of the Earth in the World, on Which Occasion the More Notable Systems of the World Are Set Out, with an Appendix on the Manifold Motion of the Earth according to the Hypothesis of Copernicus.]

Although more will have to be said about the systems of the world in Book 9, sections 3 and 4, for a fuller understanding of what will be said about the Sun the principal systems of the world must nevertheless be indicated here.

I. Systema Pythagoræ Ptolemæi &c.

[I. The System of Pythagoras, Ptolemy, etc.]

Diagram. Concentric circles about a central Earth, which is drawn with hatched land inside a ring of small flame-like or wave-like marks. Seven rings carry the planetary symbols in a vertical line above the centre. Outside them a ring carries scattered stars, and the outermost band is divided by short rules into twelve compartments, each holding a zodiac sign.

- Planets, from the outermost inward along the vertical line: ♄, ♃, ♂, ☉, ♀, ☿, ☾
- Zodiac band, going anticlockwise from the right side: ♈, ♉, ♊, ♋, ♌, ♍, ♎, ♏ (drawn as a small scorpion), ♐ (an arrow), ♑, ♒ (wavy lines), ♓
- Asterisks for stars in the ring just inside the zodiac band

[Margin: The most ancient system.] I. In this system, the oldest of all of which there is any record, the Earth rests motionless at the centre of the world, and around it are the elements and the heavens, in the order indicated by the symbols of the planets and by this series of names: of the Moon, Mercury, Venus, the Sun, Mars, Jupiter and Saturn, and of the eighth sphere, which is also called the sphere of the fixed stars, and ἀπλάνη [Greek: ἀπλάνη (aplanē, "not wandering")], or Aplane, that is, not wandering at all, and by many the Firmament. We shall show in Book 9, section 3, chapter 2, that this system was that of Pythagoras, Archimedes, the Chaldaeans, Cicero, Pliny the Elder, Ptolemy and very many Arabs, of the Alphonsines and the followers of Peuerbach, and that it was commonly accepted by most people down to Magini and Clavius, even though the more recent among them have added other spheres above the eighth for the motions of trepidation and of the primum mobile, according to what will be said in section 3, chapter 1.

The second system, that of Plato and probably of Aristotle, Eudoxus and Callippus, and also of Tycho and Jābir ibn Aflaḥ, though Jābir elsewhere had followed Ptolemy, places the Sun immediately above the Moon, and sets Venus above the Sun, Mercury above Venus, Mars above Mercury, Jupiter above Mars, Saturn above Jupiter, and the fixed stars above Saturn. The author of *De Mundo* to Alexander, however, and Porphyry, Apuleius, Marsilio Ficino and certain Platonists placed Mercury above Venus, keeping the rest; and so you see two series in the following diagram. But more on this system in Book 9, section 3, chapters 3 and 5.

II. Systema Platonis, aut Platonicorum.

[II. The System of Plato, or of the Platonists.]

Diagram. Concentric circles about a central Earth, drawn with an irregular land mass inside a wavy ring and a dotted ring. Two columns of planetary symbols run upward from the centre, side by side, each headed by a name printed in curved letters outside the outermost circle, which carries scattered stars.

- "Plato" (above the left column); symbols from the outermost inward: ♄, ♃, ♂, ♀, ☿, ☉, ☾
- "Porphyrius" (above the right column); symbols from the outermost inward: ♄, ♃, ♂, ☿, ♀, ☉, ☾
- Asterisks for stars in the outermost ring

There are, however, reasons and authorities by which it could be made probable that Eudoxus, Callippus and Aristotle followed the system of Pythagoras; of these in their place. Meanwhile what Clavius says in his *Sphaera* is false, that

the author of the little book *De Mundo* to Alexander is the only one who places Mercury below Jupiter and above Venus. Finally, Plato grants in the *Timaeus* that the Earth is turned about its own centre, which Aristotle denies.

III. Systema Ægyptiorum, Vitruuij, Capellæ, Macrobij, Bedæ &c.

[III. The System of the Egyptians, of Vitruvius, Capella, Macrobius, Bede, etc.]

Diagram. Concentric circles about a small central Earth, drawn with hatched land inside its own small circle. On the next circle stands ☾, and on the large circle beyond it, at the top, stands ☉, rayed. Two smaller circles are drawn about ☉ as centre: the inner carries ☿ at its lowest point and the outer carries ♀ at its highest point. Beyond these, circles carry ♂, ♃ and ♄ near the top, and the outermost ring carries scattered stars.

- ☾ (on the circle nearest the Earth), ☉ (top of the next circle)
- ☿ (below ☉, on the smaller circle about it), ♀ (above ☉, on the larger circle about it)
- ♂, ♃, ♄ (upper left, on successive outer circles, moving toward the top)
- Asterisks for stars in the outermost ring

II. This system is that of the Egyptians, in which, as can be seen in the preceding figure, the Earth is set in the middle of the world with the elements, and the first heaven is that of the Moon, the second that of the Sun, but in such a way that around it Mercury goes on a tighter epicycle and Venus on a wider one, and so they are carried now below the Sun, now above it, though they appear larger and more clearly when they are near their greatest digressions below the Sun than when they approach apogee above the Sun. In fifth place is the heaven of ♂, in sixth of ♃, in seventh of ♄, in eighth of the fixed stars; these four heavens, like those of ☉ and ☾, are described about the Earth. To this system Vitruvius, Martianus Capella, Macrobius, Bede and Argoli have subscribed, as we shall show in Book 9, section 3, chapter 4.

But Argoli has the Earth moving about its own centre. Al-Biṭrūjī followed the same system in part, insofar as he places Venus above the Sun and Mercury below the Sun, for reasons to be explained in the same section, chapter 6.

IV. Systema Philolai Aristarchi & Copernici.

[IV. The System of Philolaus, Aristarchus and Copernicus.]

Diagram. Concentric circles about a central Sun, drawn as a rayed disc. Two inner rings carry the labels for Mercury and Venus. Next comes a dotted circle, the annual orb, on which stands a small circle about the Earth, drawn as a hatched globe, with the Moon's symbol on that small circle. Three circles beyond it carry, at upper left, the symbols of Mars, Jupiter and Saturn with their periods lettered along the arc. The outermost circle carries scattered stars.

- Top, outermost planetary ring: ♄, "Reuolutio Annorum. 30"
- Top, next ring: ♃, "Reuolut. Annor. 12"
- Top, next ring: ♂, "Reuol. Annor. 2."

- Beside the small circle about the Earth, on the left: "Terre"; on the right: "et Lun…" [?] (the ending of the word is not legible)
- Inner rings: "Reuolutio mensium. 9.", with ☿, and "Reuolutio Dierum 80.", with ☿
- Lettered round the dotted circle: "Annuus" (left), "orbis" (lower left), "annua reuolut." (foot), "orbis" (right)

III. This fourth system is called Copernican after Copernicus, who perfected it and propped it up with many arguments and ingenious hypotheses. Otherwise it is usually called Pythagorean, and said to have been born in the Samian or even the Italian school, as regards the annual motion of the Earth. For that motion was asserted long ago by Pilolaus [recte: Philolaus] the Pythagorean, in the part of Italy called Magna Graecia, and by Aristarchus of Samos, as reported by Aristotle, *De caelo* 2, from text 72; Cicero, *Academic Questions* 2, and *Tusculan Disputations* 1; Plutarch, *De Placitis*, book 3, chapter 13; Archimedes in the *Sand-Reckoner* [Arenario]; and Laërtius in their lives. This system revived, moreover, under Nikolaus von Kues, but imperfectly, until Nicolaus Copernicus asserted it, not merely as a hypothesis, as the ignorant keep saying, but absolutely. He was followed by Georgius Ioachimus Rheticus [Georg Joachim Rheticus], Mästlin, Rothmann, Kepler, Simon Stevin, Galileo, Schikardus [Wilhelm Schickard], Lansbergen, Boulliau, Giordano Bruno, Celio Calcagnini, Didacus Astunica [Diego de Zúñiga], Paulus Antonius Foscarinus [Paolo Antonio Foscarini], Pierre Hérigone, Descartes, and Anton. Laurentius Politianus [?]. Not, however, by Wendelen, nor by Gassendi: although they leaned towards it, they held back their opinion on hearing the decrees of the Sacred Congregation of Cardinals. In Gassendi's case this is plain from the end of the last letter *De motu impresso a motore translato*; in Wendelen's, I know it from his own letters and replies, most courteously sent to me. Boulliau and Lansbergen also dissent from Copernicus in this, that they grant the fixed stars a proper motion, which Copernicus denies.

Copernicus, then, places the Sun immobile at the centre of the universe, at least as regards motion of translation. Around it he sets first, nearest to it, Mercury, completing its revolution in 80 days; then Venus, with a nine-month revolution; then the Earth with the whole elementary sphere on the annual orb, completing an annual revolution of 365 ½ days from west toward east. That is, the orb or circle it travels on is like the one on which the Ptolemaic, Egyptian and Tychonic systems have the Sun revolving in an annual period. To this Earth Copernicus also attributes other motions, namely the diurnal, by which the Earth moves about its centre and about an axis inclined to the plane of the ecliptic in the space of 24 hours from west to east, as we shall say shortly in the Appendix. The Moon goes round the Earth in a monthly revolution. Next, again about the Sun as the centre of the universe, Mars completes its two-year revolution, then Jupiter its twelve-year one, and finally Saturn its thirty-year one. The sphere of the fixed stars, for its part, is the outermost and entirely immobile, and stands at so vast a distance from the sphere of Saturn

that the Earth's annual orb is like a point in relation to it. Nor can we perceive any sensible parallax in observing the fixed stars, and hence the altitudes of the pole, whether the Earth is at one point of the annual orb, nearer to one of the fixed stars, or at the opposite point, farther away. The arguments for and against this hypothesis I more prudently defer to the fourth section of Book 9, for by then, after the treatment of all the planets, they will be better understood. The decrees of the Sacred Congregation of Cardinals I shall set out in that same section, together with my own opinion, and I shall weigh the arguments with which many today attack this hypothesis. For granted that a great many arguments, both physical and mathematical, have been hurled against it up to now, they have not yet shaken it among those who have penetrated the depths of the Copernican hypothesis (which is certainly given to few). Indeed, day by day, among the Germans and the French above all who itch to be Copernicans [Copernicoturientes], however many decrees cut it back it sprouts again, and, to use the music of the Venusine lyre,

Through losses, through slaughter, from the very steel it takes strength and spirit.

Nor is there anyone of this kind who, as Plutarch relates of Aristarchus in the essay *De facie in Orbe Lunae*, *fears being charged with violated religion, for having moved the household gods and Vesta of the universe from their place*. But we shall throw no little religious scruple into them.

V. Systema Tychonicum.

[V. The Tychonic System.]

Diagram. A large outer circle carrying scattered stars, centred on the dark globe of the Earth. A small circle about the Earth carries ☾. A larger circle about the Earth is the Sun's path, and on it stands the rayed disc of ☉, drawn above the Earth, with small circles about it carrying ☿ and ♀. Three large circles centred on the Sun, and therefore eccentric to the Earth, carry the outer planets; one of them, the circle of ♂, passes close about the Earth.

- Top, near the outer circle: ♄, and below it ♃
- About the Sun: ♀ (upper), ☿ (close by the Sun), ☉ (centre of this group)
- About the Earth: ☾ (on the small circle)
- Below the Earth: ♂
- Foot: ♃, ♄ (set upside down)

[Margin: Tycho's newest system.] IV. The fifth system is the Tychonic, invented by Tycho himself and indicated in his letters to Rothmann, p. 147, where he also claims it for himself against Nicolao Dithmarso Vrso [Nicolaus Reimers], who had been passing it off as his own; and in volume 1 of the *Progymnasmata*, p. 479, and volume 2, p. 189. Longomontanus followed him, but with the Earth's diurnal motion added (book 1 of the *Theorica*, chapter 1). Scheiner leans towards it in the *Disquisitiones Mathematicae*, no. 22, though there he wrongly says that this system shares nothing with the Copernican; so do Biancani in his *Sphaera* and most members of our Society. As you see, this system has the Earth immobile in the middle of the universe, with the

elements. About the Earth the Moon turns in a monthly motion, and then the Sun in an annual one. Last of all visible things comes the sphere of the fixed stars, which stand at unequal distances from the Earth, a sphere that moves both with a diurnal motion of 24 hours and with a proper and very slow motion toward the east. And so the centre of the Earth is also the centre of the lunar and solar heaven and course, and also of the sphere of the fixed stars. But the centre of the other five planets is the Sun itself: that is, not only of Mercury and Venus, which go around the Sun itself below and above it between the Sun and the Moon, as in the Egyptian system, but also of Mars, Jupiter and Saturn, as the Copernican system has it. [Margin: The affinity or equivalence of the Tychonic system with the Copernican.] The orb of Mars, moreover, goes round the Sun in such a way that, at opposition to the Sun, Mars becomes perigean, descends below the orb of the Sun and comes nearer to the Earth than the Sun itself, and so then appears much larger than it does near apogee. In this respect too the system is equivalent to the Copernican, in which Mars, opposed to the Sun, comes far nearer to the Earth, which lies between it and the Sun, and appears larger than in the Ptolemaic system, or the Egyptian. It also rivals the Copernican system, insofar as with fewer revolutions, and without the solidity and superfluity of the Ptolemaic or rather Peuerbachian spheres, it very easily defends all the phenomena, although the Copernican displays greater simplicity and elegance.

VI. Systema Nostrum olim.

[VI. Our Former System.]

Diagram. A large outer circle carrying scattered stars, within which two further circles, about the dark globe of the Earth near the centre, carry at the top ♄ and ♃, each with small rings of its own beside it. The rayed disc of ☉ stands above the Earth, with small circles about it carrying ☿ and ♀, and a larger circle about the Sun carries ♂, which appears both above and below. A small circle about the Earth carries ☾.

- Top: ♄, with a pair of concentric rings beside it
- Below it: ♃, with four concentric rings beside it; then ♂
- About the Sun: ♀, ☿; the circle to the right of the Sun is drawn with a heavy stroke
- About the Earth: ☾
- Below the Earth: ♂

[Margin: Our former system.] V. With the reader's kind leave, I should like to indicate here a system that came to my mind when I was once publicly teaching philosophy at Parma, while dealing with the heavens. It is semi-Tychonic: it has everything else in common with the Tychonic, except for the orbs of Saturn and Jupiter, whose centre in my version was not the Sun but the Earth itself, as you see in the diagram. I was moved to this because Saturn, attended by two planets or bodyguards [Lateronibus], and Jupiter, by four planets going around it, seemed to me to be primary planets, exercising their

monarchy in their own world and heaven no less than the Sun, attended by Mercury, Venus and Mars, this last as a large and more widely ranging satellite. For if we viewed Saturn or Jupiter from as near as we do the Sun, they would not seem to us so much smaller than the Sun, nor would their satellites seem so much smaller than Venus, Mercury and Mars as they do now. I also thought it probable that there is some intermediate planet, sharing in its motions with the two superior planets and with the inferior ones, and that Mars is of this kind: though in many respects it is more like Saturn and Jupiter, in others it is more like Venus and Mercury. In this way Mars will enter not the foreign heaven of the Sun but its own, or its sovereign's, as Venus and Mercury do. [Margin: The system of Baliani, not yet mature.] Meanwhile I shall finish the chapter by indicating the invention of D. Io. Bapt. Baliani [Giovanni Battista Baliani], a patrician of Genoa, who had begun to construct a new system in which the Moon would hold the centre of the universe and the other bodies would move around it. But it has not yet come to light, and would that Lucina could successfully act as midwife at this birth. For my part I would suppose that he meant to move the Earth on the monthly orb of the Moon, as Copernicus moves it on the annual orb attributed elsewhere to the Sun, as I shall explain shortly in the Appendix. On the jumble of other old systems, see Plutarch, *De Placitis*, book 2, chapter 15; Pliny the Elder, book 2, chapters 8 and 17; and Io. Antonius Delphinus [Giovanni Antonio Delfino], in his book *De Globis Caelestibus*.

APPENDIX.

De Loco Solis ac Terræ, Deq. Multiplici Terræ ipsius Motu, iuxta Hypothesim Nicolai Copernici. [On the Place of the Sun and of the Earth, and on the Manifold Motion of the Earth Itself, according to the Hypothesis of Nicolaus Copernicus.]

I. Taking the occasion of the Copernican system, I should like to set out his opinion in this place, insofar as it concerns the motions of the Sun, which he transferred to the Earth, granted that I have not yet discussed the motions of the Sun. I do so lest this explanation, inserted elsewhere, disturb the order and interrupt what I have indicated is to be treated later, jointly and continuously. Copernicus himself gives his opinion on the place and motion of the Earth in book 1, from chapter 5 to 12, and in book 3, chapters 1 and 3. So do Rheticus in the first *Narratio* on the books of Copernicus, with Mästlin's annotations; Kepler in the *Mysterium Cosmographicum*, chapter 1, in the *Commentaries on Mars*, and in the *Epitome of Copernican Astronomy*; Galileo in the dialogues on the world system; Pierre Gassendi in book 2 of the *Institutio Astronomica* and in letter 2 *De motu impresso*; and Pierre Hérigone in volume 5 of the *Cursus Mathematicus*, from p. 575.

II. In the diagram below, then, let S be the centre of the world, and next to it the centre of the solar globe, which, as the heart of the universe and the source of light, is to rest immobile and free from all motion of translation; for the

motion of rotation, treated in chapter 4, does not conflict with the Copernican hypothesis. About S let the celestial ecliptic ACLK be described, and in its plane let there be the line of the equinoxes LA and, cutting it at right angles at S, the line of the solstices CK. Again, from the centre S, or from a point as near to it as the eccentricity of the annual orb of the Sun among other authors allows, let the annual orb EFBD be described in the plane of the celestial ecliptic. On its circumference let there be the centre of the Earth GHIP, and let this centre be understood to stand successively at the four cardinal points, as the annual revolution requires: namely at B, at D, at E and at F.

Diagram. A large circle, broken at the upper and lower right, is the celestial ecliptic, with its four points marked by zodiac signs outside it. A vertical line CK and a horizontal line LA cross at its centre S, where the Sun is drawn as a large rayed disc. Inside it a smaller circle, the annual orb, carries four small circles of the Earth, each with its own crossed diameters: at the top about F, on the left about B, on the right about E, at the foot about D.

- Top, outside the circle: ♋; below it: C
- Top small circle: P (upper right), G (left), F (centre), I (right), H (lower left)
- Far left: L, and outside it ♎, set sideways
- On the line at far left, inside the ecliptic and below L: ☾
- Left small circle: P (upper right), G (left), B (centre), I (right), H (lower left)
- Between the left small circle and the Sun: ☾ on the line, with N below it
- Centre: S
- Right small circle: P (upper right), G (left), E (centre), I (right), H (lower left)
- Far right: A, and outside it ♈, set sideways
- Foot small circle: P (upper right), G (left), D (centre), I (right), H (lower left)
- Foot: K, and below it ♑

[Margin: 1. The diurnal motion of the Earth.] First, then, let the Earth be at B, where the Sun S appears to Earth-dwellers at the beginning of ♈, under the point A, and let the equator of the Earth be GHIP (for according to Copernicus the equator, with the tropics, the polar circles and the other parallels to the equator, should be conceived on the Earth rather than in the heavens), with its diameter GI coinciding with the diameter BE of the annual orb, as the position of the equinox requires. Let the globe of the Earth, with its whole elementary atmosphere, move about its centre B in a diurnal revolution toward the east, or in the order of the signs, from I to P, from there to G, and through H back to I, describing on its surface the equinoctial or equidial circle and returning to I in the space of 24 solar hours. For in this way all the stars will seem to us to move toward the west, since our eyes go to meet them toward the east, whether they are above the Earth or between the Sun and the Earth, as we said in chapter 6, at system 4. Recall that here. But this holds above all for

the Sun S: for when the point I and its inhabitant have revolved to P, the Sun will seem more westerly by the whole arc PI, whereas before it seemed to the inhabitant of I to be on the meridian. And so, once this single motion of the Earth is posited, the diurnal motion of the fixed stars and of all seven planets is removed, a motion that would otherwise have to be multiplied in each of them, or else placed in some highest sphere, as a primum mobile that carries the lower spheres along with it, or impresses or communicates that motion to the lower ones. There is removed, besides, that contradiction which appears between the diurnal motion toward the west and the proper motion of the stars toward the east; nor is it necessary to recognise in the planets any motion but one to the east, speaking of the motion in longitude. It is no wonder, however, that the stars seem to us rather to move with this diurnal motion, because of a deception of sight similar to the one the Virgilian Aeneas meant, in book 2 of the *Aeneid*, when he indicated the apparent motion of the shores, which truly belongs to the ship and the sailors, in that line:

We are carried out from the harbour, and lands and cities recede.

For the phenomena of the risings and settings of the stars are exactly the same whether the stars themselves are carried round the Earth to the west, or, with them thus unmoved, the Earth revolves to the east about its centre and the axis of its equator in an equal interval of hours.

[Margin: The agreement of the elementary motions with the diurnal motion of the Earth.] III. According to Copernicus's view, the air nearer the Earth moves with the terrestrial globe, to say nothing of the element of water joined to the Earth, and all bodies cognate to the Earth share in this circular motion of diurnal revolution. On the other hand, if heavier things are removed from their place, when let go they naturally tend downward, not to the centre of the universe S but to the centre of the cognate body, or of the whole atmosphere. For this reason their descent is a motion mixed of straight and circular, by virtue of which things thrown perpendicularly upward fall back to the same place, notwithstanding the motion of the Earth. Birds, clouds and other things driven or thrown toward the west still share in this eastward motion of the whole elementary sphere, and are carried less far to the west than they would be if, with the Earth and the atmosphere standing still, they were borne to the west with the same impetus. Copernicus does, however, except from this motion that highest region of the air in which comets or similar phenomena appear, because they seem either to remain suspended in still air or at least to rise and set in the manner of the stars. As for Sacred Scripture, when it ascribes rising and setting to the Sun, the followers of Copernicus contend with him that it speaks in accommodation to the understanding of the common people and to the deception of our sight and imagination, and figuratively rather than properly and to the letter. But in this they certainly err, as we shall teach in its place.

[Margin: The authors of this motion, and the ecclesiastical censure passed upon them.] This, then, is that diurnal motion which Heraclides of Pontus,

Ecphantus the Pythagorean, Plato in the *Timaeus*, and Nicetas or Hicetas of Syracuse, as reported in Cicero, Plutarch and Laërtius, attribute to the Earth; as do now the semi-Copernicans William Gilbert (*De Magnete*, book 6, chapter 3), Origanus (*Ephemerides*, volume 1), Longomontanus (book 1, pp. 161 and 220) and Argoli (*Pandosion*, chapter 3), though they place it at the centre of the world, as I reported in book 2, chapter 3. Their opinion, however, is judged by the Sacred Congregation of Cardinals *at the least erroneous in faith, and absurd and false in philosophy*, as I said in book 2, chapter 3, no. 3, and shall say more fully in Book 9, section 4. Nor does Tycho stand up for this motion anywhere in volume 1 of the *Progymnasmata*; indeed he attacks it sharply in his letters, pp. 147 and 188.

[Margin: 2. The annual motion of the Earth's centre.] IV. Hitherto we have considered the centre of the Earth at B, from which the Sun S appeared under A, the beginning of ♈. Let it now move from there in the order of the signs toward D, each day by as much as the Sun's centre moves on the ecliptic in the hypothesis of others, that is, completing on the annual orb by mean motion about 59′ 8″ 20‴ a day. For when the Earth is at D, the Sun S will appear to us under C, at the beginning of ♋; when the Earth is at E, the Sun S will be seen under the point L, at the beginning of ♎; when it is at F, the Sun S will be seen under the point K, which is the beginning of Capricorn; and finally, when the annual revolution is complete and the Earth has been restored to B, the Sun will again appear under A, at the beginning of Aries. And so this single motion of the Earth will display to us the alternations of the equinoxes and solstices, provided that the diameter HP of the terrestrial equator is inclined to the ecliptic, or the annual orb, by as much as the obliquity of the ecliptic for the time being in the common hypothesis [obliquitas Eclipticę temporaria]; that its diameter GI, at right angles to HP, always lies in the common section of the planes of the annual orb and the terrestrial equator, but at the equinoctial points B and E coincides with the diameter BE, the planes nevertheless being inclined as the obliquity of the ecliptic requires; and finally that the terrestrial equator proceeds through the whole year always parallel to itself, its axis to itself, and so GI also to itself.

[Margin: 3. The Earth's motion of declination.] V. But suppose the parallelism of the equator to itself and of the axis to itself were not kept, and the axis instead followed the motion of the Earth's centre, that is, were inclined to the axis of the ecliptic always in the same way, facing the same point of the axis of the ecliptic or annual orb, and the axis of the terrestrial equator did not point throughout the year to sensibly the same regions of the world. This would be contrary to the most manifest phenomena, and no inequality of days and nights would appear: there would always be either equinox or solstice, either spring or autumn or summer or winter, or some other unvarying temperature and measure of days and seasons. Let P, then, be the limit of the equator's greatest declination to the south, and H to the north. For with the Earth placed at F, the Sun will appear under the beginning of Capricorn to make the winter solstice

and to reach its greatest southern declination, while the equator's limit H there declines most toward the north, because the slope of the equinoctial to the line FS, by virtue of the diurnal revolution, turns out for itself on the surface of the Earth the winter tropic, parallel to the terrestrial equator, according to the obliquity contained under the angle SFH. Now let the centre F go on to B, completing the quadrant FB, but let P, the end of the greatest declination, be carried by about the same amount against the order of the signs, so that BP does not follow the course of the ecliptic, or the same longitude as SB, but is turned back through a quadrant toward C, and so the angle SFI has meanwhile been kept equal to the angle FSB. For there the diameter GI will coincide with the straight line drawn from S, as it also will at E, and the equinoxes will occur. With the Earth placed at D, the Sun will be seen to enter Cancer and to reach its greatest northern declination, while the limit P declines most toward the south, by the angle SDP. On other days, according to the varying inclination of the axis of the equator from the axis of the ecliptic, the Earth by virtue of the diurnal motion traces out on its surface other and yet other parallels to its equator, and produces the difference of artificial days and nights. Since the Earth in its annual motion carries the lunar heaven around with it, it follows that, given the diurnal motion, the changes of the lunar phases are saved, eclipses especially. Thus, with the Earth placed at B, we at the point I see ☾ N conjoined with and set beneath ☉ S; but placed at G, we see the Moon L opposite the Sun S and eclipsed by the Earth's shadow, unless latitude prevents it.

VI. But since the two annual motions just mentioned, one of the centre and the other of the axis of the equator, made in opposite directions and running to meet each other, are almost equal, the annual revolutions of the centre and of the declination are also almost equal. For if they were exactly equal, the equinoctial and solstitial points would not change places under the sphere of the fixed stars, nor would they seem to recede from the fixed stars toward the west, or the fixed stars toward the east, with that slow motion that was at length detected in them. [Margin: 4. The Earth's motion of the equinoctial points, elsewhere ascribed to the fixed stars.] But because they are not exactly equal, and while the centre of the Earth in its annual motion completes about 59′ 8″ 20‴ a day on the annual orb in the order of the signs, the axis of the terrestrial equator is supposed to move 59′ 8″ 20‴ against the order of the signs, the centre of the Earth has therefore not yet been restored to the point B when, the motion of declination having got ahead, the Earth's equator is found to have directed one of its diameters, namely GI, at the ☉ from a more westerly point between B and F. So the line LA of the mean equinox appears shifted, and the mean vernal equinox occurs at a more westerly point between A and K. And hence a fixed star, for example the first of Aries, when the equinoctial point from which we count longitudes deserts it, seems to have receded eastward from A toward C; whereas, as Copernicus would have it, the fixed stars themselves do not move, but rather the equinoctial and solstitial points recede from them toward

the west, completing their period in 1717 Egyptian years, 5 days. And this is, for Copernicus, the mean precession of the equinoxes, which for others would be the mean succession, or the mean motion of the fixed stars according to the succession of the signs. It is a certain fourth motion included in the Copernican motion of the Earth, but an apparent one, since in reality it is the same as the motion of declination, somewhat faster than the annual motion of the Earth's centre.

[Margin: 5. The motion of the Earth by which the obliquity varies.] I said, moreover, that the Earth's equator always faces almost the same part of the world, because if the obliquity of the equator and the ecliptic varies with time, the position of the terrestrial equator varies also, and a certain fifth motion, of the obliquity, must be conceived. Its period from greatest to greatest or from least to least obliquity is twice as long as the mean motion of the precession of the equinoxes, that is, of 3434 Egyptian years and 10 days. This motion occurs because of a certain libration, by which the axis of the terrestrial equator nods toward the sides of the world.

VII. Finally, since each of the motions just mentioned, namely that of the precession of the equinoxes and that of the obliquity, is unequal, now fast and now slow, then to account for the anomaly of both we must conceive two reciprocal motions of the poles of the terrestrial equator, resembling hanging librations. By one of them the poles are carried up and down about the angle at which the equator cuts the ecliptic, and the inclination of the equator to the ecliptic is altered. By the other the precession of the equinoxes is now increased and now diminished, by a transverse motion, from the preceding parts into the following and from the following into the preceding, so that the poles themselves describe certain lines resembling twisted garlands, as we shall set out in a diagram placed at chapter 28, number 9. [Margin: 6 & 7. The motions of the Earth's poles.] So, with this twin libration added, a certain sixth and seventh motion, or rather an affection of the annual motion, is included in the Copernican hypothesis.

VIII. Moreover, an annual motion of the Earth besides the diurnal, as though the Earth were some planet, was attributed long ago to it by Philolaus the Pythagorean, a man of so great a name that Plato came to Italy for the sake of visiting him; and by Aristarchus of Samos; then by Nikolaus von Kues; and, after Copernicus, by Rheticus, Mästlin, Giordano Bruno, Kepler, Celio Calcagnini, Rothmann, Schickard, Stevin, Galileo, both Lansbergens, Boulliau, Pierre Hérigone, Baranzano, Diego de Zúñiga, Paolo Antonio Foscarini, Descartes, and many others here and there in Germany and France. And yet this hypothesis has been pronounced by the Sacred Congregation of Cardinals *formally heretical as regards the immobility of the Sun*, inasmuch as it is *expressly contrary to Sacred Scripture*; I spoke of this in Book 2, chapter 3, and more will be said in Book 9. Granted, it very ingeniously disposes of all the phenomena of the Sun and of the fixed stars by the motions of one body in the world, and that not a very large one, with a truly marvellous economy; indeed it also shows, from the

motion of the Earth alone, the cause of the retrogradations, direct motions and stations that appear in the planets.

[Margin: 8. The motion of the Earth up and down.] IX. Lastly, the Sun seems at some times to recede from the centre of the Earth so far as to be at its greatest distance in apogee, and at other times to approach the Earth so as to be nearest to it in perigee, so that the annual orb is eccentric to the centre of the world; and the Sun's apogee also seems to shift unequally in the order of the signs. To account for these two phenomena we must conceive either a small circle near the Sun, on whose circumference the centre of the Earth's annual orb is carried, or the Earth itself as carried now higher, now lower, and that with a certain anomaly, as Copernicus holds. So much for the fivefold motion of the Earth, namely the diurnal; the annual motion of the centre; the annual motion of the declination; the libration of the poles, mixed from the up-and-down motion and the transverse motion; and the motion of the eccentricity, or of its centre, up and down. The others are not distinct motions, but certain affections of these.

SCHOLIA.

I. The annual motion of the declination and the motion of libration of the equinoxes and of the obliquity, discussed in the preceding chapter from number 5 to number 8, do not necessarily require the Earth to be outside the centre of the world, and they are not necessarily connected with the annual motion of the Earth treated in number 4, granted that in the hypothesis of Copernicus they are connected. [Margin: A new affection of the Earth's diurnal motion.] To the diurnal motion, however, Longomontanus, Kepler and Boulliau add another motion, or affection of motion, which Wendelen also indicates: by it the diurnal motion is evidently slowed in aphelion and quickened in perihelion, and in this way the inequality of the days, which seems to arise from the unequal motion of the Sun along the ecliptic, is amply compensated; according to what is to be said in chapter 31.

[Margin: A compendium of the celestial motions in the motion of the Earth.] II. The Copernican hypothesis of the diurnal and annual motion of the Earth accounts not only for the proper motion of the fixed stars; the common diurnal motion of all the stars; the annual motion of the Sun toward the east; the oblique motion of the Sun toward the poles of the world, or motion of declination; the motion of anomaly of the precession of the equinoxes, and the motion of anomaly of the obliquity of the ecliptic, or of the two librations; and, if you add the motion by which aphelia and perihelia arise, it contains this motion too within itself. Beyond that, it removes the three eccentrics of the Sun, Venus and Mercury, by which in the hypothesis of others these two planets are moved according to the motion of the Sun; it also removes the three epicycles of Saturn, Jupiter and Mars, with their motions. From the Earth's approach to those planets and its recession alone, a reason is given why in opposition to

the Sun they are perigean and in conjunction apogean; why they undergo a certain variation of latitude, for which Ptolemy instituted five other motions; and why the five minor planets seem at times to stand still and to go backward. And if you believe Galileo, the cause of the sea's tide is also given from this. But these things, lightly indicated here, will be said more fully elsewhere; but they will be refuted.

CAPVT VII.

De Solis à Terra Distantia Mutabili, aut Immutabili. [On the Distance of the Sun from the Earth, Whether Changeable or Unchangeable.]

I. It would be the mark of Epicurean stupidity, or madness, to reckon the interval between the Earth and the Sun at as few ten-foot rods as to judge the Sun itself to be a foot across. Its height has so far exceeded the subtlety of all astronomers, and here there would be need of the wings of Astraea herself, and of *Feathers not given to man*. And yet, with the Sun's distance unknown, the distance and parallax of all the stars, except the Moon, are unknown. [Margin: Pliny the Elder's saying, still notable today, Book 2, chapter 23, on the uncertain distance of the Sun.] So that saying of Pliny the Elder about these intervals holds to this very day: *These things are undiscovered and inextricable*; and shortly after: *If anyone should care to pursue these matters more deeply, not so that there may be a measure (for to want that is the idleness almost of a madman), but only so that the mind may hold an estimate for conjecturing.* Kepler confessed something similar in the *Commentaries on Mars*, p. 71. *The Sun*, he says, *is not nearer than 230 semidiameters of the Earth, yet it is not infinitely many distant; but between 700 and 2000 no certain number seems yet to have been demonstrated.* What do you say, Kepler: between 700 and 2000? I for my part say not even between 700 and 7000, and indeed perhaps not even within 15000, as I shall show below. But first I must set out the choicer methods by which the distance of the Sun from the Earth can be measured in some fashion, the other, less certain ones being relegated to the Scholia.

I. PROBLEMA DE SOLIS DISTANTIA PER PARALLAXES.

[I. Problem: On the Sun's Distance by Parallaxes.]

[Margin: The first method, by the horizontal parallax.] II. What parallax is I explained in Book 1, chapter 35, which anyone who has forgotten it should reread; but the following diagram will dispose of this matter more simply. In it let AC be a quadrant of the Earth, and let H be the centre of the Earth and of the solar heaven, and also of the world; about H let YSR be a quadrant of a vertical circle conceived in the Sun's orb. Let HR be the rational horizon, on which the vertical line YH, drawn from the zenith Y to the Earth's centre H, falls perpendicularly. Let the eye be at A, and its sensible horizon AB, parallel to HR; and let the centre of the Sun appear at B, rising on the sensible horizon, or setting.

Diagram. A woodcut quadrant set into the right column: an outer arc runs from the top of a vertical line down to the right end of a horizontal base, and a smaller inner arc concentric with it runs from a point on the vertical to a point on the base. Both straight lines meet at the lower-left corner. A horizontal line runs from the point on the vertical to the outer arc, and straight lines run from the lower-left corner and from that same point on the vertical up to two points on the outer arc.

- Top of the vertical line: V (the text calls this point Y)
- Upper point on the outer arc: S
- Point on the vertical, at the end of the inner arc and of the horizontal line: A
- Lower point on the outer arc, at the other end of the horizontal line: B
- Lower-left corner, the centre: H
- End of the inner arc on the base: C
- Right end of the base: R

For when the straight line HB is drawn from the centre H to the Sun, the greatest and horizontal parallax of the Sun will be the angle BHR, or the arc BR; for its true altitude above the horizon HR will be the arc BR; and yet to the eye at A, the Sun seen at B will appear not at all elevated above the horizon. Now the angle ABH is equal to the alternate angle BHR, made by the line HB falling on the two parallels HR and AB, by 29 of the First Book of Euclid; and by the same proposition the angle HAB is a right angle and equal to the angle AHR, also a right angle, being made by the perpendicular YH. Therefore, given in the triangle AHB, right-angled at A, the horizontal parallax, that is, the angle B, and taking the Earth's semidiameter as one, the distance of the Sun from the Earth, namely the base HB, will be found by 5 of our *Plane Right-Angled Triangles*: that is, if you look up the residual of the logarithm [Residuum Logarithmi] of the angle B, for this will be the logarithm of the base HB; or if you subtract the angle B from 90° and divide the secant of the remainder by the radius of the tables, for the quotient will be the base HB itself, in parts of which the Earth's semidiameter AH is one. Therefore, if the horizontal parallax is as in the following small table, the Sun's distance from the centre of the Earth will also be, as you see in that same table; and a difference of a few seconds in the parallax, let alone of minutes, will bring a great difference in the Sun's distance.

Horizontal parallax of the ☉	Secant of the angle AHB	Distance of the Sun HB, in semidiameters of the Earth
0′ 15″	154698556112	15470
0′ 30″	68754937464	6875½
1′ 0″	34377468732	3438
2′ 0″	17188734366	1719
3′ 0″	11459157557	1146

With the radius set at 10000000.

[Margin: 2. The method by any parallax whatever.] III. Now let the Sun be at S, its true altitude the arc SR, and its true distance from the zenith the arc SY; and let the straight lines HS and AS be drawn. The angle YHS will belong to the true distance from the zenith, and the angle YAS to the distance seen from the eye at A. This angle is greater than the former, by 32 of the First Book of Euclid, and by the same proposition equal to the two interior and opposite angles S and H of the triangle SHA. So the angle S will be the difference between the angle SHA, of the Sun's true distance from the zenith Y, and the angle YAS, of the apparent distance, and hence it will be the measure of the parallax. Therefore, if any parallax of the Sun in the vertical circle, or parallax of altitude, is given, namely the angle S, then added to the Sun's true distance from the zenith it will give the angle SAY, whose complement to two right angles, by 13 of the First Book of Euclid, is the angle SAH. But the same parallax S, subtracted from the Sun's apparent or observed distance from the zenith, will give the angle AHS. So in the triangle SAH, with the Earth's semidiameter AH taken as 1, and given the angle S of the parallax together with either of the angles SAH or SHA,

Diagram. A woodcut quadrant of the same construction as on the previous page, set into the left column at its right: a vertical line and a horizontal base meeting at the lower-left corner, an outer arc from the top of the vertical to the right end of the base, a smaller inner arc, a horizontal line from a point on the vertical to the outer arc, and straight lines from the corner and from that point on the vertical to two points on the outer arc.

- Top of the vertical line: V (the text calls this point Y)
- Upper point on the outer arc: S
- Point on the vertical: A
- Lower point on the outer arc: B
- Lower-left corner: H
- End of the inner arc on the base: C
- Right end of the base: R

the other will also be known, being the complement of the two remaining given angles to two right angles, by 32 of the First Book of Euclid. [Margin: A shortcut of the rule.] So use the angles S and HAS, and by 2 of our *Plane Oblique-Angled Triangles* find the side HS, that is, the distance of the Sun from the centre of the Earth. That is, add together the logarithm of the angle S and the residual of the logarithm of the angle SAH; for their sum, with one taken off at the left, will be the side HS, in parts of which AH is one. Or else divide the right sine of the angle SAH by the sine of the angle S, and at once the side HS will come out, in parts, however, of which AH is one semidiameter of the Earth.

[Margin: The parallax of the Sun, without its distance from the Earth, cannot be observed outside the torrid zone.] But if only the way of finding the parallax of the Sun, independently of its distance from the Earth, were as certain as either part of this problem is easy! Outside the torrid zone, however,

this is simply impossible [adynaton]. One would have to know the Sun's true altitude from its motion beforehand, independently of the parallax, so that the difference between the true altitude and the apparent one, or the one observed with instruments, might reveal the parallax of altitude. But the Sun's true motion cannot be gathered from tables more exactly than from the mean motion deduced from observed equinoxes; and the moments of the equinoxes cannot be determined unless the altitude of the Sun then observed is corrected, by adding the parallax to the observed altitude. In the same way, neither the Sun's greatest declination nor the obliquity of the ecliptic can be known from observation unless the Sun's altitude taken at the solstices, or its rising amplitude, is corrected by the parallax. And so, although Gotefridus Vendelinus [Govaert Wendelen], in a letter sent to me this very year, truly says that *parallaxes of the Sun are assumed and feigned rather than grasped*, and that whether no parallax or one of at most 3′ is assumed at the equinoxes, no error can be committed exceeding 10′, *mocking almost all sense*, nevertheless the intervals of the equinoxes, or the distance of the tropics, cannot be known exactly except through altitudes observed at the equinoxes or solstices and reduced to true ones by adding the parallax; especially since refraction mixes itself into the winter altitude, and refraction itself is not known unless the parallax is known beforehand.

IV. I said *outside the torrid zone*. [Margin: Snellius's method of observing the parallax of the Sun.] For, as the very acute Snel points out in his notes to the Hessian observations, let the Sun's greatest declination be observed with instruments showing at least every ten seconds. This will be done if there, from some circumpolar fixed star or from the very certain declination of some fixed star, the distance of the equator from the zenith, or the altitude of the pole, is observed; and let a second observer, outside the torrid zone, observe on the day of the summer solstice the greatest apparent declination of the Sun, the true altitude of the pole having first been observed from the fixed stars. For the difference between this apparent declination and the true declination observed by the inhabitant of the tropic, and hence true (since the Sun, then standing at his zenith, undergoes no parallax at noon), would be the parallax of the Sun. This holds provided that all these things are done beyond the hazard of refractions, and that you can be certain that no sensible refraction intervenes, without prior knowledge of the parallaxes [Greek: παραλλάξεων (parallaxeōn, "of the parallaxes")]; and likewise that you are certain you are directly under the tropic itself. If precision is looked for here, this last is very difficult, because the space in which gnomons cast no shadow at noon on the solstitial day occupies 300 stadia, as was observed by Eratosthenes and others, in Strabo, Book 17, in Cleomedes, Book 1 of the *Cyclical Theory*, and in Pliny the Elder, Book 2, chapter 73. So, even if wells in that tract are then wholly lit, and styles set up perpendicularly cast no noon shadow, the observer still cannot conclude that he is under the tropic itself, but only in that tract of 300 stadia, which subtends

as large an arc of the heaven as the Sun's apparent diameter, namely about 30′. So this method too is slippery.

[Margin: Another, better method, of Father Francesco Maria Grimaldi.] V. A subtler and sounder method, therefore, is the one that Father Francesco Maria Grimaldi recently suggested to me, the day after I had discussed this matter with him. Let someone, he says, stand directly under the equator, and on the equinoctial day let the Sun's distance from the zenith be taken with a large quadrant showing tens of seconds, about two hours before or after noon, that is, before or after the Sun's passage through the zenith. And let a second companion, using a most exact pendulum [Perpendiculum], count the time between the Sun's passage through the zenith and the moment the altitude was taken, and let that time be converted into an arc of the equator. For if this arc is equal to the observed distance of the Sun from the zenith, the parallax of the Sun will be nil to the senses. But if that arc is less than the observed arc, their difference will be the very parallax of the Sun that is sought, corresponding to the apparent distance. Here, moreover, one must use the table that converts the time, not of the day of the primum mobile, but of the solar day, into parts of the equator, and a pendulum that does not stray by a single second in this time; otherwise, for every second it strays, the parallax will be wrong by fifteen seconds. Finally, you would need to be certain both that the equinox occurs on that day not far from noon and that you are directly under the equator itself. This you will be able to know if the declination of some fixed star is exactly known, observed elsewhere by someone who has observed the altitude of the pole and of the equator from circumpolar stars placed beyond the hazard of refraction; of this kind are the Tychonic declinations of the fixed stars and ours. For if the distance of such a star from the zenith, observed in the meridian, is equal to its declination observed elsewhere, you will be certain that your zenith lies on the equator itself. But for the present we cannot make this trial. So we must rise to this height by other ladders, and the first step must be fixed on the Moon, so that from there you may ascend to the Sun.

II. PROBLEMA DE SOLIS DISTANTIA PER ECLIPSES.

[II. Problem: On the Sun's Distance by Eclipses.]

[Margin: The authors of the second problem.] VI. The author of this second problem is held to be Hipparchus, and its restorer Ptolemy, *Magna Constructio*, or *Almagest*, Book 5. He was afterwards imitated by Jābir ibn Aflaḥ, *Astronomy*, Book 5; al-Battānī, chapter 30; Regiomontanus in the *Epitome of the Almagest*, Book 5, from proposition 19 to 21; Copernicus, Book 4, chapters 19 and 20; Longomontanus in the *Astronomia Danica*, Book 1 of the *Theorica*, chapter 9; [Margin: Three data required for this problem.] Maurolico, *Cosmographia*, Dialogue 3, p. 85; Magini in the *Theoricae Planetarum*, Book 2, chapter 24; Lansbergen in the Prolegomena to the *Uranometria*; Bettini, *Apiaria*, Apiary 8, Progymnasma 3, proposition 11; and Ismaël Boulliau, Book 4 of the *Astronomia*

Philolaica, chapter 1. Granted, most of them have gathered by this method results that contradict their own hypotheses, as Lansbergen shows in the same place. Now three data are supposed here. The first is the apparent semidiameter of the luminaries, observed by radii, dioptras, or otherwise. The second is the Moon's distance from the centre of the Earth by means of parallaxes, which we shall show in the next Book can be known independently of the Sun's parallax. The third is the apparent semidiameter of the Earth's shadow at the place through which the Moon passes at the time of some lunar eclipse; how this is investigated is to be said in Book 5, which is on eclipses. These being given:

In the adjoining figure let A be the centre of the Earth, B that of the Sun, and CD the diameter of the Sun. Let two extreme rays of the Sun be drawn, touching the Sun at C and D and the Earth at M and N, until they meet at E, and let these be CME and DNE. And from the Sun's centre B, through the Earth's centre A, let the straight line BA be drawn as far as E; for AE will be the axis of the Earth's shadow. Now let the centre of the Moon be at F, as it eclipses the whole Sun without delay, and let the straight line AID be drawn, touching the Moon at I and the Sun very nearly at D, so that the angle FAI subtends the apparent semidiameter both of the Moon, FI, and of the Sun, BD, without sensible difference. After this, in AE let AG be taken equal to the Moon's distance AF, G being the place of the Moon's passage in a lunar eclipse. Let the diameter of the Earth's shadow, PL, be drawn, cutting AE at right angles, and let GL be its semidiameter. From A let the straight line AL be drawn to the point L, and let LK be drawn parallel to the straight line AG. With these laid down:

Diagram. A tall, narrow woodcut set into the left column at its right. A large circle at the top has a horizontal diameter. Two long lines run from the ends of that diameter down past a smaller circle, which also has a horizontal diameter, and converge at a point at the foot, forming a long cone. A central vertical axis runs from the large circle to the foot. A small circle stands on the axis between the large circle and the middle circle, and a further small circle with a horizontal diameter stands on the axis below the middle circle. Further straight lines cross the region from the middle circle's centre toward the top and the lower diameter.

- Left end of the upper diameter: C
- On the upper diameter, left of centre: R
- On the upper diameter, at the axis: B
- Right end of the upper diameter: D
- In the small upper circle: F
- Beside the small upper circle, on its right: I
- In the middle circle, left of the axis: T and A
- In the middle circle, right of the axis: K
- Left end of the middle diameter: M
- Right end of the middle diameter: N

- Left end of the lower diameter: P
- In the lower circle: G
- Right end of the lower diameter: L
- Foot of the cone: E

FIRST, in the triangle AGL, right-angled at G, there are given through Ptolemy the distance of the Moon at apogee, AG, of 64⅙ terrestrial semidiameters, and the apparent semidiameter of the Earth's shadow, that is, the angle GAL, of 40′ 45″. Therefore by trigonometry GL, the true semidiameter of the shadow, will be 45 63867/100000 parts, of which, in the Ptolemaic manner, the Earth's semidiameter AN is 60. Now because the straight lines AG and KL are parallel, the straight line GL is equal to AK, by 33 of the First Book of Euclid. Therefore, with the equal AK taken away, there remains KN, of 14 36133/100000 parts.

SECOND, then, in the triangle KLN, right-angled at K, there are given KL, equal to GA, that is, of 64⅙ parts of which AN is one, or of 3850 parts of which AN is 60; and KN, of 14 36/100 such parts. By trigonometry the angle KLN is found to be 12′ 49″. By 29 of the First Book of Euclid this angle is equal to the angle AEN, of the half cone of the shadow; and to this angle and the angle ADE taken together the exterior angle BAD is equal, by 32 of the First Book of Euclid. This is the angle subtending the semidiameter of the Sun and of the Moon at apogee, which for Ptolemy is 15′ 40″.

THIRD, then, with the straight line BN drawn, the angle BND will subtend the same semidiameter of the Sun, and by the same 32 of Euclid it will be equal to the angles NEB and EBN taken together. So, when the angle BEN of 12′ 49″ is taken from the angle BND of 15′ 40″, there will remain the angle ABN of 2′ 51″, which is evidently the horizontal parallax of the Sun. And thus far with Lansbergen; for the others cited at the beginning of this number 6 set up this problem differently, and hunt first for the axis of the shadow, AE, and then for the Sun's distance, AB. But it will be found more briefly through the horizontal parallax, with the help of the First Problem, on which see number 2. So to a parallax of 2′ 51″ there will correspond a distance of the Sun of 1206 16/60 terrestrial semidiameters; or if you take the Ptolemaic parallax of 2′ 50″, AB will be 1210 terrestrial semidiameters.

[Margin: The ageometrical hypothesis of al-Battānī.] VII. Using roughly this method, Lansbergen convicts al-Battānī of inconsistency. For al-Battānī, with Ptolemy, puts the semidiameter of the Sun at apogee at 15′ 40″ and the distance of the new and full Moon from the Earth at 64⅙ semidiameters of the Earth; but the semidiameter of the Moon at that time at 14′ 45″, and of the shadow at 38′ 20″. From these he thinks it follows that the Sun's horizontal parallax is 3′, when only 26″ follows, and that the distance of the Sun at apogee from the centre of the Earth is 1146, when 7936½ semidiameters of the Earth follow. [Margin: And of Copernicus.] Further, Lansbergen refutes Copernicus for a similar inconsistency and want of geometry [ageometria]. For Copernicus puts the distance of the new and full Moon from the Earth at 65½ semidiameters

of the Earth, and the apparent semidiameters as follows: of the Sun at apogee 15′ 50″, of the Moon 15′ 0″, and of the shadow at the place of the Moon's passage 40′ 18″. From these he gathers the Sun's horizontal parallax as 2′ 55″ and the Sun's distance from the centre of the Earth as 1179 semidiameters of the Earth, whereas from those data there follow a parallax of 3′ 39″ and a distance of the Sun at apogee of 941 53/60 terrestrial semidiameters. [Margin: And of Tycho.] Besides this, Tycho too is charged by Lansbergen with a similar inconsistency. For Tycho puts the distance of the new and full Moon, also at apogee, at 58 8/60 semidiameters of the Earth, and the apparent semidiameters of the Sun at apogee at 15′ 0″, of the Moon at apogee at 16′ 0″, and of the shadow there at 43′ 0″. From these it follows that the angle of the half cone of the shadow, AEN, is 16′ 8″, greater than the semidiameter of the Sun, when it ought to be less. [Margin: And of Longomontanus.] Into this absurdity he also throws Longomontanus, who puts the new and full Moon, at the Sun's mean distance, at 57 38/60 semidiameters of the Earth, and the apparent semidiameters of the Sun at 15′ 0″, of the Moon at 16′ 0″, and of the shadow at 43′ 0″, as Tycho also does. From these it follows that the angle of the half cone of the shadow is 16′ 38″, and greater than the semidiameter of the Sun, when it ought to have been less, by 32 of the First Book of Euclid. As for Kepler's inconstancy in gathering the distance of the Sun, we shall speak of it below, in Scholium 2.

[Margin: Two notable corollaries, and] VIII. Gather from what has been said, first, how circumspect an astronomer must be, so that in his hypothesis the apparent semidiameters of the luminaries and of the shadow, the parallaxes and distances, and the angle of the cone of the shadow cohere by a geometrical bond. Second, how little suited this method, or this second problem, is to the precision that astronomy requires. For in observing the semidiameters of the luminaries an error of one half-minute can scarcely be clearly avoided, and much less in the semidiameter of the shadow, in which it is very easy to commit an error of two and three minutes; nor can it be observed accurately enough, as Longomontanus admits, Book 1 of the *Theorica*, chapter 9, p. 298. [Margin: The uncertainty of the second problem.] So, with the phenomena of eclipses preserved, the Sun could be distant from the Earth by far more semidiameters than the astronomers just mentioned have put. Suppose it is as far away as Wendelen wishes, 14000, or indeed 15470 semidiameters of the Earth, so that to this distance, according to what was said in number 2, there corresponds a horizontal parallax of the Sun of 15″, which in the figure of number 6 is the angle ABN; and suppose the Sun's apparent semidiameter to be only 15′. For the angle of the half cone of the shadow, by Lansbergen's method, will have to be 14′ 45″, and the angle KLN will have to be as large. With this angle, and with the Moon's distance AG, that is, KL, set at 64 parts of which AN is 1, or 3840 parts of which AN is 60, there is gathered in the right-angled triangle KLN the side KN of 15⅓ parts, and there remains AK, or GL, of 44⅔. With these, and with AG of 3840 parts, in the right-angled triangle AGL, the angle GAL, subtending the semidiameter of the shadow GL, is gathered as 40′ 54″, that is,

nearly 41′, the amount the Alphonsines put, which could hardly be convicted of falsity. Certainly Wendelen declares that, with so great a distance of the Sun assumed, he will represent eclipses perfectly. And on the uncertainty of this method, see Kepler's words below, at number 10. So let us carry our step over from the ladders of Hipparchus and Ptolemy to those of Aristarchus.

III. PROBLEMA DE SOLIS Distantia per Lunæ Distantiam, & Διχοτομίαν.

[III. Problem: On the Sun's Distance by the Moon's Distance and the Dichotomy.] [Greek: Διχοτομίαν (dichotomian, "dichotomy", the Moon's half phase)]

[Margin: The notable problem of Aristarchus.] IX. The third problem is that of Aristarchus of Samos, a fellow-citizen of Pythagoras, which he set out in an outstanding little book on the *Magnitudes and Distances of the Sun and Moon*, as it is entitled. Pappus of Alexandria, in Book 6 of the *Mathematical Collections*, from Proposition 38, and Federico Commandino have illustrated it with notes. The problem presupposes nothing except that the Moon's distance from the centre of the Earth is known, and also its elongation from exact quadrature, that is, from the quadrate aspect to the Sun, at the time when she shines half-lit for us in the evening before the first quadrature, or in the morning after the second quadrature. This elongation is obtained by observing the Moon's place at the time of the half phase, in the way this is usually done on other occasions: for from the Moon's true place in the zodiac, and from the Sun's place observed at noon or deduced from corrected tables, the arc of the said elongation will be known. This being assumed:

In the following figure let the centre of the Earth be T, from which let the Sun's orbit, or ecliptic, ABSC be described, and the Moon's orbit GLRF. Let the Sun be on the horizon ATS, or about at S, and let the Moon, dichotomous [Greek: διχότομα (dichotoma, "halved, cut in two")], that is, bisected, or shining half-lit for us, be at L, a little before the first quadrature. Let IK be the circle dividing the dark part of the Moon from the bright part, and let a straight line KIT be drawn through the plane of this circle as far as our sight, since at that time that plane inclines toward our sight. Finally, from the centre of the Sun S to the centre of the Moon let the straight line SL be drawn, perpendicular to the said plane. For since the Moon is lit by the Sun, the plane marking off the dark part from the illuminated part receives perpendicularly, at the Moon's centre, the ray coming from the centre of the Sun. In the triangle LTS, then, right-angled at L, there will be given the side TL, which is the Moon's distance from the centre of the Earth, and the angle LTS, which is the Moon's elongation from the Sun in the ecliptic, together with its complement to the 90° required for the Moon's exact quadrature; and this complement, by 32 of the First Book of Euclid, will be the angle S. Given therefore the angle S and the opposite side TL, you will easily find, by the fifth of our *Plane Right-Angled Triangles*, the

base TS, which is the distance of the Sun from T, the centre of the Earth. I shall report a problem of Father Grimaldi that rivals this one in Scholium 5.

Diagram. A woodcut in the left column, with the text wrapped at its left from "Sit in sequēti" to "paulò ante". Two circles share the centre T. The outer circle is the Sun's orbit, or ecliptic; the inner is the Moon's orbit. A horizontal straight line runs from A through T to S. A small circle at S stands on the outer circle and represents the Sun. A small circle on the upper right of the inner circle represents the Moon, its upper left half shaded black. A straight line runs up from T through I to K at the Moon, and a second straight line joins S to the centre of the small lunar circle at L.

- A (left, on the outer circle): end of the horizon line
- B (top, on the outer circle)
- C (bottom, on the outer circle)
- S (right, within the small solar circle): the Sun
- G (left, on the inner circle)
- R (right, on the inner circle, near the horizon line)
- F (bottom, on the inner circle)
- T (centre): the Earth
- K (upper right, at the Moon): end of the line from T
- I (on the line from T to K, below the Moon)
- L (faint, within the small lunar circle): the Moon's centre

[Margin: A closer discussion of this problem.] X. To carry out this problem more scrupulously, it should be used above all when the Moon has no latitude, or very little. Two times are to be noted: one at which you begin to doubt whether she is shining half-lit, having previously been certain that she appeared less than half-lit in the evening, or more than half-lit in the morning; the other at which, after she has already appeared half-lit for some minutes of time, you now begin to doubt whether she exceeds or falls short of the exact phase of dichotomy. Between these two times the midpoint is to be taken as the moment of the half phase, for that phase has a certain breadth. The difference of that moment from the moment of true quadrature, converted into an arc of the ecliptic according to the Moon's hourly motion from the Sun, will give the angle S. Aristarchus, for his part, takes this angle as 3°, certain that it cannot be greater; for that was enough for him to show from it that the Sun is much further from us than Pythagoras, himself also a Samian, had placed it, following harmonic ratios, as I shall say in the Scholia, when he made the Sun's distance now three times, now one and a half times the distance of the Moon. [Margin: Longomontanus's opinion on the angle S.] Longomontanus, however, in Book 1 of the *Theorica*, chapter 6, p. 241, sets this angle at 2° 30′, from selected observations of Tycho with the Moon and the Sun placed at their mean distance, that is, between apogee and perigee; and to this corresponds, according to Longomontanus himself, a mean motion of the Moon from the Sun of $4^{h}\ 55\frac{1}{3}^{m}$. With this angle assumed, therefore, and with the Moon's mean distance at 56 terrestrial semidiameters, he gathers from the analysis of

the triangle LTS a mean distance of the Sun of 1283 semidiameters of the Earth, and indeed even 1288. [Margin: And Kepler's.] Kepler, by contrast, says in his Ephemeris for the year 1618 that the Moon appears halved, or bifalcate [bifalcatam], about 4 hours before the first quadrate aspect or after the second. On the Ephemeris for the year 1619 he has the following, worth noting: *But as for the difference of time between the dichotomous phase and the quadrature, although it has remained here too, its quantity, and that of the Sun's parallax as well, is still uncertain. And what I long ago reasoned from the slightness of the parallaxes of Mars, I am now most of all confirmed in, since I have been engaged in bringing out the Harmonics: that the Sun's horizontal parallax is not greater than one minute. Yet I still use it at two minutes, as in the years 1617 and 1618, because the matter is not yet fully settled. Therefore the interval of time between the dichotomous phase and the quadrature will be less than is gathered from the Ephemeris. This I leave to Galileo and Marius [Simon Marius] to determine with the eyes and the telescope, if so much trust is to be placed in it in this matter, especially given the roughness of the lunar globe. Exert yourselves, you men of philosophy: the matter is not to be despised, and is entirely worthy of having account taken of it in an Ephemeris; namely, from the bare sight of the Moon exactly bisected, and a faithful noting of the time, to the hour and at least its quarter, to pronounce on the ratio of the Sun's orb to the Moon's orb, and hence on the quantity of the Sun's parallax; and lastly on the very ratio both of the altitudes and of the globes of all the planets, compared with the semidiameter of the Earth. All of these have so far depended on the untrustworthy shadow of the Earth, and on the estimation of the digits eclipsed in the Moon, with their most vexing diversity; and lastly on the confusion of very many causes entering into the demonstration, each of which can be emended separately while the rest stand, with an incredible variation in the resulting parallax of the Sun.*

[Margin: The author's opinion on this.] XI. Mindful therefore of the problem of Aristarchus, and spurred on by Kepler's exhortation, I began, as often as I could, to direct at the dichotomous Moon my eye, both bare and aided by the telescope, with Father Francesco Maria Grimaldi striving at this along with me. I gave particular care to those phases in which the Moon held, as nearly as possible, apogee or perigee, or an equal distance from either; and to these, by God's favour, another piece of good fortune was sometimes added: that the Sun was at those times once near perigee and again around apogee, as I shall report in the Observations to be weighed in tome 3 of the *New Almagest*. And although I have not yet fully decided this matter, and am waiting for some other lunar dichotomies so as to pluck almost every scruple from my mind, I nevertheless believe that I have not served astronomy badly, and that I can declare, far more probably than others so far, that this angle S is never much greater or less than half of one degree; and hence that about one hour elapses between the phase of the half Moon and the quadrate aspect with the Sun.

Here I shall select two of our clearer observations of the lunar dichotomy. In the year 1646 October 16 the quadrature of the Moon was observed, from which the parallax was derived, and from that the Moon's distance TL, of 66⅔

terrestrial semidiameters, as I shall say in Book 4, chapter 14, number 11. Taking the time midway between the two extremes of the doubtful period, that is, the period within which, and neither before nor after it, we were certain that the phase of dichotomy occurred, the phase of dichotomy preceded the quadrature by 59^m 48^s. To this time, according to the true hourly motion of the Moon, belong 31′ 34″, which was the size of the angle S. Therefore, by the solution of the triangle TLS, the distance of the Sun TS was 7260 terrestrial semidiameters. The Sun, moreover, was 106° from apogee. Again, in the year 1648 June 13 the quadrature was observed, of which I shall speak in Book 4, chapter 14, number 11, and from the parallax the Moon's distance TL was derived, of 66 42′ terrestrial semidiameters. The time of the dichotomy, midway between the doubtful extremes, by which the phase of dichotomy followed the quadrature, was 58^m 33^s; and to this, from the Moon's true hourly motion at that time, belong 30′ 15″, and such was the size of the angle S. Therefore the distance of the Sun TS was 7572 terrestrial semidiameters, and it was then 15° from apogee. Moreover, at that middle time the section of the line separating the bright part of the Moon from the dark passed, as the telescope showed, through the spots of Amalfi, Pamphili, Mazarin, Leopold and Frederick of Holstein, of which I shall speak in Book 4, chapter 7. Now from the Sun's observed eccentricity, of 3460 parts of which the radius, or semidiameter, of the solar eccentric is 100000, as I shall show in chapter 24, number 4, and from the said solar distances, with the arc of anomaly assumed in which the Sun stood at the time of the said dichotomies, it follows by trigonometry that the radius, or mean distance of the Sun, is 7327 terrestrial semidiameters, the greatest, or at apogee, 7580, the least, or at perigee, 7074, and the eccentricity 253. This precision, however, will not always be needed, just as it is needed in defining the Sun's apparent semidiameters, parallaxes and equations; but sometimes round numbers will be enough: 7300 for the mean distance, 7600 for the greatest, and 7000 for the least, as we shall do in chapters 11 and 12.

XII. Not resting content with this, I wrote, both before and after, to the two explorers of the lunar phases most famous and most sharp-eyed in this century, Govaert Wendelen and Michael Florent van Langren, the Royal Cosmographer. [Margin: Wendelen's opinion on the distance of the Sun from this problem.] Wendelen, then, whom I was astonished to see raising the Sun, in the *Idea of the Atlantic Tables* [Idea Tabularum Atlanticarum], as far as 14656 semidiameters of the Earth at mean distance, and whom I had asked for the reason for this height, at last replied, in the year 1647 November 9, that he had done so because a parallax of the Sun of at most 15″ better represented the equinoxes and their intervals, and eclipses, and better reconciled the altitude of the pole, taken from circumpolar stars at Forcalquier in Provence, with the distance of the tropics taken at the solstices; but chiefly because of the lunar dichotomies [Greek: δικοτομίας [recte: διχοτομίας] (dichotomias, "dichotomies")]. For although it had earlier seemed to him that the Moon, when she shines half-lit for us, is 89° from the Sun, and hence that the Sun is about sixty times the lunar interval

[diastematis Lunaris] away from us, or about 3600 terrestrial semidiameters, yet, he says: *Using greater care after that, and better telescopes, I found, as you too did, that dichotomy [Greek:* διχοτομίαν *(dichotomian, "dichotomy")] occurs at a distance of the Moon from the Sun of about 89½°, from which the semidiameters now came out at 7000, more or less. Finally, however, comparing the dichotomies with one another, morning as well as evening, as far as the roughness of the Moon allowed one to reason, and considering also that the light of the Sun, falling into the lunar air, hastens the evening dichotomy and delays the morning one, I could, with every factor weighed, find nothing else than that dichotomy [Greek:* δικοτομιαν *[recte:* διχοτομίαν*] (dichotomian, "dichotomy")] comes down to a distance of 89° 45′, or even one that is too great. From this the distance of the Sun from the Earth was built up to at least 13740 semidiameters, which matched excellently with the earlier examination by parallaxes.* After this, having weighed the intervals of the planets, even the Jovian ones, and their admirable harmony, of which he speaks elsewhere, he concludes a mean distance of the Sun from the Earth of 14656 terrestrial semidiameters.

To this I reply that neither does that air around the Moon appear in telescopes, the large and very bright ones that I have at last obtained, nor, if it is there, is it to be reckoned of such height and density that by the refraction of the Sun's rays it could vary the phase of dichotomy by a whole quarter of an hour. So too Kepler, in the *Optics*, p. 303, said that the lunar air is of no great depth and very rarely attains a sensible refraction of the Sun's rays, and that one is not to take refuge in it except in the extreme necessity of saving a phenomenon otherwise indefensible. With that air, then, or its effect, set aside, Wendelen's observations of the dichotomy support me, who knew nothing of them (I call heaven to witness) when I first began my own, in order to bring the problem of Aristarchus back into practice, being the first to do so, as I thought. Let us now see what van Langren reported.

[Margin: Van Langren's reply on this, and his noble efforts.] XIII. Van Langren, then, replied to me in a letter dated 1646 August 22 that if the dichotomous Moon were 89° from quadrature, and the Moon's distance from the Earth were 60 terrestrial semidiameters, the Sun's distance would be 3420 terrestrial semidiameters. Although he indicates his opinion here, he nevertheless adds that he is wholly taken up with a certain device for this and for investigating other lunar phenomena more accurately, and that when he has finished it he will communicate everything to me. Meanwhile, the bisection of the Moon near the quadratures occurs now between the spots Isabella and Maria, now between Roma and Harum [?], with an admirable variety in the theory of the Moon, which he hopes will please astronomers. He is alluding to the spots of the Moon marked with those names, and to the lunar libration, of which I shall speak in the Book on the Moon. You see then, reader, that if van Langren asserts this distance, mine is almost the mean proportional between that of van Langren and that of Wendelen: for as 3420 is to 7300, so very nearly is 7300 to 14656. You see, moreover, how great the variety is in this very problem.

To make it more apparent, I have added the following small table, in which, according to the variation of the angle S, or of the distance of the dichotomous Moon from quadrature, and of the Moon's distance from the centre of the Earth, one may survey the variation of the Sun's distance from the Earth, gathered from the solution of the triangle LTS treated in number 9.

Distance of the Sun from the centre of the Earth in semidiameters of the Earth, with the distance of the dichotomous Moon given likewise in semidiameters of the Earth.

Distance of the dichotomous Moon from quadrature	34 terr. semid.	44 terr. semid.	52 terr. semid.	56 terr. semid.	60 terr. semid.	64 terr. semid.	66 terr. semid.	72 terr. semid.

Aristarchi Suppositiones, & Conclusiones.

The Suppositions and Conclusions of Aristarchus.

XIV. So far we have treated the problem of Aristarchus and adapted it to more recent hypotheses. Let us now return to Aristarchus and set out the suppositions on which this third problem rests, and the distance of the Sun that he gathers from them. They are as follows.

[Margin: The suppositions of Aristarchus.] Supposition 1: *The Moon receives her light from the Sun.* Hence it comes about that of the lunar sphere one hemisphere is bright and the other dark, and that the ray issuing from the centre of the Sun falls perpendicularly on the plane of the circle separating the bright part from the dark, as, in the figure of number 9, the ray SL falls on the plane IK.

Supposition 2: *The Earth has the ratio of a point and centre to the sphere of the Moon.* So it makes no difference whether the phase of the half Moon is viewed from the surface of the Earth or from the centre. It is better, however, in the triangle treated in number 9, to take the lunar distance TL shortened by one semidiameter of the Earth, because that phase is seen by observers on the surface of the Earth.

Supposition 3: *When the Moon appears half-lit to us, the great circle of the Moon that marks off her dark part from the bright one inclines toward our sight*;

that is, the plane of the circle IK lies on the straight line KT; otherwise it falls elsewhere, outside the whole Earth and our sight, toward G or R. But this supposition Aristarchus demonstrates afterwards in Proposition 5. Earlier, however, he shows in Proposition 2 that *the Sun illuminates more of the Moon than a hemisphere*, being larger than the Moon, and in Proposition 4 that *the circle dividing the dark part of the Moon from the bright does not differ sensibly from the great circle of the Moon.*

Supposition 4: *When the Moon shines half-lit for us, she is distant from the Sun by less than a quadrant by the thirtieth part of a quadrant.* So she is 87° from the Sun, and he takes the angle LTS to be that size, and hence the angle S is 3°, to which correspond about 6 hours of the Moon's motion in the zodiac. He assumes this generously, however, since it is certain even to those who take up the Moon carelessly near the quadratures, that no more than 6 hours elapse between her half phase and the quadrature. In much the same way the early astronomers were content to define the times of the equinoxes if they avoided an error of 6 hours. Moreover, in Proposition 6 he demonstrates that when the Moon shines half-lit for us, she is not a whole quadrant from the Sun; otherwise the angle LTS would be right, as TLS also is, and so in a rectilinear triangle there would be three angles together greater than two right angles, against 32 of the First Book of Euclid.

Supposition 5: *The breadth of the shadow is that of two Moons*, namely at the place where the Moon passes through the shadow of the Earth.

[Margin: A knot in Aristarchus is untied.] Supposition 6: *The Moon subtends the fifteenth part of a sign*, that is, 2°, and he repeats the same in Proposition 4. But since the Moon does not subtend even 40′, this has seemed absurd to many, and neither Pappus nor Commandino unties this knot. But Aristarchus may have assumed this in a sense excluding any greater diameter, certain that there would be no one to contend that the Moon ever appears larger, not even on the horizon; and if anyone wanted her to be smaller, that would further confirm his assertion. For since Pythagoras had said that the distance of the Sun was either three times or at most one and a half times the lunar distance, it was more than enough for Aristarchus to purge the Samian school of this error, and to show, from hypotheses that no one, however dull his wits, could deny, that the ratio of the solar distance to the lunar is much greater than triple or one and a half times. Otherwise Aristarchus, as Archimedes reports in the *Sand-Reckoner* [Arenario], held that the diameter of the Sun, and hence of the Moon eclipsing it, was 30′ at apogee.

[Margin: The conclusion of Aristarchus on the distance of the Sun.] The conclusion of Aristarchus, then, in Proposition 7, is this: *The distance at which the Sun stands from the Earth is more than eighteen times the Moon's distance from the Earth, but less than twenty times.* And so it is to the Moon's distance about as 19 to 1. This thesis is also reported by Plutarch, *On the Opinions of the Philosophers* [de Placitis], Book 2, chapter 31, and by Pliny the Elder, Book 2, chapter 21, who says: *Many have also tried to track down the intervals of the stars from the*

Earth, and have declared that the Sun is nineteen parts distant from the Moon, as much as the Moon herself is from the Earth. Aristarchus, however, does not state definitely the absolute distance of the luminaries from the Earth, nor do Pappus or Commandino following him; because Aristarchus did not want to tie his demonstrations to observations still uncertain, but, by assuming what no one could deny, to show that the mere proportions of the distances and magnitudes of the Sun, the Moon and the Earth are greater than many thought.

[Margin: A warning that the variation of the Sun's distance must be properly harmonized with the other things connected with it.] XV. However the distance of the Sun may be investigated and established, if the Sun is supposed to become now apogean, that is, farthest from the Earth, and now perigean, that is, nearest to the Earth, the mean distance will have to be determined from half the difference between the greatest and the least; but these must agree with the difference of the parallaxes and of the Sun's apparent semidiameter at such distances. And if not only does the Sun become now apogean and now perigean within the same year, but these distances themselves vary as the eccentricity of the Sun's orb varies, those who admit this must determine various distances of the Sun agreeing with it. Finally, those who bisect the Sun's eccentricity must make the difference of the greatest distance from the least half as great. All of this will be set out below, each in its own place.

[Margin: The authors from whom the following table was compiled.] Meanwhile it will be worth the effort to set before the eyes the more notable opinions on the distance of the Sun from the Earth. They are supplied, though scattered about, by Pliny the Elder, Book 2, from chapter 21 to 23; Plutarch, *On the Opinions of the Philosophers*, Book 2, chapter 31; Censorinus, *De Die Natali*, chapter 11; Ptolemy, Book 3 of the *Almagest*, chapter 4, and Book 5, chapter 15, and there Theon, and Regiomontanus in the *Epitome*; al-Battānī, chapters 28, 30, 50; al-Farghānī, Difference 21; Copernicus, Book 3, chapter 16, and Book 4, chapters 19 and 21; Neander [Michael Neander] in the *Elementa Sph.*, p. 124; Fernel, Book 1 of the *Cosmotheoria*, chapter 7; Maurolico at the end of the *Cosmographia*; Clavius in the *Sphere*, p. 215; Magini in the *Theoricae Planetarum*, Book 1, chapter 3, and Book 2, chapter 24, and in the *Supplement to the Ephemerides*, p. 58; Barozzi, Book 1 of the *Cosmographia*, p. 48; Mästlin in the Appendix to the *Mysterium Cosmographicum* of Kepler; Tycho, tome 1 of the *Progymnasmata*, pp. 98, 119, 472; Longomontanus, Book 1 of the *Theorica*, chapters 1, 5, 6, 9, that is, pp. 177, 231, 241, 298; Kepler in the *Nova Stella*, chapter 16, in the *Ephemerides*, p. 2, in the *Mars*, chapter 30, and in the *Epitome of Astronomy*, Book 4; Biancani, Book 10 of the *Sphere*, chapter 1; Lansbergen in the Prolegomena to the *Uranometria* and Book 2, Element 11; Bettini, *Apiaria*, Apiary 10, Progymnasma 1; Athanasius Kircher in the *Ars Magna Lucis et Umbrae*, Book 9, Problem 9; Antonín Maria Šírek in his *Radius Sydereomysticus*, Book 4; Boulliau, Book 4 of the *Astronomia Philolaica*, chapter 1; Wendelen in the *Idea of the Atlantic Tables* and in letters sent to me; Michael Florent van Langren in letters sent to me; Renieri and Argoli in their tables; Galileo, Dialogue 3 of

the *System of the World*. The opinion of Hipparchus, however, is gathered as varying, from the distance he gives for the Moon at apogee, now 72, now 83 semidiameters, and at perigee now 62, now 71, as Theon reports on Book 5 of the *Almagest*, chapter 11; and from the angle LTS, of 87°, which he too took as the greatest, as Pappus reports, and following him Commandino, in the notes to the little book of Aristarchus. If he thought that angle was in fact smaller, a smaller distance of the Sun results. On Posidonius, read Scholium 1.

