I think, Kepler, is that we should not, without some enormous reason, depart far from the place of the apogee and the motion established by Ptolemy and Copernicus, but should examine and perfect it a posteriori, from the comparison of observations supporting it in greater or better number. When we have done this, we shall surely find that there are no tables by these authors which yield all the observations, or such and so great a number of them that they must without fear be preferred to the others; nor, likewise, any which cannot defend themselves by some great number of observations, say 10 or 12; and that sometimes the Tychonic or Danish tables come closer to the truth, sometimes the Lansbergian, sometimes the Rudolphine, sometimes Boulliau's.

[Margin: 1. Choice of the apogee of ♀ and ☿.]

Therefore, if someone should put his tables to the test by choosing a mean between these, he will not in the meantime have acted unwisely, roughly in this manner.

Year of Christ		Place of the apogee
1, at the beginning	♀	1ˢ 22° 40′
	☿	6ˢ 10° 0′
1600, completed	♀	3ˢ 0° 0′
	☿	7ˢ 29° 0′
Hence the annual motion of the apogee		
	♀	1′ 24″ 0‴
	☿	1′ 50″ 15‴

[Margin: 2. Relation of the apogee to the beginning of the world.]

VIII. The second way is similar to the one we gave on the occasion of the solar apogee in Book 3, ch. 25, nos. 5 and 6: namely, if we so distribute the motion and the roots of the motion of these apogees that at the beginning of the world they fall on some notable point of the zodiac. There, moreover, we said that the most probable beginning of the world was the year 4063 before Christ. So, multiplying the annual motion of the apogee of ♀ and ☿ chosen here a little earlier by 4063 years, and subtracting the sum from the beginning of the year of Christ, the apogee of ♀ at the beginning of the world would fall at ♒ 17° 35′ 48″ and that of ☿ at ♌ 6° 36′ 14″ 15‴, much too far from the

cardinal points of the zodiac. They could therefore be drawn back, at most, so that the apogee of ♀ would be at the start of ♒ and that of ☿ at the start of ♌; they would then have wholly reversed apsides, and the apogee of one would coincide with the perigee of the other. From this and from other indications arises the third way, to be set out shortly.

IX. Pliny the Elder notes, Book 2, ch. 17, that Mercury and Venus have reversed apsides, but he spoke in another sense; for the apogee of ♀ and the perigee of ☿ are nearer to the solar apogee, as Kepler too noted, Book 6 of the *Epitome of Copernican Astronomy*, Part 3. We have already seen that from the beginning of the world this antithesis of the apogees was not far off, if we embrace the motion and the roots of the more celebrated astronomers. Moreover, from the places of the apogees in nos. 3, 4, 5 and 6 it is evident that some digressions yield, for Ptolemy's century, the apogee of Venus around ♈ 22° and the apogee of Mercury then around ♎ 25°; and now the apogee of Mercury around the start of ♍, where astronomers set the perigee of Venus. What, then, if someone should affirm that these planets have always had apsides plainly and diametrically opposed, and that the apogee of Venus always has been and always will be where the perigee of Mercury was and will be, especially since they have many other opposite properties? With this granted, it would follow that the motion of each apogee is equally great, and the eccentricity, the semidiameter and the anomaly of the orb would have to be so arranged that, taken together, they agreed with all observations, or with the most select. I have not been ashamed to point this out to students of astronomy.

SCHOLIA.

Scholia.

[Margin: Equality of the diameter of the epicycle required.]

I. I said in no. 1 that, to discern the places of the zodiac through which the line of apsides passes, it is required that the semidiameter of the orb or epicycle be the same either always, or at least at the same distance from the apogee of the eccentric. Otherwise the inequality of the diameter in another position could present us with equal digressions, so that the line bisecting the arc between the Sun's places would not be the line of apsides. And indeed Regiomontanus, when in Book 9 of the *Epitome of the Almagest*, props. 8 and 9, he shows that the greatest and contrary digressions from the Sun's mean place are also equal to one another, supposes that the epicycle there, at least, has an equal diameter. Moreover, two greatest digressions, one morning and the other evening, could be equal to each other and yet the line bisecting the arc between the Sun's places not be the line of apsides, if either the eccentricity were unequal or the equations of the eccentric unequal. For those digressions must also be contrary in this respect: that is, the additive equation of the eccentric place in one must be as great as the subtractive equation in the other digression.

[Margin: Geber's censure of Ptolemy.]

Otherwise, as Jābir ibn Aflaḥ shows acutely but at length in Book 7 of the *Astronomy*, from p. 110 in my copy, at almost infinitely many places of the eccentric there can occur two equal digressions from the Sun, one morning and the other evening, in which the centre of the epicycle is not equally distant on either side from the line of apsides. And so he sharply rebukes Ptolemy for thinking that two greatest digressions, one evening and the other morning, suffice to discern the place of the zodiac through which the line of apsides passes. He adds, however, that Ptolemy erred little, not of himself but by accident, in setting the apogee of Mercury at 10° of Libra and that of Venus at 25° of Taurus; I believe because in those digressions he met with an arc between the Sun's places much smaller than a semicircle. For the smaller that arc is, the smaller are the equations of the eccentric and the differences of the equations, and so the less is the danger of straying from the place of the apogee or perigee. And since the equality of these equations cannot be known unless the apogee is known beforehand, which is, however, what is being sought here, no other way remains except through smaller and smaller arcs between two places of the Sun at the time of the digressions of Venus and Mercury; or else an assumed place of the apogee must be confirmed a posteriori by the agreement of more observations.

[Margin: Copernicus's inconsistency on the apogee of ☿ refuted by Mästlin.]

II. There survives in Kepler, in the *Mysterium Cosmographicum*, ch. 19, part of a letter written by Mästlin to Kepler, in which he complains of Copernicus both that he used none of his own observations of Mercury, and that in deducing its apogee he is not consistent with himself. For in Book 5, ch. 26, for around the year of Christ 140, Copernicus sets the apogee of Mercury at ♎ 10°, but at 183° 20′ from the first star of Aries; and in that same 183° 20′ he sets it in ch. 29 for year 21 of Ptolemy Philadelphus, as though it had rested motionless under the sphere of the fixed stars for 400 years, although in ch. 30 it seems to him to have completed one degree in 63 years, provided that motion is taken as equal. Mästlin adds that Reinhold too stuck at this point in the Prutenic Tables: he fitted the place of the apogee at ♎ 10° and at 1[?]3° 20′ from the first star of ♈ to the time of Ptolemy Philadelphus, but for the time of Ptolemy the astronomer placed it at ♎ 15° and 188° 50′ under the orb of the fixed stars, against Ptolemy's observations. Therefore, unless the fixed stars are admitted to move, truly from the equinox or apparently because of the recession of the equinoxes against the order of the signs, these tenets of Copernicus can scarcely be reconciled.

CAPVT X.

Chapter 10.

De Artificio Eccentricitatis, & Commenſurationis orbium Veneris ac Mercurij inueſtigandæ; vbi occaſio iterum de Mercurij Digreſſionibus Maximis.

On the technique for investigating the eccentricity and the commensuration of the orbs of Venus and Mercury; where there is occasion again to speak of the greatest digressions of Mercury.

[Margin: Authors on this technique.]

I. The following treat this matter: Ptolemy, Book 9, ch. 9, on Mercury, and Book 10, chs. 2 and 3, on Venus; Regiomontanus, in the *Epitome of the Almagest*, Book 9, props. 15, 16, 17, 18, 19, 20, and Book 10, props. 1 and 3; Jābir ibn Aflaḥ, Book 7 of the *Astronomy*; Pedro Nunes, on Peuerbach's *Theoricae*, p. 247; Copernicus, Book 5, chs. 21 and 27; Longomontanus, Book 2 of the *Theorica*, chs. 18 and 20; Boulliau, Book 9, ch. 1, and Book 10, ch. 1; and Hérigone, vol. 5 of the *Cursus Mathematicus* book 3 of the *Theorica*, prop. 31. From these, but in a better order and more clearly, we shall carry out our purpose through the following problems.

Problema 1. Proportionem inuenire quam habent Semidiameter Epicycli & Eccentricitas Deferentis ad Radium Eccentrici.

Problem 1. To find the proportion that the semidiameter of the epicycle and the eccentricity of the deferent bear to the radius of the eccentric.

II. What must be given here are the places of the apogee, and so also of the perigee, of the eccentric; and then two greatest digressions of the planet from the Sun, one with the Sun standing in the apogee of Venus or of Mercury, the other with it standing in the perigee, or as near to it as possible. This is taken according to the mean motion in the old astronomy, or according to the apparent motion in the new; and the quantity of the semidiameter of the epicycle is supposed to be always the same. On these assumptions, let BE be the line of apsides, on which let A be the centre of the Earth and of the world, and O the centre of the eccentric, whose diameter is BE, whose semidiameter or radius is OB or OE, and whose eccentricity is AO. Let the centre of epicycle DK be under the apogee, and E the centre of epicycle GM under the perigee. Then draw from A to the circumferences of the epicycles the tangents AD and AG, and join these to the centres of the epicycles by the semidiameters BD and EG. This being laid down:

Diagram. Set into the left column, at the right of the text. A vertical line of apsides runs down the figure. At its head stands a circle with an inner arc about a centre on the line (the epicycle under the apogee); at its foot, a smaller circle with an inner circle about a centre on the line (the epicycle under the perigee). Two straight lines from a point on the axis, A, run up to touch the upper circle at D on the right and down to touch the lower circle at G on the

right. Radii are drawn from the centres out to the tangent points and to one further point in each circle.

- B (on the axis, in the upper circle): centre of the upper epicycle, as the text uses it
- C (upper circle, to the right of and above B): at the end of a line from B
- H (on the axis, just below B): unnamed in the text of this page
- D (right side of the upper circle): tangent point
- K (on the axis, at the foot of the upper circle)
- O (on the axis, midway down, to the left of the line): centre of the eccentric
- A (on the axis, where the lines cross): centre of the Earth and the world
- M (on the axis, at the head of the lower circle)
- L (on the axis, just below M)
- G (right side of the lower circle): tangent point
- F (lower circle, right of E)
- E (on the axis, in the lower circle): centre of the lower epicycle

[Margin: First step of the problem.]

First, in triangle ABD, the angle at D is right because of the contact, by 18 of Book 3 of the *Elements*; and the angle BAD is known from the greatest digression observed when the Sun is under the apogee of the planet in question, under which B lies. Therefore the third angle ABD, which measures the arc DK, is also known, by 32 of Book 1 of Euclid. So from the tables of sines the proportion of the three sides of this triangle to one another will be known, if BD is taken as the whole sine, and AD is sought as the tangent of the angle ABD, that is, KBD, and AB as the secant. Similarly, in triangle AEG, right-angled at G, the angle EAG is known from the other greatest digression; and from that the remaining acute angle GEM, and so the proportion of its secant AE to the whole sine EG. Since, then, BD is supposed to be as great as EG (granted that for another purpose we have drawn them unequal), if the secants AB and AE are joined, the proportion of the whole diameter BE to BD or to EG, as to the whole sine, will be known. And by bisecting BE at O, the proportion of the semidiameter OB to BD will also be known; and the remainder or difference AO will likewise be known in parts of which BD is the whole sine.

Second, then, let the semidiameter OB be taken in another kind of parts, say either as 60 degrees or as a radius of 100000 parts. So let it be made: as OB in the former kind of parts is to OB taken as 60 or as 100000, so BD, the whole sine, is to a fourth term; and the semidiameter BD of the epicycle will be known in parts of which the radius of the eccentric is either 60 or 100000. Again, let it be made: as BO in the former kind of parts is to BO as 60 or 100000, so AO in the former kind is to a fourth term; and the eccentricity will become known in parts of which the radius of the eccentric is 60 or 100000.

EXEMPLVM.

Example.

Ex Ptolemæo in ☿.

From Ptolemy, on ☿.

[Margin: First digression of ☿, with ☉ placed in its apogee.]

III. Ptolemy, Book 9, ch. 8, in year 19 of Hadrian, observed two greatest digressions of Mercury from the mean place of the Sun. One was in the morning, on the day Athyr 14 with the 15th following; and from its distance from Regulus, taken with the astrolabe, he reckoned Mercury to be in ♍ 20° 12′. The mean Sun, for him, was in 9° 15′ ♎, that is, very nearly under the apogee of Mercury. So the angle of digression BAD was 19° 3′, and KBD 70° 57′, whose secant AB is 306379 of the parts of which BD is 100000.

[Margin: Second digression of ☿, with ☉ placed in its perigee.]

The other was in the evening of Pachon 19, when, from the distance of Mercury from Aldebaran, or the southern eye of Taurus, he reckoned Mercury to be in 4° 20′ ♉, and the mean place of the Sun in ♈ 11° 5′, that is, very near the perigee of Mercury. So the greatest digression of Mercury and the angle EAG was 23° 15′, and the angle MEG 66° 45′, whose secant AE is 253229 parts, of which EG is 100000. The whole BE, therefore, is 559608 of such parts, and its half OB 279804, which, subtracted from AB, leaves AO, 26575. Now, as 279804 is to 100000, so BD, 100000, is to 35758. Again, as 279804 is to 100000, so AO, 26575, is to 9498. Therefore, from what Ptolemy gives, the semidiameter of Mercury's epicycle is 35758 parts, and the simple or whole eccentricity 9498, of which the radius of the eccentric is 100000.

[Margin: So also Regiomontanus, Book 9, prop. 15.]

Ptolemy, however, using another kind of parts and a more troublesome trigonometry, in Book 9, ch. 9, concludes that, in parts of which AB is 120, BD is 39° 9′ and AE 99° 9′, the whole BE 219° 9′, and therefore BO 109° 35′ and AO 10° 25′.

EXEMPLVM.

Example.

Ex Ptolemæo in ♀.

From Ptolemy, on ♀.

[Margin: First digression of ♀, with ☉ placed in its apogee.]

IV. The same Ptolemy, Book 10, ch. 2, reports that Theon observed, in year 13 of Hadrian, on Epiphi 2 in the morning, Venus at its greatest digression from the mean place of the Sun, placed in ♉ 25° 24′, that is, very nearly under the apogee B of Venus. From the distances from fixed stars taken by Theon, he concludes that Venus was in ♈ 10° 36′. So the angle of digression BAD was

44° 48′, and the remaining angle KBD 45° 12′, whose secant AB is 141918 of the parts of which BD is 100000.

[Margin: Second digression of ♀, with ☉ placed in its perigee.]

He himself, in year 21 of Hadrian, on Tybi 2, in the evening, observed Venus at its greatest elongation from the mean place of the Sun, placed in ♏ 25° 30′, that is, almost in the perigee of Venus; and from the distance of Venus from the Horns of Capricorn he reckoned Venus to be in ♑ 12° 50′. So the angle of greatest digression EAG was 47° 20′ and MEG 42° 40′, whose secant AE is 135274 of the parts of which the whole sine EG is 100000. The whole BE, therefore, is 277192, and its half OB 138596, which, subtracted from AB, leaves AO, 3322. Let it be made, then: as 138596 is to 100000, so BD, 100000, is to 72094. Again let it be made: as 138596 is to 100000, so 3322 is to 2339. For in this way the semidiameter of Venus's epicycle will come out as 72094 parts, and the eccentricity 2339, of which the radius of the eccentric is 100000.

[Margin: So also Regiomontanus, Book 10, prop. 3.]

But Ptolemy, Book 10, ch. 2, using another kind of parts and his usual roundabout calculations, concludes that, in parts of which AB is 120, the semidiameter of the epicycle of ♀ is 84° 33′ and AE 115° 1′, the whole BE 235° 1′, and the half OB 117° 30′; and that, in parts of which OB is 60, the semidiameter BD is 43° 10′ and the eccentricity AO 1° 15′. But since it was not yet established for Ptolemy from these figures whether the eccentricity so found was the eccentricity of the point about which the planet's motion is uniform, that is, whether it was the eccentricity of the equant or rather of the deferent, another inquiry was needed, of which I shall speak in Problem 4.

[Margin: The author's excuse for neglecting this method.]

We, for our part, from the observations set out above in ch. 9, no. 2, using digressions 24 and 30, in one of which the Sun was at almost the beginning of Capricorn and in the other of Cancer (that is, there in the perigee, here in the apogee of ♀), could have fished out the eccentricity and the semidiameter of the orb. But we were not certain whether 24 was the greatest; indeed, from the motion of the anomaly we found that Venus was not then at the very contact of the orb. So we are waiting, in the hope that, God favouring, as it was possible at the beginning of Cancer, so it may be possible at the beginning of Capricorn to observe the greatest digression of Venus. And we wish for the same in Mercury, with the Sun around the beginnings of Sagittarius and Gemini. Meanwhile, the measure of the orbs will have to be tracked down a posteriori.

Problema 2. Eccentricitatem Mercurij ac Veneris à Sole, & Semidiametrum Orbis eorumdem, Inueſtigare.

Problem 2. To investigate the eccentricity of Mercury and Venus from the Sun, and the semidiameter of their orb.

[Margin: For the hypothesis of the moved Earth.]

V. On the hypothesis of the Earth circling the unmoving Sun, one must investigate the eccentricity of these planets from the Sun, and the semidiameter of the eccentric orb, which is equivalent to the Ptolemaic epicycle, since the Earth's annual orb takes the place of the Ptolemaic eccentric. Let AB, then, be the diameter of the annual orb and at the same time the line of apsides, not of the Earth but of these planets, and let the annual orb AB be described from the centre C; and let D be the centre of the orb of ♀ or ☿. While by mean motion the Earth is at A, under the apogee of ♀ or ☿, so that the centre D is then at its greatest distance from the Earth, let the planet be observed at E, at its greatest digression from the mean place of ☉, or of the Earth. Then let the Earth be at B, under the perigee of the planets, and let the planet then be observed at F, at its greatest digression from the mean place of the Sun or of the Earth.

Diagram. Set into the left column, at the right of the text. A large circle (the annual orb) with a vertical diameter from A at the top to B at the foot. On the diameter, just above the middle, stand C and, below it, D, with a small circle about D. From A a straight line runs down to touch the small circle at E on its left; from B a straight line runs up to touch it at F on its left. Radii join D to E and D to F.

- A (top of the large circle)
- B (foot of the large circle)
- C (on the diameter, at the head of the small circle's area): centre of the annual orb
- D (on the diameter, centre of the small circle)
- E (left side of the small circle, upper): tangent point
- F (left side of the small circle, lower): tangent point

[Margin: First step.]

For when the tangents AE and BF and the radii ED and FD are drawn, the triangles will be right-angled at E and F, by 18 of Book 3 of the *Elements*. So once the angles A and B are known from the digression, the remaining acute angles, namely ADE and BDF, will be known, each being the complement of its own digression to a right angle; and the secants AD and BD of these angles will be known in parts of which the radius ED or FD of the orb has been assumed. When these are added, the whole AB will be known, and, when it is bisected, the half AC, which is the semidiameter of the annual orb; and when this is taken from the secant AD, the difference CD will be known. Now, then, if AC is taken as 100000 parts, or in semidiameters of the Earth corresponding to the Earth's mean distance from the Sun, let it be made: as CA is to the 100000 parts, or to the semidiameters of the Earth just mentioned, so the whole sine DE, say 100000, is to another term. And again let it be made: as CA is to the 100000 parts, or to the semidiameters of the Earth contained in the mean distance of ☉ from the Earth, so DC, known in the former kind of parts, is to another term. The semidiameter DE of the orb will then be known, and its eccentricity from the point C about which the Earth moves uniformly; known,

I say, in parts of which the semidiameter of the annual orb, or the Earth's mean distance, is 100000, or contains so many semidiameters of the Earth.

[Margin: Second step.]

Second, then, with the said eccentricity known, and the eccentricity of the Sun from the Earth, or of the Earth from the Sun, and the angle they contain, which is known from the difference between the places of the Sun's apogee and the apogee of these planets, or from its complement to two right angles, the base subtending this angle will also be known, namely the eccentricity of the centre of the orbs of ♀ or ☿ from the Sun, as will be clear from the figure set out in Section 2, ch. 10, no. 3.

[Margin: Copernicus's conclusion from this problem.]

Further, Copernicus, Book 5, ch. 20, sets out two observations of ♀ taken from Ptolemy, which I have already reported at no. 4. Then, in ch. 21, supposing the Earth at A, under about 25° of Scorpio, so that B is under the apogee of Venus, which was in 25° ♉, and then at B, so that A is the perigee, as regards the mean motion, he concludes, but by another and less easy calculation, that in parts of which AC is 100000, the semidiameter DE of the orb of Venus is 7193, and DC about 208. Similarly, in Book 5, ch. 26, he sets out the two digressions of Mercury that I reported at no. 3, and concludes in ch. 27 that, in parts of which AC is 100000, the semidiameter of the orb of Mercury is 35731, and the eccentricity CD 9479, not without some error of calculation.

But Mästlin, in the notes to ch. 15 of the *Mysterium Cosmographicum*, sets out from Copernicus's data the eccentricities both from the Sun and from the centre of the great orb, which we have reported in the table at the end of ch. 2.

Problema 3. Diſcernere ac determinare Quibus in locis Eccentrici contingant Veneris ac Mercurij Maximæ Maximarum Digreſſionum à Sole.

Problem 3. To discern and determine at which places of the eccentric the greatest of the greatest digressions of Venus and Mercury from the Sun occur.

VI. Supposing, as Ptolemy and the whole of the old astronomy suppose, that the quantity of the epicycle is the same at any place of the eccentric, the greatest digressions from the Sun, that is, those occurring at the contacts of the epicycle, become smaller with the centre of the epicycle standing in the apogee of the eccentric than in the perigee. Even so, it could be doubted whether the greatest of the greatest occur in the perigee or elsewhere. Considering, then, the greatest digressions of Venus, Ptolemy finds that the greatest of all always occur at the perigee of the eccentric, and the least of the greatest at the apogee. But in Book 9, chs. 7 and 8, comparing the greatest digressions of Mercury, he finds that the greatest of the greatest do not occur when the centre of the epicycle is in 10° ♈, where the perigee of Mercury then was, but with the centre placed near 10° ♒, and again near 10° ♊. For the greatest digression near 12° ♈ was found by him to be 23° 15′, whose double is 46° 30′. But with

the centre of the epicycle placed near 10° of Aquarius, he obtained a greatest evening digression of Mercury of 21° 15′ and a morning one of 26° 30′; when these are added, the arc of the epicycle comprehended by the tangents drawn from the Earth comes to 47° 45′. Conversely, at 10° of Gemini, he finds the greatest evening digression of Mercury to be 26° 30′ and the morning one 21° 15′; when these are likewise added, the arc of the epicycle is 47° 45′, certainly greater than the arc with the centre of the epicycle placed in the perigee of the eccentric.

[Margin: Corollaries on ☿ being nearest to the Earth twice a year.]

From these observations, Ptolemy there, and also Jābir ibn Aflaḥ, Book 7 of the *Astronomy*; Regiomontanus, Book 9 of the *Epitome*, props. 16 and 21; Pedro Nunes, on Peuerbach's *Theoricae*, from p. 247 to p. 255; Magini, in the theory of Mercury, ch. 9; and most expositors of this old theory, draw these corollaries. First, that the centre of Mercury's epicycle comes nearer to the Earth at the places of the eccentric distant on either side by a third part of the circle, or by 4ˢ, from the apogee of the eccentric, than in what is commonly called the perigee, that is, than at the point opposite the apogee itself. Second, that Mercury, or at least the centre of the epicycle, comes nearest to the Earth twice a year: formerly, namely, in 10° ♒ and ♊, where it stood a third part from the apogee; but now (if Ptolemy's hypothesis were true) in about 1° ♈ and ♎, where it stands a third part from the apogee. Third, that the eccentricity of the deferent of the epicycle is not the same as the eccentricity of the equant, and that the centre of the deferent is joined with the centre of the equant only once in a year, but at other times moves against the succession of the signs and comes to be more distant from the centre of the world than the centre of the equant. For in this way it can happen that, at the thirds from the apogee, the centre of the epicycle approaches nearer to the Earth than in the perigee; and the rest, of which we spoke in this Section, ch. 1, from no. 4 to no. 8.

[Margin: Copernicus's opinion on the cause of the greater digressions of ☿ away from the perigee.]