If anyone wants the greatest or least distance of the Sun in parts of which the radius, or semidiameter, of the Sun's orb is 100000 or 10000000, let him multiply the apogean or perigean distance by that radius and divide the total by the mean distance; for the mean distance is as great as the semidiameter of the Sun's orb. On the distances to be assigned to the individual degrees of anomaly I shall speak in chapter 33, number 8.

Distance of the Sun from the centre of the Earth in semidiameters of the Earth.

The distance corresponding to the individual degrees of anomaly is obtained from the base of a rectilinear triangle, one side of which is the mean distance, or radius of the eccentric, and the other the eccentricity; and the angle they contain is the complement of the anomaly.

SCHOLIA

[Margin: Opinion of Empedocles and of Eratosthenes on the Sun's distance.]

I. The opinions of the ancients on the distance of the Sun and of the Moon from each other and from the Earth are reported as follows. Plutarch, in Book 3 of *De Placitis Philosophorum*, Chapter 31, writes: "Empedocles holds that the Moon stands twice as far from the Sun as from the Earth; the mathematicians, that the Moon stands nineteen parts from the Sun for the distance it stands from the Earth; Eratosthenes, that the Moon is seven hundred and eighty thousand stadia from the Earth." Therefore, since Eratosthenes gives the Earth's semidiameter 39772½ stadia and its diameter 79545 stadia, as we showed in the table of Book 2, Chapter 7, it follows that he set the Moon's distance at more than 19 and less than 20 semidiameters of the Earth.

[Margin: Opinion of Pythagoras on the same.]

Pliny the Elder, moreover, in Book 2, Chapter 21, after indicating Aristarchus's view with his name suppressed, adds: "Pythagoras, a man of

shrewd mind, inferred that from the Earth to the Moon is one hundred and twenty thousand stadia; from the Moon to the Sun, double that; and from there to the twelve Signs, triple; and our own Gallus Sulpicius was also of this opinion." So the earlier view of Pythagoras, like that of Empedocles, made the Sun's distance triple the Moon's distance from the Earth; but it made the Moon's distance about six times smaller than Eratosthenes later did. Censorinus agrees with Pliny the Elder, in *De Die Natali*, Chapter 11, at p. 59 in my Aldine copy, where he says: "Therefore Pythagoras thought that from the Earth to the Moon is about 126 thousand stadia." I said "the earlier", because he adopted harmonic intervals and preferred another opinion of the Sun's distance, and made it one and a half times the Moon's distance, as we shall report presently from Pliny the Elder, Book 2, Chapter 22, and from Censorinus above, when we speak of the harmonic intervals of the stars.

[Margin: Opinion of Posidonius on the same.]

Pliny the Elder goes on, in Book 2, Chapter 23, and says that according to Posidonius it is at least four hundred stadia from the Earth to the region of clouds and winds; from there to the Moon, twenty times a hundred of stadia, that is, twenty times a hundred thousand stadia, or 2000000 stadia; and from there to the Sun, five thousand times (I understand, in the Roman manner, a hundred thousand) stadia, or 500,000,000 stadia. So, adding those three numbers together, there would be from the Earth to the Sun 5020004000 stadia. Now Posidonius assigns to the Earth's semidiameter 38182 stadia and to its diameter 76364, from the table set at the end of Chapter 7 of Book 2. He therefore gives the Moon's distance as 52 15/38 semidiameters of the Earth, and the Sun's distance from the Earth as 13141.

[Margin: Pliny the Elder's conjecture on the Sun's distance.]

Having recited these, Pliny the Elder offers his own opinion in that same Chapter 23. He does not call it certain, only conjectural, yet such that the reasoning of geometric inference in it, which never deceives, cannot be rejected, if anyone cares to pursue these matters more deeply: namely, that from the Earth to the Sun is a sixth part of the circle of the solar heaven. Why? Because that circle is of about 366 parts, as is clear from the days of the year; and the diameter is to the circumference as about 7 to 22, or nearly a third part; therefore the semidiameter, or the Sun's mean distance, is about a sixth part of the solar circle. (He neglects the Sun's eccentricity.) And since the Moon's period, being monthly, is twelve times shorter than the Sun's annual period, the Moon's distance from the Earth is for that reason twelve times smaller than the Sun's distance from the Earth. With these things laid down, Pliny the Elder continues: "It is a marvel how far the shamelessness of the human heart will go, lured on by some slight success, as in the matters above reason furnishes the occasion for impudence. Having dared to divine the distances from the Sun to the Earth, they apply the same to the heaven, since the Sun is in the middle, so that the measure of the World itself comes straightway to the fingers. For they say that

as many sevenths as the diameter has, so many twenty-seconds has the circle, as though the measure of heaven were plainly settled by the plumb line."

[Margin: Childish opinion of Petosiris and Nechepso on the Sun's distance.]

Finally, Pliny the Elder closes Chapter 23 with the opinion of Petoniridis [Petosiris] and Necepsi [Nechepso], kings of Egypt, who said that each part or degree of the lunar circle contains 33 stadia or a little more, that of the circle of Saturn double, that is, 66 stadia, and that of the Sun's circle half the sum of the two measures, that is, 49½ stadia. So if these are multiplied by 360 degrees, there will be 11880 stadia in the Moon's circle, 17820 in the Sun's, and 23760 in Saturn's; and their distance from the Earth, or the semidiameter of the lunar heaven, is about a sixth part of this, or about 1980 stadia, that of the solar heaven 2970, and that of the Saturnian heaven 3960. "This computation carries a great deal of shame, since at the circle of Saturn, once the interval of the zodiac itself is added, the multiplication becomes countless." These are the words of Pliny the Elder, lashing the childish opinion of those kings and indicating his own opinion of a far greater interval.

[Margin: Tycho's opinion and its basis.]

II. So much for the outdated opinions of the ancients, among which, however, the opinion of Posidonius strongly favours the hypothesis of Wendelen. But the ancients were imitated by those who have tried to assess the distances of the Sun and of the other stars from certain other proportions. Thus Tycho, in Volume 1 of the *Progymnasmata*, p. 472, seeing that the Sun's mean distance was set by Copernicus at 1142 semidiameters of the Earth and by Ptolemy at 1165, chose roughly the mean, namely 1150. He was confirmed in this by the little book of Io. Franci Offusij [Jofrancus Offusius], *De Divina Astrorum Facultate*, where he arranges the distances of the heavenly bodies from the Earth harmonically, and has the Sun stand 576 terrestrial diameters from here, so as to assign to this interval that sacred number celebrated by the Pythagoreans and Platonists, since eclipses do not object to it. In that interval there are 1152 terrestrial semidiameters. But Tycho neglects two semidiameters.

[Margin: Kepler's opinion, long inconstant.]

Kepler too, though only hypothetically, assigns 1432 semidiameters of the Earth to the Sun's distance in his book *De Nova Stella*, Chapter 16, so as to make the Sun's diameter six times greater than the terrestrial diameter. In the *Ephemerides*, however, p. 2, he gives the Sun an apogeal distance of 1800 terrestrial semidiameters and the Moon about 60, so that the Sun's distance is thirty times the Moon's, just as the Sun's revolution of 365 days is about thirty times 12 revolutions of the Moon, which are contained thirty times in the Sun's revolution. But he wavers in fixing the Sun's horizontal parallax. For in the same place he says that he sets it smaller than the Tychonic value by two-thirds [beſſe]. The Tychonic value with the Sun at apogee is 3′ 7″; therefore, with eight-twelfths, or two-thirds, taken away, a parallax of 1′ 2″ remains. And in the preface to the Ephemeris for the year 1619 he says that the slightness of the parallaxes of Mars and the harmonic intervals confirm him in the view that

the Sun's parallax is not greater than 1′. "Yet in the Ephemeris for the years 1617 and 1618," he says, "I use one of 2′, because it is not yet fully settled." Why, then, does he assert on that p. 2 that he has set it smaller than the Tychonic by two-thirds, if he was still retaining 2′? In the *Commentaries on Mars* too, p. 162, he sets the Sun's distances: the apogeal at 101800 parts, the mean at 100000, and the perigeal at 98200, of which parts the radius of the Sun's orbit, or the mean distance, is 100000. So if the apogeal distance is 1800 semidiameters of the Earth, the mean will be 1768 and the distance at perigee 1736.

[Margin: But at last constant.]

But in the Rudolphine Tables, Precept 141, the Sun's parallax is always the fifteenth part of the Sun's semidiameter; and this semidiameter, in the same Tables, p. 92, is 15′ with the Sun at apogee; so the parallax is 1′. Now by the analysis of the triangle treated in number 2 of the preceding chapter, given a parallax of 1′, the Sun's distance is shown to be 3438 semidiameters of the Earth. But if the distance of 1800 semidiameters of the Earth is retained, the parallax will be 1′ 55″. It is not to be retained, however; one must stand by his last work, the Rudolphine Tables, in which the Sun's apogeal semidiameter is 15′ and the horizontal parallax 1′; the mean semidiameter 15′ 16″ and the parallax 1′ 1″; and the perigeal semidiameter 15′ 32″ and the parallax 1′ 2″. Therefore the distances corresponding to these, in order, are 3438, 3381 and 3327 semidiameters of the Earth. Remember, however, that in Kepler's mind the eccentricity is to be bisected, by his own advice in the Appendix to Tycho's *Progymnasmata*, p. 821, and from what will be said below when we treat of the eccentricity.

[Margin: Opinion of Šírek.]

III. Antonín Maria Šírek, in his *Radius Sidereomysticus*, p. 20, says that the Sun's distance from the Earth is 2000 terrestrial semidiameters. On p. 94 he says that, from observations of his own and of others made with the greatest diligence, the Sun stands 200 of its own semidiameters from the Earth, and that its semidiameter is to the semidiameter of the ecliptic as 1 to 10, or as 10 to 100, or as a square root to its square. And on p. 193 he says that the bulk of the Earth is to the bulk of the Sun as a square root, but to the distance as a cube root, the former being as 10 to 100 and the latter as 10 to 1000 diameters; and that the Sun thus stands 1000 diameters, or 2000 terrestrial semidiameters, from the Earth. He proves this mean distance, he says, because the apparent diameter of the Sun that he observed at middling distance is 34′ 41″, to which in the table of sines correspond 100 parts, of which the whole sine is 10000. "Therefore," he says, "the Sun's diameter of 100 parts is the square root to the radius, that is, to the true distance." He adds that, just as the Earth's diameter is contained a thousand times in the Sun's distance, so the diameter of the Sun's body is contained a thousand times in the mean distance of Saturn from the Sun; and that the diameter of the body of Saturn is the square root, in solar diameters, to the radius of the firmament, and that this radius is 1000000 solar diameters, which multiplied by 10 give 10000000 diameters of the Earth, or 20000000 semidiameters. But in this at least Šírek is mistaken: that sine of

100, for the angle of 34′ 41″, would stand even if the Sun were almost infinitely many semidiameters of the Earth away; and unless the distance of the Sun is established with definiteness from elsewhere, nothing can be concluded by this method.

[Margin: Why the harmonic intervals are not given here.]

IV. The harmonic intervals of the Sun and the other planets, which Pliny the Elder, Book 2, Chapter 22, and Censorinus, at the end of Chapter 11 of *De Die Natali*, report on the opinion of Pythagoras; and Macrobius, Book 2 on the *Dream of Scipio*, Chapter 4, on the opinion of Plato; or those of Jofrancus Offusius in *De Divina Astrorum Facultate*; or of Johannes Kepler in his *Harmonice* and in the *Mysterium Cosmographicum*; or of Mario Bettini in *Apiarium* 10, we do not insert here, because they cannot be weighed until the distances of the remaining planets have been explained; nor is there such force in them that these distances could be defined from them alone. I have therefore put all this off to the Book on the Systems, where there will be special chapters on the harmonic system of the world.

[Margin: Father Francesco Maria Grimaldi's problem, a rival to the Aristarchan.]

V. Father Francesco Maria Grimaldi of the Society of Jesus has rivalled Problem 3, or the Aristarchan problem, even outside the dichotomies, by observing the part of the Moon's diameter that shines for us, together with the Moon's place at the same moment, either observed or deduced from the most corrected tables, so that the Moon's elongation from the Sun in the zodiac becomes known from the Sun's known place; here too the Moon's distance from the Earth and her apparent semidiameter are assumed. The observation will be better if the Moon is in the nonagesimal degree of the ecliptic counted from the horizon, or, what comes to the same thing, if both her horns are in the same vertical circle.

Let the centre of the Earth, then, be T, that of the Moon A, and that of the Sun S, and let these be joined by the three straight lines TA, TS, AS. For in the triangle ATS the Moon's distance from the Earth, AT, and the Moon's elongation from the Sun in the zodiac, namely the angle ATS, are assumed as given. So if the angle TAS is found, the third angle S can be known by 32 of the First Book of Euclid, as the complement of two right angles; and in this way the side TS, namely the distance of the Sun from the Earth, can be found by the second of our *Plane Oblique-Angled Triangles*.

Diagram. A woodcut in the left column, with the text wrapped at its left from "recidit, si vtrumq." to "inuestigetur an-". A circle stands for the Moon's disc, with its left part hatched dark and the part on the right, past a curved boundary running from H down to I, beside which stand F, K and C, left white. Curved lines cross the disc between G and E and between H and I, and a further curve runs through D, F and E and through B and C. Straight lines run from T, at the foot, up to I, to C and to E, and from T to S at the top right, and a straight line runs from S down to the disc at F.

- S (top right, at the apex of the long lines): the Sun
- H (top of the circle): one horn of the Moon
- D (upper left within the circle)
- F (upper right, on the lit side)
- G (left end of the horizontal diameter)
- K (right of centre, on the horizontal diameter)
- E (right end of the horizontal diameter)
- A (centre): the Moon's centre
- C (lower right, at the edge of the shading)
- B (lower centre, within the shading)
- I (bottom of the circle): the other horn
- T (foot of the figure): the Earth's centre

So, to find the angle TAS, let there be observed with the radius, or with another more exact instrument, one of those that we treat in the Book on Instruments [Libro Organico], the part of the Moon's diameter that appears shining to us, namely KE, but as seen by means of the arc CE. This is done more accurately if through a fine telescope some small spot is noted that then, in the middle of the Moon's disc and equally distant from the horns H and I, begins to be lit before the first quadrature or ceases to be lit after the second, and if the situation of such a spot is known from the *Selenography* of Michael Florent van Langren, on which we speak in Book 4, which is on the Moon. This done, let GHEI be the boundary of the hemisphere, or quasi-hemisphere, of the Moon apparent to us, whose dark part is GHKI and whose shining part is HKIE; and further let the circle that divides the part of the Moon lit by the Sun from the part not lit be HKID. Let a great circle of the Moon GDEB be understood, whose plane inclines both toward the Sun S and toward our eye T, and in which AB and AF are semidiameters of the Moon. The circle GDEB will be described from the horns H and I, as being virtually diametrically opposite, both because it is a great circle and because the point F is equally distant on either side from the Moon's diametrically opposite horns, since the line AF produced runs to the centre of the Sun illuminating the Moon, by the ray SA perpendicular to the plane of the circle HKID, and this ray SA stands equally distant on one side and the other from the extreme rays that determine the Moon's horns H and I. Therefore both the dark point B and the points C and E, which are luminous and visible to us, as being equidistant from the horns, lie in the same plane of the circle GDEB. So, with TC and TE drawn, and with the observed arc CE subtracted from the known arc of the Moon's semidiameter BCE, the arc BC, that is, the angle ATC, will remain known. With this angle in the triangle ATC, and with the true semidiameter of the Moon AC, find the angle TAC, and add it to the right angle SAC, which the Sun's central ray makes with the plane of the circle dividing the lit part of the Moon from the unlit part; and the angle SAT, which we needed, will be known.

CAPVT VIII.

De Solis Parallaxibus.

I. Reread what we said about parallaxes in general in Book 1, Chapter 35, especially about the parallax of altitude, or in the vertical circle, which we said is the difference between the true altitude of the Sun above the rational horizon, as viewed from the centre of the Earth, and its apparent altitude, or the altitude seen by an eye on the surface of the Earth. Its measure is the angle made at the centre of the Sun by the straight lines drawn to it, one from the centre of the Earth, the other from the sight placed on the surface of the Earth. This parallax is easily found if the Sun's distance from the centre of the Earth is given in parts, of which the Earth's semidiameter is one.

[Margin: ⊙ Finding the horizontal parallax.]

II. For let the figure of Chapter 6, Problem 1, be repeated here, in which VSR is a quadrant of a vertical circle in the heaven of the Sun, AC beneath it is a quadrant of a vertical circle on the globe of the Earth, H is the centre of the Earth, HR is the rational horizon, AB, parallel to it, is the sensible horizon, and the line VAH, perpendicular to both, is drawn from the zenith V. Then the angles HAB and VAB are right angles. Now let the Sun appear at B, a point of the sensible horizon, to which let the straight line HB be drawn from H. Then the horizontal parallax is the angle ABH, in the same triangle, right-angled at A, in which the base HB is given, namely the distance of the Sun from the centre of the Earth, and also HA, as 1 part of those known in HB. So by the second of our *Plane Right-Angled Triangles* you will find the angle B, and very easily too; for here the side HA is unity, and it will therefore be enough to divide the radius, or whole sine of the tables, by the distance HB: the quotient [Quotus, seu Quotiēs] will be the sine of the angle B, that is, of the Sun's horizontal parallax. Or if you use logarithms, the residual of the logarithm of the distance HB will give the logarithm of the angle B. Now since this parallax is equal to the alternate angle BHR, by 29 of the First Book of Euclid, which measures the arc BR described from H, it reveals the Sun's true altitude above the rational horizon HR, which is the arc BR. So if the horizontal parallax is, for example, 3′, you will conclude that the Sun, appearing at B and with its centre not raised at all above the sensible horizon, is nevertheless raised 3′ above the true and rational horizon.

Diagram. A woodcut in the right column, with the text wrapped at its left from "Repetatur enim" to "Horizon Sensibilis AB". A quadrant VSBR is centred on H, with the vertical side HAV and the horizontal side HCR; a smaller arc runs from A to C. Straight lines join A to S, A to B, H to S and H to B.

- V (top left, on the vertical side): the zenith
- S (on the outer arc, upper): the Sun
- A (on the vertical side, below V): the eye on the Earth's surface
- B (on the outer arc, right): point of the sensible horizon

- H (bottom left): the centre of the Earth
- C (on the base, at the foot of the small arc)
- R (bottom right, at the end of the base)

[Margin: Finding the parallaxes that are not horizontal. Given the apparent altitude.]

III. Secondly, let the Sun be above the sensible horizon at S, and let the line of true altitude, HS, be drawn to its centre from the centre of the Earth, and from the eye A the line of seen altitude, AS. And let the angle VAS be given by observation or assumed by hypothesis, namely the complement of the seen altitude to 90°, or the Sun's seen distance from the vertex; for by 13 of the First Book of Euclid the angle SAH will be known, as its complement to two right angles, or to 180°. With this angle, and with the given distance of the Sun, HS, and with the side AH, which here is unity, you will find in the triangle AHS, by the first A[13] of our *Plane Oblique-Angled Triangles*, the angle S, which is the measure of the parallax sought in the circle of altitude, or vertical circle. But since the angle SAH will always be greater than one right angle, and by the rules of trigonometry you must take in its place its complement to two right angles, namely the angle VAS, and since the side AH is here unity, you will therefore easily find the parallax S if you divide the right sine of the Sun's seen distance from the vertex by the Sun's distance HS; for the quotient will be the sine of the angle S. Or, working by logarithms, add the logarithm of the angle VAS, or of the seen distance from the vertex, to the residual of the logarithm of the distance HS; and there will result, with a redundant unit or two taken away on the left, the logarithm of the angle S.

[Margin: Use of this parallax.]

This parallax, further, is to be added to the seen, or apparent and observed, altitude, to obtain the Sun's true altitude, or the arc RS. Conversely, it is to be subtracted from the seen distance from the vertex, to obtain the true distance, or the arc VS. For by 32 of the First Book of Euclid the angle VAS is equal to the two angles AHS and ASH taken together; therefore the angle S is the amount by which the angle VHS differs from the angle VAS.

[Margin: How a table of parallaxes is to be constructed.]

IV. By this art the tables of the parallaxes of the Sun, or of any star, in the circle of altitude must be made, if their distance from the centre of the Earth is given. And it is expedient to construct them for three distances of the star, namely the apogeal, the mean and the perigeal, as we shall show at the end of the Book. For other distances one must use a proportional part, or else, setting those tables aside, have recourse to the problem given here in number 2 or 3.

[Margin: Error of certain astronomers in the use of the parallactic table.]

So far we have spoken of finding parallaxes when the seen or observed altitude of a star is given and it has to be converted into the true altitude. This use is served by the table of parallaxes that Kepler gives in the *Astronomia*

[13] so printed, an unexplained letter

Optica, and after him Boulliau in the *Philolaic Tables*, p. 174, and Dom Vincenzo Renieri in the reprinted *Medicean Tables*, p. 332. But when the true altitude of the star is given and the parallax to be subtracted from it must be found, in order to obtain the visible or apparent altitude, another problem and another table must be used. For although the angle S, for example, may be the same, the same value cannot be inferred if the seen altitude and the true altitude are taken for one and the same; nor can the angle VAS be equal to the angle VHS. Those who seek parallaxes in one and the same table, therefore, using the same degree of altitude whether given or seen, as not a few do, are seriously mistaken, especially in lunar parallaxes, which are larger and more perceptible. I shall nevertheless show below, in number 7, how one may use a single one of these tables without error by a double entry. Meanwhile, however, you must be taught the way to construct and use a separate table when the altitude of the star, or its complement or distance from the vertex, is not seen but true.

[Margin: Horizontal parallax, given a star on the true horizon.]

V. First, in the following figure, let the Sun be at R, a point of the rational horizon with respect to the eye A, so that its true altitude is nil and its true distance from the vertex is the arc VR, of 90°. For the parallax at R will be not one of altitude, as many think, but one of depth. But the Sun cannot first be seen below the horizon HR except by an eye raised at least to C, along the line CIR, which, however, will be the sensible horizon of the eye C; whereas the rational horizon of the eye I will be HN, and each horizon will serve the eye I, not raised. Now since AH, the distance of the eye A from the centre of the Earth H, is equal to IH, the distance of the eye I from the same centre, and the Sun's distance HB is equal to its distance HR; and since the angle HAB, made by the tangent BA, is a right angle by 16 of the Third Book of Euclid, as is also HIR, made by the tangent RI, then by 4 of the First Book of Euclid the angle R, which is the horizontal parallax for the eye I, will be equal to the angle B, or the horizontal parallax of the eye A. In this case, therefore, it is enough to find the horizontal parallax by the problem treated in number 2, for that will be the parallax, though one of depth, namely the angle R; and if the eye were raised to C, it would see the star below the horizon HR by just as much as this parallax amounts to.

Diagram. A woodcut in the left column, with the text wrapped at its left from "Sit Primò in sequenti" to "infra Horizontem HR, nisi". A vertical straight line runs from V at the top through C, A and H to M at the bottom, and a large arc runs from V around the right through B, R and N to M. A smaller circle is centred on H and passes through A. Straight lines run from A to B and from H to R; further straight lines run from H to B and from H to N, a line runs from C through I to R, and a dotted line runs from H up to I.

- V (top, on the vertical line): the zenith
- C (on the vertical line, below V): the raised eye
- A (on the vertical line, on the small circle): the eye
- B (upper right, on the large arc)

- I (small letter, on the small circle, upper right): the eye on the Earth's surface
- H (centre): the centre of the Earth
- R (right, on the large arc)
- N (lower right, on the large arc)
- M (bottom, on the vertical line)

[Margin: Non-horizontal parallax, given the true altitude.]

But if the true altitude of the star, as is usual in the use of parallaxes, raises the star above the sensible horizon as well, and in the earlier figure the Sun is, for example, at S, then in the triangle AHS, treated in number 3, the star's distance from the centre of the Earth is given, as I assume, which is the side HS; and the side AH, as one part of such parts; and the angle AHS, of the true distance from the vertex, or the complement of the true altitude above the horizon. So by the third of our *Plane Oblique-Angled Triangles* the angle S can be found, which is the measure of the parallax sought, to be subtracted from the true altitude to obtain the apparent one, or conversely to be added to the true distance from the vertex to obtain the seen distance VAS.

[Margin: Use of this parallax.]

For the angle S is the amount by which VAS exceeds VHS, by 32 of the First Book of Euclid.

[Margin: In which authors these tables of parallaxes are found.]

VI. By this art the tables of parallaxes in the circle of altitude must be constructed, given the true altitude of the star above the horizon and its distance from the centre of the Earth; and the same tables are to be applied using the true altitude. Most of the tables made so far for the parallax of the Moon and of the Sun in the circle of altitude are of this kind. Since we are now speaking of the Sun, such are those given by Ptolemy, Book 5, Chapter 18 of the *Almagest*; Copernicus, Book 4, Chapter 24; Reinhold in the *Prutenic Canons*, p. 121; Magini in the *Canons of the Second Mobiles*, p. 681, and in the *Supplement to the Ephemerides*, p. 59; Tycho in Volume 1 of the *Progymnasmata*, p. 98, and after him Mullerius [Nicolaus Mulerius?], Adriaan Metius and Pierre Hérigone; likewise Longomontanus in Book 1 of the *Theorics*, Chapter 8; Lansbergen in his tables, p. 46; Wendelen in the *Idea of the Atlantic Tables*; and others here and there.

[Margin: Kepler's self-contradiction.]

Kepler gives no such table in the Rudolphine Tables, but in Precept 141 he says that the Sun's horizontal parallax is always the fifteenth part of the Sun's apparent semidiameter, and on p. 2 of the *Ephemerides* he states that it is smaller than the Tychonic parallax by two-thirds. There, however, he contradicts himself, in assigning to such a parallax a distance of the Sun of 1800 terrestrial semidiameters, as we showed in the preceding chapter, Scholium 2.

[Margin: Use of these tables for either altitude.]

VII. You can, however, use the tables treated in number 6 to convert a seen altitude into a true one, in this way. Look up the seen altitude in these tables

just as if it were true, and add the parallax corresponding to it to that same altitude. Then with this sum look up another parallax in the same table; for this is the one that, subtracted [recte: added, per the book's errata] [Margin: *addita* (”added”), written by hand in ink, with a pen stroke through the printed word] from the seen altitude first given, will give the true altitude.

However the Sun's horizontal parallax has been derived by the authors from a presupposed distance of the Sun from the Earth, treated in the preceding chapter, I wish to set out their opinions on it in the following table, so that they can be compared with the distances set by the same authors and reported at the end of the preceding chapter. For Lansbergen, in his *Uranometria*, p. [no number printed], Book 2, Element 8, asserts that, with the exception of Ptolemy, the parallaxes of the other earlier astronomers disagree with the distances, or with the half-angle of the cone of the Earth's shadow and the apparent semidiameter of the Sun. But of this more conveniently below, in Chapter 11, numbers 7 and 8.

Horizontal parallax of the Sun at the Sun's three distances from the centre of the Earth.

Authors	☉ mean distance	☉ at apogee, max. distance	☉ at perigee, min. distance
Posidonius	1′ 45″	1′ 40″	1′ 50″
Ptolemy	2′ 57″	2′ 51″	3′ 4″
al-Battānī	3′ 7″	3′ 0″	3′ 14″

SCHOLIA

I. Another way of inferring the horizontal parallax I shall give very shortly, and more conveniently, in Chapter 11, number 7.

But I have indicated ways of observing the Sun's parallaxes independently of its distance in Chapter 7, nos. 3 and 4; they are, however, very difficult. Ways of deriving the other kinds of parallax from the parallax of altitude, namely those of longitude, latitude, declination and right ascension, we shall indicate in Book 5, where we treat eclipses of the Sun, and in the Precepts on eclipses, and in the Optical Book, in the section on parallaxes. But in the view of Wendelen and of Posidonius, and indeed very nearly in our own, the horizontal parallax is so slight that the other kinds can for the most part be safely neglected.

[Margin: Uncertainty of the Sun's parallaxes.]

II. All the ways of gathering the parallax from the Sun's distance, treated in Chapter 7, nos. 6 and 9, are just as uncertain as the distance of the Sun found by means of them. For that reason Hipparchus, or even Ptolemy (Book 5, Chapter 11), left it in doubt whether the Sun has any sensible parallax at all. Maurolico, in Dialogue 1 of the *Cosmographia*, p. 11 ½ [?], considers this variation of view insensible. And Kepler says in the *Astronomia Optica*, p. 304: "On the length and breadth of the Earth's shadow and on the Sun's parallax, if you look to quantity, deliberation is still timid." In the same work, p. 351, speaking of observing the digits of the Moon's diameter in eclipse, he says: "I wish astronomers would take pains to establish some surer methods of this observation. For on this one thing depends what is commonly valued most in astronomy: the measure of the height, and of the body, of the Sun. For if the Sun's greatest parallax is 3′ and one errs by a third of a digit in estimating the lunar defect, 600 semidiameters of the Earth are gone; but if the Sun's greatest parallax is 2′, we shall go astray by 1700 semidiameters of the Earth through the omission of a single 1′ in the lunar defect." Yet in the *Ephemerides* he prefers another method to this one, namely that of Aristarchus, and thinks little of this one that relies on eclipses, as I showed in Chapter 7, no. 10, toward the end. Therefore this business does not depend on this one thing, as is said here. Still, reader, with everything weighed, you see how far from ignorantly, let alone rashly, Wendelen said, in a letter sent to me, that the hypothesis of a Sun [Greek: ἀπαραλλακτικὴν (aparallaktikēn, "without parallax")], that is, one using no parallaxes, cannot be convicted of falsehood from the phenomena, and that from it motions no less exact, and indeed often more exact, are derived. Recall the foundations on which the Sun's distance rests, from Chapter 7 and its Scholia, and you will give Wendelen a kinder hearing.

CAPVT IX.

De Refractionibus Solis.

On the Refractions of the Sun.

[Margin: The refractions of the stars known to the ancients.]

I. First, what we said about refractions in general in Book 1, Chapter 36 should be read again. The evident cause of refractions appears from it: the rays of the Sun and of the other stars fall into the atmosphere, which is denser than

the aether and the purer air and of a different transparency from theirs. And some astronomers or writers on optics did recognise that the lines of the rays of the stars reach our eye refracted, as is clear from Ibn al-Haytham, Book 7, Propositions 15 and 16; from Witelo, Book 10, Propositions 49 and 50; and from Werner in his notes on Book 1 of Ptolemy's *Geography*. Bernardus Vualtherus [Bernhard Walther] too, as he himself relates in his observations under the year 1489 March 6, recognised that Venus in the evening appeared to him above the horizon because of broken rays, when it was in reality below the horizon. The same thing is reported to have happened with ♀ to the Landgrave of Hesse, in Tycho's *Epistolae Astronomicae*, p. 22, and to Mästlin, in Kepler's *Astronomia Optica*, p. 156.

[Margin: Tycho the first measurer of refractions.]

But no one brought a remedy, and before Tycho no one taught a way of correcting observed altitudes of the stars by subtracting the refraction, let alone of measuring those refractions. By way of the circumpolar stars Tycho had obtained the altitude of the equator at Uraniborg as 34° 5′ 15″. From the Sun's meridian altitude at the solstice, corrected by adding a parallax of 1′ 35″ and brought to 57° 36′ 45″, he had gathered the Sun's greatest declination from the equator to be 23° 31′ 30″. Then at the winter solstice, with one instrument after another, exactly divided and applied, he always found the Sun's meridian altitude to be 10° 39′ 42″; and when its parallax of 3′ 3″ was added he had obtained a true altitude of 10° 41′ 45″ [recte: 10° 42′ 45″]. Subtracted from the altitude of the equator, this left the Sun's greatest southern declination as 23° 22′ 30″, which is less than the northern by a full 9′. He concluded that this arose from no other source than the refraction of the solar ray produced in such close proximity to the horizon, which apparently raised the Sun's centre above the horizon, as he himself relates in volume 1 of the *Progymnasmata*, from p. 14. So he devised a way of bringing to measure the refractions of the Sun, of the Moon and of the other stars, which he gives in volume 1 of the *Progymnasmata*, p. 93. We, however, shall make that way more universal, and useful by another method as well. It is as follows.

[Margin: Tycho's problem for measuring refractions.]

II. Let the horizon be HR and the meridian HVRD, in which are the pole of the equator P and the zenith or vertex V; and let the semicircle of altitude or vertical be VAD, in which let the true place of the Sun, corrected for parallax, be at B, but let it appear by the force of refraction at the point A of the horizon. Let two arcs, complements of the Sun's declination, be drawn to the pole P, one from the seen place A, which is AP, and the other from the true place B, which is BP. On a day, then, but a very clear one, of the summer solstice, when the variation of declination from one day to the next is scarcely sensible, let alone within a few hours, let the azimuth of the rising Sun at A be observed, that is, the arc of the horizon AH between the Sun at A and the meridian at H, an arc measured by the angle AVH, for its complement to 180° will be the angle AVP. Moreover, let there be given in the triangle BVP, from the Sun's true

declination, the complement BP, and the complement of the pole's altitude, VP. From these three givens you will find the arc VB by analysis of triangles; and if you subtract from it the quadrant VA, or 90°, there will remain the known arc AB, which is the difference between the true place of the Sun, B, and the seen place, A, and so the horizontal refraction.

Diagram. Set into the right column beside number II: a circle with a vertical line from V at the top to D at the foot and a horizontal line from H at the left to R at the right, meeting at A. P stands on the circumference at upper right. C lies on the vertical above A and B below it, and lines run from P to C, to A and to B. Labels read: V, P, C, H, A, R, B, D. Labels not read: none.

- V (top of circle): zenith or vertex
- P (circumference, upper right): pole of the equator
- C (on the vertical, above A): the Sun's apparent place in number III
- H (left): horizon, meridian point
- A (centre, on HR): the Sun's seen place in number II and true place in number III
- R (right): horizon
- B (on the vertical, below A): the Sun's true place in number II
- D (foot of circle): foot of the vertical

[Margin: Part 2 of the problem.]

III. Now let the Sun be at A, its true place, but let it appear by the force of refraction at C, so that the seen altitude is the arc AC; and let the arc CP be drawn from C, the complement of the known declination; and let the azimuth AH have been observed as above when the Sun appears at C. For so the angle AVH will be known, as above, and from it the angle AVP in the triangle AVP. Since in that triangle VP, the complement of the pole's altitude, is given, and AP, the complement of the true declination, the arc AV can certainly be found by trigonometry. Therefore if, when you observed the azimuth of the apparent Sun at C, you also observed its seen distance from the vertex, namely the arc VC, then with VC subtracted from the arc VA the refraction AC will become known. And so for the others, by observing on the solstitial day the individual degrees of the Sun's apparent altitudes, with their azimuths, from its rising to noon and from noon to its setting. The same is done proportionally for the Moon and for the fixed stars.

[Margin: Our method in observing refractions.]

IV. We, for our part, did use this method, but we observed the azimuths with the help of a filar triangle [Trianguli filaris], which shows the plane of the vertical circle with the greatest exactness, and we waited for the Sun to reach a determined degree of azimuth. This is far more certain than the usual azimuthal quadrants, in which a modest error in the inclination of their plane to the horizon produces an error in the altitude of the stars near the horizon that is not to be despised. For that reason Tycho confessed more than once that azimuthal observations are slippery and full of suspicion, as we shall show in the *Liber Organicus*, which is the second book of volume 2 of our *New*

Almagest. But we have investigated another method besides this one. Having taken the altitude of a known fixed star before sunrise, and having deduced from it the time before noon, we began, with companions well trained for the purpose, to count the times by means of a pendulum, which showed us the time of the primum mobile with the greatest exactness. In this way, in place of azimuths, we used angles at the pole P. So if the Sun appeared at C, the true time before noon was known and the angle APV was also known; with it, and with VP, the complement of the pole's altitude, and AP, the complement of the declination, the arc VA, of the Sun's true distance from the vertex, was found. From this, when there was de- ducted the seen distance VC, observed with a large quadrant, the refraction AC remained known.

[Margin: Tycho's other method.]

V. The other method, which Tycho suggests in volume 1 of the *Progymnasmata*, p. 94, uses the Sun's declination observed with equatorial armillaries in place of azimuths, and with the remaining quantities, given as above, it reveals the refractions. For in the triangle VCP there are given VP, the complement of the pole's altitude; VC, the Sun's seen distance from the vertex, observed with the astronomical quadrant; and CP, the complement of the Sun's seen declination, observed with the armillaries. So the angle VCP will not stay hidden, and when it is subtracted from two right angles, or from 180°, it will reveal the angle ACP. With this, and with CP, the complement of the seen declination, and AP, the complement of the true declination, you will find in the triangle ACP the arc of refraction AC. But this method is of little use for the horizontal refraction. Nor is observation with armillaries as simple, evident and safe as is required here, as I shall teach in the *Liber Organicus* from Tycho himself; and it demands, besides, the analysis of a double triangle.

[Margin: Use of refraction.]

VI. The primary use of a refraction once found is in correcting a star's apparent altitude. To that altitude the parallax of altitude is to be added but the refraction of altitude subtracted, and in this way the true altitude will remain, since the effect of refraction is entirely contrary to the effect of parallax: parallax apparently lowers the star, whereas refraction apparently raises it. The secondary use is in correcting declination, right ascension, longitude, latitude and distance from another star, and in converting these from apparent into true, or from true into seen and apparent. To indicate this too: if in the triangle VCP there are given VC, the complement of the observed altitude, VP, the complement of the pole's altitude, and CP, the complement of the seen declination, the angle CVP can be found. Then with it, in the triangle AVP, and with VP, and with VCA (that is, with the refraction AC added to CV), AP, the complement of the true declination, can be found. Likewise, in the triangle ACP, given AC, the arc of refraction in altitude, and the complements of declination AP, true, and CP, seen, the angle APC can be found, which is the difference of right ascension. And so for the others, as will be set out more fully in the common Problems of the primum mobile [Pimi] [recte: Primi] and in the Optical Book,

in the section on refractions, where, God willing [D.O.M. volente], we shall teach many subtler things about refractions, worth knowing.

[Margin: Tables of refractions.]

VII. Tycho, then, having measured refractions in Denmark by the method set out in nos. 2, 3 and 5, left us a table of them: the solar refractions at p. 79 of volume 1 of the *Progymnasmata*, the lunar at p. 124, and those of the fixed stars at p. 280. Others have since copied these out, such as Longomontanus, Book 1 of the *Theorica* [Theoricor.], Chapter 8; Kepler in the *Astronomia Optica*, p. 121, and at the end of the Rudolphine Tables; Bettini, *Apiarium* 8, Progymnasma 1, Proposition 2; Hérigone, volume 4 of the *Cursus Mathematicus*, p. 98; Boulliau in the *Philolaic Tables*, p. 179; and Metius in the *Astrolabium*. Lansbergen, however, gives his own in his tables, p. 46, and we shall give ours at the end of this Book. Meanwhile it is worth noting that refractions near the horizon vary by a headlong increase or decrease; and that with Tycho those of the Sun and of the Moon vanish around the 45th degree of altitude, and those of the fixed stars around the 20th degree. With the same author the refractions of the fixed stars are 4½′ less than the solar, and can serve for the refractions of the other planets, as he himself admits on that p. 280. But the refractions of the Moon nearer the horizon are less than the solar, and afterwards at some points greater, whereas on account of the greater inclination of the ray that is refracted they ought all to be greater than the solar, as I shall show in the Optical Book. So for Tycho the horizontal refraction is 34′ for ☉ but 33′ for ☾, and for the fixed stars 30′ or 29′ 30″. Kepler touches on the cause in the Rudolphine Tables, Precept 197, but we say more on this in the *Optics*, where the following point of Kepler's in the *Astronomia Optica*, p. 283, must also be weighed: whether, namely, through an eclipse the total refraction at any place can be 61½′.

SCHOLIA.

[Margin: Variety and inconstancy of refractions.]

I. Since the causes of refractions are various, they also yield various refractions. The density of the air and the thickness of the atmosphere, and its height, are not the same on every horizon, but greater in more humid places and colder ones. Nor are they constant on the same horizon through the whole time of the year, but greater about the borders of winter and spring, and greater at the equinoxes than at the summer solstice, and in rainy or cloudy weather or in snowy. Tycho, however, in the *Epistolae* and in volume 1 of the *Progymnasmata*, p. 280, denies that refractions in Hesse are twice as small as in Denmark (as Rothmann kept saying had been observed); he ascribes that rather to a fault of the observations.

[Margin: Various questions about these refractions.]

We must discuss in our *Optics* whether a difference of light, and of distance from the Earth, and of figure, in the star itself or in the surface of the atmosphere, and of the depth of that same atmosphere, makes for a different refraction.

Likewise, how great is the height of the refracting air, and whether it is as great as that of the exhalations that produce twilight, as Tycho and Longomontanus held, but Kepler otherwise. Likewise, whether the density of the atmosphere, decreasing uniformly difformly toward the heavens, reduces the refracted ray to a curved line, or to one straight line, or to several straight lines disposed circularly or parabolically. Likewise, whether the cause of the headlong difference of refractions near the horizon is the far longer stretch of atmosphere through which the refracted ray must pass, as Tycho, Longomontanus, Metius and Cabeo thought, or only the difference of inclination of the ray falling into the atmosphere, or something else. Again, whether Tycho compiled his table of refractions separately from the parallax or with it included. For this reason I have now obtained, from Father Albert Curtz, S.J., who at the Emperor's order now directs the bringing to light of Tycho's observations, the observation of the solar refractions made by Tycho at the summer solstice. Finally, whether a double table is needed, one for the star's true altitude and the other for its apparent altitude, as I said of the parallactic tables in the preceding Chapter; and whether Tycho's table must be corrected again on account of the perhaps excessive parallax of the Sun that he adopted; and things like these, which could not conveniently be treated in this place. The ignorance of Christmann, who denies that the ray leaving a star's centre is refracted, and who keeps saying that star altitudes are therefore not to be corrected by subtracting the refraction, on the ground that the altitudes of stars are observed by that ray alone, is to be refuted more clearly in the same place.

[Margin: The more striking effects of refractions in astronomy.]

II. It is astonishing how many and how striking are the effects of refraction, especially in the luminaries, so much so that if they are unknown astronomy is almost lacking one eye. For first, by visibly raising a star and all its visible points, refraction changes its ascensions and descensions, and its longitude, latitude and declination. II. It contracts the distance between two stars, or two luminous points, above the horizon, but increases it below. III. In the oblique sphere, among northern peoples, it increases the northern rising and setting amplitude and diminishes the southern, if they are compared with the points of rising and setting of the true equinoctial. IV. In the torrid zone and the temperate zones it increases the artificial day by about 8^m or 10^m, on the one side hastening sunrise by 4^m or 5^m of time, and on the other delaying sunset. But in the parallel sphere and in the frigid zones it sometimes increases the day by several hours, and indeed by days, as I shall presently relate. V. It hastens the vernal equinoxes and delays the autumnal, and sometimes makes the hollow of equinoctial armillae appear equally lit on both sides twice on the same day, so that the equinox seems to occur twice. This astounded Hipparchus, who did not know the cause, and gave Ptolemy a handle for suspecting the Alexandrian armillae, as though they had slipped from their original position. VI. It shrinks the apparent diameters of the stars along the altitude, and so shows us the Sun and Moon at the horizon egg-shaped and almost elliptical. VII. It makes the

luminaries, though diametrically opposite and placed on or below the horizon, appear above the horizon, as Cleomedes observes toward the end of Book 2; so that a lunar eclipse is seen even though the Moon is really below the horizon and the Sun above. This was observed, on the testimony of Pliny the Elder, Book 2, Chapter 13, when the two Vespasians were consuls for the third time [Conſulib. duobus Veſpaſianis tertium], namely in the year of Christ 72 February 22; and by Mästlin in the year 1590 July 17, on the testimony of Kepler in the *Astronomia Optica*, p. 136.

and it will happen in the year 1668 May 25, in the morning, on the horizon of Rome. VIII. It makes several Suns and Moons appear in the atmosphere at the same time, on different horizons; and the same Sun at the same moment is below the horizon for some and above it for others. I say the same of the Moon, especially the full Moon.

[Margin: The remarkable Dutch observation for the refractions of ☉.]

IX. In the frigid zones it makes the Sun rise several hours earlier than it otherwise should, and indeed in some places several days earlier, and set later. This is what happened to the Dutch at Novaya Zemlya [nouam Zemblam] in the year 1596, as is told in the account of that voyage of the Dutch. At a pole altitude of 76°, taken again and often by their navigators, they saw the Sun set on 1596 November 4 and stay hidden below the horizon until 1597 January 24, when its rising was unexpected to them, since according to the situation of that horizon and the Sun's declination it should not have risen until February 11 and should have set on October 17 of the preceding year. So the refractions delayed the setting by 17 whole natural days and brought forward the rising by as many days. That this was the effect of refractions is rightly taught by Kepler in the *Astronomia Optica*, p. 138, by Magini in the *Primum Mobile*, Book 6, Problem 16, and by us in the Optical Book. X. If there is vaporous air around the Moon and it has its own atmosphere, of density sufficient for sensible refractions, its phases must vary in eclipses and outside them, and more of the lunar hemisphere, as also of the terrestrial, must be lit by the Sun than would otherwise be the case; and so the shadow of the Moon and of the Earth must be contracted and cut off, as I shall explain more fully in the proper places.

CAPVT X.

De Magnitudine Solis Apparenti.

On the Apparent Size of the Sun.

[Margin: The difficulty of observing the Sun's diameter exactly.]

I. The Sun's apparent size is estimated from its apparent diameter, which it is either impossible or very difficult to determine evidently without an error of 1′. Archimedes at last perceived this after his own efforts and those of Aristarchus, in *The Sand-Reckoner*, where he says:

[Margin: On the testimony of Archimedes.]

"We assume this, since Aristarchus says that the Sun appears as if it were the seven hundred and twentieth part of the circle of the zodiac. For he himself considered how he might capture with instruments the angle that fits the Sun, having its vertex in the eye. But to take any such thing exactly is not so readily done, since neither sight, nor hands, nor the instruments with which the observation is made, are sufficiently worthy of trust to demonstrate it exactly." Now the 720th part of a circle is 30′, and Sosigenes, in Proclus's *Hypotyposis* [Hippot. Astron.], judged this diameter to be always that many minutes.

[Margin: And of Ptolemy.]

Nor did Ptolemy, as he relates in Book 5 of the *Almagest*, Chapter 14, using Hipparchus's dioptra, [find][14] either an exact measure of this diameter or any sensible difference between the diameter of the Sun at apogee and at perigee. For he says: "We too constructed a dioptra with a rod of four cubits, which Hipparchus indicated, and observing the Sun's diameter by it we found that it is everywhere comprehended under very nearly the same angle, no sensible difference worth attention being produced by the distances." He goes on to say that the Moon at apogee and the Sun appear under an equal angle, but adds: "How great an angle is subtended, however, seems very doubtful to us; for the measurement, which is made by repeatedly moving forward or drawing back along the length of the rod, between the sight and the plate, a little plate set against the luminaries, can lead into error away from the exact truth." So he has recourse to lunar eclipses, from which, as I shall teach when treating the Moon's diameter, he derives the diameter both of the Moon at apogee and of the Sun as 31′ 20″, although this very method relies on an estimate of eclipsed digits, which has no greater certainty than the use of the Hipparchan dioptra.

[Margin: And also of Kepler.]

II. Kepler recognised this difficulty, and at the same time the necessity of determining the diameters of the luminaries, in the *Astronomia Optica*, p. 212, saying: "The more careful astronomers do not trust the eye. This is to be guarded against much more when very slender quantities are called to the measure of an angle, as when we inquire into the diameters of the luminaries; which must be done, as a foundation, by all who have undertaken the restoration of astronomy." And on p. 339 he expressly admits: "In any ray whatever let in through a window of any kind, even a square one, the senses do not follow mathematical subtlety; but, by 29 of the first chapter, they do not apprehend the extremities of the luminous image, to which few particles of the Sun radiate, because of the brightness of the intermediate parts of the image, to which all the particles of the Sun radiate." It is as if he were saying that the penumbra which lies between the image of the Sun received through a hole or little window on a plate and pure shadow cannot be exactly distinguished from pure shadow or from the brightness of the luminous image, as I shall teach more clearly below.

[Margin: Kepler's excessive confidence.]

[14] no main verb is printed here; "find" is supplied, as the book's errata supply *reperit* after *ſenſibilem*

If this is so, how then does Kepler, who professes on p. 340 to have used this method, say so confidently on p. 343: "But the matter is certain and open to anyone to investigate, that the Sun's diameter is 30′ at apogee and 31′ at perigee"? Is it really open to anyone? Certainly not to Archimedes, not to Ptolemy, not to Scheiner, not to other very celebrated astronomers, as I shall presently say; not to us; and not even to your own Tycho.

[Margin: Tycho's opinion.]

For Tycho, using a channel or tube of about 32 feet at the solstices and equinoxes, detected the diameter of the Sun at apogee as nearly 30′, and rather less by a few seconds, and at perigee as exceeding 32′ by very few seconds. On account of the evidence of his own experiment, he could not on anyone's authority set the Sun's diameter at mean distance greater than 31′; and he set the apogeal at 30′ and the perigeal at 32′, as he himself reports most expressly in volume 1 of the *Progymnasmata*, p. 471. What more need be said? Do you yourself not relate in the *Astronomia Optica*, p. 339, that Tycho's people used a square hole, but one too wide for a complete intersection of the rays to be possible? And on p. 341, that Tycho's channel was of 1000 parts, of which the breadth of the square hole was 10; that the Sun's diameter found by him at the summer solstice was 29′ 54″, and that in other observations it stands between 28′ 40″ and 31′ 20″; and that on December 5, with the channels changed three times, it was found to be 31′? And there you add that Tycho sets the perigeal diameter of the Sun greater than the apogeal by 2′, on account of the Sun's eccentricity, found to be 3600 parts of which the Sun's mean distance, or the semidiameter of its orb, is 100000. Finally, on p. 342 you relate the altitudes of the Sun's limbs observed by Tycho on March 15, and the varying diameter found from them, namely 29′ 30″, and 30′ 4″, and 30′ 6″, and 30′ 40″, and 30′ 44″, and 30′ 50″.

But of course Kepler, in whose mind it had already settled that Tycho's eccentricity of 3600 parts must be bisected and reduced to 1800 parts, could not admit a difference of more than 1′ between the apogeal and perigeal diameters of the Sun. Yet on p. 330 of the *Astronomia Optica* he confirms this bisection from a subtly observed diameter of the Sun. But this could not persuade us, who have almost wasted away in investigating this same diameter by several methods. Now the causes of this difficulty cannot be perceived unless the methods by which the Sun's diameter is usually or can be investigated are known. There are indeed several of these, and among them not a few devised by us, as will be clear from our *Liber Organicus*, where we shall describe the old and new instruments for the purpose. In this place, however, at least the chief ones must be indicated, the reader being referred there for inspection of the instruments.

Primus Modus obſeruandi Solis Diametrum.

First Method of Observing the Sun's Diameter.

[Margin: The astronomical radius.]

III. All the methods of this practice are carried out either with the eye, whether naked or covered with plates or coloured glasses, directed at the luminaries themselves, or on their shadow or luminous image received on some plate or wall. Among these the most ancient is the one carried out with the astronomical radius [Radium Aſtronomicum], described by Regiomontanus in *De Cometis*, Problem 13; by Gemma Frisius in an entire little work on the subject; by Nonius, Book 2 of *De Observatione*, p. 73; by Finé in *De Re et Praxi Geometrica*, Book 1, Chapter 6; by Pierre de la Ramée, Book 9; by Longomontanus in the *Astronomia Danica*, Book 2 of the *Sphaerica* [Sphæricor.], Chapter 7, and Book 1, Chapter 9; by Metius, Book 3 of the *Doctrina Sphaerica*, Chapter 2; and by Bettini, *Apiarium* 2, Progymnasma 3; and it is indicated by Tycho at p. 33 of the *Astronomia Mechanica* [Aſtronomiæ Mechanicæ]. This radius was succeeded by the Latin radius [Radius Latinus], so called from its inventor Latino Vrſino [Latino Orsini], and illustrated with a commentary by Egnazio Danti.

[Margin: The unreliability of both radii.]

But in truth both radii are deceptive, and in the diameters of the luminaries are exposed to an error of 3′ and more, as Tycho observed above, and in volume 1 of the *Pro- gymnasmata*, pp. 247 and 672, and in the *Epistolae Astronomicae*, pp. 8, 22, 28, 38; Longomontanus above; Kepler in the *Astronomia Optica*, pp. 215 and 343, where he calls that instrument crude [craſſum]; and Scheiner in his *Oculus*, or Optical Foundation, Book 3, p. 246.

There are four causes of the deception. The first is the difficulty of moving the cross-piece [Tranſuerſarium] forward or back while keeping it at right angles to the index; but the Latin radius removed this one. The second is the cheekbone, which prevents the eye from being applied exactly to the head of the radius. The third is the parallax of the visual angle [anguli viſorij], which is formed not at the surface of the eye but either at its centre or at its back. So the angle under which the diameter of the luminaries is seen is smaller than the one under which it is thought to be seen at the surface of the eye; and unless it is known in which part of the eye this angle is formed, an operation begun with these radii cannot be corrected. The fourth is the straddling [diuaricatio] and pulling apart of the eye this way and that, to the right and left margin of the luminaries, since it cannot attend exactly to both at the same point of time.

[Margin: New kinds of radius.]

For this reason, in the *Liber Organicus*, which is the second book of volume 2 of the *New Almagest*, we set out several other kinds of radius; among these, the ones that need two observers are larger and harder to use, but more certain. And in the Optical Book, which is the third of the same volume 2, in the section on the eye, we have investigated the part of the eye in which the so-called visual angle is formed; and in the same place we have treated the correction of an observation begun with radii.

Secundus Modus obſeruandi Solis Diametrum.

Second Method of Observing the Sun's Diameter.

IV. So, to cheat the cheat of the old radius, Hipparchus and Ptolemy chose the dioptra instead, if we believe Kepler in the *Optics* [in Optic.], p. 216, and Cabeo on the *Meteorologica*, text 9, question 1. This dioptra, with the plate near the eye fixed, is described by Proclus in the *Hypotyposis Astronomica*, Chapter 3; by Maurolico in the *Cosmographia*, Dialogue 3; by Biancani in the *Sphaera*, Part 6, Chapter 5; and by Cabeo above. But Egnazio Danti describes it with the plate near the eye movable, in the *Astrolabe*, p. 293.

[Margin: The Hipparchan dioptra is deceptive.]

But Ptolemy, in Book 5 of the *Almagest*, Chapter 14, admits that it is liable to error and does not yield an exact diameter of the luminaries. We too have used this dioptra, and one of 12 feet at that, so that the error in the length of the rule and in the distance of the plates would turn out smaller. We detected that the centres of the two small bright circles do not unite in one sensibly indivisible point, and that the place of the angle subtending the Sun's diameter is not certain to the point that it does not lie beyond or short by several sensible particles.

Tertius Modus Obſeruandi Solis Diametrum.

Third Method of Observing the Sun's Diameter.

V. Others, therefore, chose to take at the same moment, with two astronomical quadrants, the altitudes of the upper and lower limb of the luminaries, or with two armillae their declinations, by means of two observers; for the difference of altitude or of declination gives the apparent diameter. Kepler relates in the *Astronomia Optica*, pp. 342 and 348, that Tycho used this method, but with astonishing diversity and inconstancy of observations.

[Margin: A blemish of Lansbergen.]

And yet Lansbergen, in the *Treasury of Observations* [Theſauro obſeruationum], pp. 100 to 105, does not hesitate to call them "indubitable"; though when he sees Tychonic observations conflicting with his own tables, he nevertheless corrects them as faulty and deceptive.

The altitude of each margin can also be taken by admitting a ray of the Sun through a chink of known height in a wall, onto a pavement on which the wall stands at right angles, and measuring the length of the ellipse that the ray forms and its distance from the wall. Kepler teaches this method in the *Astronomia Optica*, p. 342, and so do we in the *Liber Organicus*, where we shall report our observations made in the church of San Petronio at Bologna, in which there is a metal plate with a hole for admitting the Sun's ray, at a height of 65 Bolognese feet. But all these methods suppose that the margins of the luminaries, or the boundaries of light and shadow, can be distinguished and reached precisely, without suspicion of sensible error, and without taking in any sensible particle;

and anyone willing to make the trial will find it evident that this can scarcely, or not even scarcely, be done.

Quartus Modus obſeruandi Solis Diametrum.

Fourth Method of Observing the Sun's Diameter.

VI. This method consists in counting the time in which the entire disc of a luminary rises above the horizon. The kings of Egypt, indeed, used for this purpose the running of a very swift horse, which they let go when the upper limb of the Sun was rising and checked when the whole Sun had now risen. For knowing the stadia that the horse usually covered in one hour, and the stade or part of a stade it had completed in the meantime while the Sun was rising, they worked out the time, and from it the parts of the equator corresponding to the Sun's diameter.

[Margin: The Sun's ascent counted by a horse's run.]

Although this method is very crude, because of the horizontal refractions and the varying obliquity of the ascensions, Cleomedes nevertheless uses it, in Book 2 of the *Cyclical Theory*, to blunt the grossness of Epicurus, who thought that the Sun could be said to be one foot across, as large as it commonly appears.

But a slightly better method of counting the same time, of the Sun or the Moon ascending, was by clepsydras, or water-clocks [Hydrologia]. These are discussed by Cleomedes in the same place; by Proclus in the *Hypotyposis Astronomica*, Chapter 3; by Martianus Capella, Book 8 of the *Philology*; by Maurolico in the *Cosmographia*, Dialogue 3; by Egnazio Danti, *Astrolabe*, Part 6, p. 290; by Reinhold in the *Theoricae*, p. 206; by Barozzi in the *Cosmographia*, Book 4, p. 339; by Kepler, *Astronomia Optica*, p. 147; and by Bettini, *Apiarium* 8, Progymnasma 3, Proposition 8.

[Margin: The use of clepsydras is deceptive.]

Now Cleomedes relates that the water of the lower clepsydra, which had flowed down from the upper while the whole Sun was ascending, was found by the Egyptians to be to the water of the clepsydra of the entire day as 1 to 750 or 700; and that the Sun's diameter was accordingly estimated, against the equator, as 1 to 750 or 700, that is, 28′ 48″ or 30′ 52″. Proclus and Macrobius relate that this was usually done at the time of the equinox. But even then, in Egypt, where the equator ascends obliquely, the obliquity of the ascent, the horizontal refractions and the uniformly difform fall of the water made this procedure [pragmatiam] uncertain, and so it was rejected by Ptolemy, Book 5, Chapter 14, and by Proclus, Theon, Pappus and Kepler.

[Margin: And of the sand-glass.]

Now David Rivault, on the *Sand-Reckoner* of Archimedes, would have this done, in place of the Ctesibian clepsydra [Cleopſydræ Creſibianæ], by a sand-glass [horologium arenarium], weighing the sand that has run out while the Sun ascends against the sand run out through an entire hour. But he is mistaken, because more sand falls at the beginning, owing to the weight of the greater

mass, which presses from above and drives the sand downwards; and more than once, from the motion of the pendulum, of which more shortly, I have learned that more sand falls in the first quadrant than in the second.

[Margin: The quicksilver clock is deceptive.]

For this reason neither are these clocks suited to such subtleties, nor are those that Tycho had devised from mercury [hydragiro], as he himself admits in volume 1 of the *Progymnasmata*, p. 149, having found Mercury, or quicksilver, no less cunning in this than in eluding astronomers in the heavens and chemists on Earth.

[Margin: Striking clocks are deceptive.]

Nor are striking clocks [Horiſona horologia] suitable either, because toward the end the weights, by reason of leverage, turn the toothed wheels more than at the start; besides the other inequalities to which they are subject on account of humid or dry air and of winds. Tycho perceived this in the same place, p. 145.

[Margin: *Scaphia* are useless for this.]

Sundials in bowls [Sciaterica … horologia in Scaphijs], which used to be employed for this purpose, as Macrobius relates, *On the Dream of Scipio*, Book 1, Chapter 20, are also useless. For although on the equinoctial day they observed two termini of the Sun's shadow, one when the upper limb was rising, the other when the lower limb of the Sun had now risen, and found that interval to be the ninth part of an hour, that is, 1° 40′, this method was nevertheless most deceptive, because the motion of the shadow is far greater around the rising and setting of the Sun than far from them, and very unequal; whereas the ancients, like the good Macrobius, thought it equal. And in all sundials the arrival of the shadow at the lines cannot be discerned without fear of an error of one or several minutes.

[Margin: The times of a pendulum are far better suited to this.]

VII. I, therefore, having at last been assured, on the occasion of another experiment, that the oscillations of one and the same pendulum, keeping the same height, since it was suspended not from a thread but from a small chain, and travelling through the same plane, are of equal duration among themselves, with no sensible difference ever appearing, acquired for myself, among others, a pendulum of which one simple vibration was of one half-second and the compound vibration of one second, as I said in Book 2, Chapter 20; and with this second pendulum I made fifty observations on the Sun. For with my head resting immovably on a trans- verse little beam [trabeculæ], and with my eye protected by coloured glasses and set in a motionless little tube, I waited until the western limb of the Sun began to pass across the meridian, which was marked by two very fine threads set up perpendicularly in the plane of the meridian. Immediately, at a given signal, my assistant, who was usually either Father Francesco Maria Grimaldi, or his brother Father Vincenzo Maria, or Father Zenus, counted the simple oscillations of the pendulum toward one side until the Sun's centre reached the meridian, and then until the whole Sun had

passed and its eastern margin came, as it were, to optical contact with the two threads mentioned.

I did the same very often with the round image of the Sun, admitted through a tiny hole onto a white plate parallel to the Sun, the room being darkened all round, while my assistant counted the time in which that entire base of the radiant cone crossed a little line drawn very finely in the plane of the meridian. When the days were equinoctial, it was enough to convert that time into parts of the equator for the Sun's apparent diameter to become known; but on other days, the Sun's declination being assumed, the arc of the parallel that had crossed the meridian had to be reduced to an arc of the equator, according to the proportion of the parallel to the equator. We shall bring out these observations in volume 3 of the *Almagest*, together with others.

[Margin: In this method too there is some suspicion of a small error.]

In the meantime I frankly confess that with all this subtlety and patience I did not attain the certainty I had hoped for from it. The cause was the uncertain beginning and end of the transit of the Sun's margins, because the threads, however very fine, nevertheless take off and cover some particle of the Sun on either side; so that about 2 seconds of time are counted before you are sure of that beginning and end. As a result, suspicion of an excess or deficiency of one half-minute cuts off exact knowledge of the solar or lunar diameter (for we have very often examined the lunar one too by this method). In the transit of the bright base, moreover, the doubtful boundaries of light and of pure shadow, on account of the penumbra related to both, raise the same suspicion; for the diameter of the hole was subtracted from the space traversed, and so deception could not creep in on us from this source. Yet each method is far more certain than any of those proposed so far, and sufficient to refute clearly those who foist on us a diameter of the Sun greater than 35′ at perigee, or less than 29′ at apogee. All things considered, I judge the truest of all to be 30½′ at apogee and 33′ at perigee, with a few seconds wanting on either side.

Quintus Modus Obſeruandi Solis Diametrum.

Fifth Method of Observing the Sun's Diameter.

VIII. This method was used by that Atlas of the last age, Tycho, with the help of a channel [canalis], as he himself relates in volume 1 of the *Progymnasmata*, p. 471. It was also used by Kepler in the *Astronomia Optica*, Chapter 11, from p. 340 on; by Scheiner in the *Rosa Ursina*, Book 4, Part 2, from Chapter 4 on; by Father Cysat at Ingolstadt; and by us at Bologna, more than sixty times, both in our observatory and in the church of San Petronio.

The procedure is as follows. Into a room thoroughly darkened on all sides a ray of the Sun is admitted, especially around noon, through a round hole in a small plate [lamellæ], or through a square little window, whose breadth, however, should be known in the smallest possible particles, say in hundredths of one inch [vnciæ]. The diameter of the hole or the breadth of the little

window ought not, however, to exceed about two inches of the Roman foot. That plate must be movable in such a way that its plane receives perpendicularly the central ray of the Sun, that is, the axis of the radiant cone or pyramid. The circular base of the other radiant cone, or the square base of the pyramid, is to be received on a white plate [tabellâ] parallel to the plane of the plate in which the hole or little window is; and the distance of these plates must be known in the parts in which the diameter of the hole or the breadth of the little window is known.

Next, with very sharp compasses, the diameter of the bright base of the radiant cone, or the breadth of the pyramidal base, is to be measured, including the penumbra as well, and circumscribing, that is, excluding, only the simple and pure shadow. From that measure the breadth of the little window or the diameter of the hole is to be taken away, for the reason demonstrated by Kepler, and by us in the Optical Book. And so there will remain the corrected base of the image of the Sun, half of which will be one side of a right-angled rectilinear triangle; the other side about the right angle will be the distance of the plates; and with these, by analysis of triangles, the angle subtending the Sun's apparent semidiameter is found.

[Margin: A twofold method within this method.]

Further, others use plates alone, parallel to one another and receiving the Sun's central ray perpendicularly, especially when their distance is very great, as with Tycho, for whom it was about 32 feet, and with us, sometimes 50, and sometimes, as in the church of San Petronio, even greater than 170 feet. But in these cases the boundaries of light and shadow turn out more doubtful, and the motion of the bright base becomes faster, so that a sudden and very attentive observation is needed. Others, however, such as Kepler, Scheiner, Cysat, and we ourselves more often, use a small beam with the already mentioned plates fixed at its ends, so that they can raise and lower them and move them to the right and to the left, as the opportunity of catching the Sun's ray requires, and, as a short way to greater darkness, can place between the plates a blackened paper tube, which also gathers the fibres of the rays so that they are not scattered.

[Margin: Scheiner's error [Greek: ἀμάρτημα (hamartēma, "error, fault")].]

Now Scheiner's distance of the plates was indeed 10000 parts, but 10 Roman feet; and although he varied the holes from time to time, larger and smaller, he never subtracted from the diameter of the bright base, as he should have, the diameter of the hole; and so he found that diameter both inconstant and almost always larger than it should be. Nor does Bettini mention this correction when he indicates this method in *Apiarium* 8, Progymnasma 3, Proposition 10; but in Scholium 2 he applies another remedy, far more difficult, by which the full crossing of the rays [plenaria radiorum decuſſatio], made far from the hole, has to be found. Of this discovery more fittingly in the Optical Book.

But Kepler's distance of the plates was 10368 parts, of which the diameter of the hole was 16½. We, for our part, have used various tubes and distances of the plates, namely of 8, 10, 12 and 15 feet. But we added two things for a more

exact observation. First, we employed an assistant, namely Father Francesco Maria Grimaldi, who from the right, with a very fine needle, would prick the plate at the boundary of pure shadow, as soon as I, from the left, gave the sign that the eastern margin of the bright base was arriving at a little line drawn in the vertical plane of the plate; a sign, I mean, that was instantaneous, given by pronouncing the monosyllable *Sic*. Besides this, repeating the observation, we generally used two holes, one twice as large as the other, so that it would be clear to us whether, after the diameter of either had been subtracted, the same quantity of the diameter of the bright base remained, as it should.

[Margin: Suspicion of a small error here too.]

And this method is indeed the most excellent of all, if the circumspection I have indicated is applied. But since, after all, the boundaries of light and shadow are not entirely evident, and while the eye is busy removing the doubt the bright base moves quickly with the motion of the Sun, a slight suspicion always sticks in the observer's mind of an excess of about half a minute in the Sun's diameter deduced from it. But we are helped by the deficiency in the following method, so that by choosing the mean we may establish a fairer diameter; otherwise, by this method I generally obtained it as 31′ at apogee and 33½ at perigee.

IX. Finally, Pierre Gassendi suggests to us a sixth method, in his Letters to Fortunio Liceti and in the book *On the Apparent Magnitude of the Sun Low and High*. He fixed at right angles to the ends of a small beam two plates, quite equal and equidistant, each having a breadth of 796 particles, of which the distance between the plates was 38308, that is, 22 Paris or Royal feet; and with the plates turned toward the Sun he measured the breadth of the shadow cast by the front plate onto the rear plate, and from it, by analysis of triangles, he hunted out the Sun's apparent diameter. So as to omit nothing that could be useful, we too used this small beam, with the room darkened on all sides. The method of finding the Sun's diameter from the breadth of the shadow is as follows.

[Margin: Problem for the sixth method.]

Let the extreme rays of the Sun be AC and BC, touching the margins of the more remote plate, DE; and let the shadow, parallel to it but narrower, be FG, and the union of the rays at C. Let GL be drawn perpendicular to DE, and from C a perpendicular to the plates FG and DE, and indeed also to AB, dividing the angle ACB in two, as also FG, DE and AB, by 9 and 10 of Book 1 of Euclid. Since, therefore, the angles at O, K and L are right angles, OG, the half-breadth of the shadow, will be known from measure- ment, and equal to KL, and KO equal to LG, by 33 of Book 1. So when OG is taken from KE, the half-breadth of the plate DE, LE will remain known, in the triangle LGE, right-angled at L; in which LG is also known, being equal to the known distance of the plates, KO. Therefore, by analysis of right-angled triangles, the angle LGE will not stay hidden; and to it the angle ICB is equal, by 29 of Book 1, because BC falls on the parallels IC and LG. But ICB subtends the semidiameter of the Sun, and ACB the apparent diameter, which was to be found.

Diagram. A figure set into the left column beside the demonstration: an inverted triangle with its base AB at the top and its apex C at the bottom. A vertical line runs from I, at the middle of the base, down to C. Two horizontals cross the triangle: DE, the upper, and FG, the lower and shorter. A second vertical runs from L on DE down to G.

- I (top centre, above the base): the middle of AB
- A (upper left), B (upper right): ends of the base
- K, L (on DE, side by side, K on the central vertical and L to its right)
- D (left), E (right): ends of the upper horizontal
- F (left), G (right): ends of the lower horizontal
- O (on the central vertical, at the level of FG)
- C (bottom): the apex

Moreover, here too the boundary of light and shadow is doubtful, and a rather large breadth of shadow is usually taken because of the penumbra, and so a diameter of the Sun somewhat smaller than it should be. But if this method is joined with the fifth, since that one tends to produce an excess and this one a deficiency, there will be a certain compensation; and from this one compared with method 4, the fairer estimate of the Sun's diameter, to my mind, is 30½′ at apogee and very nearly 33′ at perigee. The remaining methods, which I deliberately omit, either reduce to these, or are more uncertain than these, or are derived from eclipses; I shall indicate them in Book 4, Chapter 15, no. 2, where Ptolemy is discussed. As for Lansbergen's extending the diameter of the Sun at perigee to 36′, in Class 4 of the lunar observations, this clearly conflicts with our direct observations; and the eclipses he brings forward there can be accounted for in another way, by adjusting the diameters of the luminaries so that they nevertheless do not conflict with observations.

[Margin: Authors on the Sun's apparent diameter.]

XII. It remains for us to gather the opinions of astronomers on the Sun's apparent diameter into one table. In support of its reliability the following stand and can be consulted: Archimedes in the *Sand-Reckoner*; Pappus and Commandino on Aristarchus, *On the Magnitudes and Distances of the Sun and Moon*; Cleomedes, Book 2 of the *Cyclical Theory*; Ptolemy, Book 5 of the *Almagest*, Chapters 14, 15 and 16, and Theon on that place, and Regiomontanus in the *Epitome*, from Proposition 21; al-Battānī, Chapter 30, and Regiomontanus in his notes on that place; al-Farghānī, Difference 22; the Alphonsines, Canon 18; Peuerbach in the *Tables of Eclipses*; Copernicus, Book 4, Chapters 18 to 20; Reinhold in the *Theoricae Planetarum*, p. 210, and in the Prutenic Tables, Precept 49, with the table on p. 123; Daniel Santbech, *De Observationibus*, Propositions 14 and 23; Magini in the *Theoricae Planetarum*, Book 2, Chapters 19 to 24, and Canon 68 of the *Secunda Mobilia*, and in the Supplement to the Ephemerides, p. 291; Clavius on the *Sphere*, p. 186; Barozzi, *Cosmographia*, Book 4, p. 337; Mästlin in his *Theoricae* of eclipses [Thor. Eclipſium]; Tycho, volume 1 of the *Progymnasmata*, pp. 467 and 485; Longomontanus, Book 1 of the *Theorica*, Chapter 9; Kepler, Chapter 11 of the *Astronomia Optica*, in the

Appendix to Tycho's *Progymnasmata*, at the start of the Ephemerides, and in the Rudolphine Tables, Precepts 141 and 148, and pp. 92 and 98 of the tables; Lansbergen in the *Uranometria*, pp. 49 and 115, in the tables, p. 37, and in the *Treasury of Observations*, pp. 100 to 105; Biancani in the *Sphaera*, Book 10, Chapter 3; Scheiner in the *Rosa Ursina*, Book 4, Part 4; Bettini, *Apiarium* 8, Progymnasma 3; Nicolaus Mulerius in the *Tabulae Frisicae*, p. 420; Redento Baranzano, *Uranoscopia*, Part 2, p. 114; Athanasius Kircher, Book 9 of the *Ars Magna*, and in the *Magnes*, p. 561; Boulliau, *Astronomia Philolaica*, Book 4, Chapter 2, and in the tables, p. 138; Šírek in the *Radius Sidereomysticus*, Book 4, Chapter 2, M. 4; Wendelen in the *Idea of the Atlantic Tables*, p. 29; Hérigone, volume 4 of the *Cursus Mathematicus*, p. 59; Johann Baptist Cysat in his papers [in Schedis]; Vincenzo Renieri in the *Tabulae Mediceae*; Pierre Gassendi, *On the Apparent Magnitude of the Sun Low and High*, and in the *Institutio Astronomica*, Book 2, Chapter 9; Michael Florent van Langren in letters addressed to me; Galileo, Dialogue 3 on the Cosmic System; Georges Fournier, *Hydrographie*, Book 13, Chapter 2, from Gassendi. Of these, Copernicus considers the least eccentricity, but Reinhold and Magini in the *Theoricae Planetarum* a threefold eccentricity; Lansbergen nearly the least; but Magini in the Supplement to the Ephemerides, as also Kepler, bisect the eccentricity, and hence the difference of the diameter. The opinions of the Egyptians, however, are reported by Macrobius, Cleomedes and Proclus.

And so otherwise at other times			

SCHOLIA.

[Margin: Notable advice for establishing the diameters of the luminaries.]