VII. I said at no. 6, supposing the same quantity of the semidiameter of the epicycle, in the old astronomy, or of the orb equivalent to it in the new one, which moves the Earth. For if the semidiameter of this epicycle or orb is supposed to vary, so that around the trine from the apogee of the eccentric, or around the sides of the hexagon, it becomes greater than in the perigee, the greatest of the greatest digressions can occur at those places of the eccentric, even if the centre of the epicycle does not approach nearer to the Earth at them than in the perigee. And thus Copernicus, Book 5, ch. 28, attributes that excess of the digressions at those places away from the perigee, not to an approach of the epicycle to the Earth, but to an excess of the semidiameter of the orb, as we shall say at no. 14. For already in ch. 27, as I shall show in Problem 5, he had set the semidiameter of the orb of ☿ at least 3573 parts, mean 3763, greatest 3953, of which the radius of the annual orb is 10000, and had given the law of its variation. Of this I have said enough in ch. 2, no. 10, and ch. 3, no. 4, step

5, where I speak of Lansbergen imitating Copernicus in this, and I shall speak of it again shortly in Problem 6.

[Margin: Kepler's opinion on the same.]

Kepler, however, attributes the reason why Mercury seemed to Ptolemy to approach nearest to the Earth at two places of the eccentric each year to the elliptical figure of the orb, as we shall show in Scholium 2. Supposing Ptolemy's opinion, however, we must give the method of investigating the eccentricity of the deferent and of the equant and of distinguishing them.

Problema 4. Dıſcernere Eccentricitatem Aequantis ab Eccentricitate Deferentis, & Semidiametrum circelli eam in Mercurio ac Venere variantis.

Problem 4. To distinguish the eccentricity of the equant from the eccentricity of the deferent, and the semidiameter of the small circle that varies it in Mercury and Venus.

VIII. In the figure below, let AP be the line of apsides of Mercury or Venus, and on it the centre of the Earth T;

and the centre of the equant, or of the mean motion, C. From C, therefore, let CD be erected perpendicular to AP, so that the centre of the epicycle is a quadrant distant from the apogee at the unequal greatest digressions; for although this is not necessary, it is easier, as Regiomontanus notes, Book 9, prop. 17, and Book 10, prop. 4. On that line, from E, describe the epicycle, and to it draw from T the tangents TV and TM, and to the points of contact draw the radii EV and EM. Join the centres of the Earth and of the epicycle by the straight line TE, and apply, in this position of the eccentric, two greatest digressions of the planet from the mean place of the Sun according to Ptolemy's teachings, one in the evening, of the planet at V, the other in the morning at M.

Diagram. Set into the left column, at the right of the text. A horizontal line of apsides runs along the foot, with A at the left and P at the right. A perpendicular rises from it at C to D at the top. A circle (the epicycle) stands about E on that perpendicular, with D at its head. From T on the base line two tangents rise to the circle, to V on the left and to M on the right. A line rises from T, parallel to CD, to F, on the horizontal chord through E that ends at M.

- D (top of the perpendicular, at the head of the circle)
- E (on the perpendicular, centre of the circle)
- F (right of E, on the chord)
- M (right end of the chord, on the circle): tangent point
- V (left side of the circle): tangent point
- A (left end of the base line)
- K (on the base line, between A and C)
- C (on the base line, at the foot of the perpendicular)
- T (on the base line, right of C)
- P (right end of the base line)

For in the triangles ETV and ETM, right-angled at the contacts V and M, each of the acute angles will be known. When the two greatest and unequal digressions are added, the angle VTM will be known; TE, the common base of the similar triangles, bisects it. So ETM will be known, whose complement to a right angle is TEM, and from this the secant of TEM will be known in parts of which EM is the whole sine. And since EM is known by Problem 1 in parts of which EC, the radius of the eccentric, is 100000, ET will therefore be known in that kind of parts; and in the same parts, in the right-angled triangle ECT, CT will become known.

[Margin: A more universal solution of the problem.]

But if the centre E is not 90° from the apogee, then draw TF parallel to CD, the line of mean motion drawn from the centre of the ecliptic. So if the morning digression is less than the evening one, as is supposed in the figure, then when it is taken from the angle ETM, or from the half of the whole MTV, the angle ETF will be known, since it is known from elsewhere that CT, or EF, is far less than FM, and that the said remainder therefore subtends EF rather than FM. Since, then, EC and FT are parallel, CET will now be known; and ECT is supposed, being the distance of the centre E from the apogee. Therefore in triangle ECT, in parts of which EC is 100000, CT also will be known in the same parts: the eccentricity of the centre of the equant, or of the point about which the motion is uniform. When this is compared with the whole eccentricity treated in Problem 1, it will be established whether and by how much it differs from it. But in this treatise the same semidiameter of the epicycle is supposed at every place of the eccentric; and since we do not suppose that, as was established above, we shall have to proceed by another way.

[Margin: The opinion of Ptolemy, Regiomontanus and Copernicus on the difference between the eccentricities of the equant and the deferent.]

IX. In roughly this way, but with a more troublesome calculation than by secants, Ptolemy, Book 10, ch. 3, and with him Regiomontanus, Book 10 of the *Epitome*, prop. 4, finds the eccentricity of the equant of ♀, or TC, to be about 2° 30′ in parts of which the radius of the eccentric is 60. So, since by Problem 1 he had found the eccentricity of the deferent to be 1° 15′, he concluded that this is about half of that, and that the whole eccentricity of the equant is to be bisected to obtain the eccentricity of the deferent. By a somewhat different reasoning, Ptolemy, Book 9, ch. 9, and Regiomontanus, prop. 18, found that the semidiameter of the small circle varying the eccentricity of Mercury is about a third of the greatest eccentricity of the deferent, that is, 3 parts of which the radius of the eccentric is 60; that the eccentricity of the equant is the same number of parts; and that the centre of the said small circle has an eccentricity of 6 parts, and so has double the eccentricity of the equant, as I have already said in ch. 1, no. 4. But whether this itself is true, Regiomontanus, Book 9, prop. 20, urges us to test by examining whether this hypothesis agrees with many observations of Mercury, especially at the greatest digressions from the Sun; if, however, he says, *you wish to amuse yourself in play.*

[Margin: Copernicus's method for the eccentricity of ☿ and ♀.]

X. But Copernicus, Book 5, ch. 27, says that the whole and greatest eccentricity of the deferent of Mercury's epicycle is 948 parts of which the radius of the eccentric is 10000, but that the diameter of the small circle varying the eccentricity is 424 parts, and its semidiameter 212. To demonstrate these he uses the right-hand part of the following diagram, in which AB is the line of apsides of Mercury, and on it C is the centre of the Earth's annual orb, and I the centre of the small circle that varies the eccentricity of Mercury's orb and places its centre now at D, the point of greatest eccentricity, now at F, the point of least eccentricity, the one due to the equant itself, so that FD is the diameter of the small circle varying the eccentricity. Further, with the perpendicular CE drawn from C, which is to be the semidiameter of the annual orb, with the Earth placed at E, a quadrant distant from Mercury's apogee A, and with the semi-orb OHGQ of Mercury described from F, he draws to it the tangents EH and EG with the radii FH and FG, and finally he draws the straight line EF from the centre of the Earth to the centre of the orb.

Diagram. Set across the right column. A vertical line runs from A at the top to B at the foot, with O, C, F, I, D and Q on it in that order downward. A circle about F passes through O at its head and Q at its foot, with P on it at the upper left and H and G on its right; its right half is the semi-orb OHGQ. A small circle about I stands between F and D. From E, far to the right on the level of C, straight lines run to H and G and to F and C. From M, far to the lower left, straight lines run towards the upper arc and across the figure, with L near F; a dotted line runs from M to N, near the foot of the vertical.

- A (top of the vertical)
- O (on the vertical, top of the arc)
- H (upper right of the arc): tangent point
- C (on the vertical): centre of the annual orb
- K (right of C)
- P (upper left of the arc)
- F (on the vertical, below C)
- E (far right): the Earth
- L (left of F)
- I (on the vertical, in the small circle)
- D (on the vertical, below I)
- G (lower right of the arc): tangent point
- Q (on the vertical, below D)
- N (lower left, at the end of the dotted line)
- M (far lower left)
- B (foot of the vertical)

Further, taking from Ptolemy two greatest but unequal digressions of Mercury, observed when the Sun, and accordingly the Earth, stood a quadrant from the apogee of Mercury as regards mean motion, of which the morning one was 20° 15′ and the evening one 26° 15′, he concludes from them the whole

angle GEH, 46° 30′, and the half HEF, 23° 15′. And taking the smaller angle, that of the lesser digression, from the angle HEF, he concludes the angle CEF, 3°. Therefore in triangle CEF, right-angled at C, the remaining acute angle CFE is given, 87°, whose secant is FE, tangent CE, and whole sine CF. So, with CE, the radius of the annual orb, set at 10000 parts, he concludes FE as 10014 such parts, and from the proportion of the whole sine to the tangent CE he concludes CF as 524 parts of which the radius CE is 10000. So when CF is taken from the whole eccentricity of the deferent, which, as I said, in Problem 2 he finds to be 948 parts, there is left the diameter FD of the small circle, 424 parts, the semidiameter FI, 212, and the whole CFI, 736.

[Margin: Copernicus's view on the eccentricity of ♀.]

The eccentricity of Venus, moreover, he derives in Book 5, ch. 22, by a similar method from the greatest digressions at the mean distance from the apogee, but Ptolemaic ones; and he concludes that the whole eccentricity, or that of the equant, namely CD, is double the eccentricity of the deferent he had concluded in ch. 20, which here shall be CF. For he found this to be 208 parts, but CD to be 416 parts, and therefore the diameter FD of the small circle 208 parts, the semidiameter FI 104, and the distance of the centre of the small circle from the centre of the great orb, that is, CI, 312 parts, of which the radius of the annual orb is 10000. He ends chapter 22, however, by saying: *All these things that have been demonstrated about Venus are found to agree also with our times, so that what was formerly 416 parts in all is now 350, as many observations teach us.* Hence Kepler, ch. 15 of the *Mysterium Cosmographicum*, and Rheticus, in his first *Narratio*, infer that Copernicus believed that the eccentricity of Venus had decreased, as had the Sun's.

Finally, Copernicus holds that the motion of the centre of the eccentric on the small circle FD, in both ♀ and ☿, is double the mean motion of the Earth.

Problema 5. Inueſtigare an & quantum Semidiameter orbis Mercurij in Apogeo & Perigeo Eccentrici, differat à Semidiametro in Medijs diſtantijs.

Problem 5. To investigate whether and by how much the semidiameter of Mercury's orb in the apogee and perigee of the eccentric differs from the semidiameter at the mean distances.

XI. I said at no. 7 that Copernicus, and with him Lansbergen, the variation in the digressions of Mercury that are greater outside the perigee than at the perigee, explain away by a varied size of the epicycle. Copernicus investigated this variation in Book 5, ch. 27, in the immediately preceding diagram. For in triangle EHF, right-angled at the contact H, with angle HEF of 23° 15′, as we said at no. 10, he gathers by Problem 2 that the semidiameter of the orb FH, in this position of the Earth, namely when it is at mean longitude, or distant from the apogee of Mercury by a quadrant, is 3947 parts of which EF is 10000; but of which EF is 10014 and CE 10000, FH is 3953. Above, however, by Problem

2, when the Earth was at the apogee or perigee of Mercury, he had gathered the semidiameter of this orb to be 3573 parts of which the semidiameter of the annual orb CE is 10000. He therefore sets the difference of these semidiameters, shown by the line HK, at 380 parts, and accordingly the mean semidiameter at 3763. But although at the mean distances of the centre of the epicycle Mercury describes its largest orb, it does not for that reason undergo there the greatest of its greatest digressions, but lower down, around the thirds [trientes], because of its greater nearness to the Earth. At the perigee, on the other hand, where it ought to undergo the greatest, it does not undergo them, because it describes its smallest orb there.

[Margin: The threefold size of the semidiameter of the orb of ☿.]

Problema 6. Digreſſiones Mercurij maiores extra Perigeum, ex varia Orbis quantitate cum Copernico demonſtrare.

Problem 6. To demonstrate with Copernicus, from the varying size of the orb, that the digressions of Mercury are greater outside the perigee.

[Margin: Copernicus's three suppositions for the hypothesis of ☿.]

XII. Copernicus states in Book 5, ch. 28, that around the sides of the hexagon Mercury makes greater digressions from the mean place of the Sun than at the perigee of the eccentric, that is, at the places of the eccentric orb where it is distant from its apogee by 60° or 120° on one side or the other; indeed, greater than at the mean distances. This holds provided that three things are assumed. First, that the centre of the orb is carried round on the small circle of the anomaly of the eccentricity, with a double revolution to one revolution of the Earth itself (which for others is the mean motion of the Sun), beginning from the apogee of the small circle. Next, that Mercury librates along a straight line in the semidiameter of the orb, but according to the laws of another, imaginary small circle, whose anomaly likewise is double the mean motion of the Earth, and that it therefore describes now a larger, now a smaller orb around the Sun. Third, that the centre of this small circle is carried by the orb of Mercury having the mean semidiameter. With these things assumed, look at the left-hand part of the preceding diagram, in which the line of apsides of ☿ is AB, and on it the apogee A and the perigee B; C is the centre of the annual orb, and the Earth is at M, making angle MCB of 60°, so that it thus sees, on the opposite side along the line MC, the Sun distant in its mean place from A, the apogee of Mercury, by the same number of degrees; for in this way ACM will be 120°. Meanwhile the centre of the orb on the small circle FD, with its double revolution, that is, of 120° counted from D, will have completed the arc DL, subtended by angle DIL, and let the centre of the orb be at L. From L let the half-orb OPNQ be described, and to it from M let the tangents MP and MN be drawn, together with the radii LN and LP to the points of contact, at which Mercury is supposed to be when it digresses furthest from the mean place of the Sun. Finally, from M let two straight lines be drawn, one, ML, to the centre of the orb, the other,

MI, to the centre of the small circle FD. With these things assumed, it will be established that in this position, that is, at a hexagonal distance of the Sun from the apogee of Mercury and of the Earth from the perigee, the digressions are greater than at the perigee, as will appear presently in the Example.

EXEMPLVM Demonſtrationis Copernicanæ.

Example of the Copernican demonstration.

[Margin: 1. Step of the demonstration.]

XIII. First, since CI was shown by Copernicus to be 736 parts of which MC, the radius of the orb of the Earth, is 10000, as I said at the end of Problem 4, and angle MCB, that is MCI, has been set at 60°, from this angle and the sides CM and CI there follows, by the analysis of triangles, the third side MI of 9655 parts, and angle CMI of 3° 47′. By this amount the interior angle CIM, by 32 of Book 1 of Euclid, is less than the exterior angle MCA, now set at 120°. Therefore CIM is 116° 13′. But angle LID is also given as 120°, and accordingly FIL, or CIL, by 13 of Book 1 of Euclid, is 60°. When this is subtracted from angle MIC, there remains angle MIL of 56° 13′. With this, and with MI, already found to be 9655 parts, and IL, the semidiameter of the small circle, shown from what was said at the end of Problem 4 to be 212 parts, angle LMI of 1° 4′ is gathered trigonometrically. When this is taken from angle CMI, found above to be 3° 47′, there remains angle CML of 2° 43′. By this angle the centre of the orb of Mercury is separated from the mean motion of the Sun, indicated or seen from the Earth along the line MC; and from the same data side ML is gathered, of 9540 parts. Therefore in triangle MLP, side ML is known, and angle P at the contact is right, by 18 of Book 3 of Euclid. So, in order that we may know how large the angle PMI of greatest digression is in this hexagonal position, we must inquire into the size of the semidiameter of the orb, that is, LP.

[Margin: 2. Step.]

Second, then, let the star of Mercury be understood to librate on the small circle ADBF drawn alongside, whose diameter AB, from what was said in Problem 5, is 380 parts and its semidiameter CB 190, of which the semidiameter of the annual orb of the Earth is 10000. Let this diameter be understood to be a portion of the line PL of the preceding figure, whose anomaly is according to the laws of this small circle, just as if it took place on its circumference, and with as much motion as is the motion of the small circle performing the anomaly of the eccentricity, that is, double the mean motion of the Sun, counted from A. So in our case let the arc ADH of 120° be counted. When HK, the sine of arc HB, which is 60°, has been drawn, BK will be cut off, a versed sine of 95 parts, as is clear from 15 of Book 5 and 12 of Book 13 of Euclid's *Elements*, or from the tables of sines. For CK, the second sine of arc HB of 60°, is 5000 of which CB is 10000; therefore KB, the remainder of the radius, is 5000. So it will come out that as CB, 10000, is to 190, so KB, 5000, is to 95. Accordingly

the remainder AK will be 285 parts, namely the portion to be added to the smallest semidiameter of the orb, 3573, on which see Problem 5. And thus in the earlier figure the semidiameter PL comes out at 3858 parts, of which CE, or CM, is 10000.

Diagram. A small circle set into the right column, with a vertical diameter from A at the top to B at the bottom, and three horizontal chords crossing it: an upper one through I, the horizontal diameter through the centre C, and a lower one through K.

- A (top of the circle): end of the diameter
- G (left end of the upper chord)
- I (on the vertical diameter, at the upper chord)
- L (right end of the upper chord)
- D (left end of the horizontal diameter)
- C (centre)
- F (right end of the horizontal diameter)
- H (left end of the lower chord)
- K (on the vertical diameter, at the lower chord)
- M (right end of the lower chord)
- B (bottom of the circle): end of the diameter

[Margin: 3. Step.]

Third and finally, in triangle MPL, right-angled at P, from the sides ML, 9540 by step 1, and PL, 3858 by step 2, the angle PML of the greatest digression of Mercury from the mean place of the Sun is gathered as 23° 52′, and accordingly the whole angle PMN, from the morning and the evening digression, as 47° 44′, when the mean place of the Sun is distant from the apogee of Mercury by 60° and the Earth by 120°, that is, there in a trigonal, here in a hexagonal position. But when the Sun or the Earth is at the apogee or perigee of Mercury, the angle of digression consisting of the morning and the evening, by the Ptolemaic observations, on which see us in Problem 1, no. 3, and Copernicus Book 5, ch. 26, was only 42° 18′, because the evening one was 23° 15′ and the morning one 19° 3′. And when the Sun was at the mean distance from the apogee, or distant by a quadrant from the apogee of Mercury, the aggregate of the greatest morning and evening digression was 46° 30′, as is clear from the observations of Ptolemy, on which see no. 10, at the end of Problem 4. Therefore the greatest digressions of Mercury from the Sun are greater in the hexagonal position than at the perigee, and indeed than at the mean distance from the apogee, which was to be shown.

[Margin: Conclusion of the demonstration.]

[Margin: Copernicus's obscurity made clear.]

XIV. What has been said throws light on the beginning and the end of ch. 28 of Book 5 of Copernicus, which otherwise seemed obscure. For he begins thus: *From this, too, it will seem less surprising that around the sides of the hexagon of the circle Mercury makes greater digressions than at the perigee, since they are even greater than those we have just demonstrated, so that in one revolution of the Earth its*

orb was believed by the ancients to become nearest to the Earth twice; that is, because it makes greater digressions than those which in ch. 27 he had taught occur at the mean distances. And he concludes ch. 28 by saying: *So here it has become greater than both by one degree and 14′* [parte vna & ſcrup. XIIII.], *not because the orb of the planet is nearer to the Earth than it was at the perigee, but because the planet describes a larger circle here than there. All of this agrees with present as well as past observations, and flows from equal motions.* He said *than both* [vtroque] because by a slip of the pen he had written the sum of the perigee digressions as 46½° [Gr.XLVI. S.] in place of 44½° [XLIV. S.]; for that is how this copy is to be emended from ch. 26. So the aggregate of the hexagonal digressions is greater than the quadrantal ones by 1° 14′, but than the perigee ones by 3° 25′. It is also clear why in Book 5,

[Margin: *Metodum* [?] in Copernicus, and from it a slip of Copernicus, is corrected.]

ch. 25, he said that Mercury, especially in the time of Antoninus, used to make its smallest digressions from the Sun in Libra, and greater ones in Aries, yet not the greatest, which it makes in ♒ and ♊.

[Margin: Longomontanus's opinion on the eccentricity of ♀ and the semidiameter of the epicycle.]

XV. Let us now move on to Longomontanus. We do not repeat his diagrams here, which are sufficiently set out in ch. 4, nos. 2 and 3, because he shows the eccentricity of these planets, or the semidiameter of their orbs or epicycles, with no demonstrations offered a priori. Instead he works only a posteriori, testing which values best fit certain observations, and finally adopts those so tested, as if they would satisfy all observations. Since we have already set out this method of his, with our critique of it, on the occasion of the apogee, together with the observations he used, in ch. 8, from no. 7 to no. 10, there is no reason to repeat it, and we therefore send the reader there. It is enough to repeat that the semidiameter of the orb of Venus is set by him at 72248½, and the whole eccentricity at 3208, of which the radius of the eccentric is 100000; but the semidiameter of the orb of Mercury at 38500, and the whole eccentricity at 5685 parts.

[Margin: Kepler's measures and foundations.]

XVI. What Kepler determined on this point is gathered from the *Mysterium Cosmographicum*, the Rudolphine Tables and the *Epitome of Copernican Astronomy*. At p. 761 of that work he indicates the method of investigating the eccentricity that we set out beforehand in Problem 2. But at pp. 732 and 765 of the same work, and Hérigone after him in vol. 5, p. 765, he expresses the eccentricity of the centre of the ellipse from the Sun in parts of which the semidiameter of the planet's orb is 100000. In the same parts he sets the distances of the planet from the Sun, the other focus of the ellipse; among these the mean distance from the Sun is as large as the greater semidiameter of the ellipse. Boulliau, on the other hand, in Book 1 of the *Astronomia Philolaica*, expressed the Keplerian values in parts of which the semidiameter of the annual,

or great, orb of the Earth itself is 100000. He sets them, I say, as fitted to the harmonic proportions and intervals, and to the regular solids of which he had spoken in the preface to the *Mysterium Cosmographicum*: *The Earth is the circle that measures all; circumscribe a dodecahedron about it, and the circle enclosing this will be Mars. Circumscribe a tetrahedron about Mars, and the circle enclosing this will be Jupiter. Circumscribe a cube about Jupiter, and the circle enclosing this will be Saturn. Now inscribe an icosahedron in the Earth, and the circle inscribed in it will be Venus. Inscribe an octahedron in Venus, and the circle inscribed in it will be Mercury. You have the reason for the number of the planets.* It seems good, then, to gather here into a table, from Kepler, the eccentricities and the distances from ☉ of all these.

Planet	Eccentricity from ☉, in parts of which the radius of the planet's orb is 100000	Eccentricity from ☉, in parts of which the radius of the annual orb is 100000		Distance from ☉, in parts of which the radius of the annual orb is 100000
			Aphelion	1005207
♄	5700	54207	Mean	951000
			Perihelion	896793
			Aphelion	544708
♃	4822	25058	Mean	519650
			Perihelion	494592
			Aphelion	166465
♂	9263	14115	Mean	152350
			Perihelion	138235
			Aphelion	101800
♀	694	500	Mean	100000
			Perihelion	98200
			Aphelion	72900
☿	21000	8149	Mean	72400
			Perihelion	71900
			Aphelion	46955
Earth	1800	1800	Mean	38806
			Perihelion	30657

66

Kepler himself openly teaches, at p. 732 of the *Epitome of Copernican Astronomy*, that the measures of these orbs which we have set out in the little table were taken from Copernicus, and corrected and worked through by him to the harmonic intervals of the world, and at the same time to distances from the Sun that fit the five regular solids. He says: *These intervals have been built up from observation of the parallaxes of the orb, on which see below; but I have explained their archetypal causes in Book 4, fol. 454, from the* Mysterium Cosmographicum*, and fol. 471, from Book 5 of the* Harmonics. But more on these intervals in Book 9, where the harmonic system is treated. Meanwhile, however, I have chosen to give together the Keplerian eccentricities and distances from the Sun of the 5 planets, and the eccentricities in parts of which 100000 is both the radius of the planet's orb, as Kepler has it in the *Epitome* and Hérigone has it, and the radius of the annual orb of the Earth, as Boulliau has it and as Kepler himself assumes in the tables of equations of the Rudolphine Tables, though not without some disagreement with himself.