I. In establishing the Sun's apparent diameter, account must be taken not only of the observations by which it was obtained through one of the six methods described, but also of the horizontal parallaxes and of the distances from the Earth, and much more of the eclipses of the Sun and Moon. For the difference of the diameter between greatest and least must be consistent with the distance of the Sun at perigee and at apogee, and with the difference of the horizontal parallaxes that follows those distances. Next, the record of solar eclipses and the diameter of the Moon must be kept safe; since some of these eclipses are reported as total without delay, some as total with a delay of the Sun in darkness, and some as partial but annular, that is, those in which a bright ring of the Sun, not eclipsed, appeared around the Moon, according to what is to be said in Book 4, Chapter 6, no. 4, and its Scholium 1. For it is not certain that this is to be attributed either to contraction in the total eclipses, or to an optical dilatation, or to refractions of rays in the annular ones, occurring in the air around the Sun, the Moon or the Earth, as some think; more on these in the Book on Eclipses, and Book 4, Chapter 17, no. 8. Furthermore, those who with Kepler bisect the Sun's eccentricity, since the diffe- rence in the Sun's distance is cut almost in half by them, must also reduce the difference between the Sun's diameter at apogee and at perigee. And those who think that the Sun's eccentricity varies in different ages must also admit a variation of the Sun's diameter at any of its three distances from the Earth, and compute it with trigonometric exactness. But whether, as Copernicus (Book 4, Ch. 21) and Magini (*Theoricae Planetarum*, Book 2, Ch. 24) report from others, the Sun's apparent diameter stands to its true hourly motion as 66 to 5, depends on each of the two having been established separately, rather than being a rule for establishing them. This business is therefore of incredible subtlety, and calls for a deeper and more circumspect inquiry than some suppose. Many distinguished astronomers have not reconciled all these things well together in their hypotheses, as Lansbergen shows in the *Uranometria*, pp. 58, 59 and 116, and as we show below, Ch. 11, no. 7.

[Margin: Whether the Sun's apparent diameter is always the same.]

II. It is very probable that the Sun does not keep the same distance from the centre of the Earth, but is sometimes at apogee, that is, at its farthest from the Earth, and sometimes at perigee and nearest, and that it therefore appears now larger, now smaller. Yet this cannot be demonstrated with evidence from

mere and immediate observation of this diameter, or even of eclipses, as I shall show in Book 4, Ch. 17, in the Scholium. Scheiner admits the same in the *Rosa Ursina*, though he thinks this difference is almost demonstrated by the use of the telescope, which must be drawn out by about a palm more at the winter solstice than at the summer solstice in order to show the sunspots distinctly; others, from direct inspection of the winter and the summer diameter. But someone could ascribe this difference to the vapours of the horizon, which show the Sun larger in winter, as Io. Bapt. Amicus [Giovanni Battista Amico] does (*Opusculum de motibus coelestibus*, Ch. 10) and Io. Anton. Delphinus [Giovanni Antonio Delfino] at the end of his book *De Globis Coelestibus*: in the same way as they show the rising or setting Sun larger than the Sun at noon, whether because of refractions or because of the dilatation of our pupil, as I shall say shortly. So if someone were to suppose that the Sun's diameter is perpetually, for example, 32′ 20″, were to refer the variation of eclipses to the variation of the Moon, and were able to defend the inequality of the Sun's motion without an eccentric or an epicycle or any other hypothesis founded on a variation of distances, it would not be easy to convict him of falsehood. Fracastoro, for his part, attributes this difference to refractions, on account of the different parts of the sky that lie between the Sun and our sight.

[Margin: Why the Sun and the other stars appear larger at the horizon.]

III. Since the Sun, the Moon and all the stars appear larger at the horizon than far from the horizon, astronomers and writers on optics dispute over the cause. Is it to be attributed to our estimation, which, because of the tracts of land or sea lying between, judges an arc of the sky near the horizon larger, other things being equal, than when we see no distance by which to estimate the sizes in the sky? So think, with Ibn al-Haytham (Book 7, Prop. 55) and Witelo (Book 10, Prop. 54), Kepler in the *Epitome of Astronomy*, p. 81, and in the *Astronomia Optica*, p. 133, Hortensius in his dissertation with Gassendi, and before him the author of the *Perspectiva communis* (Book 1, Prop. 82) and Rogerius Baccon [Roger Bacon], Part 2 of the *Perspectiva*, Dist. 3, Ch. 6. Or is it that our pupil, shaded by the vapours of the horizon, which blunt and intercept the rays, is dilated, and with its opening takes in the images of the stars under a wider angle? So contend Scheiner in the *Sol Ellipticus* and in the *Oculus, seu fundamentum Opticum*, and Gassendi in his letters on the apparent size of the Sun low and high. Or, finally, is it due to the moist vapours of the horizon, which by the force of refraction show the stars larger in just the same proportional way in which coins are seen larger under water? So it seemed also to Ibn al-Haytham (Book 7, Prop. 51) and to Witelo (Book 10, Prop. 53), and so judged long ago Posidonius, in Strabo, Book 3 of the *Geography*; Cleomedes, Book 2, p. 427 in my copy; Ptolemy, *Almagest*, Book 3, Ch. 3; Johannes de Sacrobosco, *Sphere*, Ch. 1, and Clavius there, p. 108; Longomontanus, Book 1 of the *Theorica*, Ch. 9, p. 290; and Barozzi, *Cosmographia*, p. 17. But we shall have to examine these views one by one in the Optical Book, in the Section on Refractions.

IV. So much for the diameter of the Sun viewed from the centre of the Earth. But if it were viewed from the planets, at their mean distance from the Sun, or at their greatest, when they are said to be at aphelion [Aphelij], that is [Greek: ἀπὸ τοῦ ἡλίου (apo tou hēliou, "away from the Sun")], namely removed from the Sun, or at their least, when they are said to be at perihelion [Perihelij], in Greek [Greek: περὶ τὸν ἥλιον (peri ton hēlion, "around the Sun")], it would be seen under a very different angle. On this, take the opinion of Boulliau, *Astronomia Philolaica*, Book 1, Ch. 9, and of Šírek, Book 4, Ch. 2, part 5, founded on Kepler's distances.

The Sun's apparent diameter, viewed from the planets

At the distance of the planets from the Sun

CAPVT XI.

De Solis vera Magnitudine, cæteriſq. ex illa & ex diſtantia eius, aut Apparenti Semidiametro dependentibus: Vbi de Cohærentia horum cum Parallaxi Horizontali, Semiangulo Coni & Axe Vmbræ terreſtris, & Portione Terræ illuminata à Sole.

On the true size of the Sun, and the other quantities that depend on it and on its distance or apparent semidiameter; where the agreement of these with the horizontal parallax, the semi-angle of the cone and the axis of the Earth's shadow, and the portion of the Earth illuminated by the Sun is also treated.

I. PROBLEMA.

De vera Solis Semidiametro.

Problem 1. On the true semidiameter of the Sun.

I. The true size of the Sun must be sought from its true semidiameter: doubling this gives the true diameter, and from the diameter the remaining kinds of magnitude are derived by the rules given in Book 1, Ch. 4 and 6. The true semidiameter, in turn, is gathered from the given apparent semidiameter and the distance from the centre of the Earth of any star whatever, not only of the Sun.

[Margin: Let the distance and the apparent semidiameter be given.]

Thus, in the diagram added here, let A be the centre of the Sun at apogee, P at perigee, and C the centre of the Earth, these being joined by the straight line APC; and let BC and DC be the extreme rays of the Sun, touching the Sun at B and D and there making, by Euclid 3.16, a right angle with the semidiameters BA and DP. Then the apparent semidiameter, or the angle measuring it, will be ACB with the Sun at apogee and PCD at perigee. So if either semidiameter is given, namely ACB with the distance AC, or PCD with the distance PC, you can find by the rules of right-angled triangles the true semidiameter AB in the triangle CAB, right-angled at B, or the semidiameter DP in the triangle CPD, right-angled at D. These must always be the same, provided that the apparent semidiameters and the distances have been correctly established.

Diagram. Set into the right column beside the text. Two circles stand one above the other on a single vertical straight line, which descends to a point at the foot; from the same point two straight lines rise to touch each circle on its left side, and a short semidiameter runs from each circle's centre to the point of contact.

- A (centre of the upper circle): the Sun's centre at apogee
- B (left edge of the upper circle): point of contact of the ray, end of the semidiameter BA
- P (centre of the lower circle): the Sun's centre at perigee
- D (left edge of the lower circle): point of contact of the ray, end of the semidiameter DP
- C (foot of the figure): the Earth's centre

[Margin: A shorter form of the rule.]

In brief, then, the logarithm of the given distance, taken as base, added to the logarithm of the apparent semidiameter will yield the logarithm of the Sun's true semidiameter. Or multiply the distance by the sine of the angle subtending the apparent semidiameter, and divide the total so produced by the whole sine: the quotient will be the true semidiameter, in parts of which the given distance is expressed.

[Margin: Authors who treat of the size of the Sun and of the Earth's shadow.]

By this device the first column of the following table was produced, partly by us and partly by the authors who treat of the Sun's true size; the rest of the table was completed from the rules on the measurement of the circle and the sphere given in Book 1, Ch. 4 and 6. The authors who treat of the Sun's true size, and on that occasion of the Earth's shadow and so on, are first of all Aristarchus, in his book on the size of the Sun, Ptolemy, *Almagest*, Book 5, Ch. 14 and 15; Regiomontanus, *Epitome of the Almagest*, Book 5, Props. 19, 20 and 21, and in his notes on al-Battānī, Ch. 30; Copernicus, Book 4, Ch. 19 and 21; Mästlin, in the appendix to Kepler's *Prodromus*, p. 154; Tycho, Vol. 1 of the *Progymnasmata*, p. 473; Longomontanus, Book 1 of the *Theorica*, Ch. 9, p. 295; Lansbergen, in the Prolegomena, Book 2 of the *Uranometria*, from Element 7 to 12, and Book 1, Elements 11 and 12; Maurolico, at the end of Dialogue 3 of the *Cosmographia*; Barozzi, *Cosmographia*, Books 1 and 4, pp. 50 and 338;

Magini, *Theoricae Planetarum*, Book 2, Ch. 24; Clavius, in the *Sphaera*, from p. 186; Biancani, in the *Sphaera*, at the end of Book 18 and Book 4, Ch. 3; Boulliau, *Astronomia Philolaica*, Book 4, Ch. 1 and 2; Gassendi, *Institutio Astronomica*, Book 3, Ch. 11; Athanasius Kircher, in the *Magnes*, p. 561, and in the *Ars Magna*, Book 9, at the end; Šírek, *Radius Sidereomysticus*, Book 4, Ch. 2, part 4. The numbers that are missing in some of these I have supplied myself, using a ratio of diameter to circumference of 100 to 314.

The true size of the Sun compared with the Earth

☼ Authors	True diameter contains (Earth's diameters)	Circumference contains (Earth's diameters)	Area of a great circle contains (square Earth diameters)	Convex surface contains (square Earth diameters)	Solidity contains (times the Earth's solidity)

[Margin: The size of the Sun in miles.]

I have not expressed these measures in miles, stadia or leagues, because of the excessive diversity of opinions on the miles contained in the Earth's diameter,

on which see Book 2, Ch. 7. Following the tables given there, multiply the Sun's diameter by the Earth's diameter, and you will obtain this measure. For example, since the Earth's diameter contains 8278 Bolognese miles, but 10348 ancient Roman ones, if you multiply these numbers by 33 5/6, the Sun's diameter, or by 106 1/7, the Sun's circumference, the Sun's diameter will have 280073 Bolognese miles and 350068 Roman miles, and the Sun's circumference 878651 Bolognese miles and 1097768 Roman miles. Kircher, however, in his magnetic work, p. 561, following other measures, gives the Sun's diameter only 42900 Italian miles, and its solidity 7895358900000 cubic miles. On so great a disagreement among astronomers in this and similar measures, see what I shall say in Book 4, Ch. 18, no. 2.

II. PROBLEMA.

Data vera Solis Semidiametro, inuenire Semidiametrum eius apparentem datæ Diſtantiæ congruam.

Problem 2. Given the true semidiameter of the Sun, to find its apparent semidiameter corresponding to a given distance.

II. In the preceding figure, already explained, let the distance of the Sun be given, for example at perigee, namely CP, and the true semidiameter DP. For in the triangle DCP, right-angled at D, from the given base PC and the side DP you will find, by the analysis of triangles, the angle DCP, which subtends the apparent semidiameter of the star, corresponding to the given distance. Thus, since for us the Sun's true semidiameter is 33 5/6 semidiameters of the Earth, and the perigean distance 7000 semidiameters of the Earth, the apparent semidiameter of the Sun at perigee had to be set at 16′ 34″ out of geometric necessity, even if it should not be gathered from observations to be exactly so much, but greater or less by a few seconds.

[Margin: A shorter form of the problem.]

In brief, the logarithm of the true semidiameter, added to the residual of the logarithm of the distance, will yield the logarithm of the apparent semidiameter. Or multiply the true semidiameter by the whole sine and divide the total by the given distance: the quotient will be the right sine of the angle subtending the apparent semidiameter.

III. PROBLEMA.

Quanta ſit portio Solis à nobis ex Terra viſa.

Problem 3. How large is the portion of the Sun seen by us from the Earth.

III. Since MCLF, the sphere of the Sun, is larger than our eye, the whole of its hemisphere CDL cannot be seen from the eye at B, but only MDF, namely as much as is taken in by the rays BM and BF, which touch the Sun at M and F and there make right angles with the Sun's semidiameters MA and FA, by

Euclid 3.16. One can ask how large the arc MDF is, or how large the true diameter MF is, of a circle that is not a great circle, which separates the visible part of the Sun from the invisible; or how large is the arc NAK, described from B through the Sun's centre A and intercepted by the tangents BM and BF. But this arc is as large as the angle B.

Diagram. Set into the right column. A large circle at the top, with a horizontal diameter through its centre and a chord below it; two lines from the foot of the figure touch the circle on either side at the ends of the chord, and a vertical line from the foot passes through the lowest point of the circle to the centre. An arc passes through the centre and across the tangents.

- A (centre of the circle): the Sun's centre
- C (left end of the horizontal diameter)
- L (right end of the horizontal diameter)
- Q (left of C, outside the circle): not cited in the text on this page
- G (right of L, outside the circle): not cited in the text on this page
- M (left end of the chord): point of contact of the tangent BM
- F (right end of the chord): point of contact of the tangent BF
- N (left end of the arc, on the tangent line)
- K (right end of the arc, on the tangent line)
- D (lowest point of the circle)
- B (foot of the figure): the eye

[Margin: A twofold conception of this problem.]

For the first, let AB be drawn, bisecting the angle MBF, which subtends the Sun's apparent semidiameter, that is, the arc NAK. For since the angle ABF is supposed given, as large as the Sun's apparent semidiameter, and the angle at F is a right angle, the angle BAF will be known by Euclid 1.32, as the complement of the angle ABF to a right angle; and by the same reasoning the angle BAM will be known, and hence the whole angle MAF, which measures the arc MDF seen by us.

[Margin: A shorter form of the rule.]

In brief, then, the Sun's apparent diameter, taken from the table of Chapter 10 and subtracted from 180°, will leave the arc of the Sun that is seen. Thus in our opinion, [Margin: The portion of the Sun seen by us.]

the arc of the Sun seen by us is:

With the Sun	Arc
at apogee	179° 29′ 30″
at mean distance	179° 28′ 10″
at perigee	179° 26′ 52″

For the second part of the problem: in the isosceles triangle MAF the angle at A is known, as I have said, and from it the angles at the base, each of which is half the complement of the angle MAF to two right angles; and the Sun's true semidiameter, both MA and AF equal to it, is supposed given, or found by

Problem 1. So the base MF, that is, the true diameter of the circle separating the visible portion of the Sun from the invisible, cannot remain hidden from a trigonometer. For us, therefore, with the Sun at perigee, MF is 33 and almost 5/6 Earth diameters, and thus imperceptibly smaller than the diameter CL.

IV. PROBLEMA.

Quanta ſit Portio Terreſtris Hemiſphærij illuminata à Solis radijs Irrefractis.

Problem 4. How large is the portion of the terrestrial hemisphere illuminated by the Sun's unrefracted rays.

[Margin: If the distance and the true semidiameter of the Sun are given.]

IV. Let EMF be the hemisphere of the Sun and ABCD the globe of the Earth, and let EG and FG be the extreme rays of the Sun, touching the Sun and the Earth at the points E, F and A, C, and there, by Euclid 3.16, making right angles with the semidiameters EK of the Sun and AH of the Earth, and so on. Let a straight line be drawn through the centres K, H as far as the meeting of the rays at G, this being KG. Then the illuminated part of the Earth will be the arc ABC, and the dark part ADC; AGC will be the cone of the Earth's shadow, and HG its axis or height. Finally let the straight line HL be drawn from H, parallel to EA. By Euclid 1.29 the angle AHI, like HLE and HLK, will be a right angle, and by 33 the side EL will be one semidiameter of the Earth, as being equal to the side AH. So in the triangle HLK, right-angled at L, if the Sun's distance KH is given, and the side LK, obtained by taking EL, one semidiameter of the Earth, from the whole EK, the Sun's true semidiameter, you can find the angle LHK. This angle measures the arc IB, which, added to the quadrant AI (since, as I have shown, AHI is a right angle), will yield the arc AB, to which the arc BC is equal. So the arc of the Earth illuminated by the Sun's rays will be known, these rays being imagined to touch the Earth and to meet, unrefracted, at G.

Diagram. Set into the left column. A large semicircle at the top, under a straight line through K, from which two semidiameters run down to E and F; two straight lines descend from its ends to a point at the foot, touching a small circle on the way. A vertical line runs from K through the small circle's centre to the foot, and a slanting line runs from L on the upper figure down to the small circle's centre.

- E (upper left corner): point of contact on the Sun
- K (top centre): the Sun's centre
- F (upper right corner): point of contact on the Sun
- L (on the upper figure, right of E): foot of the line HL
- M (lowest point of the semicircle)
- I (upper left of the small circle): end of the arc IB
- B (top of the small circle)
- H (centre of the small circle): the Earth's centre

- A (left of the small circle): point of contact of the ray
- C (right of the small circle): point of contact of the ray
- D (lowest point of the small circle)
- G (foot of the figure): the meeting of the rays

[Margin: Why the problem is limited to unrefracted rays.]

I said "unrefracted" because, as Kepler notes in the *Astronomia Optica*, pp. 269, 279, and after him Bettini in *Apiarium* 8, Progymnasma 2, Prop. 4, on account of refraction, by which the Sun's rays falling on the spherical surface of our denser air are broken and bent towards the portion ADC of the hemisphere, they illuminate more of it than if they passed through unrefracted. Kepler demonstrated in the same place, Bettini pointed out the demonstration, and we shall show more clearly in Book 5, in treating of the Earth's penumbra, that refracted rays light more than a quadrant of the hemisphere beyond what unrefracted rays light, by as much as the Sun's horizontal refraction. So if that refraction is 34′, as Tycho holds, 34′ must be added to the arc IB in order to have the arc AB, whose double ABC will be the arc of illumination. Therefore in our opinion, since the arc of illumination by unrefracted rays beyond 180° is 29′ 40″ with the Sun at apogee and 32′ 16″ at perigee, if you add to each the double of the horizontal refraction, the arc of true illumination beyond 180° will be 1° 37′ 40″ with the Sun at apogee and 1° 40′ 16″ at perigee, whereas the ancient astronomers judged it to be far smaller, through ignoring or dissembling the refractions.

[Margin: Authors who treat of the illuminated portion of the Earth.]

First, however, one must determine that part of the Earth which is illuminated by rays supposed, by a fiction, to be unrefracted, according to the Sun's given distances from Ch. 7 and its true semidiameter from the table of Problem 1. This portion is determined by Ibn al-Haytham, Nunes and Clavius, in the opuscule *De Crepusculis*, Prop. 5; by Witelo, Book 10, Prop. 59; and by Reinhold, on Peuerbach's *Theoricae*, p. 165, who take from Ptolemy a true semidiameter of 5 1/2 semidiameters of the Earth and an apogean distance of 1210. But Magini, *Primum Mobile*, Book 11, Prop. 28, takes from Tycho a mean distance of 1150 and a true semidiameter of 5 2/3. Kepler, in the *Astronomia Optica*, p. 233, reports Witelo's demonstration. We shall review their opinions and, from our own calculation, which you will see in the table of Problem 5, shall add what follows from the data of others and from ours.

[Margin: The portion of the Earth beyond the hemisphere lit by the Sun.]

The arc of the Earth beyond 180° illuminated by the Sun's unrefracted rays

Authors	☉ at apogee	☉ at perigee
Ibn al-Haytham	27′ 52″	✝ ✝
Witelo	25′ 36″	✝ ✝
Reinhold	25′ 40″	✝ ✝
Magini	34′ 0″	✝ ✝

Authors	⊙ at apogee	⊙ at perigee
By me, from the data of Ptolemy	25′ 26″	27′ 20″
of al-Battānī	28′ 4″	30′ 4″
of Copernicus	25′ 32″	26′ 48″
of Tycho	24′ 22″	25′ 40″
of Longomontanus	24′ 20″	26′ 26″
of Kepler	28′ 0″	30′ 56″
of Lansbergen	28′ 52″	31′ 0″
of Boulliau	27′ 44″	28′ 44″
of Wendelen	29′ 4″	30′ 4″
of Šírek	29′ 52″	32′ 4″
from our own	29′ 40″	32′ 16″

Add to these twice the Sun's horizontal refraction, and the true arc illuminated beyond 180° will result.

V. PROBLEMA.

Quantus ſit Angulus Coni Vmbræ terreſtris Comprehenſæ à Radijs Irrefractis.

Problem 5. How large is the angle of the cone of the Earth's shadow enclosed by unrefracted rays.

V. In the preceding figure the angle of the cone of the Earth's shadow is AGC, and its half-angle AGH. But this, as Kepler indicates in the *Astronomia Optica*, p. 233, is equal to the angle LHK, and this is easily shown: for by construction HL is parallel to EG, and the straight line KG falls on them; therefore by Euclid 1.29 the external angle LHK is equal to the internal opposite angle AGH. So once the angle LHK has been found by Problem 4, the angle AGH is known, whose double is AGC; and thus the preceding table gives this angle.

[Margin: Why the limitation to unrefracted rays?]

Here too I said "unrefracted", because on account of the refraction of the Sun's rays, just as the arc of illumination grows in the portion ADC, so the angle of the shadow enclosed by refracted rays grows, and the axis of the shadow contracts, as we shall say in Book 5, which is on eclipses.

[Margin: Blemishes or slips of Lansbergen and of other astronomers.]

VI. Now Lansbergen, in the Prolegomena and in Book 2 of the *Uranometria*, Element 7, sets the angle of the Earth's shadow with the Sun at apogee at 29′ 8″[15] from his own principles; but from Ptolemy's data at 25′ 38″, from al-Battānī's at 30′ 28″, from Copernicus's at 24′ 22″, and from Tycho's at 32′ 4″ or 32′ and 16″. He investigates it, however, from the semidiameter of the Earth's shadow and the Moon's distance, and from this he concludes, as I shall relate later, that their hypotheses disagree with themselves. This very disagreement is indeed

[15]the page sets the double mark after 29 as well, "29″. 8″."; the same value stands as 29′ 8″ later in this paragraph

gathered from our calculation, since we have obtained this angle differently from the given distances and the Sun's true semidiameter; but what Lansbergen objects against others is also turned back on Lansbergen himself. For from the distance of the Sun at apogee and the true semidiameter this angle comes out 28′ 52″, whereas from the Moon's distance and the semidiameter of the shadow he gets 29′ 8″. So difficult is it for all astronomers to reconcile these subtleties in such a way that they do not disagree by some minutes. And I believe that some small error comes also from the repeated multiplication and division by sines; hence the analysis of triangles by the addition of logarithms alone is easier and safer, as we shall show in Vol. 2 of the *New Almagest*, Book 1, which is the trigonometric book. So I am pleased to set down our calculation, in which, from the distances given in Ch. 7, that is, from the base HK, and from the side LK, which, with one semidia- meter of the Earth EL removed, is known from the table of Problem 1, we have gathered the angle LHK, which is equal to the angle AGH, whose double you have in the preceding table of Problem 4. In the following table, *Log.* means logarithm; and RL the residual of the logarithm [Residuum Logarithmi], which is obtained by subtracting the logarithm from the radius 1000000; and *Dist.* the distance of the Sun from the centre of the Earth.

Sun at apogee			Angle of the Cone of the Earth's Shadow	Sun at perigee		
Sum	*Log.*	763548	14′ 50″ [recte 14′ 52″, per the book's errata]	*Sum*	*Log.*	76711916′ 8″

Moreover the investigation of the angle of the Earth's shadow is far simpler by our method, and Problem 4 or 5, than by Lansbergen's, because the semidiameter of the shadow that he uses was deduced from a longer and more drawn-out calculation. Two givens are enough for us, namely the Sun's distance and its apparent semidiameter, from which the true one is gathered.

VI. PROBLEMA.

Parallaxin Solis Horizontalem ex Semiangulo Coni Vmbræ terreſtris & Semidiametro Solis viſuali; & viciſſim Semiangulum Vmbrę ex Parallaxi Horizontali, & Semidiametro Solis apparenti elicere.

Problem 6. To derive the Sun's horizontal parallax from the semiangle of the cone of the Earth's shadow and the Sun's visual semidiameter; and conversely the semiangle of the shadow from the horizontal parallax and the Sun's apparent semidiameter.

VII. Subtract the semiangle of the cone of the Earth's shadow from the Sun's apparent semidiameter, and the horizontal parallax will remain. Conversely, subtract the Sun's horizontal parallax from the Sun's apparent semidiameter, and the semiangle of the cone of the Earth's shadow will remain, without sensible error.

For let the figure set on p. 107 be repeated here, in which the centre of the Sun is B, that of the Earth A, and the apex of the Earth's shadow E, these being joined by the straight line BAE. Let the Sun's ray be DNE, and let NB be a straight line drawn from the point N to the Sun's centre. The angle ABN will then be very nearly the Sun's horizontal parallax. And let the straight line AD be drawn from A: BAD will then be the Sun's apparent semidiameter, or its measure. The angle ADN is sensibly equal to the angle ABN, because they stand on the same base AN, and the sides that form them are sensibly equal on account of the Sun's enormous distance from the Earth. Now by Euclid 1.32 the angle BAD is equal to the interior angles AED, which is the semiangle of the shadow, and ADN, which is sensibly equal to the horizontal parallax. Therefore the angle of the Sun's horizontal parallax is the excess of the Sun's apparent semidiameter over the semiangle of the shadow, without

sensible difference. In geometrical rigour, however, the ray AD touches the Sun at a point below D, the point at which the ray ED touches the Sun; just as the ray BN touches the Earth at a point above N, the point at which the Earth is touched by the ray DE. And so this demonstration lacks the exactness [Greek: ἀκριβεία (akribeia, "exactness")] of geometrical rigour. This is why the parallax so deduced does not agree to a hair with the semiangle of the shadow and the Sun's semidiameter, as will be clear to anyone comparing the horizontal parallax set in the table of Ch. 8, deduced exactly from the Sun's distance, with the parallax obtained by subtracting the angle set in the table of Problem 5 from the Sun's apparent semidiameter set in the table of Ch. 10. So the parallax this gives me is at most 3″ less than the exact one; and conversely, if I join the exact parallax to my semiangle of the shadow, the Sun's semidiameter becomes 15′ 17″ 10‴ at apogee and 16′ 37″ 28‴ at perigee, insensibly greater than the exact semidiameter. Therefore, unless a sensible difference of several seconds arises from this, the astronomers' hypotheses are not to be convicted of inconsistency, even though Lansbergen, in the Prolegomena of the *Uranometria* and in Elements 7, 8 and 9, may refute them. He evidently does so because he both uses this demonstration as though it were exact and uses a semiangle of the Earth's shadow derived from elsewhere, that is, from the Moon's distance and the apparent semidiameter of the shadow at that distance of the Moon, as given by those very astronomers. For from these givens he gathers the semiangle of the shadow, as I shall presently show at no. 8; and by subtracting it from the Sun's semidiameter given by them he gathers a horizontal parallax and a distance of the Sun different from the one they themselves laid down, as can be seen in the table set at the end of no. 8.

Diagram. A tall, narrow construction standing in the left column beside the text. At the head, a large circle (the Sun) crossed by a horizontal diameter; two long rays run down from the ends of this diameter and converge to a point at the foot, and further lines descend from the same diameter through the figure. Lower down, on the axis, stand three smaller circles in descending order: a small one, a larger one crossed by a horizontal line, and a small one crossed by a horizontal line just above the point of convergence, with crossing lines between the second and third.

- C (left end of the diameter of the large circle)
- R (above the diameter, left of centre)
- B (above the diameter, at the centre)
- D (right end of the diameter)
- F (inside the upper small circle); a very small mark at this circle's right edge is not resolved
- M (left end of the horizontal line through the middle circle)
- T, A, R (inside the middle circle, on the horizontal line; the R set smaller than the other labels)
- [?] (right end of the same line: a heavy, blotted letter, M or N by its shape)

- P (left of the lowest small circle)
- L (right of the lowest small circle)
- G (inside the lowest small circle, below its horizontal line)
- E (the foot of the figure, at the point of convergence)

VIII. Next, in the figure immediately preceding, Lansbergen gathers the semiangle of the shadow by this method. Given the Moon's distance AG and the angle PAG, which subtends the apparent semidiameter of the shadow, he gathers in the triangle AGP, right-angled at G, the true semidiameter of the shadow, PG. Then, with PT drawn parallel to AG, the angle MTP arises by Euclid 1.20, a right angle, as being equal to TPG, which by the same proposition equals AGP; and by 33, TA is equal to PG, and PT to AG. Therefore, with PG, that is TA, taken from the whole semidiameter of the Earth AM, the side MT remains known. With this and with the side TP, the angle MPT is sought, which by Euclid 1.29 is equal to the semiangle of the shadow PEG, because the straight line ME falls on the two parallels TP and AGE, by construction.

[Margin: Investigation of the true semidiameter of the shadow.]

Thus from badly assembled theories of the Moon and the Sun these and similar absurdities arise, and in the Tychonic and Longomontanic hypothesis it follows that the semiangle of the shadow, namely AED, is greater than the external angle BAD, that is, than the Sun's apparent semidiameter; whereas by Euclid 1.32 it ought to be smaller.

[Margin: Error of Tycho and of Longomontanus.]

The contradiction that Lansbergen found in the hypothesis of the three astronomers is the one you see in the following small table.

DATA AB AVCTORIBVS

Authors	Distance of the Moon at apogee from the centre of the Earth (Earth semidiameters and ′)	Apparent semidiameter of the Sun at apogee	Apparent semidiameter of the Earth's shadow
al-Battānī	64 10′	15′ 40″	38′ 20″
Copernicus	65 30′	15′ 50″	40′ 18″
Tycho	58 8′	15′ 0″	43′ 0″

COLLECTA A' LANSBERGIO

Authors	True semidiameter of the shadow, in parts of which the Earth's semidiameter is 60 (sixtieths)	Semiangle of the shadow	Horizontal parallax	Distance of the Sun at apogee from the centre of the Earth (Earth semidiameters)
Albat.	43	15′ 14″	0′ 26″	7936 30′
Copern	47	12′ 11″	3′ 39″	941 53′
Tych.	44	16′ 8″	0′ 0″	infinita

Now recall from Ch. 7 the Sun's distance at apogee, and from Ch. 8 the horizontal parallax set by these authors, and you will recognize the contradiction.

VII. PROBLEMA

Semiangulum Coni Vmbræ Terreſtris aliter inueſtigare.

Problem 7. To investigate the semiangle of the cone of the Earth's shadow in another way.

See no. 8 and Lansbergen's method set out there; but our method, which we applied in the problem and at no. 5, is certainly simpler.

VIII. PROBLEMA.

Axem, ſeu Altitudinem Coni Vmbræ Terreſtris à radijs Solis irrefractis comprehenſæ inuenire.

Problem 8. To find the axis, or height, of the cone of the Earth's shadow enclosed by the Sun's unrefracted rays.

IX. The first and simplest way, which is independent of the Moon except so far as the Sun's distance became known from the distances of the Moon, is the one we use, with the semiangle of the cone of the Earth's shadow already given or found through Problem 5. For in the figure of Problem 4 and its triangle AGH, right-angled at A, given the angle AGH and the side opposite it, AH, namely one semidiameter of the Earth, we seek the axis or height HG. So the residual of the logarithm of the angle AGH, already set in the table of no. 6, gives the logarithm of the base HG. Therefore take from the table of no. 6 the logarithm corresponding to the Sum, and subtract it from 1000000; the logarithm of the shadow's axis will remain. Or the secant of the angle AGH, divided by the whole sine, gives the base HG, in parts of which AH is one.

[Margin: 1. Way of deriving the axis of the shadow.]

The second way, that of Ptolemy, Book 5, Ch. 15, of Regiomontanus in the *Epitome*, Book 5, Prop. 20, and of Copernicus, Book 4, Ch. 19, depends on the Moon's distance and the true semidiameter of the shadow. For in the figure of Problem 6, as AN, the semidiameter of the Earth, is to GL, the true semidiameter of the shadow, so is AGE to EG, by Euclid 6.4; and, by separation, by the fraction by which GL is exceeded by AN, the whole AG, the Moon's distance, is exceeded by AE, the axis of the shadow. Or, as Boulliau does in Book 4, Ch. 1: with PG taken from AM, MT will be known; so let MT be to the Moon's distance TP as PG is to GE; and with AG added to this, AE will be known.

[Margin: 2. Way.]

The third way, which Longomontanus uses in Book 1 of the *Theorics*, Ch. 9, p. 295, and Biancani nearly so, Book 4, Ch. 3, depends on the true semidiameter of the Sun and its distance. For in the same figure of Problem 6, with MR drawn

parallel to AB, since the angles at B and A are supposed right by construction, each angle at R is a right angle by Euclid 1.29, and by 33, MR is equal to AB, and MA

[Margin: 3. Way.]

to RB. So with one semidiameter of the Earth MA, that is RB, taken from the Sun's true semidiameter CB, CR remains. Now as CR is to RM, so is CB to BE; and with BA, the Sun's distance, subtracted from the whole BE, the height of the shadow AE will be known. Or, by separation, as CR is to RB, so is BA to AE; hence, by dividing the Sun's distance BA by the excess of its true semidiameter over the Earth's semidiameter, the axis of the shadow results. Now Lansbergen, in the Prolegomena of the *Uranometria* and in Book 2, Element 7, uses the semiangle of the cone of the shadow discussed above in the table of Problem 6. We, however, use the semiangle of the cone of the shadow set in the table of no. 6, while the authors cited a little earlier use other givens and another method. For that reason different quantities for the axis of the Earth's shadow are found with us and with Lansbergen, and with the authors already mentioned and others who treat the quantity of the axis of the Earth's shadow; these are the ones I cited before the table of no. 1. See their opinion in this table.

Axis of the Earth's shadow with the Sun at apogee, unless perigee or something else is added.

[Margin: Why the remaining measures of the shadow are deferred.]

X. I have deferred, as is opportune, the remaining dimensions of the Earth's shadow, namely its true and apparent semidiameter at the place where the Moon passes through, to Book 5, which is on eclipses, since that measure varies with the varying distance of the Moon from the Earth. Meanwhile, however, from what has been said at this point, remember that it must agree with the true semiangle of the cone of the Earth's shadow and with its axis, both now established here, and that one may not stray outside these limits without inconsistency and want of geometry [ageometria]. And indeed an astronomer must be an Argus, keeping watch on all the links by which the theories of the Sun and the Moon are entwined. And so it is good to gather into one place the theorems, to be committed deeply to memory, that are deduced from what has been demonstrated in this chapter, the last one excepted.

THEOREMATA EX VERA SOLIS Semidiametro, & Diſtantiâ ſequentia.

Theorems following from the true semidiameter and distance of the Sun.

[Margin: From Problem 3.]

Theorem 1. The portion of the solar hemisphere not seen is as great as the Sun's apparent diameter; and the portion seen is as great as the complement of the apparent diameter to 180°.

[Margin: From Problem 3.]

Th. 2. The circle of the Sun separating the portion visible to us from the invisible portion, and its true diameter, are insensibly smaller than the Sun's great circle and its true diameter.

[Margin: From Problem 4.]

Th. 3. The arc of the terrestrial globe beyond the hemisphere of 180° that is illuminated by the Sun's unrefracted rays, even with the Sun at perigee, is smaller than the Sun's apparent diameter, and indeed by very nearly one minute.

[Margin: From Problems 4, 5 and 6.]

Th. 4. The angle of the cone of the Earth's shadow is as great as the arc of the terrestrial hemisphere illuminated by the Sun's rays beyond the hemisphere, and it is always smaller than the Sun's apparent diameter.

[Margin: From Problem 6.]

Th. 5. The semiangle of the cone of the Earth's shadow, together with the Sun's horizontal parallax, is sensibly equal to the Sun's apparent semidiameter, and insensibly greater. Or the Sun's horizontal parallax is insensibly greater than the difference between the semiangle of the shadow and the Sun's apparent semidiameter.

[Margin: From Problem 8, way 1.]

Th. 6. The secant of the semiangle of the cone of the Earth's shadow, divided by the radius, gives the axis or height of the shadow.

[Margin: From Problem 8, way 2.]

Th. 7. The excess of the Earth's semidiameter over the true semidiameter of the Earth's shadow is to the Moon's distance as the true semidiameter of the shadow is to the Moon's distance from the apex of the shadow.

[Margin: From Problem 8, way 3.]

Th. 8. The excess of the Sun's true semidiameter over the Earth's semidiameter is to the Earth's semidiameter as the Sun's distance is to the axis, or height, of the Earth's shadow.

[Margin: From Scholium 1, Ch. 10.]

Th. 9. The Sun's apparent diameter is to the Sun's apparent hourly motion very nearly as 66 to 5.

SCHOLIA.

[Margin: The crude opinions of the ancients on the magnitude of the Sun.]

I. Epicurus and Heraclitus held that the Sun is a foot across, as large as it appears, and that the opposite cannot be proved, assigning it the breadth of a human footprint. Anaxagoras, by contrast, judged it much larger than the Peloponnese, and Anaximander judged it equal to the Earth, as Plutarch reports, *De Placitis*, Book 2, Ch. 21; and regarding Epicurus, Cleomedes confirms this in Book 2 of the *Cyclical Theory*, where he refutes him at length, as I shall indicate in Scholium 2. Certainly, in the figure of Problem 3, if the Sun's distance BA were at least 30 semidiameters of the Earth, each consisting of 4000 Italian miles, so that AB were 120000 miles, that is, 600,000,000 feet, and the Sun's diameter GQ were one foot and its semidiameter AF half a foot, trigonometry proves that the angle MBF under which the Sun would be seen would not amount to one second, and so the Sun would be invisible to us, let alone a foot across. How much more so if it stood more than a thousand semidiameters of the Earth away, as in fact it does? Yet Macrobius, on the *Dream of Scipio*, Ch. 20, on the basis of the fallacious observations of the ancients, laid down the Sun's diameter as double the Earth's diameter, and its solid volume to that of the Earth as 8 to 1. So did infant astronomy once babble about this giant. For the Sun is like a giant, as it says in Psalm 18, not only in its course but also in its magnitude; indeed, it is also a colossus among the planets, and therefore worthy that for it the Rhodians should erect that huge Colossus, and be called Colossians [Colossenses] on account of it. Pliny the Elder, too, in Book 2, Ch.

11, confirms by various arguments that the Sun is much larger than the Earth; these can be looked up in his text.

[Margin: Cleomedes' arguments against Epicurus.]

II. Cleomedes, for his part, affirms in Book 1 of the *Cyclical Theory* that the Earth viewed from the Sun either could not be seen or would appear like a point or a tiny star; but that if we tried to see it from the fixed stars it would still not appear, even if it possessed the Sun's brilliance. From this he argues that the Sun, and indeed the fixed stars too, are larger than the Earth, since despite that same distance the Sun appears as large as it does to us, and the fixed stars also appear. The argument about the Sun holds, given the supposition of a very great distance of the Sun. Now if the Earth had to appear at 1′, the Sun would have to stand 6876 terrestrial semidiameters away from it; on this matter see what we said in Book 2, Ch. 6, Scholia 4 and 5.

In Book 2, moreover, Cleomedes refutes at length Epicurus, who judges everything by the senses alone, and therefore asserts that the Sun is in actual fact a foot across, just as it appears. I. Because the Sun appears larger at rising and at setting than at midday: therefore it would truly become now larger, now smaller in itself; and indeed at the same time, since at the moment when it rises for us, it is on the meridian for others; and according to the approach and withdrawal of the eye, it would be larger for one person and smaller for another at the same time; and larger when viewed from the bottom of a well than from elsewhere. II. Because if it were a foot across and stood at so great a distance, it would not appear. III. Because over 300 stadia gnomons cast no midday shadow among those for whom the Sun is at the zenith. IV. That an intervening island, or a mountain far off, does not prevent us from seeing both edges of the rising or setting Sun on either side. V. From the true magnitude of the Sun as defined by the astronomers, since Hipparchus made the Sun 150 times larger than the Earth; besides other arguments of lesser weight, which can be read in Cleomedes.

[Margin: Pliny the Elder's arguments for the Sun's magnitude.]

III. Most of the reasons by which Pliny the Elder tries to show in Book 2, Ch. 11, that the Sun is larger than the Earth are not very firm, though some are firm. For from this magnitude, he says, it comes about that trees standing in the east and in the west cast shadows separated by equal intervals; and that on equinoctial days all who are in the first climate seem to themselves to have the Sun above their own zenith, just as if that whole tract in latitude were one and the same point; and that the rising Sun suddenly embraces the highest and broadest mountains, such as Ida, lighting them with its rays on both sides; and that it approaches the poles and recedes, lest it otherwise burn up the lands by its magnitude. Finally, that the Earth's shadow is conical, as is established from eclipses of the Moon; otherwise, if the Sun were equal to the Earth, that dulling shadow would be cylindrical; but if it were smaller than the Earth, the shadow would be calathoid [Calathoides: basket-shaped], as we shall show in Book 5.

CAPVT XII.

Chapter 12.

De Motu Diurno Solis ab Ortu in Occaſum, eiuſq. aut Terræ, ſi ſic moueretur, Velocitate.

On the diurnal motion of the Sun from east to west, and on its velocity, or the Earth's if it moved in this way.

I. The diurnal motion of the Sun from east towards west, until it returns to the east and completes a whole natural day, is one whole revolution of the Sun from the same point to nearly the same point of the same horizon or of the same meridian, according as some begin the natural day from sunrise and others from noon, as was said in Book 1, Ch. 28. I said "nearly" both because of the Sun's declination and because of refraction, which do not allow it on the following day to rise for us, truly or apparently, or to reach mid-heaven, at the same point as on the day before. But to avoid being too long-winded, let what we said in Book 1 be taken as repeated: in Ch. 11, on the motion of the primum mobile, on the 15° of the equator ascending in each hour, and on the difference between the day of the primum mobile and the day of the Sun; in Ch. 24, on the distinction between natural and artificial days; and in Chs. 25 and 26, on the inequality of natural and artificial days, although the inequality of natural days must be discussed more fully, and more fittingly, towards the end of this book in Ch. 31. See also what was said in Book 1, Ch. 27, on finding the semidiurnal arc; in Chs. 29 and 30, on the various kinds of hours; and in Ch. 31, on the addition to the days made by twilight. For from these you will grasp all the properties of the diurnal motion.

[Margin: Velocity of the Sun in the diurnal motion.]

II. As for the Sun's velocity: although it seems slow when viewed directly, yet if you catch its bright image through an aperture on a board many decempedae [ten-foot rods] away from the aperture, you will see it flash across very swiftly. We have shown this to many people at Bologna in the church of San Petronio, with the board more than 20 decempedae from the aperture. Now, for the Sun's velocity, commonly thought incredible, by which it completes a whole circle in 24 hours, to be established, an equinoctial day must be taken: for on that day the Sun completes a great circle; and in these present centuries it is then at about its mean distance from the centre of the Earth, and this mean distance is the semidiameter of the circle already mentioned, and therefore suitable for investigating the circumference of the circle by the rules of Book 1, Ch. 4.

For when the Sun is in the Tropic of Cancer, its distance, now almost at its greatest, is not the semidiameter of the circle that the Sun goes round on that day; nor is that circle the greatest in its sphere, even granted that it is larger than a great circle of a smaller sphere, and so than the equator, because of its greater distance from the centre of the Earth. Likewise in the Tropic of Capricorn, the distance from the centre of the Earth, now almost the least,

is not the semidiameter of the circle that the Sun traverses; and that circle is smaller than the equator. Further, one of the mean distances of the Sun must be taken from the table in Ch. 7, p. 110, and doubled, to obtain the diameter of the solar equator; this diameter must be multiplied by 314, and the resulting total divided by 100, and there will come out the circumference, in semidiameters of the Earth, that the Sun traverses on the equator in 24 hours. From this, by the rule of proportion, it will be clear, if it traverses so many semidiameters in 24 hours, how many it traverses in one hour, or in one minute or second of time. But if you wish to know this velocity in stadia or miles, you will have to choose from Book 2, Ch. 7, some more probable opinion on the size of the Earth's semidiameter.

III. But in the condemned hypothesis, which assigns this diurnal motion not to the Sun or to any of the stars but to the Earth, turned about its own centre towards the east in a space of 24 hours, the very circumference of the Earth's great circle, completed in that motion by the Earth's rotation, can be found in its table in Book 2, Ch. 7; and by dividing it by 24 one can find the distance covered in one hour, and by dividing this by 60 the distance covered in one minute of time by the Earth's rotation. In the little tables of the following Scholium, however, we have contented ourselves with the opinion that gives the Earth's semidiameter 860 German miles and one degree of a great circle 15 German miles, because German mathematicians commonly use these. But in the last column we have added the measures agreeing with our own opinion, which gives the Earth's semidiameter 4139 modern Italian and Bolognese miles, and one degree 72¼. And from the authors named in the first column of the former table we have taken nothing but the Sun's mean distance from the Earth. It should be understood, moreover, that one second of time is about equal to one and a half beats of a human artery.

SCHOLION.

Scholium.

[Margin: Fernel's less apt comparison.]

Fernel, in *Cosmotheoria*, Book 1, Ch. 7, sets out the Sun's daily and hourly velocity, using its proper motion towards the east; and he says that the Sun accomplishes on the ecliptic each day 84476 Italian miles, in one hour 3519, and in one minute 58. But the velocity of the motion towards the west is far greater, since it completes the whole circle there in one year, here in one day; and to this velocity belongs that verse of Psalm 18: "He rejoiced as a giant to run his course", etc.

[Margin: The Earth's annual velocity, on the hypothesis, greater than its diurnal velocity.]

Conversely, if the Earth moved with an annual and a diurnal motion, the velocity would be greater in the annual motion than in the diurnal: for each day it would traverse about one degree of the ecliptic. Or, according to Copernicus

on Kepler's calculation in the book *De Nova Stella*, Ch. 16, the centre of the Earth would traverse in one hour, by its annual motion towards the east, 740 German miles; but by the diurnal motion a city situated on the equator would traverse in one hour about the centre of the Earth, likewise towards the east, only 240 German miles. Now the mean distance of the Earth and the Sun is 1142 terrestrial semidiameters; therefore the diameter of the annual orb is 2284, and the circumference 6943 semidiameters of the Earth; one degree therefore has 19 103/360 semidiameters of the Earth. But let there be 20: since Kepler puts 860 German miles in a semidiameter of the Earth, there will be 17200 German miles in one degree of the annual orb, of which the 24th part is 717. But Kepler will have used an apogee distance. Now let us have the little table promised in Ch. 12.

The Sun's velocity in the diurnal motion from east towards west, the Sun being supposed on the equator and at that time at its mean distance from the Earth.

Authors	Sun's mean distance	Traverses in one day	In one hour	In one minute	In one second	In one second

CAPVT XIII.

Chapter 13.

De Motu Solis Annuo, & de Annorum Solarium Speciebus.

On the annual motion of the Sun, and on the kinds of solar years.

[Margin: Motion of the Sun in latitude.]

I. Besides the motion by which the Sun revolves daily to the same horizon or meridian, another motion has been detected in it, compounded of a motion in latitude and in longitude, and therefore oblique to the equator. For as regards latitude, the Sun now approaches our zenith and pole, now recedes from it towards the opposite pole of the world. It approaches most on the day of the summer solstice, when it enters Cancer; in the century of Christ this day was about June 25, but now it is June 21 in the Gregorian calendar. On that day it describes by its motion a circle parallel to the equator, called the Tropic of Cancer, and comes closest to the zenith of those living in the northern temperate and frigid zones; and it approaches the north pole in such a way that it stands 66½° from it on the meridian and has the greatest declination it can from the equator, namely 23½°, as has been found from corrected observations of the Sun's meridian altitudes. From there it bends its course and turns southwards, and for this reason that circle has been called the Tropic of Cancer: for the Greeks call the limits from which the turning takes place, and the turnings themselves, τροπὰς [Greek: τροπὰς (tropas, "turnings")].

But when it has crossed the equator and entered the sign of Capricorn, it recedes furthest from the inhabitants already mentioned. This used to happen in the century of Christ on about December 25, but now on the 21st; and then comes the winter solstice, in Latin *bruma*, perhaps a word contracted from *the shortest day* [breuissima die] of the year, which then occurs for northerners, since at the summer solstice the longest day of the year occurs for them. On the day of the winter solstice, therefore, it describes by its diurnal motion the other tropic, called that of Capricorn, and recedes furthest from the equator towards the south, namely by another 23½°; and at once, its course reversed, it returns northwards.

Therefore the distance of the tropics, and the whole arc of the meridian within which the Sun's recession from and approach to the poles of the world is contained, is 47°. And since it returns from one tropic to the other in about six months, and from a tropic to that same tropic in 12 months, or 365^{d} and about 6^{h}, it thereby unrolls for us the year called tropical. This same motion has been and is evident not only from the Sun's meridian altitudes, but also from the shadows of gnomons at noon, and from the points of the horizon at which the Sun rises and sets, now nearer the north, now nearer the south. By this motion, through the Providence of God, Best and Greatest, it comes about that the heat and cold of the seasons are more tolerable, and that by their alternation the life and senses of living creatures are refreshed and restored. And this, finally, is the motion of which Ecclesiastes 1 speaks: "The Sun rises and sets, and there, born again, it circles through the south and bends towards the north, and returns to its circles; surveying all things in its circuit, the Spirit goes on."

[Margin: Motion of the Sun in longitude, and by what signs it was detected.]

II. The remaining part of the annual motion, namely that in longitude towards the east, is not indeed so commonly evident, yet it became known to astronomers from the Sun's apparent elongation towards the east from one of the fixed stars around the zodiac. Let Spica serve as an example, a star celebrated in the observation of astronomers ever since Timocharis and Hipparchus. In the time of Augustus it used to rise heliacally at Rome shortly after the autumnal equinox, namely on about the first day of October. Suppose, then, that when the Sun's rising is imminent at the autumnal equinox, say half an hour before sunrise, Spica does not appear, because of its excessive nearness to the Sun's brilliance; then, a few days later, about half an hour before sunrise, that Spica rises heliacally and is seen on the eastern horizon. For if, getting up in good time in the morning on one day after another, you looked at the east half an hour before sunrise, you would see Spica more and more raised from the horizon and shifted further west; so much so that after about three months [mentes; recte: menses] you would see it on your meridian shortly before sunrise, and after six months near the western horizon, and already setting with the cosmic or morning setting, when the Sun rises almost diametrically opposite. And when the year has rolled round, you would again see Spica, about the beginning of October, after its conjunction with the Sun, rise heliacally in the morning in the east. From these and similar phenomena, once observed, the astronomers concluded either that the fixed stars are carried westwards by the diurnal motion in a swifter course than the Sun, or at any rate that the Sun advances eastwards at a slow pace, striving against the motion of the primum mobile; because it is established that all the stars, wandering and unwandering, are swept from east towards west in 24 hours until they revolve back to the east. But since that other motion in latitude was apparent in the Sun, they decided to attribute this apparent recession of the Sun from the fixed stars towards the east rather to the Sun.

[Margin: Obliquity of the Sun's motion, and the discovery of the ecliptic and the zodiac.]

III. From the Sun's motion, then, compounded of a bending in latitude towards the poles of the world and of a progress in longitude towards the east, there arises an oblique motion. When the daily declinations are examined, this has been found to take place in one and the same circle, which cuts the equator in two equal parts at the two equinoctial points and at an oblique angle to the equator of 23½°, on poles likewise 23½° distant from the poles of the equator; and this whole circle is completed by the Sun in 365 days and nearly 6 hours, about one degree out of 360 being completed each day. This circle they called the ecliptic, from the eclipses of the Sun and Moon, which have been observed never to occur except when the luminaries, in conjunction or mutual opposition, that is, at new or full Moon, are with the centre of their body in the plane of this circle, or decline little from it. The ecliptic midway among the others which (if its obliquity to the equator varies over the course of the

centuries) the Sun describes by its annual motion, Kepler calls the Royal Road [Viam Regiam].

And because the other planets have been observed to move, they too, eastwards in an oblique motion, just as the Sun does, but to recede from the ecliptic in latitude towards the poles of the world, some by 6°, some by 8°, some by about 10°, but not more, they therefore devised a certain zone in the heavens within which the wandering of the planets would be contained, 12°, 16° or 20° wide and bisected by the ecliptic. This zone they named the zodiac, from the figures of celestial animals, with which the stars shining within or around this zone had already been endowed by the poets or by the initiates of hieroglyphics; or [Greek: ἀπὸ τῆς ζωῆς (apo tēs zōēs, "from life")], that is, from life, which depends chiefly on this motion of the Sun. They also named it the Signifer [Signiferum], from the 12 celestial signs, and, antonomastically [antonomasticῶς], the oblique circle.

[Margin: Anaximander, discoverer of the zodiac. Cleostratus, its divider. Atlas, inventor of the sphere.]

Concerning its discoverer among the Greeks, Pliny the Elder, in Book 2, Ch. 8, records as follows: "Anaximander of Miletus is said to have been the first to understand the obliquity of the Signifer, that is, to have opened the doors of things, in the fifty-eighth Olympiad; then Cleostratus the signs in it, and first those of Aries and Sagittarius, etc.; the sphere itself, much earlier, Atlas." Plutarch, in Book 2 of *De Placitis*, Ch. 23, relates that this view of the Sun's oblique course through the ecliptic was accepted by Plato, Pythagoras and Aristotle. The figure of the zodiac in the armillary sphere you can see at the beginning of Book 1, and its explanation in that same Book, Chs. 7 and 14.

[Margin: Names and kinds of the year.]

IV. Furthermore, just as natural and artificial days arose from the Sun's diurnal motion, so from the Sun's proper oblique motion there arose the year, which we enjoy by the gift of the immortal God, or the period of 365 natural days with almost a quarter of a day. In Hebrew this year is SCHANAH, that is, Revolution; in Greek it is called [Greek: ἔννος (ennos, "year")], as if Renewing all things, and [Greek: ἔτος (etos, "year")], that is, a whole revolution of the Sun. And although we have dealt with years more fully in the Chronological Book, it must nevertheless be indicated here that the year is usually divided into natural, and political or civil or ecclesiastical; that the natural is subdivided into temporal and sidereal; the temporal into tropical and equinoctial, mean or true; and the civil into various kinds used by different nations, but chiefly into the Egyptian, and the Julian and Gregorian. Lunar years are meanwhile omitted here and deferred to the Book on the Moon.

[Margin: The temporal year.]

V. The temporal year is a whole revolution of the Sun, of about 365¼ days, from one point of the ecliptic to the same point. If this is the point of the solstice occurring in either tropic, the year is called tropical, and by Cicero in the *Dream of Scipio* and by Censorinus, Ch. 7, *Vertens* [the turning year]; if it

is one of the two equinoctial points, it is, and is called, the equinoctial year, which, however, I shall show in Scholium 5 can be called tropical.

[Margin: The sidereal year.]

VI. The sidereal year is a whole revolution of the Sun from one fixed star to the same, accomplished in $365^{d}\ 6^{h}$ and about $9\frac{2}{3}^{m}$. It is longer than the temporal year because, while the Sun once completes the whole zodiac, the fixed stars meanwhile, by a motion that is slow and was understood only late, creep forward towards the east by about 50″; and the Sun by its mean motion does not complete these except in about 21^{m}. And so, when the annual motion through the zodiac has been completed, it has not yet reached the same fixed star, and reaches it only after 21^{m}.

[Margin: The synodic and periodic year.]

This year could also be called synodic, just as the temporal year could be called periodic: in the same way as the month in which the Moon runs through the zodiac is called periodic, and that in which it is again joined to the Sun is called the synodic month. The sidereal year could indeed be imagined in various kinds, according as the Sun revolves to one planet or another, at least those slower than itself; but the fixed stars have been chosen because their motion is either uniform or the least irregular of all, and this sidereal year comes closer to the temporal. The others are too inconstant, and were therefore rejected by Ptolemy, Book 3, Ch. 2.

[Margin: The mean and the true year.]

VII. The mean year, or equal or regular year, in Greek [Greek: ἔννος ὁμαλος (ennos homalos, "even year")], is that which either is, or is assumed as being, of perpetually the same quantity and measure, or the mean between the longest and the shortest, if the view is true of those astronomers who affirm that temporal as well as sidereal years are unequal; on this matter see below, Ch. 30. Therefore the true year, that is, the one that truly comes about in the heavens and is observed on Earth, and for that reason called apparent, is irregular, in Greek [Greek: ἔννος ἀνόμαλος (ennos anomalos, "uneven year")].

[Margin: The threefold measure of the year according to Copernicus.]

Thus, for example, for Copernicus the longest temporal year is $365^{d}\ 5^{h}\ 55^{m}\ 37^{s}$ 40 thirds; the shortest, $365^{d}\ 5^{h}\ 42^{m}\ 55^{s}$ 7 thirds; and finally the mean, $365^{d}\ 5^{h}\ 49^{m}\ 16^{s}$ 29 thirds. On this supposition the sidereal year must turn out unequal, even if the proper motion of the fixed stars were equal and uniform; and unequal for a double reason if the motion of the fixed stars is unequal; on this matter see below, Ch. 28.

[Margin: The civil year.]

VIII. The civil year, also called ecclesiastical, is a whole revolution of the Sun accomplished in as many whole days as has pleased the legislators or pontiffs in each state or hierarchy. The best known, and eventually received throughout almost all Europe or the Roman world, have been these two kinds and forms: the one used by the Egyptians, and the one devised, or rather introduced, by

Julius Caesar; hence the Egyptian and the Julian year, and, from its reformer, the Gregorian, prevailed.

[Margin: The Egyptian and the Persian year.]

IX. The Egyptian year formerly, like the Persian, consisted of 360 natural days, as many as there are degrees in a circle, so that each month had 30 days. They reckoned an appendix of 5 days, which the Greeks called [Greek: ἐπαγόμενας (epagomenas, "added")], that is, additional, as lying outside the round circle of the months; they did reckon these before beginning the new year, but nevertheless outside all the months, which among them were counted in this order: Thòth, Paophì, Athyir, Chœàc, Tybì, Mechir, Phamenòth, Pharmuthì, Pachòn, Paynì, Epiphì, Mesorì. So when Mesorì was finished, the first of the intercalary or additional days was called [Greek: πρώτη ἐπαγομένων (prōtē epagomenōn, "first of the added days")], and the 2nd [Greek: δεύτερη ἐπαγομένων (deuterē epagomenōn, "second of the added days")], the 3rd [Greek: τρίτη (tritē, "third")], the 4th [Greek: τετάρτη (tetartē, "fourth")] and the 5th [Greek: πεντή (pentē, "fifth")], understanding [Greek: ἐπαγομένων (epagomenōn, "of the added days")]. Since, therefore, if you look at the days of the months alone, there were 360 days, but if you add the appendix usually entered upon before the beginning of the new year from the first day of Thoth, there were 365 days, the intercalation of the 6 hours being neglected, or of the day that arises every fourth year from the 6 hours taken four times, the Egyptian and the Persian year, taken absolutely, was therefore of 365 days, as Ptolemy has throughout the *Almagest*, and Censorinus, Ch. 6, and Scaliger, *De emendatione temporum*, Book 3.

[Margin: The golden circle of Osymandias.]

And so Osymandias [Osymandies], king of Egypt, as Dionysius of Halicarnassus relates, encircled his tomb with a golden ring of 365 cubits to signify the year, marking out the Sun's golden path on earth; and 365 Egyptian priests were maintained in the city of Heliopolis, each assigned to observing the Sun's course on his own day; and in Quintus Curtius 365 Persian priests are counted, bearing the sacred fire before the image of the Sun.

[Margin: The Canicular year, and its beginning.]

Now from the omission of the almost 6 hours required for the Sun to return after 365 days to the same point of the solstice or equinox, it came about that every fourth year the Egyptian year was completed almost one whole day before the day of the previous solstice or equinox, and the new year was entered upon; and that in 40 years it ran ahead by 10 days, and in 1460 years by 365 days. So when 1460 celestial years had rolled round, 1461 Egyptian years had already passed, and the beginning of the Egyptian year, that is, the first day of the month of Thoth, returned to the same day and season, in agreement with the sky. This period of 1460 Julian and almost celestial years, but of 1461 Egyptian years, was called the *Great Canicular Year* and the *Sothiac* or *Cynic Period*, from Canicula, the Dog Star, which in Greek or Syriac is called [Greek: Σώθις (Sōthis, the Dog Star)] or [Greek: Κυνὸς (Kynos, "of the Dog")], because this

period was entered upon from the conjunction and morning rising of the Sun with Canicula, or Sirius.

[Margin: The beginning of the Sothiac Period.]

And indeed it could have been entered upon, as Govaert Wendelen observes in our own Denis Pétau, *Dissertations of the Uranologion*, Book 2, Ch. 4, in the year 1263 before Christ, July 5, at about 6^{h} after midnight at Heliopolis; for at that time Sirius was joined to the Sun at the beginning of Cancer, the true new moon having occurred 46^{m} after midnight. If this is true, the beginning of this period was most celebrated, from its concurrence with the beginning of the tropical year, or the summer solstice, with the *neomenia* or new Moon, and with the conjunction with the greatest of the fixed stars and the most brilliantly red, namely Sirius.

[Margin: Apparent disagreement between Wendelen and Censorinus.]

However, this ingenious conjecture of Wendelen's does not agree with Censorinus. Speaking in *De die natali*, Ch. 8, of the year of the consulship of Ulpius and Pontianus, which, as we show in the Chronological Book and as most chronographers admit, falls in the year 238 of the common epoch of Christ, he adds: *So it may also be known that of that Great Year, which, as was said above, is called the Solar, the Canicular and the Year of God, the hundredth circling year is now current.* Therefore the preceding Canicular Year had been completed in the year of Christ 138; and when 138 is subtracted from the period of 1460, its beginning falls back to the year 1322 before Christ, and is older than Wendelen's beginning by 59 or 60 years. But Wendelen and Pétau do not assert that it was in fact entered upon in that year 1263, only that it could have been.

[Margin: And of Censorinus from Clement of Alexandria.]

Clement of Alexandria, however, says in Book 1 of the *Stromata* that the Sothiac period began after the migration of the Israelites from Egypt by, as the Greek codex has it, 345 years, not 445 as the translator has it; and that migration, according to the better chronology, was in the year 1491 before Christ. Therefore the beginning of the Sothiac period would have been in the year 1146 before Christ. But more fittingly elsewhere on this disagreement. Meanwhile I suspect that this period was not brought into civil use, but only among the learned and those skilled in astronomy; and it is no wonder if, given their differing opinions on the motion of the fixed stars and on the other phenomena congruent with this beginning, some thought it should be entered upon in one way and others in another.

[Margin: The Julian and Gregorian Years.]

X. The *Julian Year* is so called because it was introduced into the Roman world by *Julius Caesar*, at the urging and with the help of *Sosigenes*, the Alexandrian astronomer, whom he brought with him to Rome when the Alexandrian war was finished. It consists of 365 days and, in every fourth year, of 366, on account of the day that arises from the almost 6 hours taken four times, and that is intercalated after February 24 by pronouncing *Bis-sexto Kalendas Martij*;

from this it is called the *Bissextum* and the *Bissextile Year*. The Roman Church used the form of this year, with the months as ordered by Julius Caesar, until the year 1582, in which the year was reformed by *Gregory XIII*, a truly supreme pontiff, and called *Gregorian*. For since the equinoctial or tropical year is not of $365^{d}\ 6^{h}$, as *Sosigenes* assumed, but shorter by about 11^{m} of time, it came about that in every 133 ½ years the celestial and true equinox preceded by one day the day assigned to the equinox in the calendar; which in the time of Julius Caesar was March 25, but in the year of Christ 325, by decree of the Council of Nicaea and by the observation of the Alexandrians, was March 21. And so in the year 1582 the celestial equinox was observed by astronomers, namely by Tycho, to precede March 21 by those very 10 days, and to occur at about March 11. So that the equinox might therefore be kept at March 21, out of reverence for the Nicene Synod and because of the custom of the peoples, and might no longer differ noticeably from the celestial equinox, Gregory XIII ordered October 5 of the year 1582 to be called the 15th, that year being shortened by the omission of 10 days; and that the intercalation of the bissextile day should be omitted not in every 133rd year, as *Giovanni Lucido* once urged upon Leo X in *De emendatione temporum*, but in the years 1700, 1800 and 1900, and resumed in the year of Christ 2000, and so on, so that in every four hundred years the three days by which the equinoxes would run ahead in the Julian year are used up.

And Gregory XIII could indeed have fixed the day of the equinox at March 11 or 10, just as the Council of Nicaea, following the observations of the Alexandrian astronomers, had brought it back to March 21, even though in the time of the Apostles it was celebrated near March 25; and this would have been less inconvenient for the astronomers' calculations for past ages; but other just causes outweighed it.

[Margin: God, Best and Greatest, supporter of the Gregorian Year.]

And while the sectaries, to whom everything papal stinks, bark in vain, God, Best and Greatest, by His vote and by the tally of miracles, confirmed the decree of His Pontiff, or greatest Vicar on earth. For the miracles that still flourish continually in the Church He transferred to the days of the Gregorian Year, the leap of 10 days having been made. If then God is for us, who is against us?

SCHOLIA.

Scholia.

[Margin: The conflict between the diurnal motion of the primum mobile and the annual motion.]

I. A great dispute still flourishes among astronomers as to how the two motions of the Sun, and indeed of all the stars, are to be reconciled with one another, since they seem entirely contrary and in conflict with each other, being made towards contrary regions of the world and to opposite limits: namely, the diurnal from east to west, and the annual from west to east. For although we commonly help the imagination of beginners with the example of an ant

crawling in the direction contrary to that in which a potter's wheel is carried round, or of someone walking eastward on a ship while the ship is carried westward, so that in one way or another we may explain the sphere to them, nevertheless these examples in no way satisfy men practised in philosophy and astronomy alike. We shall treat this matter more exactly in the Book on the Systems. Meanwhile I point out three hypotheses by which these motions are commonly reconciled.

[Margin: The first way of reconciling these.]

The first is that of those who, with Sacrobosco, Peuerbach and a few others, admit solid orbs. For they say that the sphere of the primum mobile, which some call the eighth, others the 9th, others the 10th, others the 11th, by the motion of rapture turns all the lower spheres in 24 hours from east through west back to the east; but that these, being really distinct from it, notwithstanding that contact and rapture, strive against it, with a partial sphere (on which see Ch. 20, Schol. 2), by the force of their own motion towards the east, and carry with them the body of the planet fixed in them.

[Margin: The second way.]

The second is that of those who, with Plato in the *Timaeus*, Hicetas of Syracuse, Heraclides of Pontus and Ecphantus the Pythagorean, say that the Earth, placed in the middle of the world, is moved about its centre by a diurnal rotation in 24 hours towards the east; and that therefore, as we go to meet the Sun and the other stars, which are carried eastward, they seem to move westward, just as the shores seem to move while the ship moves in the contrary direction. These have been followed by Boulliau, Lansbergen, William Gilbert, Longomontanus, Mulerius, Origanus and Argoli, besides Philolaus, Aristarchus, Copernicus and the Copernicans, who give the Earth both this motion and the annual one. This opinion has indeed been condemned by the Sacred Congregation of Cardinals as erroneous in the faith, as was said in Book 2, Ch. 3.

[Margin: The third way.]

The third hypothesis is that of those who say that there are not in the heavens the two motions in longitude already mentioned, but a single one, and that diurnal, made in a kind of spiral towards the poles of the world; and that the swiftest is the motion of the primum mobile, of exactly 24 hours; that after this the motion of the fixed stars is the swifter, yet does not keep pace with the motion of the primum mobile but falls short by some small part, which in the end becomes perceptible; that after this Saturn is the swiftest of the planets and the Moon the slowest, since she does not return to the same meridian until after almost 25 hours, and that therefore she seems to move eastward because of her slowness, although she moves only westward, but more slowly.

[Margin: Greater diurnal speed in the higher stars.]

So think Averroes, al-Biṭrūjī, Alexander Achillinus [Alessandro Achillini], *De orbibus*, Book 1, Francesco Patrizi and Giovanni Antonio Delfino, and indeed some Peripatetics in Martianus Capella, Book 8; nor does Cabeo reject

it (on *Meteorologica* 1, text 38, question 2). And all those favour this opinion who, in distributing the seven strings among the planets, assign the *nete* to Saturn as the most highly strung, and the *hypate* to the Moon as the slowest: such are Cicero in the *Dream of Scipio*, and Macrobius on that passage, Servius, Philander, Valla, Glareanus, and indeed St Ambrose, as I shall say when treating of the harmonic system of the world. But Agostino Ricci, p. 16, maintains that there is no primum mobile distinct from the 8 spheres.

[Margin: The various forms of years.]

II. The forms of years have varied at different times and among different nations. For the Gauls once and the Saxons, and now the Tartars, Turks, Arabs, Chinese, Japanese, Peruvians and Chileans use a purely lunar year; the Hebrews, however, a solar and lunar year together. But the Mexicans formerly, as José de Acosta relates, and the Greeks before and at the beginning of Solon's time, as is gathered from Aristotle, *History of Animals*, Book 6, Ch. 20, from Herodotus, Book 1, from Pliny the Elder, Book 34, Ch. 6, and from St Augustine, *De Trinitate*, Book 4, Ch. 4, used a year midway between the lunar and the solar, namely of 360 days; and for that reason 360 statues to Demetrius of Phalerum were erected and overthrown at Athens in one and the same day. But on Solon's advice they directed the year by the course of the Moon, yet equalizing it with the solar year by various intercalations; and first Romulus, crudely, then Numa and the Romans up to Julius Caesar imitated them.

That boast of the Arcadians, who [boasted that they were] [Greek: προσελιναίους (proselinaious, "before the Moon")] [recte: προσεληναίους], that is, older than the Moon, and of the Egyptians, who from the number of their years displayed themselves as the most ancient of mortals, is to be understood of years that were monthly among the Arcadians, and afterwards three-monthly, or of four-monthly years among the most ancient Egyptians, or of the six-monthly years of the Acarnanians. But on this diversity, if you lack our Chronological Book, you can consult Pliny the Elder, Book 7, Ch. 48; Solinus, Ch. 3; Macrobius, *Saturnalia*, Book 1, Ch. 12; Censorinus, *De die natali*, from Ch. 7; Giraldi, in the book *De annis et mensibus*; Alexander ab Alexandro [Alessandro Alessandri], *Genialium*, Book 3, Ch. 24; Joseph Justus Scaliger, in the books *De emendatione temporum*; and Denis Pétau, in the books *De ratione temporum*.

[Margin: Cycles, and Great Luni-Solar Years.]

III. Great Luni-solar Years are cycles or periods on whose completion the syzygies of the Moon and Sun at last return to the same moment of the same day. Such a period was judged to consist of 19 solar years by Meton; of 59 by Philolaus and Oenopides; of 76 by Callippus; of 82 by Democritus; of 84 by the Hebrews under Constantine the Great; of 247 by Gamaliel; of 304 or 344 or 441 by Hipparchus; of 3400 by Franciscus Vieta [François Viète] and very nearly by Kepler: on these see Book 4, Ch. 20. So that new moons and full moons might return to the same weekday, given the cycle of the Dominical letters, which computists call the Cycle of the Sun and which is of 28 years, various cycles

were devised: namely of 95 years by St Cyril of Alexandria, which consists of five Metonic lunar cycles; or of 318 by Theophilus of Alexandria; or of 532 by Victorinus of Aquitaine, Victor of Capua and Dionysius Exiguus, which arises from multiplying the lunar cycle of 19 years by the solar cycle of 28 years. But if you multiply the cycle of 532 years by the period of the indictions, or 15 years, there results the period of 7980 years, which Scaliger calls the Julian, and which is commended by him too much, and indeed by Pétau as well, *Rationarium temporum*, Book 1, Ch. 4, as outstanding for marking dates. But in this way, if you multiply Viète's period of 3400 by the solar cycle of 28, a Great Period of 95200 years would result.

[Margin: Greater and Great Years.]

IV. The remaining periods of solar years can be called Greater Years, as was the Jubilee Year among the Hebrews, of 49 completed years, but of 50 when both limits are counted; and the Secular Years among the Romans, of 100, 110 or 120 years, on which our Petrus Taffinus [?] has recently written most learnedly in the book *De anno saeculari*; and the Wheel of 52 years among the Mexicans, at whose end they feared the end of the world, as José de Acosta relates in Book 6; and the period of 470 years among the Japanese; and the Canicular period of 1460 years among the Egyptians, of which I spoke in the preceding chapter, no. 9.

[Margin: The Platonic Year.]

But the Great or Platonic Year is most celebrated among writers: on it see Cicero, *Dream of Scipio*, and Macrobius on that passage; Censorinus and Giraldi, cited above; Manutius, the book *De anno magno* in the *Quaesita per epistolam*; Justus Lipsius, *Physiologia Stoica*, Book 2, Ch. 21 and 22; and the scholiasts of Virgil on Eclogue 3. For the Stoics thought, as did the Platonists, that on the complete *apocatastasis*, or revolution of all the stars to the same point, there would be a restoration of all things and an *anastasis*, or resurrection, but preceded by a universal cataclysm or deluge if the stars came together in Capricorn; or by [Greek: ἐκπυρῶσι (ekpyrōsi, "conflagration")], or a general burning, if they came together in Cancer.

But since some look only to the *apocatastasis* of the planets, others only to that of the fixed stars, others to that of absolutely all the stars, they have defined the Great Year variously, according to their differing opinions on the stars' motions: namely as 1460 years, Julius Firmicus Maternus, misusing the Canicular period; or as 2494, Aristarchus; or as 5552, Aretes of Dyrrhachium; or as 9987, Heraclitus and Linus; or as 9994, Dion; or as 12000, Orpheus; or as 15000, Cicero; others as 28000, others as 3000. The Jews who compiled the Alphonsine Tables said that after a thousand Jubilees, that is, in 49000 years, the fixed stars would complete their course, and that then all things were to be renewed.

[Margin: The incommensurability of the celestial motions.]

Perhaps it was better said by Didymus, in Censorinus, and by Kepler in the *Mysterium Cosmographicum*, Ch. 23, that the motions of all the stars are

incommensurable with one another, and that therefore, even if the world endured, they would never all complete their periods at the same point of the heavens.

[Margin: A more learned notion of the tropical year.]