[Margin: Boulliau's inquiry into the eccentricities of ♀ and ☿.]

XVII. Boulliau, in Book 9, ch. 1, of the *Astronomia Philolaica*, chooses four greatest digressions of Venus from the Sun, two observed by Tycho and two by Iustus Byrgius [Jost Bürgi], instrument-maker to the Landgrave of Hesse. I have already reported these at ch. 8, no. 13, in the earlier little table along with the others, but they must now be separated from them, and there must be added from Boulliau both the equated anomalies of the Sun, and the distances of the Earth from the Sun corresponding to those anomalies, and the remaining things required for this business. The sequence of the observations, in the style of the new calendar, with the hours after noon reduced to the meridian of Uraniborg, is therefore as follows.

	Year	Month	Day	Time
I.	1592	March	2	$17^h\ 30^m$
II.	1594	December	27	$5^h\ 0^m$
III.	1600	February	21	$20^h\ 27^m$
IV.	1601	May	9	$8^h\ 30^m$

Look now at the following figure, in which the annual orb of the Earth, described from the centre O, is BCAD, and the line of apsides of the Sun and of the Earth is ♈ ♋. The orb of Venus, on the other hand, is ST, described from the centre I; F is the Sun; the eccentricity of the annual orb from the Sun

[66] The table is given as printed. In its last three rows the distance groups stand one row out of step with the eccentricities beside them: in the other rows each group differs from its mean by the second eccentricity (54207, 25058, 14115), whereas the group printed against ♀ differs by 1800, the Earth's figure; that against ☿ by 500, Venus's; and that against the Earth by 8149, Mercury's.

is OF, and that of the orb of Venus IF; and the line of apsides of Venus is ST, whose aphelion is S and perihelion T.

Diagram. Set in the right column. A large circle with a smaller circle inside it, off-centre towards the lower left of the large circle's interior. A vertical line runs from the top of the large circle to B at its foot. From the point at F straight lines radiate to points on both circles, including the tangents the text names.

- sign (top of the large circle, just right of the vertical line): two stacked loops on an upright stem; not identified [?]

- I (left of O)
- F (below the point from which the lines radiate)
- ♀ (large sign, left of I, inside the small circle)

Now Venus at the first digression was at G; at the 2nd, at V; at the 3rd, at *a*; at the 4th, at *d*. And the Earth at the 1st was at A, seeing Venus in ♍ along the tangent AG; at the 2nd it was at B, seeing Venus in ♒ along the tangent BV; at the 3rd it was at C, seeing Venus along the tangent C*a*, in ♍; finally, at the 4th the Earth was at D, seeing Venus along the tangent D*d*, in ♋. So when the already mentioned tangents have been drawn from the Earth to the places of Venus, and these places have been joined to F, which is barely perceptibly distant from the centre I of the orb of Venus, the angles at the points of contact come out, by 18 of Book 3 of Euclid, imperceptibly different from right angles. Therefore, given the true places of the Sun seen from the Earth along the lines AF, BF, CF and DF, and compared with the places of Venus, the angles of the greatest digressions of ♀ will be given, whose complements to the remaining right angle are the angles at the Sun; and from this the places of ♀ seen from the Sun will be established. And given the equated anomalies of the Sun, the distances of the Sun from the Earth will be given from the Philolaic table of the Sun, in parts of which the radius of the annual orb is 100000.

All of these stood as follows, in the order in which I listed the observations.

[Margin: 1. Step of the demonstration.]

True places of the Sun	Places of ♀ seen from the Earth
♓ 13° 58′ 37″	♍ 27° 17′ 36″
♍ 5° 48′ 51″	♒ 23° 1′ 36″

True places of the Sun	Places of ♀ seen from the Earth
♓ 3° 8′ 12″	♍ 16° 22′ 12″
♉ 19° 4′ 17″	♋ 4° 27′ 50″

Angles of digression of ♀ from ☉	Places of ♀ seen from ☉
FAG 46° 41′ 1″	♎ 27° 17′ 33″
FBV 47° 12′ 45″	♉ 23° 1′ 36″
FC*a* 46° 46′ 0″	♎ 16° 20′ 32″
FD*d* 45° 23′ 53″	♎ 4° 27′ 50″

Equated anomaly of ☉	Distances of the Earth from ☉
8^s 7° 34′ 24″	AF 99328
6^s 0° 18′ 48″	BF 99216
7^s 26° 40′ 44″	CF 99027
10^s 12° 44′ 33″	DF 101205

[Margin: 2. Step.]

Second, since in the already mentioned triangles, right-angled at the contacts, the angles of digression are given, and the bases, which are the distances of the Earth from the Sun, the distances of Venus from the Sun, in parts of which the radius of the annual orb is 100000, will not be hidden from a trigonometer. They stand in order as follows.

In the triangles	Distances of ♀ from the Sun
AFG	FG 72267
BFV	FV 72077
CF*a*	F*a* 72148
DF*d*	F*d* 72052

[Margin: 3. Step.]

Third, given the places of ♀ seen from ☉, and compared with the apogee of ☉ and its distance, the arcs on the circle of Venus corresponding to the coequated anomaly will be given. These arcs become known according to the technique indicated in Book 3, ch. 24, in method 4, and in this Book 7, section 2, ch. 8, no. 9, on the circle of the diagram below, in which let the line of apsides be MV and the aphelion V, and let the first observation be at A, the second at B, the third at Y and the fourth at D. For if the arcs AD, DB and BA are known from the differences of the arcs corresponding to the anomaly, the angles at the circumference will also be known, since they are half the angles at the centre, by 20 of Book 3 of Euclid's *Elements*; and the chords of those arcs, which are the sides of the triangles below, will not be hidden, from the tables

of sines. According to Boulliau the arcs, angles and chords or sides are as you see in the following synopsis.

Diagram. Set into the left column with the text running down its left side. A circle with a vertical diameter from V at the top to M at the foot and a horizontal diameter from C at the left to T at the right, crossing at I. Chords join B, D, A and others, and several short horizontal and vertical lines are ruled inside the upper right quadrant.

- V (top of the circle)
- O (on the vertical diameter, just below V)
- D (upper right of V, on the circle)
- B (upper left, on the circle)
- N (on the vertical diameter, level with B)
- E (right of N)
- X (upper right, on the circle)
- s (small italic letter, inside, below E and X)
- Y (right, on the circle, below X)
- H (on the vertical diameter, below N)
- F (inside, below s)
- G (on the vertical diameter, below H)
- A (right, on the circle, level with G)
- C (left end of the horizontal diameter)
- I (centre)
- L (on the horizontal diameter, right of I)
- K (on the horizontal diameter, right of L)
- T (right end of the horizontal diameter)
- ♀ (below the horizontal diameter, left of the vertical)
- M (foot of the circle)

Arcs	Angles	Sides
AD 22° 49′ 46″	ABD 11° 24′ 53″	AD 19792
DB 131° 26′ 14″	BAD 65° 43′ 7″	DB 91152
BA 205° 15′ 40″	BDA 102° 37′ 50″	BA 97489

[Margin: 4. Step.]

Fourth, as Boulliau taught in Book 1 of his *Astronomia*, the lines drawn from the umbilicus or focus of the ellipse, which here is the Sun, to the periphery increase from the point of perihelion to the quadrant in the ratio of the versed sines, and from the quadrant to the aphelion in the ratio of the right sines, and they decrease from the aphelion V to the focus in the ratio of the versed sines. Therefore the versed sines will be VG for the first observation, VN for the second, VH for the third and VO for the fourth, and the differences will be OG 216 for the first and fourth and ON 25 for the second and fourth. So, recalling the method given in Book 3, ch. 24, method 4, and Book 7, Section 2, ch. 8, no. 9, the ratio of the eccentricity of Venus and of the semidiameter of each

ellipse to the radius of the annual orb, and the aphelion, will be found in like manner through the following proportions.

[Margin: 5. Step.]

Fifth, then, as OG, or DF, is to DA, so ON, or DE, is to DS, of 2300 parts. From this angle DBX is gathered as 1° 24′ 3″ and arc DX as 2° 48′ 6″, being double it by 20 of Book 3 of Euclid; therefore BDX will be 134° 14′ 20″, and BV 67° 7′ 10″. But point B is the place of Venus seen from the Sun, which was ♉ 23° 1′ 36″. From this Boulliau gathers the aphelion in ♒ 0° 8′ 46″.

[Margin: 6. Step.]

Sixth, since arc DV is 64° 19′ 4″ and DT 25° 40′ 56″, with right sine DL 43358, and AT is 2° 51′ 10″, with right sine FL 4977, the remainder DF is therefore 38361. So let it be that as DF, or OG equal to it, 38361, is to the difference in the other kind of the parts OG, which we said is 216, so the radius 100000 is to 566; and that would be the size of the eccentricity of the orb of Venus. From these he gathers the perihelial distance of Venus as 71738, the mean as 72304 and the aphelial as 72870, of which the radius of the annual orb is 100000. But in ch. 2, from other observations of Venus, with similar obscurity and method, he gathers the aphelion of ♀ in ♒ 5° 19′ 43″, the eccentricity VI as 575 parts, the mean distance of Venus from the Sun as 72398 parts, the perihelial as 71823 and the aphelial as 72973, which he retains in ch. 4. By not dissimilar reasoning in Book 10, using, however, confirmations a posteriori through the agreement of the assumed hypothesis with the observations, he draws out the eccentricity of Mercury from the Sun as 8105 parts, the aphelial distance as 46690 parts, the mean as 38585 and the perihelial as 30480, of which the radius of the annual orb is 100000.

[Margin: Boulliau's conclusion on the eccentricity and the measures of the orb of ♀ and ☿.]

XVIII. Among other diagrams he uses this following one, which it may suffice to indicate, from his Book 10, ch. 1. In it the line of apsides of Mercury is PF, on which I is the centre of the annual orb PBF, and D the Sun, the focus of the ellipse; LEN is the orb of Mercury, DN the perihelial or least distance of Mercury from the Sun, and DL the aphelial and greatest. The half-difference of these reveals the eccentricity of the centre of the ellipse from the Sun, while their sum, halved, reveals the greater semidiameter of the ellipse and the mean distance from the Sun. The Earth is placed at three places: namely at A, from which it sees the Sun along AD, and along the tangent AE sees Mercury at E, there digressed furthest from the Sun; the difference of the true place of the Sun and the true place of Mercury, that is, the greatest digression, is angle DAE; and angle ADE is the difference of the place of the Earth seen along DA, and of Mercury along DE, seen from the Sun. Next, the Earth at B sees Mercury at K, and sees the same from C. But having sampled this indication, let us hurry on to other things.

Diagram. Set across the right column. A large circle with a vertical diameter from P at the top to F at the foot, and a smaller circle inside it, off-centre to the

right. From the point at D straight lines run out to C, A, E, B and other points; one line, from D through N towards L, is dotted.

- P (top of the large circle)
- A (upper right, on the large circle)
- L (on the smaller circle, on the dotted line)
- E (right, on the smaller circle)
- ☿ (large sign, inside the large circle, left of the smaller circle)
- I (on the vertical diameter)
- D (below I, where the lines meet)
- C (left, on the large circle)
- N (lower left, on the smaller circle, on the dotted line)
- G (below N)
- K (lower right of G)
- B (lower right, on the large circle)
- F (foot of the large circle)

XIX. But we, using observations selected chiefly from the preceding chapter, were never able to exhibit all of them by any change of a new hypothesis, much less by the hypotheses of others, although that labour wore us out with 300 analyses of triangles for Venus and nearly 500 for Mercury. So, compelled by necessity, we chose those measures which, of the more certain observations, all or most would yield, leaving the final refinement to the third volume, in case an abundance of the most certain observations should compel us to change the measures and numbers. Meanwhile, using the method a posteriori, we have judged that the eccentricity of Venus is by no necessity different from the solar eccentricity, and is therefore always 3460 parts of which the radius of the eccentric is 100000; and that the whole eccentricity of Mercury is 10000 parts, the mean 8000 and the least 6000, provided that it varies by libration on the diameter of the small circle, according to what was said in ch. 6.

[Margin: Our opinion on the eccentricity of ♀ and ☿.]

We noticed that the semidiameter of the epicycle of Venus varies not at all, or not very perceptibly, from the apogee of the eccentric down to the mean longitudes, and that as long as the centre of the epicycle is in the upper part of the eccentric, it is 73140 parts or as close to that as possible; but that when the centre of the epicycle is below the mean longitudes, it varies and shrinks more and more until it becomes least at the perigee, about 70140 parts; and that this variation takes place in the ratio of the second sines corresponding to the complement of the anomaly of the eccentric to the semicircle, or to its excess above the semicircle.

[Margin: And on the semidiameter of the epicycle of ♀.]

Finally, by the same inquiry the semidiameter of the epicycle of Mercury was found to be least at the apogee and at the perigee, 38500 parts, but greatest at the mean longitudes, about 45500 parts; and this variation takes place in the ratio of the second sines corresponding to the anomaly of the eccentric, or to its complement to the circle, if the centre of the epicycle is in the upper

part of the eccentric; or corresponding to the complement of that anomaly to the semicircle, or to its excess above the semicircle, if it is in the lower part. Granted, we know that some few observations resist this hypothesis; but they either reject all analogy with the many others, or require a far larger number of observations than those that exist so far, in order that the hypothesis may be fitted to them too.

[Margin: And on the semidiameter of the epicycle of ☿.]

SCHOLIA.

Scholia.

[Margin: Copernicus's excessive confidence in Ptolemy.]

I. Certainly trusting too much in Ptolemy's observations, Copernicus judged that the measures and the hypothesis, of Mercury especially, could satisfy all ages; and in Book 5, ch. 30, he did not hesitate to say: "We think it must be granted that the commensurations of the circles have remained from Ptolemy even now, since in other matters too they are not found to have misled the good earlier authors." And Mästlin, in a letter to Kepler printed after ch. 19 of the *Prodromus*, says that this is a monstrous assumption, since the eccentricity whether of the Sun or of the Earth, and indeed of Mars and of Venus too, having varied in Copernicus's opinion, gives rise to a suspicion of variation in the others. Kepler, however, who denies that the Sun's eccentricity has varied, is free of this suspicion as to the remaining planets.

[Margin: Cause of the digressions of ☿ in Aquarius and Gemini, according to Kepler.]

II. Kepler refers the reason why Ptolemy posited two places of the eccentric in Mercury, at which the centre of the epicycle seems to come closer to the Earth than at the perigee, to the elliptical figure that ☿ describes around the motionless Sun, and to the motion of the Earth. That is, when the Earth was in the 10th degree of Aries, formerly the perigee of Mercury, and the Sun at 10° of Libra, the shortest part of the line of apsides was turned toward the Earth, namely the perihelion of Mercury, situated in the 4th degree of ♉. So the Earth viewed the eccentric ellipse, which for Ptolemy was the epicycle, as trimmed at the sides with its lunules cut off, and therefore the epicycle appeared very small and more elevated. Likewise, when the Sun was seen to pass to Aries, or the Earth had crossed to Libra, the epicycle was again seen with its sides narrowed, the aphelion of Mercury tending toward the Earth, since the Earth was in ♎ and the aphelion of ☿ at about 4° of ♏. Therefore one cause of the epicycle's apparent smallness at the apogee remained at the perigee as well, namely the shortness of the transverse diameter of the ellipse. But conversely, when the Sun appeared in ♒ or in ♊, and the Earth had been carried to the 10th degree of ♌ or ♐, the greater diameter of the ellipse was presented to sight less obliquely, just as if the epicycle had become larger.

[Margin: Kepler's censure of the observations of Ptolemy, as begging them and dragging them to his own opinion.]

So Kepler, at any rate; yet he adds that the calculated numbers do not represent this exactly on both sides, and that Mercury does not wander in ♒ to the same extent as in ♊. He therefore asserts that the observations were sought out by Ptolemy and, as it were, begged from the ancients; and that, since they had been recorded crudely, they were easily fitted so that what happened in one third from the apogee of the eccentric would happen in the other third also. In Venus, the cause Kepler adduces ought to have presented the same thing; but because of its very small eccentricity from the Sun, the ellipse of Venus falls imperceptibly short of a perfect circle.

[Margin: The motions of ☿ and ♀ are neither circular nor uniform in actual fact, even in the hypothesis of Copernicus.]

III. From what has been said, especially about Mercury, it can be established that the celestial motions which Copernicus and his attendant Lansbergen so doggedly maintain to be both circular and uniform are not in fact such. For that libration of Mercury along the diameter of the small circle, by which the diameter of the orb varies, certainly takes place along straight lines, according to the increments and decrements of the second and versed sines, which are unequal in equal degrees of the periphery. And from that motion, together with the motion of the orb carrying that small circle or its diameter, or rather carrying Mercury as it nods away from or toward the Sun, Mercury must describe a kind of spire with a remarkable inequality of real motion. Copernicus seems tacitly to have met this objection in Book 5, ch. 28, with the words "all of which flow together from uniform motions". He did not say "come about", since no real part of the orb of Mercury moves along the periphery of that small circle, by which the recession from and approach to the Sun occurs; at most the motive force of Mercury, an Intelligence, say, looks to that small circle shining back in its own mind, just as we contemplate it on our sheets of paper, so as to receive from it the law for moving the star of Mercury away from the Sun or toward the Sun. Similarly, in Boulliau's hypothesis, rules are drawn out by means of a circle feigned in the imagination, for increasing or diminishing the lines of the ellipse according to the ratio of the sines of a circle in which there is nevertheless no real motion. And the same holds proportionally in Venus.

CAPVT XI.

Chapter XI.

De Motu & Epocha Anomaliæ mediæ Orbis ſeu Epicycli Mercurij & Veneris conſtituendis.

On establishing the motion and epoch of the mean anomaly of the orb, or epicycle, of Mercury and Venus.

[Margin: How many kinds of motion ♀ and ☿ have.]

I. It must be recalled that Venus and Mercury have a twofold principal motion (for the motion of the centre of the eccentric on the small circle, the motion of libration on the other small circle of Mercury, and the motion of the apogee of the eccentric are less principal than these). The first is that of the eccentric, by which, in the hypothesis of the Earth at rest, the centre of the epicycle of these planets moves; and this is as great as the mean motion of the Sun, and is begun from the same starting point and root. But in the hypothesis of a moving Earth it is the mean annual motion of the Earth itself, for in that hypothesis the annual orb plays the part of the ancient eccentric. If this motion is reduced by equations to the true or apparent motion, it then becomes irregular and anomalous. Therefore, by subtracting the motion of the apogee of these planets from the true motion of the Sun or Earth, the residual motion is truly called the anomaly of the eccentric, because it is irregular owing to the irregularity of the true motion of the Sun or Earth. But if the motion of the apogee is uniform in itself and is subtracted from the mean motion of the Sun or Earth, as is done in the older astronomy, it can be called the anomaly of the eccentric only by a kind of imperfect resemblance, since it has in it no anomaly or irregularity. The second motion is that by which the circumference of the Ptolemaic epicycle, or of the Copernican eccentric orb that takes the place of that epicycle, moves carrying the planet with it, or by which the planet moves on the epicycle or orb; and since this motion is irregular it is called the motion of the anomaly of the orb. Insofar as this motion exceeds the mean motion of the Earth, Copernicus, in Book 5, ch. 1, calls it the motion of commutation and the anomaly of commutation. The sum of this motion and of the mean motion of the Sun or Earth makes up the mean motion of longitude of these planets, and it is this that our discussion and our last labour concern in determining the second inequality of the motion in longitude of these planets.

[Margin: Authors on the investigation of this motion.]

How this is done is taught above all by Ptolemy, Book 9, ch. 10 and 13, on Mercury, and Book 10, ch. 4 and 5, on ♀, although he had proposed such motions earlier in Book 9, ch. 3; likewise by Regiomontanus, Book 9, from prop. 2 to 5 and props. 20, 22 and 23, on Mercury, and Book 10, prop. 6, on Venus; Copernicus, Book 5, ch. 22, 23, 29 and 30; Longomontanus, Book 2 of the *Theorica*, ch. 18, 19, 20, 21; Boulliau, Book 9 of his

Astronomia, ch. 2 and 8, on ♀, and Book 10, ch. 9 and 10, on Mercury. From these I shall briefly indicate the technique of collecting this motion, first crudely, then more finely.

[Margin: 1st precept, for finding the motion of the anomaly of the orb.]

II. First, count the greatest digressions from the Sun that immediately succeed one another and are of the same kind, that is, all morning or all evening, so that it may be known how much time passes from one morning digression to the next morning one made immediately after it, or from one evening digression to the next evening one. These times will indeed be found unequal; but from many revolutions of this kind (and the more of them you obtain from your

own and others' observations, the better), by choosing a middling one between the fastest and the slowest, you will be certain that within the given number of completed years only so many whole revolutions can be accomplished. For example, in 8 years no more epicyclic revolutions of Venus than 5, and in 46 years no more of Mercury than 145.

[Margin: 2nd precept.]

III. Second, from digressions observed in antiquity and from those observed recently, but with many centuries between the former and the latter, choose two of the same size and of the same kind, made at the same place of the eccentric, or at the same anomaly of the eccentric, with the Sun placed at the same anomaly of its own, one ancient and the other recent. Of this sort would be two morning digressions, each of 46° in ♀, or of 26° in ☿, if in both cases the Sun or the Earth were then distant from the apogee of these planets by 30° in the order of the signs, or were at the apogee of the eccentric of these planets, or at the perigee. For by Precept 1 it is established how many whole revolutions were made in so great an interval of years, but more crudely; in this way, by the rule of proportions, the same thing can be known more finely. For with these things set down, the planet has returned to the same point of the epicycle and the same distance from the apogee of the epicycle, and nothing remains over and above the whole revolutions. But if it is difficult to obtain two such digressions with the conditions already mentioned, use the following precept.

[Margin: 3rd precept.]

IV. Third, then, choose two very accurate observations of the true place of the same planet, especially when it has digressed furthest from the Sun, one very ancient and distant by a long interval of years, the other new, near the apogee or perigee of the eccentric. From the given commensurations of the orbs, and from the mean or even the true motion of the Sun or Earth, and from the observed true place of the planet, you will be able, according to whichever form of hypothesis you have chosen for the purpose (say the Ptolemaic, or the Copernican, or the Tychonic, etc.), to collect the angle of the prosthaphaeresis of the orb, and from it the arc of the epicycle by which the planet stood distant in both observations from the mean apogee of the orb or epicycle. That arc will be the very mean anomaly of the orb which you seek. This will also help in establishing the epoch of this anomaly. By distributing, then, the number of whole revolutions with its remainder, if there is any beyond the whole ones, over the number of years, days and hours by which the recent observation is distant from the ancient one, according to the rule of proportions, you will learn both how great the mean or uniform motion on the epicycle is, appropriate to any given time, and conversely how much time is required for completing a given arc of the epicycle by uniform motion.

[Margin: 4th precept.]

V. Weigh one pair or triple after another of observations of the place of Venus or Mercury, according to the form of hypothesis you have chosen, applying the motion of the anomaly of the orb found so far by the preceding precepts,

and see whether the difference of anomaly, that is, between the anomalies of the orb applied to the individual observations, agrees with the observations, or whether something should be added to or subtracted from them. The better observations for this will be those of pairs of greatest digressions, one evening and the other morning, taking their sum; and of these, better still are those made at the apogee or at the perigee of the eccentric, or at the mean longitudes, or pairs of digressions for each of the three places mentioned.

[Margin: An objection is dispelled, with a particular warning.]

For although the disagreement with the observations may be attributed not wholly to a badly established anomaly of the orb, but to the eccentricity, or the semidiameter of the orb, or the motion of the Sun, all of which require some filing, yet no other way remains for us except to examine, by more and more observations, the lines and numbers of the motions assumed in this way a posteriori. But if you see that some observations can be reconciled by no change with others more certain, and keep no analogy with them, you will rightly suspect the observations of being deceptive. Now it seems that some light should be added to the precepts by an example.