V. We have defined the *tropical year* as the revolution from one point of the solstice to the same point, at the contact of the tropical circles, following the use of this name among more recent writers. Otherwise the equinoctial year can be called tropical, since not a few have also called the beginnings of Aries and Libra [Greek: τροπὰς (tropas, "turnings")], because of the changes of weather that occur in them, as Pétau learnedly observes in *Rationarium temporum*, Book 1, Ch. 1. In his text Sextus Empiricus, *Against the Mathematicians*, Book 5, Ch. 1, says: "The tropic signs are those in which the Sun, when placed, works a change and makes the turnings of the air; such is Aries, and Libra diametrically opposite it, likewise Capricorn and Cancer. For in Aries there occurs the [Greek: ἐαρινὴ (earinē, "of spring")], the vernal turning; in Capricorn the [Greek: χειμερινὴ (cheimerinē, "of winter")], the winter one; in Cancer the [Greek: θερινὴ (therinē, "of summer")], the summer one; in Libra the [Greek: ὀπωρινὴ (opōrinē, "of autumn")], the autumnal one." So Oppian [Oppinnus], *Cynegetica*, Book 1, names the autumnal turnings [Greek: ὀπωρινὰς τροπὰς (opōrinas tropas, "autumnal turnings")]; and Procopius, *De bello Gothico*, Book 1, for the vernal equinoxes has [Greek: τροπὰς ἐαρινὰς (tropas earinas, "spring turnings")]; and Philo in the *Cosmopoeia*, for the autumn equinox, [Greek: μετοπάρου τροπὰς (metoparou tropas, "turnings of autumn")] [recte: μετοπώρου]; and Manilius, Book 3, speaking of the beginnings of the 4 cardinal signs:

Which they call tropic, because in them the four seasons of the year turn, in those signs.

CAPVT XIV.

Chapter 14.

De Obſeruatione Aequinoctiorum & Solſtitiorum, & de Quatuor Anni Cardinibus.

On the observation of the equinoxes and solstices, and on the four cardinal points of the year.

I. The length of the tropical year and the annual inequality of the Sun's motion, which are to be discussed in the following chapters, depend on the observation of the solstices and equinoxes. This cannot be carried out unless the day assigned to the solstice and to the equinox in some ephemeris or in the calendar, and the way of observing each, are known beforehand. As regards the day, our Pétau, in the *Uranologion*, Book 1, Ch. 8, and Book 2, Ch. 5, having computed the Sun's motion from the more recent tables for the Roman meridian, and for the first Julian year, which was 45 before Christ, gathers the Sun's ingress into the four cardinal signs, that is, into the beginning of ♈ ♋ ♎

♑, as you see in the following table, both according to the mean motions and according to the true ones, in hours after noon.

[Margin: The days of the 4 cardinal points in the first Julian year.]

The Sun's true and mean ingress into the cardinal signs, in the year 45 before Christ, at Rome. [Solis Ingreſſus Verus, ac Medius in Signa Cardinalia Anno ante CHRISTVM 45. Romæ.]

	Months	Mean	True
Vernal equinox and ingress into ♈	March	$24^{d}\ 21^{h}\ 11^{m}$	$22^{d}\ 23^{h}\ 47^{m}$
Summer solstice and ingress into ♋	June	$24^{d}\ 4^{h}\ 39^{m}$	$24^{d}\ 23^{h}\ 3^{m}$
Autumnal equinox and ingress into ♎	September	$23^{d}\ 12^{h}\ 6^{m}$	$25^{d}\ 11^{h}\ 11^{m}$
Winter solstice and ingress into ♑	December	$23^{d}\ 19^{h}\ 34^{m}$	$24^{d}\ 23^{h}\ 54^{m}$

[Margin: The day of the vernal equinox in the first Julian year.]

From this it is clear that Sosigenes, who drew up the Julian calendar, had regard to the mean motions rather than the true ones. For, as Pliny the Elder explicitly has it in Book 18, Ch. 25, 26 and 28, Varro in *De re rustica*, Book 1, Ch. 28, and Columella in Book 9, Ch. 14, and Book 11, Ch. 2, he fixed the cardinal points of the year at the 8th before the Kalends of March, June, September and December [VIII. Kalendas Martij, Iunij, Septembris, & Decembris], that is, on March 25, June 24, September 24 and December 25. And thus in the calendar of Julius Caesar, in Giraldi's book *De annis*, in Johannes Rosinus's book of *Roman Antiquities* and in Macrobius, *Saturnalia*, Book 1, the Hilaria, which was a festival for the beginning of spring, are placed on March 25; and it is clear from the same calendar that the Quinquatria usually ended on March 23. And so the equinox was celebrated on the third day from then, inclusive, as Ovid elegantly sings in *Fasti* 3, after reviewing the end of the Quinquatria:

When the coming Dawn has sent ahead three Morning Stars, she will bring daylight hours equal to the nocturnal.

The Fathers too connect these two things, namely that St John the Baptist was born at the summer solstice on June 24, when the days begin to decrease, and Christ at the winter solstice on December 25, when the days begin to increase, expounding that saying of the same Baptist, *He must increase, but I must decrease*: in particular St Augustine and St John Chrysostom, in the sermon on St John the Baptist.

[Margin: The day of the vernal equinox in the year of Christ's Passion.]

Moreover, the same St Chrysostom and St Augustine, and also Tertullian, Cyril, Jerome, Cassiodorus, Bede, Albert the Great and Marianus Scotus, record that Christ the Lord suffered and died at the vernal equinox and on March 25. Finally, that in that age the vernal equinox was fixed [Greek: πολιτικῶς (politikōs, "civilly")], or for civil purposes, to March 25, is taught by Stöffler on Proclus, p. 15, and in the *Calendar*, Propositions 38 and 39; by Reinhold on Peuerbach's *Theoricae*, p. 232; by Longomontanus, *Theorica*, Book 1, p. 175; and by Pétau, cited above.

But since, according to the rules of Rabbi Adda in the Hebrew calendar, the *Tekupha* of the month of Nisan, that is, the cardinal point and equinox of the spring season and of the first ecclesiastical month, fell in the year of Christ 34 on March 22, or according to the true motions on about the 23rd, perhaps for that reason Nicetas and Lactantius, *Institutes*, Book 4, say that Christ died on March 23, and others otherwise, as we shall say in the Chronological Book.

[Margin: The day of the vernal equinox in other centuries after Christ.]

II. But because the true equinox gradually precedes the day assigned to it in the Julian calendar, in the year of Christ 140 it was therefore observed by *Ptolemy* to fall on March 22, and Anatolius of Alexandria followed him in determining the day of Easter; while in the year 325 it was observed at Alexandria on March 21, and for that reason the Fathers of the Nicene Synod assigned this day to the equinox. Dionysius Exiguus retained it in his cycles in the year 525, although it then in fact fell on the 19th. In the year of Christ 1079, 8 distinguished Persian mathematicians, summoned by the Emperor of the Persians to reform the calendar, observed the vernal equinox and found that it occurred on March 14, as Scaliger reports from the Persian tables, *De emendatione temporum*, Books 3 and 4, and Boulliau, *Astronomia Philolaica*, Book 2, Ch. 3. Further, in the years 1290 and 1303 it was observed in Lower Germany on March 13, as Cardinal Nikolaus von Kues relates in his treatise *De reparatione Kalendarii*. Again, about the year 1400, that common couplet was on the lips of the people:

Lambert, Gregory: the night is made equal to the day; Vitus, Lucy give you the two solstices.

By this it was signified that the equinoxes fell on March 12, sacred to St Gregory, and on September 13, sacred to St Lambert; and the solstices on June 15, dedicated to St Vitus, and on December 13, dedicated to St Lucy. At last, from the year 1470 to 1520, Peuerbach, Regiomontanus, Bernhard Walther, Johannes Werner, Copernicus, Pietro Pitati and others observed that the vernal equinox fell on March 12 or 11; and from the year 1570 to 1590 the mathematicians of the Landgrave of Hesse, and then Tycho Brahe, found it on March 11 or 10. For these reasons the restoration of the calendar, once debated in the Councils of Constance and the Lateran, was carried out by order of *Gregory XIII* in the year 1582, and was set forth and defended by our *Clavius*. The vernal equinox was fixed to March 21, not, as Giovanni Lucido and Johannes Stöffler had once judged should be done, to March 10 or 11, but with 10 days taken from the calendar; and it was decreed that at the end of each of three centuries the day otherwise to be intercalated should be omitted, the bissextile being suspended, namely in the years 1700, 1800, 1900, yet the year 2000 should be bissextile in the usual way.

[Margin: The day of the vernal equinox in the Gregorian calendar is always the same.]

If this rule is kept, the civil vernal equinox will always fall on March 21, and yet it will never differ from the mean celestial equinox by a whole day and a

half, as *Clavius* clearly shows against Mästlin in the *Apologia* of the Gregorian calendar, Ch. 6. So this advantage arises from this calendar, that the day on which, or nearest to which, the true equinox is to be observed is now certain. Let us now come to the way of observing these.

Modus Obſeruandi Solſtitia.

The way of observing solstices.

[Margin: The observation of the solstitial day.]

III. First, if you are seeking only the day of the solstice, disregarding the hours, then around the day assigned to the solstice in the calendar or in an ephemeris you must observe the Sun's meridian altitude with a quadrant, an astronomical square or similar instruments; or else the meridian and direct shadow of a gnomon perpendicular to the horizon. For on the day on which the Sun's altitude has been found greatest, so that it no longer approaches your zenith, or the shadow of the gnomon least, you will conclude that the summer solstice occurred within that natural day. But on the day around midwinter on which the Sun's altitude has been found least among all the meridian altitudes of the year, or the meridian shadow longest, judge that the winter solstice occurred within that natural day.

[Margin: The great gnomon of Marseille.]

But the day of either solstice is observed more evidently at noon if the gnomon is very tall, such as Gassendi describes in the *Life of Peiresc*, used at Marseille from as far back as the time of Alexander the Great by Pytheas of Massalia, who found the solstitial shadow at noon to be 213 ⅛ parts of which the gnomon was 600. In the same place Gassendi himself used a gnomon 52 royal feet high, and found the meridian shadow at the summer solstice to be 31950 parts of which the gnomon was 90000; from this he gathered that the obliquity of the ecliptic is now the same as in the time of Alexander the Great.

[Margin: The great gnomon of Bologna in the church of San Petronio.]

We too here at Bologna have the use of a gnomon erected in the church of San Petronio in the year 1576 by the Reverend Father Master *Egnazio Danti*, at the expense and on the authority of the most illustrious Count *Io. Pepuli* [Giovanni Pepoli], perpetual president of the fabric of San Petronio. Take a specimen of it from the following diagram.

In this AB is the wall of the church facing south, at whose summit, at the edge of the vault, there is a metal plate of a thickness equal to the width T, and in it an aperture exactly equal to the circle Z. The plate is inclined from the perpendicular AX, as you see in XB, namely by 60°, as I measured it with *D. Bartholomæus Provalius* [?]; for that is how the workmen inclined it in repairing that vault. Otherwise *Egnazio*, as I learned from his papers and from the account of it, had inclined it by only about 45 ½°, which is the altitude of the equator here. Further, the height of the aperture, AX, is 65 Bolognese feet and 9 ¼ inches [vnciarum]. The meridian line is AV, from which towards the west

there declines (as I measured accurately with Fathers *Francesco Maria Grimaldi* and *Francesco Zeno* from observation of noon, on which I shall say more in the *Liber Organicus*), there declines, I say, by 9° 6 ⅓′ the line, or rather the marble path, AN, by my measure 169 Bolognese feet and 2 ½ inches long, laid in the pavement from A towards the north door of the church; for, since the columns of the church stood in the way, it could not be laid on the meridian line itself. The twelve signs of the zodiac are cut into this marble band, and LN is the greater diameter of the elliptical solar ray from the aperture XB, projected onto the pavement on the day of the winter solstice. For on the day on which a little after noon its end is at N, or very near it, the winter solstice is concluded to occur within that natural day; for on the preceding and following days the northern end of this ellipse stands off from N towards L by a most evident interval of several inches. In the same way the ellipse FH serves for observing the equinoxes, and C for the summer solstice. But on our correction of this gnomon, and on the very many observations undertaken by means of it, it remains for us to speak both in the *Liber Organicus* and in the solar observations to be reviewed in the last volume of the *New Almagest*. Meanwhile one must know that the angle XAN must be exactly right, if gnomons of this kind are to be brought into practice without error.

[Margin: Other ways of observing the solstices.]

I pass over the way of observing solstices by the rising and setting amplitudes of the Sun, for the vapours of the horizon and refractions hinder those; yet more exact it is made, if the Sun's setting is observed behind a mountain, but so that part of the northern limb stands out on this side of the mountain, towards the north; for the day on which the largest part of the solar limb appears will be the solstitial one. *Galileo* touches on this method in Dialogue 3 on the System of the World. Now let there be the figure of the gnomon set out a little earlier.

Diagram. *The Great Gnomon of Bologna, in the Church of San Petronio, set up by the Reverend Father Master Egnazio Danti on the authority of the Most Illustrious Count Ioannes Pepulus [Giovanni Pepoli], in the year 1576.* A full-width woodcut standing across both columns. At the left, a tall hatched wall in section, its top broken off irregularly, with an arched opening at its foot. High in the wall a small disc (the aperture) lies between X and B. Thin lines run up and to the left from the aperture to the letters R, S, Q, P, O and Y, standing for incoming rays. From the aperture, lines, some solid and some dotted, fan down and to the right to a long horizontal ground line running from A at the wall's foot to N at the far right. A short line rises from A to V. On the ground line stand a small circle under C, near the wall; a lens-shaped ellipse between F and H, at mid-length; and a longer lens-shaped ellipse between L and N, at the far end. Signs of the zodiac are set in pairs along the line, one above and one below. At the upper right, separate from the rays, stand a small rectangle lettered T and a large circle lettered Z.

- R, S (top left, above the wall): ends of the two highest rays
- Q, P, O, Y (left of the wall, descending): ends of lower rays

- X, B (either side of the aperture disc): X at left, B at right
- A (foot of the wall, left end of the ground line)
- V (on the short line rising from A)
- C (in the small circle, upper half), with the sign ♋ in the lower half
- D (on the line), with ♊ below it
- ♌ and ♍ above the line, either side of E; ♉ below E
- F, H (ends of the middle ellipse), with ♎ in its upper half, crossed by two short oblique strokes, and ♈ in its lower half
- ♏ above the line, with K and ♓ below it
- ♐ above the line, with I and ♒ below it
- L, N (ends of the far ellipse), with ♑ in its upper half and M in its lower half
- T (in the rectangle, upper right)
- Z (in the large circle, upper right)

IV. But if you wish to know not only the day but also the hour of the solstice, you will achieve this only with the greatest difficulty; and yet you must strive for it, if you are held by a zeal for cultivating astronomy. First, then, you must know the altitude of the pole with the utmost exactness, not from the Sun's altitude but from the circumpolar stars. Next, on the day assigned to the solstice in the ephemeris, and on the days immediately before and after it, take the Sun's meridian altitude with large quadrants that show at least each single ten seconds. Then correct the altitudes of these 3 days by adding the parallax and subtracting the refraction, if any occurs; and you will have the Sun's true altitudes. If it is the winter solstice, subtract these from the altitude of the equator, that is, from the complement of the altitude of the pole; but if it is high summer, subtract the altitude of the equator from them, and the Sun's declinations will remain.

Now if the altitudes of the day immediately before and the day immediately after the solstitial day are wholly equal, the solstice will have occurred at noon of the intermediate day, and the declination found on that day will be the greatest; and with one and the same labour you will have observed the obliquity of the ecliptic. But if they are unequal, and at the summer solstice the altitude of the preceding day is greater than the altitude of the day following the intermediate day, the solstice will have occurred before noon; if it is less, after noon of the intermediate day. And if you multiply the difference of the altitudes by 24 and divide the product by 15, the result will be the hours before or after noon at which the solstice occurred; for the whole difference of declination over one complete day is then about 15″. But if it is the winter solstice, a lesser altitude on the preceding day will mark a solstice before noon, and a greater one a solstice after noon.

[Margin: The difficulty of observing the hour of the solstice.]

So if there is an error of 16″ in the altitude of the pole, or of the Sun, or in the parallax, the solstice will be wrong by one whole day; if of 8″, the error will be half a day; and if the error is 4″, the error will be a quarter of a day. It was therefore with good reason that *Willebrord Snellius*, in his notes on the Hessian

observations, said it is a labour of Hercules to avoid an error of a quarter of a day in solstices.

[Margin: The confidence of Ptolemy, timid elsewhere.]

But *Ptolemy*, in Book 2 of the *Almagest*, Chapter 2, said too confidently: *But in the solstitial observations, I hope that neither we nor Archimedes erred, in observation and calculation, by as much as a quarter of a day.* For the instruments Ptolemy used, as I shall say in the *Liber Organicus*, did not contain so fine a division that they showed tens of seconds. And since the dispute over the parallax of the Sun is still undecided among astronomers, whether it is 3′, or 2′, or 1′, or 30″, or 15″, as is clear from what was said in Chapter 8, the determination of the solstice also remains uncertain, with a doubt of 2¾′, that is, of 4 whole days and more, let alone hours, if we relied on a single noon altitude. But if we take three, as I said, then even if there has been an error in the parallax, it will still affect all the altitudes equally, and the difference of the altitudes is enough for us. Since, however, by God's favour, we have obtained among several observations of solstices one from which we inferred that the solstice occurred at noon itself, and from it the obliquity of the ecliptic, we shall bring this one forward as an example.

EXEMPLVM. Solstitij Obseruati.

Example of an observed solstice.

[Margin: A notable summer solstice observed by the author.]

V. In the year 1646, at Bologna, where the altitude of the equator had been observed by us from the circumpolar stars more than forty times and found to be 45° 30½′, the Sun's meridian altitude was taken with three large quadrants. On June 20 it was seen at 68° 59′ 45″, exactly as on the 22nd. But on the 21st it was observed at precisely 69°. Therefore, from the equal altitude of the 20th and 22nd, and from the difference of declination of 15″, I concluded that the solstice occurred at noon itself, as far as human diligence could observe. Now, at so great an altitude the refraction was not perceptible at all; and the parallax, from the Sun's distance from us as observed through the dichotomies of the Moon, is 30″ at most. So the true altitude on the 21st was 69° 0′ 30″. Subtracting from this the altitude of the equator, 45° 30′ 30″, leaves the obliquity of the ecliptic, 23° 30′. But if I had applied the Tychonic parallax of 1′ 2″, I should have concluded an obliquity of 23° 31′ 2″. Now let us move on to the equinoxes.

[Margin: For the parallax see Chapter 8.]

Modus 1. Obseruandi Aequinoctia per Vmbras Gnomonum.

Method 1. Of observing the equinoxes by the shadows of gnomons.

VI. This is done in two or three ways. First, one observes the day on which the shadow of a gnomon, by its tip, describes through the whole day one and the same straight line on a horizontal plane; for that day is taken as the

equinoctial day. On other days, the tip of such a shadow describes a hyperbolic line in the Torrid Zone and the Temperate Zones; for those who live under the polar circles, that is, for whom the pole is raised 66½°, a parabolic line; and in the frigid zones an elliptical line, approaching more and more to a circle, until for those living under the poles themselves it describes a circular line. The Sun placed in the equator also does this for them, because on account of refractions it appears higher above the horizon; for this is how *Maurolico* must be corrected, who discusses these figures of shadows subtly in Dialogue 2 of his *Cosmographia*, p. 61.

[Margin: Method 1. What figure the tip of the shadow of gnomons describes.]

[Margin: Method 2.]

Secondly, that day which, on an astronomical and horizontal sundial, is found to have 12 hours, or because of refra- ctions that lengthen the artificial day at both ends by about 4^{m}, as I have quite often observed, to have $12^{h}\ 8^{m}$, is to be taken as the natural day of the equinox.

[Margin: Method 3.]

Thirdly, the noon shadows of gnomons are observed, and from their ratio to the height of the gnomon the Sun's altitude is derived. If this is equal to the altitude of the equator known beforehand, as is assumed from the altitude of the pole, it will show that the equinox occurred at noon; but by as many minutes as it exceeded or fell short of the altitude of the equator, by so many hours was the time of the equinox before or after noon.

[Margin: Equinoctial shadows observed long ago in notable cities.]

So from Strabo, Book 2, Vitruvius, Book 9, Chapter 8, Pliny the Elder, Book 2, Chapter 72, Ptolemy, *Almagest* Book 2, Chapters 2, 3, 5, 6, and Cleomedes, Book 1 of the *Cyclical Theory*, you will learn that the equinoctial noon shadow was observed in relation to the gnomon as follows: at Alexandria in Egypt as 3 to 5; at Ancona as 34 to 35; at Athens as 3 to 4; at Byzantium as 111 to 120; at Carthage as 7 to 11; at Rome as 8 to 9; at Tarentum as 9 to 11; and in the Venetian region equal to the gnomon. *Pliny the Elder*, moreover, Book 36, Chapters 9 and 10, relates that Augustus brought from Egypt an obelisk of 116¾ feet, which had once belonged to King Sesostris, and set it up in the Campus Martius in the role of a great gnomon. A stone pavement was laid, on which the noon shadow would fall, and a gilded ball was added to the tip of the gnomon by Manlius the mathematician, to gather the shadow.

But *Ptolemy* admits how far this method is from accurate, *Almagest* Book 2, Chapters 5 and 6. And the ancients erred in taking the altitude of the Sun's upper edge, whose ray bounds the direct shadow [vmbram rectam], in place of the altitude of the Sun's centre, as I shall explain more fully in both the *Liber Organicus* and the Geographical Book; for they ought to have subtracted the Sun's apparent semidiameter from the altitude found by the direct shadow.

Modus 2. Obseruandi Aequinoctia per Armillas Aequatorias.

Method 2. Of observing the equinoxes by equatorial armillaries.

VII. This method was very famous at Alexandria, used by Hipparchus and Ptolemy and described in *Almagest* Book 3, Chapter 2, and by *Egnazio Danti* in the *Astrolabe*, Part 4,

Diagram. A column-width woodcut of an equatorial armillary instrument. A vertical line runs from F down to G, with a bracket at its foot. Against it stands an upright ring, CD, the meridian, drawn as a flat band in perspective, held by two clasps at its left side. A plumb line hangs from C within the ring and ends in a small ball. A second, horizontal ring in perspective, HK, passes through the first; it is the equator, and the two cross at O at the front. At the lower part of the upright ring a curved strap with a clasp runs down to G.

- F (top, at the head of the vertical line)
- C (top, at the head of the upright ring)
- O (front crossing of the horizontal and upright rings)
- B (upper clasp on the upright ring)
- A (lower clasp on the upright ring)
- I, L (small letters on a short horizontal bar inside the upright ring, between B and A)
- E (right of the upright ring, inside the horizontal ring)
- H (left end of the horizontal ring)
- K (right end of the horizontal ring)
- M (below the plumb ball, inside the upright ring)
- N (lower inner part of the upright ring)
- Q (left of the upright ring, at the fastening above D)
- D (foot of the upright ring, at right)
- P (on the lower curved strap)
- G (foot of the vertical line, at left)

p. 317. These rings are made like the rims of wheels, from four-sided, right-angled rulers bent into hoops, as you see here in the accompanying figure. One of them, CD, represents the meridian. It must be placed exactly in the plane of the meridian with the help of the plumb line CM, and be fixed immovably to a wall or column, fastened with the clasps A and B, and rest on a very firm support G, to which it must be so secured by means of the clasp PQ that it is kept immovable in the plane of the meridian.

[Margin: Description of equinoctial rings.]

The other ring, HK, represents the equator. For its plane must coincide with the plane of the equator and bisect the meridian, and be raised in it by as much as the altitude of the equator, that is, the complement of the altitude of the pole. From this placing it follows that, when the Sun passes from the southern signs to the northern and enters Aries, the shadow of the upper part of the ring HOK, which on the preceding day was shading the northern hollow of the lower part, HMK, shades the southern part, HNK. But when at the autumn

equinox the Sun passes from the northern signs to the southern, the shadow in the hollow of the lower ring, which on the preceding day had been southern, becomes northern.

Indeed, if the equinoxes fall during the day, the passage of the shadow does not appear until the hollow lower part of the ring HK is lit equally on both sides; for the shadow is narrower than the upper part of the ring HOK that casts it, since that part is lit by the Sun, which is far larger than the ring. And when it is lit on both sides, that is the sign of the apparent equinox. But if this passage does not appear by day through equal lighting on both sides, and if instead, in spring, on March 20 for example, the ring's shadow is northern until evening but southern on the following morning, it will mark an equinox that occurred in the night between the 20th and the 21st. In autumn, if the shadow was southern in the evening, say on September 22, and northern on the following morning, it will indicate an equinox that occurred in the night between the 22nd and the 23rd, at least apparently. And from the size of the part lit you will infer the hour of the equinox: if the evening lighting was equal to the morning lighting, it will indicate an equinox at midnight; if unequal, beyond or short of midnight, according to the proportion of the excess.

[Margin: The fallacy of rings, unless it is corrected.]

VIII. I said *apparently*, because two things vitiate this practice unless they are corrected. The first is the parallax of the Sun. For the equinoctial ring HOKM is not concentric with the centre of the Earth, but has its centre on the Earth's surface. Parallax therefore hastens the autumnal equinoxes and retards the vernal ones, by showing us the Sun lower than if it were viewed from the centre of the Earth. So from a vernal equinox observed in this way one must subtract as many hours, or minutes of an hour, as the minutes or seconds of the Sun's parallax proper to that altitude; for an autumnal one they must be added. Granted that, as *Lansbergen* judged in Class 2 of his solar observations, *Ptolemy* omitted this correction, let alone *Hipparchus*.

The other and greater fault comes from refraction, which, by raising the Sun in appearance, hastens the vernal equinoxes and retards the autumnal ones. And it sometimes causes the lower hollow of the ring to appear lit equally on both sides twice in the same day: either first in the morning near sunrise and then around noon, when, the refraction having ceased, the truer vernal equinox occurs; or first around noon without refraction and afterwards near sunset because of refraction, when the autumnal equinox has already occurred.

[Margin: Ptolemy's faulty judgement of a fault in the rings.]

Ptolemy, Book 3, Chapter 2, relates that this happened both to Hipparchus, who was astonished at it, and to himself, and he attributes it to a fault in the ring, as having by then slipped from its original and proper placing. But that this was the effect of refraction is the better judgement of *Longomontanus*, Book 1 of the *Theorica*, Chapter 1, p. 172, *Boulliau*, Book 2 of the *Astronomia Philolaica*, Chapter 2, and *Kepler* in the *Astronomia Optica*, p. 146, who adds there that the same thing happened to *Tycho* while he was observing equinoxes by rings, so

that, the ring being lit equally on both sides twice in the same day, the equinox seemed to occur twice.

But from this way of observing, as *Ptolemy* reports, *Hipparchus* was content to assign the equinoxes only to the cardinal points of the day, namely noon, midnight, sunrise and sunset, and felt sure that he had admitted no error of 6 hours; whereas because of refractions he could sometimes have admitted a greater error, indeed up to almost half a day, if we believe *Longomontanus* above.

[Margin: A method of correcting equinoxes observed by rings.]

IX. Nor shall I pass over in silence the method of correcting the error that has crept, through refractions, into equinoxes observed in this way around sunrise or sunset (for I spoke above about the correction for parallax). *Boulliau* indicates this method in the place already cited. It assumes that the time of the observation made is known, say a quarter of an hour after sunrise or before sunset. For that time one seeks, from the altitude of the equator, the true altitude of the Sun; from the tables of refractions, the refraction proper to that altitude; and from this, by the general problems, the refraction of declination. On these problems we treat in the Optical Book, in the section on the refractions of stars in the air, and perhaps in the Book of Universal Problems. As many minutes as there are in the refraction of declination, so many hours are to be added to the apparent vernal equinox, and subtracted from the autumnal.

As for Hipparchus's equinoxes observed by rings, however, which we need, as being the most ancient, for tracing the length of the tropical year, two are more notable, one vernal and the other autumnal, observed at noon or very close to it, and so beyond the hazard of perceptible refraction. Of these the vernal one appeared twice to Hipparchus: once in the morning, when the ring was lit equally on both sides because of refraction, and again around the 5th hour of the day, when the refraction had ceased. But if he had observed the autumnal one in the evening, he would likewise have seen the ring lit again on both sides because of refraction, and not only at noon. In all there are nine equinoxes of Hipparchus observed in this way, reported by Ptolemy in *Almagest* Book 3, Chapter 2. The Ptolemaic ones, likewise observed by rings but at a more precise time, and reported by him in the same place, are 3. I choose to report these, for their antiquity, without any correction; for we must treat that at greater length in Volume 3 of the *New Almagest*.

Ptolemy's equinoxes observed in the same place. [Ptolemaica Aequinoctia ibidem obſeruata.]

[Margin: Equinoxes observed by Ptolemy, from the same, Book 3, Chapter 2.]

No.	Year of the Roman emperors	Year of Christ	Egyptian month	Day	Julian month	Day	Hours
1	Hadrian 17	132	Athyr	7	September	24	About 2 after noon
2	Antoninus 3	139	Athyr	9	September	25	About 1 after sunrise
3	Antoninus 3	140	Pachon	7	March	22	About 1 after noon

Modus 3. Obſeruandi Aequinoctia Per Inſtrumenta Certiora.

Method 3. Of observing the equinoxes by more reliable instruments.

[Margin: Which instruments are best for this.]

X. By more reliable instruments I mean either parallactic rulers [Regulas Parallacticas] or, better, quadrants or sextants, built with so fine a division that they show, if not each single second, at least each ten seconds, according to what is to be said in the *Liber Organicus*. With instruments of this kind, then, first take the altitude of the pole from circumpolar stars free from refraction, and so its complement to 90°, which is the altitude of the equator itself. Afterwards, on the days assigned to the equinox in the calendar, or better in some well-known ephemeris, the Sun's meridian altitude is to be taken. For greater certainty it is useful to take it with at least two instruments, one showing the Sun's altitudes directly and the other its distances from the zenith.

Next, the observed altitude of the Sun is to be corrected and converted into the true one by adding the parallax and subtracting the refraction, taken from

the tables we shall give at the end of the work. For if the Sun's true altitude is equal to the altitude of the equator, know that the equinox has certainly occurred at noon itself on your horizon. But if at the vernal equinox the Sun's true altitude is greater or less than the altitude of the equator, the equinox was away from noon: before it if greater, but after noon if less. At the autumnal equinox, on the other hand, it was after noon if greater, before if less. And as many minutes as there are in the difference of the altitudes, so great will be the Sun's true declination, and by so many hours before or after noon you will determine that the equinox has occurred or will occur.

If, however, one cares to be scrupulous, from the declination found, and from the angle of obliquity of the ecliptic opposite it, which for us is always 23½°, find by the rules of right-angled spherical triangles the base, that is, the Sun's distance from the equinoctial point. Then find in the tables of the Sun's mean motion the time corresponding to it, to be added to or subtracted from noon, so that you have the exact moment of the equinox. But in a matter of such moment the precept must be illustrated by an example.

EXEMPLVM. Modi 3.

Example of Method 3.

[Margin: Our most exact observation of an equinox.]

In the year 1646, on September 22 by the Gregorian style, together with Father Francesco Maria Grimaldi, I obtained with large quadrants at Bologna the Sun's meridian altitude of 45° 44′ 40″. So, adding my parallax, determined meanwhile elsewhere from the Sun's distance, which is almost 30″, and with no perceptible refraction detected at this altitude, the Sun's true altitude becomes 45° 45′ 10″. Subtracting from this the altitude of the equator, which I found in the same place more than forty times, 45° 30′ 30″, there remains the Sun's northern declination of 14′ 40″. From this, therefore, we deduced that the equinox would occur at 14^h 40^m after noon.

But from this declination, and from the obliquity of the ecliptic of 23½°, trigonometry gives the Sun's distance from the beginning of Libra as 32′ 32″, which the Sun completes by its mean motion in 14^h 56^m. So, more scrupulously, the equinox was at 14^h 56^m after noon on September 22. But *Lansbergen's* Tables give this equinox at Bologna at 15^h 54^m after noon, evidently because of a parallax greater than ours, set by Lansbergen on p. 46 of his Canons at 1′ 36″. On Tycho's reckoning, however, the parallax at this altitude would have been 2′ 5″, and so the equinox at 16^h and at least 15^m after noon.

By this method we have examined a great many meridian altitudes observed at the time of the equinox by notable astronomers, from Hipparchus down to ourselves, gathered with the utmost search and compared with our own, in order to establish the length of the tropical year. These, with the favour of God, Best and Greatest, we shall communicate to you in Volume 3 of the *New Almagest*. This method, moreover, is the simplest of all, and the most

evident, and for that reason this way of observing equinoxes is preferred to the others by *Regiomontanus*, Book 3 of the *Epitome of the Almagest*, Prop. 1; *Alessandro Piccolomini*, Book 1 of the *Theorica Planetarum*, Chapter 3; *Tycho*, *Progymnasmata* vol. 1, p. 14; *Longomontanus*, Book 1 of the *Theorica*, Chapter 2; *Lansbergen*, Classes 2 and 3 of his observations; *Biancani* in his *Sphaera*, Book 10, Chapter 5; and *Boulliau*, Book 2 of the *Astronomia Philolaica*, Chapter 2. Of these, *Regiomontanus* and *Tycho* prefer the autumnal equinoxes, because the temper of the air, more thoroughly baked out by the preceding heat, is less subject to refractions.

[Margin: The excellence of this method.]

[Margin: Autumnal equinoxes better for this than vernal ones.]

SCHOLIA.

Scholia.

[Margin: The ancients' opinion on the annual cardinal points.]

I. Since it is certain that the four cardinal points of the year [Anni Cardines] occur either at the common intersection of the equator with the ecliptic, namely the equinoxes, or at the contact of the ecliptic with the tropics, namely the solstices (that is, at the very beginning of Aries, Libra, Cancer and Capricorn, conceived in the rational and invisible zodiac), it is remarkable on what reasoning not a few of the ancients appear to have recognized these cardinal points at the 15th, or 8th, or 6th, or 4th parts, or degrees, of these signs. For if we believe the younger Hipparchus, or the Bithynian, in Book 2 of his *Commentary on the Phaenomena of Aratus and Eudoxus*, Eudoxus and Meton assigned these cardinal points to the middle parts of the signs, or the 15th degree. Columella, however, Book 9, Chapter 14, places them, on the opinion of the same men, at the eighth parts of the signs, which Manilius, Book 3, Chapter 2, and Pliny the Elder, Book 18, Chapter 28, also retained in their own age. Geminus, Chapter 16, on the opinion of Eudoxus, puts the summer solstice at the 6th part of Cancer, the winter solstice at the 4th of Capricorn, and the vernal equinox at the 6th of Aries; but on the opinion of Euctemon he puts the winter solstice and the autumnal equinox at the 1st part. Finally Ovid, *Fasti* 3, places the vernal equinox after the 4th day from the Sun's entry into the visible Aries.

Here it is incredible with what unreason [Greek: ἀλογι[?]ία (the sixth letter is σ or the στ ligature; "unreason, want of reckoning")] and clash of mutually conflicting statements Scaliger, in his books *De emendatione temporum* and in the *Diatriba on the Equinoxes*, and also Salmasius [Claude Saumaise], in his *Exercitations on Solinus*, have tried to reconcile these opinions. Longomontanus too, Book 1 of the *Theorica*, p. 175, thinks that Pliny the Elder is speaking of influences, which for the most part set in at the eighth degree of the signs. But the true view is the one explained by Stöffler on Proclus, pp. 17 and 18, by Reinhold on Peuerbach's *Theoricae*, p. 231, and by Pétau in the *Dissertations* of the *Uranologion*, Book 2, from Chapter 3 to 8, Book 3, Chapters 1 and 2,

and Book 6, Chapter 10, taken together, where much is said learnedly against Salmasius.

For the ancient astronomers and compilers of calendars, although they knew that the cardinal points of the year occur at the beginning of Aries, Libra, Cancer and Capricorn of the rational and invisible zodiac, nevertheless, in order to serve farmers, sailors, physicians and finally the people, said that these points occur at determinate degrees of the starry and visible zodiac, so that people might learn the times of the cardinal points from the very sight of the stars. Once, moreover, the cardinal points stood 15° from the beginning of the visible signs, which happened, if we go by Wendelen as cited in Pétau, around the year 1263 before Christ, but according to Tycho's table in the year 2600. Later, as the fixed stars advanced towards the east, the cardinal points stood 8° from the beginning of the asterisms (for Tycho, that is, or for Kepler in the Rudolphine Tables, around the year 900 before Christ), and at length the cardinal points reached 4°, 2°, and so on. Now, however, the beginnings of the visible asterisms lie further east than the annual cardinal points by 28° and more.

Now some were unaware of the proper motion of the fixed stars to the east, and thought that the cardinal points stayed forever at the same parts of the asterisms. Others knew of it, but, so as not to seem to disturb the calendars and to strive against the ingrained custom of the peoples with a subtlety not easily persuasive to the crowd, they preferred to accommodate themselves to the old calendars. This should not seem surprising, since even from the Council of Nicaea down to the year 1582 the Church calendars kept the equinox at March 21, although it had by then slipped back to the 11th. For hear Columella, Book 9, Chapter 14: "Nor am I unaware of the reckoning of Hipparchus, which teaches that solstices and equinoxes are completed not at the eighth but at the first parts of the signs. But in this discipline of husbandry I now follow the calendars of Eudoxus and Meton and of the ancient astrologers, which are fitted to the public sacrifices, because that old opinion, formed among farmers, is also the better known," etc. So that diversity arose from a catachresis and misuse of the signs of the two zodiacs, and from the divergence of popular usage from the true reckoning.

[Margin: Pliny the Elder's apparent contradiction on the days of the cardinal points.]

II. There remains another knot in Pliny the Elder, to be either untied or cut. For in Book 18, Chapters 25 and 28, he assigns the winter solstice [Brumam] to December 25 [VIII. Kal. Ianuarij] and the solstice to June 24 [VIII. Kal. Iulij]; yet in the same Chapter 25 he takes from Sosigenes a year of 365 days and a quarter, and puts from the winter solstice to the vernal equinox $90^{d}\ 3^{h}$, from there to the summer solstice $93^{d}\ 12^{h}$, and from the autumnal equinox to the winter solstice $89^{d}\ 3^{h}$, which makes a sum of $272^{d}\ 18^{h}$. When this is taken from the year, there remain from the summer solstice to the autumnal equinox $92^{d}\ 12^{h}$. But if these intervals are kept, the summer solstice and the autumnal

equinox ought to fall on June or September 25 or 26 [VII. aut VI. Kalendas Iulij, aut Octobris], and so Pliny the Elder seems to disagree with himself by an interval of two days. But if the surplus of hours is reckoned in, and the limits are taken inclusively on one side and exclusively on the other, the apparent contradiction will cease; Pétau's solution of it, in Book 2 of the *Uranologion*, Chapter 5, is somewhat more intricate.

Those intervals are therefore to be arranged as follows. From March 25 exclusive to June 25½ inclusive, $93^{d}\ 12^{h}$. From June 25½ exclusive to September 26 inclusive, $92^{d}\ 12^{h}$. From September 26 exclusive to December 24⅛ inclusive, $89^{d}\ 3^{h}$. From there, exclusive, to March 25 and 6 hours, $90^{d}\ 3^{h}$, disregarding some very small difference. Thus according to Sosigenes and Pliny the Elder there will have been from the beginning of Aries to the beginning of Libra 186^{d}, and from Libra to Aries $179^{d}\ 6^{h}$. But these intervals will come up for discussion again below, in Chapter 18, and some things were said in Chapter 14, nos. 1 and 2.

CAPVT XV.

Chapter 15.

De Methodo colligendi Quantitatem Anni Aequinoctialis, ſeu Tropici.

On the method of finding the length of the equinoctial, or tropical, year.

[Margin: Authors on the way of finding the length of the year.]

I. I find among the practitioners of the art four methods in all for investigating the measure of the celestial and natural year, whether it is called equinoctial or tropical. All or some of them are discussed by *Ptolemy*, Book 3, Chapter 2; *Regiomontanus* in the *Epitome of the Almagest*, Book 3, Props. 2 and 3; *al-Battānī*, Chapters 27 and 53; *Geminus* in the *Elements of Astronomy*, Chapter 6; *Nikolaus von Kues*, *On the Reform of the Calendar*; *Copernicus*, Book 2, Chapter 14, Book 3, Chapter 13, and Book 4, Chapter 4; *Tycho*, *Progymnasmata* vol. 1, Chapter 1; *Daniel Santbech*, *De Observatione*, Prop. 11; *Scaliger*, *De emendatione temporum*, Book 2, p. 109, and Book 4; *Pétau*, Book 7 of *De doctrina temporum*, Chapter 25; *Biancani* in his *Sphaera*, Book 10, Chapter 6; *Clavius* on the *Calendar*, Chapters 5 and 6; *Longomontanus* in the *Astronomia Danica*, Book 1 of the *Theorica*, Chapters 2 and 5; *Lansbergen*, Class 4 of his solar observations, towards the end; and *Boulliau*, Book 2 of the *Astronomia Philolaica*, Chapters 2 and 3.

Prima Methodus Colligendi Quantitatem Anni ex Anno Sydereo.

First method of finding the length of the year: from the sidereal year.

[Margin: Copernicus's view set out in his own words.]

II. The Babylonians once, as *al-Battānī* and *Ptolemy* indicate, and in imitation of them *Thābit ibn Qurra* and several Indians and Arabs, as *Nikolaus von Kues* attests, and finally *Copernicus*, Book 2, Chapter 13, considered that the measure of the year should be sought from the Sun's revolution to the same fixed star, that is, from the sidereal year, and that a treatment of the fixed stars should therefore be put before the treatment of the luminaries. "We have therefore thought that this view should be followed by us" (the words are Copernicus's) "because among our principles and hypotheses we have assumed that the sphere of the non-wandering stars is entirely immobile, and the wanderings of all the roaming stars are referred to it on equal terms. But let no one wonder why we have adopted this order, since Ptolemy in his great *Constructio* held that no account of the fixed stars could be given unless knowledge of the places of the Sun and Moon came first, and therefore judged that what concerns the fixed stars should be deferred until then. But if you understand this of the numbers by which the apparent motion of the Moon and Sun is computed, that view will perhaps stand. For Menelaus the geometer too determined most stars and their places from lunar conjunctions, by means of numbers." By this he means by tables of mean motions and then of true ones, by which the apparent motion of the luminaries is found; but this presupposes that the mean motions too are known beforehand, from the Sun's annual motion and the Moon's monthly one. He goes on as follows: "But we shall do much better if, with the aid of instruments, we take any given star by way of the carefully examined places of the Sun and Moon, as we shall presently teach. We are also warned by the vain attempt of those who thought that the length of the solar year should be defined simply from equinoxes or solstices, and not also from the fixed stars; on this they have never, right down to us, been able to agree, so much so that on no point has there been greater discord."

He then adds a way of observing with a quadrant the Sun's declination and the distance between the tropics, so that from the obliquity of the zodiac [Signiferi] and the Sun's meridian declination the Sun's place at noon becomes known, and from that its place at any given hour, since it covers about 2½′ on the ecliptic in each hour. He next directs that the distance of the Moon from the Sun be taken by astrolabe when the Sun is close to the horizon, and on the following night the distance of some fixed star from the Moon, and that so one arrives at knowledge of the fixed star's place, adding: "For without the Moon there will be no way of grasping the places of the stars, since she alone of all of them has a share in both day and night."

[Margin: Copernicus not altogether skilled in observing.]

In this he is mistaken: for Venus and Jupiter and Sirius are also seen in daytime, so that we ourselves have been able to take their distance directly from the Sun, as we shall relate among the observations in Volume 3; and Tycho determined the places of the fixed stars by way of Venus and the Sun, without the Moon.

But in Book 3, Chapter 13, after setting out the way of finding the length of the year from equinoxes, and the variation of the year arising from this, he goes on: "The equality of the solar year is therefore more correctly taken from the sphere of the non-wandering stars, as Thābit, son of Qurra, first discovered, and that its length is $365^d\ 6^h\ 9^m\ 12^s$," etc. And a little later: "So Ptolemy is not to be listened to on this point, who thought it absurd and irrelevant to measure the Sun's annual equality against any restitution of the fixed stars." And at length he adds: "But error can also occur about the *asteroterida*, or sidereal, year, though only in a small way and much less than the one we have now explained." But Tycho too, *Progymnasmata* vol. 1, p. 38, and Longomontanus, above, p. 178, support Copernicus in this, and call him a man of lofty judgement.

[Margin: The view of Hipparchus and Ptolemy defended.]

III. But surely of loftier judgement on this were *Hipparchus* and *Ptolemy*, who, in Book 1, Chapter 2, and Book 3, Chapter 1, judged that the treatment of the luminaries should be put before the treatment of the fixed stars, and that the mean length of the year should be found from the Sun's revolution, above all to the equinoctial points. For we cannot know the place of the fixed stars unless the Sun's motion is known beforehand, as *Copernicus* has already admitted; and *Tycho*, at the start of Chapter 2, acknowledges that "without a precise investigation of the Sun's course the places of the fixed stars, and without the fixed stars those of the other planets, cannot be established." Accordingly he defined the places of the fixed stars from the distances of the fixed stars from Venus and of Venus from the Sun, the Sun's place being known first.

Now the whole of that error which spills over from observing equinoxes into the measure of the equinoctial year can also be committed in any observation of the Sun's place from which the places of the fixed stars are to be defined, whether it arises from an uncertain solar parallax, or from refraction, or from a false altitude of the equator and pole, or from the obliquity of the ecliptic, or from the fallibility of instruments, or from carelessness in calculation. Further, even if the error or the inequality were smaller in the length of the sidereal year, when comparing a sidereal year with a sidereal year found by different authors, or a revolution of the Sun to the same star, say Regulus, made and observed after a long interval of time, nevertheless, in separating the equinoctial, or tropical, or temporal [Temporario] year from the sidereal, it is necessary to know beforehand, separately and antecedently to the sidereal, the Sun's revolution to the equinoctial points and its measure; for the Sun revolves to those points before it revolves to the same fixed star, and if there is any greater anomaly in this conjunction of the equinoxes with the Sun, it cannot be avoided by means of the equality of the sidereal year. Since, then, the sidereal year is composed of the Sun's revolution to the equinoctial points and of the motion by which, having passed those points, the Sun must overtake the same fixed star, there is no way that the length of the temporal year can be distinguished from the length of the sidereal year unless the length of the temporal year is known beforehand, separately from the sidereal.

But why say more? Neither *Copernicus*, nor *Tycho*, nor anyone else, so far as I know, has taught or could teach a practical way of separating the temporal year from the sidereal by the Sun's revolution to the same fixed star alone. And *Copernicus* indeed, in Book 3, Chapter 13, having said "For this reason the reckoning of the annual equality is neither simple nor easy to know," and having said much about this difficulty, in the following chapter, with no observation brought forward, as if the pronouncements of this second Pythagoras had to be believed without proof, says that he has found the length of the year, and its equality, which Thābit ibn Qurra published, to be greater by only 1″ 10‴ of a day, so that it is $365^{d}\ 6^{h}\ 9^{m}\ 40^{s}$. He then finds the Sun's simple mean motion and, adding the motion of the precession of the equinoxes, which in others is the motion of the fixed stars, finds the Sun's compound motion, both daily and annual. *Tycho*, by contrast, from a comparison of the equinoxes observed by *Walther* and by himself, first finds the length of the temporal year, and then, from the annual proper motion of the fixed stars, finds the sidereal year, which is composed of both.

So anyone who wishes to define the length of both years will run into two difficulties, one from the motion of the fixed stars or, as *Copernicus* prefers, from the motion of the equinoctial points, the other from the Sun's own motion and its revolution to the equinoctial points. But whoever inquires into the length of the temporal year separately has no concern with the motion or anomaly of the fixed stars. And it is the length of the temporal year that we are seeking here, because it is rather this that we need for defining the motion of the Sun and of the other planets; and this alone would stand even if there were no fixed stars in the heavens, and it is more observable, and more independently so.

[Margin: The Alphonsine method contrary to the Copernican.]

Let us then leave *Copernicus*, to whom *Alfonso* was opposed on another ground. For from the Sun's motion remaining to the quarter of a day he established the annual motion of the fixed stars at 26″ 26‴ 54⁗, which the Sun traverses in $10^{m}\ 44^{s}$ of time, exactly as much, that is, as it lacks of filling out a year of $365^{d}\ 6^{h}$. We depart from Copernicus the more willingly, the more evident or the more probable it is to us that the fixed stars rather than the equinoctial points move, that there is no anomaly in the motion of the former or of the latter, and that the temporal year is not unequal, at least not with as great an inequality as Copernicus supposed, as will be clear from what is to be said below in Chapter 30. Even granting that these were unequal, the inequality would be greater in the equinoxes than in the motion of the fixed stars.

Secunda Methodus Colligendi Anni Quantitatem ex Cyclis Lunæ ſimul & Solis.

Second method of finding the length of the year: from the cycles of the Moon and the Sun together.

[Margin: The year of Meton, Euctemon and Philippus.]

IV. Nearly all astronomers who held that the cycles and revolutions of the Sun and Moon are commensurable derived the length of the tropical year from the Sun's revolution to the equinoctial or solstitial points, but in such a way that they tested it against the syzygies of the luminaries, as against a Lydian touchstone. So Meton, Euctemon and Philippus, as *Geminus* relates in the *Elements of Astronomy*, Chapter 6, and *Censorinus*, *De die natali*, Chapter 7, defined the year as 365 and 5/19 days, as Geminus has it, or 365 days and five nineteenth parts of a day, as Censorinus does, which comes to the same thing, namely $365^{d}\ 5^{h}\ 18^{m}\ 56^{s}\ 51'''$. For they thought that in 19 years of 6940 days the lunations and the meetings of the Sun and Moon were restored exactly to the same moment; and 6940 divided by 19 gives 365 5/19 days.

[Margin: The year of Callippus.]

But *Callippus*, as *Geminus* relates in the same place, and *Ptolemy*, Book 3, Chapter 2, noticed that in four Metonic cycles, that is, in 76 years, there was one day too many and that new moons came one day sooner, and so he took one day from the 76 years, that is, from 27760 days, and his period was 27759 days. Divided by 76, these make for one year 365 and 19/76 days, that is, a quarter of a day, or 6^{h}. *Geminus* says that this measure of the year fits the appearances best, and so Archimedes, Aristarchus, Sosigenes and many others embraced it; although *Censorinus*, Chapter 7, says that the year of Callippus is 365 days, and that of Aristarchus the same and in addition the 1532nd part of one day, a passage which is surely convicted of an error by *Geminus* and *Ptolemy*.

But *Hipparchus*, comparing eclipses and equinoxes, found

[Margin: The year of Hipparchus.]

that in four Callippic periods, that is, in 304 years, there was one day too many, and so that from a year of $365^{d}\ 6^{h}$ the 304th part of a day, or in round terms the 300th, should be subtracted. Accordingly he set the tropical year at $365^{d}\ 5^{h}\ 55^{m}\ 12^{s}$. But if he had subtracted the 304th part, the result would have been $365^{d}\ 5^{h}\ 55^{m}\ 15^{s}\ 45'''$. So they wanted to hunt two hares with one leap: on the one hand the restitutions of new and full moons, on the other the revolutions of the equinoxes after fixed intervals of time. And since *Ptolemy* kept exactly the same length of the year as *Hipparchus*, and this is sufficiently gathered from *Ptolemy*'s Greek text, *Scaliger*, *Longomontanus* and *Boulliau* affirm for that reason that *Ptolemy* had regard to lunisolar cycles, and not only to equinoxes, in determining the length of the year, and *Copernicus* indicates the same, although *Pétau* denies it.

[Margin: The year of Rabbi Adda.]

But *Rabbi Adda* too, who flourished under Constantine the Great, held that in 19 years, but astronomical ones, the syzygies of the Sun and Moon return to the same part of the heavens and the same point, and that meanwhile 235 lunations are completed. So he took, with the most learned rabbis, a lunar month of $29^{d}\ 12^{h}$ and 793 points [punctorum], that is, $44^{m}\ 3^{s}\ 20'''$; he multiplied

it by 235, and dividing the resulting sum of $6939^{d}\ 16^{h}\ 33^{m}\ 3^{s}\ 20'''$ by 19, he found a year of $365^{d}\ 5^{h}\ 55^{m}\ 25^{s}\ 26'''\ 20''''$, as is given in the Hebrew calendar of Rabbi Adda, of Münster [Sebastian Münster] and of others.

[Margin: The year of Meton, Philolaus, Oenopides and Democritus.]

By a similar method *Meton*, *Philolaus*, *Oenopides* and *Democritus* gathered the measure of the year from cycles of the luminaries, as I shall show in Book 4, Chapter 20, nos. 6, 7 and 9. But although observations of new moons, or rather, so that parallax may not interfere, of full moons, are made more easily and more certainly by way of eclipses, it has not yet appeared that two new moons or full moons have taken place at the same point of the heavens and at the same moment of the same day. And indeed, as *Boulliau* says in the passage cited at the beginning, "Who has yet demonstrated that the Sun's annual motion is commensurable with the lunar cycles?"

[Margin: The period of Viète.]

Not even the period of 3400 years which *François Viète* devised in his *Calendar* restores the turns of the Sun and Moon perfectly; rather it falls short by $1'\ 19''$, as *Kepler* says in the Rudolphine Tables, Precept 135. For this period to achieve it, the lunar month would have to be $29^{d}\ 12^{h}\ 44^{m}\ 3^{s}\ 10'''\ 43''''$ and a little more, "which has not yet been established by any observation," says *Clavius* in the *Calendar*.

Tertia Methodus Inueſtigandi Anni Tropici Quantitatem per Solſtitia.

Third method of investigating the length of the tropical year: by solstices.

[Margin: The unreliable observation of solstices.]

V. *Ptolemy*, Book 3 of the *Almagest*, Chapter 2, admits that the length of the tropical year is gathered from the Sun's revolutions to the same solstitial point not without danger of error, in these words: "For the sake of antiquity, therefore, the summer solstices observed in the times of Meton and Euctemon, and afterwards of Aristarchus, are to be compared with those which took place in our own times. But since observations of solstices are hard to discern, and those which these men handed down do not seem to have been taken exactly, which is also confirmed by the judgement of Hipparchus, we have passed over them." *Copernicus*, Book 3, Chapter 13, affirms however that *Callippus* too and *Archimedes* used summer solstices for this, because they took the beginning of the year from the summer solstice, after the manner of the Athenians. But how easy it is to slip in solstices and to err, not merely by a quarter of a day, as *Ptolemy* thought, but by a whole day or even whole days, I have already shown in Chapter 14 at the end of no. 4, and so I shall add no further word on them here.

Quarta Methodus Inueſtigandi Anni Tropici Quantitatem per Aequinoctia.

Fourth method of investigating the length of the tropical year: by equinoxes.

[Margin: Equinoxes to be preferred for this.]

VI. So we must at last take refuge in equinoxes, or in the Sun's revolution to the equinoctial points, if we wish to obtain the measure of the equinoctial year, as *Ptolemy*, Book 3, Chapter 2, *Regiomontanus* in the *Epitome*, Book 3, Prop. 1, *Tycho*, *Progymnasmata* vol. 1, p. 14, and the others mentioned at the start of the chapter have advised. So that this method may be carried out clearly and exactly, the precepts must first be given one by one, and then illustrated by one or two examples. These, then, are to be the precepts.

[Margin: Precept 1.]

1. Choose two vernal equinoxes or, which would be better, two autumnal ones, observed by two highly skilled astronomers and separated from each other by the greatest possible interval. For speaking of this very thing, *Ptolemy*, Book 3, Chapter 2, says: "This restitution will be taken the more exactly, the longer and greater the time between the observations," etc. And he adds the reason: a small error lying hidden in a few years can turn out and show itself as large after a long time; but if the interval between the observations is large, a small error admitted in the length of the year will turn out smaller in fewer years. So *Longomontanus*, in the *Commentary on the Sun*, rightly denies that *Tycho* could have reached an accurate measure of the solar motion solely from the interval of a hundred years between Walther and Tycho himself. *Tycho*, however, chose so small an interval because he was not attempting a length of the year that would agree with all ages, and because he distrusted the observations of the ancients, as appears from him, *Progymnasmata* vol. 1, pp. 45 and 54.

[Margin: Precept 2.]

2. If each equinox was observed in a different horizon, reduce the time of one to the time of the other's horizon, by a proper table of the difference of longitude, or of the meridians, such as we shall give at the end of the work, drawn from our *Geographical Book* and reformed by way of various eclipses or the intervals of journeys.

[Margin: Precept 3.]

3. If the second equinox has been noted on a date according with the Gregorian calendar, take 10 days from the interval between the equinoxes.

[Margin: Precept 4.]

4. Although it is not strictly necessary, it is nevertheless very convenient to choose two equinoxes that have fallen either in a bissextile year or in years equally distant from the bissextile year immediately preceding.

[Margin: Precept 5.]

5. Subtract the time of the more recent equinox from the time of the older one, and the remainder will be the precession of the equinox. Resolve it

into the smallest fractions of time, and at least into minutes of an hour, and keep it as the number to be divided.

[Margin: Precept 6.]

6. Gather the whole Julian years, with the remaining days, hours and minutes, that have passed from the old equinox to the recent one, but so that those days, etc., count as one whole year, and keep the sum of these years as the divisor.

[Margin: Precept 7.]

7. Divide the precession of the equinox, as in Precept 5, resolved into fractions, by the sum of the years, as in Precept 6, and there will come out the precession of the true equinox ahead of the equinox of the Julian year, or the difference by which the year of Sosigenes, of $365^{d}\ 6^{h}$, exceeds the true temporal year. This, then, subtracted from the year of Sosigenes, will leave the true length of the equinoctial, or tropical, year, but derived from true equinoxes, when it ought to be from mean ones. Hence the eighth precept.

[Margin: Precept 8, where note the depth of astronomical science.]

8. The length of the year drawn out in the way already mentioned would be perfectly right if the Sun's motion were equal; or if, though unequal, both equinoxes occurred at points of the anomaly, or of the distance from the apogee, at which the prosthaphaeresis, or equation, was either nil or equal and of the same kind, that is, both subtractive or both additive. But this cannot happen exactly unless the interval from one equinox to the other is so great that the Sun's apogee, having completed its revolution through the zodiac, has returned to precisely the same point; and for this restitution about 21000 years are required, as will be clear from what is to be said in Chapter 25. Yet 6000 years have not so far elapsed since the beginning of the world. And within this very interval we have no observed equinoxes, at least none extant, older than those of Hipparchus. So each true and apparent equinox must be reduced to the mean equinox, and the rest carried out as above.

[Margin: A vicious circle in astronomy, but an apparent one.]

But this reduction needs knowledge of the prosthaphaeresis, and that needs the eccentricity and the place of the Sun's apogee, as will be clear from what is to be said from Chapter 19 to 21. Yet the eccentricity and the place of the apogee cannot be investigated unless the Sun's mean motion is already known beforehand, as will be plain from the method to be given in Chapter 24. So we seem to fall into a vicious circle, and to be seeking the unknown through the unknown. *Copernicus*, Book 3, Chapter 13, saw this knot, but he untied it by asserting that it is enough, for investigating the solar equations by means of the eccentricity and apogee, to use a length of the year of $365^{d}\ 6^{h}$: "Since what differs so little from the whole circle vanishes entirely when taken up in a smaller magnitude," he says. But *Tycho*, *Progymnasmata* vol. 1, p. 12,

denies, indeed, that the Sun's mean motion, *known with exact precision*, is required for investigating the eccentricity and apogee; but he nevertheless assumes for this purpose a tropical year of $365^{d}\ 5^{h}\ 49^{m}$, and on this supposition, as far as p. 51, he investigates the Sun's apogee and the eccentricity suited to both times, those of the equinoxes observed by Walther and by himself. *Boulliau*, however, in Book 2 of his *Astronomy*, Chapter 1, begins from the investigation of the aphelion and the eccentricity, assuming the Tychonic tropical year and its mean motion.

I, for my part, do not think that one should, out of order, take on at this point as much labour as we shall show in Chapter 24 is required for twice investigating the eccentricity and apogee, for the two equinoxes. It is enough, rather, to use an apogee and eccentricity already found by more expert men, even if it were not exactly true; indeed, to use tables of equations, Tycho's for instance, assuming the place of the apogee handed down by Hipparchus or Ptolemy or whoever it may be whose anciently observed equinox we are going to use. For what Copernicus and Tycho say about the length of the year to be assumed here, I say about the Sun's equation and the place of the apogee: namely, that a modest difference vanishes completely in so great an interval. Or at any rate the precept about investigating the eccentricity and apogee must be put off to another place, so that the order and the imagination of beginners are not disturbed; and afterwards, from there, the final polish must be applied to the length of the year derived here from true equinoxes, by reducing each true equinox to the mean equinox, and deriving the precession from the interval between the mean equinoxes, as above.

EXEMPLVM. Methodi 4.

Example of Method 4.

VII. Ptolemy reports, in Book 3, Chapter 2, of the *Magna Syntaxis*, that Hipparchus observed the autumnal equinox with the Alexandrian armillae in year 20 of the third period of Callippus, on the first of the intercalary days, in the morning about sunrise. And not only is it said τῇ πρώτη ἐπαγομένων [Greek: tē prōtē epagomenōn, "on the first of the intercalary days"]; in another manuscript codex as well, which Boulliau cites from the Royal Library at Paris, and in the Basel edition, there is added τῇ νεομηνία ἐπαγομένων [Greek: tē neomēnia epagomenōn, "at the new moon of the intercalary days"], that is, at the new moon of the intercalary days. Moreover, from our Chronological Book and among all those expert in chronology, that year was, in the Julian form, the current year 159 before Christ, and September 27 was to begin, in the astronomical manner, from the following noon. When Hipparchus observed the equinox, September 26 was still running, begun at the preceding noon, and 18 hours of it had passed. It was also the civil new moon, and the Moon's first phase had appeared the previous evening, although the true new moon had occurred two days before. This is indeed a notable chronological mark of

the truth of this year. But I posit, from what will be said in Scholium 1, that the equinox was at 18^h $11¼^m$ after noon on the 26th; for I shall establish in the Scholia that refraction is not to be taken into account here.

I, however, at Bologna in the year 1646, observed the autumnal equinox most accurately, as I have already recounted at the end of Chapter 13. It fell with September 22 completed according to the Gregorian calendar, but the 12th according to the Julian, at 14^h 56^m after noon. Now Bologna, as I have shown in the Geographical Book, lies further west than Alexandria in Egypt by 1^h 43^m. So the Hipparchan equinox was at Bologna at 16^h $28¼^m$ after noon on September 26. Again, as is clear from our Chronological Book, the year 159 before Christ, like the year 1646 after Christ, was the second after the preceding leap year. So if the year were 365 days and 6 hours, the equinox should have fallen in the Julian year on September 26, at 16^h $28¼^m$ after noon at Bologna. But it came earlier, and was on the 12th, at 14^h 56^m after noon. So, with the 12 days etc. subtracted from the 26 days etc., the precession was 14^d 1^h $32¼^m$, which resolved into seconds of time is 1215135 seconds. Now from the Hipparchan equinox to ours there are 1803 full Julian years, 350 days, 21^h 59^m; if the precession already mentioned were added to these, they would make 1804 years. Say, then: if in 1804 Julian years the precession of the equinox, taken according to the true year, is 14^d 12^h 1^m[16], or was 1215135 seconds, in one Julian year how great is the precession? Evidently, dividing 1215135 by 1804 yields a precession of 673 1043/1804 seconds of time, that is, 11^m 13^s $34‴$, etc. When these are taken from the year of Sosigenes, that is, from 365 days and 6 hours, there remains an equinoctial, or tropical, year of 365^d 5^h 48^m 46^s $32‴$.

[Margin: Delimiting the year from mean equinoxes.]

Now in Hipparchus's time the Sun's apogee was at about 6° Gemini, as is plain from Ptolemy, Book 3, Chapter 1; and so the Sun at the beginning of Libra was 114° from the apogee. To this anomaly there answers, in the tables of Tycho's equations, an equation of 1° 54′, but in ours 1° 50′, to be added to the true place so that it comes out mean at the equinox. So by my prosthaphaeresis, at the time of the true equinox, the Sun's mean place was at 1° 50′ of Libra. But the Sun in its mean motion runs through 1° 50′ in 44^h 30^m 8^s. So the Hipparchan mean equinox was at Bologna on September 24 at 19^h 58^m 7^s after noon. But in the year 1646 the Sun's apogee was at 7° Cancer, by what will be said in Chapter 24; so at the beginning of Libra the Sun was 83° from the apogee. So the equation, given my eccentricity, on which see Chapter 24, was 1° 56′, to which the Sun's motion in 46^h 56^m answers. So the mean equinox was on the 10th at 16^h 0^m after noon. So from the Hipparchan equinox to ours the precession was 14^d 3^h 58^m 15^s, which resolved into seconds is 1223895 seconds; and this, divided by 1804, gives an annual precession of 678 783/1804 seconds, or

[16]so printed; the value given a few lines above is 14^d 1^h $32¼^m$, and it is that value which amounts to 1215135 seconds

11^m 18^s 26‴. Subtracted from the year of Sosigenes, 365^d 6^h, this gives a tropical year of 365^d 5^h 48^m 41^s 34‴.

EXEMPLVM SECVNDVM. Methodi 4.

Second Example of Method 4.

VIII. Because Hipparchus's equinox may appear suspect on account of refraction, since it seems to have been observed in the morning around sunrise, I therefore take the equinox of the following year, which is free of this suspicion, having been observed at noon, and which Boulliau, Book 2, Chapter 2, therefore rightly preferred. So, as Ptolemy reports in Book 3, Chapter 2, Hipparchus observed at Alexandria the autumnal equinox in year 21 of the third Callippic period, which was the year 158 before Christ, on the first intercalary day, namely September 27, at noon itself; for then the lower concavity of the armilla appeared equally lit on both sides. But on account of my parallax of 30″ it was on the 27th at 0^h 30^m; and it was the third year after a leap year. At Bologna, however, that equinox was at 22^h 47^m, with September 26 completed. We, at Bologna in the year 1643, likewise the third after a leap year, observed the equinox most accurately with September 22 completed, at 22^h 25^m after its noon. But in the Julian manner and old style it was the 12th at 22^h 25^m. So the precession was 14^d 1^h 22^m, or 1214520 seconds. This, divided by the 1800 whole years between these equinoxes, if the precession did not detract from their wholeness, gives an annual precession of 674 1320/1800 seconds, or 11^m 14^s 43‴. Taken from 365 days and 6 hours, this leaves an equinoctial year of 365^d 5^h 48^m 45^s 17‴.

Moreover, the apogee in Hipparchus's time was at about 6° Gemini, and in the year 1643 at about 7° Cancer. From these places there comes an equation to be added to the Sun's true place: there 1° 50′, here 1° 56′, as I said at the end of the preceding example. So the difference is 6′, by which our mean equinox preceded our true one further than Hipparchus's mean preceded Hipparchus's true; that is, by 2^h 56^m. So the whole precession over the interval of 1800 years was 14^d 4^h 18^m, or 1225080 seconds, which divided by 1800 gives an annual precession of 680 1080/1800 seconds, or 11^m 20^s 37‴. When this is subtracted from the year of Sosigenes, 365 days 6 hours, there is left a length of the tropical year of 365^d 5^h 48^m 39^s 23‴. And by choosing roughly the mean between this and the length in the preceding example, the length of the tropical year will be 365^d 5^h 48^m 40^s. We shall retain this, as derived from the very long interval of 1804 or 1800 years, in accordance with Ptolemy's advice, Book 3, Chapter 2, and with a parallax applied not gratuitously but drawn from our own observations.

IX. The following table, moreover, has been compiled from the authors listed in number 1, to whom are to be added Censorinus

[Margin: Authors on the length of the year.]

Chapter 7 of *De die natali*, where he reports the opinions of Ennius, Harpalus, Aphrodius, Philolaus and Oenopides; Africanus in his fragments; Rabbi Adda and Samuel in the Hebrew calendar; Isaacius Argyrus [Isaac Argyros] in the *Computus Ecclesiasticus*; Dante, in Mazzoni, Book 3 of the *Defence*, Chapter 26; Pitati in the preface to the *Ephemerides*; the Alphonsine Tables; Reinhold in the Prutenic Tables; Magini in the *Theorica Solis*, Chapter 10; Mästlin, cited by Clavius in Chapter 6 of the *Calendar* and by Kepler in the *Epitome of Copernican Astronomy*, p. 341; Tycho, p. 53; Kepler in the Rudolphine Tables; Origanus, Volume 1 of the *Ephemerides*, Chapter 2; Govaert Wendelen in the *Idea of the Atlantic Tables*. Finally, the opinions of Meton, Euctemon, Aristarchus, Archimedes and Sosigenes are reported partly by Ptolemy, Pliny the Elder and Censorinus, partly by Geminus in the *Elements of Astronomy*, Chapter 6. That of the Persian mathematicians, who are called Gelalaei, is reported by Scaliger, Longomontanus and Boulliau. Leaving aside Philolaus's length of 364½ days, the rest set it at 365 days with a surplus, as in the following table.

ANNI AEQVINOCTIALIS QVANTITAS est Dierum 365. & præterea.
The length of the equinoctial year is 365 days and, in addition:

SCHOLION.

Scholium.

If the Tychonic year and its annual precession beyond the year of Sosigenes are retained, and in the year 158 before Christ the autumn equinox was at noon itself, or half an hour after noon on the 27th at Alexandria, then in the year 159 it was on September 27, $5^h\ 18^m\ 45^s$ before noon, that is, after noon on the 26th at $18^h\ 41^m\ 15^s$. So Hipparchus was not wrong to conjecture, from his armillary observation of the preceding day, that the equinox would come the following morning about sunrise. From this I gather that he determined the equinox from noon observations, and that on the 26th he saw the northern concavity of the armilla lit four times as much as the southern concavity on the 27th, and so that the Sun crossed the equator after about three quarters of a day. For if he had determined it from an observation near the horizon, refraction would have delayed the equinox by more than 6 hours. So the true equinox would have been before 12^h after noon on the 26th, and thus between this and the equinox of the following year, which occurred at noon itself, there would have been 365 days and more than 12 hours, which is a manifest absurdity. So let us keep, as is proper, the equinox of the year 158 on the 27th at $½^h$ after noon, since no refraction intervened: then even if the year of Sosigenes of 365 days and 6 hours were retained, the equinox in the year 159 before Christ could not have happened before 18^h after noon on the 26th. But since, from the better opinions, as above, the greatest year is $365^d\ 5^h\ 55^m$ and the least $365^d\ 5^h\ 42^m$, leaving seconds aside for now, the equinox of the year 159 could not have occurred either earlier than $18^h\ 35^m$ or later than $18^h\ 48^m$ after noon on the 26th. The time midway between these was $18^h\ 41^m\ 30^s$, or, keeping the Tychonic precession, 15^s. On these foundations, then, we have established that

Hipparchan equinox from the equinox of the following year and from many others, from which the greatest and the least among the probable measures of the year have confirmed its mean length for us.

CAPVT XVI.

Chapter 16.

De Quantitate Anni Syderei.

On the length of the sidereal year.

[Margin: What the sidereal year is.]

I. The sidereal year is the Sun's revolution from a given fixed star back to the same fixed star. It consists of the equinoctial year and, in addition, that surplus of time which is required for the Sun, having passed the equinoctial point, to catch up with the same fixed star, which has advanced eastward in one year. Three things, therefore, are required for determining the length of the sidereal year: namely, the mean length of the equinoctial year, if you think the years unequal, or the single true length if you do not; next, the annual motion of the fixed stars along the zodiac eastward, on which see the book on the fixed stars; and finally, the time in which the Sun in its mean motion can get past the small part of the zodiac completed by the fixed stars in their annual motion, which is derived from the tables of the Sun's mean motions. The Alphonsines, however, determined the sidereal year from 1000 jubilees, or 49000 years, in which the fixed stars would complete the zodiac, and from the surplus of the tropical year remaining up to a quarter of a day. It should be noted, though, from the Rudolphine Tables, p. 115, that 25411 sidereal years are equal to 25412 tropical years. But according to Wendelen in the *Idea of the Atlantic Tables*, 25519 sidereal years equal 25520 tropical years. It is not yet certain, however, that these are commensurable. Now let there be a synopsis of selected opinions on the sidereal year.

[Margin: Authors from whom the sidereal year is drawn.]

II. The authors in whom I have found the measure of the sidereal year are Ptolemy, Book 3, Chapter 2, and Book 7, Chapter 3; al-Battānī, Chapters 27 and 51, who also touches on the opinion of the Babylonians and Egyptians; Cardinal Nikolaus von Kues, *On the Reform of the Calendar*, where he reports the opinion of the Indians and of Avraham ibn Ezra; Copernicus, Book 3, Chapter 14, who adds the view of Thābit ibn Qurra; Reinhold in the Prutenic Tables; Magini in the *Theorica Planetarum*, Book 1, Chapter 4, and in the same work on the Sun, Chapter 10; Giuseppe Moletti in the *Gregorian Calendar*, Canon 7; Tycho, *Progymnasmata* vol. 1, p. 44; Longomontanus, Book 1 of the *Theorics*, Chapter 5; Kepler in the *Epitome of Copernican Astronomy*, p. 713, but otherwise from the motion of the Sun and the fixed stars in the Rudolphine Tables; Lansbergen, from p. 101 of the tables and p. 160 of the *Thesaurus of Observations*; Boulliau in the motion of the Sun and the fixed stars. We, however, from a tropical year

of $365^{d}\ 5^{h}\ 48^{m}\ 40^{s}$, and from an annual motion of the fixed stars of 50″, which the Sun completes in its mean motion in $20^{m}\ 17^{s}\ 25'''$ of hours.

ANNI SYDEREI QVANTITAS est Dierum 365. & præterea.

The length of the sidereal year is 365 days and, in addition:

CAPVT XVII.

Chapter 17.

De Motu Medio Solis Annuo, Diurno, &c. ex Tropico Anno Eliciendo, & in Tabulas Distribuendo.

On deriving the Sun's mean annual, daily, etc. motion from the tropical year, and arranging it in tables.

I. This is done by the rule of proportions, by reducing to the smallest parts, but of the same kind, first the tropical year, which is to be set as the divisor; then the zodiac, which stands in second place in the rule of three; and finally either the common civil year of 365 days, if you seek the annual motion, or the day, if you seek the daily motion. For when the small parts of the zodiac are multiplied by this, the total, divided by the small parts of the tropical year, will give what you seek. Now the zodiac resolved into seconds is 1,296,000″, while one common year is 31,536,000 seconds, and one natural day 86,400 seconds. Multiplying the seconds of the zodiac by these gives the total to be divided: there, 40,870,656,000,000 from the product with the year; here, 111,974,400,000 from the product with the day. It remains, then, for the tropical year to be resolved into seconds, according to the opinion you prefer to follow.

EXEMPLVM.

Example.

II. For me the tropical year is $365^{d}\ 5^{h}\ 48^{m}\ 40^{s}$, that is, 31,556,920 seconds. Dividing by these the total made from the product of the common civil year by the zodiac, which is 40,870,656,000,000, the quotient is 1,295,140 26631200/31556920 seconds. That is, $11^{s}\ 29^{\circ}\ 45'\ 40''\ 50'''\ 38''''$; and that is the Sun's mean motion belonging to one civil and common year of 365 days.

III. Again, dividing by 31,556,920 seconds the total made from the product of the zodiac by the day, which is 111,974,400,000, the quotient is 3548 1045/3156 seconds, that is, $59'\ 8''\ 19'''\ 51''''\ 46^{v}\ 20^{vi}$. This, then, is the Sun's mean motion belonging to one day. Dividing it by 24 hours yields the hourly motion, $2'\ 27''\ 50'''\ 50''''$; and dividing this by 60 gives the motion belonging to one minute of time, namely $2''\ 27'''\ 50''''\ 50^{v}$. But note, with Tycho, *Progymnasmata* vol. 1, p. 52, that the tables of hourly motion do not exactly contain the measure of the equinoctial year, because of tiny fractions finally neglected. So from the multiplication or aggregation of this motion you will not rightly gather the annual length. By this device, then, the table of the Sun's mean motion is constructed; let a sample of it stand here.