VI. But an example of the first precept is not needed, for Ptolemy, Book 9, ch. 3, from Hipparchus, and Copernicus, Book 5, ch. 1, have already handed down to us both the time owed to many whole revolutions and the revolutions corresponding to definite sums of days and hours, as I reported in Section 2, ch. 9, in connection with the three superior planets. The mean motions then derived by them and corrected by others I have indicated sufficiently in the small tables placed at the ends of the chapters, after the explanations of each of the hypotheses of the distinguished astronomers. Whatever else you may want for this I shall give at the end of this chapter. Let us therefore give an example for the other precepts, and in the form of the Copernican hypothesis, to which many are less accustomed; for from it you will easily gather by what reckoning and method to proceed in the others.

EXEMPLVM

3. Præcepti pro ♀.

In Forma Copernicæa, præmiſſa figuræ delineatione.

Example of Precept 3 for ♀, in the Copernican form, with the delineation of the figure set out first.

[Margin: Delineation of the Copernican figure.]

VII. Suppose one or even two greatest digressions of Venus from the mean place of the Sun to have been observed, one morning and the other evening, when the Earth by its mean motion was distant by 45° from the apogee of the eccentric of Venus; and let the morning digression be 47° 20′ and the evening one 45° 40′. You will then draw the figure thus. Bisect at B the line of apsides of Venus AD, whose apogee is A and perigee D; from B describe the Earth's

annual orb AED; and having counted from A, in the order of the signs, 45° of the anomaly of the eccentric, that is, the arc AE, place the Earth at E, and join it to the centre of the annual orb, or of the mean motion of the Earth, by the straight line BE, which will be the radius of the annual orb, taken by Copernicus to be 10000 parts. Next, taking BK of 312 parts, by which, in Copernicus's opinion, the centre of the small circle producing the anomaly of the eccentricity is distant from the centre of the Earth's annual orb, from centre K, at the interval CK of 104 parts, describe the small circle CFL, if the observation is ancient and close to the times of Ptolemy; but if it is recent and nearer to the time of Copernicus, let BK be 246 parts and CK, as above, 104. Since the centre of the orb of Venus moves on the periphery of this small circle from its perigee C toward the same parts toward which the Earth moves, but with a doubled motion, and the mean motion of the Earth has been set at 45°, you will count twice as many degrees, that is 90, from C to F, that is, the arc CF; and from F as centre you will describe the orb of Venus INHM, whose diameter IH you will draw parallel to the line of the Earth's mean motion, that is, to line BE. And with the star of Venus set at N, the point of morning digression, and at M, the point of evening digression, you will draw to

Diagram. The Copernican delineation for Venus, set in the right column. A large circle, the annual orb, has A at the top and D at the bottom, joined by the vertical line of apsides, with B near the middle of that line. E stands on the upper left of the large circle, with lines running from it down to the inner figures. A smaller circle, the orb of Venus, lies within, carrying I at upper left, N at the left and M at the right, each with a star-shaped mark, H at the lower right, and G just below its lower edge beside the line of apsides. A much smaller circle lies around K, with F on its left and L below it, and a small C at the top of the small circle, just below B. A dashed line runs from P on the upper right of the large circle, through the inner figures, to Q at the lower left of the large circle.

- A (top of large circle): A
- D (bottom of large circle): D
- E (upper left of large circle): E
- P (upper right of large circle): P
- I (upper left of orb of Venus): I
- N (left of orb of Venus, star-shaped mark): N
- M (right of orb of Venus, star-shaped mark): M
- H (lower right of orb of Venus): H
- G (just below the lower edge of orb of Venus, beside the line of apsides): G
- B (on the line of apsides): B
- K (centre of the small circle): K
- F (left of the small circle): F
- L (below the small circle): L
- C (top of the small circle, just below and left of B; set small): C

• lower end of the dashed line: Q it from the Earth the tangents EN and EM; and you will join the points of contact by the straight lines FN and FM with the centre of the orb of Venus, so that angles N and M become right, by III.18 of Euclid's *Elements*. Therefore, with EF drawn from the Earth to F, the centre of the orb, triangles ENF and EMF will be right-angled at N and M. Finally, from the Earth to the centre of the small circle you will draw the straight line EF [recte: EK], and through the centres of the orb of Venus and of the annual orb the straight line PBFQ, and KF, the semidiameter of the small circle. The portion BF will be the eccentricity of the centre of the orb of Venus.

[Margin: Distinguishing the true and the mean apogee in the hypothesis of Copernicus and of Ptolemy.]

With this done, G will be the true apogee of the orb of Venus, at which Venus, if she were there, would be furthest from the Earth placed in such a position; for this apogee, like the true apogee of the epicycle in the Ptolemaic hypothesis, is marked by the straight line EFG, drawn from the centre of the Earth through the centre of the orb or epicycle to the opposite point of its periphery. But the mean apogee will be H, marked by the line IH, as being parallel to line BE of the Earth's mean motion, drawn through the centre of the mean motion of the planet, which in this hypothesis is the motion of the Earth, whose annual orb supplies the place of the Ptolemaic eccentric. In the same way, in the Ptolemaic hypothesis the mean apogee is marked by a line drawn from the centre of the equant eccentric, that is, from the centre of mean motion, through the centre of the epicycle to the opposite point of the periphery of the epicycle. Now suppose, around the times of Ptolemy, the apogee of Venus A at 25° of Taurus; for thus the Earth E will have been, from the observations set down, at ♋ 10°, as being 45° distant from A, and from there it will see along line EB the mean place of the Sun under the 10th degree of ♑. Therefore Venus at N, in the morning, distant from that place by 47° 20′ against the order of the signs, and seen from the Earth along line EN, was at ♏ 12° 50′. But Venus at M, in the evening, distant from the same place by 45° 40′ in the order of the signs, and seen along line EM, was at ♒ 25° 40′. With these things properly understood, let the places of Venus be examined by the following method.

EXEMPLVM.

Calculi Geometrici.

Example of the geometrical calculation.

[Margin: Step 1.]

VIII. First, in triangle KEB, the radius BE, 10000, is given, and BK of 246 parts, and angle KBE of 135°, as the complement to two right angles of angle ABE, set at 45° as the anomaly of the eccentric. So by the laws of triangles KEB will be 1° 18′ [recte: 1° 8′, per the book's errata], and therefore BKE 43° 52′, by I.32 of the *Elements*, and the base KE 10203 parts.

[Margin: Step 2.]

Second, in triangle KEF, side KE of 10203 parts is now given, and FK, the semidiameter of the small circle, of 104 parts; and angle FKE is known by subtracting BKE, found to be 43° 52′, from the doubled anomaly of the centre, that is, from angle CKF of 90°. So FKE is 46° 8′. Therefore, by trigonometry, angle KEF is 0° 25′ and side EF 10133.

[Margin: Step 3.]

Third, adding angles BEK and KEF gives angle BEF of 1° 33′, which is the prosthaphaeresis of the centre, to be subtracted (since the Earth is within the first semicircle of the anomaly of the eccentric) from the mean place of the Sun, which was ♍ 10°; and there remains the eccentric place of Venus, that is, the place of the centre F, seen along line EF, at ♍ 8° 27′. But Venus at M, in the evening, is taken as observed at ♒ 25° 40′. So the difference of the true place of Venus from the place of the centre, that is, the equation of the orb, was 47° 13′, namely angle MEF. Conversely, Venus in the morning at N was observed at ♏ 12° 50′. So the difference between the apparent place of Venus and the place of the centre was 55° 37′, namely angle FNE, which follows from the data of the fictitious example, even though in fact the equation of the orb of Venus can never be 55° 37′.

[Margin: Step 4.]

Fourth, in triangle MEF, angle MEF has now been found, 47° 13′, by the third step (or, from Copernicus, the semidiameter FM of the orb of Venus is 7193), and the angle at M is right, because this was a greatest digression. So, without side EF, angle EFM can be found at once, as the complement of angle MEF to a right angle; EFM is therefore 42° 47′. But if the observed digression were not greatest, or you were unsure of it, use side EF, found by step 2 to be 10133 parts, and with it and the semidiameter FM and angle FEM, find angle EFM; add to it angle EFI, which is as great as BEF, that is, 1° 33′, because of the parallelism of lines BE and HI, which makes the alternate angles equal, by Euclid I.29. For the whole angle IFM results, which here is 44° 20′, and so great is the arc MI; when it is subtracted from the semicircle IMH, there remains the arc of the mean anomaly of the orb MH, 45° 40′, as counted from the mean apogee of the orb in the order of the signs. But if you wished to consider Venus placed at N, with angle NFE found as above, angle EFI would have to be subtracted from it, and the remaining angle IFN, that is, arc IN, would have to be increased by the semicircle HMI, so that the arc of mean anomaly HMIN, computed from the mean apogee H in the order of the signs, might become known.

[Margin: Use of the already mentioned calculation, and conclusion of the procedure.]

IX. It is clear, then, by what device, even from a single place of Venus properly observed, whether at a greatest or at a not-greatest digression, the mean anomaly corresponding to the time of observation is to be gathered. So in this way let two places of Venus, one very ancient, the other new, be

observed after a long stretch of years, and from them let the mean anomaly be found; from the number of years you will gather by the first precept the whole revolutions of this anomaly, and besides them the remainder, if there is any. Thus if in the second observation the anomaly HMN was found to be 140°, and in the earlier one HM 45° 40′, apart from the whole revolutions, the remaining arc MIN will be 94° 20′. You will then reason like this: if in so much time, or so many years, days, hours and minutes (the time, that is, being resolved into minutes), Venus beyond the whole revolutions completed 94° 20′, then in one year or one day (first resolved into minutes) how many degrees and minutes will it complete on its orb by uniform or mean motion? And you will proceed similarly with Mercury.

[Margin: A universal rule for any hypothesis using circles.]

In other hypotheses too, after finding the equation of the centre, and from it the place of the centre and the distance of the centre of the orb or epicycle from the Earth, what has to be sought is not the equation of the orb, since that is known from the true observed place of Venus and from the place of the centre. Rather, from that equation, the semidiameter of the epicycle and a right angle, if it is a greatest digression, or from the already mentioned distance, the arc of the epicycle must be sought, subtended by the angle made by that distance and by the semidiameter of the epicycle. To this arc the equation of the centre must be added, if it was subtractive with respect to the centric place; and then the complement of the arc so increased to the semicircle will be the desired mean anomaly of the orb. But if the equation of the centre was additive, it must be subtracted from the already mentioned arc of the orb or epicycle, and to the remainder of the arc a semicircle must be added, to obtain the mean anomaly of the orb.

[Margin: Mean motion of ♀ and ☿.]

Moreover, when the digressions reported in ch. 9, no. 2, are examined by this technique, the mean annual motion of Venus is found to be 225° 1′ 53″ 35‴, and that of Mercury 53° 57′ 33″ 32‴, so that in Venus Lansbergen, and in Mercury Kepler and Longomontanus, are in this respect nearer the truth.

De Epocha motus huius.

On the epoch of this motion.

X. On establishing the epochs of this motion there is no need to say more. For once the mean anomaly has been found from some exact observation made at a definite time, and from its mean motion corresponding to the given interval of time, the place of the planet on the epicycle, computed from the mean apogee, that is, the anomaly of the orb, is easily carried over to any other time. And we have set our own roots at the end of ch. 6.

De Periodis motuum Veneris ac Mercurij.

On the periods of the motions of Venus and Mercury.

[Margin: Authors from whom the following table comes.]