CAPVT XVIII.

Chapter 18.

De Interuallis inter Quatuor Anni Cardines, & de Annua Motus Solis Inæqualitate.

On the intervals between the four cardinal points of the year, and on the annual inequality of the Sun's motion.

[Margin: Arguments for the inequality in the Sun's motion.]

I. Although in astronomical tables the Sun's motion, like that of the other planets, is feigned to be equal and uniform, the motion that truly and in fact appears to us observing it from the Earth — and which is therefore called at once the True and the Apparent motion — is unequal and non-uniform, since in equal times the Sun completes unequal arcs of the ecliptic. This is plain from the meridian altitudes and declinations observed before Hipparchus and from then on by all astronomers, and it cannot be denied by any evasion, or by shifting the blame onto the observers, except perhaps by the most ignorant. Certainly this is how it was found to be by al-Zarqālī the Spaniard, with more than 400 observations; by Regiomontanus and Bernhard Walther, with more than 800; by the mathematicians of the Landgrave of Hesse, by Jacob Christmann and by Tycho, with far more; and finally by ourselves, with so many observations that there is scarcely a day of the year without its own observation to answer to it. From all these taken together it appears that in one semicircle of the ecliptic the Sun is faster than its mean motion and covers in one day more than 59′ 8″ etc., so that when it is fastest it completes 61′ and more in one day; whereas in the other semicircle it is slower, and when it is slowest it barely traverses 57′ of the ecliptic in one day.

II. But this inequality appears most evidently in the intervals of time in which the Sun traverses the four quadrants of the ecliptic, or the two semicircles, namely the northern and the southern; for it crosses these equal arcs in far from equal times. Indeed, from observation of the equinoxes it is established that the Sun spends 186 or 187 days in the northern semicircle, that is, from the start of ♈ through Cancer to the start of ♎; but in the southern semicircle, from the start of ♎ through Capricorn to the start of ♈, only 178 or 179 days.

[Margin: A most powerful argument for the inequality.]

Moreover, from Hipparchus to al-Battānī and beyond, it lingered more days or hours in the first quadrant of the ecliptic than in the second, in the 2nd more than in the 4th, and in the 4th more than in the 3rd; so that it lingered more days in the ascending semicircle — that is, the one from the start of Capricorn to the start of Cancer through Aries — than in the descending semicircle of the

ecliptic, which runs from the start of Cancer through Libra all the way to the start of Capricorn. But from observations from about the year of Christ 1400 up to the present it is evident that the Sun lingers longer in the 2nd quadrant of the ecliptic than in the first, in the first than in the 3rd, and in the 3rd than in the 4th; so that it now lingers longer in the descending semicircle than in the ascending. Astronomers attribute this difference to the Sun's apogee, on the ground that it produces longer stays of the Sun in the quadrant or semicircle of the ecliptic in which it lies; so much so that if it ever happened that the apogee was in the last quadrant of the ecliptic, or if it will ever be in the 3rd, the Sun will also have lingered, or will linger, more days or hours in the southern semicircle.

III. And although astronomers do not agree on the measure of these intervals, even when observed in the same century, they do agree on what I have said so far. Both points will be clear from the four small tables below, which are collected from the authors indicated in them and from observed solstices and equinoxes, according to the rules indicated in Chapter 14, whose scholia on the annual cardinal points should be re-read. And when Copernicus, Book 4, Chapter 21, teaches that the Sun's true hourly motion is to its apparent diameter roughly as 5 to 66, he presupposes the same anomaly.

CAPVT XIX.

Chapter 19.

De Hypothesibus Antiquis, quibus excusatur, seu explicatur Inæqualitas apparens in motu Solis Annuo.

On the ancient hypotheses by which the apparent inequality in the Sun's annual motion is excused, or explained.

I. To the Peripatetics, in the books *De caelo*, to Ptolemy in Book 3, Chapter 3, to Copernicus in Book 3 from Chapter 15, and to many others, it seems absurd that a celestial body, especially the Sun, should move unequally in its own circle and about the centre of its own circle. Astronomers therefore, considering the cause of the apparent inequality discussed in Chapter 18, attributed it to a difference of circles and centres. From *theoria*, or their contemplation, they called the figures of these *Theoricae*, and, from the supposition of the motion described by them, *Hypotheses*.

[Margin: What are the Theorics and Hypotheses of the planets?]

Now the ancients have two hypotheses, or theorics, of the Sun's motion, equivalent to one another as regards very many properties. The first works by way of an ecliptic of the solar heaven that is concentric with the world, or with the Earth's centre, but carries the centre of a small circle called the epicycle, on whose periphery the Sun moves. The second works by way of a circle eccentric to the centre of the world. On these, and on their equivalence: Ptolemy, Book 3, Chapter 3; al-Battānī, Chapter 28; Geber [Jābir ibn Aflaḥ], Book 3 of the *Astronomy*; Peuerbach in the *Theorica Solis*, and on that work Nonius, Osualdus [Erasmus Oswald Schreckenfuchs], Reinhold and Vurstitius [Christian Wurstisen]; likewise Copernicus, Book 3, Chapter 15; Maurolico, *Cosmographia*, Dialogue 3; Alessandro Piccolomini in the *Theorica Planetarum*, from Chapter 1 to 13; Regiomontanus in the *Epitome of the Almagest*, Book 3, Proposition 4; Longomontanus in the *Astronomia Danica*, Book 1 of the theorics, Chapter 2; Kepler in the *Commentaries on Mars*, Chapter 2; Biancani, Book 10 of the *Sphere*, Chapter 8. Yet only the eccentric was used by Nonius (above); Fernel, *Cosmotheoria*, Book 1, Chapter 7; Magini in the *Theorica Solis*; Clavius at the end of the *Sphere*; Barozzi, *Cosmographia*, Book 4, p. 250; Tycho, *Progymnasmata* vol. 1, Chapter 1; Lansbergen in the planetary *Theoricae*, Chapter 1; and Hérigone, vol. 5, in the *Theoricae*, Book 1, Chapter 4, Proposition 3. And all of them, except Longomontanus, prefer the eccentric to the concentrepicycle [Concentrepicyclus]. Both hypotheses must now be set out.

De Concentrepicyclo.

On the concentrepicycle.

[Margin: What are a concentric, an epicycle, and a concentrepicycle?]

II. In the theorics of the planets a concentric circle, in Greek [Greek: κύκλος ὁ μό κεντρος (kyklos homokentros, "concentric circle")], is a circle having the same centre as the centre of the world. An epicycle, on the other hand, is a circle, usually smaller, attached to the circumference of a larger circle, or having its centre on the circumference of another circle. Now if the circle carrying the epicycle is concentric with the world, the aggregate of these is called a concentrepicycle.

Let the centre of the world — and, as most suppose, of the Earth — now be at C, and from it let the circle BMRNB be described, concentric with the world. On its periphery let the centre B lie, and from B let the little circle AGFE be described as the epicycle, to which the little circles KMRN are to be understood as equal. When the two straight lines AR and MN have been drawn, cutting each other at right angles at the centre C, AB will be the semidiameter of the epicycle, and BC the semidiameter of the concentric. BC must be as great as the Sun's mean distance from the Earth's centre, AC as great as its greatest distance, and CF as great as its least; and so AB is as great as the difference between the mean and the greatest distance.

Diagram. A large circle about the centre C, set into the right column with the text running down its left side. A vertical diameter runs from the small circle at the top, through F, C and P, to the small circle at the bottom; a horizontal diameter runs from the small circle at the left, through C, to the small circle at the right. Four small equal circles stand on the large circle at top, left, foot and right, and a fifth at upper left. From C straight lines run to the upper-left small circle, to the left small circle and to the right small circle, the upper-left and the upper of the two left-hand lines touching the small circles away from their centres.

- A (top, in the small circle's upper half): point on the epicycle
- G, E (left and right of the top small circle, outside it)
- B (inside the top small circle, at its centre): faint, read at magnification
- F (below the top small circle, on the vertical)
- D (above the upper-left small circle)
- Z (left of the upper-left small circle)
- K, I (inside the upper-left small circle, K left, I right)
- L (above the left small circle)
- M (inside the left small circle)
- V (above the right small circle)
- N (inside the right small circle)
- C (the centre)
- P (above the bottom small circle, on the vertical)
- Q (right of the bottom small circle)

• R (inside the bottom small circle)

Therefore, if the body of the Sun, fixed by its centre to the periphery of the epicycle, completes the whole epicycle in one year, or if the whole epicycle completes its revolution carrying the Sun around, the Sun will be once at A, the point of greatest distance from the Earth, which is called the apogee; once at P, the point of least distance, or at perigee; and twice at mean distance, namely at the points L and V. And so, in passing, an account is given of the Sun's apparent approach to the Earth and withdrawal from it.

[Margin: Theory of the Sun's distances.]

Now let the concentric move according to the succession of the signs, toward the east, from B to K, M, etc., with the Sun's mean motion, that is, completing equal arcs in equal times; and meanwhile let the epicycle move in the opposite direction, turning the Sun from A to E, completing its own arcs equal in equal times and physically similar to the arcs of the concentric. Thus when the centre of the epicycle has completed the quadrant of the concentric BM, from B to M, the Sun will have completed a quadrant in the epicycle and be at L; and when the centre of the epicycle is at R, the semicircle BMR of the concentric having been completed, the Sun will have completed a semicircle of the epicycle and be at P; and when the centre of the epicycle is at N, three quadrants of the concentric BMRN having been completed, the Sun will have completed three quadrants of the epicycle and be at V, etc. I said *physically*, because if the place of the apogee shifts in the order of the signs with a very slow motion, as below, when on the apogee [?], the epicycle's motion must be a little slower than the motion of the concentric; and when the concentric's point has returned from B to B, the apogee of the epicycle is not at A, but between G and A.

[Margin: Theory of the Sun's motion in the epicycle.]

With this hypothesis made, it is plain: when the Sun is on the line of apsides AP, that is, at apogee and perigee, there will be no difference between the mean motion and the true or apparent motion, and the Sun will be seen on one and the same line of mean place, B or R, and of true place, A or P. But as long as the centre of the epicycle is in the first semicircle of the concentric, BMR, and so the Sun is in the right-hand and first semicircle of the epicycle, AEF, the Sun will be seen further west than the centre of the epicycle, and therefore slower than the mean motion; whereas in the other semicircle it will be seen further east. And when it is at L, a little beyond the first quadrant of the epicycle, that is, at the point of contact where the line from the centre C touches the epicycle, the difference between the mean motion of the point M and the true motion of the Sun at L will be greatest, and is to be subtracted from the mean motion so as to leave the Sun's true motion in the ecliptic. Likewise it will be greatest, but to be added, at the point of contact V, for there the Sun will be further east than the point N, if the mean motion is to be converted into the true and apparent; for if the true is to be converted into the mean, it will have to be subtracted.

III. From what has been said it is plain how the Sun's motion, although in its own circle, can nevertheless appear unequal to us; how in the first semicircle of

each circle it seems slower than the mean motion, so that something must be subtracted from the mean motion to establish the true and apparent, or added to the true to obtain the mean; and how, conversely, in the other semicircle it is faster than the mean motion, so that something must be added to the mean if the mean is to be changed into the true, or taken away if the true is to be changed into the mean. This alternating addition and subtraction is called in Greek [Greek: προσθαφαίρεσις (prosthaphairesis, "addition-and-subtraction")], *Prosthaphærisis*, as if *Addidemptio*; but the Latins call either one an equation [Aequationem], additive or subtractive.

[Margin: The data required for finding the Sun's equation.]

To find it, four givens are required: 1. The Sun's mean motion. 2. The mean motion of the solar apogee, which, subtracted from the Sun's mean motion in longitude, will leave the Sun's mean motion from the apogee, that is, its mean distance from the apogee and the arc of the epicycle completed. 3. The Sun's mean distance from the Earth's centre, that is, the semidiameter or radius of the concentric. 4. The semidiameter of the epicycle, whether from the given distances of the Sun in the table of Chapter 7, or from what is to be said below on eccentricity, in Chapter 24, where the finding of the place of the Sun's apogee will also be treated. For the present, however, by a kind of prolepsis, we must assume these as if known. With these given:

[Margin: Problem for finding the Sun's prosthaphaeresis.]

Let the concentric's point be at K, and meanwhile let the Sun have come from A, that is, Z, to D. From the centre C let the line of mean motion CKZ be drawn, on which the Sun would be seen if the mean motion were being considered. Then let the line of true place and motion CD be drawn, on which the Sun truly appears to the eye at C, and let it be connected with the centre K by the semidiameter of the epicycle KD. For in the triangle CKD there are given CK, the Sun's mean distance, and KD, the semidiameter of the epicycle, in parts of the same kind, and the angle CKD, since by Proposition 13 of Book 1 of Euclid it is the complement to two right angles of the angle ZKD. That angle is known from the arc measuring it, ZD, that is, from the Sun's distance D from the epicycle's apogee Z. Therefore by trigonometry the angle KCD will not remain hidden, which measures the arc KI, namely the difference of the mean and true motion, or the desired prosthaphaeresis [Prosthaphæresim].

[Margin: How the greatest equation is to be found.]

IV. The greatest equation, or prosthaphaeresis, is gathered in the triangles CML or CNV, and indeed more easily, because they are right-angled at the contact L or V, by Propositions 16 and 18 of Book 3 of Euclid. It is therefore enough that the base MC, or the star's mean distance from the Earth, and the semidiameter of the epicycle ML be known; for from these is gathered the angle MCL, subtending and measuring the arc ML, which is the greatest prosthaphaeresis; and the angle NCV is equal to it.

De Excentrico.

On the eccentric.

[Margin: What is an eccentric?]

V. In the theorics of the planets an eccentric circle [Excentricus circulus] is a circle whose centre lies outside the centre of the world, and the distance of its centre from the centre of the world is called the eccentricity [Excentricitas]. Let us then explain, with a diagram added, how an account of the apparent inequality in the Sun's annual motion is given by a simple circle of this kind.

Let T be the centre of the Earth and of the supreme ecliptic, and let the ecliptic itself be the circle AMPQA, divided into four quadrants by the straight lines AP and MQ, cutting each other orthogonally at T; and let AP be the line of greatest and least distance. On it, taking the centre E, let the eccentric HIRN be described, so that its eccentricity is ET, and as great as the difference between the Sun's greatest distance from the Earth's centre, which is the line TH, and the mean distance, which is the radius of the eccentric EH. Let the Sun's apogee be at H, beneath the point A of the ecliptic, and the perigee at R, beneath the point P; and let the line of the apogee, or of the apsides, be HR in the eccentric but AP in the ecliptic.

Diagram. A large circle with an inner circle set within it, standing in the right column with the text running down its left side. A vertical diameter of the large circle runs from A at the top to P at the foot, and a horizontal diameter from M at the left to Q at the right, crossing at T. The inner circle's centre lies on the vertical above T. Through each of the points B, K, I and N on the inner circle a pair of straight lines runs out from the neighbourhood of the two centres to the large circle.

- A (top of the large circle)
- D, C (upper left, on the large circle, D above C)
- F, G (upper right, on the large circle, F left of G)
- M, L (left, on the large circle, M above L)
- Q, V (right, on the large circle, Q above V)
- P (foot of the large circle)
- H (top of the inner circle, on the vertical)
- B (upper left of the inner circle)
- K (upper right of the inner circle)
- I (left of the inner circle)
- N (right of the inner circle)
- R (foot of the inner circle, on the vertical)
- T (the crossing of the diameters)
- E (above T, at the meeting of the lines): small and faint

And let the centre of the solar body be on the periphery of the eccentric, and let the Sun be carried by it according to the order of the signs, in the direction of succession, eastward, from H to B, etc., with the mean or equal motion of the eccentric. For notwithstanding this equality, to us who are at the centre T

the Sun will seem to move unequally as long as it is off the line of apsides. On that line, indeed, the Sun at H will be seen beneath A, and placed at R will be seen beneath P, and the line of mean motion EH or ER will coincide with the line of true motion TA or TP. Let the Sun then be at B, and through its centre let the straight lines EBC and TBD be drawn from the centres of the Earth and of the eccentric, as far as the ecliptic. The line of mean motion and place will be EBC, and if our eye were at E, the Sun at B would be seen beneath the point C of the ecliptic; but because the eye is at T, the line of the true place and motion, apparent to us, is TBD, and the Sun at B is seen beneath the point D of the ecliptic, and therefore further west than the mean motion would bring it, and so slower. Thus the Sun placed at I is not seen beneath L, along the line of mean place EIL, but from T is seen beneath M, along the line of true place TIM. Hence throughout the first semicircle of distance from the apogee A, which is called the anomaly, namely in AMP, the Sun will be seen further west than its mean place, and its motion slower than the mean motion.

Now let the Sun have passed the perigee R and be at N: the line of mean place and motion will be ENV, but that of the true will be TNQ, and so the Sun at N will be seen further east, that is, beneath the point Q, which is further east than the point of the mean place V. And if it is at K, it will be seen along the line TKF, beneath the point F, which is further east than the point G, marked by the line of mean motion EKG. Accordingly, in the second semicircle of the anomaly, or of distance from the apogee, the Sun will appear further east than its mean place, and its motion faster than the mean motion.

VI. The prosthaphaeresis, or equation, in the eccentric is found from four givens, namely: 1. the Sun's mean motion in

[Margin: How the prosthaphaeresis is investigated through the eccentric.]

the ecliptic; 2. the mean motion of the solar apogee, for this, subtracted from the Sun's mean motion, leaves the mean distance of the Sun from the apogee, which is called the Sun's annual anomaly, or Argument, because from it one argues whether, and how much, is to be added to or taken from the Sun's mean place or motion to obtain the true or apparent one, and conversely; 3. the Sun's mean distance from the Earth, or the radius of the eccentric; 4. the Sun's eccentricity. These being given:

Let the Sun be at B; for TBE will be the angle of the equation, or the angle measuring the equation. It is the angle by which the angle BEH, measuring the mean distance of the Sun at B from the apogee H, exceeds the interior angle DTA, by Euclid I.32; and that angle measures the true distance of the Sun's true place D from the true place of the apogee A. Therefore in the triangle BTE we are given EB, the semidiameter or radius of the eccentric; TE, the eccentricity; and the angle BET, since by Euclid I.13 it is the complement to two right angles of the angle BEH. BEH in turn is as large as the anomaly BH, or the distance of the Sun at B from the apogee H. Hence by the rules of oblique-angled triangles the angle B will become known.

[Margin: The greatest equation in the path of the eccentric.]

The greatest prosthaphaeresis, however, is derived from the triangle ITE, right-angled at T, as will be demonstrated in the next chapter. For given EI, the semidiameter or radius of the eccentric, which is the mean distance of the Sun from the Earth, and ET, the eccentricity, the angle I is sought by the rules of right-angled triangles; this angle measures the greatest prosthaphaeresis, namely the angle TIE.

[Margin: Figure 2, for the hypothesis of the eccentric.]

Diagram. Woodcut set into the foot of the first half of the left column, with the text of section VII running down its left side. A large circle (the ecliptic), with centre T, encloses a smaller circle (the eccentric) drawn about E, which stands above T on the vertical line of apsides; that line runs from A at the top through H, E, T and R to P at the foot. Straight lines run from E and from T up to the left and up to the right, through the inner circle to the outer, and a horizontal line through T meets the outer circle on the left at M/L and on the right at Q/V.

- A (top of outer circle): apogee of the ecliptic
- H (top of inner circle, below A)
- C, D, X (upper left, on or beside the outer circle, reading from the top down)
- B (upper left, on the inner circle)
- F, G, O (upper right, on or beside the outer circle, reading from the top down)
- K (upper right, on the inner circle)
- E (on the vertical, above T)
- T (centre of the outer circle)
- M, L (left end of the horizontal, M above L)
- Q, V (right end of the horizontal, Q above V)
- R (foot of inner circle)
- P (foot of outer circle)

VII. But since in the preceding figure the angle HEB does not measure an arc of the ecliptic, the ecliptic not being described from it as a centre, in the present figure, in which the rest is set out as in the preceding figure, the line TX is therefore drawn parallel to the line of mean motion EC, and the line TO parallel to the line EG. For in this way, by Euclid I.29, the angle HEB becomes equal to the angle ATX, which measures the arc XA of the ecliptic; this arc will accordingly be similar to the arc BH, or of as many degrees. And so the arc of the anomaly is counted on the ecliptic itself rather than on the eccentric.

Moreover, since the arc XD of the ecliptic is as large as the angle DTX, and this angle, because of the already mentioned parallelism, is by Euclid I.29 equal to the alternate angle TBE, which is the measure of the prosthaphaeresis, the arc XD is therefore the prosthaphaeresis to be taken from the arc XA, or from the Sun's mean distance from the apogee reckoned on the ecliptic, so that its true distance DA from the apogee may become known, and from that its distance from the beginning of Aries, since the distance of the apogee A from

the beginning of Aries is now supposed known. Conversely, in the second semicircle of the anomaly, AQP, the prosthaphaeresis, namely the arc FO, is to be added to the distance from the apogee reckoned in the order of the signs, namely to the arc AMPO, so that the Sun's true place in the ecliptic and its true distance from the place of the apogee may be known.

[Margin: The prosthaphaeresis applied to the 2nd figure.]

In this figure the prosthaphaereses are obtained from the triangle TEB, as above, given EB, the semidiameter of the eccentric, ET, the eccentricity, and the angle HEB, namely the Sun's anomaly, or annual Argument as they call it, that is, the Sun's distance from the apogee; for by Euclid I.13 its complement to two right angles is the angle BET. Therefore from these three givens the angle EBT, that is DTX, which is the measure of the prosthaphaeresis XD, is obtained by trigonometric analysis.

Comparatio Hypothesis Concentrepicycli cum Hypothesi Excentrici.

Comparison of the hypothesis of the concentrepicycle with the hypothesis of the eccentric.

[Margin: Reasons for the homocentrepicycle.]

VIII. Longomontanus, in his *Astronomia*, Book 1 of the Theorics, chapters 2 and 5, prefers the hypothesis of the homocentrepicycle to the hypothesis of the eccentric, as most suited to nature. For in the minor planets too, having removed the equant and the motion of a star about a centre not its own, he sets out the phenomena of the planets by epicycles, with Copernicus and Tycho. And indeed this hypothesis would favour the annual rotation of the Sun acknowledged by Šírek and Scheiner, as we said in chap. 4, no. 2.

[Margin: Reasons for the eccentric.]

Nearly all the other astronomers brought forward at the beginning of the chapter, and Copernicus and Tycho themselves, although defenders of epicycles in the theory of the 5 minor planets, nevertheless in the theory of the Sun preferred the eccentric to the epicycle. They did so not so much lest the Sun seem direct in the upper part of the epicycle and retrograde in the lower (for that is not to be feared so long as the motion of the epicycle, as we have laid down, is somewhat slower than the motion of the concentric), nor because it is absurd that the Sun at the apogee A should turn one of its hemispheres toward us and at the perigee P the opposite hemisphere of its body (for that is not manifestly absurd, and if it were, it could be avoided by another annual rotation about its own centre). They preferred the eccentric rather because the Sun's phenomena are explained by it with a single and simple circle, and because they are explained with a single motion in the same direction; whereas the homocentrepicycle requires two circles, and the motion of the epicycle is contrary to the motion of the concentric and slower than it, since otherwise it would not satisfy the appearances, as I shall show in the next chapter to have been demonstrated. Since, however, for the motion of the apogee and of

the eccentricity, of which I shall speak below in their places, a small circle is usually employed, on whose periphery the centre of the eccentric is carried, the argument taken from the simplicity of circles and of motion does not seem to hold. It does hold, however, if we confine ourselves to the annual motion, for the whole motion of the Sun in one year can be explained by the eccentric alone, and that rather slow change of the apogee does not sensibly alter it.

CAPVT XX.

Chapter 20.

Colliguntur in vnum Nomina, Definitiones, deinde Regulæ, ac Proprietates ad Hypothesim Epicycli & Excentrici spectantes.

The names and definitions, then the rules and properties, belonging to the hypothesis of the epicycle and of the eccentric are gathered into one place.

[Margin: What the concentric is.]

I. The *concentric* circle, in Greek [Greek: κύκλος ὁμόκεντρος (kyklos homokentros, "homocentric circle")], in the theories of the planets is a circle whose centre is the same as the centre of the world. The *eccentric*, in Greek [Greek: ἔκκεντρος (ekkentros, "off-centre")], is a circle whose centre lies outside the centre of the world; and the distance of its centre from the centre of the world is called the *eccentricity*, in Greek [Greek: ἐκκεντρότης (ekkentrotēs, "eccentricity")], genitive [Greek: ἐκκεντρότητος (ekkentrotētos)]. Such in the nearest figures is the line ET, which ought to be as large as, in the former hypothesis, the semidiameter of the epicycle, such as KD.

[Margin: What the epicycle is.]

II. The *epicycle*, or *epicyclion*, in Greek [Greek: ἐπίκυκλος (epikyklos, "circle upon a circle")], is a circle, generally smaller, attached or fixed by its centre to the circumference of a larger circle. Ptolemy and al-Farghānī call it the circle of diversity [Greek: κύκλος τῆς διαφορᾶς (kyklos tēs diaphoras, "circle of difference")], or of irregularity [Greek: τῆς ἀνωμαλίας (tēs anōmalias, "of the anomaly")]. Such in the first figure is the small circle GAEF.

[Margin: What the concentrepicycle is.]

III. The *concentrepicycle*, or homocentrepicycle [Hemocentrepicyclus], in Greek [Greek: ὁμοκεντρεπίκυκλος (homokentrepikyklos, "homocentric epicycle")], is the aggregate of a concentric and an epicycle, just as the aggregate of an eccentric and an epicycle is called the *eccentrepicycle*.

IV. *Simply concentric* is said of a circle or orb whose surfaces, the convex as well as the concave, are concentric with the world; *simply eccentric*, of one each of whose surfaces is eccentric to the centre of the world. But *concentric in a certain respect* and *eccentric in a certain respect* is one of which one surface is concentric with the world and the other eccentric, as will be clear from the figure of the scholium.

[Margin: Deferent.]

V. The *deferent* is a circle or orb carrying not so much an epicycle as the body of the Sun itself; and so the eccentric and the deferent are the same in the theory of the eccentric. Al-Farghānī and al-Battānī also call it the circle of the departing cusp [Circulus Egressæ Cuspidis].

[Margin: The highest apsis, the aux and the apogee are the same.]

VI. The *highest absis*, or apsis, from the Greek [Greek: ἀψίς (apsis, "arch, vault")], is the topmost apex of a circle, at which the planet is farthest from the centre of the Earth; the Arabs call this point *Aux*, genitive *Augis*, and in Greek [Greek: Ἀπόγειον (apogeion, "apogee")], because in it the planet is [Greek: ἀπόγεος (apogeos, "away from the Earth")], or, as Ptolemy puts it, [Greek: ἀπογειότατος (apogeiotatos, "farthest from the Earth")], that is, most distant [Greek: ἀπὸ τῆς γῆς (apo tēs gēs)], that is, from the Earth.

[Margin: The same: the lowest apsis, the opposite of the aux, and the perigee.]

The *lowest absis*, or *opposite of the aux*, is the point of the circle at which the planet is least distant from the Earth. It is called [Greek: περίγειον (perigeion, "perigee")], because the planet is there [Greek: περίγεος (perigeos, "near the Earth")], or rather [Greek: περιγειότατος (perigeiotatos, "nearest the Earth")], that is, most [Greek: περὶ τὴν γῆν (peri tēn gēn)], namely around or near the Earth. By Copernicus, however, Book 5, chap. 1, the planet's perigee point [Planetæ Perigęi] is called *Hypaugi*.

[Margin: Aphelion.]

VII. *Aphelion*, in Greek [Greek: ἀφήλιον (aphēlion)], is the point at which the Earth or any other planet is farthest from the Sun. For the Earth is called aphelian, or a planet aphelian, because it is farthest [Greek: ἀπὸ τοῦ ἡλίου (apo tou hēliou)], namely from the Sun, which in Greek is called [Greek: Ἥλιος (Hēlios)].

[Margin: Perihelion.]

Perihelion, in Greek [Greek: περιήλιον (perihēlion)], is the point at which the Earth or some planet is least distant from the Sun; for this reason it is called perihelian, as an adjective, that is [Greek: περὶ τὸν ἥλιον (peri ton hēlion)], around or near the Sun.

[Margin: The line of the apsides, or of the apogee.]

VIII. The *line of the apogee*, or of the auges, or of the apsides, is the straight line passing through the centre of the world, and through the centre of the eccentric or epicycle, drawn from the highest to the lowest apsis, or from the aux or apogee to the opposite of the aux or perigee. Such in the first figure is the line ACR, and in the two following figures the line HETR; but if it is extended to the supreme ecliptic, it will be the line AP.

[Margin: The longer and the nearer longitude.]

IX. The *longer longitude*, for Ptolemy, is the greatest distance of a planet from the centre of the universe, in Greek [Greek: ἀπόστασις μεγίστη (apostasis megistē, "greatest distance")], or [Greek: ἀπόστημα μέγιστον (apostēma

megiston, "greatest interval")]; as in the first figure the line CA, and in the others TH.

The *nearer longitude*, on the other hand, is the least distance of a planet from the centre of the universe, in Greek [Greek: ἀπόστασις ἐλαχίση [recte: ἐλαχίστη] (apostasis elachistē, "least distance")]; as in the first figure the line CP, in the others TR.

[Margin: Mean longitude and mean transit.]

X. The *mean longitude* is sometimes taken for the mean distance of a planet from the centre of the Earth, called in Greek [Greek: ἀπόστασις μέση (apostasis mesē, "mean distance")]; such is the line CM, the semidiameter of the concentric, or in the second figure EI, the semidiameter of the eccentric. Sometimes, however, it is taken for the point of the epicycle or eccentric at which the difference between the mean and the apparent motion is greatest, or the greatest prosthaphaeresis, although Ptolemy more properly calls this [Greek: πάροδος μέση (parodos mesē)], namely the mean transit, because the planet passes from the greatest differences of the motions to smaller ones, or because this point in the ecliptic is equally distant from the points of apogee and perigee, as will be said below.

[Margin: Mean and true motion.]

XI. *Motion*, in Greek [Greek: κίνησις (kinēsis)], is either mean, in Greek [Greek: μέση (mesē)], or regular, in Greek [Greek: ὁμαλὴ (homalē)], that is, equal and uniform, in Greek [Greek: ἴση (isē)]; or it is true, in Greek [Greek: ἀλιθινὴ [recte: ἀληθινὴ] (alēthinē)], and such as it truly appears to us, and therefore called apparent, in Greek [Greek: φαινομένη (phainomenē)]. This last, excepting the points of apogee and perigee, is irregular, in Greek [Greek: ἀνωμαλὴ (anōmalē)], or rather unequal, in Greek [Greek: ἀνίση (anisē)], yet nevertheless regulable, uniformly difform.

[Margin: Motion in consequentia and in præcedentia.]

XII. *Motion in consequentia* (understand "of the signs"), or according to the succession and order of the signs in the zodiac, is called in Greek [Greek: κίνησις εἰς τὰ ἑπόμενα (kinēsis eis ta hepomena, "motion toward what follows")]. *Motion in præcedentia*, or against the order or series of the signs, is called [Greek: εἰς τὰ προηγούμενα (eis ta proēgoumena, "toward what precedes")] by Ptolemy and the other Greeks. In the zodiac the former is reckoned toward the east and the latter toward the west; but in other circles, which are divided after the manner of the zodiac into 12 signs and 360 degrees, there is no need to look to these regions of the world. The less skilled, however, take the phrases *in consequentia* and *in præcedentia* in the sense of the ablative case. [Greek: Ψηφορία (psēphoria, "reckoning")], on the other hand, is not motion but the calculation of the motion itself.

[Margin: Apocatastasis, period, synod, parodus.]

XIII. *Apocatastasis*, in Greek [Greek: ἀποκατάστασις (apokatastasis, "restoration")], is the complete revolution of a star, by which, its whole circle completed, it is restored to the same point from which it began to revolve;

this is also called a *period*, in Greek [Greek: περίοδος (periodos)]. But if after completing the circle it revolves further until it is conjoined with another star, it is called a synod [Greek: σύνοδος (synodos)], while the passage from one notable arc or point to another is called [Greek: πάροδος (parodos)].

[Margin: The line of mean motion.]

XIV. The *line of mean motion or place* is the straight line terminating the mean motion or place of a star. In the hypothesis of the epicycle it is the line drawn from the centre of the world to the centre of the epicycle, such as CK, CM, etc.; but in the hypothesis of the eccentric it is the straight line drawn from the centre of the eccentric through the centre of the star as far as the ecliptic, such as EBC and EKG, likewise EIL and ENV; and so, in the third figure, the lines parallel to them, such as TX and TO.

[Margin: The line of apparent motion.]

XV. The *line of true or apparent motion or place* is the straight line drawn from the centre of the Earth through the centre of the star as far as the ecliptic; as in the first figure the line CD, and in the other two the line TBD or TKF.

[Margin: Anomaly.]

XVI. *Anomaly*, in Greek [Greek: ἀνωμαλία (anōmalia)], is the irregularity of motion; sometimes, however, it is taken for the argument of the irregularity and of the equation to be applied. This argument is the arc between the line of the apsides and the line of mean motion, or it is the distance of the planet's mean place from the apogee: as in the first figure the arc ZD, in the second figure BH, but in the third XA, etc.

[Margin: Equation.]

XVII. The *equation* is the arc of the ecliptic to be added to or subtracted from the mean motion or place so that it is converted into the true, or from the true so that it is converted into the mean. Ptolemy also calls it [Greek: διαφορᾶ τῆς κινίσεως [recte: κινήσεως] ὁμαλῆς, παρὰ τὴν ἀνομαλὴν (diaphora tēs kinēseōs homalēs, para tēn anomalēn, "difference of the regular motion from the irregular")], namely the difference of regular motion from irregular. The angle that is the measure of this arc is also usually called the equation. Thus in the first figure the equation is both the arc KI and the angle KCI, while in the third figure it is both the arc XD and the angle XTD.

[Margin: Prosthaphaeresis.]

XVIII. The *prosthaphaeresis* is the equation spoken of above, so called because it is now to be added, now to be subtracted; for in Greek [Greek: πρόσθεσις (prosthesis)] is addition and [Greek: ἀφαίρεσις (aphairesis)] removal, and from these comes the compound name [Greek: προσθαφαίρεσις (prosthaphairesis)], in Latin *Addidemptio*, since the same equation that is added to the mean place to give you the true is to be subtracted from the true to give you the mean.

Regulæ & Proprietates Selectæ ad Hypothesim Epicycli, aut Eccentrici spectantes.

Selected rules and properties belonging to the hypothesis of the epicycle or of the eccentric.

I. It is impossible for the same star to move circularly and equally about different centres of different circles. Therefore if the Sun moves equally on the epicycle or on the eccentric, it will necessarily move unequally on the concentric or on the ecliptic: so Peuerbach, and Reinhold in the Theorics, p. 32. Otherwise, with a side of the triangle produced, the exterior angle would be equal to the interior and opposite angle, contrary to Euclid I.16 and I.32; as in the first figure the angle ZKD, measuring the arc ZD, would be equal to the angle KCI, measuring the arc KI, and in the other two figures the angle BEH, measuring the arc BH, would be equal to the angle DTA, measuring the arc DA, which is absurd.

[Margin: The motion of the epicycle compared with the motion of the concentric.]

II. If the epicycle moves with a motion equal to the motion of the concentric, the point of the apogee will always, on the completion of a revolution, be restored beneath the same point of the ecliptic. If it moves more slowly than the concentric, the apogee point, after a single revolution of the epicycle, will have advanced in consequentia; but if faster, it will have been drawn back in præcedentia of the signs. Copernicus, Book 3, chap. 15, and Reinhold in the Theorics, p. 31.

III. If the epicycle moves with a motion contrary to the motion of the concentric itself, the planet fixed on the epicycle will appear slower than the mean motion in the first semicircle of the epicycle, reckoned from apogee to perigee, and faster in the second semicircle, reckoned from perigee to apogee. Ptolemy, Book 3, chap. 3. Regiomontanus in the *Epitome of the Almagest*, Prop. 4. Copernicus, Book 3, chap. 15. Reinhold in the Theorics, p. 31. Kepler on Mars, chap. 2.

[Margin: The motion of the eccentric examined.]

IV. If the apparent motion is bisected by the line of mean longitude, the equal motion of that time will be as great as the apparent; and if in some time the mean motion of a star on the eccentric and its apparent motion at the centre of the world are equal, the point of mean longitude will be enclosed within their endpoints. Nonius on Peuerbach's Theorics, Annotation 1, Props. 1 and 2.

V. If the Sun's motion were equal in the ecliptic and unequal on the eccentric, the greatest and swiftest motion of the eccentric would be at the apogee, and from there it would decrease gradually as far as the perigee, where it would be least and slowest. Reinhold, above, p. 33. This will easily be clear to anyone who divides the ecliptic into equal parts and draws straight lines from the centre

of the ecliptic to the points of division: for the arcs of the eccentric will be larger at the apogee than at the perigee.

[Margin: The points of greatest slowness and swiftness.]

VI. If the Sun, as agrees with observations, moves equally on the eccentric and unequally under the ecliptic, the apparent or true motion is slowest at the apogee, and from there increases little by little, and always becomes greater than the apparent motion of the preceding day, until at the perigee it becomes greatest and swiftest; from there, however, it begins to decrease, and smaller and smaller it becomes than the apparent motion of the preceding day. Ptolemy, Book 3, chap. 3, and Theon on that passage; Regiomontanus in the *Epitome*, Book 3, Prop. 5; Copernicus, Book 3, chap. 15; Reinhold in the Theorics, pp. 33 and 34; Kepler on Mars, chap. 2. This will easily be demonstrated by dividing the eccentric into equal parts by straight lines drawn from the centre of the eccentric, and drawing straight lines from the centre of the world to the ecliptic through the points of division of the eccentric. For it will at once appear that in the left-hand semicircle, which runs from the apogee to the perigee, the arcs of the ecliptic intercepted by those lines are larger and larger than the preceding ones as far as the perigee, and from there in the other semicircle smaller and smaller.

[Margin: The beginners' delusion.]

Here, however, the imagination of beginners is usually confused, and they do not at once grasp how in the first semicircle the apparent motion can be slower than the mean motion and yet the apparent motion be faster and greater than the apparent motion of the preceding day. These two things nevertheless stand together and are perfectly true, since the term of comparison is different.

VII. In that semicircle or quadrant of the ecliptic in which the Sun's apogee lies, the Sun's apparent and true motion is slower than in the other. This follows from Prop. 6.

[Margin: The use of the equations.]

VIII. From apogee to perigee in consequentia the mean motion is greater than the apparent motion, but from perigee to apogee it is smaller. And so in the first semicircle of the anomaly the equation is to be subtracted from the mean motion to obtain the true, or added to the true to obtain the mean; conversely, in the second semicircle it is to be added to the mean motion to obtain the true, or subtracted from the true to obtain the mean. This is clear from the exposition of figures 1, 2 and 3.

IX. The equations are equal at points of the eccentric or epicycle equally distant from the apogee, and also at opposite points of the ecliptic. Peuerbach and Reinhold in the Theory of the Sun, no. 11, Rules 2 and 4. Regiomontanus in the *Epitome*, Book 3, Prop. 11. For these, look at figure 3.

[Margin: Where the Sun's mean distance occurs.]

X. The Sun's mean longitude, taken for its mean distance from the Earth, occurs at that point of the eccentric from which a straight line can be drawn perpendicular to the line of the apsides, cutting the eccentricity in half. Reinhold

in the Theorics, p. 42. For in this little diagram let the eccentric be ACP, with centre E; let the centre of the world be T, the line of the apsides AP, and the eccentricity ET, cut in half at B. To this point let CB be drawn perpendicular to AP, and let the point C be connected by the straight lines CE and TC with the centres of the world and of the eccentric. Then by Euclid I.4 the triangle CBT will be equal to the triangle CBE, since the side CB is common, EB is equal to BT, and both CBE and CBT are right. Therefore the base CT too is equal to the base CE, which is the semidiameter of the eccentric, or the mean distance from the Earth. Therefore CT is the mean distance, and it occurs at the point C, etc.

Diagram. Small woodcut in the left column, with the text of section X running beside it: the left half of an eccentric, drawn as an arc from A round through C to P, with the straight line AP as its right-hand side. Three straight lines run from C on the arc to the points E, B and T on AP.

- A (top of the line AP)
- E (on AP, below A)
- B (on AP, below E)
- T (on AP, below B)
- P (foot of the line AP)
- C (left, on the arc)

[Margin: The point of mean distance: at what degree of the anomaly it occurs.]

Further, the distance of the point C from the apogee A becomes known by seeking through trigonometry the angle CEB from the givens CE, the radius of the eccentric, and EB, half the eccentricity, in the right-angled triangle CBE. For the complement of the angle CEB to two right angles is, by Euclid I.13, the angle CEA, measuring the arc CA. Thus if EB is 3460 parts of which CE is 100000, CA will be 91° 59′.

XI. The mean longitude, taken for the mean transit, or the passage of the mean motion from, or to, its greatest difference from the apparent motion, occurs at that point of the eccentric from which a line perpendicular to the line of the apsides can be drawn to the centre of the world. In this sense Peuerbach uses *mean longitude* in the Theory of the Sun, no. 4, and Copernicus, Book 3, chap. 3. This will be demonstrated in the next proposition.

[Margin: Where the greatest equation occurs.]

XII. The greatest equation, or the greatest difference between the mean and the apparent motion, occurs at the point of the eccentric from which a straight line can be drawn to the centre of the world perpendicular to the line of the apsides. Ptolemy, Book 3, chap. 3. Regiomontanus in the *Epitome*, Book 3, Prop. 7. Copernicus, Book 3, chap. 15. Nonius on Peuerbach's Theorics, Annotation 1. Reinhold, in the same place, p. 43. Magini in the Theory of the Sun, chap. 9. Tycho, vol. 1, p. 29. On the eccentric ABPC let there be the line of the apsides AP, on which are the centre of the eccentric E and of the world T, through which let the straight line BC be drawn at right angles, and

let the points B and C be joined with the centre E by the straight lines BE and CE. For by Euclid III.3 the straight line ET will bisect BC at T.

Diagram. Woodcut at the head of the right column, with the opening of the text running down its left side. A circle with a vertical diameter from A at the top to P at the foot, and on it the points E and T, E above T. Straight lines converge on C at the right from K, B and N on the left of the circle; further lines join K and N to E and T, and B to E. A dotted line runs from I, at the left side of the circle, to E, and a second dotted line runs down from I to B.

- A (top)
- K (upper left, on the circle)
- E (on the vertical, above T)
- T (on the vertical)
- C (right, on the circle)
- I (left, at the end of the dotted line, just inside the circle)
- [Z?] (left, outside the circle, below the preceding: a letter whose strokes most resemble Z)
- B (left, on the circle)
- N (lower left, on the circle)
- P (foot)

I say, then, that the angles of the equations EBT and ECT are the greatest of all those that stand on the eccentricity as base, ET, at the circumference of the eccentric. For on ET let there stand toward the apogee any angle at the circumference, such as EKT, and toward the perigee the angle ENT, and join their points K and N to the point C by the straight lines KC and NC. By the definition of a circle the lines EB, EK, EN and EC will be equal, and so the triangles EBC, EKC and ENC will be isosceles, and in them, by Euclid I.5, the angles at the base will be equal, namely EBC to ECB, EKC to ECK, and also ENC to ECN. But by Euclid III.7 the side TK is greater than the side TC; therefore by I.19 the angle KCT is greater than the angle CKT. So when the equals EKC and ECK are taken away, the remaining angle ECT is greater than the angle EKT. It is similar with all the angles between A and B standing on ET, and indeed also with all those between B and P: for they are always smaller than the angle ECT, to which EBT is equal. For by III.7 of the *Elements* TB, or TC which is equal to it, is greater than TN; therefore by I.18 the angle TNC is greater than the angle TCN. When these are taken away from the equals ENC and ECN, the remaining angle ECT, and therefore EBT, is greater than the angle ENT. And so for the others.

XIII. The closer the line of apparent motion is to the line of mean transit, or to the line making right angles at the centre of the world with the line of the apsides, the greater is the prosthaphaeresis. Regiomontanus, above; and it is a corollary of the preceding.

XIV. The point of greatest prosthaphaeresis is equally distant from the apogee and the perigee on the ecliptic, but on the eccentric it is more than 90 degrees from the apogee, by an excess above the quadrant as large as the

greatest equation. For if in the preceding figure the straight line EZ is drawn perpendicular to AP, it will be parallel to TB, by I.28 of the *Elements*. Therefore by I.29 of the same the angle ZEB, by which AEB exceeds a right angle, will be equal to the angle B, the greatest prosthaphaeresis.

SCHOLION.

Scholium.

[Margin: The solidity of the orbs rejected.]

I. Hipparchus and Ptolemy, in the theories of the planets, used bare orbs and mere circles. That neither they nor the ancients asserted solid orbs, but set out the circular path of the planets only under the hypothesis of a homocentrepicyclic circle or of an eccentric, is taught by Thomas Aquinas, Lect. 10 on *Metaphysics* 12; Piccolomini in his Theorics; Philaltæus [?] on *De caelo*, Book 2, text 51; Clavius at the end of the *Sphere*; and many others to be brought forward in the book on the System of the World. That the planetary heaven is fluid, however, many Fathers once taught, and it agrees with Holy Scripture, which nowhere attributes motion to these heavens, but to the planets alone [Solis Planetis]. Nearly all the more recent astronomers affirm it, Tycho above all, Longomontanus and Kepler: both from the trajectories of comets, and from the spirals of Mars, Mercury and Venus and their motion about the Sun, so that Mars too descends into the region of the Sun and in its oppositions with the Sun becomes closer to the Earth than the Sun is; and because that solidity would produce remarkable refractions of the lights, and would serve the motion only with great violence; and finally because so tangled and so vast a farrago of orbs inserted one into another is superfluous.

[Margin: A specimen of solid orbs.]

II. Yet, lest you be wholly ignorant of how Sacrobosco and Peuerbach, who are reckoned the chief asserters of the solidity of the orbs, explain the motion of the Sun, let the orb of the Sun in the adjoined figure be SBTK, concentric as to its outermost and convex surface with the centre of the world C, but hollowed out within, so that the concave surface MPDO is eccentric to the world and described from the centre E. And let there be a second partial orb OMPD, carrying the Sun and consisting of a white wheel, which matches the body of the Sun in its thickness and marks out the Sun's path, and of a black lunate part;

Diagram. Woodcut set in the left column: the solid-orb specimen. Concentric black outer ring, thickest at the bottom; inside it a white ring carrying a small circle with a central dot (the Sun); inside that a black ring, thickest at the top, enclosing a white disc that holds two dotted centres.

- S (top, above the outer ring)
- B (far left, outside the outer ring)
- K (far right, outside the outer ring)
- T (bottom, below the outer ring)

- M (left, in the white ring)
- D (right, in the white ring)
- P (bottom, in the white ring)
- E (upper centre point, in the central white disc)
- C (lower centre point, in the central white disc)

eccentric to the world as to its convexity OMPD, but concentric with the world as to its convex surface, which contains the little white circle. This orb is to carry the Sun uniformly about the centre E, as we said above of the eccentric, striving toward the east, while meanwhile the outermost orb SBTK revolves with the diurnal motion of 24 hours toward the west, and by that same motion sweeps the inner orb along with it toward its setting. Moreover, the entirely white circle, in which the centres C and E lie, represents the elementary sphere together with the heaven of the Moon, of Venus and of Mercury. They therefore devise similar things for the orbs of the other planets. But if the motions of the apogee, of the eccentricity and of the obliquity, and their anomalies, are real, how many segments of these orbs will have to be devised?

CAPVT XXI.

Chapter 21.

De Aequationibus seu Prosthaphæresibus motus Solis inuestigandis, & in tabulas distribuendis.

On investigating the equations, or prosthaphaereses, of the Sun's motion, and on arranging them in tables.

Although, when the opportunity offered, I have already suggested this in chapter 19, both through the epicycle at numbers 3 and 4 and through the eccentric at number 6, and in chapter 20 I gave the definitions or notions of the terms relating to it, from number 15 to 19, and the rules from number 8 to the end, I should nevertheless like to gather into a small compass, and distinctly, the precepts necessary for it, referring the reader for the demonstrations to the diagrams and expositions of the chapters already mentioned. First, then:

[Margin: A short method of finding the greatest equation.]

I. *The greatest equation* is investigated by the rules for right-angled rectilinear triangles if, as I assume, there is given the semidiameter of the concentric or of the eccentric, that is, the radius of the Sun's annual orb, and either the semidiameter of the epicycle or the eccentricity, in parts of which the said radius is known. For the angle opposite the eccentricity is the greatest equation.

[Margin: By sines.]

Therefore make: as the semidiameter of the Sun's orb is to the radius, or whole sine, of the tables, so the semidiameter of the epicycle, or the eccentricity, is to another quantity; and you will have the sine of the angle of the greatest equation.

[Margin: The same by logarithms.]

Or join the residual of the logarithm of the semidiameter of the Sun's orb to the logarithm of the semidiameter of the epicycle, or of the eccentricity; and, with unity taken away on the left, the result will be the logarithm of the angle of the greatest equation. So if the eccentricity is 3460 parts of which the radius of the Sun's orb is 100000, the greatest equation will be 1° 59′.

[Margin: The place of the greatest equation.]

II. The arc of anomaly at whose extremity, or distance from the apogee, the greatest equation occurs is found if the greatest equation is added to 90°, by the 14th rule demonstrated in the preceding chapter. So in the preceding example the arc of anomaly to which the greatest equation corresponds is 91° 59′ in the first semicircle, and 268° 1′ in the second. Through forgetting this precept not a few practitioners place the greatest equations short of or beyond the already mentioned limit of the anomaly, as can be seen in their tables.

[Margin: Method for the other equations.]

III. *The other equations* are investigated in an oblique-angled rectilinear triangle, in which there are assumed as given the eccentricity, or the semidiameter of the epicycle, as one side, the radius of the Sun's orb as the other side, and the complement of the anomaly, or of the distance from the apogee, to two right angles. For the angle opposite the eccentricity, or the semidiameter of the epicycle, is the equation itself or its measure, belonging to the degree of the given anomaly.

[Margin: By sines.]

Therefore make: as the sum of the given sides is to their difference, so the tangent of the half-sum of the angles adjacent to the base is to the tangent of the difference, which, subtracted from the half-sum of the angles at the base, will leave the angle of the desired equation.

[Margin: By logarithms.]

Or add the residual of the logarithm of the sum of the given sides to the logarithm of their difference and to the mesologarithm of the half-sum of the angles at the base; and, with unity or two taken away on the left, the result will be the mesologarithm of the angle which, subtracted from the half-sum of the angles at the base, leaves the equation sought. But know that here the sum of the angles at the base equals the arc of anomaly: so when this is known, that sum is known.

EXEMPLVM.

Example.

[Margin: Example of an equation that is not the greatest.]

Let the equation belonging to an anomaly of 46° be sought. Its complement to two right angles will be 134°. Hence the sum of the angles at the base, which is required for two right angles by proposition 32 of Euclid's first book, will be 46°, and the half-sum 23°, whose tangent is 42447. Let the radius of the

Sun's orb be, as above, 100000 parts, and the eccentricity 3460 such parts. For their sum will be 103460, and their difference 96540. Multiply this difference, then, by the already mentioned tangent, and the total will be 4097833580 [recte: 4097833380]. This, divided by the sum 103460, gives the quotient 39607. To this, as a tangent, corresponds the arc of an angle of 21° 36′ 26″, which, subtracted from 23°, gives the equation of 1° 23′ 34″ belonging to an anomaly of 46°.

IV. When the equations for the first semicircle have been found by this method, those of the second semicircle of anomaly will be known: for at points of anomaly equally distant from the apogee the equations are equal, for example at 46° and 314° of anomaly, that is, at 1^{s} 16° and at 10^{s} 14° of anomaly, by rule 9 of chapter 20.

V. It remains, then, for us to give the method of investigating the eccentricity, which is always equal to the semidiameter of the Sun's epicycle, and the place of the Sun's apogee, so that, when the Sun's mean motion or place is subtracted from the motion or place of the apogee, the anomaly, or the Sun's annual argument, may be known. This will be done in chapter 24. Once these have been declared, we shall give the greatest equations corresponding to the eccentricity, according to the more notable opinions. But first we must explain the distinction between the physical and the optical equation [Aequationem Physicam & Opticam]. For so far we have dealt with the whole equation, resting, as on a base, on the whole eccentricity.

CAPVT XXII.

Chapter 22.

Quid sit circulus Aequans, quid Aequatio Physica, & Optica, & quomodo seorsim inuestigentur.

What the equant circle is, what the physical and the optical equation are, and how they are investigated separately.

I. Ptolemy had completed the theory of the Sun by a simple eccentric, but in the five minor planets he used a double eccentric. One of these carries the planet, or the planet's epicycle; the other, which he calls the equant [Aequantem], is the one in which the measure of the uniform or mean motion is observed, that is, the one with respect to which the planet moves uniformly. This equant, however, was brought into the theory of the Sun by Kepler, and Magini, Boulliau and Wendelen followed him.

[Margin: Description of the equant.]

So that the notion and properties of the equant may be made clear, let T, in the adjoined diagram, be the centre of the Earth and of the world, from which describe the ecliptic HRV, etc., and, having drawn through T the line of apsides HV, take on it a straight line CT as great as the whole eccentricity,

given or found by the methods to be set out below in chapter 24, and bisect it at E; then,

Diagram. Geometrical figure inset in the left column. A large circle (the ecliptic), with a vertical diameter from H at the top to V at the bottom; two smaller overlapping eccentric circles inside it, a small epicycle on the upper left of the inner circles, and straight lines radiating from the centres on the diameter through the epicycle; two dotted horizontal lines from the diameter to the left.

- H (top of the large circle)
- G (top, left of H, on the large circle)
- L, I (upper left, side by side by the epicycle, on the line ends; set close together)
- D, K (inside the small epicycle)
- B, A (on the diameter, below H, in that order)
- N, O (left, at the end of the upper dotted line)
- C (on the diameter, at the upper dotted line)
- F (right, at the crossing of the two eccentric circles)
- S (left, at the end of the lower dotted line)
- E (on the diameter, at the lower dotted line)
- T, M, P (on the diameter, below E, in that order)
- R (left, on the large circle)
- V (foot of the diameter)

from centre E describe the eccentric AOPF, whose apogee is A, its perigee P, and its semidiameter EA; and from centre C, with the interval of the semidiameter CB, equal to EA itself, describe as the equant another eccentric BOMF, whose apogee is B and perigee M; and from these, at the centres C and E, draw two perpendiculars to the line of apsides, namely NC and SE. In this way there will be the quadrant AS in the first eccentric and the quadrant BN in the equant. Now imagine the centre of the Sun's globe at D, or, in the five minor planets, the epicycle LK that carries them. And through the centre D, from the three centres C, E, T, draw the straight lines TDG as far as the ecliptic, and EI and CL as far as the circumference of the equant.

When this is done, the circle in which are to be counted the equal arcs that the Sun is imagined to traverse in equal times by its mean motion is not the eccentric AOPF, in which the Sun's body nonetheless lies, but another eccentric, BOMF; so that the Sun moves uniformly with respect to a circle and centre not its own, and hence non-uniformly in its own circle and with respect to the centre of the circle in which the Sun itself lies. For example, if in 94 days the Sun by its mean motion completes a quadrant reckoned from the apogee, and hence in 47 days a half-quadrant, this quadrant will be BN, determined by the line CN, and not AS, made by the line ES. So when the Sun is on the line CN, it has not yet completed the quadrant AS of its own circle, but is at O; and to obtain the place where it stands when the half-quadrant has been completed, one must draw, as I said, a line from the centre C of the equant through the centre D of the Sun's globe, so that it cuts off from the

equant the half-quadrant LB, namely the line CDL. When this has been done, if a line EDI is drawn from the centre E of the first eccentric through the Sun's centre, the arc DA will be less than a half-quadrant: because, by proposition 32 of Euclid's first book, the angle DEA, which measures the arc DA, is less than the angle LCB, which measures the half-quadrant LB. Since, then, the circle BOMF is the measure of the Sun's uniform motions, although it is not the subject or immediate instrument of the Sun, it is called the *equant*.

[Margin: What the physical equation is.]

II. This being laid down, the cause for which the Sun's motion partakes of inequality is twofold. One is physical and real, and independent of the eyes of observers: namely that in the eccentric in which the Sun's body lies it moves non-uniformly according to this hypothesis, even though with respect to a circle not its own, or external to it, it moves uniformly; and the difference of these motions is hence called the *physical*, or real, *equation*, that is, one proceeding from a physical cause, whose measure in our example is the angle EDC, standing on half the eccentricity, EC, as on a base. The other cause is apparent, arising from the fact that we are not at the centre E, or C, but at T; and so the Sun, placed at D, is seen under G, a point of the ecliptic less distant from the place H of the apogee, that is, at a smaller arc GH than the arc DA, measured by the angle DEA, and smaller by far still than the arc LB, measured by the angle LCB, by proposition 32 of Euclid's first book.

[Margin: What the optical equation is.]

This difference, which increases the former inequality, is in our case the angle TDE, resting as on a base on the other half of the eccentricity, ET, and it is called the *optical equation*, because it arises not from the Sun's own circles in which it lies, or to which it has regard of itself in its motions, but incidentally from the position of our eyes, as we observe the Sun from T. In this way Ptolemy, Book 3, Chapter 3, said that the motions of the Sun [Greek: ἀνίσους φαίνεσθαι ταῖς ὄψεσιν ἡμῶν (anisous phainesthai tais opsesin hēmōn, "appear unequal to our sight")], that is, appear unequal to our eyes. The equation composed of the physical and the optical, moreover, is that whole equation which we taught in the preceding chapter to gather from the whole eccentricity, namely the angle TDC.

[Margin: Method of investigating the physical and the optical equation.]

III. These equations are investigated separately as follows. The physical one, namely the angle EDC, is investigated in the same triangle EDC, given EC, half of the whole eccentricity, and ED, the radius of the Sun's orb, and the angle DCE, namely the complement to 180° of the angle LCB, which measures the given anomaly. When the physical equation has been found, and the two angles DCE and CDE are thus already known, the third, DEC, will be known by proposition 32 of Euclid's first book, as being the complement of two right angles. Hence the angle TED will also be known, which is the complement to two right angles of the angle CED, by proposition 13 of Euclid's first book. So in the triangle DET, with the angle already mentioned, and with half the

eccentricity, ET, and the radius ED of the Sun's orb, the optical equation TDE can be found. Added together, these give the composite equation TDC.

[Margin: Who introduced the equant into the theory of the Sun, and why.]

IV. So the equant circle, or an ellipse equivalent to it, was devised for the theory of the Sun, as I said, by Kepler: in the *Commentary on Mars*, chapters 4, 23 and 31; in the *Astronomia Optica*, chapter 10; in the *Epitome of Astronomy*, Book 4; and in the Appendix to Tycho's *Progymnasmata*, after volume 1. For that reason he insisted that the Sun's eccentricity must be bisected. Kepler was followed by Magini in the *Supplement to the Ephemerides*, who gives a table of the Sun's equations gathered from a halved eccentricity[17] and composed of the physical and the optical equation; likewise by Wendelen in the Atlantic Tables, by Boulliau in Book 2, chapters 1 and 4, and by Cavalieri in the *Directorium Uranometricum*, chapter 4, pages 140 and 149. Finally, as is related in the Appendix just mentioned, Tycho himself had thought of introducing the equant into the theory of the Sun, but had not yet fully decided on it.

[Margin: Arguments for the Sun's equant.]

Kepler's foundation was twofold. First, he detected a difference of only one minute between the Sun's apparent diameter at apogee, 30′, and at perigee, 31′. Second, the approach of Venus and of Mars, but above all of Mars, to the Earth in opposition with the Sun at perigee. He considers that neither of these phenomena is saved if the whole eccentricity is employed: for the difference of the Sun's diameters would be about twice as great, and Mars in such an opposition with the Sun would not approach the Earth so closely, nor appear half as large again as near conjunction, as it does appear.

[Margin: Arguments against the Sun's equant.]

V. Against the equant, by contrast, stand the objections that Copernicus makes in general, Book 5, chapters 2 and 4, thinking it absurd to posit in the heavens a real inequality, or an equality sought from an external circle and a centre not its own. In the theory of the Sun it is also rejected by Longomontanus, who used the whole eccentricity; by Lansbergen in Class 4 of the Lunar Observations, at the end, who denies that the eccentricity should be bisected and asserts a difference of 2′ 24″ between the diameters of the Sun at apogee and at perigee; and by Antonín Maria Šírek, Book 1, chapter 2: if Mars is stripped of its mane of adventitious rays and observed with the telescope, it does not appear so much larger as to force us to bisect the Sun's eccentricity; or at any rate the eccentric of Mars will have its centre outside the centre of the Sun's body.

SCHOLIA.

Scholia.

I. Kepler, to distinguish the physical and optical equations, once judged it sufficient that the whole equation, drawn out in the usual way, be cut in

[17] the print reads *bissexta* for *bissecta*, halved

two, and that one could not err in this way by more than 6″ at the 45th degree of anomaly; and therefore he had corrected the difference, which in fact is 1′ 6″ there when the Tychonic eccentricity is assumed, by striking out a whole minute.

[Margin: Kepler's error.]

But Magini, in the letters to Kepler found in the *Supplement to the Ephemerides* from page 255, shows that at 45° and 135° of anomaly the difference of the equation so obtained from the equation obtained separately from the physical and the optical can reach 1′ 6″. And so lene, and that the axis of the cone is not perpendicular to the planes of the circles. Boulliau demonstrates this further in the same place, adding the way of cutting a scalene cone so that an ellipse arises having the properties already mentioned.

[Margin: This cone cannot be right.]

[Margin: Equality and inequality shown by means of the ellipse.]

VI. Now, to show in the cone and ellipse already mentioned both the equality and the whole apparent first inequality, in which the Sun too, or the Earth, shares, let the following figure be taken from Boulliau, Book 1, chapter 15. In it ABC is the scalene cone, AI its axis, and BIC its base. Parallel to this base are to be understood the planes of the circles which the planet looks to in its revolution around the surface of the cone: such are ESD and POK, with the others in between; and let their centres be on the axis of the cone, AI.

Diagram. Woodcut in the left column: a triangle standing for the scalene cone, apex at the top and a hatched, flattened oval for its base. A tilted ellipse lies across the cone and bulges beyond its right side; five parallel horizontal chords run from the left side of the cone to the right, crossed by the axis from the apex to the base and by the two diameters of the ellipse, which meet at its centre.

- A (apex): vertex of the cone
- B, C (base, left and right ends): the ends of the base
- I (centre of the base; small and partly within the hatching): foot of the axis
- E, F, V, L, P (left side of the cone, top to bottom): left ends of the chords
- N (upper right, outside the cone): end of the minor diameter on the ellipse
- D (just right of M, inside the circle); G, T, Q, K (right side, top to bottom): right ends of the chords; K is the lower end of the major diameter
- S (upper chord): on the circle ESD
- M (next chord, on the axis): umbilicus on the axis
- Z (middle chord): centre of the circle VZT
- X (centre of the figure): centre of the ellipse
- Y (fourth chord, left of the axis): point on the ellipse and the circle FMG
- H (lower right inside the ellipse): the other umbilicus
- O (lower chord region, on the ellipse): lower end of the minor diameter

- R (below the ellipse, on the lowest arc): label only; not cited in the text on this page

Labels read: A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, V, X, Y, Z. Labels not read: none.

Between the extremes of the circles let there be the ellipse EOKN, whose transverse or major diameter, or axis, is EXK, while its conjugate or minor diameter, or latus rectum, is OXN. Let one of the umbilici, which *Apollonius* calls the *points from the comparison* [puncta ex comparatione], be M, on the axis of the cone itself, and the other, H, off the axis of the cone; and let the centre of the ellipse be X. Further, let the circle VZT, which passes through the centre of the ellipse, have its centre at Z and its diameter VT, so that VZ and ZT are equal. Therefore the plane passing through AI, the axis of the cone, will likewise cut in two all the diameters of the circles, ED, FG, VT, LQ, PK. But since the centre of the ellipse, X, is distant from the axis AI by the quantity MX, the plane that will bisect the ellipse through the conjugate diameter OXN will not bisect the circles, but will cut off a greater part, say VX, towards E, and a lesser, XT, towards K.

Now let the planet move around the axis of the cone uniformly, describing on the surface of the cone an elliptical line, and in equal times equal angles around the axis AI; and let the terminus of the apparent motion, to which it is referred, be the umbilicus H, in which the Sun stands. For the part most remote from the Sun, or aphelion, will be E, and the nearest part, or perihelion, K. And while the planet (for example, the Earth) completes by its mean motion a quadrant of its revolution around the cone, it is still distant from the quadrant of the ellipse by the quantity of the straight line MX, and is at the point Y, which lies both on the ellipse and on the circle FMG. The straight line MY, drawn from the centre of the circle FG, is an ordinate at right angles upon the diameter both of this circle and of the ellipse; and so the angle FMY is right. Therefore the planet has completed a quadrant of mean motion around the axis of the cone when it reaches Y, but on the ellipse it has traversed less than a quadrant, and to complete the quadrant of the ellipse it lacks the portion YO, or MX. Hence a twofold inequality arises, although the ancients reckoned it single: one from a physical cause, namely from the distance of the centre of the ellipse from the axis of the cone and from the inequality of the circles; the other from an optical cause, from the distance of the centre of the ellipse from the Sun, H. And both together show that the difference of the mean motion from the apparent and the distance of the umbilici of the ellipse are the same. I do not say, however, that the planet describes those circles, but only that it takes, with respect to them, the measure of its uniform motion along the elliptical line.

[Margin: Agreement of the elliptical hypothesis with the phenomena.]

VII. With these things posited the phenomena are saved: there is equality in the motion around the cone but apparent inequality on the ellipse, and half of the inequality is attributed to the eccentricity HX, the other half to that

cause which holds the planet back at aphelion and advances it at perihelion, without the equality being disturbed meanwhile. For since the umbilicus M, around which the motion is uniform, is on the axis of the cone, and the planet, descending from aphelion E, has completed a quadrant of the circumference of the cone and has come to the line MY, it is distant from the quadrant of the ellipse by the difference between the ellipse and the circumference of the circles, which MX measures. Next, since from aphelion to perihelion the circles FG, VT, etc. continually grow, and meanwhile the planet makes equal angles in them at the axis of the cone, the motion from aphelion to perihelion on the ellipse also grows, because equal angles formed by smaller lines subtend smaller circles, and those formed by greater lines, greater ones. Towards the apex of the cone, A, and aphelion the circles are smaller than towards the base and perihelion; therefore the motion on the ellipse is slower around aphelion and faster at perihelion. Yet the equality is not disturbed, because in an equal time the planet completes the other quadrant around the cone, namely the angle YMK, equal to the former, while meanwhile on the ellipse it completes more than a quadrant, namely the circumference YOK. Nor meanwhile has the planet been carried elsewhere: it proceeds along the one surface of the cone, always looking, as the measure of its equality, to the centre of its own circle, the circle it holds on the surface of the cone, that centre being placed on the axis of the cone; and not to another's centre, as in the Ptolemaic hypothesis of the equant circle. Nor are motions multiplied, as in other hypotheses, in order to keep that equality intact. And [?] it is clear for what reason the mean motion from aphelion to the mean longitudes is greater than the apparent, and from there to perihelion is less; nor does this change arise from an intensification or remission of the moving power, but from the wider or narrower circuit of the circles which it must run through. Finally, in this hypothesis no motion contrary to the mean motion is supposed, as in the Copernican and Tychonic theory of the five planets, or in the solar theory of *Longomontanus*. Nor is there any need of the fibres invented by *Kepler*, by which the Sun magnetically attracts the planets and, having seized them, drives them back again towards aphelion. *Boulliau*, Book 1, chapter 16, demonstrates that the difference of the semidiameters of the least and the greatest circle in the cone is equal to the distance of the umbilicus from the centre of the ellipse. In this ellipse, however, and in Kepler's, it is conceded from first to last that part of the inequality of motion is physical and real, such as it would be even if we were at the centre of the ellipse; whereas if we were at the centre of the eccentric circle, the whole inequality would cease. Therefore the physical equality of the Sun's motion is better saved by the hypothesis of the eccentric circle than by the ellipse. Let us now come to the practice of the equations, to be investigated by this hypothesis.

Prima Methodus Inquirendi Aequationes in Ellipsis Hypothesi.

First method of finding the equations in the hypothesis of the ellipse.

[Margin: First method of the equations, from Boulliau.]

VIII. Let there be a circle KGDP, as large as the annual orb or eccentric of the Sun usually is for others, in which KD is the line of apsides; and in it let there be described, by the usual rules, the ellipse KEDC, whose transverse or major diameter, or axis, is KD, while its conjugate or minor diameter, or latus rectum, is EC, cutting KD at right angles at B, the centre of the circle already mentioned and of the ellipse. And let one of the points from the comparison, as *Apollonius* says, or one of the foci, as *Kepler* says, or of the umbilici, as others say, be A, at the centre of the world, in which the Sun stands, distant from the centre B by as much as is the planet's bisected eccentricity in the other hypothe-

Diagram. Woodcut in the right column, standing within paragraph VIII: a circle with a vertical diameter from K at the top to D at the bottom and a horizontal diameter from G to P through the centre B; an ellipse on the vertical diameter, narrower than the circle, passing through E and C on the horizontal. Horizontal chords stand near the top (N to M; H to L) and near the bottom (through A; through R to Q). Straight lines run from I through B towards V, from I to A, and from A and R to V.

- K (top), D (bottom): ends of the vertical diameter
- G (left), P (right): ends of the horizontal diameter
- B (centre): centre of the circle and of the ellipse
- E, C (left and right on the horizontal diameter): ends of the conjugate diameter of the ellipse
- N, M (upper chord; N on the circle, M on the vertical diameter)
- O (just below N's chord, on the ellipse)
- H, L (second chord; H on the left of the circle, L on the right)
- I (on the second chord, at the ellipse)
- F (on the vertical diameter, below M)
- A (on the vertical diameter, below B): the focus or umbilicus, centre of the world
- S, T (on the chord through A, left and right)
- V (below T, on the ellipse)
- R (on the vertical diameter, near the foot)
- Q (lower right, on the circle)

Labels read: A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, V. Labels not read: none.

ses. The other focus, or umbilicus, is to be F, distant from B by just as much as A is from that same B, so that AF is the whole eccentricity and the base of the first inequality, while BA is half of it, although BA is the whole eccentricity of the centre of the ellipse from the centre of the world. And let the aphelion

be at K and the perihelion at D. Now let the straight lines HF and ST be drawn through the umbilici A and F, perpendicular to KD. For SAT will be what *Kepler* calls διήλιος [Greek: διήλιος (diēlios, "through the Sun")], just as EBC is called διάκεντρος [Greek: διάκεντρος (diakentros, "through the centre")]. And let the planet be at I, from which two straight lines, IB and IA, are drawn, one to the centre of the ellipse, the other to the Sun, A. For the angle BIF will be the physical equation, and AIB the optical equation. The former will be found by the rules of triangles in the triangle IFB, right-angled at F, if the sides about the right angle, namely IF and FB, are known; the latter in the oblique-angled triangle IAB, if its three sides are known. You will find these sides as follows. *Boulliau* demonstrated, in Book 1 of the *Astronomia*, chapter 18, that as GB, the semidiameter of the circle and also the major semidiameter of the ellipse, is to EB, the conjugate semidiameter of the ellipse, so is any ordinate in the circle to any ordinate in the ellipse, if they terminate at the same point of the axis: for example, NM to OM, QR to VR, and HF to IF. Therefore if, as is supposed, the conjugate or minor semidiameter of the ellipse, EB, is given, and the arc of anomaly KH, or of the distance from aphelion, and so its sine HF, make the sine HF to the ordinate IF as the whole sine GB is to the semidiameter EB, and thus IF will be known. And if the planet's bisected eccentricity AB is given, FB, equal to it, will now be given; so the two sides about the right angle F will be known, for investigating the physical equation. If the squares of these sides are added together, the result will be a square whose square root will be the line IB, by Euclid I.47. Now let FB and BA be added together, and let the square of the whole FA be added to the square of the side IF: for the sum will be a square whose square root will be the line IA. Thus, together with the eccentricity AB, the three sides of the triangle IAB will be known, for the optical equation. The whole angle AIF will be the composite equation, which in the first semicircle KGD, or KED, is to be subtracted from the mean anomaly, so as to obtain the coequated anomaly and the true distance of the planet I from the aphelion K.

In the same way, in the other semicircle DPK, the additive equation will be investigated. Let the planet be at V; let the ordinate QR be drawn perpendicular to KD, and let V be joined by the straight lines VB and VA to the centre of the ellipse B and to the centre of the world A. Now from the given conjugate semidiameter of the ellipse, EB or CB, and from the arc of anomaly KGDQ, with the semicircle discarded and DQ thus given, and so its sine QR, if you make the sine QR to another as the whole sine PB is to the semidiameter CB, the ordinate VR will be known. And when the eccentricity BA has been taken from the major semidiameter BD, AD will be known; if RD, the versed sine of the arc DQ, is subtracted from it, RA will be known. So from the two sides about the right angle at R, which are VR and RA, you will find by trigonometry the optical equation RVA; and from their squares you will find a square whose square root will be the line A[?]. Now join the eccentricity AB to RA; and add the square of the whole [?] to the square of RV: for the sum [?] a square

whose square root will be the line VB. And so all the sides of the triangle AVB will become known, for investigating the physical equation, namely the angle AVB, which, joined to the angle AVR, will make up the whole equation to be added to the mean anomaly, so as to obtain the equated anomaly and the true distance of the planet V from aphelion. And so for the rest.

[Margin: The foundation of this method is demonstrated.]

IX. It is not difficult to demonstrate the proportion already mentioned, on which that practice rests: because both in the circle and in the ellipse GB and EB are ordinates to the same point of the axis, and also HF and IF. Therefore, as the rectangle DBK is to the square of GB, so is the rectangle DFK to the square of FH; for each rectangle is equal to its square. But also in the ellipse, by *Apollonius*, as the same rectangle DBK is to the square of the conjugate semidiameter EB, so is the rectangle DFK to the square of the ordinate IF. Therefore, *ex aequali*, as the square of GB is to the square of HF, so is the square of EB to the square of IF. Therefore, by *Euclid* VI.22, as the line GB is to the line HF, so is EB to IF; and by alternation, as GB to EB, so HF to IF; and by conversion, as GB to the excess GE, so HF to the excess HI; finally, by alternation and division, as GE to EB, so HI to IF.

[Margin: Correction of the preceding figure.]

Note further that this figure, taken from Boulliau as it stands, is ill-proportioned: for in the theory of the Sun the distance of the foci from the centre of the ellipse is not as great as is represented here, but far less, since according to Boulliau AB is to BD as 1784 to 100000.

Methodus Altera inueniēdi easdem Aequationes in Ellipsis Hypothesi.

Another method of finding the same equations in the hypothesis of the ellipse.

[Margin: Second method of the equations, from Boulliau.]

X. But since the method already mentioned is rather long and rather troublesome, *Boulliau*, Book 1, chapter 20, and Book 2, chapter 4, devised another, in which the calculation is completed by the usual solution of triangles, by resolving the ellipse into the motions of two circles. For suppose both semidiameters of the ellipse are given, and so their difference, and half of this difference is added to the lesser semidiameter of the ellipse; with the interval of this sum, as semidiameter, let a circle be described; on the circumference of this circle let there be the centre of an epicycle carrying the planet, the semidiameter of the epicycle being equal to half the difference between the two semidiameters of the ellipse given above; and let the motion of the epicycle, beginning from aphelion, be contrary to the motion of its centre and double it, so that while the circle completes a quadrant the epicycle completes a semicircle. If these things, I say, are done, the planet describes an ellipse; and so motion along the ellipse is equivalent to a motion compounded of two circular motions. And in chapter 21 he shows that the inequality of the equations is distributed through

the whole semicircle in proportion to the right sines standing on the line of aphelion and perihelion, counted from the beginning at aphelion. Accordingly, given three or four inequalities and differences of the mean motion from the true, along with the mean motion, the position of the diameter and the line of apsides will be given. *Boulliau* shows this in chapter 22, using two problems of *François Viète* in the Appendicula to the *Apollonius Gallus*. From these he gathers a lengthy method of finding the apogee and the eccentricity of the Sun and, in their own place, of the other planets.

[Margin: The semidiameters of the solar ellipse.]

To conceive the two circles into which *Boulliau* resolves the ellipse, inspect here the figure of the concentrepicycle, given in chapter 19, number 2; and in it let the major semidiameter of the ellipse be CA and the minor CF, and let half the difference, and so the semidiameter of the epicycle, be BF. *Boulliau*, Book 2, chapter 1, determines the minor semidiameter CF to the major CA as 99984 to 100000; so AF is 16 and AB 8 of such parts; and therefore this ellipse differs insensibly from the circle.

Diagram. Woodcut in the right column, between "mi-" and "nor": the figure of the concentrepicycle. A large circle with centre C, with a vertical line from the top epicycle to the bottom epicycle and a horizontal line from the left epicycle to the right. Four small epicycles are set at the top, left, right and bottom of the large circle, and a fifth at the upper left. Straight lines run from C to the upper-left epicycle (two lines, to its upper and lower parts), and from C to L and V at the left and right epicycles.

- A, B (top epicycle; A at its head, B within it, on the large circle)
- G, E (on the large circle, either side of the top epicycle)
- F (on the vertical line, just below the top epicycle)
- D, Z, K, I (upper-left epicycle; D above, Z outside to the left, K and I within it)
- L, M (left epicycle; L above it, M within it)
- V, N (right epicycle; V above it, N within it)
- C (centre of the large circle)
- P, R (bottom epicycle; P above it, R within it)
- Q (on the large circle, right of the bottom epicycle)

Labels read: A, B, C, D, E, F, G, I, K, L, M, N, P, Q, R, V, Z. Labels not read: none.

SCHOLIA.

Scholia.

[Margin: The elliptical hypothesis is not necessary for the Sun.]

I. Now by the admission of Kepler *and* Boulliau *the ellipse described by the motion of the Sun differs so little from a circle that the difference is scarcely sensible, and it cannot be demonstrated, as in the case of Mars, by calculations from observations, as is clear from what was said in the preceding chapter, numbers 3 and 4. On the other*

side, many observations of the apparent diameter, and the difference between them at apogee and perigee, urge that the Sun's eccentricity be kept whole. We therefore think it advisable in the theory of the Sun to use a simple eccentric and the customary method of the equation; especially since the whole equation from the elliptical form is never greater or less than the equation gathered by the simple eccentric by 69″. Seconds, and usually less; so that from the data given by Tycho, Magini, *by bisecting the eccentricity, and* Tycho, *by not bisecting it, gather the equations written below, at the ends and middles of the signs of anomaly.*

Deg.		Anomaly 0^s	1^s	2^s	3^s	4^s	5^s
15	Magini	0° 31′ 20″	1° 26′ 2″	1° 58′ 28″	1° 59′ 32″	1° 28′ 14″	0° 32′ 28″
	Tycho	0° 30′ 48″	1° 24′ 56″	1° 57′ 52″	2° 0′ 4″	1° 29′ 23″	0° 33′ 1″
30	Magini	1° 0′ 40″	1° 45′ 46″	2° 3′ 10″	1° 47′ 40″	1° 2′ 33″	0° 0′ 0″
	Tycho	0° 59′ 54″	1° 44′ 46″	2° 3′ 9″	1° 48′ 36″	1° 3′ 33″	0° 0′ 0″

[Margin: The ellipse in the hypothesis of a stationary Earth.]

Moreover, the Sun's parallax is not so certain that the difference between these equations can be proved from observations, as arising from a hypothesis determined in the heavens. Further, this hypothesis is fitted to the annual motion of the Earth, which we cannot admit. Therefore either this hypothesis is to be rejected altogether, or in the hypothesis of a stationary Earth the theory of the ellipse must be arranged differently: for the Earth is to be placed at the centre of the world, A (according to the figure given above at number 8), and the Sun is to be moved on the ellipse, so that it descends from the apogee K through E to the perigee D. In the other planets it will have to be arranged as will be indicated in the proper places.

[Margin: Among which authors is the practice of describing an ellipse found?]

II. The practice of describing an ellipse is taught by Eutocius *on Apollonius, Book 1, Prop. 21;* Commandino *in the Horologia following Ptolemy's Analemma;* Maurolico, *De lineis horariis, Book 3;* Guidubaldus de Monte [Guidobaldo del Monte] *in the Theory of the Planisphere;* Clavius, *Gnomonics, Book 1, at the end of Prop. 8;* Dauid Riualtus [David Rivault] *on Archimedes' book On Conoids, Problem 3;* Bartholomæus Souerus [Bartolomeo Sovero] *in his book On the Proportion of the Curved and the Straight, Advanced;* Franciscus Aguillonius [François d'Aguilon], *Optics, Book 6, Lemma 22;* Kepler *in the Astronomia Optica, p. 95;* Cavalieri, *De speculo ustorio, chapters 43 to 51;* Bettini, *Apiarium 3, Prog. 10, Prop. 13, and Apiarium 10, Prog. 2, Prop. 6;* Claudius Mydorgius [Claude Mydorge], *Prodromus Catoptricorum, Book 2;* Descartes, *Dioptrics, chapter 8, number 2; and* Boulliau, *Book 1, chapter 20.*

[Margin: Boulliau's equations.]

III. Boulliau, *Book 2, chapter 4, teaches how to investigate the equations in the form of the ellipse, from an epicycle of semidiameter 8 parts, of which the semidiameter of the ellipse is 100000, and from the semidiameter of the circle carrying the epicycle, which is 99992 parts, and from the motion of the epicycle in the contrary direction,*

double the motion of the circle already mentioned: first the simple equations, then the optical separately from the physical. From this he builds a table of equations of his own, which we shall perhaps give at the end of the work, so that its difference from the others may appear.

[Margin: The apparent inequality in the Sun's motion set out by means of a spiral line and the diurnal motion alone.]

IV. If, as al-Biṭrūjī, *and* Patrizi, *and other authors not to be despised hold, the Sun does not move towards the east, but by a single spiral motion towards the west, the diurnal one; and if it therefore seems to become more easterly each day because in its diurnal motion it is slower than the fixed stars and the primum mobile, and does not have the ecliptic as the measure or subject of its path; then there is no need to recognise inequality in its motion. For if it stays about 7 days longer on this side of the equator, it also makes more spirals, but less wide or less distant from one another than beyond the equator. And so it can be said to traverse equal spaces in equal times, so that the spiral line made on this side of the equator is to the whole line beyond the equator as the time of its stay on this side is to the time of its stay beyond. And the differences of declination can be saved by the distances of the partial and daily spirals; indeed, even the apogee and perigee states, by wider and narrower spirals. The cause for which the Sun stays longer among the northerners is that on this side of the equator the tract of the inhabited Earth is greater, and indeed inhabited by people of greater intellect, and where religion, the sciences, the liberal arts and civil culture were to flourish according to the decree of Divine Providence: for this reason I would also believe that there are more fixed stars in the northern tract of the sky than in the southern. But since from this hypothesis, just as it very well follows among other things that there are not two contrary motions in the Sun but one simple diurnal motion, so it is difficult to set out by geometrical figures a method of the equations, for this reason it has been neglected, and indeed condemned by* Kepler *in Mars, chapter 1, to the point of branding* Patrizi, *its restorer, with the mark of insanity. But men should be more sparing with such things; for it is not false for the reason that we cannot with our geometrical little machines bring its reasons to calculation by lines. But more on this elsewhere. For what if someone were to show that such is the line by which the Sun, describing it around the cone, emulates the Keplerian, or rather the Boullialdian, ellipse?*

CAPVT XXIV.

Chapter 24.

De Solis Apogeo, & Eccentricitate, aut Epicycli diametro inuestigandis vna eademq. opera.

On investigating the Sun's apogee and eccentricity, or the diameter of the epicycle, by one and the same procedure.

Up to this point the equations of the Sun's motion have presupposed both the eccentricity, as the base of the prosthaphaeretic angle, and the anomaly, or mean distance from the Sun's apogee, which cannot be known unless the place

in the ecliptic under which the Sun's apogee lies is known beforehand. We must therefore investigate these carefully; for once the eccentricity is found, the semidiameter of the epicycle will be known, because it is equal to the eccentricity; and also both semidiameters of the solar ellipse, because the excess of the greater over the lesser is equal to the doubled eccentricity.

Prima Methodus Inuestigandi Eccentricitatem, & Apogeum Solis.

First method of investigating the Sun's eccentricity and apogee.

I. This first method is taught by *Ptolemy*, *Almagest*, Book 3, chapter 4; *al-Battānī*, chapter 28; *Regiomontanus* in the *Epitome of the Almagest*, Book 3, Prop. 13; *Nonius* on the *Theorics* of Peuerbach, Annotation 1; *Reinhold* on the same, p. 41; *Copernicus*, Book 3, chapter 16; *Snellius* at the end of the *Hessian Observations*; *Longomontanus*, Book 1 of the *Theorics*, p. 176; *Biancani*, *Sphaera*, Book 10, chapter 9; and *Metius* in the *Theory of the Sun*, chapter 7. It rests on the observation of two equinoxes and the solstice between them.

Diagram. Woodcut in the right column: a large circle (the ecliptic) with horizontal diameter C to A and vertical diameter B to D, crossing at the centre E. A smaller circle stands inside it, displaced upward and to the right, touching near the upper right. A second vertical line runs through F, from the short chord near the top down to the smaller circle's foot; a second horizontal line runs through F from the smaller circle's left side to K. A straight line runs from E up through F to T and H; a short vertical joins Q and P at the right.

- B (top of the large circle), D (foot of the large circle)
- C (left), A (right, italic): ends of the horizontal diameter
- E (centre of the large circle, below the crossing)
- L (top, small, above G)
- R (on the vertical diameter, near the top), G (on the second vertical, near the top)
- H (upper right, on the large circle), T (just inside H, on the smaller circle)
- M (left, italic, on the smaller circle), S (on the vertical diameter, on the line M to K), F (at the crossing of the second vertical and the line M to K)
- Q, K (right; Q on the smaller circle, K on the large circle)
- Y (left, on the line C to A), V (on the second vertical, below the line C to A), P (right, below the line C to A)
- N (italic, foot of the smaller circle)

Labels read: A, B, C, D, E, F, G, H, K, L, M, N, P, Q, R, S, T, V, Y. Labels not read: none.

Let ABCD be the ecliptic, whose centre is E, in which the line of the equinoxes AC and the line of the solstices BD cut each other at right angles; let A be the point of the vernal equinox, or the beginning of Aries, C the point of the autumnal, and B the beginning of Cancer. And since in Ptolemy's time,

as is clear from the table of Chapter 18, the Sun stayed longer in the northern semicircle ABC than in the southern, and longer in the first quadrant of the ecliptic AEB than in the others, therefore the cen- tre of the Sun's eccentric is to be placed in this first quadrant, say at F. Let the eccentric GMNP be described from it, and let the apogee line EFH be drawn through the centres E and F; for the point of the apogee will be T on the eccentric but H on the ecliptic, and the eccentricity will be EF. Next, draw through the centre F two straight diameters of the eccentric: KM, parallel to CA, and LN, parallel to BD. In this way, by Proposition 29 of Euclid's Book 1, the angles at S and V will be right; by Proposition 34, SF will be equal to EV, and SE to FV, and the triangles ESF and EVF will be right-angled at S and V; and when the right sines RG and QP are drawn, by the same Proposition 34 RG will be equal to SF, and QP to SE. Therefore, if the sines PQ and RG are known from the known arcs PK and RL, SE and SF will also be known. The rest I shall teach by Ptolemy's example.

[Margin: Ptolemy's example.]

Ptolemy had observed that 178 [recte: 187, per the book's errata] days pass from the vernal equinox to the autumnal, and that to these days the Sun's mean motion according to Ptolemy, namely the arc PLY, corresponds at 184° 20′. And the straight line LV, by Proposition 3 of Euclid's Book 3, cuts the arc PLY in two at L; so the arc LP was 92° 10′. He had next observed that the Sun stays 94^{d} 12^{h} in the first quadrant of the ecliptic, to which the arc PR and a mean motion of 93° 9′ correspond; so the arc RY was 91° 11′. Therefore, when the arc PL was subtracted from the arc PR, there remained the arc LR, 59′, whose sine RG is 1716 of the parts of which the radius FL is 100000, and the side SF is just that much. Next, when the quadrant KL, of 90°, was subtracted from the arc PL, there remained the arc PK, 2° 10′, whose sine PQ, that is SE, is 3781 parts. And from the sides SF and SE already mentioned, in the triangle ESF, right-angled at S, the base EF, or the Ptolemaic eccentricity, is gathered trigonometrically: 4152 of the parts of which the eccentric's radius FT is 100000; or, as *Ptolemy* puts it, 2° 29′ 30″ of the parts of which FT is 60°; or, as *Hipparchus* had roughly found, one twenty-fourth of the radius. In the same triangle there is also found the angle SFE, to which by Proposition 29 of Book 1 the angle FEV is equal, of 65° 30′. This angle measures the arc AH, namely the distance of the apogee H from Aries A on the ecliptic. So *Ptolemy* concluded that the Sun's apogee is at 5° 30′ of Gemini, and that it does not move, because *Hipparchus* had found it in that same place 260 years earlier. [Margin: Al-Battānī's observation.] Yet by the same method *al-Battānī*, chapter 28, finds the Sun's apogee at 22° 17′ of Gemini and the eccentricity 3465 15/54, in the year 1194 of Dijlkarnaim[18], or of Christ 883. But *Nunes*, in the year 1552, from data given by *Pietro Pitati*, obtained an apogee at 1° 28′ of Cancer with an eccentricity of 3781 3/10 of the parts of which the eccentric's

[18]supplied identification — Dhū al-Qarnayn, the era of Alexander

radius is 100000; and he admits that this does not agree with the motion of the apogees [Augium] laid down by the Alphonsines.

Secunda Methodus Inuestigādi Eccentricitatem simul, & Apogeum Solis.

Second method of investigating the eccentricity and the Sun's apogee together.

[Margin: And of Pietro Pitati, with whom Nunes.]

II. The method of *Ptolemy* and of *al-Battānī* rests on the observation of the solstices, from which the interval between equinox and solstice is fixed, and that observation is exposed to an error of at least a whole day, as we showed in Chapter 14, numbers 3 and 4. For this reason *al-Zarqālī* the Spaniard used a more exact method, which, besides the observation of two equinoxes, [Margin: Al-Zarqālī's more exact method.] rests on a place of the Sun observed at about the middle parts of Taurus or of Leo, or at those times when the difference of the Sun's declinations is very perceptible. For that reason this method was chosen by *Regiomontanus*, Book 3 of the *Epitome of the Almagest*, Proposition 14; *Copernicus*, Book 3, Chapter 16; *Nunes* on Peuerbach's *Theorics*, Annotation 1, page 201; *Daniel Santbech*, *On Observation*, Proposition 9; *Tycho*, Volume 1 of the *Progymnasmata*, Chapter 1, from page 20; *Longomontanus*, Book 1 of the *Theorics*, Chapter 2; *Lansbergen* in the *Progymnasmata* on the Sun; *Snellius* and *Iustus Byrgius* [Jost Bürgi] in the notes to the Hessian observations; and *Metius* in the *Theoric of the Sun*, Chapter 8.

Diagram. Woodcut at the foot of the left column, with the text wrapped to its left: a circle for the eccentric, with the vertical diameter BD and the horizontal chord LA below the centre. O stands on BD above C. From T on the upper right a straight line runs down through C to P on the lower left; radii run from O to T and to A; a chord runs from P to A; a short perpendicular falls from the line LA to P, with R on LA above it.

- B (top): upper end of the diameter BD
- D (bottom): lower end of the diameter
- L (left end of the chord): under Libra
- A (right end of the chord): under Aries
- T (upper right, on the circle): the Sun's observed place
- P (lower left, on the circle): the point where the line from T through C meets the circle
- O (on BD, above the chord): centre of the eccentric
- C (on BD, at the chord): centre of the Earth and of the ecliptic
- R (on the chord, right of L): foot of the perpendicular from P
- I (small, right of the diameter, between O and C): foot of the perpendicular from O to TC

Labels read: A, B, C, D, I, L, O, P, R, T. Labels not read: none.

Let ABLD be the eccentric, described from the centre O, and let C be the centre of the Earth and of the ecliptic. Through these centres let the diameter

BD be drawn, and through C the line of the equinoxes AL, so that the point A of the eccentric lies under Aries and L under Libra. Let the portion ABL be the greater, corresponding to the time for which the Sun stays longer in the northern semicircle than in the southern; this arc will be known from the mean motion matching the time already mentioned. Let a place of the Sun between solstice and equinox be observed, say T at the middle of Taurus, and to it draw the eccentric's radius OT, and from O the radius OA. For from the time between the equinox A and the observed place T, the Sun's mean motion will be known, and the arc AT, and so the angle TOA. Next, from T through C draw the straight line TP; for CT will be the line of the Sun's true place, which is known from observation. So the angle TCA is known, which measures the Sun's true distance from Aries on the ecliptic. Now from O draw the straight line OI perpendicular to TC, so that the triangle OIC is right-angled at I. Finally, from the point P draw the straight line PA to A, and to AL the perpendicular PR.

When this has been done, the angle at the centre AOT, now known, stands on the arc TA, and the angle APT at the circumference is, by Proposition 20 of Euclid's Book 3, half the angle AOT; so it too is known. But TCA was also known; therefore, by Proposition 13 of Euclid's Book 1, PCA is known, as its complement to two right angles. So when the angles APT and PCA, taken together, are subtracted from the sum of two right angles, the angle PAC, that is PAL, will be known by Proposition 32 of Book 1. By Proposition 20 of Euclid's Book 3 the arc LP is double this angle; and when LP is subtracted from the arc LDA, the complement of the known arc ABL, the known arc PDA remains, whose chord PA is known from the tables of sines. And when the arcs PDA and AT are added together, the arc PAT will be known, whose chord PT will likewise be known from the tables of sines. Now the angle PCR is known, since by Proposition 15 of Euclid's Book 1 it is equal to the angle ACT, already known, and the angle PRC is right by construction. So the sine of the angle PCR will become known, and that sine is to the whole sine as PR to PC. Again, the sine of the known angle LAP is known, and the ratio of the chord PA to PR is as the whole sine to the sine of the angle LAP; therefore PR will become known in the parts in which the chord AP was given. And since PR is to PC as the sine of the angle PCR to the whole sine, and the sine of the angle PCR was known, PC too will become known in the same parts. When PC is subtracted from the chord PT, CT remains known; and when PT is cut in two at the point I by the perpendicular OI, the side CI will be known. Finally, if you imagine a parallel to the chord PT drawn through the eccentric's centre O, to the periphery on both sides, that chord will turn out to be the chord of a semicircle. So when the known arc PAT is subtracted from the semicircle, its complement to the semicircle will remain, and the right sine of half of that will be the right sine OI. Then, with the sides OI and CI and their squares known in the right-angled triangle OIC, by Proposition 47 the square will be known whose square root will be the base OC, namely the eccentricity, in the parts of

which the eccentric's radius OB was taken. And in the same triangle, by the rules of right-angled triangles, you will find the angle OCI at the centre of the ecliptic, which measures the distance of the Sun's apogee from the beginning of Aries.

This method seemed suspect to *Jābir ibn Aflaḥ* in Book 3 of his *Astronomy*, as *Nunes* also noted in the place cited above, because through the many combinations of numbers, often fractions, and the extraction of a square root, [Margin: Jābir's suspicion of this method.] a small error at each step can end up large by the close of the working. Yet for this reason *Snellius*, in the place cited above, calls Jābir [Greek: μισάριθμον (misarithmon, "number-hater")], that is, a hater of numbers and of calculation. In the end this method was used by *Copernicus*, though he took the Sun's place in the middle of Scorpio and did not correct it for refraction; and by *Tycho*, *Longomontanus*, *Iustus Byrgius* and *Snellius* in the places cited above, though they chose observed places of the Sun beyond the hazard of refractions.

Tertia, & Nostra Methodus Inuestigandi Eccentricitatem, & Apogeum Solis.

Third method, our own, of investigating the eccentricity and the Sun's apogee.

[Margin: Our method.]

III. Our method, then, is easier and not exposed to so many small errors; I make it clear with the following diagram and example. Let ABPD be the ecliptic, described from T, the centre of the Earth and of the world, with BD the line of the equinoxes and AP the line of the apogee, on which let the eccentricity be CT and let C be the centre of the eccentric KMVN. Let C be joined to the points of intersection M and N by the eccentric's radii CM and CN. For MCN will be an isosceles triangle, and by Proposition 5 of Euclid's Book 1 the angles at M and N will be equal. And let the apo- gee of the Sun be K, under the point A of the ecliptic, and the perigee V, under P. Let there be observed the moment of the vernal equinox, occurring at D, and of the autumnal equinox immediately before or after it, occurring at B; and, besides these, in the same year a third place of the Sun far from the solstice, say when it is in the sign of Taurus or Leo, if you are on this side of the equator, or in Scorpio or Aquarius, if you live beyond it. Let that place be the point L of the ecliptic, under which the Sun is at S. To L draw from the centre of the Earth the line of the true place TL, and to the Sun S, from the centre of the eccentric, the line of mean motion CS. When this has been done, proceed as in the example below.

Diagram. Woodcut at the head of the left column, with the opening lines wrapped to its left: a large circle for the ecliptic, and inside it a smaller circle for the eccentric, set off-centre towards the top. A horizontal line BD crosses the large circle and cuts the small one at M and N. A line runs from A at the top down through K and C to V and P at the bottom; another runs down from L

through S, crossing MC at I, to T on the horizontal line. C is joined to M and to N.

- L (top, left of A): on the large circle, the Sun's place on the ecliptic
- A (top): on the large circle, under which the apogee stands
- S (just inside the small circle, near the top): the Sun
- K (beside S): the apogee on the eccentric
- C (below K): centre of the eccentric
- I (small, on the crossing below and left of C): intersection
- B (left) and D (right): ends of the equinoctial line
- M and N (left and right, on the horizontal): the eccentric's intersections with that line
- T (on the horizontal, between M and N): centre of the Earth
- V (below T): the perigee on the eccentric
- P (bottom): on the large circle, under the perigee

Labels read: A, B, C, D, I, K, L, M, N, P, S, T, V. Labels not read: none.

EXEMPLVM. Methodi 3.

Example of Method 3.

In 1646 we observed the autumnal equinox at B, on September 22, at 14^{h} 56^{m} after noon at Bologna; and in 1647 the vernal equinox at D, on March 20, at 5^{h} 56^{m} after noon at the same place. So the Sun was in the southern signs, or on the arc BPD of the ecliptic, for 178^{d} 15^{h}, to which, from the table of mean motion given in Chapter 17, the arc MVN of the eccentric corresponds, of 176° 3′ 41″; and the angle MCN is just that much. Therefore, by Proposition 32 of Euclid's Book 1, the angles at the base MN are together 3° 56′ 19″, which is the complement to two right angles; taken singly, M is 1° 58′ 9½″; and the remainder to the whole circle, namely the arc MKN, is 183° 56′ 19″. Further, in 1646, with two great quadrants at Bologna, at noon on July 28, we observed the Sun S under L, at 5° 14′ of Leo. So the arc LD, that is the angle LTD, was 125° 14′, for that was the longitude from the beginning of Aries; and the remaining angle to the semicircle, that is LTB, was 54° 46′. The interval from the noon of this observation to the following equinox at B was 56^{d} 14^{h} 56^{m}, to which the mean motion corresponds, namely the arc SM and the angle SCM, of 55° 48′ 34″. And so the angle ICS is known, since it is the same as the angle SCM. Now add the angle M, 1° 58′ 10″, to the angle MTL, of 54° 46′, and the sum is 56° 44′ 10″. When this is subtracted from 180°, the angle MIT remains, 123° 15′ 50″, and the vertical angle SIC is just that much; the angle TIC will be 56° 44′ 10″, and the angle S, namely the equation, will be 55′ 36″. So we have, without tables of sines or chords, all the angles we need.

First, then, in the triangle CIS, the eccentric's radius CS is given, of 100000 parts, and the angle SIC, 123° 15′ 50″, and ICS, 55° 48′ 34″; so the third angle S, by Proposition 32 of Book 1, is 0° 55′ 36″. From this, by trigonometry, CI is found to be 1913½ parts. When these are subtracted from the radius CM, of

100000 parts, there remains MI, of 98086½ parts. With this side, and the angle M, 1° 58′ 10″, and the angle ITM, that is BTL, 54° 46′, IT is gathered to be 4084½ parts. Finally, with this side, and the side IC, and the angle TIC, 56° 44′ 10″, there is found TC, the eccentricity, of 3431 of the parts of which the radius CK is 100000, and the angle LTA, 27° 47′ 45″. Subtracted from the angle LTD, of 125° 14′, this leaves the angle ATD and the arc AD, 97° 26′ 15″, which is the distance of the place A of the Sun's apogee from the beginning of Aries, D. [Margin: The eccentricity found from this.] [Margin: Place of the apogee.] Therefore in 1646, on July 28, the Sun's apogee was at 7° 26′ 15″ of Cancer.

EXEMPLVM II.

Example 2.

[Margin: A second example.]

IV. Again, in the same year 1646, on August 4, the Sun's meridian distance from the vertex, taken at Bologna with the great quadrants, was 27° 14′ 50″; but with my parallax of 30″ subtracted it was 27° 14′ 20″, and the northern declination 17° 15′ 10″. From this, with the obliquity of the ecliptic set at 23° 30′, the Sun's place was 11° 56′ 40″ of Leo [♌], and the interval to the autumnal equinox $49^{d}\ 14^{h}\ 56^{m}$. So the true motion, that is the angle LTD, was 131° 56′ 40″, and the mean, that is the angle SCI, 48° 54′ 36″. Therefore the angle LTB, or ITM, was 48° 3′ 20″, and M was 1° 58′ 10″, as in the earlier example. So the angles MIT and also SIC are given, 129° 58′ 30″, and MIS and also CIT, 50° 1′ 30″. Hence the equation CSI is 1° 6′ 54″.

First, then, in the triangle SIC, from the side SC, or radius, 100000, and CSI, 1° 6′ 54″, and SIC, 129° 58′ 30″, the side IC is found trigonometrically to be 2577 of the parts of which CS or CM is 100000. So MI is 97423 parts. Next, in the triangle MIT, from the side MI, 97423, and the angles MTI, 48° 3′ 20″, and M, 1° 58′ 10″, the side TI is found to be 4527 parts. Third, in the triangle CIT, from the sides IC, 2577, and IT, 4527, and the angle CIT, 50° 1′ 30″, there is found [Margin: The eccentricity found from this.] CT, the eccentricity, of 3491 parts, and the angle ITC, 34° 27′ 36″. When this is subtracted from the angle LTD, which was 131° 56′ 40″, there remains the distance of the place of the apogee A from the beginning of Aries, D, that is the angle ATD, 97° 29′ 4″. [Margin: And the place of the apogee.] Therefore the Sun's apogee was at 7° 29′ 4″ of Cancer.

[Margin: Determination of the eccentricity and of the apogee.]

On account of these and other observations, from which I now refrain, I have settled, choosing a middle value, on an eccentricity of 3460 of the parts of which the eccentric's radius is 100000: about what *al-Battānī* and al-Zarqālī found by their 402 considerations, as Regiomontanus says, which was 3465. The apogee, however, I have kept at 7° 26¼′ of Cancer, or 7° 26′. And it is almost midway between the one that the Rudolphine Tables give this year, at 6° 30′ 23″ of Cancer, and Lansbergen's, at 7° 48′ 49″.

Quarta Methodus inuestigandi Eccentricitatem, & Apogeum Planetæ.

Fourth method of investigating the eccentricity and apogee of a planet.

[Margin: The method of François Viète and of Boulliau.]

Boulliau, in Book 1 of his *Astronomy*, Chapter 22, and Book 2, Chapter 1, proposes this method, from two problems of *Viète* demonstrated in the second little appendix of the *Apollonius Gallus*; it is suited, indeed, to the hypothesis of the ellipse, but serves others as well.

Diagram. Woodcut in the right column, with the text wrapped to its left: a circle with the horizontal diameter FG. From C on the upper left, D on the upper right and B on the right, normals fall to the diameter at K, H and I, the last two running on below it to N and M on the lower circle. A vertical from L at the top falls to the centre A. Chords run from C to B and from C and B to D, and E stands where DHN crosses CB.

- L (top): on the circle, above the centre
- D (upper right): on the circle, the second observed place
- C (left, on the circle): the first observed place
- B (right, on the circle): the third observed place
- E (inside, right of centre): the point on the chord CB
- F (far left) and G (far right): ends of the diameter, outside the circle's rim
- K (on the diameter, left): foot of the normal from C
- A (on the diameter, centre): centre of the circle
- H and I (on the diameter, right, set together): feet of the normals from D and B
- M (lower right, on the circle): lower end of the normal from B
- N (bottom right, on the circle): lower end of the normal from D

Labels read: A, B, C, D, E, F, G, H, I, K, L, M, N. Labels not read: none.

Let there be given three observed places of the planet, C, D, B, on the circle described from A. For from the interval of the observations the mean motions will be given, and so the arcs CD and DB; and then, from the tables of sines, the chords CD and DB; and of the compound arc CDB the chord CB will be given. And since, by Proposition 20 of Euclid's Book 3, the angle at the centre, which measures the arc of the circle, is double the one at the circumference, the angle CBD will be half the arc CD, and the angle DCB half the given arc DB. Now let the diameter FG be understood as drawn, so that, when the normals CK, DHN, BIM are dropped from the given points C, D, B, the segment KI of the diameter has to the segment HI the ratio which the chord CB has to EB, by Viète's problem; that is, from the difference of the mean motion from the apparent, let the part KI on the diameter FG be the difference of the mean motion from the apparent for the interval CDB, while for the interval DB let the difference of the mean from the apparent be HI. Let it be, then: as the sine of the half-difference of the mean and apparent motion corresponding to the interval CB, that is, as KI, is to the half-difference of the mean and apparent

motion corresponding to the interval DB, namely to HI, so is the chord CB to its portion EB. For in this way, in the triangle EBD, the sides EB and DB, the chord of the arc DB, will be given, and the angle EBD, which we said is half the arc CD. So by trigonometry the angle EDB will not stay hidden, and when doubled, by Proposition 20 of Euclid's Book 3, it will give the arc BGN. If the arc NM, which is equal to the arc DB, is subtracted from this, the arc BM will remain, half of which is BG. This arc, added to DB, the apparent motion, will give the arc GD, from which the complement LD to the quadrant will be known. So let the arc LD be subtracted from the planet's apparent place D, and known will be the apogee or aphelion L, whose line is AL. Further, half of the whole first inequality, that is, the distance of the umbilici from the centre of the ellipse, is the line AG, which is found in this way. For the arcs of apparent motion CL, the distance from the aphelion, and LB, find the right sines KA and AI, and add them into one sum for the sine KI, which you keep as the divisor. Then multiply by the whole sine the sine of the half-difference of the apparent and mean motion corresponding to the arc CDB, namely KI; divide the product by the divisor you have kept, and AG will come out. Doubling this, you will have the distance of the umbilici FG or, in the hypothesis of others, the whole eccentricity.

But since *Boulliau* admits that neither the mean nor the apparent motion is to be assigned to the arcs CB and DB, because in the circles the planet undergoes only half of the first inequality, he therefore says that the planet is to be considered as seen not from one of the umbilici but from the centre of the ellipse, and that the arithmetic mean between the mean and apparent motions is to be taken.

EXEMPLVM BVLLIALDI.

Example of Boulliau.

V. An example will perhaps make the practice clearer. In 1588 *Tycho* observed, from C, the middle of Taurus [♉], to D, the middle of Leo [♌], an elapsed time of $94^{d}\ 5^{h}\ 55^{m}$, to which a mean motion of 92° 53′ 34″ corresponds, but the apparent motion was 90°. And from D, the middle of Leo, to the beginning of Libra [♎], B, $46^{d}\ 9^{h}\ 40^{m}$, to which a mean motion of 45° 44′ 16″ but an apparent motion of 45° corresponds; and from the middle of Taurus to the beginning of Libra, $140^{d}\ 15^{h}\ 35^{m}$, whose mean motion is 138° 37′ 50″ but the true motion 135°, corresponding to the arc CB. The arithmetic mean between the apparent and true motion of the arc CD is 91° 26′ 47″, half of which is the angle CBD, 45° 43′ 23″. And the arithmetic mean of the arc DB is 45° 22′ 8″, half of which is the angle DCB, 22° 41′ 4″. So the angle CDB is 111° 35′ 37″. Finally, the arithmetic mean of the arc CB is 136° 48′ 55″. The chords corresponding to the arcs already mentioned are CD, 71597; DB, 38565; CB, 92983, of the parts of which the whole sine is 100000.

Next, the difference of the mean and apparent motion in the first interval CD is 2° 53′ 34″, half of which is 1° 26′ 47″, and its sine is 2524, corresponding to KH. The difference of those motions in the second interval DB is 44′ 16″, and half of it 22′ 8″, whose sine is 644, corresponding to HI. And finally the difference of the mean and apparent motion in the whole interval CDB is 3° 37′ 50″, half of which is 1° 48′ 55″, whose sine is 3168, corresponding to KI.

With these prepared, make: as KI, 3168, to CB, 92983, so HI, 644, to another; and EB will come out, of 18902 parts. With this side, and the side DB, 38565, and the angle DBC, 45° 43′ 23″, you will find by the analysis of triangles the angle EDB, 28° 4′ 42″, whose double is the arc BN, 56° 9′ 24″. If you take from this NM, that is, the equal of DB, 45° 22′ 8″, BM will be given, 10° 47′ 16″, and half of it, BG, 5° 23′ 38″. DB, 45° 22′ 8″, added to this, gives DG, 50° 45′ 46″, whose complement to the quadrant gives the arc LD, 39° 14′ 24″. So when this arc is subtracted from 15° of Leo, there remains 5° 45′ 37″ of Cancer. If you take from this half the difference of the true and apparent motion corresponding to the second interval, which was 22′ 8″, there remains L, the place of the aphelion, at 5° 23′ 29″ of Cancer [♋], for the year 1588.

Lastly, CL is 50° 23′ 29″, whose sine KA is 77042, and LB is 84° 36′ 31″, whose sine AI is 99557, and the sum is the sine KI, 176599; and the half-difference of the mean and true motion corresponding to the arc CDB, that is KI, was found above to be 3168. If you make as 176599 to 100000, so 3168 to another, AG will come out as 1784 parts, which is the distance of the umbilici from the centre of the ellipse, or half of the first inequality. Therefore the whole eccentricity in the hypothesis of a simple eccentric is 3568 of the parts of which the eccentric's radius is 100000.

EXEMPLVM ALTERVM.

Another example.

VI. But since the investigation of the eccentricity and apogee usually proceeds from observations of the equinoxes together with a place of the Sun observed between them and the solstice, [Margin: Example for equinoctial observations, etc.] Father *Paulus Casatus* [Paolo Casati] applies Boulliau's method to our observations listed under number 3, in this way. Let the circle MBLC be described from the centre O, and let BC be the line of the mean equinoxes, so that the vernal equinox is at C and the autumnal at B; and let the third, mean place of the Sun be A, which is to be joined to B and C. Next, since from observation the motions both true and mean are given in Example 1 of number 3, and their arithmetic mean, in accordance with this mean there are given the arcs AC, 126° 40′ 52½″, and AB, 55° 17′ 17″, and the whole arc CAB, 181° 58′ 9½″; [Margin: By Proposition 20 of Euclid's Book 3.] and so the angles ABC, 63° 20′ 26¼″, ACB, 27° 38′ 38½″, and BAC, 90° 59′ 4¾″. And so from the tables of sines there are given the chord AC, 17833796 [?], of the parts of which the radius is 10000000, and AB, 9279537, and BC, 19997046.

Diagram. Woodcut in the right column, with the opening lines of the column wrapped to its left: a circle with the horizontal diameter HG through its centre O, slightly tilted on the block. Chords run from A at the upper left to B on the left, from A down to L, and from A to C at the lower right; a line runs from B to C through D and X and past O; a perpendicular falls from M at the top to the diameter at O; a chord runs from B down to F, crossing the diameter at S; another runs from C up to T, crossing the diameter at N.

- A (upper left, on the circle): the third, mean place of the Sun
- M (top, right of A): upper end of the perpendicular from O
- T (upper right, on the circle): upper end of the perpendicular from C
- B (left, on the circle): autumnal equinox
- H (left, just below B): left end of the diameter
- F (lower left, on the circle): lower end of the perpendicular from B
- L (bottom left, on the circle): lower end of the line from A through D
- S (on the diameter, left): foot of the perpendicular from B
- D and X (set together, just above the diameter): on the line BC
- I (just below D, on the diameter): where AL crosses the diameter
- O (on the diameter, centre): centre of the circle
- N (on the diameter, right): foot of the perpendicular from C
- G (right, on the circle): right end of the diameter
- C (lower right, on the circle): vernal equinox

Labels read: A, B, C, D, F, G, H, I, L, M, N, O, S, T, X. Labels not read: none.

Hence the line BC is to be divided so that BC is to BD as the sine of the half-difference between the mean and true motion belonging to the whole arc BAC is to the sine of the half-difference between the mean and true motion of the arc AB. The former half-difference is 1° 58′ 9½″ and its sine 343641; the latter is 0° 31′ 17″ and its sine 90998. So as 343641 to 90998, so BC, 19997046, to BD, 5295326. Then let AD be drawn all the way to L, and from O, the centre of the circle, let the perpendicular OI be raised to AL; extended on both sides until it reaches the periphery, it will give the diameter HG, on which let the perpendicular OM be erected from O. And from the points B and C let the perpendiculars BF and CT be dropped, which cut off from the diameter HG the segment SN, so that the proportion of BC to BD is the proportion of NS to IS. For since the angles at S and N are right and equal, the lines SB and CN are parallel by Proposition 27 of Euclid's Book 1; and so, by Proposition 29 of the same, the angles SBX and XCN are equal; and the angles at X, by Proposition 15 of Book 1, being vertical, are equal. So the triangles BSX and CNX are proportional by Proposition 4 of Book 6. And since DI falls perpendicularly on the diameter HG and so is parallel to SB, it also cuts the sides of the triangle BSX proportionally, by Proposition 2 of Book 6; and the triangle XDI is proportional to the triangle CNX. So as CX is to XD, so NX to XI; and therefore, by composition, as CD to XD, so NI to XI. But as XD to

DB, so XI to IS; therefore, *ex aequali*, as CD to DB, so NI to IS; and therefore, by composition, as CB to DB, so NS to IS.

Now in the triangle ABD we have the angle ABD, 63° 20′ 26¼″, and the side AB, 9279537, and BD, 5295326, as found above. So by trigonometry the angle BAD is 34° 21′ 43″ 28‴. And therefore, by Proposition 20 of Euclid's Book 3, we have its double, the arc BL, 68° 43′ 26″ 56‴, from which the arc FL is to be subtracted, which is equal to the arc AB. For the radius OH cuts the line AL at I in two and at right angles, by Proposition 3 of Euclid's Book 3, and by the same proposition BF is cut in two at S; so the arc BH is equal to the arc HF, and AH to the arc HL. So when the equals BH and HF are taken away on each side, AB and FL remain equal. Therefore FL is 55° 17′ 17″; subtracted from BL this leaves BF, 13° 26′ 9″ 56‴, half of which, BH, is 6° 43′ 4″ 58‴. If you add to this AB, 55° 17′ 17″, the result is HA, 62° 0′ 21″ 58‴. And so its complement to the quadrant is the arc AM, 27° 19′ [recte: 59′] 38″ 2‴. The true place A was at 5° 14′ of Leo, whose distance from the equinox C is 125° 14′. If you take the arc AM from this, there remains CM, namely the distance of the Sun's apogee from the beginning of Aries, 97° 14′ 21″ 58‴, which by our method was found to be 97° 26′ 15″. But if, following Boulliau, you subtract the half-difference of the true and apparent motion corresponding to the interval AB, which was 0° 31′ 17″, the distance already mentioned remains, 96° 43′ 5″. But this arises from that arithmetic mean, which does not attain geometric rigour.

VII. In this form, however, the eccentricity is found from half the eccentricity, which in the preceding figure is shown by the line OH, the distance of the umbilici from the centre of the ellipse. For from what has been said the angle BAC is given, 90° 59′ 4″ 45‴, and the angle BAD, 34° 21′ 43″ 28‴. When the latter is subtracted from BAC, there remains the angle DAC, 56° 37′ 21″ 17‴, to which the alternate angle ACT is equal, by Proposition 29 of Book 1. Therefore the arc AT is double that, and so 113° 14′ 42″ 34‴. If AM, 27° 59′ 38″ 2‴, is taken from it, there remains MT, 85° 15′ 4″ 32‴, whose sine is ON, 9965673. And since the arc AB is 55° 17′ 17″ and AM 27° 59′ 38″ 2‴, the whole arc BM is 83° 16′ 55″ 2‴, whose sine is OS, 9931338. So if NO and OS are added, the whole of NS will be 19897011. Let it be, then, as NS, 19897011, is to the radius 10000000, so the sine of the half-difference of the true and mean motion corresponding to the interval BAC, which is 343641, is to OH, 172710, half the eccentricity, or the distance of the umbilici from the centre of the ellipse. Doubled, this gives the whole eccentricity, 345420; but with the radius taken as 100000 it becomes 3454, close to the value we set in no. 4 as 3460.

Quinta Methodus Inuestigandi Eccentricitatem.

Fifth method of investigating the eccentricity.

[Margin: Kepler's method.]

VIII. *Kepler*, in his commentaries on Mars, from chapter 23 to chapter 25, assumes three distances of the Sun, and the Sun's apogee, and from them fishes

out the eccentricity. But the Sun's distance, the parallax and the Sun's apogee are more uncertain than the eccentricity. It is therefore enough to have pointed out the passages in Kepler, and it is not worth the effort to tread so slippery a path of his.

IX. It now remains for us to present, after the Scholium, a table according to the more notable opinions, in which will stand not only the place of the apogee but also the greatest equation corresponding to the eccentricity. Some teach that this eccentricity, and so also the greatest equation, is changeable, as we shall recount later in chapter 26. The eccentricity is expressed here in three ways: in parts or degrees of which the radius of the orbit, or semidiameter of the eccentric, or mean distance of the Sun from the centre of the Earth, is 60; then in parts of which the same radius is 100000; and lastly in semidiameters of the Earth.

[Margin: The fabrication of Antonín Maria Šírek.]

Now *Antonín Maria Šírek*, seeing that the eccentricity comes close to 365 parts of which the radius is 10000, chose exactly this figure, so that it should have as many parts as there are days in the common year. That is a very flimsy basis indeed, since when the radius is increased, as can be done, and made 100000, the number of days in the year is not for all that increased tenfold. Yet in order to keep our radius at 100000, in reporting his view we have made his eccentricity one cipher greater than he did.

SCHOLION.

Scholium.

Wendelen, in Lamp 3 of the *Arcana Caelestia*, says: The speeds of the apsides are to one another in the sextantal ratio [ratio sextantaria] of their eccentricities, which he also indicates in this line of verse:

The sextantal ratio gives the apsides their law.

He calls a ratio sextantal when the root of a proposed number, multiplied six times, creates it. Thus the sextantal root of the number 64 is 2, because 2 by 2 makes 4, and 2 multiplied by 4, 8, and 2 by 8, 16, and 2 by 16, 32, and 2 by 32, 64: so by six progressions one reaches 64. Likewise the sextantal root of the number 729 is 3. So he says that if the eccentricity of planet A is to the eccentricity of planet B as 64 to 729, the motion of the apogee of A will be to the motion of the apogee of B as 2 to 3; and if the former completes 2° in one century, the latter completes 3°. And he adds that he has found the Sun's eccentricity, but bisected, to be of 1745 parts.

SOLIS APOGEVM, AEQVATIO MAXIMA, ET ECCENTRICITAS.

The Sun's apogee, greatest equation and eccentricity.

CAPVT XXV.

Chapter 25.

De Motu Apogei Solaris.

On the motion of the solar apogee.

I. I find four controversies about the Sun's apogee. 1. Whether it moves. 2. Whether with a motion always direct. 3. Whether with an equal one. 4. And how great this motion is.

[Margin: Is the Sun's apogee changeable?]

As to the first, *Ptolemy*, in *Almagest* Book 3, chapter 4, when he had found the Sun's apogee at the same place on the ecliptic where Hipparchus had very nearly found it, namely at 5° 30′ of Gemini, did not dare to assign it any motion such as he attributes to the apogees of the five planets. In this he is excused by *Cardano* in *Daniel Santbech*, in the book *De Observatione*, Prop. 9: for he was unwilling to rely on so short an interval of time between himself and

Hipparchus, namely 280 years, or, on account of a tiny difference that could have arisen from the instruments, to devise new motions in the heavens. But *al-Battānī* and the other astronomers after him, having detected that the apogee had plainly advanced in the order of the signs, affirmed that it moves, although with a rather slow motion, not immediately perceptible. We certainly detected it in the year of Christ 1646, as I said in chapter 24, at 7° 26′ 15″ of Cancer; and other astronomers of this and the preceding century, advanced by about one whole sign from the Ptolemaic place, as is clear from the preceding table.

[Margin: Al-Zarqālī's opinion on the regression of the apogee.]

II. The seeds of the second controversy were sown by *al-Zarqālī*, who, though later than al-Battānī by 193 years, nevertheless found the Sun's apogee nearer the beginning of Aries than al-Battānī had found it. For al-Battānī in the year of Christ 883 found it at 22° 17′ of Gemini, but *al-Zarqālī* in the year 1076 at 17° 53′ of Gemini. From this four opinions arose. The *first* was that of *al-Zarqālī* himself: that the Sun's apogee now advances, now regresses, and that with an unequal motion, because from Ptolemy to al-Battānī, in 740 years, it appeared to have advanced 16° 27′, but from al-Battānī to al-Zarqālī, in 193 years, to have regressed 4° 27′. He therefore devised a small circle on whose periphery the centre of the Sun's eccentric should move forward and backward alternately, so that the motions of the apogee would vary together with the eccentricity, as *Regiomontanus* indicates in Book 3 of the *Epitome*, Prop. 13, *Nunes* in Annotation 1 on Peuerbach's *Theoricae*, and *Copernicus* in Book 3, chapters 16 and 20. And *Agostino Ricci*, in his treatise on the motion of the eighth sphere, imputes the same opinion on the regression of the apogee to King Alfonso.

[Margin: To whom al-Battānī is suspect of fallacy.]

The *second* opinion was that the Sun's apogee always advances, but that al-Battānī's observation, resting on the solstices, was fallacious. So *Nunes*, on Peuerbach's *Theoricae*, Annotation 1, and *Reinhold*, p. 41, and *Georg Joachim Rheticus* in the first account of the books of Copernicus, who adds that al-Battānī misuses the mysteries of astronomy too freely, and wrongly chose eclipses around the mean longitudes, not around the apogee, and that therefore the Sun's apogee, placed six degrees from its true place, could not have introduced any noticeable error. But from where does Rheticus divine that al-Battānī looked to eclipses here, when al-Battānī himself relates that he looked to the solstices and equinoxes?

[Margin: To whom al-Zarqālī rather is suspect.]

The *third* opinion was that the Sun's apogee never regresses, and that it was rather al-Zarqālī who erred in his observations, or in the prolixity of his calculation, and in reconciling the 402 observations or considerations which, as *Regiomontanus* attests above, he had in this matter. *Willebrord Snellius* thinks much the same of him in his notes on the Hessian observations [recte: ad; the page prints ab], concluding that he [Greek: παρατηρῆσαι (paratērēsai, "observed amiss")], that is, observed wrongly, even granted that *Avraham ibn*

Ezra, who flourished 71 years after al-Zarqālī, asserts in the book entitled *Initium Sapientiae* that no one in that age was to be compared with al-Zarqālī in observing the motions of the heavens. *Jābir ibn Aflaḥ*, moreover, held al-Zarqālī's calculations suspect, because he deduced the same eccentricity as al-Battānī and yet a far different place of the apogee. And *Longomontanus* too, in Book 1 of the *Theoricae*, in the commentary on the Sun, though he thinks both erred, nevertheless thinks al-Zarqālī did so more, because the apogee's progress from Ptolemy to al-Battānī agrees better with its progress from al-Battānī to us.

The *fourth* opinion, therefore, is that the Sun's apogee always advances, and it ascribes that apparent regression partly to al-Battānī's, partly to al-Zarqālī's fallacy in observing or in computing. So *Longomontanus*, in the passage just cited. *Tycho*, for his part, promises in vol. 1 of the *Progymnasmata*, p. 33, that this controversy will be settled by him; but death removed him from the living before he could make this good.

[Margin: Inequality of the apogee's motion.]

III. As regards the equality of this motion, nearly all those who say that the eccentricity varies, or that the motion of the fixed stars and of the apogees is unequal, deny it; of these in chapters 26 and 28. But what presses us more is to determine how great the motion of the solar apogee is, for that is quite indispensable for the anomaly and the equations of the Sun's motion.

[Margin: The quantity of the motion of the apogee of ☉ is hard to determine.]

How uncertain it is, however, is clear from what has been said so far; and, to leave al-Battānī and al-Zarqālī aside, it is not yet clear whether the Sun's apogee stood at 5½° of Gemini in Ptolemy's time, or rather in Hipparchus's. For if in Ptolemy's, then from the year of Christ 139 to our observation there are 1507 years, in which the apogee has advanced 31° 56¼′, since we found it in the year 1646 at 7° 26′ 15″ of Cancer. Now when the 15″ are discarded and the progress is resolved into units of ‴, 6897600‴, and these are divided by the 1507 years, the apogee's motion corresponding to one year is found to be 1′ 16″ 17‴. But if it was there in Hipparchus's time, namely in the year 140 before Christ, at 5½° of Gemini, then since there are 1786 years, and almost 1800, to our observation, when the same progress of 6897600‴ is divided by these, the annual and mean motion of the apogee becomes 1′ 3″ 52‴. And yet *Tycho*, from an interval of only 100 years between himself and *Bernhard Walther*, gathers an annual motion of the solar apogee of 45″, which, as *Longomontanus* notes in the commentary on the Sun, does not suit our age;

[Margin: Tycho's slip on the apogee's motion.]

nor should so generous a motion have been derived from so short an interval of years, when even from an interval of 280 years Ptolemy did not dare to determine anything about the apogee's motion.

[Margin: The opinion of al-Farghānī and the Arabs on the motion of the Sun's apogee.]

IV. *Ptolemy*, indeed, in Book 9, chapter 5, held that the apogees of the five minor planets move with the motion of the fixed stars, because of their affinity in slowness of motion; and for Ptolemy the fixed stars creep forward one degree in 100 years by their proper motion. So *al-Farghānī*, Differentia 13, and many Arabs, who flourished in the 11th and 12th centuries of Christ, transferred this to the Sun's apogee, and said that it completes one degree in the zodiac in 100 years.

[Margin: The Alphonsines' opinion on the same.]

So the Jews and Arabs who constructed the Alphonsine Tables came over to a share of this opinion, for they affirmed that the apogees of all the planets except the Moon, and so of the Sun too, move with the same motion as the eighth sphere. But they set the annual motion of the fixed stars and apogees at 26″ 26‴ 54⁗, for two reasons. First, because the space of the zodiac that the Sun traverses with its mean motion is such that, when the 365^{d} 5^{h} and the minutes required for their tropical year are completed, it makes up the quarter of a day, and the sidereal year, as they themselves think, is of 365^{d} 6^{h}. Second, because with this motion assumed the whole zodiac will be completed, if the world lasts, in 49000 years, in which are contained one thousand Jewish Jubilee years, which consisted of 49 full years. So they defined the motion both of the apogees and of the fixed stars by a revolution of 49000 years: an ingenious fabrication, to be sure, but a fabrication, without foundation. *Agostino Ricci*, pp. 34 and 40½, attributes the same opinion on the common motion of the apogees and fixed stars to al-Battānī and Thābit ibn Qurra.

[Margin: The ingenious opinion of Longomontanus and Kepler.]

V. Another path, therefore, was taken by *Longomontanus*, in the *Astronomia Danica*, commentary on the Sun, and by *Kepler* in the Rudolphine Tables, p. 42. For having considered the places and progress of the Sun's apogee, and the more probable epoch of the world's creation, they saw that at the world's beginning this apogee was very close to the start of Aries. Why, then, should they not think that God at the beginning placed the Sun's apogee at the very start of Aries and of the rational zodiac? So they placed the Sun's apogee at the start of Aries in the year before Christ *Longomontanus* 3964, *Kepler* 3993, the year they assign to the world's creation, and they set its annual motion at 1′ 1″ 50‴ 14⁗, as Longomontanus does, or 1′ 2″, as Kepler does; for in this way, with a modest little correction applied, it is held to agree with the places of the solar apogee observed by Hipparchus, al-Battānī and Tycho.

[Margin: Our opinion.]

VI. For my part, building on these: in my chronological book I clearly proved that the world was created by God neither beyond the year 4076 before Christ nor after or short of 3993, and that among all the intermediate years of this range the year 4063 was very probably the one in which the world began from the vernal equinox and a new moon. From that year to our observation, discussed in the preceding chapter, no. 3, there are 5709 years, in which the Sun's apogee has advanced from the start of Aries 97° 26′ 15″. Therefore,

resolving these into units of ‴, I find the annual motion to be 1′ 1″ 10‴. I shall confidently keep this for the present, until someone brings forward something better. For an error of one minute in the Sun's place requires an error of about one degree in the place of the solar apogee; and that cannot come about by omitting one second in the apogee's annual motion except after 3600 years.

[Margin: The authors on the apogee's motion.]

Now in our usual way we shall present a table and synopsis of the chief opinions on this matter, which the authors either state or we have gathered from the data they give. The authors are: *Ptolemy*, Book 3, chapter 4; *al-Battānī*, chapter 28, compared with Hipparchus's observation; *al-Zarqālī* in Regiomontanus, *Epitome*, Book 3, Prop. 13, and in Copernicus; *al-Farghānī*, Differentia 13; *the Alphonsines* in the Tables, Proposition 12, and in *Ricci*, on the motion of the eighth sphere; *Copernicus*, Book 3, chapter 22; *Reinhold* in the Prutenic Tables, and *Magini* in the *Theoricae* of the planets, Book 1; *Mästlin* in the *Theorica* of the Sun appended to Kepler's *Prodromus*; *Tycho*, vol. 1 of the *Progymnasmata*, p. 55, and with him *Magini* in the *Supplement to the Ephemerides*; *Longomontanus*, *Theoricae*, Book 1, chapter 5; *Kepler* in the Rudolphine Tables, p. 42, and in the *Epitome of Astronomy*, p. 118; *Lansbergen* in the Tables, Canon 12; *Boulliau* in the *Philolaic Tables*, and *Astronomia*, Book 2, chapter 2; *Wendelen* in the *Idea of the Atlantic Tables*, on whose opinion in gathering the apogee's motion from the sextantal proportion of the eccentricities see what I said in the Scholium of chapter 24.

Apogei ⊙ Motus Annuus, ac Periodus.

The annual motion and the period of the apogee of ⊙.

CAPVT XXVI.

Chapter 26.

De Mutatione Eccentricitatis, & Maximæ Aequationis Solis, earumq. & motus Apogei Anomalia.

On the change of the eccentricity and of the Sun's greatest equation, and on their anomaly and that of the apogee's motion.

I. From the table placed at the end of the Scholium of chapter 24 it is clear, if we are to abide by the observations of the astronomers as they have been handed down, that the eccentricity of the Sun's orbit is not the same, nor the greatest equation the same, nor constant in all ages. For in the ages closest to the birth of Christ an eccentricity of 4152 parts was found by *Hipparchus* and *Ptolemy*, with a greatest equation of 2° 23′. Then, at the end of the ninth century of Christ, *al-Battānī* found an eccentricity of 3465 3/11 parts, of which the eccentric's radius is 100000, with a greatest equation of 1° 59′. *Copernicus*, once the 16th century had begun, deduced from his observations an eccentricity of 3230 and a greatest equation of 1° 51′. And so others differently in other ages.

[Margin: The necessary connection of the eccentricity with the Sun's equation and apogee.]

Now it is certain, from the hypothesis of the eccentric or of the Sun's epicycle (whose semidiameter is always as great as the eccentricity in the hypothesis of the eccentric), and from the method of gathering the apogee, of which I spoke in chapter 24, and from the method of gathering the Sun's equations, on which see chapters 20, 21, 22, 23: it is certain, I say, that if the eccentricity, or the semidiameter of the Sun's epicycle, is varied, the greatest equation and all the others vary too, because their measure is the angle standing on the eccentricity as a base; that a different place of the apogee is gathered; and that if the motion or change of the eccentricity is unequal, the motion or change both of the apogee and of the solar equations is likewise unequal. This, accordingly, was the reason why I set these three before you in the same table at the end of chapter 24. And if anyone in astronomy should set one of these as invariable while the others vary, he could easily be convicted of inconsequence and geometric inelegance. But since the root and foundation of these inequalities is the eccentricity, the whole controversy reduces to the change of the eccentricity, namely whether it truly changes, and with a regular or an irregular change: for there are those who affirm both, and those who deny them.

[Margin: Authors asserting the change of the eccentricity of ☉, etc.]

II. That the eccentricity, and so also the greatest equation, changes, and that their motion is anomalous, as is the motion of the solar apogee, was affirmed by *al-Zarqālī* the Spaniard, in *Regiomontanus*, *Epitome of the Almagest*, Book 3, Prop. 13, who therefore introduced into the theory of the Sun a small circle eccentric to the centre of the world, on whose periphery the centre of the Sun's orbit is carried round, because he had found an eccentricity other than

the Ptolemaic, although the same as al-Battānī's. Likewise *Peuerbach*, and before him the *Alphonsines*, as *Nonius* assumes in Annotation 1 on Peuerbach's *Theoricae*; *Copernicus*, Book 3, ch. 5, 20 and 21; *Georg Joachim Rheticus* in the *First Narration* on Copernicus's books, and there *Mästlin* in his annotations, and in the Copernican *Theorica* of the Sun; *Reinhold* in the Prutenic Tables, Precept 17; *Michael Neander* in the *Elementa Sphaerica*, p. 124; *Giuseppe Moletti* in the *Gregorian Calendar*, Canon 10; *Giovanni Antonio Magini* in the *Theoricae* of the planets, ch. 4, *Theorica* of the Sun; *Tycho*, vol. 1 of the *Progymnasmata*, pp. 31 and 38; *Willebrord Snellius* in the notes to the Hessian observations; *Pitiscius* [Bartholomäus Pitiscus], Book 4 of the Astronomical Problems; *Lansbergen* in the *Theorica* of the Sun, ch. 1; and our own *Joseph Lange* in the *Elementale*, on ch. 9 of the *Theorica* of the Sun. Among these, however, the *Copernicans* and *Lansbergen* determine a greatest, a mean and a least; on these consult our table at the end of ch. 24.

[Margin: Authors denying the change of the eccentricity.]

III. Yet the eccentricity of the Sun and the greatest equation, etc., were judged to be UNCHANGEABLE by *Ptolemy*, Book 3, ch. 2; *Scaliger*, Exercise 99 against Cardano; *Kepler* in the notes to his *Mysterium Cosmographicum*, ch. 1, and in the *Astronomia Optica*, pp. 146 and 147, and in the *Commentaries on Mars*, ch. 69; *Longomontanus* in the *Astronomia Danica*, Book 1 of the *Theorics*, ch. 2, in the commentary on the Sun, under the title [Greek: Σύστασις (systasis, "constitution")] of the Eccentricity, and in his work *Holigerius Rosækrantcius* [Holger Rosenkrantz]; likewise *Antonín Maria Šírek* in the solar hypothesis of the *Radius Sidereomysticus*, who sets it always at as many parts as there are days in the Egyptian year, namely 365, of which the radius is 1000; *Ismaël Boulliau*, Book 2 of the *Astronomia Philolaica*, ch. 3; and *Govaert Wendelen* in the *Idea of the Atlantic Tables*, p. 29. We too side with them, since we see that this change cannot be demonstrated, nor asserted any more solidly than it is denied, either from eclipses and the growth or decrease of shadows, or from observations of the Sun, especially solstitial ones; nor should so many inequalities be shifted onto the heavens on the strength of a slight difference that could have arisen from parallax and refraction, or from some small fault in the instruments. This holds especially since, at the very time when according to our opponents' hypotheses such a measure ought to have been found, a far different one has been found by us, and by others, as is clear from the preceding table; nor do those hypotheses agree with themselves, or with a greater number of observations. We shall, however, set out the theory of this change where we deal with the anomaly of the obliquity of the ecliptic and of the precession of the equinoxes.

[Margin: To where is the theory of this motion deferred?]

[Margin: The period and epoch of the anomaly of the eccentricity are the same as those of the obliquity of the ecliptic.]

IV. Note, however, that the *Copernicans* and *Lansbergen* agree that the period of the anomaly of the eccentricity is as long as the period of the anomaly of

the obliquity of the ecliptic, of which we must speak in ch. 27; that both move equally in their circles; and that when one is greatest, the other is also greatest, etc. But they do not agree on the length of the period, nor on the beginning or epoch of the anomaly, nor on the amount of the greatest, or the mean, or the least, as can be seen from the table at the end of Chapter 24. From this, and from the authors themselves, it is gathered that the period of each, in which the revolution from the greatest back to the greatest eccentricity and obliquity is made, is for *Copernicus* 3434 Egyptian years, which make 3431 ⅔ Julian years, and that its beginning was in the year 63 completed before Christ, and 302 days; for *Lansbergen*, however, the period is of 3002 Egyptian years but 3000 Julian, and its beginning in the first year of Christ. But for other years, see these and the rest in the following small table.

		Eccentricity, in parts of which the radius of the orbit is 100000	Greatest equation of the Sun	In the year before Christ		and of Christ		Period of the anomaly of the eccentricity	
For Copernicus	Greatest	4170	2° 23′ 20″	3495	& 64	3369	& 6800	Of years	
	Mean	3694	2° 7′ 0″	6068	2637	795	4226	Egyptian	Julian
	Least	3219	1° 50′ 30″	5210	1779	1653	5085	3434	3431 ⅔
For Lansbergen	Greatest	4216	2° 24′ 56″	6000	3000	1. 3000	6000	3002	3000
	Mean	3853	2° 12′ 30″	3720	720	720	3720	✝	✝
	Least	3490	2° 0′ 0″	4500	1500	1500	4500	✝	✝

SCHOLION.

Scholium.

[Margin: Rheticus's empty prophecy.]

I. *Georg Joachim* Rheticus, in the *First Narration* on the books of Copernicus, affirms that all monarchies began when the centre of the Sun's eccentric stood at some notable point of the small circle on which the motion of the anomaly of the eccentricity takes place. For when the eccentricity was greatest, the Roman Empire passed under Augustus to monarchy; when the first quadrant had been completed and the eccentricity was mean, the Muhammadan monarchy began; when the semicircle is finished and the least eccentricity is at hand, this monarchy will fall; and when the period is finished, the Lord JESUS CHRIST will come. For at the beginning of the world too it was greatest; and this small circle is that celebrated Wheel of Fortune by whose turning monarchies change. But from the small table set out at the end of the preceding chapter it will be evident that this assertion is empty, provided you hold a correct chronology.

Nor indeed was the beginning of the world in the year 3495 or 6000, as we shall show in the chronological book of our *New Almagest*; and the monarchy of the Assyrians began under Ninus in the year 2055 before CHRIST; that of the Medes under Arbaces in 817; and that of the Persians, finally, under Cyrus in the year 535 before CHRIST. See a similar fiction in ch. 27, Scholium 2.

[Margin: On the theory of the anomaly of the eccentricity and of the apogee.]

II. To learn the theory of al-Zarqālī's small circle, and by what method Copernicus investigated its anomaly, as well as that of the Sun's apogee, and the equation of these, see Copernicus himself, if you wish, Book 3, ch. 20 and 21, where he gathers the least eccentricity as 3210 parts and the greatest prosthaphaeresis of the apogee's motion as 7° 28′. But Reinhold in the Prutenic Tables, Precept 17, with Copernicus's numbers and calculation corrected, sets the least eccentricity at 3219 parts. And Magini, in the *Theorica* of the Sun and in the *Tables of the Second Mobiles*, Canon 23, following Reinhold's numbers, says that the semidiameter of the small circle carrying the centre of the Sun's eccentric is 17′ 7″, of which the radius of the eccentric is 60°, that is, 472 5/22 parts, of which the radius is 100000; that the greatest equation of the apogee's motion is 7° 23′ 36″; that the anomaly of the apogee and of the eccentricity is called in the Tables the Centre of the Sun, and its equation the Equation of the Centre; and that this small circle moves against the order of the signs while the eccentric moves in the order of the signs. But Mästlin, in the Copernican *Theorica* of the Sun, gathers from Reinhold that the semidiameter of the already mentioned small circle is 475 ½, and from Copernicus, Book 3, ch. 22, he notes that the annual motion of the Sun's apogee on a circle concentric with the world is 24″ 20‴ 14⁗, and that it is completed under the sphere of the fixed stars in 54000 years. Granted, Reinhold gathers from Copernicus's data that its annual motion is 25″ 33‴ 12⁗ and its period a little more than 50000 years, but under the zodiac 17000.

CAPVT XXVII.

Chapter 27.

De Solis Maxima Declinatione, & Obliquitate Eclipticæ, harumq. Mutatione, & Anomalia.

On the Sun's greatest declination and the obliquity of the ecliptic, and on their change and anomaly.

I. The Sun's greatest declination occurs at the contact of the tropics and the ecliptic, that is, at the beginning of Cancer and Capricorn, and it is reckoned on the arc of the meridian circle intercepted between either tropic and the equator. This arc is measured by the angle made at the equinoctial points by the equator and by the ecliptic inclined to it. This angle is called the obliquity of the ecliptic, in Greek [Greek: λόξωσις Ξωδιακοῦ [recte: Ζωδιακοῦ] (loxōsis

zōdiakou, "obliquity of the zodiac")], and it is as great as the Sun's greatest declination, and as the distance of the pole of the ecliptic from the nearer pole of the world. Let us now see by what method these are observed, and whether they change, and with what change.

Primus Modus obſeruandi Declinationem Solis Maximam.

The first method of observing the Sun's greatest declination.

[Margin: The first method, by the distance of the tropics.]

II. The first method is through the distance of the tropics, taken from the Sun's meridian altitudes at both solstices. For when the true winter altitude is subtracted from the Sun's summer altitude, what remains is the distance of the tropics, half of which is the distance of either tropic from the equator, that is, the Sun's greatest declination.

[Margin: Ptolemy's observation and opinion on the obliquity of the ecliptic.]

In this way *Ptolemy*, Book 1 of the *Magna Constructio*, ch. 11 and 13, relates that he found the distance of the tropics to be 11 parts of which the whole meridian is 83, that is, 47° 42′ 40″ of which the whole meridian is 360, and thus the obliquity of the ecliptic to be 23° 51′ 20″, which is as much as *Eratosthenes* and *Hipparchus* had once found, says Ptolemy. He therefore judged it to be always that great, and unchangeable.

[Margin: Al-Battānī's observation and opinion.]

Al-Battānī, for his part, relates in ch. 4 that he found in the city of Aracta [al-Raqqa] the Sun's least distance from the vertex, at noon of the summer solstice, to be 12° 26′, and its greatest, at noon of the winter solstice, 59° 36′; and he says that he used a very long alidade, namely the parallactic rulers, which we shall treat in the *Liber Organicus*. From this, then, he deduced the distance of the tropics as 47° 10′, and the obliquity of the ecliptic as 23° 35′, which he thought true and stable, since he doubted the observations of the ancients and founded his hypotheses on this one; and the altitude of the pole at Aracta as 36°. For he says: *On this, then, we shall build this book of ours, because this we received with our eyes, but that by hearing.*

[Margin: Regiomontanus's observation and opinion.]

After these, *Regiomontanus*, Book 1 of the *Epitome of the Almagest*, Prop. 17, says that he observed at Nuremberg the Sun's greatest altitude, at the summer solstice, as 65° 6′, and its least, at the winter solstice, as 18° 10′, from which he gathers the obliquity of the ecliptic as 23° 28′. But if you add to the altitudes his parallax, or rather ours, of about 30″, and take from the winter altitude a refraction of 4′, or Tycho's 5′ ¾, you will gather the obliquity of the ecliptic as 23° and 30′ or 31′. Yet *Clavius*, in the *Sphere*, p. 263 in my copy, reports from Regiomontanus the Sun's greatest altitude observed at Vienna, at the summer solstice, as 65° 30′, and its least as 18° 30′; from these, applying our parallax and refraction, the obliquity is gathered as 23° 31′ or 32′. Granted, *Lansbergen* in the *Thesaurus of Solar Observations* deduces the obliquity as 23° 30′ from another

Viennese observation of Regiomontanus. I, however, from the chords of the distances from the vertex taken at Nuremberg by *Regiomontanus* and *Walther* at the solstices, gather the obliquity as 23° and sometimes 29 ½′, sometimes 30′ or 31′, disregarding the small appendages of seconds. Therefore, from all these values bounded on one side and the other, I cannot more prudently establish any obliquity other than the one finally chosen by Regiomontanus himself in his tables and by *Clavius* in the table of declinations, namely 23° 30′.

[Margin: The opinion of Clavius and of Scheiner, Galileo and Finé.]

Scheiner chose the same amount in the *Rosa Ursina*, p. 356, and *Galileo* in the *Dialogues on the System of the World*, and before them *Oronce Finé* in the *Cosmographia*, Book 2, ch. 24.

[Margin: Copernicus's observation, opinion and error.]

After these *Copernicus*, Book 2, ch. 2, says that in the year 1525 at Frombork he observed the Sun's winter altitude as 12° 16′ 6″, and the summer one as 59° 8′ 54″, from which he gathers the altitude of the pole as 54° 19′ 30″ and the obliquity of the ecliptic as 23° 28′ 24″, about as much as his predecessor *Domenico Maria Novara* and his contemporaries *Johannes Werner* and *Gemma Frisius* found. But *Tycho*, in the *Epistolae Astronomicae*, p. 74, and in vol. 1 of the *Progymnasmata*, p. 34, affirms that he sent to Frombork the very well-instructed *Elias Olai* [Elias Olsen Morsing], who from the circumpolar stars found the altitude of the pole there to be 54° 22′ 15″, from which he detected that Copernicus, not indeed by omitting parallax but by omitting refraction, had erred in the altitude of the pole by 2′ 45″. Now subtract from the winter altitude the 8′ 56″ of Tycho's refraction, and add to both my parallax of 27″ or 30″, and you will gather the obliquity of the ecliptic as 23° 30′ 47″, and with the slightest of corrections, 23° 30′.

[Margin: Egnazio Danti's observation.]

[Margin: Peter Apian's method and opinion.]

Finally *Egnazio Danti*, Part 2 of the *Astrolabe*, ch. 34, relates that in the year 1570 at Florence the Sun's solstitial altitude taken by him at noon was 69° 49′, and the winter one 22° 51′, from which he gathers the obliquity of the ecliptic as 23° 29′. If you subtract from the winter altitude a refraction of 2′ or 3′ and add our parallax to both altitudes, the obliquity of the ecliptic will become 23° 30′ or 23° 30′ 30″. But because of a certain uncertainty and inconstancy of the refractions contained in winter altitudes, this method is not of such precise evidence that an error of one or two minutes cannot creep in. Far less evident still is the method of *Peter Apian*, who says in the *Instrument of the Primum Mobile* that he detected the obliquity of the ecliptic as 23° 30′ from the Sun's rising amplitude, observed many times; for the inconstancy of refractions is far greater in these horizontal observations.

Secundus Modus Obſeruandi Declinationem Solis Maximam.

The second method of observing the Sun's greatest declination.

III. It is better, therefore, first to have investigated the altitude of the pole through circumpolar stars, so that its complement to a quadrant shows the altitude of the equator; and then, on the day of the summer solstice, to take the Sun's meridian altitude with the most exact instruments and to correct it by adding the parallax. For the altitude of the equator, subtracted from this, will give the Sun's greatest declination. Within the torrid and temperate zones, if the day is clear, there is no need to fear any sensible refraction at that time; a somewhat larger variation, however, will arise from the variation in the parallax assumed, which must be added to the solstitial altitude. Let us come to examples.

[Margin: Nonius's observation.]

Nonius, in Book 2 *On Observation*, affirms that at Coimbra he observed more than once the Sun's solstitial and greatest altitude as 73°. If you add a parallax of 30″, it becomes 73° 0′ 30″. But the altitude of the pole taken there by our *Clavius*, while he was teaching at Coimbra, as he has it in the *Sphere*, is 40° 30′, and *Nonius* sets the same above on p. 64. So the altitude of the equator is 49° 30′; when this is taken from the solstitial altitude, the Sun's greatest declination becomes 23° 30′ 30″. But how easily can those 30″ be imputed to an observation not so precise, since Nonius admits in the same book that he did not yet have large instruments at hand for observations, and in the table on p. 65 he sets it at 23° 30′.

[Margin: The observation of the Landgrave of Hesse.]

Christoph Rothmann and *Jost Bürgi*, mathematicians of the Landgrave of Hesse, as is related in Tycho's letters and in Snel in the notes to the Hessian and Bohemian observations, finally found the altitude of the pole at Kassel from circumpolar stars as 51° 19′ 20″, which they had earlier obtained as one minute less, with uncorrected instruments and an inexact placement; so the altitude of the equator was 38° 40′ 40″. I find, moreover, in the last and more correct Hessian observations the Sun's solstitial altitude as 62° 11′ and 62° 12′, from which there results, on our assumed parallax, an obliquity of the ecliptic of about 23° 32′ or 33′; but if the earlier altitude of the pole had been right, it would be 30′ or 31′ above 23°.

[Margin: Homelius's observation.]

Ioannes Homelius [Johannes Hommel], as *Tycho* reports in vol. 1 of the *Progymnasmata*, p. 631, in the year 1570 at Leipzig took the Sun's greatest and solstitial altitude as 62° 11′; the altitude of the pole, however, is set by him at 51° 17′, although Tycho says it is 51° 19′. So the altitude of the equator is either 38° 43′ or 38° 41′. Now add to the altitude taken a parallax of 30″, and the obliquity of the ecliptic will become 23° and in addition either 28′ ½ or 30′ ½, of which the mean is 29′ 30″. And if there is doubt here about two minutes, how much more easily can an error of half a minute be conceded, and the obliquity be brought to exactly 23° 30′? Let us now turn to Tycho himself.

[Margin: Tycho's observations and opinion.]

Tycho, then, in vol. 1 of the *Progymnasmata*, p. 17, from the altitude of the equator established at Uraniborg as 34° 5′ 30″, and from the Sun's solstitial altitudes, applying his own parallax, which at an altitude of 57 ⅗° is 1′ 35″, gathers the obliquity of the ecliptic as 23° 31′ 30″ for the year 1587, as is given in the table of declinations in the same place, p. 28, and in the *Epistolae Astronomicae*, p. 40. *Kepler*, however, says in the Rudolphine Tables that too great a parallax was assumed by Tycho, and that we can always use an obliquity of 23° 30′ 30″. But I have very select Tychonic observations made in the year 1589 to explore the refractions of the Sun, which Father *Albert Curtz* of our Society sent me from Tycho's manuscript at my request; he by the Emperor's order presides over Tycho's observations being brought to light. We also have from *Longomontanus*, Book 1 of the *Theorics*, ch. 2, three selected meridian altitudes observed by *Tycho* at Uraniborg at the summer solstice. If you add to these our parallax of 30″ or 27″, and use the altitude of the equator at Uraniborg, mentioned above, the obliquity of the ecliptic is gathered as you see in the following small table.

In the style of the old calendar	June	Year	⊙ Apparent altitude	True altitude	Obliquity of the ecliptic
From *Longomontanus*	12	1586	57° 35′ 36″	57° 36′ 6″	23° 30′ 36″
	14	1587	57° 34′ 30″	57° 35′ 0″	23° 29′ 30″
	11	1593	57° 35′ 0″	57° 35′ 30″	23° 30′ 0″
From Father *Albert Curtz*					
By quadrant: the larger steel one	11	1589	57° 35′ 25″	57° 35′ 55″	23° 30′ 25″
the revolving one	11	1589	57° 35′ 45″	57° 36′ 15″	23° 30′ 45″
the Tychonic one	11	1589	57° 35′ 45″	57° 36′ 15″	23° 30′ 45″
the other one	11	1589	57° 35′ 50″	57° 36′ 20″	23° 30′ 50″

Will you concede, then, in view of these, that an obliquity of exactly 23° 30′ cannot be evidently overturned from Tycho's observations? For from the last, of the year 1593, just that value follows, and from the two extremes, 29′ 30″ and 30′ 50″, very nearly the same results by choosing the mean. But if you adhere to Tycho's parallax, which here is greater than ours by 1′ 5″, the obliquity of the ecliptic will sometimes become 23° 31′ 55″; but on no foundation, or almost none, he determined his parallax, as I have shown in ch. 8.

[Margin: Lansbergen's observation.]

Philips van Lansbergen, in the *Thesaurus of Observations*, first class of the solar ones, observation 9, says that in the year 1589 at Goes in Zeeland, at the summer solstice, he observed with a large quadrant the Sun's meridian altitude as 61° 58′, but that with his parallax added it was 61° 59′ 4″; and the winter altitude as 15° 2′ 30″ apparent, but 14° 58′ 43″ true. From this he gathers the distance of the tropics as 47° 0′ 21″ and the obliquity of the ecliptic as 23° 30′ 10″, *as much*, he says, *as the Landgrave's men found, as nearly as possible*, and the altitude of the pole as 51° 31′ 7″.

[Margin: And his carelessness in observing.]

Now if we apply our parallax of 30″, the solstitial altitude will become 61° 58′ 30″; the altitude of the equator, 31° 29′ [recte: 38° 29′], taken from this, gives the obliquity as 23° 29′ 30″. I should have preferred him to take the altitude of the pole from circumpolar stars, and not to deduce it from a slippery observation of the winter altitude, with which an uncertain parallax and refraction are mixed. So greater care in observing is wanted here.

[Margin: Wendelen's observation.]

[Margin: Gassendi's opinion.]

Govaert Wendelen wrote to me recently that in Provence he detected from circumpolar stars the altitude of the pole at Forcalquier as 43° 54′, and the Sun's meridian distance from the vertex, in the same place, for several years in succession at the solstices, apparent, as 20° 24′. If you take Wendelen's parallax of 15″ from this, the obliquity of the ecliptic becomes 23° 30′ 15″; but if mine, it becomes 23° 30′ 30″. *Pierre Gassendi*, however, in the *Institutio Astronomica*, p. 24, says that it cannot be greater than 23° 31′.

[Margin: Our observations.]

I, however, from among the other observations of the Sun's solstitial altitudes at noon that I made at Bologna with Father *Francesco Maria Grimaldi*, select those taken with four quadrants, but chiefly with two large ones. The parallax of 30″, added to them, gives the true altitudes; and when the altitude of the equator, 45° 30′ 30″, which was taken more than forty times from a circumpolar star, is subtracted from them, there remains the obliquity of the ecliptic, which you see in the following small table.

Obliquitas Eclipticæ ex Noſtris Obſeruationibus Bononiæ habitis.

The obliquity of the ecliptic from our observations made at Bologna.

At the summer solstice: Year	Month	Day	☉ Meridian altitude, by quadrants	☉ Apparent altitude	True altitude	Obliquity of the ecliptic
1643	June	21	Largest	68° 59′ 55″	69° 0′ 25″	23° 29′ 55″
			Large	68° 59′ 55″	69° 0′ 21″ [recte: 25″]	23° 29′ 55″
			Middling	69° 0′ 0″	69° 0′ 30″	23° 30′ 0″
1644	June	20	Largest	68° 59′ 50″	69° 0′ 20″	23° 29′ 50″
			Large	68° 59′ 50″	69° 0′ 20″	23° 29′ 50″

		Large	68° 59′ 45″	69° 0′ 15″	23° 29′ 45″

[Margin: The author's opinion.]

Led chiefly by these observations, therefore, we set the obliquity of the ecliptic at 23° 30′, laying the very small difference on the instruments and observations, and we find that in the year 1646 the solstice occurred at the very noon of the 21st, from the equal altitude found on the 20th and the 22nd, so far as could be observed by us through human diligence.

[Margin: Authors who write on the obliquity of the ecliptic.]

[Margin: Lansbergen's deceitful good faith.]

IV. It remains, for the purpose of pursuing the controversy over the change of the obliquity of the ecliptic, to relate the obliquity found in different ages. This is also reported, wholly or in part, by *Regiomontanus*, Book 1 of the *Epitome of the Almagest*, Prop. 17, and Problem 63 of the *Primum Mobile*; *Copernicus*, Book 2, ch. 2, and Book 3, ch. 2; *Reinhold* on Peuerbach's *Theoricae*, p. 238, and in the same place *Vurstisius* [Christian Wurstisen], p. 422; *Nonius*, *On Observation*, Book 2; *Clavius* in the *Sphere*, p. 262; *Tycho*, vol. 1 of the *Progymnasmata*, p. 17; *Barozzi* in the *Cosmographia*, p. 70; *Snellius* in the notes to the Hessian observations; *Lansbergen* in the *Thesaurus of Observations*, from p. 37; *Kepler* in the *Epitome of Astronomy*, Book 3, p. 244, and Book 7; *Biancani* in the *Sphere*, Book 1, ch. 8; and *Boulliau*, Book 5 of the *Astronomia*, ch. 5. Among these, *Lansbergen* places Jacob ben Machir ibn Tibbon [Prophatium] only 68 years after Almeon [?], so as to draw his observation to his own tables, although in fact he came about 160 years after Almeon. Some also attribute to Thābit ibn Qurra an obliquity of 23° 33′, but *Regiomontanus* 23° 33′ 30″.

An Reuerà Mutetur Obliquitas.

Whether the obliquity really changes.

V. Because of the observations already mentioned, therefore, the following have held that the obliquity of the ecliptic changes from greatest to least, and with an unequal motion at that: *Peuerbach* in the *Theorica* of the eighth sphere, and there his commentators *Erasmus Oswald Schreckenfuchs*, p. 388, *Io. Bapt. Capuanus* [Giovanni Battista Capuano], p. 260, *Christian Wurstisen*, p. 420, and *Reinhold*, p. 238, and in the Prutenic Tables, Precept 13; *Pierre d'Ailly*, q. 9 on the *Sphere*; *Regiomontanus*, Book 1 of the *Epitome*, Prop. 17; *Copernicus*, Book 2, ch. 2, and Book 3 from ch. 2 onward; *Georg Joachim Rheticus*, *First Narration* on Copernicus's books; *Girolamo Fracastoro* in the *Homocentrica*, sect. 3, ch. 8; *William Gilbert*, Book 6 of *De magnete*, ch. 9; *Scaliger* in the *Diatribe on the Equinoxes*, ch. 4, Corollaries 8 and 9, who puts it at 24° at the beginning of the Olympiads; *Clavius* in the *Sphere*, p. 262; *Magini* in the *Theoricae* of the planets, Book 1, ch. 2, and in the *Directions* of the primum mobile, Canon 1; *Tycho*, vol. 1 of the *Progymnasmata*, p. 100; *Longomontanus*, Book 1 of the *Theorics*, ch. 2 and 4; *Snellius* in the notes to the Hessian observations; *Lansbergen* in the

Tables, Precept 5, and in the *Theorica* of the Sun, ch. 1, and in the *Thesaurus of Observations*, from p. 37; *Boulliau*, Book 5 of the *Astronomia*, ch. 5; *Wendelen* in the *Idea of the Atlantic Tables*; and *Baranzanus* [Redento Baranzano] in the *Uranoscopia*, part 2, q. 3.

[Margin: Authors who assert the change of the obliquity of the ecliptic.]

From these, *Copernicus* in Book 2, ch. 2, promises *to show below, by a sufficiently probable conjecture, that it was never greater than 23° 52′, and will never be less than 23° 28′*, and he makes this good in Book 3, ch. 10. The arguments for this change are as follows. First, it was always found smaller from the time of Aristarchus down to Copernicus. Second, in the very century in which the Sun's eccentricity, the Sun's equation and the length of the year were greatest, and the motion of the fixed stars, or of the equinoctial points, was slowest, namely around the birth of Christ, the obliquity of the ecliptic too was found to be greatest. Third, the decreases of the eccentricity and of the obliquity were proportional: in the 743 years between Ptolemy and al-Battānī the eccentricity decreased by 687 parts and the obliquity by 16⅓′, while in the 632 years from al-Battānī to Copernicus the eccentricity decreased by 235 parts and the obliquity by 6⅗′. And as 687 is to 16⅓, so, very nearly, is 235 to 6⅗. These things, therefore, do not seem to have come about by chance, or from a fallacy of the observations, but from some true cause producing these changes.

[Margin: Arguments for the changed obliquity.]

Very many attribute this cause to the trepidation, or first libration towards the sides of the world, that is, a slow approach and withdrawal towards the poles of the world, produced by the motion of sphere 9 (for those who admit ten spheres) or sphere 10 (for those who admit eleven). *Copernicus*, however, and his followers attribute it to a certain libration of the Earth, as will be explained below in ch. 29. On these premises *Copernicus*, *Lansbergen* and *Longomontanus*, whom *Boulliau* follows outright in this, set out the quantity of the greatest, mean and least obliquity, the epoch and period of this anomaly, and the mean annual motion, even though *Longomontanus* does not recognize the change of the eccentricity. *Kepler* too sets these out, not absolutely, since, as we shall say shortly, he denies the change of the obliquity, but on a feigned hypothesis, in the first of the five forms that I shall discuss in the Scholium. And it is truly remarkable that *Longomontanus* puts the greatest obliquity in the first year of the created world, and *Kepler* the least, even though on that beginning they do not differ by more than 25 years. So far is this change, or its anomaly, from being evident from the observations. We shall give the tables of the equation of this motion at the end of the work.

[Margin: The theory of this anomaly is indicated.]

[Margin: A huge disagreement between Longomontanus and Kepler.]

Auctores, & Argumenta pro Immutabilitate Obliquitatis Eclipticæ.

Authors and arguments for the immutability of the obliquity of the ecliptic.

VI. Yet the obliquity of the ecliptic was judged immutable by *Ptolemy*, Book 1 of the *Almagest*, ch. 11; by *al-Battānī*, ch. 4, who ranks the old observations of it below his own as uncertain; by *Thābit ibn Qurra* according to *Maurolico* in the *Cosmographia*, p. 88; by *Agostino Ricci* in the treatise on the motion of the eighth sphere, pp. 34 and 40; by *Pierre Gassendi* in the *Life of Claude Fabri de Peiresc* [Claudij Fabricij Peireskij], at the year 1636, and in the *Institutio Astronomica*, Book 2, ch. 8, or p. 40; by *Athanasius Kircher* in his *Magnes*, p. 477; by *Stevin* according to *Hérigone*, vol. 5, p. 579; by *D. Vincenzo Renieri* in the *Tabulae Mediceae* newly reissued, ch. 7, no. 7; by *Kepler* in the Rudolphine Tables, ch. 12 and 34; and very nearly by *Galileo* in Dialogue 3 on the world system, when he says that it undergoes a very small and negligible slight change, one not perceptible except after many thousands of years. I agree with them, but I am led to it by arguments from a deeper inspection of astronomical matters. They are content to hold the observations of the ancients suspect of error, and *Kepler* adds only an argument from the latitude of the fixed stars. I, however, shall show that even in the time of Eratosthenes, and indeed of Pytheas of Massalia, the obliquity of the ecliptic was 23° 30′, as great as it is now, and I shall point out the root of the error lurking in the observation of Eratosthenes.

[Margin: Our opinion on the immutability of the obliquity of the ecliptic.]

VII. Eratosthenes, then, intending to measure the globe of the Earth, first established by his own experiment, and not merely from a constant tradition, that Syene lies under the Tropic of Cancer. There, as also at Berenice, at noon on the day of the summer solstice gnomons cast no shadow over a space of 150 stadia on this side and 150 on that, that is, 300 stadia all round. So report *Cleomedes*, Book 1 of the *Cyclical Theory*, *Strabo*, Book 17, and *Pliny the Elder*, Book 2, ch. 73, and Book 6, ch. 29. Pliny the Elder adds that a well made at Syene for this purpose is wholly lit at solstitial noon, and that the Sun is therefore then over the zenith of Syene, and he calls this a place *of immense subtlety, the world having been detected there, since from it Eratosthenes began to publish the measure of the Earth by the indubitable reasoning of the shadows.* Holding this as established, he set up a scaphe [Scaphium] with a gnomon at Alexandria, and at noon on the summer solstice observed the shadow of the gnomon in the spherical hollow of the scaphe. He assumed that the Sun's rays, because of its enormous distance from the Earth, reach us parallel, which we showed in ch. 5 to be true of rays propagated from one and the same point of the Sun. He used the method that *Pedro Nunes*, Book 2 of *On Observation*, p. 132, and *Willebrord Snellius* in the *Eratosthenes Batavus*, Book 1 from ch. 9, report from *Cleomedes*, and it is as follows.

[Margin: Eratosthenes' observations for the measure of the globe of the Earth.]

Diagram. Set into the foot of the left column, with the text running down its left side. At the top a semicircle, curving downward, stands for the Sun, its diameter AD horizontal with C at the middle, and K on its arc. A long vertical line descends from C through E to B. At the foot a semicircle RET stands for

the hemisphere of the Earth, with its diameter RT and its centre B. On its left, at G, a small scaphe FGH sits on the Earth's arc, with the point I at its centre. Long converging lines run from the upper semicircle down to I, and a line runs from I through G to B. Two letters, L and M, stand side by side on the lower arc of the scaphe.

- A (top left, end of the diameter): label A
- C (top centre): label C
- D (top right, end of the diameter): label D
- K (on the upper arc, left): label K
- H (upper end of the scaphe): label H
- I (centre of the scaphe, apex of the gnomon): label I
- F (left end of the scaphe): label F
- G (foot of the gnomon, on the Earth's arc): label G
- L, M (lower arc of the scaphe): labels L and M
- E (top of the Earth's arc): label E
- R (left end of the Earth's diameter): label R
- B (centre of the Earth): label B
- T (right end of the Earth's diameter): label T

Let there be a hemisphere of the Earth with its meridian RET and centre B. Let Syene be at E, and let the central ray CE of the Sun AKD fall perpendicularly over the zenith of Syene, and let the straight line CE be produced to the Earth's centre B. Next let Alexandria be at G, and there let there be a scaphe, or concave spherical vessel, FGH, with a gnomon IG standing perpendicular to the horizon, so that the straight line IGB produced along it falls on the centre of the Earth. Let the extreme ray of the Sun, AIM, be drawn through the apex I of the gnomon to the bottom of the scaphe. At the bottom of the scaphe, then, the shadow will be MG. Now since the quadrant FMG of the scaphe was divided into 90 degrees, and the degrees into some number of minutes, Eratosthenes found the arc MG, and hence the angle MIG, to be 7° 12′. He could also have worked this out from the isosceles triangle MIG, the sides IG (the height of the gnomon) and IM equal to it being already given, since the apex of the gnomon was at the centre of the hemisphere FGH, and the base MG having been measured with compasses. Having found this angle, and treating the ray AIM as if it were the ray KIM, parallel to CB, with IB falling on these parallels, he concluded by Euclid I.29 that the alternate angle IBE, equal to BIM, is 7° 12′. And since the angle GBE subtends the arc GE of the meridian between Alexandria and Syene, he inferred that this arc is 7° 12′. For he thought that Alexandria and Syene lie under the same meridian, or deviate from it imperceptibly, which *Strabo*, Book 2, and *Cleomedes*, Book 1, also assume, although *Ptolemy*, Book 4 of the *Geography*, ch. 5, gives Alexandria a longitude from the Fortunate Isles of 60° 30′, with a latitude of 30° 58′, and Syene a longitude of 62°. He further assumed that there are 5000 stadia between Syene and Alexandria, and as many between Syene and Meroë, which *Strabo*, Book 2, *Cleomedes*, Book 1, and *Pliny the Elder*, Book 2, ch. 73, also

state, although in Book 6, ch. 29, Pliny the Elder says that explorers sent there by Nero found 874 Roman miles between Syene and Meroë, that is, 6992 Roman stadia. But Eratosthenes and others in that region more probably used the Alexandrian stadium, which stood to the common Greek and the Roman stadium as 6 to 5, as I have shown in the Geographical book. Those stadia would therefore be 5827 in Alexandrian stadia. But this in passing.

Now, says Eratosthenes, if the arc GE of the meridian, of 7° 12′, contains 5000 stadia, then one degree of a great circle of the Earth has 694⅘ stadia, and the whole circle 250000 stadia, as *Cleomedes* and *Strabo*, cited above, report of Eratosthenes' opinion. For taking the round number of 700 stadia to one degree, there would be 252000 stadia in the whole circle; and this is the number that *Vitruvius*, Book 1, ch. 6, *Pliny the Elder*, Book 2, ch. 108 and 109, *Censorinus*, *De Die Natali*, ch. 11, *Capella*, Book 6, ch. 4, and Book 8, p. 192, and *Macrobius* on the *Dream of Scipio*, Book 1, prefer to report as Eratosthenes' mind. Such was the method of Eratosthenes, so that *Pliny the Elder* could say, in Book 2, ch. 108: *A shameless venture, but grasped by such subtle reasoning that one is ashamed not to believe it*; and *Macrobius*, in the place cited, confirms that this measure stands *on most evident and indubitable reasons*.

[Margin: The size of the Earth's circumference according to Eratosthenes.]

Yet in fact we have shown in the Geographical book that this method must be corrected, both because Alexandria and Syene are not precisely under the same meridian, and above all because Eratosthenes misused the parallelism of the Sun's rays. For the ray CB, propagated from the centre of the Sun, and the ray AIM, the extreme ray bounding the shadow of the gnomon, are not parallel, not even to sense. He ought therefore to have drawn from the same point C the ray CIL, and to have added to the angle MIG that he found, 7° 12′, the angle AIC subtending the apparent semidiameter of the Sun, which is 15′ or 16′, and hence the angle LIM vertically opposite and equal to it. Thus the angle LIG, and therefore the angle IBE, equal to it to sense, or the arc GE, would be 7° 27′ or 28′, and so great would be the distance of the Sun's centre C from the zenith of Alexandria; or, with my parallax of 30″ taken away, it would be 7° 26′ 30″ or 7° 27′ 30″. Eratosthenes is therefore rightly convicted of this error by *Snellius* and by *Pedro Nunes* in the places already cited, though they had no inkling from it of anything that would overflow onto the obliquity of the ecliptic.

[Margin: The error of Eratosthenes.]

With this premised: the altitude of the pole at Alexandria, or the distance of its zenith from the equator, was observed to be 30° 58′, as *Ptolemy* has it, Book 4 of the *Geography*, ch. 5, and Book 5 of the *Almagest*, ch. 13. If you subtract the arc between Alexandria and Syene, which from the corrected observation of Eratosthenes is 7° 28′, there remains the distance of Syene, and hence of the Tropic of Cancer, from the equator, namely an obliquity of the ecliptic of 23° 30′, as great as is found now also. It was therefore not 23° 51′ 20″ in those times, as is handed down, and that tradition had no other origin than the faulty

observation of Eratosthenes. For Eratosthenes, subtracting from the altitude of the pole at Alexandria, which he perhaps thought to be about 31° 4′, the arc between it and Syene, thought to be 7° 12′, will have found the distance of the tropic from the equator to be about 23° 52′, and hence the distance between the tropics to the whole circle as very nearly 11 to 83; for that is how *Ptolemy* speaks of

[Margin: The obliquity of the ecliptic was 23° 30′ also in the age of Eratosthenes.]

him, and of Hipparchus, in Book 1, ch. 11, indicating that it was not found to be precisely that much. However Ptolemy came to observe the altitude of the pole at Alexandria, it is enough for me to have established, from the pole altitude he gives and from the arc between Alexandria and Syene observed by Eratosthenes but necessarily corrected, that in that age too the obliquity of the ecliptic was no greater than in ours; or else, if you say that they hunted down the distance of the tropics and the altitude of the equator and of the pole by one and the same operation, that all these observations conflict with one another. But we have said more about the altitude of the pole at Alexandria in the Geographical book.

VIII. *Strabo*, towards the end of Book 2, states that at Byzantium the summer solstitial shadow at noon was found to have to the gnomon the ratio of 41⅘ to 120, and from so great a number of small parts I gather that the observation was quite fine. *Snellius*, in Book 1 of the *Eratosthenes Batavus*, reports from Hipparchus that the equinoctial shadow was found to be to the gnomon as 111 to 120. Now let a triangle be made, right-angled at the point where the gnomon stands perpendicular to the horizon, and from the sides about the right angle, namely from the shadow and the height of the gnomon, let the angle opposite the gnomon be found by the analysis of triangles; this angle measures the apparent altitude of the Sun's upper limb above the horizon. The altitude of this limb will be found to be 70° 45′ 25″ at the solstice and 47° 13′ 55″ at the equinox. The difference of these gives the distance of the Tropic of Cancer from the equator, or the obliquity of the ecliptic, 23° 31′ 30″. Before *Strabo*, then, who flourished under Tiberius Nero, that obliquity was very nearly 23° 31½′, and reducible to 23° 30′ by a very small correction of the observation.

[Margin: 2nd ancient observation, for an obliquity of the ecliptic of 23° 30′.]

IX. *Pytheas of Massalia*, who flourished under Alexander the Great, or about 324 years before Christ, observed at Massalia that at noon the solstitial shadow was to the gnomon as 213⅛ to 600, as *Pierre Gassendi* reports from the old records of the people of Massalia in the *Life of Peiresc*, at the year 1635. Gassendi himself, together with the Peiresc already mentioned, in the great hall of a certain college at Marseille, received the Sun's ray at noon on the summer solstice through a hole made in the wall facing south, which was 52 royal feet high. He found that shadow to this gnomon to be 31950 small parts, of which the gnomon, for the sake of greater fineness, was 90000, which is exactly as

213⅛ to 600. From this he inferred that the distance of the tropic from the zenith of Marseille is now exactly the same as it had been in the time of Pytheas and Alexander the Great, and hence that the obliquity of the ecliptic is the same; which, however, *Gassendi* thinks is 23° 31′.

[Margin: 3rd ancient observation, for the immutability of the obliquity of the ecliptic.]

X. *Ptolemy*, Book 2 of the *Almagest*, ch. 6, at Parallel 11, and Book 1 of the *Geography*, ch. 23, at Parallel 10, says that the longest day of $14^{h}\ 30^{m}$ observed at Rhodes is the indication of a pole altitude of 36°. But this cannot hold unless an obliquity of 23° 30′ is assumed: for to this obliquity, in the problems of the primum mobile and in the tables of semidiurnal arcs compiled from them, at a pole altitude of 36°, there corresponds precisely a semidiurnal arc of $7^{h}\ 15^{m}$.

[Margin: 4th argument, from the semidiurnal arc at Rhodes.]

XI. Although a few latitudes of fixed stars favour the opinion of Tycho, who holds that they change latitude from an extrinsic cause, namely from a variable obliquity of the ecliptic, more of them oppose this opinion, as we shall show in the book on the fixed stars, and they suggest to us the immutability of this obliquity, as *Boulliau* also admits in Book 5.

[Margin: 5th argument, from the latitude of the fixed stars.]

XII. The change of the obliquity of the ecliptic is so closely connected with the change of the Sun's eccentricity, of the tropical year, and of the annual motion of the fixed stars, or, as *Copernicus* thinks, of the precession of the equinoxes, that Copernicus may have been most confirmed by this very fact in asserting and investigating the anomaly of these things, as I said at no. 5. But in the book on the fixed stars I shall show that there is no necessity to acknowledge any anomaly in the motion of the fixed stars; and in ch. 30 of this book, that the quantity of the tropical year is more probably called immutable than mutable; and in ch. 26 we showed that there is no necessity to assert a change of the Sun's eccentricity. And *Longomontanus* and *Boulliau* themselves, who admit the change of the obliquity, nevertheless reject the variation of the eccentricity. There is therefore no confirmation from this of a changed obliquity of the ecliptic.

[Margin: 6th argument.]

XIII. Some authors who fight for the change of the obliquity nevertheless fight against themselves, or against the observations from which they deduced that change. Thus *Lansbergen*, in the *Thesaurus of Observations*, p. 41, because his hypothesis gives this obliquity as 23° 32′ in the year of Christ 1207, also states that so much was observed by *Jacob ben Machir ibn Tibbon* the Jew [Prophatio Iudæo] in the year 1207. But *Reinhold*, on Peuerbach's *Theorics*, p. 238, says that this obliquity was observed by *Jacob ben Machir ibn Tibbon* the Jew in the year 1300; and *Copernicus* himself, to whom *Lansbergen* sends us, Book 3, ch. 2, stands against Lansbergen. For he says that *al-Zarqālī* observed the obliquity of the zodiac 190 years after al-Battānī, and Jacob ben Machir 230 years after al-Zarqālī, and so 420 years after al-Battānī. Yet it is established from *Lansbergen*

himself, in the same place, p. 40, that al-Battānī observed in the year of Christ 880; therefore Jacob ben Machir observed in the year of Christ 1300. But more than once I have caught Lansbergen dragging chronology itself by main force towards his hypotheses. *Longomontanus*, too, differs so far from Kepler that he puts the greatest obliquity of the ecliptic in the first year of the world, which for him is 3968 before Christ, while *Kepler* puts the least in the same year, which for him is 3993 before Christ, as we showed above.

[Margin: 7th argument.]

[Margin: Lansbergen's unreliable credit.]

XIV. On the one side, the change of the obliquity of the ecliptic throws very many astronomical tables into disorder and lays an intolerable burden on astronomers, since those tables would have to be altered every century: above all the tables of oblique ascensions, of the latitude of the planets and fixed stars, and of semidiurnal arcs, and the Sun's motion itself as derived from the declination, and finally all problems resting on latitude; and these things surely should not be laid on astronomers without the strongest foundation. On the other side, as *Boulliau* says, Book 5, ch. 5, no physical cause of this change can be brought forward, nor any probable purpose. Indeed, I judge it more probable that God, the Best and Greatest, willed that the royal road, that is, the ecliptic, along which the Sun should travel, be always one and the same, and be a constant limit and boundary of the latitude of the planets; or at any rate that the Sun itself changes latitude rather than that the ecliptic varies, and that from its mean latitude, which our opponents call the mean obliquity of the ecliptic, the declinations and latitudes of the other stars are to be computed, as from a constant boundary. But on this statement, elsewhere. Meanwhile I think I can appropriate what *Kepler* said in ch. 12 of the Rudolphine Tables, without bringing forward any observations: *That the obliquity of the ecliptic was formerly greater is a matter not only doubtful, but overthrown by me with strong arguments from the very observations of the ancients, and beyond doubt plainly false.* On what foundations I have set it at 23° 30′ is clear from no. 4 and from the table placed before no. 5.

[Margin: 8th argument. The change of the obliquity of the ecliptic is most troublesome to astronomers.]

SCHOLIA.

Scholia.

I. Although *Kepler*, as I showed at the end of the chapter, rejects the mutability of the obliquity of the ecliptic outright, yet in the Rudolphine Tables, ch. 34, he offers anyone wishing to retain it five forms of this anomaly. The first is taken from pure trust in the ancient observations, yet limits this motion by a modest correction so that the least obliquity, 23° 28′ 28″, falls at the beginning of the world, or in the year 3993, and again in the year 1329 before Christ and in the year 1338 of Christ; for he gives it a period of 2664 Julian years. The

second comes from what is said in the *Epitome of Astronomy*, pp. 337 and 917, where he says that if the mean obliquity at the beginning of the world were as much greater than that of Eratosthenes as that of Eratosthenes is greater than the obliquity observed in our century, that is, if it were 24° 17′ 42″, then the combined width of the two temperate zones would come to as much as that of the three intemperate ones, namely the torrid and the frigid, and there would be an equal distribution between excess and equality. And this opinion seems to be favoured by what *Māshā' allāh* the Arab reports in Book 2 of the *Astrolabe* from an observation of the Indians, namely that the obliquity of the ecliptic was observed to be greater than 24°. The third form is fashioned from the second, but so that at the beginning of the world the obliquity is set smaller than the mean obliquity of the second form, in order that it may conflict less with the observations thereafter. The fourth form is if at the beginning of the world there is placed that greatest obliquity, which arises from the second form, or from the division of the zones devised there, namely 26° 5′ 20″. Finally, the fifth is mixed from the observations and archetypal causes, or from the distribution of the zones already mentioned, in which the least obliquity is assumed as 23° 30′ 30″, *suited*, he says, *to our century*, the mean as 23° 54′ 5″, and the greatest as 24° 17′ 40″, but in such a way that this mean obliquity held at the beginning of the world.

[Margin: Five forms of the anomaly of the obliquity, feigned by Kepler.]

II. Just as *Rheticus*, from the change of the eccentricity at the cardinal points of the small circle, dared to prophesy about changes of monarchies and the end of the world, as I said in Scholium 1 of ch. 26, so *Longomontanus*, in the *Astronomia Danica*, Book 1 of the Theorics, ch. 4, p. 221, holds that from the change of the obliquity of the ecliptic and of the equinoctial points *one may declare more about the universal state and change of nations, in all the ages of the world.* But we consider this fiction of Longomontanus as empty as that one of Rheticus, especially given such licence in abusing astronomical observations that from the same observations, for nearly the same year and for the beginning of the world, the former ascribes the greatest obliquity of the ecliptic and *Kepler* the least. As for the end of the world, however, our surest rule must be that decree of Christ the Lord in Matthew 24 and Mark 13: *But of that day or hour no one knows, neither the angels of heaven, nor the Son, but the Father alone.* On which St Augustine says, no more acutely than soundly: *This one sentence loosens the fingers of all who calculate.*

[Margin: A vain attempt to predict the end of the world astrologically.]

III. *Girolamo Fracastoro*, for his part, in the *Homocentrica*, sect. 3, ch. 8, thinks it not improbable that the obliquity of the ecliptic was once greater and greater; indeed, on the fabrications of the Egyptians, so great that the equinoctial colure and the ecliptic were once the same, and the Sun rose in the north and set in the south; indeed, that there was once a time when the Sun set where it now rises, as *Herodotus* and *Mela* report from the records of the Egyptians, who boasted such great antiquity that, since they had existed, the stars had traversed their

courses four times, and the Sun had twice set where it now rises. *Girolamo Fracastoro* adds that the obliquity of the ecliptic will diminish more and more, until the ecliptic coincides with the equator without any obliquity; that then, once the Sun's course has been made oblique, the signs that are now northern will turn out southern, and the vernal equinox will be entered from Libra, etc. Anyone might justly call these the ravings of men dreaming ingeniously rather than the inventions of men philosophizing soberly.

[Margin: Fracastoro's fiction about the obliquity of the ecliptic.]

IV. On the change in the latitude of the fixed stars that follows incidentally from the apparent change of the obliquity, I shall have to speak when treating the fixed stars. Meanwhile, if you are in a hurry, see *Pierre d'Ailly*, q. 9 on the *Sphere*; *Tycho*, vol. 1 of the *Progymnasmata*, from p. 233 to p. 247, and in the Letters, pp. 43, 65, 71; *Lansbergen* in the Precepts of the tables, Precept 12; *Boulliau*, Book 5, ch. 4; and *Kepler* in the Rudolphine Tables, chs. 12 and 34, Precept 193. In the meantime, know that this change, established by Tycho from a few stars, has been overthrown by me from many others, as I shall show in the book on the fixed stars, and as I afterwards found in Boulliau.

[Margin: Latitude of the fixed stars.]

V. Scaliger's fiction in Book 4 of *De emendatione temporum*, in the chapter on the year, where he imagines that the pole of the world is different from the pole of the equator, and that the obliquity of the ecliptic must diminish until the two poles are joined, has already been refuted by *Guldin*, *Pétau* and *Boulliau*, as I shall say in ch. 28, no. 10. For Scaliger was one of those who are least wise just when they are wisest.

[Margin: Scaliger's fabrications.]

CAPVT XXVIII.

Chapter 28.

De Præceſſione Aequinoctiorum Motuque Octauæ Sphæræ.

On the precession of the equinoxes and the motion of the eighth sphere.

I. The precession of the equinoxes is taken in two ways. First, in the civil sense, for the time by which the true, celestial or astronomical equinox precedes the day assigned to the civil equinox in the Julian calendar. This precession arises from the fact that *Sosigenes* and *C. Julius Caesar* assumed a tropical year of 365 days and a quarter of a day, or 6 hours, though the quarter is in fact smaller, and ordered that every fourth year a whole day compounded of the four quarters be added, so that the leap year should come out at 366 days, and four years should contain 1461 days. But four tropical years in reality contain only $1460^{d}\ 23^{h}\ 15^{m}$, as is clear from what was said in ch. 15. Therefore in every four years the equinox anticipates by 45^{m}, in 16 years by 3^{h}, and in 128 years by a whole day. It is no wonder, then, if in the year 1582 the true equinox had

come to 10 or 11 March, an anticipation of at least 10 days. But we have already spoken of this precession in chs. 13 and 17.

[Margin: What is the civil precession of the equinoxes?]

II. The precession of the equinoxes, taken astronomically and in the more common sense, is the motion of the equinoctial and solstitial points in *Præcedentia*, that is, against the order of the signs, toward the west, whether true, or apparent on account of the motion of the fixed stars, or of the eighth sphere, in *Consequentia*, that is, in the order of the signs, toward the east. For this mutual recession, namely of the equinoctial points and the fixed stars from one another, some attribute to the fixed stars, others rather to the equinoctial points, that is, to the points at which the equator and the ecliptic intersect; so that however great the motion of the fixed stars in longitude toward the east is for the one party, just so great is the motion of the equinoctial points toward the west for the other. For some this motion is always uniform; by others it is held to be anomalous and irregular. From this arose the anomaly of the precession of the equinoxes [*Anomalia Præcessionis Aequinoctiorum*], which is nothing other than a non-uniform motion of the equinoctial points toward the west, in the opinion of those who think that these points, rather than the fixed stars, move. Among these there was, as it were, a middle opinion, that of those who said that the fixed stars move now against the order of the signs, now in it, and who posited the motion of trepidation, or a second libration in longitude. So that these things may be better understood, I shall briefly indicate the principal opinions and their authors. For although, if this whole motion belongs to the fixed stars, this discussion would pertain to the book on the fixed stars, yet if it belongs to the equinoctial points, it certainly pertains to this book on the Sun, which by its motion, compared with the motion of these points, brings about for us the equinoxes and the equinoctial year.

[Margin: What is the astronomical precession of the equinoxes?]

[Margin: What is the anomaly of the precession of the equinoxes?]

III. First, then, the *Babylonians* and *Egyptians* once thought that the non-wandering stars, or the Aplanes, and the eighth sphere are moved by no other motion than the diurnal one, toward the west, in the space of 24 hours; and so the eighth sphere, glittering with almost innumerable fixed stars, was their primum mobile. This opinion is also attributed to the Greeks, and first of all to Plato, and to Aristotle, Eudoxus, Callippus and most astronomers who flourished in the third century before Christ; although Cicero, *On the Dream of Scipio*, reporting Plato's opinion, and Plato himself in the *Timaeus*, require for the Great Year *that the eight heavens complete their circuits*, by which words they indicate a proper motion of the eighth sphere in longitude. Since, then, the Babylonians thought the fixed stars immobile as regards motion in longitude, it is no wonder if they defined the year by the revolution of the Sun back to the same fixed star.

[Margin: Who thought the fixed stars immobile as regards proper motion.]

IV. *Hipparchus*, however, comparing his own observations with those of Timocharis and Aristillus, found that Spica and all the other fixed stars, which had earlier been farther from the equinoctial points toward the west, were later less distant; and that therefore either they move toward the east, or the equinoctial points toward the west. He wrote a treatise on the transit, or change, of the equinoctial and solstitial points, which *Ptolemy* mentions in Book 3 of the *Almagest*, ch. 2, and Book 7, chs. 2 and 3, where he confirms from his own observations made with the astrolabe that the fixed stars move in an orderly and uniform way in the order of the signs, toward the east, on the poles of the ecliptic, and complete one degree in 100 years, about as much as *Hipparchus* too had found, although he says that Hipparchus once suspected an inequality in this motion and in the equinoctial year.

[Margin: The proper motion of the fixed stars detected by Hipparchus.]

V. Later authors followed Ptolemy, not all of them indeed in the size of the motion, but in its kind and uniformity. That the fixed stars move uniformly in longitude toward the east, in the ecliptic or in circles parallel to the ecliptic, was affirmed by *al-Battānī*, ch. 51; *al-Farghānī*, Differentia 13; *Rabbi Levi*, in the book of the *Defences of God*; *Albuassim* the Moor [?], in the book on the fixed stars; *Avraham Zacuto* and his

[Margin: Uniform motion of the fixed stars.]

disciple *Agostino Ricci*, in the treatise on the motion of the eighth sphere; and, as cited by him, *Rabbi Yehoshua* in the Talmud; *Rabbi Moshe* in the book *Mishneh Torah* [Miſnetora], or of the repeated law; *Rabbi Avraham ibn Ezra* in the book *Taamin*, or of reasons; and *Haly* [ʿAlī ibn Riḍwān] on the *Quadripartitum*, ch. 11; *Tycho*, vol. 1 of the *Progymnasmata*, ch. 2; *Kepler* in the Rudolphine Tables, ch. 34; *Ismaël Boulliau*, Book 5 of the *Astronomia*, ch. 2, and the mathematicians of the Persians cited by him; and King *Alfonso*, as cited by Ricci, p. 29, after he changed his opinion.

VI. Some before al-Battānī, however, as he himself relates in ch. 52, and after him *Regiomontanus* in Book 7 of the *Epitome of the Almagest*, Prop. 6, said that the fixed stars move now toward the east, up to 8°, completing one degree in 80 or 84 years, and then return toward the west through as many degrees; or, as *Peuerbach* has it in the Theoric of the eighth sphere, perhaps following Gerard of Cremona [Gerardo da Cremona], that they advance toward the east only as far as 7°, together with the apogees of the planets, and complete these in 900 years. But *al-Zarqālī* thought that the fixed stars advance toward the east from the head of invisible Aries up to 10° over 750 years, completing one degree in 75 years; that from there they return through as many years and degrees, and through as many again are carried to the west: so that the whole extent of this motion was 20°, and its period from east to west 1500 years, but the whole period from east back to east 3000. *Thābit*, however, if we believe *Erasmus Reinhold* on the Theorics of Peuerbach, p. 251, said that the beginning of the fixed stars cannot recede beyond 22° from the head of Aries of the primum mobile. Further, *Agostino Ricci*, from treatise 2 of *De Mundi fundamento* by

Yitzchak Yisraeli, reports that al-Zarqālī and Thābit were led to this because Hermes, older than Ptolemy by 1985 years, had once found some of the fixed stars at a longer longitude from the beginning of Aries than Ptolemy did later: for example, the Falling Vulture at 24° of Sagittarius, which Ptolemy has at 17° of Sagittarius, and the bright star of Hydra at 7° of Leo, which Ptolemy has at 30° of Cancer. Ricci adds, from the same Yitzchak, that al-Zarqālī thought that in the year of Christ 560 the head of visible Aries was beneath the head of Aries of the invisible zodiac, and that from there it was carried eastward through 10° in 750 years, so that in the year of salvation 1310, when Yitzchak Yisraeli was writing, it should have turned back toward the west. But if this were so, the head of visible Aries ought in the year 1474 to have stood only 7° 11′ from the beginning of invisible Aries; whereas in that year *Avraham Zacuto*, Ricci's teacher and a very great astronomer, observed that it stood 13° 52′ from it, and Spica at 17° 10′ of Libra. Rightly, then, this motion of access and recess, or of trepidation in longitude, was refuted by *Agostino Ricci* in the treatise on the eighth sphere, by *Regiomontanus* against the hypotheses of Thābit, and by others, who attribute that discrepancy between the observations of Hermes and of Ptolemy to equivocal names of stars. The *Alphonsines* too, when in the year 1252 they saw the fixed stars advanced far beyond the limits of al-Zarqālī and Thābit, departed from their opinion.

[Margin: The motion of access and recess of the fixed stars in longitude.]

VII. So the motion of trepidation, or libration in longitude, was asserted or admitted by others in another sense: namely, that the fixed stars always indeed move toward the east by their mean motion, but unequally by their true motion, and at times seem retrograde on account of slowness, and direct on account of speed. This was the opinion of the Alphonsines, that is, of the Jews and Moors who, convened by Alfonso, King of Castile, composed the Alphonsine Tables. Over them, as *Agostino Ricci* reports, and after him *Reinhold* (the former in his treatise, the latter in the Theoric of the eighth sphere, p. 235), presided *Rabbi Yitzchak*, cantor of the Synagogue of Toledo. They defined the period of the eighth sphere as 49,000 years, namely a thousand Jubilees, and the motion of trepidation as 7000 years, namely a thousand Sabbaticals, of which Leviticus 25 and Deuteronomy 15 speak. Although *Reinhold*, p. 163, *Clavius*, p. 56 of the *Sphere*, and *Maurolico* in the *Cosmographia*, p. 88, think that they defined the annual motion of the fixed stars by the precession of the true equinox before the civil one, or from the Sun's residual motion needed to complete the quarter of a day after the tropical year, namely 26″ 26‴ 54⁗, which the Sun completes in the time of 10^{m} 44^{s}. These authors ridicule these fictions, just as *Boulliau* does in Book 2, ch. 3, and Book 5, ch. 2. However, King *Alfonso*, in the fourth year after the publication of the Alphonsine Tables, namely in the year 1256, having read the book of *Albuhassim* [?] on the motion and places of the fixed stars, translated from Arabic into Spanish, in which al-Battānī's opinion was confirmed, followed al-Battānī and published another table of the fixed stars, different from the earlier canon of the motion of the

apogees and fixed stars. So *Avraham Zacuto* relates in his *Magna Compositio*; and it is clear even from this alone, that the northern star in the forehead of Scorpius is placed by Alfonso at 23° 28′ of Scorpius, which *al-Battānī* in the year of salvation 880 had found at 17° 50′. So in 376 years it advanced 5° 38′, and completed one degree in 66 years, which is al-Battānī's very opinion; whereas according to the older Alphonsine canons it ought to have advanced only 4° 32′. The opinion of al-Battānī is followed by *Rabbi Levi*, *Avraham Zacuto*, and *Agostino Ricci* in the treatise on the eighth sphere, pp. 5, 29 and 31.

[Margin: Another sense of the motion of trepidation among the Alphonsines.]

[Margin: Disagreement of the Alphonsine Tables with Alfonso's final opinion.]

VIII. After the Alphonsines, however, *Io. Bapt. Turrianus* [Giovanni Battista della Torre] and *Girolamo Fracastoro*, in the *Homocentrica*, sect. 2, from ch. 9 to ch. 17, said that the motion of trepidation of 7000 years asserted by the Alphonsines is indeed not established, and that if it were admitted in the eighth sphere, more orbs would have to be admitted; but that it is more probable that the fixed stars always advance directly toward the east on the poles of the ecliptic, because from the time of Meton none of the fixed stars has been seen to go back. This motion, however, is anomalous, and the mean motion is one degree in 100 years; from Christ to al-Battānī, over 900 years, it was fast and increasing, until they traversed one degree in 66 years, but from then until the year 1800 it is fast and decreasing, and the whole period of this anomaly is completed in 3600 years.

[Margin: The motion of trepidation according to della Torre and Fracastoro.]

IX. Now *Copernicus*, in Book 3 of *De revolutionibus*, taught that the fixed stars are moved by no motion. The diurnal motion he ascribes to the Earth's revolution about its own centre, completed toward the east in the space of 24 hours; the proper and slow motion that appears in the fixed stars toward the east he attributes to the equinoctial points, always tending against the order of the signs, though on the terrestrial equator rather than the celestial. This motion, he says, is anomalous, and the point of the mean equinox always tends toward the west; but the point of the true equinox sometimes coincides with the point of the mean equinox, as happened in the year 63 before Christ, and sometimes moves on this side of it, sometimes beyond it, and the whole period of this anomaly is completed in 1717 Egyptian years. The anomaly of the obliquity of the ecliptic, however, is completed in an interval twice as long, namely 3434 years; or, as *Magini* has it from the data given by Copernicus, in the Theorics, Book 1, from ch. 2 to ch. 4, the former is completed in 1717 years and 5 days, the latter in 3434 years and 10 days. But the mean motion of the equinoctial point against the order of the signs is daily 8‴ 15⁗, and annual 50″ 12‴ 15⁗, so that the whole period of this motion is 25,816 Egyptian years, but 25,798 Julian. But if the apparent longitude of the first star of Aries is computed from the

true equinox, this motion is at times fast, so much so that when it is fastest one degree is completed in 54 years; at times slow, so much so that at its slowest one degree is completed in 102 years; and at times moderate, and then one degree is completed in 72 years. *Copernicus* adds, in Book 3, ch. 11, that at the beginning of the Olympiads the first star of Aries was more westerly than the point of the mean equinox by 5° 16′, but at the birth of Christ had come to be more easterly by 5° 32′. *Magini*, however, attributes this anomaly and second libration not to a libration of the Earth, as *Copernicus* does, but to the motion of the ninth sphere, just as he attributes the first libration to the motion of the tenth sphere, which varies the obliquity of the ecliptic, and the mean motion of the fixed stars to the motion of the eighth sphere. With Copernicus, however, as regards this libration made in the Earth's equator, agree *Reinhold* in the Prutenic Tables, Precepts 10 and 11; *Lansbergen*, Precepts 4 and 11 of the tables, and in the Theoric of the motions, chs. 1, 7 and 8; and *Longomontanus*, Book 1 of the Theorics, chs. 2 and 4. But they disagree in the size of the motion: *Lansbergen*, with *Reinhold*, fixes the period of this anomaly at 1717 years, but *Longomontanus* at 3600 solar years, as also the anomaly of the obliquity, for he does not make this one twice that period. Both, however, attribute to the fixed stars a proper motion that is uniform from the mean equinox.

[Margin: Copernicus's opinion on this.]

[Margin: And Magini's.]

[Margin: The opinion of Reinhold, Lansbergen and Longomontanus.]

The foundations of this anomaly are, first, the apparent irregularity in the motion of the fixed stars, since they were seen to complete one degree

[Margin: Foundations of this anomaly.]

in Ptolemy's age in 100 years, in al-Battānī's age in 66 years, and in the fifteenth century of Christ in about 72 years; and, second, the inequality of the tropical or equinoctial year, which appeared greater in Ptolemy's time than in al-Battānī's, etc. For both, they hold, arise from the motion of the equinoctial points themselves against the order of the signs, but an irregular motion.

X. In the last place we must point out the fiction of *Joseph Justus Scaliger* in Book 4 of *De emendatione*, in the diatribe on the anticipation of the equinoxes, which *Clavius* tacitly indicates in the *Sphere*, p. 61, but which is refuted by *Pétau*, Book 3 of the Dissertations of the *Uranologion*, from ch. 3; by *Guldin*, in the refutation of the Calvisian *Elenchus* written against the Gregorian calendar, ch. 10; and by *Boulliau*, Book 5, ch. 4. *Scaliger* says that the equinoctial points recede from the fixed stars toward the west, but on mobile poles of the equator, which he further makes different from the immobile poles of the world; and that from this arose the variation of the obliquity of the ecliptic, the change of the meridian line and of the magnetic declinations, and other such things. For if that motion took place, as Ptolemy would have it, on the poles of the ecliptic, the fixed stars ought to have changed their declinations, and some of them to have come closer and closer to the poles of the world and others to have receded. But this, he says, is false, because the Pole Star, which is now near the

north pole and not a full three degrees from it, was near the same pole in the time of Eudoxus, or about the year 367 before Christ. For *Eudoxus* says in his *Phaenomena*: *There is a certain star which always remains in the same place; that star is the pole of the world.* And in *Hyginus*, from Eratosthenes, who flourished 140 years after Eudoxus, he says of Cynosura: *Among the first stars of the tail is the lowest, which is called the pole, as Eratosthenes says, through which place the world itself is thought to turn.* Moreover, Canopus too now grazes the horizon of Rhodes, just as, on the testimony of *Pliny the Elder*, Book 2, ch. 70, it once did; and these are signs of a declination not changed after so many centuries. But about Canopus there is nothing to wonder at, since it is near the solstitial colure, on which the declination of the fixed stars varies insensibly. Nor was the star which is now the Pole Star, and last in the tail of Ursa Minor, the one which in the time of Eudoxus, Eratosthenes and Hipparchus was the Pole Star, or nearest to the pole of the world. For the last star of this tail, as is found in *Ptolemy*, Book 1 of the *Geography*, ch. 7, and *Strabo*, Book 2, stood 12° 24′ from the pole of the world in Hipparchus's time; and it was then the most southerly, as is said in the same place, which is now the most northerly. And all those who with *Magini* emended Ptolemy's text, calling it the most northerly, were deluded, since in the text it is truly called the most southerly. So there was then another star, which then deserved the name of Pole Star; and this one, which is now the Pole Star, is approaching the north pole of the world more and more, as will be shown from the observations of others and from ours in the book on the fixed stars. From this you may also correct *Proclus* in the *Hypotyposes Astronomicae*, and *Giovanni Antonio Delfino*, on the celestial globes, who, moved by the argument from the Bear and Canopus, denied a motion of the fixed stars on the poles of the ecliptic.

[Margin: Scaliger's fabrication.]

[Margin: The error of Proclus and Delfino.]

Noſtra Sententia de Præceſſione Aequinoctiorum, eiuſq. Anomalia.

Our opinion on the precession of the equinoxes and its anomaly.

XI. First, we are certain that from the time of Aristillus and Timocharis down to our own, that is, from the year 330 before Christ to the year of salvation 1640, there exists no observation in which any fixed star has been seen to go back, but that they have always been seen to advance toward the east; and so we consider the fiction of *al-Zarqālī* and *Thābit*, on which see no. 6, completely empty. Second, before Copernicus, *Proclus Diadochus*, in ch. 2 of the *Hypotyposes Astronomicae*, reports that it seemed to some that the equinoctial and tropical points, rather than the stars, move some degrees in either direction and return again to the same places; and *Copernicus*, taking all motion away from the fixed stars, had to transfer this motion too to the equinoctial points of the terrestrial equator. Yet all who are compelled to follow the hypothesis of a stationary

Earth, among whom we shall show in Book 9, sect. 4, that we too stand, with the best right, must recognize this motion in the heavens; and if we rely on the senses, as one must as long as no reason proves the opposite, we must attribute this motion to the fixed stars rather than to the equinoctial points (indeed *Lansbergen* and *Boulliau*, who attribute the annual and diurnal motion to the Earth, still grant the fixed stars a proper motion): whether those stars then, besides the diurnal motion to the west, perform a second, proper motion to the east, or have a single motion to the west, but slower than the Sun's motion which makes the equinoxes, so that the stars seem to move toward the east. Third, although the anomaly or inequality of the apparent motion of the fixed stars toward the east offers at first sight some appearance of probability, when the observations of Ptolemy, al-Battānī and more recent authors are viewed as they lie, yet no necessity has so far appeared for asserting the inequality of this motion as more probable, let alone as evident; and so we prefer to follow on this point the opinion of Ptolemy, and of the others we related in no. 5. For, first, one may rightly have doubts about the unreliability of the ancient observations, since they used the astrolabe and armillae, taking the distance of the Moon from the Sun when it was near the horizon, and then at night the distance of some fixed star from the Moon, so as to determine the places of the fixed stars in this way, as *Ptolemy* teaches in Book 7, ch. 4, and *Copernicus* in Book 2, ch. 14. But that only the tens of minutes were marked on those armillae is gathered from *Ptolemy's* table in Book 7, ch. 5, in which only those tens are indicated. Further, the horizontal refraction of the Sun, omitted by the ancients, gave a distance of the Sun from the Moon differing from the true one by about 30′; and the parallaxes of the Moon and Sun, and the Sun's motion, not so exactly known to Ptolemy, give rise to a suspicion of variation that is not to be despised; so much so that, with everything reckoned, the places of the fixed stars established by them in this way are suspect of an error of at least one degree. From this, I think, it came about that *al-Battānī*, ch. 52, and after him, in nearly as many words, *Regiomontanus*, Book 7 of the *Epitome*, Prop. 6, said: *Whether, then, the multitude of instruments introduced this variation, or nature has placed in the fixed stars some motion still hidden from us, it is very difficult, and will be, to attain the quality of this motion, because of its slowness. For if our forefathers were deceived by their instruments, we too shall necessarily be deceived, since our considerations, unless compared with the considerations of the ancients, can never teach anything. But if we judge that hidden motion to be in the stars, it will be expedient to keep an eye constantly on the fixed stars, and for posterity likewise to weigh the written considerations.* But *Stevin* too, in Hérigone, vol. 5, p. 579, and *Nonius*, Book 2 of *De observatione*, ch. 4, have called the inequality of this motion into doubt, and suspect that it arose from an error of the observations; and *Erasmus Reinhold*, on the Theorics of Peuerbach, begins thus at the opening of the Theoric of the eighth sphere: *Now we enter a disputation in which the very uncertainty and obscurity of the matter seems to contend with the difficulty of the hypotheses, since this motion, because of its excessive slowness, has not yet been sufficiently explored*

even, as I think, in our own age. Finally, *Kepler* in the Rudolphine Tables, ch. 34, Precept 191, says: *This prosthaphaeresis of the equinoxes, of uncertain credit, when taken into the calculation, turns all astronomy upside down.* And *Pierre Gassendi*, in the *Institutio Astronomica*, Book 2, ch. 8, says at the beginning: *perhaps it rests on no firm foundation*, and at the end: *The matter seems too fictitious for us to pursue it more scrupulously.* And *Boulliau*, Book 2, ch. 3, rejects it absolutely.

[Margin: 1. Our assertion.]

[Margin: And of Stevin and Nonius,]

[Margin: and of Reinhold,]

[Margin: and of Kepler,]

[Margin: and of Gassendi, and of Boulliau.]

Then, from the observations of the ancients themselves, compared with one another and with Tycho's and ours, it is gathered that the motion of the fixed stars was sometimes fast at a time when, according to the Copernican hypotheses, it ought to have been slow, and conversely; which *Tycho* also noted in vol. 1 of the *Progymnasmata*, p. 254, and which will be shown by us in Book 6, ch. 17, from many fixed stars. And we shall add, from *Tycho*, p. 255, that the difference of longitude and the distance of the fixed stars from one another not rarely disagree in the ancients with what he and we have clearly deduced from our observations. Nor is the inequality of the tropical year certain, or more probable, as will be said in ch. 29. Nor do the Prutenic, or the Danish, or Lansbergen's tables, which use the anomaly of the precession of the equinoxes, give us the places of the stars more certainly than other tables; indeed they are sometimes farther from the observations. Why, then, on account of slight suspicions, do we entangle astronomy in one anomaly after another?

Fourth, therefore, we shall choose a uniform annual motion of the fixed stars of 50″, and thus so great that they complete one degree in 72 years, as great as it was in Callippus's time, as *Reinhold* notes on Peuerbach's Theorics, p. 241, and as great as

[Margin: 4. Assertion.]

very nearly, is their true motion according to *Tycho*, *Kepler* and *Boulliau*, or their mean motion according to *Copernicus* and *Longomontanus*, as can be seen in the small table that follows, in which we have set out the principal opinions of others, adding however, in a second table, the opinion on the anomaly of the fixed stars, or of the precession of the equinoxes. The foundation of our opinion consists above all in the observations written below. For *Hipparchus*, on the testimony of *Ptolemy*, Book 7, ch. 2, observed the Heart of the Lion [Cor Leonis], or Regulus, in the fiftieth year of the third Calippic period, that is, 128 years before Christ, at Cancer 29° 50′. But *al-Battānī*, ch. 51, observed the same star in the year of Christ 879, which was of Dijlkarnaim [Dhū al-Qarnayn] 1191 and of Nabonassar 1627, at Leo 14° 0′. *Tycho*, in vol. 1 of the *Progymnasmata*, ch.

2, p. 260, observed it for the year 1600 at Leo 24° 17′; and we, in the year 1644, at Leo 24° 55′ 20″. Therefore if in 1006 years, from Hipparchus to al-Battānī, it advanced 14° 10′, then in one year it certainly completed 50″ 7/10. Again, if in 1729 years, from Hipparchus to Tycho, it advanced 24° 27′, then in one year 50″ 54‴. Likewise, if in 722 years, from al-Battānī to Tycho, it covered 10° 17′, then in one year 51″. And if in 1773 years, from Hipparchus to us, it completed 25° 5′ 20″, then in one year 50″ 1670/1773. But since it is probable that the longitude of the Moon was taken by him about 30′ less than it should have been, on account of the horizontal refraction of the Sun, which diminished the evening distance of the Moon from the Sun; and that therefore Regulus, believed at night, from the lunar distance, to be at Cancer 29° 50′, was at Leo 0° 20′; and that it has thus advanced from that year down to us 24° 35′ 20″ in 1772 years, and in one year 49″ 169/177, and in round numbers 50″. Now let this be Table 1.

	493	4655 December 15				

The whole period of the anomaly of the precession of the equinoxes is, for Copernicus, 1717 Egyptian years and 5 days, or 1715 Julian years and 302 or 307 days.

CAPVT XXIX.

Chapter 29.

Qua Hypotheſi, aut Theorica ſolitæ ſint Explicari Anomaliæ Eccentricitatis Solis, Obliquitatis Eclipticæ, & Præceſſionis Aequinoctiorum.

By what hypothesis or theory the anomalies of the Sun's eccentricity, of the obliquity of the ecliptic and of the precession of the equinoxes are customarily explained.

I. Although, from what was said in chs. 26, 27 and 28, we hold that there are no such anomalies, the schemes must nevertheless be indicated by which they are usually set out by those who assert them, or even by those who merely invent them as a hypothesis. For the sake of ease, it is our choice to begin with the more recent authors, so that the theories of the older ones may be better understood.

Lansbergiana Solis Theoria.

Lansbergen's theory of the Sun.

Let ABDCA be the annual orb, or eccentric circle, whether of the Sun or of the Earth, with centre M; let the centre of the world and of the ecliptic be T; let the line of the equinoxes be BMC, which the line of the solstices DMO cuts at right angles at the centre M; and let the line of the apogee be AMTP, on which the apogee or aphelion is A, the perigee or perihelion P, and the eccentricity MT. Now let there be drawn from the centre of the world T a line TR, parallel to DO, as great as the greatest eccentricity of the Sun, which for *Lansbergen* is of 4216 parts of which the radius AM of the eccentric has 100000; and let the least eccentricity TN be of 3490 parts, so that the diameter of the small circle RN is of 726 parts, and the semidiameter ME 363. With centre at E, therefore, let there be described the small circle of eccentricity RMN, carrying on its circumference the centre M of the eccentric, so that while the eccentric carries the Sun, or the Earth, in the order of the signs from A towards B, this small circle carries the centre of the eccentric against the order of the signs from M towards R, completing each day 1″ 11‴ 0⁗ 49⁗′ 19⁗′′, and each year 7′ 12″; since for *Lansbergen* the greatest eccentricity was at the beginning of the years of Christ, when the centre of the eccentric was at R, and the least in the year 1500, when that centre was at N; and the whole period of this small circle is 3000 years. By this small circle, then, first devised by *al-Zarqālī*, as *Regiomontanus* indicates in Book 3 of the *Epitome of the Almagest*, Prop. 13, an account is given of the change in the eccentricity. For once tables of the mean motion of this anomaly have been drawn up, according to the proportion

of daily and annual motion already indicated, and its numbering is begun from the point R, through N, towards M, its equation is found as follows. Let the year of Christ be 1650. The Lansbergian tables of this mean motion will give a motion of 6^{s} 18° 7′ 56″, which is the arc RNM. Discarding, then, the 6 signs for the semicircle RN, there remains the arc MN, 18° 7′ 56″; and so great is the angle MET in the triangle MET, in which the sides are known: ME, the semidiameter of the small circle already mentioned, of 363 parts, and ET, consisting of the semidiameter EN and the least eccentricity NT, that is, of 3853 parts. From these three givens, therefore, by means of trigonometry, you will gather the base MT, namely the eccentricity belonging to the given time, which in our case is of 3512 parts.

[Margin: Anomaly of the eccentricity.]

Diagram. Lansbergen's theory of the Sun, set in the left column, where it interrupts the first sentence of this page. A large circle, the eccentric, is drawn with its top lost behind a small circle and its centre at M. A vertical line runs from the small circle at the top through M to D at the foot; a horizontal line runs from B through M to the small circle at the right; a diagonal runs from A at upper left through M and T to P at the foot. Three small circles stand on these lines: one at the top of the large circle, one at the right end of the horizontal, and one in the interior, to the right of M, passing through M. A vertical line through the interior circle descends past N to T.

- K (top of the upper small circle): upper end of the diameter KL of the small circle of the obliquity
- O (small letter at the centre of the upper small circle): the point O
- L (below the centre of the upper small circle): lower end of the diameter KL
- A (upper left, on the large circle): apogee or aphelion
- B (left, on the large circle): end of the line of the equinoxes
- D (foot of the vertical): end of the line of the solstices
- P (foot of the diagonal): perigee or perihelion
- M (centre of the large circle): centre of the eccentric
- T (on the diagonal below M): centre of the world and of the ecliptic
- R (top of the interior small circle): upper end of its diameter RN
- E (centre of the interior small circle)
- N (foot of the interior small circle): lower end of its diameter RN
- G (top of the right-hand small circle)
- C (centre of the right-hand small circle): the mean equinox
- V (right of the right-hand small circle)
- F (left of the right-hand small circle)
- I (foot of the right-hand small circle)

II. Now the anomaly of the motion of the Sun's apogee must be set out from *Lansbergen*. For the line of the apogee AP moves perpetually: the mean apogee is O, which moves about the centre of the world T, each day, according to *Lansbergen*, with a mean motion of 11‴ 5⁗ 51⁗⁗ 30⁗⁗⁗, and each year 1′ 7″ 30‴

38‴. The true apogee is A, now, when the eccentricity is growing from N to M. For in the semicircle of increase NMR the prosthaphaeresis must be added to the mean apogee to obtain the true one; but when the eccentricity has diminished from R to N, rightwards, the prosthaphaeresis must be subtracted from the mean apogee. In the case already mentioned, therefore, the prosthaphaeresis is the angle AMO, subtending the arc AO; and by Euclid I.29 this angle is equal to the interior and opposite angle ETM, since RT is parallel to OD. This angle is found in the triangle ETM, given, as above, the sides ME and ET and the angle MET contained by them. So in the example already mentioned MTE is 1° 50′ 36″. For the year 1650, the mean motion of the apogee from *Lansbergen*'s tables is 3ˢ 6° 7′ 17″; if you add 1° 50′ 36″ to this, the true apogee results, that is, the arc AOC, 3ˢ 7° 57′ 53″, reckoned from the mean equinox. For *Lansbergen*, the period of the mean motion of the Sun's apogee is 19255 Julian years.

[Margin: Anomaly of the apogee.]

III. In the same diagram the small circle KL contains the anomaly of the obliquity; for its diameter KL is an arc of the solstitial colure, as great as the difference between the greatest and the least obliquity of the ecliptic: namely, for *Lansbergen*, 22′. He posits that in the year 1 of Christ the greatest obliquity of the ecliptic, 23° 52′, was at K, and at that time likewise the greatest eccentricity at R; and that when the right-hand semicircle from K to L had been completed, in the year 1500, the least obliquity was at L, and the least eccentricity at N, 23° 30′. So for him the motion in the small circle KL is as great as in the small circle RN, namely 1″ 11‴ 0⁗ 49⁗′ 19⁗′′ daily and 7′ 12″ annually. Thus the head of Cancer of the mean ecliptic, when the obliquity is 23° 41′, is the point O; but the head of Cancer at the greatest obliquity, and at its most northerly, is the point K, from which the mean motion of this anomaly is numbered rightwards; at the least obliquity, the head of Cancer at its most southerly is the point L. The equation of the obliquity is found by the method to be given below, in Kepler's hypothesis, no. 5. This first libration, therefore, takes place on the diameter KL, although the motion of the anomaly is numbered on the small circle.

[Margin: Anomaly of the obliquity.]

IV. Finally, the small circle FGVI serves the anomaly of the precession of the equinoxes. For the points of the true equinox librate from west to east and from east to west on the diameter GCI, which for *Lansbergen* is of 4320 parts of which the radius MC has 100000, or 2° 28′ 32″ of the degrees of which the ecliptic has 360°; and the mean motion of this anomaly begins from V and proceeds against the succession of the signs towards I: daily 2″ 4‴ 4⁗ 39⁗′ 3⁗′′, and annually 12′ 34″ 48‴ 17⁗ 37⁗′. So when the anomaly is nil, that is, at V, or 180°, at F, the head of Aries of the primum mobile and that of the second mobile coincide at C, and the mean and true equinoxes are the same. But when the anomaly is 90°, at I, the prosthaphaeresis of the equinoxes is greatest and is to be subtracted from the mean equinox C, so as to obtain the point of the true equinox at I, a point of the ecliptic OBDC. But if the anomaly is 270°, and

at G, the prosthaphaeresis is greatest and is to be added, etc. And in the first semicircle VIF the equation is subtracted from the mean equinox to obtain the point of the true equinox, which is therefore farther west than the point C, and so the true equinox occurs sooner than the mean; but in the second semicircle of the anomaly, FGV, the equation is added, and the true equinox occurs later than the mean. Now it is clear from what has been said that the semidiameter CI, or the arc of the greatest equation, is for *Lansbergen* 1° 14′ 16″, which the Sun completes in one day and about 7 hours; and therefore that there cannot be a greater difference between the true and the mean equinox than $1^{d}\ 7^{h}$. Further, the method of finding the prosthaphaeresis of the equinoxes, given the mean motion of this anomaly and the semidiameter of the small circle CI, is similar to that by which the equation of the obliquity is found, namely by sines, as we shall show below in explaining Kepler's theory, at no. 6.

[Margin: Anomaly of the precession of the equinoxes.]

[Margin: The greatest difference between the true and the mean equinox.]

Kepleri Hypotheſis Pro Anomalia Obliquitatis Eclipticæ, & Præceſſionis Aequinoctiorum.

Kepler's hypothesis for the anomaly of the obliquity of the ecliptic and of the precession of the equinoxes.

V. In the Rudolphine Tables, ch. 34, *Kepler* does not explain his invented hypothesis of the anomaly of the obliquity and of the precession with figures, but indicates it by the bare names of small circles, and proposes five forms, of which we spoke above in ch. 26, in the Scholium. Although this is so, it seems that it can be explained as follows by the scheme below. Let AB be a portion of the solstitial colure, as great as the greatest obliquity of the ecliptic; let B be the pole of the equator and C the pole of the mean ecliptic, from which let a circle ADEF be described, carrying round the pole of the moving ecliptic from A, the point of greatest obliquity, against the series of the signs towards G; and let the semidiameter of the circle, AC, be the difference between the greatest and the mean obliquity: namely, in Kepler's first form 12′ 24″; in the second and third 1° 47′ 40″; in the fourth 0° 41′ 10″; and finally in the fifth 0° 23′ 35″. Let the mean obliquity BC in the first form be 23° 40′ 55″, the greatest, BA, 23° 53′ 19″, and the least, BE, 23° 28′ 31″. But in forms 2, 3 and 4 let the mean obliquity be 24° 17′ 40″, the greatest 26° 5′ 20″, the least 22° 30′. Finally, in the fifth let the mean obliquity be 23° 54′ 5″, the greatest 24° 17′ 40″, the least 23° 30′ 30″. Now if the anomaly of the obliquity, or its argument, from the tables of mean

[Margin: Anomaly of the obliquity.]

motion is nil at A, the obliquity will be greatest; if it is 6 signs, or 180°, and at E, it will be least; but if 90° at D, or 270° at F, the mean and true obliquities will coincide. Beyond these limits, the terminus of the anomaly will be either in the first quadrant, as at G; or in the second, as at I; or in the third, as at L; or in the fourth, as at M. With semidiameters drawn, then, to these points, namely

CG, CD, CI, CL, CF, CM, and with the right sines GH, IK, LK, MH, right triangles will arise by the definition of sines; from one of these you will learn the analysis of the others. Let the terminus of the anomaly of the obliquity, then, be at G, and its mean motion the arc AG, which the angle GCA measures. Look up in the sine tables its second sine CH; multiply this by the semidiameter of the circle given according to one of the five Keplerian forms, or others; divide the total by the radius of the sine table, and the arc of the equation HC will result, to be added to the mean obliquity BC, so that the true obliquity BH may be known. But if the terminus of the anomaly were at M, and the arc of the anomaly ADEFM, then, discarding three quadrants, there will remain the arc FM, whose right sine will be CH; use it as above. And so in the first and fourth quadrants of the anomaly the equation will be added to the mean obliquity. Now if the terminus already mentioned is in the second quadrant, as at I, and the arc of the anomaly is ADI, then, discarding the quadrant AD, the arc DI will be known, whose right sine is KC; but if it is at L, and the arc of the anomaly is ADEL, then, discarding the semicircle ADE, the arc EL will be known, whose second sine is KC. In both cases, therefore, multiply the sine KC by the semidiameter of the circle given in whichever form you choose to use, and divide the product by the whole sine; for the equation KC will result, in the second and third quadrants of the anomaly, to be subtracted from the mean obliquity BC, so that the true obliquity BK remains.

[Margin: Equation of the obliquity.]

Diagram. Kepler's hypothesis, set in the right part of the left column with the text wrapped round it. A long vertical line runs from B at the top, through the top of a circle, to A at the circle's foot. A horizontal diameter joins D and F; two horizontal chords join I and L above the centre and G and M below it; diagonals run through the centre joining the points on the circle.

- B (top of the long vertical): pole of the equator
- E (top of the circle)
- K (on the vertical, where the upper chord crosses it)
- I (left end of the upper chord)
- L (right end of the upper chord)
- D (left end of the horizontal diameter)
- F (right end of the horizontal diameter)
- C (small letter, at the centre): pole of the mean ecliptic
- G (left end of the lower chord)
- M (right end of the lower chord)
- H (on the vertical, where the lower chord crosses it)
- A (foot of the circle): point of greatest obliquity

VI. You will find the prosthaphaeresis of the equinoxes in exactly the same way in the scheme already mentioned, supposing AB to be a portion of the ecliptic and C the point of the mean equinox, but F the point from which the anomaly, or argument of the precession, begins to be numbered towards A; for when the anomaly is nil at F, or 180° at D, the mean and true equinoxes will

coincide. But if the anomaly is 90° at A, the prosthaphaeresis of the equinoxes will be greatest, namely the arc AC, to be subtracted from the mean equinox; but if 270° at E, it will be greatest and to be added. By Kepler's invented hypothesis it is indeed 30′ 31″ in the first form, and so great is the semidiameter of the small circle AC. Outside these cases the prosthaphaeresis is sought exactly as was said above of the prosthaphaeresis of the obliquity: by seeking the right or second sines HC or KC from the mean motion of this anomaly, multiplying them by AC, or the greatest prosthaphaeresis, and dividing the total by the whole sine; for from this the prosthaphaeresis will result, to be subtracted in the first semicircle of the anomaly, FAD, and added in the second, DEF.

[Margin: Anomaly of the precession of the equinoxes, and equation.]

VII. *Kepler* and *Lansbergen* differ, moreover, not only in the measures of the semidiameters and in the mean motions, but also in the epochs. For in Kepler's first form the greatest obliquity of the ecliptic, 23° 53′ 16″, with nil prosthaphaeresis of the equinoxes, was in the year 2661 before Christ, and in the years of Christ 6 and 2670. The least obliquity, 23° 28′ 28″, likewise with nil prosthaphaeresis of the equinoxes, was in the years 1329 and 3993 before Christ, at the beginning of the world, and in the year of Christ 1338. And the mean obliquity, 23° 40′ 55″, with the greatest prosthaphaeresis of the equinoxes, 30′ 31″, to be added, was in the year 1995 before Christ and of Christ 672; with it to be subtracted, in the years 663 and 3327 before Christ and of Christ 2004. And the whole period of the anomaly is of 2664 years. *Kepler* notes, moreover, in the Rudolphine Tables, Precept 187, that if there is no change in the obliquity of the ecliptic, or one such that the pole of the moving ecliptic librates on the solstitial colure from A to E, there is no anomaly of the equinoxes; but that if the pole of the ecliptic is carried round the circumference of the circle, say AGEF, an anomaly of the equinoxes arises, and a prosthaphaeresis of them; and that this is to be added in the first semicircle of the anomaly and subtracted in the second. But *Kepler* begins the anomaly from D, towards E; *Lansbergen*, by contrast, from F, towards A.

[Margin: The difference between Kepler and Lansbergen.]

Longomontani Hypotheſis.

Longomontanus's hypothesis.

VIII. *Longomontanus*, in Book 1 of the *Theorics*, ch. 1, from p. 160, and ch. 4, p. 220, rejects the annual motion of the Earth and that of the Earth's libration, while keeping the Earth's daily motion. He assigns the anomaly of the obliquity to a motion of the poles of the terrestrial equator about the axis of the ecliptic. For this, let A be the north pole of the terrestrial ecliptic, from which let two concentric circles be described. Of these, BC is the arctic ecliptic small circle: let it move from C to B, against the order of the signs, and measure the precession of the equinoxes, or the apparent motion of the fixed stars in the order of the signs; and let the arc H be a portion of the mean ecliptic; and

from centre B let the celestial equator be understood as described, of which the arc L is a portion. Now let the true pole of the ecliptic on the surface of the terrestrial globe move about its own axis, in the order of the signs, on the small circle FEDG; and let it be supposed to have changed its apogee with the motion CB. For with the pole of the terrestrial ecliptic set at F, the distance of the ecliptic from the equator will be greatest, by the interval KL, to which FB is equal. But if the pole F ascends through E to D, the obliquity will be least, LI, to which BD corresponds; and at E or G the obliquity will be mean. The greatest prosthaphaeresis of the equinoxes is at E, subtractive, and at G, additive. *The semidiameter of the small circle AF is 10′ 53″, namely in the ratio which the third number in the order of perfect numbers, that is 496, has to the quadrant of the circle on the surface, 5400, both being understood in minutes.* This is evidently why he fixed the difference of the mean obliquity from the greatest and from the least at 10′ 53″. For him the greatest is 23° 53′, in the first year of the world and in 3600; the least 23° 31′, in the year of the world 5400; and the period, both of this and of the precession of the equinoxes, is of 3600 years. So far *Longomontanus*, with his customary obscurity and wrappings of words, which it is neither pleasant nor useful to unfold at greater length, especially in a hypothesis that is not necessary, and without which astronomy proceeds more readily and no less safely.

Diagram. Longomontanus's hypothesis, set in the right part of the right column with the text wrapped round it. A long vertical line runs from L at the top to M at the foot. Near the top it is crossed by a long curved arc just below L, then by two shorter strokes and a third below them. Lower down, two concentric circles are centred on the vertical; a horizontal diameter is drawn across the inner circle.

- L (top of the vertical, above the long arc)
- I (on the vertical, below the long arc)
- H (on the vertical, below the first short stroke)
- K (on the vertical, below the second short stroke)
- B (on the vertical, below the third stroke and at the top of the outer circle)
- D (on the vertical, at the top of the inner circle)
- A (centre of both circles): north pole of the terrestrial ecliptic
- G (left end of the inner circle's horizontal diameter)
- E (right end of the inner circle's horizontal diameter)
- F (on the vertical, at the foot of the inner circle)
- C (left of the outer circle)
- M (foot of the vertical, below the outer circle)

Copernici Hypotheſis.

Copernicus's hypothesis.

IX. *Nicolaus Copernicus*, in Book 1, ch. 11, and Book 3, ch. 3, ascribes the change in the obliquity of the ecliptic and of the equinoctial points, rather

than of the fixed stars, to the motion of the Earth and to a certain flexing of the terrestrial equator and of its poles, by which it is inclined reciprocally to the plane of the celestial ecliptic. For if the annual motion of the axis of the terrestrial equator agreed exactly with the motion of the centre in longitude, no precession of the equinoxes, he says, would appear. But since they differ from one another, and with an unequal difference, the equinoxes must precede the places of the stars with an unequal motion. In the same way, the unequal inclination of the axis of the terrestrial equator to the celestial ecliptic, towards the poles of the ecliptic, alters the apparent obliquity of the ecliptic. Therefore two reciprocal motions must be understood in the poles of the terrestrial equator, resembling suspended librations, quicker in the middle and slowest around the extremes. By one of them the already mentioned poles librate up and down; by the other they deflect crosswise in longitude. The first completes the anomaly of the obliquity in 3434 Egyptian years, 10 days. The second accomplishes the anomaly of the precession of the equinoxes in half that time, that is, in 1717 years, 5 days. So while one restitution of the obliquity takes place, the whole libration of the equinoxes is completed twice, and those two librations, running together, finally make the poles of the Earth describe certain lines resembling a twisted garland, as in the following figure.

[Margin: Copernicus's theory.]

Let the ecliptic ABCD be described from centre E, in which the beginning of Capricorn is A, of Aries B, of Cancer C, and of Libra D. Let the solstitial colure be RAC, and let the celestial and mean equator, described from pole I and substituted here for the terrestrial one, be RBHD, whose moving poles go up and down through the plane of the colure RC. Let the greatest distance of the poles of the ecliptic and the equator, which produces the greatest obliquity, be FE, and the least GE. Let B and D be the points of the mean equinox, which are to be understood as moving with an equal motion in *Præcedentia*, that is, against the order of the signs, slowly beneath the sphere of the fixed stars. Then let there be two motions of the terrestrial poles: one between the limits F and G, the other, twice as fast, crosswise, from the preceding parts towards the following and from the following towards the preceding. For when the Earth's north pole stands under F, the equinoctial will pass through points B and D. But if the pole, on its way from F, the point of greatest obliquity, to I, the point of mean obliquity, does not travel along the straight line FI, but crosswise in the order of the signs, to K, by force of the second motion, then the equinoctial OQP, etc., will be described from pole K, and the true or apparent equinoctial points will be O and P, more easterly than the mean points B and D. Therefore the true equinoxes will occur later than the mean by as much time as the arcs BO and DP of the ecliptic require; the precession of the equinoxes will be diminished; and the apparent motion of the fixed or other stars, computed from the true equinox, will be less than when computed from the mean equinox. Now let the pole of the equator turn from K against the order of the signs towards I: for when it has reached I, the point of mean obliquity, the apparent

equator will return to the mean equator, and the mean and true equinoxes will coincide at points B and D. Now from I, while the pole of the equator makes for G by force of the first libration, let it be carried towards L by force of the second libration, so that at L there is the greatest deflection against the order of the signs. For from pole L an equator will be described that cuts the ecliptic at points more westerly than the mean points B and D; and therefore the true equinoxes will occur sooner than the mean, and the apparent motion of the stars, reckoned in longitude from the true equinox, will be greater than when computed from the mean equinox.

Diagram. Set in the left column, between the words "maxima distantia" and "polorum Eclipticæ". Two large overlapping circles, one standing higher than the other, cross on the left and right; a third, partial arc runs below them from the left, past O and Q, and rises to P on the right. A vertical line runs from the top of the figure to its foot. Around I on that line is a very small twisted band, drawn as two small loops one above the other. Labels read, none unread:

- R (top of the vertical, on the upper circle)
- A (on the vertical, below R, at the top of the lower circle)
- F (on the vertical, above the small loops)
- I (on the vertical, in the upper loop)
- K (left of the upper loop)
- N (right of the upper loop)
- M (left of the lower loop)
- L (right of the lower loop)
- G (on the vertical, below the loops)
- E (on the vertical, below G)
- B (left, where the large circles cross)
- D (right, where the large circles cross)
- P (right, on the partial arc, above D)
- O (far left, at the end of the partial arc)
- Q (on the partial arc, lower right of E)
- H (on the vertical, at the foot of the upper circle)
- C (foot of the vertical, on the lower circle)

Next, let the pole of the equator travel from L in the order of the signs towards G, the point of least obliquity: for the true equinoctial points will again coincide with the mean, and thus one period of the anomaly of the equinoxes will be completed, a whole circle as it were, consisting of the semicircles FKI and ILG. Meanwhile, however, only half of the first libration will have been completed, namely from F, the greatest distance of the poles, to G, the least. The rest will be completed while the period of the other libration is completed from point G to M, from M to I, from I to N, and from N to F; and thus, by force of the two motions already mentioned, the twisted garland FKILGMINF will be described.

X. However, since Copernicus maintains that celestial motions are composed of circular and equal motions, even though they appear unequal to us, he adds

this second diagram in Book 3, ch. 4, in order to demonstrate that this too can happen in the two librations already mentioned. Let the straight line BE be divided into four parts at C, A and D, and from A let two concentric circles, CIDL and BKE, be described. Taking any point F, let the circle HGA be described from it as centre, whose diameter HA will be equal to the diameter CD, and from H let the straight line HG be drawn perpendicular to BE. For if the moving body H in circle HGA is understood to move equally against the order of the signs towards G, with a motion twice as fast as the equal motion of centre F made by circle CID in the order of the signs, the moving body H will be held on the straight line BE, provided that the motion began from point B. For while centre F, starting from C, completes the half-quadrant CF, the moving body that was at B, having completed the quadrant HG in the second circle, will be at G. And when centre F has reached I, the quadrant CI being completed, the same moving body, having completed the semicircle HGA, will be at A. So when that centre has completed the semicircle CID and reached D, the revolution of the second circle, from H through G and A back to H, will be complete. It is therefore clear how a reciprocal and unequal motion in a straight line can be composed from two motions that are circular and equal taken separately but meet one another; and how the anomaly of the obliquity can be produced by four small circles, that is, two at the north pole and two at the south, and the anomaly of the equinoxes by four others, that is, two at the beginning of ♈ and two at the beginning of ♎.

[Margin: Straight motion arising from circular motions.]

Diagram. Set in the right column, with the text running down its left side. A large circle about A, with a vertical diameter BE and a horizontal line from K through A to L and on to the circle. Inside it a smaller circle concentric about A, and a third circle through H, G and A, whose centre F lies on the straight line from H to A. A straight line runs from H to G. Labels read, none unread:

- B (top of the large circle)
- H (upper left, on the large circle)
- G (on the vertical, below B)
- F (on the line HA)
- C (on the vertical, at the top of the inner circle)
- K (left of the large circle)
- I (left, on the inner circle)
- A (centre, just below the horizontal)
- L (right, on the inner circle)
- D (on the vertical, at the foot of the inner circle)
- E (foot of the large circle)

From the data given by Copernicus, Reinhold in the Prutenic Tables, and Magini in his *Theoricae*, Book 1, and in his *Secunda Mobilia*, Canon 18, set the semidiameter AB at 12′ and the diameter BE at 24′, of the units of which the solstitial colure has 21600, and this is the size of the difference between the greatest obliquity of the ecliptic, which for Copernicus is 23° 52′, and the

least, which is 23° 28′. The anomaly of the obliquity is counted in circle BKE, starting from B towards H, and the mean motion of this simple anomaly is, daily, 1″ 2‴ 2⁗ 30⁗′, and, annually, 6′ 17″ 24‴ 9⁗; its period is 3434 Egyptian years and 10 days. Given the mean motion of this anomaly, say arc BH, the angle HAB is given, and its second sine GA. If then one makes the proportion: as the radius or whole sine AB is to the sine AG, so the semidiameter AB of 12′ is to another quantity, the difference in minutes will result. This is to be added to the mean obliquity, which occurs at A, so that the true obliquity of the ecliptic at the given time may be known. But in the semicircle of the anomaly KE, etc., it would have to be subtracted.

[Margin: The commensurations of these small circles, from Copernicus.]

In the circles of the anomaly of the equinoxes, the semidiameter BC, for Copernicus, for the authors already mentioned, and for Clavius in ch. 6 of the *Calendar*, is 35′ 41″ 15‴; or, if you proceed less scrupulously, with Gassendi in the *Institutio Astronomica*, Book 2, ch. 8, and with Deusingius [Anton Deusing] in the *Cosmographia*, it is 35′, and AB is 1° 11′ 22″ 30‴, or 1° 10′. The anomaly is counted in circle BKE, and its mean motion is twice as great as the motion of the anomaly of the obliquity. It is therefore called the doubled anomaly; its daily motion is 2″ 4‴ 5⁗, its annual motion 12′ 34″ 48‴ 18⁗, and it is completed in 1717 Egyptian years and 5 days. The prosthaphaeresis of the equinoxes is found proportionally, as the prosthaphaeresis of the obliquity is, through the sines, from the given mean motion of the anomaly; and its greatest value is AB, namely 1° 11′ 22″ 30‴.

Finally, the mean motion of the mean equinoctial points, namely of point A, against the order of the signs (or, as others would say, the motion of the fixed stars), is for Copernicus 8‴ 15⁗ daily and 50″ 12‴ 5⁗ annually, with a period of 25816 years. But Gassendi, in Book 3 of the *Institutio Astronomica*, ch. 8, judging that these matters, being uncertain, are to be treated less scrupulously, gives the period of the obliquity as 3400 years and that of the anomaly of the equinoxes as 1700 years.

[Margin: In favour of Copernicus: the votes of Rheticus, Mästlin, Gilbert, Galileo, Baranzano, and formerly of Kepler.]

XI. Copernicus's theory has further been followed by Georg Joachim Rheticus in the *Narratio prima* on the books of Copernicus; by Michael Mästlin in his notes to the same *Narratio*, which are found in Kepler's *Prodromus*, or *Mysterium Cosmographicum*; by William Gilbert in *De Magnete*, Book 6, chs. 8 and 9; by Redemptus Baranzano in the *Uranoscopia*, part 2, question 3; by Galileo in Dialogue 3 of the *De Systemate Cosmico*, p. 281; by Hérigone in vol. 5, p. 577; and, formerly, by Kepler in the *Epitome of Copernican Astronomy*, Book 3, from p. 243, for later, in the Rudolphine Tables, he abandoned both anomalies. Of these, Rheticus deduces from Copernicus's hypothesis that in Ptolemy's time the true equinox was after the mean by 47′ of the ecliptic, and in al-Battānī's time before the mean by 22′. Mästlin sets out this difference in the following diagram. In it the small circle of the anomaly of the equinoxes has the

semidiameter CD, of 1° 11′ 22″ 30‴, from the Prutenic Tables; AB is a portion of the ecliptic; the centre C is the point of the mean equinox, at which the mean equator cuts the ecliptic; and A is the first star of Aries, from which point C perpetually recedes against the order of the signs towards B, with an equal motion as great as the motion of the fixed stars in the order of the signs among other authors. The segments or arcs of the remaining circles are portions of the true equator, shifted by the motion of the second libration of the Earth's axis. So at F was the true equinox in Hipparchus's time, and CF was the subtractive prosthaphaeresis of 21′. G was the point of the true equinox in Ptolemy's time, and GC the additive prosthaphaeresis of 47′. And H was the point of the true equinox in al-Battānī's time, and CH the subtractive prosthaphaeresis of 22′, in units of which CD, or the greatest prosthaphaeresis, is 71′ 22″ 30‴.

Diagram. Set in the left column, with the text running down its left side. A small circle crossed by a slightly curved line that runs from a star at the far left, through the circle, to the far right; four parallel oblique lines cross the circle from upper left to lower right, extending beyond it at both ends. Labels read, none unread:

- A (far left, above the star at the end of the line)
- E (below the line, just outside the left of the circle)
- K (upper left, outside the circle)
- G (above the line, in the left part of the circle)
- C (below the line, near the centre of the circle)
- F (above the line, right of C)
- H (above the line, right of F)
- D (below the line, at the right of the circle)
- B (far right, at the end of the line)
- M (below the circle, lower right)

Io. Antonij Magini Hypotheſis : quæ eſt ferè Verneri, & Gaſſendi, & Deuſingij.

The hypothesis of Giovanni Antonio Magini: which is almost that of Werner, Gassendi and Deusingius.

[Margin: Magini's hypothesis, mixed from the Copernican and the Wernerian.]

XII. Magini, in his *Theoricae*, Book 1, and in his *Second Mobile* from Canon 18, adopts Copernicus's hypothesis as regards the numbers and the figures, using the figures discussed in nos. 9 and 10. But he transfers it from the Copernican Earth to the heavens, and follows the number and order of the spheres handed down by Johannes Werner. For Werner, as Erasmus Oswald Schreckenfuchs explains in his work on Peuerbach's *Theorica* of the eighth sphere, posits eleven spheres: the highest for the motion of the primum mobile; the tenth for the first libration, or trepidation, towards the sides of the world, by which he maintains the anomaly of the obliquity of the ecliptic; the ninth for the second libration, in

longitude, or for the anomaly of the equinoxes; and the eighth for the equal and always progressive motion of the fixed stars. He would have the beginnings of Cancer and Capricorn of the 11th sphere be the poles around which the beginnings of Cancer and Capricorn of the 10th sphere describe the small circles of the anomaly of the obliquity; and the beginnings of Aries and Libra of the 10th sphere be the poles around which the beginnings of Aries and Libra of the 9th sphere describe the small circles of the anomaly of the equinoxes. Following this order, therefore, Magini attributes to the heavens whatever Copernicus had attributed to the librations of the Earth, and he uses the figures already set out by us in nos. 9 and 10, and the period and quantity of motion in each anomaly, exactly as the Prutenic Tables and Copernicus's hypotheses require. So there is no need to repeat what has been sufficiently set out in those numbers. Gassendi, however, in Book 2 of the *Institutio Astronomica*, gives the same number of spheres and nearly the same numbers in the motions of each anomaly; but he concludes that these things are fictitious and are not to be treated more scrupulously.

[Margin: Gassendi's judgement on this hypothesis.]

Arzahelis, Thebitij, Alphonſinorum, & Purbachij Theorica.

The theory of al-Zarqālī, Thābit ibn Qurra, the Alphonsines and Peuerbach.

[Margin: Authors who have written on the motions of the eighth sphere.]

XIII. On the theory of the authors already mentioned concerning the motions of the eighth sphere, and especially the anomalies of the equinoxes, there survive, first of all, the treatises on the motion of the eighth sphere by Thābit himself, then by Campanus of Novara, Albert Pigge, Marcus Beneventanus and Agostino Ricci; several questions by Pierre d'Ailly; Regiomontanus's short work against Thābit, and Problem 63 of the *Primum Mobile*; and some few things in Maurolico, Dialogue 3 of the *Cosmographia*, from p. 88, and in Boulliau, Book 5, ch. 1. There is also the theory of the motion of the eighth sphere by Georg Peuerbach, who illustrated the Alphonsine hypotheses. It has been explained, in notes, commentaries or questions, by Erasmus Reinhold, Erasmus Oswald Schreckenfuchs, Capuano, Nonius and Christian Wurstisen, where the hypotheses of Thābit and al-Zarqālī are also touched on, and by Io. Esler [?] in the *Speculum Astrologicum*, where Thābit's theory too is indicated. From these sources, then, take the following in summary.

[Margin: Al-Zarqālī's hypothesis.]

Al-Zarqālī the Moor, as also Yitzchak Yisraeli in his treatise *On the Foundation of the World*, said that the beginnings of both Aries were conjoined in the year of salvation 560; that from there the beginning of the movable Aries advanced towards the east; that the fixed stars do not advance beyond 10°, and complete these in 750 years, taking 75 years for 1°; that they then return through another 10°, and through as many go back from their original point towards the west;

and that thus in four times 750, that is, 3000, years the period of this trepidation is completed.

[Margin: Thābit's hypothesis.]

Then came Thābit ibn Qurra, who allowed that the fixed stars recede back and forth 22° or 21½°, and no further, but go back through as many degrees; and that the points of the true equinox recede from the mean by 4° 18′ 43″, or, in round figures, 4° 19′, which is the size of the semidiameter of the small circle described by the beginning of the movable Aries around the beginning of the mean Aries, the whole diameter being 8° 37′ 26″, or, in round figures, 9°. Finally, he held that this trepidation is completed in 4320 years, according to Capuano, or in 4056 years and 331 days, according to Campanus. As to whether Thābit admitted a variable obliquity of the ecliptic, Regiomontanus affirms it, on the ground that the beginning of the starry Aries revolves and varies the inclinations of the movable ecliptic, and so does Ricci, above, p. 40; d'Ailly, question 9 on the *Sphere*, and Maurolico, in the passage cited, deny it. So it is doubtful whether he posited 9 spheres, as most relate of him, or 10, as Clavius says on p. 44 of the *Sphere*.

[Margin: The Alphonsines' hypothesis.]

XIV. The Alphonsines, however, when in the year of salvation 1250 they noticed that the fixed stars had progressed beyond 22° of longitude, rejected the hypothesis of al-Zarqālī and Thābit and posited 10 spheres. The highest of these was the primum mobile. The ninth accomplished the mean motion of the fixed stars and of the apogees, with an always progressive motion, in a period of 49000 years, that is, a thousand Jewish jubilees. And the eighth, filled with the fixed stars, accomplished the motion of trepidation in longitude in 7000 years, namely a thousand sabbatical years, in accordance with what was said in ch. 28, no. 7. So that what we have said and shall say may be more easily understood by means of a diagram, let A be the beginning of Aries fixed in the highest sphere of the primum mobile, AC a portion of the fixed ecliptic, and B the beginning of Aries of the ninth sphere, which in the first year of Christ was conjoined with A; but in Alfonso's time, that is, in the year 1250, according to the measure of the mean motion of the fixed stars and apogees, it was distant from A by the arc AB, of 9° 18′, and in the year 1508, by 11° 5′. Now in the eighth sphere, beneath point B of the ninth, let a centre be understood, from which is described the small circle KLMN of the anomaly of the equinoxes, of the fixed stars and of the apogees, and let this circle be completed in

7000 years, in which the whole period of the trepidation is accomplished. Let its semidiameter BL be not 4° 18′ 43″, as Thābit would have it, but 9°, as the Alphonsines and Peuerbach have it. This is the greatest equation, to be added to or subtracted from the mean motion of the fixed stars and apogees, so that their true motion may be had, which is computed from A, the beginning of Aries of the primum mobile, although the motion of access and recess is computed from centre B of the eighth sphere, which lies beneath the beginning of Aries of the 9th sphere. Now from D, the pole of the fixed ecliptic, let the arc DBK of the

colure of the mean equinox be drawn, and let K be the most northerly point of the small circle, from which the anomaly begins towards L. For the mean and true motions coincide when the beginning of Aries, at which the true equinox occurs, is at M or at K, as it was, according to the Alphonsines, in the year 15 of Christ, with 137 days completed. But in the year 1508 the beginning of Aries was at H, and the arc KH was 76° 46′, to which corresponds the arc IB, 8° 45½′. This, added to the arc BA, which we said was 11° 5′ in the year 1508, makes the arc IA 19° 50′ 30″, namely the distance of the first star of the starry Aries from A, the beginning of Aries of the primum mobile.

[Margin: The Alphonsines' deviation.]

This, however, is an intolerable error, since in that year it was found by observers to be distant by more than 26°. But the error arose from that Jewish fiction, and from the too-slow mean motion of the fixed stars invented on the basis of it. So if the movable beginning of Aries is at H or P, the arc HP of the colure being drawn, the equation will be IB, and additive in the first semicircle of the anomaly, KLM; and LB will be the greatest equation. But if the beginning is at E or at G, the colure DE being drawn, the equation will be BF, subtractive in the later semicircle MNK, and the greatest will be BN; and likewise for the others. We can treat these small arcs enclosed within the small circle as straight lines. So, given the arc HK, for example, from the motion of the anomaly, its right sine will be given; let this be multiplied by the given semidiameter LB, and the total divided by the whole sine: the arc IB will result, and likewise for the other equations of the equinoxes. More on these in Reinhold, p. 243, Nonius, p. 300, and Wurstisen, 424, on Peuerbach's *Theorica*.

[Margin: The disagreement of Pigge and Beneventanus.]

I say nothing of the now obsolete dispute between Albert Pigge, who in his treatise on the eighth sphere maintains that the celestial motions are computed by the Alphonsines from A, the beginning of Aries of the primum mobile (Reinhold, p. 240, seems to favour this; Io. Esler [?] maintains the same in the *Speculum Astrologicum*; and I think it the truer view), and Marcus Beneventanus, who says that they are computed from the movable beginning of Aries with its true motion, and that the Alphonsine hypotheses therefore contradict themselves. On this dispute Nonius, in Book 2 of *De Observatione*, ch. 4, and Wurstisen, above, p. 407, still remain in doubt. For I am glad to close this chapter with the words of Gassendi in Book 2 of the *Institutio Astronomica*, ch. 8: *The matter seems too fictitious for us to pursue it more scrupulously.*

Diagram. Set in the left column, with the text running down its left side. A small circle crossed by a slightly curved line from C at the far left to A at the far right. From D at the foot of the figure three long lines rise, narrowing to a point at D, and cross the circle to its upper edge. Labels read:

- K (top of the circle)
- H (upper left, on the circle)
- E (upper right, on the circle)

- L (left, on the horizontal line)
- I (on the horizontal line, inside the circle, left of B)
- B (on the horizontal line, at the centre)
- F (on the horizontal line, right of B)
- N (right, on the horizontal line)
- C (far left, at the end of the line)
- A (far right, at the end of the line)
- P (lower left, on the circle)
- a W-shaped letter [recte: M] (foot of the circle; the text names M at this point)
- G (lower right, on the circle)
- D (foot of the figure, where the lines meet)

SCHOLION.

Scholium.

From the last table of ch. 28 you have learned that when the quantity of the year is least, or greatest, there is no prosthaphaeresis of the equinoxes, but the mean and true coincide; but when the quantity of the year is mean, their prosthaphaeresis is greatest, and it is to be added to the true vernal equinox and subtracted from the autumnal to obtain the mean equinox, but subtracted from the mean vernal equinox and added to the autumnal to obtain the true equinox. This greatest prosthaphaeresis is as you see in the following small table. But take care not to confuse this equation with that of the tropical years; and see the scholia of chapter 29.

	Greatest prosthaphaeresis of the equinoxes, in degrees	Greatest prosthaphaeresis of the equinoxes, in days and hours
Copernicus, Book 3, ch. 8, and Gassendi	1° 10′ 0″	$1^{d}\ 4^{h}\ 25^{m}$
Reinhold in the Prutenic Tables, precept 10	1° 11′ 22½″	$1^{d}\ 4^{h}\ 58^{m}$
Longomontanus, Book 1 of the *Theorica*, ch. 4	0° 27′ 5″	$0^{d}\ 10^{h}\ 58^{m}$
Lansbergen in his Tables, p. 12	1° 14′ 0″	$1^{d}\ 6^{h}\ 2^{m}$
Another prosthaphaeresis But from Longomontanus, Book 1 of the *Theorica*, ch. 5	**In the vernal equinox** (days, hours, ′)	**In the autumnal equinox** (days, hours, ′)
In the age of Hipparchus	$1^{d}\ 17^{h}\ 50^{m}$	$2^{d}\ 0^{h}\ 50^{m}$
In the age of Ptolemy	$1^{d}\ 14^{h}\ 45^{m}$	$2^{d}\ 6^{h}\ 45^{m}$
In our own age	$2^{d}\ 4^{h}\ 30^{m}$	$1^{d}\ 22^{h}\ 50^{m}$

CAPVT XXX.

Chapter 30.

De Anni Aequinoctialis ſeu Tropici Inæqualitate, aut Aequalitate.

On the inequality or equality of the equinoctial or tropical year.

[Margin: Those who assert the inequality of the year.]

I. That the temporal year, which we said is called equinoctial and tropical, is unequal, and that its quantity changes by a certain anomaly, has been affirmed first of all, along with al-Zarqālī, by Thābit in his treatise on the motion of the eighth sphere, and by his follower Campanus of Novara; indeed, before these, by the Babylonians long ago, as reported in Copernicus, who for this reason preferred the sidereal year to the tropical as less unequal. It has been affirmed by Pierre d'Ailly in q. 9 on the *Sphere*; by Yitzchak Yisraeli in the book *On the Foundation of the World*, who adds that the year was the shortest of all in the year of salvation 1310; by Henricus Baten Machliniensis [Hendrik Bate of Mechelen]; by Nikolaus von Kues in his treatise on the reform of the calendar; by Georg Peuerbach in the *Theorica* of the eighth sphere, and there by his commentators Capuano, Oswald Schreckenfuchs, Werner, Reinhold, Nonius and Wurstisen; and again by Nonius in Book 2 of *De Observatione*, ch. 4; by Albert Pigge and Marcus Beneventanus in their treatises on the motion of the eighth sphere; by Fracastoro in the *Homocentrica*, sect. 2, from ch. 9 to 17, and sect. 3, ch. 6; by Maurolico, Dialogue 3 of the *Cosmographia*, p. 88; by Giovanni Antonio Delfino in the book on the celestial globe, p. 76; by Copernicus, Book 3, from ch. 1 to 13; by Reinhold, above, and in the Prutenic Tables, precept 21; by Rheticus in the *Narratio prima* on the books of Copernicus, and there by Mästlin; likewise by Peter Apian in the *Astronomicum Caesareum*, proposition 2; by William Gilbert, *De Magnete*, Book 6, ch. 10; by Clavius in the *Calendar*, and in his *Apologia* of it, chs. 3 and 6, and in the *Sphere*, pp. 55 and 62; by Moletti in the *Gregorian Calendar*, canon 7; by Barozzi in the *Cosmographia*, pp. 7, 250, 259; by Magini in the *Theoricae*, Book 1, ch. 4, and in the tables of the *Secunda Mobilia*, from Canon 18; by Origanus in vol. 1 of the *Ephemerides*, ch. 2, precept 4; by Scaliger in the *Diatriba de Æquinoctiis*; by Tycho in vol. 1 of the *Progymnasmata*, p. 37; by Longomontanus, Book 1 of the *Theorica*, chs. 4 and 5; by Lansbergen in the *Thesaurus Observationum*, class 4, p. 54, and in his Tables, precept 4; and by Pierre Hérigone in vol. 5, in the *Theories of the Planets*, Book 2, ch. 4.

[Margin: Arguments for the inequality of the year.]

II. There were chiefly two arguments for this inequality. The first is the unequal apparent motion in the fixed stars. Since this inequality does not seem attributable to the stars themselves, it seems rather to be ascribed to an unequal motion of the equinoctial and solstitial points, now against the order of the signs, now in it. And if those points move back and forth unequally, the year, being a revolution to these points, must be sometimes longer, sometimes shorter. The second argument is the very quantity of the tropical year, derived by comparing different equinoxes and solstices with one another, as may be

seen in the table we gave at the end of ch. 15. For from Hipparchus to Ptolemy the year was $365^d\ 5^h\ 55^m\ 12^s$, but from Ptolemy to al-Battānī $365^d\ 5^h\ 46^m\ 24^s$. By the Alphonsines, moreover, it was put at about $365^d\ 5^h\ 49^m\ 16^s$. And Tycho, in vol. 1 of the *Progymnasmata*, p. 37, has it as follows.

Anni Aequinoctialis diſpares Quantitates.

The unequal quantities of the equinoctial year.

Interval	Length of the year
From Hipparchus to Ptolemy	$365^d\ 5^h\ 55^m\ 12^s$
From Ptolemy to al-Battānī	$365^d\ 5^h\ 46^m\ 20^s$
From Ptolemy to our observations	$365^d\ 5^h\ 47^m\ 52^s$
From al-Battānī to our observations	$365^d\ 5^h\ 49^m\ 29^s$

Nor does this seem to happen through deception or by chance. For at the very time when the longest year was observed, the greatest obliquity of the ecliptic, the greatest eccentricity of the Sun and the slowest motion of the fixed stars also appeared; and at the time when the year was shortest, the fastest motion of the fixed stars appeared as well. Who, then, would not concede that these things arise from some true and connected causes? For these reasons, therefore, the hypothesis of the anomaly of the precession of the equinoxes was introduced, together with its prosthaphaeresis, on which there is more than enough in the preceding chapter and at the end of ch. 28. Reread the Copernican table there, and in the table of ch. 15 the greatest, mean and least quantity of the year according to Copernicus, Reinhold, Clavius, Magini, Origanus and Longomontanus.

[Margin: Causes of the inequality of the year.]

III. Four causes of the inequality of the year are adduced by Copernicus, Book 3, ch. 13; by Rheticus in the *Narratio prima*, and there by Mästlin; by Reinhold in the Prutenic Tables, precept 21; by Moletti, canon 7 of the *Gregorian Calendar*; and by Tycho, vol. 1 of the *Progymnasmata*, p. 38. The first and chief is the unequal precession of the equinoctial points, that is, the unequal approach of the true equinox to the mean and its recession from it, on which see chs. 27 and 28. The second is the annual inequality of the Sun's motion, because of which it lingers longer in the northern semicircle of the ecliptic than in the southern; and longer formerly in the first quadrant of the ecliptic, now in the second, because of the motion of the mean apogee; on this see ch. 16. The third is the inequality of motion of the solar apogee itself, as seems to be gathered from observations; on this see ch. 25. According to the Alphonsines this inequality arises from the unequal motion of the fixed stars, since in their account the apogees of all the planets, the Moon excepted, move with the same motion as the fixed stars. The fourth is the unequal variation of the Sun's eccentricity, because of which the Sun's equations vary, and on which there is enough in ch. 26.

[Margin: Those who assert the equality of the year.]

IV. Notwithstanding all this, the equality of the tropical year was in the end retained by Hipparchus, in Ptolemy, Book 3 of the *Almagest*, ch. 2; by Ptolemy himself, in the same place; by al-Battānī, ch. 52; by Alfonso, where he changed his opinion, as Ricci reports; and by the Alphonsines, though with little consistency, as Reinhold noted from d'Ailly in the *Theoricae*, p. 240; by Agostino Ricci in the treatise on the motion of the eighth sphere, pp. 34 and 36; by Ismaël Boulliau, Book 2 of the *Astronomia Philolaica*, ch. 3, and in him the Persians; by Wendelen in the *Idea of the Atlantic Tables*; and by Antonín Maria Šírek in his *Radius Sidereomysticus*, where he treats the hypothesis of the Sun. This equality is also strongly favoured in the end by Tycho, vol. 1 of the *Progymnasmata*, p. 113, and by Kepler in the *Epitome of Astronomy*, p. 921, and in the Rudolphine Tables, precepts 182 and 189, as we shall soon see.

[Margin: The opinion of Hipparchus.]

For although Ptolemy, in Book 3, ch. 2, said: "But since Hipparchus seems to be disturbed by this restitution of the year, we shall try to show briefly that no firm reason can be gathered from it that ought to disturb us, and on account of which the annual periods should be judged unequal," yet in the same chapter he adds: "Hipparchus, in the book on the change of the solstitial and equinoctial points, after setting out the winter and summer solstices, which he believed had been observed continually and diligently, admits that the difference in them is not so great that an inequality should for that reason be posited in the annual period."

[Margin: The opinion of Ptolemy.]

Ptolemy himself declares his own opinion in the same place in these words: "Nor do we find that the years differ by a quantity that needs attention, but only by about as much as one can err through the construction and placement of instruments." And a little later, without qualification: "From all these things, therefore, and from what we have detected in successive equinoxes, we have not yet found the magnitude of the annual period to be unequal, if it is referred to one and the same point, and not now to the equinoctial or solstitial points, now to the wandering stars." Finally he says: "Since the same quantity is recognized in many years as in few."

[Margin: Tycho's later opinion.]

Tycho, on p. 113, at last saw that the quantity of the year which agrees with his own century and the nearest ones could, with no difference worth attention, fit all centuries, saying: "However, I think it can be gathered both from the findings of Hipparchus and from other very ancient ones that the very quantity of the equinoctial year, considered universally, comes as close as possible to 49^{m} beyond the ascertained days and hours, only a very few small fractions being wanting on either side, which are of scarcely any importance. On this matter I have decided to speak more accurately elsewhere and to set out my opinion more fully, rejecting meanwhile that excessive inequality of the solar year which the moderns, because of the less accurate observations of their

predecessors, think underlies the appearances." And he adds at once that the Copernican calculation, which rests on the prosthaphaeresis of the equinoxes and on the inequality of the year, goes further astray than the Alphonsine.

[Margin: The opinion of Kepler.]

Kepler, for his part, does say in the Rudolphine Tables, precept 188: "By the most certain evidence of eclipse observations I prove that the Sun's approach even to the fixed stars themselves is unequal in the smallest quantities; I shall publish a separate book on this matter, God willing." And from the *Epitome of Astronomy* he urges a motion of the Sun that fluctuates from physical causes; and from Origanus's *Ephemerides*, vol. 1, p. 99, the instability and inconstancy of the celestial motions. And in the Rudolphine precept 189 he says: "Two causes vary the mean quantity of tropical years. The first is certain and lies in the thing itself: the different beginnings of the tropical years through the year, or, as the astrologers say, the different roots of the revolutions. For the shortest tropical year is the one that begins from the Sun's apogee, the longest the one that begins from the perigee, and a middling one that which begins from the mean longitudes, which today are in the 6th degree of Aries and Libra. The other cause, the prosthaphaeresis of the equinoxes, is both uncertain and imperceptible in a short number of years." But of this second cause he says in precept 191: "To such a degree does this prosthaphaeresis of the equinoxes, of uncertain credit, once admitted into the calculation, turn all astronomy upside down."

For as to the variation of the eccentricity and of the solar equations, there is no doubt that Kepler rejects it, and on this head upholds the equality of the year. For he speaks in the *Commentaries on Mars*, ch. 69, of "the analogy of the earlier observations of Hipparchus and the later ones of al-Battānī and of Brahe, all of which conspire in one equality." Not much later he adds: "Nor is there cause just enough for us to say that the proportion of the orbs is different today from what it once was. For an assertion of the greatest moment needs the firmest testimony, which we lack. For those observations cannot be so accurate," etc. Thus, if the different beginnings of the tropical years did not stand in the way, no cause of the inequality of years would remain for Kepler.

Boulliau, moreover, reports from Kepler's *Epitome of Copernican Astronomy*, p. 927, that the equality of the year has been apparent to all observers from Hipparchus on. Boulliau himself, in Book 2, ch. 3, mocks "the ridiculous fiction of the apogees, the fables of the trepidation of the heavens, and the Jewish Jubilee of the stars returning in 49000 years"; and of an unequal precession of the equinoxes or a non-uniform motion of the fixed stars he says: "But these things are not so. The celestial motions are not subject to so many windings and gyrations of little circles, and their equality does not admit so many anomalies." He goes on to confirm the equality of the year from eclipses, and from the Persians, who in Georgios Chrysokokkes, chs. 8 and 15, recognized no inequality in the year or in the motion of the fixed stars.

Noſtra ſententia de Anni Aequalitate.

Our opinion on the equality of the year.

[Margin: The author's opinion.]

V. Indeed, after weighing on both sides not so much authorities as reasons, I at last arrive at this position: although I do not consider the inequality of tropical years wholly improbable, I nevertheless judge by far more probable their perpetual, as far as the senses can tell, or physical equality; and this chiefly by the following arguments.

[Margin: For the physical equality of the year. Arg. 1.]

First: the same quantity of the year, very nearly, that Tycho obtained from his own observations and those of Walther one single century before him, I obtained from my observations compared with those of Hipparchus and corrected, as is now clear from ch. 15, nos. 7 and 8; and the Persian mathematicians found very nearly the same, as is evident from the table in that same chapter. It is $365^{d}\ 5^{h}\ 48^{m}\ 40^{s}$. Among quantities of the year not invented but observed after Ptolemy, there is none that falls short of this quantity by 4^{m} whole, or exceeds it by 1^{m} whole. For the Hipparchan, the Ptolemaic and the Jewish quantities, which exceed it by about 5^{m} or 6^{m}, were not derived from pure observations of the equinoxes but from lunar cycles, as though these were commensurable with the Sun's course; and we showed in that same ch. 15 that this method is less accurate.

[Margin: Ptolemy's candour.]

Nor did Ptolemy cling to that quantity as the most exact; rather, he left it to posterity to correct from a longer interval, when he said in Book 3, ch. 2: "That the annual period, compared with the solstices or equinoxes, is less than 365 days and a quarter of a day is clear to us, also from what Hipparchus demonstrated. But by how much it is less we cannot detect with the utmost exactness, since the addition of the quarter seems to remain unchanged over several years, on account of its very small difference. Therefore it cannot be found except by the calculation of a longer time," etc.; "this restitution, however, will be grasped the more exactly, the longer and greater the time that has elapsed between the observations." So far, moreover, no equinox is extant older than those of Hipparchus or more recent than ours; and the interval from which we derived the quantity of the year is 1804 or 1800 years. The Ptolemaic quantity, which exceeds ours by about 6^{m}, is therefore no obstacle to us. And a difference of 3^{m}, or at most 4^{m}, which is found in some few years observed by others, is not so great that it cannot probably be ascribed either to the deception of observations or to parallax, if not to refraction, either omitted or falsely assumed. So great an affinity, therefore, and so nearly no difference among the observed years, persuades me that their equality is far more likely than inequality.

[Margin: Arg. 2.]

VI. Second: keeping the quantity of the year at $365^{d}\ 5^{h}\ 48^{m}\ 40^{s}$ and going back through the past centuries as far as Hipparchus, I find the equinoxes

observed by the more skilled astronomers without a difference in time that for the most part exceeds 1 hour, and very rarely reaches 2, let alone 3 hours. Who skilled in astronomical observations would not readily concede that this difference arises rather from the imperfection of the observations or the uncertainty of the parallax than from a true non-uniformity of the celestial year? On the contrary, there is no hypothesis of an unequal year among its asserters that satisfies all the observed equinoxes better than ours. Since, then, we have no observations of equinoxes beyond about 1800 years, and our quantity and Tycho's satisfies these as far as a prudent astronomer can require, why should we deny that it can also satisfy the future 1800 years, if the world lasts so long? But the force of this argument will appear more clearly when, God granting, in vol. 3 of the *Almagest*, we weigh the observations of the equinoxes and compare the table of revolutions and of past equinoxes with them.

[Margin: Arg. 3.]

VII. Third: that saying of Ptolemy, Book 3, ch. 2, is well known: "We think it altogether fitting to demonstrate the appearances, as far as possible, by the simplest hypotheses, provided that nothing worth attention conflicts through observations with this proposed method." And Kepler's saying in the *Commentaries on Mars*, ch. 69, must be urged at this point: "An assertion of the greatest moment needs the firmest testimony." But we neither have the firmest testimony for asserting the inequality of the year, nor is the difference of a few minutes distributed over many centuries such as ought to stand in the way of the simplicity of the hypothesis about the quantity of the year.

[Margin: Four invalid causes of the inequality of the year.]

VIII. Fourth: of the four causes of the inequality of the year listed by Copernicus and the rest in no. 3, none in fact has the force for this that the opponents suppose. Not the first and chief, because it is more probable that the equinoctial points, or rather the fixed stars, move equally, as we said in ch. 28, no. 11, Assertion 3; and this will be said again in the book on the fixed stars, and indeed more fully, with the observations compared and corrected, in vol. 3 of the *New Almagest*. The second by itself does not suffice to make one year, compared with another year, unequal, as Copernicus most expressly admits in Book 3, ch. 13, where, speaking of it, he says: "Of all these only the second was known to Ptolemy, and it alone could not have produced the inequality of the year [inæqualitatem annalem], but entangled with the others it does so the more." Nor is the inequality of the parts of the year a sufficient argument for inferring an inequality of one whole year with another whole year. The third is nothing, and rests on no conjectures, or certainly on very weak ones: namely either the variation of the eccentricity, on which presently, or an unequal motion of the fixed stars, which al-Farghānī and the Alphonsines thought to be the same as the motion of the apogee of the Sun and of the other planets, the Moon excepted. Yet the motion of the solar apogee is faster, from what was said in ch. 25, no. 5, and is at least 1′ each year, whereas that of the fixed stars is only 50″, from what was said in ch. 27; nor, if it were the same as the motion of the fixed

stars, would it for all that be unequal. The fourth, namely the variation of the eccentricity, has already been sufficiently disproved in ch. 26, from no. 3 on.

[Margin: A 5th cause, true but imperceptible, of inequality.]

IX. The fifth cause, which Kepler devises in the Rudolphine Tables, precept 189, namely the different beginnings of the tropical years through the year, cannot make the year perceptibly unequal except after many thousands of years, which perhaps the world will not reach. In reality, however, this comes down to the second cause, namely the annual inequality arising from the Sun's varying distance from the apogee; and Copernicus himself conceded in Book 3, ch. 13, that this by itself does not bring in an inequality of the year: understand, an inequality that is perceptible within a few thousand years.

[Margin: Copernicus elucidated.]

But since we have come upon this deep place in astronomy, we must dig this truth out from further down, and call out into the open what Copernicus and Kepler indicated obscurely in the passages just adduced. So when Copernicus had said: "Therefore the reckoning of annual equality is neither simple nor easy to know," he added a little later: "No one will wholly avoid error unless the Sun, on account of the motion of the Earth, then receives either no prosthaphaeresis or one similar and equal at both ends. If this does not happen, and there is some difference according to their inequality, an equal circuit will certainly not seem to have occurred in equal times. But if at both ends the whole variation has been subtracted or duly applied, the work will be perfect." It is as if he were saying: if the magnitude of the tropical year is gathered from the interval between two remote equinoxes, and all error is to be wholly avoided, both equinoxes must occur either with the Sun at apogee, or with the Sun at perigee, or at an equal distance from the apogee but in the same semicircle of the anomaly, so that the prosthaphaeresis is not only equal but also of the same kind, that is, subtractive in both places or additive in both. Otherwise, if one equinox occurs at one point of the anomaly and the other at another, the quantity of the year so gathered will not be perfectly exact; and since the Sun's apogee continually changes place, and the equinoxes occur at ever different points of the anomaly, the quantity of the year gathered from the equinoxes must incur some very slight inequality. Yet since, from what was said at the end of ch. 25, the motion of the apogee does not complete its circle except in 21245 years, while the world has not yet reached the age of 6000 years and perhaps will not last as long again, we are needlessly anxious to seek the quantity of the year with such subtlety, especially since no observed equinoxes older than those of Hipparchus survive.

X. Let us, however, for form's sake, imagine the world made at the vernal equinox with the Sun at apogee, and that after about 21000 years an equinox again occurs with the Sun at apogee. And again, let us imagine the world made at the vernal equinox, but with the Sun at perigee, and after 21000 years the other equinox occurring with the Sun's perigee revolved back to the beginning of Aries. For if the quantity of the year were gathered, by

the method given in ch. 15, no. 6, from the apogee equinoxes, it would be equal to the quantity derived from the perigee equinoxes: the Sun's revolutions would find the apogee or the perigee at the same fixed point of the sky, and the prosthaphaereses and variations between those paired mean and true equinoxes would not differ in any way. But if, before the period of the apogee is complete, an equinoctial year is begun from a vernal equinox occurring at the apogee itself, the following equinox will occur at the beginning of Aries with the Sun's apogee now advanced beyond the beginning of Aries; but the Sun will return to the beginning of Aries, where the slowness of the apparent motion compared with that of the previous day is greatest. But if the year is begun from the perigee, the Sun will return to the same beginning of the ecliptic, in a position where the apparent motion is fastest. But the difference between these revolutions in a few years is nil or imperceptible, as Pietro Pitati also admits in his *Monthly and Paschal Canons*, ch. 5, where he adds that the whole period of this difference is completed in 24000 years, in which the true quantity of the year is restored, or, according to some, in many fewer years, but at least 1800, as many as there are from Hipparchus to us. But then the quantity of the year is not to be derived from a small interval of years; and from an interval of 1800 years, the difference of the year derived from the mean equinoxes does not differ from that derived from the true ones by more than 6^s of time, as we said in ch. 15, Scholium 2.

Let it stand, then, that the tropical year is always physically equal; and that its quantity, derived from a long interval of years, say 1800 or 2000, of which kind ours very nearly is, can serve the past ages of the world, and probably the future ones, without perceptible error, the subtler mathematical inequality that could be gathered from the different beginnings of the years being set aside among imperceptible things.

[Margin: To find the quantity of the year, if it varies.]

XI. If, however, the inequality of the tropical year pleases anyone, and he wants a way of gathering its quantity for a given time, let him consult Reinhold in the Prutenic Tables, precept 21. Or if the inequality admitted only by Kepler pleases him, let him go to Kepler in the Rudolphine Tables, precept 189; on these see us in the precepts of the tables. But for the greatest, least and mean quantity of the year, and for its period and epochs, consult the table taken from Clavius and placed by us at the end of ch. 28.

SCHOLIA.

Scholia.

[Margin: The greatest and least quantity of the year for Copernicus.]

I. The tropical year, says Clavius in ch. 6 of the *Calendar*, is greatest at the beginning of the anomaly and least at the end of the semicircle of the anomaly, even though the prosthaphaeresis of the equinoxes is then nil; because the annual precession of the equinoxes, which must be subtracted from the sidereal

year to obtain the tropical year, is slowest at the beginning and in the middle of this anomaly. And when the motion of the equinoctial points against the order of the signs is slowest, the Sun, coming to meet them towards the east, certainly has the most left to complete in order to reach the point of the true equinox. Further, the equation of the equinoxes is one thing, and the equation of the precession of the equinoctial points, or of the succession of the fixed stars, another.

[Margin: Mästlin's error on the difference between the mean and the true equinox.]

II. From Copernicus and from what was said in ch. 29, no. 10, the greatest equation of the equinoxes is $1^\circ\ 11'\ 22''\ 30'''$, which the Sun completes within $1^d\ 7^h$ even when its motion is slowest. On this hypothesis, therefore, the mean equinox cannot differ from the true by more than $1^d\ 7^h$. So Mästlin was deceived when he said that they could differ by a whole four days, as Clavius refutes him in ch. 6 of the *Apologia of the Calendar*. And the greatest difference between the longest and the shortest tropical year, for Copernicus, does not exceed 13^m of time, while between the mean and the true year it does not exceed 7^m. The equation of the equinoxes, then, is not the same as the equation of the tropical year.

[Margin: Fracastoro's fiction.]

III. Fracastoro, in the *Homocentrica*, Sect. 3, ch. 6, on the basis of an unequal motion of the Aplanes communicated to the lower orbs, thinks that the year was once, 400 years before Christ, of $365^d\ 6^h$, and afterwards diminished. He has no other foundation than the obsolete opinion of the ancients, who, however, measured the year in civil rather than astronomical terms.

CAPVT XXXI.

Chapter 31.

De Inæqualitate Dierum Naturalium & eorum Aequatione.

On the inequality of natural days and their equation.

[Margin: Authors who write on the inequality and equation of natural days.]

I. Now that all the causes, true or invented, of the inequality of the motion of the Sun, which by its daily revolution completes the natural day for us, have been set out, the inequality and equation of natural days will not be so difficult to understand. They are treated in the first place by Ptolemy, Book 3, ch. 10; and there by Regiomontanus in the *Epitome*, Book 3, from Prop. 23 to the end; by the Alphonsines at the end of Proposition 33, pp. 29 and 31; by Peuerbach in the *Tables of Eclipses*; by Copernicus, Book 3, ch. 26; by Reinhold in the *Theoricae*, p. 233, and in the Prutenic Tables, p. 14, or precepts 1 and 48, and canon 5; by Sarzosus [?], Pr. 28; by Fracastoro in the *Homocentrica*, Sect. 3, ch. 3; by Maurolico in Dialogue 2 of the *Cosmographia*, from p. 53; by Magini in the tables of the *Second Mobiles*, canon 7, and in the *Supplement to the Ephemerides*,

canon 6, and in vol. 1 of the *Ephemerides*, part 2, ch. 6; by Origanus, vol. 1 of the *Ephemerides*, p. 1, ch. 6; by Johannes Stadius, canon 8 of his tables; by Giuntini, p. 6, tab.; by Tycho, vol. 1 of the *Progymnasmata*, pp. 113 and 116; by Longomontanus in the *Astronomia Danica*, Book 1 of the *Theorica*, ch. 2, p. 181; by Kepler in the *Epitome of Copernican Astronomy*, Book 3, p. 280, and Book 4, p. 552, and in the Rudolphine Tables, chs. 15 and 31, and folio 32 of the tables; by Lansbergen, precept 8 of the tables; by Mulerius in the *Isagoge* to the Frisian tables, p. 378; by Clavius in the *Sphere*, p. 399; by Barozzi in the *Cosmographia*, p. 156; by Hérigone, vol. 4 of the *Cursus Mathematicus*, in the *Sphere*, p. 111, and at the end of vol. 5, p. 875; by Ismaël Boulliau, Book 2 of the *Astronomia Philolaica*, from ch. 5 to 7; by Wendelen in the *Lampas Arcanorum Caelestium*, light 1; by Ioannes Esler [?] of Mainz in the *Speculum Astrologicum*; by Renieri in the *Tabulae Mediceae*, ch. 3; and by Ariel Bicardus [?] on the *Sphere* of Sacrobosco, p. 60. From these and from our own studies we shall set out the theory and practice of the equality and inequality of natural days.

II. The natural day, in Greek [Greek: Νυχθήμερος (nychthēmeros, "night-and-day")], that is, *Noctidies* ["night-day"], or the day consisting of an artificial day and a night, on which name I said more in Book 1, ch. 25, is threefold: namely the day of the primum mobile [Dies Primi Mobilis], the sidereal day [Dies Sydereus] and the solar day [Dies Solaris].

[Margin: What the day of the primum mobile, the sidereal day and the solar day are.]

The day of the primum mobile is the time in which some point of the equator in the highest heaven revolves, by a motion towards the west, from one point of the meridian or horizon to the same point of the same meridian or horizon, truly or apparently; for the Pythagoreans and Copernicans attribute this motion not to the heavens but to the Earth.

The sidereal day is a whole revolution of the same fixed star from and to very nearly the same point of the same horizon or meridian, completed by a motion towards the west. For this revolution of the other planets, apart from the Sun, has not yet earned the name of natural day. And if the fixed stars moved by no other motion than this, the eighth sphere would be the primum mobile, as the ancient Babylonians thought. But it is established from the observations of Hipparchus and Timocharis down to our century that they move with a proper motion towards the east, so that in our opinion they advance one degree in 72 years. The sidereal day is therefore very slightly longer than the day of the primum mobile; because, for the same fixed star to return to the same point of the same meridian at which it was yesterday, there must pass, beyond the whole circle of the equator, a portion as great as corresponds to the daily proper motion of the fixed star, which has meanwhile advanced towards the east. Since therefore, for me, they advance 50″ in one year, it follows that in one day they creep forward $8‴\ 32⁗\ 53^{v}$; to which there correspond, of the daily motion of the primum mobile, $34⁗\ 11^{v}\ 40^{vi}$. And so great is the small appendage by which the day of the primum mobile is exceeded by the sidereal day. Over 72 Egyptian

years, moreover, the excess is 4^{m}, over 1080 years one hour, and over 25820 years one day.

[Margin: The solar day.]

The solar day is what we commonly understand by the name of day, and it is a whole revolution of the Sun from and to the same horizon or meridian, completed by a motion towards the west. Granted that, for the Pythagoreans and Copernicans, it is not the Sun by a motion towards the west but the Earth by a motion around its own centre towards the east that produces the daily turning for us. Now since the Sun by its proper motion towards the east advances daily, that is, in each day of the primum mobile, by a mean motion of $59' 8'' 19''' 51'''' 46^{v} 20^{vi}$, from what was said in ch. 17, that is, about $59' 8'' 20'''$, to which there correspond, from the motion of the primum mobile on the equator, horary times of $3^{m} 56^{s}$ 32 thirds 1 fourth 20 fifths, one natural day of the Sun, the mean one, therefore contains, besides the 24 hours of the primum mobile, $3^{m} 56^{s}$ 32 thirds 1 fourth 20 fifths; and while one solar day is being completed, 360 degrees of the whole equator pass, and besides that $59' 8'' 20'''$. So it comes about that in the 365 solar days in which the common year is completed, 366 revolutions of the equator are completed, and as many days of the primum mobile, and very nearly as many sidereal ones. The following table therefore shows the increments [Appendices] and differences of these three kinds of day.

[Margin: Difference of these days.]

Difference of the days	*Times of the primum mobile:* H.	m	s	thirds	fourths	fifths	sixths
1 day of the primum mobile	24	0	0	0	0	0	0
1 sidereal day	24	0	0	0	34	11	40
1 solar day	24	3	56	32	1	20	0

The sidereal day and the solar day can, however, each be divided into exactly 24 hours, but hours of their own. One day of the primum mobile would then be 23 sidereal hours $59^{m} 59^{s}$ 59 thirds 25 fourths 48 fifths 20 sixths, and one hour of the primum mobile would contain $59^{m} 59^{s}$ 59 thirds 58 fourths 34 fifths 32 sixths of a sidereal hour. In the same way the day of the primum mobile can be divided into 24 solar hours, or compared with them, as below.

		H.	m	s	thirds	fourths	fifths	sixths
One day of the primum mobile has	sidereal hours	23	59	59	59	25	48	20
And one hour of the primum mobile	of a sidereal hour	0	59	59	59	58	34	32
One day of the primum mobile has	solar hours	23	56	3	27	58	40	0
And one hour of the primum mobile	of a solar hour	0	59	54	46	26	37	0

So although in one hour of the primum mobile 15 degrees of the equator cross the meridian, and one degree crosses in 4 minutes of the primum mobile, and a common table has been made in that proportion for the mutual conversion of parts of the equator into hours and minute parts of hours of the primum mobile, and of these into parts of the equator, another, finer one is nevertheless needed, by which solar hours may be converted into parts of the equator, giving one hour 15° 2′ 28″, and parts of the equator into solar hours, giving one degree 3^{m} 58^{s} 40 thirds [recte: 3^{m} 59^{s} 20½ thirds, per the book's errata]. We shall present both at the end of the work.

III. Leaving aside the inequality of the sidereal day, which others suppose to arise from an unequal motion of the fixed stars, since it is both imperceptible and, in my view, false, from what was said in ch. 28, no. 5 and 11: the natural days of the Sun, compared with one another, are unequal for many causes. If the anomalies refuted in ch. 24, 25, 26, 27 were real, these causes would resolve into 13, granted that the ancient astronomers reduced them to only two, and that they can be brought down to 4.

[Margin: Cause 1 of the inequality of natural days, resolved into 3 causes.]

The first cause is the inequality of the Sun's motion in the ecliptic, since the Sun moves most slowly around the apogee and most swiftly at the perigee. This cause would hold good even if the Sun's eccentricity, on which the equations depend, did not change, or changed, but uniformly. But if it changes by that anomaly discussed in ch. 26, there will now be three causes. So, according to *Copernicus*, the inequality of natural days arising from this threefold cause is as follows.

		Daily motion of the Sun in the zodiac: ′	″	‴	*Natural day of the Sun:* H.	m	s	thirds
At greatest eccentricity, with the Sun	at apogee	56	46	0	24	3	47	4
	at perigee	61	43	0	24	4	6	52
At least eccentricity, with the Sun	at apogee	57	18	0	24	3	49	12
	at perigee	61	6	0	24	4	4	24
Mean		59	8	20	24	3	56	32

According to *Kepler*, however, the Sun today completes 57′ 5″ after the solstice, but 61′ 21″ after midwinter.

[Margin: Cause 2, resolved into 2.]

The second cause is the motion of the Sun's apogee, because of which the Sun's longer days fall on different days of the civil year, and indeed of the tropical year too. For when the Sun's apogee was at the start of Aries and its perigee at the beginning of Libra, namely at the beginning of the world, the vernal equinoctial day was the shortest, because of the Sun's slowest motion, which

least resisted the motion of the primum mobile. The autumnal equinoctial day, on the other hand (we are speaking here of the natural day), was the longest, because of the Sun's swiftest motion towards the east; and at about the beginnings of Cancer and Capricorn the solstitial days were of middling length. The former fell around the end of April and of October, the latter around the end of July and of January in the Julian year. Now, however, the summer solstitial days are the shortest, around the end of June, and the winter ones the longest, around the end of December, because at those times the Sun is in the one case at apogee, in the other at perigee. The middling days, around the mean longitudes, are roughly the equinoctial ones, that is, around the end of March and of September. Now if the apogee moves with an irregular motion, which we do not admit, from what was said in ch. 24, this cause of the inequality of days is not single but double.

[Margin: Cause 3, resolved into 5.]

The third cause is the obliquity of the ecliptic to the equator, because of which equal arcs of the equator do not rise in a right sphere with equal arcs of the ecliptic, nor cross the meridian with them in any sphere. This is clear from the tables of right ascensions, and from the analysis of a right-angled spherical triangle in which, from the given angle of the ecliptic's obliquity and an arc of the ecliptic taken as base, the side adjacent to the given angle is found, namely the right ascension itself or its argument. Therefore, even if the Sun moved of itself uniformly in the zodiac, the arc of the equator, and so the increment of time to be added to the day of the primum mobile, would still not be the same or equal. This cause alone would hold good even if neither the obliquity of the ecliptic nor the precession of the equinoxes changed, or if they did change, but uniformly. But if both change, and by that anomaly against which we argued in ch. 26 and 27, then four others are entangled with this cause, so that there are not this one but five on account of which the right ascensions vary unequally. And although these causes so far stated make one day differ from another almost imperceptibly, after many days they nevertheless produce a perceptible and evident difference of days, as we shall say in no. 6.

[Margin: Cause 4, resolved into 3.]

The fourth cause is the varying obliquity of the horizon in an oblique sphere, because of which days begun from the rising or setting of the Sun become unequal, since with equal arcs of the ecliptic there rise far more unequal arcs of the equator than those which culminate with the same arcs of the ecliptic, that is, cross the meridian, in accordance with the different obliquity of the horizon to the equator. Two others are joined to this cause, namely the Sun's horizontal parallax, which varies according to the Sun's varying distances from the Earth, and the Sun's refraction, likewise horizontal, which is variable because of the inconstancy of the vapours of the horizon in different places and seasons of the year. For because of these the Sun's right ascensions and declinations vary apparently. But to avoid the inequality arising from this fourth cause, astronomers, with *Ptolemy* (Book 3, ch. 10), begin natural days not from the

horizon but from the meridian, where in every sphere, whether right or oblique, the culminations [Mediationes Cæli], other things being equal, are equal to the right ascensions of the right sphere.

IV. Since, then, the natural days of the Sun are unequal, and so cannot be taken as a common and certain measure of the celestial motions, astronomers had to substitute for them mean, equal days of the Sun, and to distribute the celestial motions over these. But once motions have been collected for equal time, that is, time consisting of equal days, that time must be converted into true time, that is, the time apparent to us, who measure and count times by the Sun's true motion. Conversely, if some celestial phenomenon, say an eclipse, observed at apparent time, is to be examined by astronomical tables consisting of mean motions, the apparent time must be converted into equal time; or at any rate, in either case, as much must be added to or taken from the celestial motion as the difference between equal and apparent time requires[19].

[Margin: This equation is more necessary in the case of the Moon and for astrologers than for astronomers.]

If anyone chooses to disregard this equation, he will indeed incur some error in the other planets, sometimes 1^m 20^s in the Sun, 2^m in Saturn, Jupiter and Mars, 4^m in Venus and 9^m in Mercury, at most, in minutes of time; yet in the Moon the error can be 36′ and more. And astrologers have a still greater need of this correction than astronomers, as *Io. Esler* [?] confirms with examples in the *Speculum Astrologicum*.

[Margin: Rule for the equation of natural days.]

V. The universal rule, used from Ptolemy down to Tycho, for finding the equation of natural days, if the epochs of the motions belong to apparent time, as in the tables of Ptolemy, the Alphonsine and the Prutenic, is as follows. First find the difference between the Sun's mean place or motion belonging to the epoch of the motions, say at the beginning of the years of Christ, and the Sun's motion belonging to the given time. Then find the difference of the right ascensions corresponding to the Sun's true motion, both at the already mentioned epoch and at the given time. Third, compare the difference of the mean motions with the difference of the right ascensions. If they are equal, the sum of equal and apparent days will be the same, and no equation will be needed; but if they are unequal, subtract the smaller difference from the greater and convert the residue into time, and you will have the equation of time you want. For its use, observe the following canons.

	THE EQUATION [ÆQVATIONEM]
If the difference of ascensions is greater than the difference of mean motions	*Add* it to apparent time, to make equal time. *Subtract* it from equal time, to make apparent time.
If the difference of mean motions is greater than the difference of ascensions	*Subtract* it from apparent time, to make equal time. *Add* it to equal time, to make apparent time.

[19]the page prints *quarum*; the correlative of *tantum* requires *quantum*

[Margin: What if the epochs relate to mean time?]

But if the epochs of the celestial motions belong to mean time, as in the Rudolphine, Danish, Lansbergian and Philolaic tables: given the apparent time, find the Sun's place both mean and true, and the right ascension of the true place. If this is equal to the mean place, there will be no equation; if unequal, the difference, turned into time, will be the equation sought, whose use will be as follows.

	THE EQUATION [ÆQVATIONEM]
If the right ascension is greater than the mean motion	*Add* it to apparent time, to make equal time. *Subtract* it from equal time, to make apparent time.
If the mean motion is greater than the right ascension	*Subtract* it from apparent time, to make equal time. *Add* it to equal time, to make apparent time.

These rules hold if the calculation is progressive. But if it is retrograde, reckoning the motions backwards before the epoch, everything must be done the opposite way, and where it is said that the equation is to be added, it is to be subtracted, etc. That the second part of the precept is to be preferred to the first part you will learn from Scholium 1 of ch. 31. But if the Sun's true place is the beginning of Aries and the mean place falls short of it, take 360° for the right ascension; if the mean place is beyond it, the mean motion itself will be the equation to be turned into time.

EXEMPLVM.

Example.

[Margin: The time of the birth of Gregory XIII.]

In the year of Christ 1502, January 7, at $6^h\ 54^m$ after noon at Bologna, in apparent time, Pope Gregory XIII is said to have been born. The equal time is sought, so that the calculation from astronomical tables can be begun for it. At the beginning of the years of Christ the Sun's mean motion, from the Prutenic Tables as applied to Bologna by Magini, was $9^s\ 7°\ 34'\ 45''$, and at the already mentioned time of Gregory's birth it was $9^s\ 25°\ 32'\ 49''$. The difference of these motions is $17°\ 58'\ 4''$. Next, the right ascension of the Sun's true place at the epoch of Christ, that is, Capricorn $8°\ 36'\ 30''$, was $279°\ 23'\ 58''$; but at the time of Gregory's birth the Sun's true place was Capricorn $26°\ 49'\ 22''$, whose right ascension was $298°\ 51'\ 53''$[20]. So the difference of the right ascensions from each other was $19°\ 27'\ 55''$, which is greater than the difference of the mean motions; and when the latter is subtracted from the former, the residue is $1°\ 29'\ 51''$ on the equator, that is, $5^m\ 59^s$ of time. This time, added to the apparent time of Gregory's birth, gives the equal time of the current year 1502, January 7, $6^h\ 59^m\ 59^s$ after noon at Bologna.

[20] the page prints *Signor.* (signs) before 298, where degrees are meant; on this copy a line is drawn through the word

[Margin: A shortcut for this procedure.]

For the proposed time, however, one could have collected the motion of the stars, say of the Sun, and then the equation of time; but as much of the Sun's motion would then have to have been added to the true motion already collected as the equation of time required. Thus in our case the Sun completes 14″ 47‴ in the zodiac in 5^{m} 59^{s} of time. These, therefore, would have had to be added to the Sun's true place collected for the apparent time, which was 9^{s} 26° 49′ 22″, and the Sun's true place would have been 9^{s} 26° 49′ 36″ 47‴. And this is indeed the more prudent course, since the calculation of the Sun's place need not be repeated, etc. Conversely, if the equation of time had had to be subtracted, the Sun's place too would have had to be reduced proportionally. A table of *Magini* is adapted to this business, but a temporary one. For

[Margin: Temporary tables.]

VI. Besides this universal and most certain rule, practitioners usually construct temporary tables [tabulæ temporariæ], which fit only one century without perceptible error, since they rest on a fixed place of the apogee and on an eccentricity and an obliquity of the ecliptic belonging to that century. Tables of this kind are given by the *Alphonsines, Reinhold, Sarzosus* [Francisco Sarzosa], *Magini, Origanus, Tycho, Longomontanus, Mulerius, Kepler, Lansbergen, Boulliau* and *Renieri*, at the places indicated in no. 1. *Regiomontanus* teaches how to construct them by means of trigonometry in Book 3 of the *Epitome*, Prop. 29 and 30, and in Proposition 25 he also gives the problem of finding, in a quadrant of the ecliptic, the point of the ecliptic at which the arc of the ecliptic counted from the equinox differs most from its right ascension, given the obliquity of the ecliptic. This point always lies around the midpoints of Taurus, Leo, Scorpio and Aquarius, and is easily found in the tables of right ascensions. But in the Alphonsine tables and those of Sarzosus, and in the second table of Peuerbach, of Regiomontanus and of Reinhold, the equation is always taken from apparent time to make mean time, and added to mean time to make apparent time. In the others their titles are to be observed. According to Ptolemy, however, it is to be subtracted from 15° of Aquarius to the end of Libra, and added from the beginning of Scorpio to 15° of Aquarius.

Three things, moreover, are worth noting in these tables or for them. The first is the limit from which natural days begin to grow above the middling ones, the limit from which they begin to decrease, and what the greatest equation in them is. The second is how great the greatest difference is between the collected mean, shorter and longer days, and where it occurs. The third is where there is none. As to the first: days begin to grow, and to become greater than equal days, from the degrees of Scorpio written below up to the degrees of Aquarius written below; and from those same degrees of Aquarius they begin to decrease, as far as the same degrees of Scorpio. At these points the equations in the astronomers' tables are greatest, as can be seen in the following small table.

	Scorpio: limit	Scorpio: greatest equation	Aquarius: limit	Aquarius: greatest equation
Ptolemy	0°	$33^m\ 20^s$	15°	$16^m\ 40^s$
Alfonso	8°	$32^m\ 52^s$	21°	✢ ✢
Peuerbach	8°	$32^m\ 48^s$	21¼°	✢ ✢
Copernicus	11°	$22^m\ 22^s$	22°	$8^m\ 9^s$
Tycho	8°	$24^m\ 30^s$	22°	$8^m\ 0^s$
Kepler	10°	$17^m\ 0^s$	12°	$15^m\ 0^s$
Lansbergen	8°	$24^m\ 18^s$	22°	$8^m\ 0^s$
Boulliau	13°	$13^m\ 8^s$	18°	$12^m\ 34^s$

The limits of the greatest difference between arcs of the ecliptic and the right ascensions corresponding to them, with their differences, vary among authors. But the Sun's apogee is, for Ptolemy, at Gemini 5°; for Peuerbach, at the beginning of Cancer; for others, beyond the beginning of Cancer.

If the obliquity of the ecliptic is 23° 52′.

Degrees of the signs	Arc of the ecliptic	Right ascension
Taurus 16°	46°	43° 26′
Leo 13°	133°	135° 34′
Scorpio 16°	226°	223° 26′
Aquarius 13°	313°	315° 34′
Difference of right ascension and arc of the ecliptic		2° 34′

If the obliquity of the ecliptic is 23° 30′.

Sign	Arc of the ecliptic	Right ascension
Taurus 16° 4′ 44″	46° 4′ 44″	43° 35′ 39″
Leo 13° 45′ 16″	133° 45′ 16″	136° 14′ 21″
Scorpio 16° 4′ 44″	226° 4′ 44″	223° 35′ 39″
Aquarius 13° 45′ 16″	313° 45′ 16″	316° 14′ 21″
Difference of right ascensions, etc.		2° 29′ 5″

For *Boulliau*, however, this difference is 2° 29′ 44″, since he follows a different obliquity of the ecliptic.

So in these centuries days grow from 16° of Taurus to 14° of Leo, because of the difference of right ascensions alone; from 14° of Leo to 16° of Scorpio they decrease. Again, from 16° of Scorpio they grow up to 14° of Aquarius, and from there as far as 16° of Taurus they decrease. The total difference of the shorter and longer days, collected at an obliquity of 23° 52′, is 10° 16′, but from our obliquity of 23° 30′ it is 9° 56′ 20″. These are composed of the difference of ascensions, 2° 34′ or 2° 29′ 5″, quadrupled; that is, in horary minutes, $41^m\ 4^s$ in the former case and $39^m\ 45^s$ 20 thirds in the latter.

[Margin: Greatest difference of natural days, compounded from all causes.]

Now suppose that the other cause, arising from the inequality of the Sun's motion in the ecliptic, is joined to this one, and that with the greatest difference of right ascensions, which for us is 2° 29′ 5″, there is joined at the same point of the ecliptic, say at Taurus 16° 4′ 44″, the Sun's greatest prosthaphaeresis, which for us is 1° 59′, and that both are additive or both subtractive. The difference in one quadrant, from the middle of Taurus to the middle of Leo, would then be 4° 28′ 5″. Quadrupled, this would be 17° 52′ 20″, that is, in time, 1^h 11^m 29^s 20 thirds between the shorter and longer days, and half of this between the mean days and the longer or shorter ones; but this is with days computed from the meridian. *Copernicus, Reinhold* and *Magini*, however, who follow the anomalies of the obliquity, of the equinoxes and of the eccentricity, say that this whole difference can be 10° between middling and smaller days, that is, 40 horary minutes, and 20° between smaller and greater days, that is, 1^h 20^m. For *Ptolemy*, on the other hand, the former is 33^m 20^s and the latter 1^h 6^m 40^s.

[Margin: Where and when natural and apparent days are equal.]

Conversely, there is no difference between mean and apparent days when the differences of right ascensions and the equation of the solar motion are equal, but one subtractive and the other additive, so that they compensate for or cancel each other; and this happens twice a year. This difference of days also ceased when the Sun with its apogee was at the beginning of Aries or at the beginning of Cancer, and it will cease if both are at the beginning of Libra or of Capricorn. For at these cardinal points no equation is to be applied, either to the Sun's motion or on account of the right ascensions.

CAPVT XXXII.

Chapter 32.

Recentiorum Aſtronomorum Sententia de Inæqualitate Dierum Naturalium, eorumq. Aequatione.

The opinion of more recent astronomers on the inequality of natural days and their equation.

Up to now, from Ptolemy to Tycho, the equation of natural or civil days has seemed necessary to astronomers, and indeed as great an equation as is gathered by the rule given in ch. 31, no. 5, especially in the Moon, according to what was said in the same place, no. 4. Nevertheless, from the time of Tycho it began to be called into doubt. So it will be worthwhile to hear the opinions of the more recent astronomers on this matter.

[Margin: Authors denying the necessity of the equation of days.]

I. The first opinion among them, then, is that of *Jacob Christmann* in his solar observations, of *Vitichius* [Paul Wittich] in Longomontanus below, and of *Govaert Wendelen* in the *Lampas Arcanorum Caelestium* and in the *Idea of the Atlantic Tables*. They judge the equation of natural days, that is, the conversion

of apparent time into equal and of equal into apparent, to be by no means necessary.

[Margin: Christmann's reasoning.]

Christmann does so because he thinks that the inequality of days arising from the Sun's unequal motion is imperceptible, and that the one which would arise from the obliquity of the ecliptic is rendered imperceptible, since the Sun, advancing along the parallels of the equator, behaves, so far as the senses can tell, exactly as if it were advancing along the equator. But he is mistaken, because the Sun does not describe parallels but spirals, or rather spherical helices, and marks out the oblique path of the ecliptic.

[Margin: And Wittich's.]

Wittich, on the other hand, thought that as much is taken from mean time by one of the already mentioned causes as is added by the other. This, however, is false, since the difference arising from right ascensions compared with the mean motion is much greater than the one arising from the Sun's unequal motion, except in only two cases, in which they compensate each other: namely when the Sun with its apogee is at some cardinal point of the equinoxes or solstices, or outside these points, twice a year, according to what was said at the end of ch. 31.

[Margin: Wendelen's foundation.]

Wendelen, having expressed his opinion in this elegant verse:

In the heavens, tomorrow's total is equal to today's. [In Cœlis par eſt hodiernæ craſtina ſummæ.]

that is: *All days* [Greek: Νυχθήμεροι (nychthēmeroi, "of a night and a day")] *are equal to one another,*

has so far put forward no other foundation a priori, but supports his opinion a posteriori, from more than 45 observed eclipses, which he finds answer to calculation without any equation of natural or civil days; using, however, luni-solar tables derived from more than two hundred eclipses, and oscillatory prosthaphaereses of the Moon. Nor does he fear for himself from the eclipses observed by Tycho, since their observation is in places suspect, for reasons indicated in the preface to the Atlantic Tables, which we shall review in the Book on Eclipses.

[Margin: Boulliau's opinion of Wendelen.]

Boulliau, however, in Book 3, ch. 15 of his *Astronomy*, nearly agrees with Wendelen as to some eclipses, but opposes him as to others. Nor can these matters be established and determined with certainty from eclipses observed at different places unless the difference of the meridians is first established; and yet between distant places this itself cannot be gathered by any surer indication than from eclipses observed at both. I nevertheless await a reply from Wendelen himself, a very dear friend and most expert in astronomy. For I have asked him how it can happen that from a necessary cause of the inequality of days the necessary effect, namely the inequality of days itself, does not follow. And if it does not follow, from where is the excess of days above the mean ones offset

by a deficiency? *Boulliau*, Book 2, ch. 6, at the end, denies that Wendelen can demonstrate this offset.

[Margin: Tycho's twofold method of equating time.]