XI. This section must be closed with a periodic table of the motions, which I promised here at no. 6 and in Sect. 2, ch. 9, no. 1. It was supplied to us, according to the mind of Ptolemy and of the Alphonsines, by al-Farghānī, diff. 17; Reinhold on Peuerbach's *Theoricae*, pp. 105 and 130; Wurstisen in the same place, p. 198; Maurolico at the end of the *Cosmographical Dialogues*; Clavius at the end of the *Sphere*; Anton Deusing and Gassendi in the *Institutio Astronomica*, Book 2, ch. 7; and Hérigone in vol. 5 of the *Cursus Mathematicus*, pp. 534 and 541. But either from their own opinion or according to the mind of Copernicus, it was supplied by Magini, Canon 33 of the *Secunda Mobilia*, and from him by Baranzanus, part 2 of the *Uranoscopia*, p. 158; by Kepler, ch. 1 of the *Mysterium Cosmographicum* and in the *Epitome of Copernican Astronomy*, p. 760; by Langius in the *Theoricae Planetarum*, ch. 12 and 13; and by Antonín Maria Šírek in the *Radius Sidereomysticus*, Book 1, ch. 2, and Book 3, ch. 1. The motion of these planets on the epicycle can, moreover, be considered together with the motion of the Sun, whose mean motion concerns their system and is common to them, as something intrinsic to their whole motion, as happens in the Ptolemaic hypothesis. On this reckoning the motion of Venus on the epicycle takes about 19 months, or 584 days etc., and that of Mercury about 4 months, or 115 days. For in that much time, by their mean motion on the epicycle, but with the Sun's motion supposed to advance meanwhile, they revolve from the mean apogee of their epicycle to the same mean apogee, from one mean and apogeal conjunction to the next apogeal one, and from one greatest digression to another of the same kind, for example from one evening digression to another evening one. But if their motion is considered around the immobile ☉, according to Copernicus, and the motion of the Earth is not their motion but an extrinsic parallax, or commutation of sight, then Venus runs through its epicycle, or rather its orb, by mean motion in 224 days etc., and Mercury in about 88 days; that is, the former in 7 ½ months, the latter in about three months. In that time Venus, it is true, appears to the moving Earth to complete the whole zodiac, whereas Mercury, because of its speed and narrow orb, does not appear to the Earth to have completed it, except in so far as it appears direct. But here are the tables promised more than once above.

SECTIO QVARTA

Section Four

DE PASSIONIBVS QVINQVE PLANETARVM MINORVM SECVNDVM LATITVDINEM.

On the affections of the five minor planets according to latitude.

CAPVT I.

Chapter 1

Obſeruationes, & Hypotheſes Veterum Aſtronomorum de Latitudine Quinq. Planetarum.

Observations and hypotheses of the ancient astronomers on the latitude of the five planets.

[Margin: Three kinds of passions in the planets.]

I. The affections, or affections and properties, of these planets belong to them in some cases according to latitude, that is, their recession from the ecliptic; in others according to longitude; and in others, finally, according to altitude. I have therefore decided to set out the doctrine on them separately, in the three sections that follow.

[Margin: The reason for the order in explaining these passions.]

We begin with latitude, both because, as Copernicus observes in the preface to Book 6, the digressions of these stars from the ecliptic make no small difference to their appearances, their occultations at rising and setting, and the other things to be discussed next; and because their true places are said to be known only when their longitude has been established together with their latitude. Latitude therefore had to be joined to longitude at once. Moreover,

the aids and instruments by which their longitude is observed will also serve to observe their latitude, whether by astrolabes or zodiacal armillaries, by the Arabic torquetum, by azimuthal quadrants, by Tychonic sextants, with which the distance of a planet from two fixed stars of known longitude and latitude is taken, or by whatever other instrument among those I have set out in my *Liber Organicus*, which, God willing, will be the second book of the second volume of my *Almagest*. What, then, the ancients, and Ptolemy above all, observed by these means concerning the latitude of these stars and the inclinations of the orbit to the ecliptic, or also of the epicycle to the plane of the orbit; and by what theory they themselves, or the Alphonsines and Peuerbachians, used to show these alternations, I shall gather in this one chapter, from what has been handed down to us by Ptolemy, Book 13, ch. 1 to 6; al-Battānī, ch. 47; al-Farghānī, diff. 18; Jābir ibn Aflaḥ, Book 9 of the *Astronomy*; Proclus in the *Hypotyposes*, ch. 3, 4, etc.; Peuerbach in the theory of the latitude of the planets, and there above all Nonius, annotation 9; Wurstisen from p. 373; Reinhold from p. 215; Franciscus Sarzosus [Francisco Sarzosa] in the *Aequator Planetarum*, Book 2, ch. 21; Regiomontanus in the *Epitome of the Almagest*, Book 13; Copernicus, Book 6; and Magini, Book 2 of the *Theoricae* from ch. 3 to 11, and Canons 49 and 50 of the *Secunda Mobilia*.

De Latitudine Obſeruata, eiuſq. conditionibus in tribus Superioribus Planetis.

On the observed latitude and its conditions in the three superior planets.

II. When the latitude of these planets had been observed at various times, partly by his predecessors and partly by himself, Ptolemy detected the following properties.

[Margin: 1st property of the latitude of ♄, ♃, ♂.]

First, the latitude of the three superior planets is northern whenever the centre of the epicycle is in that segment of the eccentric in which the apogee of the eccentric lies, and southern when it is in the segment in which the perigee lies.

[Margin: 2nd property.]

Second, they stay longer in northern latitude than in southern.

[Margin: 3rd property.]

Third, the greatest northern latitudes occur around the apogee of the eccentric, and the southern around the perigee; yet the southern are greater than the northern, that is, the perigeal than the apogeal.

[Margin: 4th property.]

Fourth, other things being equal as regards position on the eccentric, the latitudes, both northern and southern, are greater when the planet is at the perigee of the epicycle, and so near opposition with the Sun and in acronychal position, than at the apogee of the epicycle, or near conjunction with the Sun. From this and the preceding it follows that the greatest latitudes of all are those

southern ones which occur when the centre of the epicycle is placed in the lower or perigeal segment of the eccentric, and the planet at the perigee of the epicycle.

[Margin: 5th property.]

Fifth, Ptolemy found in his time the limit of greatest northern latitude: that of Mars near the end of Cancer, where he had also found its apogee, very nearly; that of Jupiter 20° from the apogee of the eccentric in the order of the signs, or around the beginning of Libra; and that of Saturn 50° away, but in præcedentia of the apogee of the eccentric, which is likewise around the beginning of Libra, since he believed the apogee of Mars to lie at the end of Cancer, that of Jupiter at about the 10th degree of Virgo, and that of Saturn at the 20th of Scorpio. From this it is inferred that Mars is at the apogee of the eccentric and at greatest northern latitude at the same time, and conversely undergoes its greatest southern latitude at the perigee of the eccentric; but that Jupiter's epicycle reaches the apogee of the eccentric before it reaches the limit of greatest northern latitude, and likewise reaches the perigee of the eccentric before the limit of greatest southern latitude; and conversely that Saturn's epicycle reaches the limit of greatest and northern latitude much sooner than the apogee, and by as much sooner the limit of greatest southern latitude than the perigee of the eccentric.

[Margin: 6th property.]

Sixth and last, comparing the places of the most ancient limits with the places found in his own age, Ptolemy recognized that the places of the limits, and those a quadrant away from them, the places of the nodes, move with a very slow motion in the order of the signs, and indeed with a motion imperceptibly different from the motion of the fixed stars and apogees, that is, 1° in 100 years. The Alphonsines accepted this property, but adapted it to their own motion of the fixed stars.

Theorica Ptolemaica & Alphonſina Latitudinis Planetarum Superiorum.

The Ptolemaic and Alphonsine theory of the latitude of the superior planets.

III. From the properties already mentioned, with the eccentric and epicycle now taken as assumed for demonstrating the motion in longitude, Ptolemy and all the Arabs after him, with the Alphonsines and Peuerbachians, laid down the following hypothesis on the motion in latitude, which I shall set out point by point.

[Margin: 1st part of the hypothesis.]

First, the planes of the eccentrics that carry the epicycles cut the plane of the ecliptic at the centre of the world, so that the greater segment of the eccentric is inclined towards the north and the lesser towards the south. The axis of the eccentric of Mars, lying very nearly in the same plane as the axis of the ecliptic, nearly intersects the axis of the ecliptic, or rather is inclined to it in as nearly

the same plane as possible; but the axis of the eccentric of Saturn and of Jupiter does not lie in the same plane as the axis of the ecliptic but in a very different one, because the points of greatest latitude do not lie at the apsides themselves, not even very nearly, as in Mars. Moreover the two diametrically opposite points at which the plane of the ecliptic is cut by the eccentrics are called nodes (as was said of the Moon). At them no latitude occurs, and they are always 90° on either side from the limits, or termini, of the greatest latitudes.

[Margin: 2nd part.]

Second, the angle of inclination by which the eccentric of these planets is obliquely inclined to the ecliptic is constant and of one and the same quantity. This angle arises at the centre of the world and is gathered from the greatest latitude, the semidiameter of the deferent, and the semidiameter of the Sun's annual orb, as I shall show below. By his calculation Ptolemy found it to be 2° 27′ in Saturn, 1° 24′ in Jupiter, 1° 0′ in Mars. This inclination of the eccentric is called, to distinguish it from the inclination of the epicycle, [Greek: ἔγκλισις τοῦ ἐκκέντρου (enklisis tou ekkentrou, "inclination of the eccentric")].

[Margin: 3rd part.]

Third, since at the same places of the eccentric a differing greatest latitude was found, none at the nodes, and a greater one at the true perigee of the epicycle than at its apogee, this phenomenon could not be satisfied by the inclination of the eccentric alone. Recourse had to be had to an inclination of the plane of the epicycle to the plane of the eccentric, one not fixed or constant, however, but variable. The Ptolemaics and Alphonsines therefore laid down that the epicycle librates on its axis, that is, on a straight line drawn through the centre of the epicycle to the points on the epicycle's circumference a quadrant distant from the true apogee of the epicycle, at which the mean longitudes from the aux of the epicycle occur. For this reason they call this axis the diameter of the mean longitudes, while the straight line bisecting it at right angles is called the diameter of the apsides of the epicycle. This libration is carried out as follows. When the centre of the epicycle is placed at the nodes, the plane of the epicycle coincides with the plane of the ecliptic, and so no latitude arises for the planet at any point of the epicycle; yet the diameter of the mean longitudes then declines from the plane of the deferent. As the centre of the epicycle recedes from the northern node, the plane of the epicycle gradually recedes more and more from the plane of the eccentric, towards the north as regards the perigee and towards the south as regards the apogee of the epicycle, until at the northern limit the inclination becomes greatest. After that, the recession of the plane of the epicycle from the plane of the deferent diminishes, until at the other node it becomes least. Then, as the centre of the epicycle recedes from the southern node and traverses the semicircle, or nearly the semicircle, of the southern segment, the perigee of the epicycle bends towards the south and the apogee towards the north, until at the limit of greatest southern latitude the inclination becomes greatest. In both places the quantity of the inclination was found by Ptolemy to be 4° 30′ in Saturn, 2° 26′ or 30′ in Jupiter, 2° 15′ in Mars.

[Margin: 4th part.]

Fourth, then, to bring about this libration of the epicycle, those who have embodied the Ptolemaic circles in matter, as Peuerbach and Magini did, add a certain small orb containing the epicycle within itself. This orb is to move on four equal small circles, two of which adhere to the eccentric, one opposite the apogee and the other opposite the perigee of the epicycle; and on the circumference of these stand the other two, on whose circumference the apogee and perigee of that small orb are fixed, and which are to move with a motion double the motion of the first small circles and in the contrary direction.

From all this the following corollaries are deduced.

[Margin: 1st corollary.]

First, the axis of the epicycle is never parallel to the axis of the deferent, nor to the axis of the ecliptic outside the nodes; at the nodes, however, it is always parallel to the axis of the ecliptic.

[Margin: 2nd corollary.]

Second, the body of the planet, outside the nodes, in the upper part of the epicycle, lies within the ecliptic and the orbit of the eccentric; but in the lower part of the epicycle it lies outside both, and farther from the ecliptic than the plane of the eccentric.

[Margin: 3rd corollary.]

Third, because of the motion of the epicycle in latitude, the apogee of the epicycle, whether mean or true, does not fall on the line drawn from the centre of the Earth or of the equant through the centre of the epicycle, although they are usually determined by such lines when the discussion concerns longitude alone, abstracting from latitude.

This is the sum of the old theory of the latitude of these three planets, which cannot be represented in a plane but instead instruments skilfully built for the purpose are needed. For those endowed with the power of imagination, however, it will not be difficult.

De Latitudine, Inclinatione, & Reflexione Veneris ac Mercurij.

On the latitude, inclination and reflection of Venus and Mercury.

[Margin: Threefold difference of latitude in ♀ and ☿.]

IV. According to Ptolemy's observation and opinion, Venus and Mercury have a threefold variation in latitude. The first of these is called [Greek: ἔγκλισις ἐκκέντρου (enklisis ekkentrou, "inclination of the eccentric")], that is, the inclination of the eccentric, or the Deviation of the plane of the eccentric from the plane of the ecliptic. The second is called [Greek: ἔγκλισις ἐπικύκλου (enklisis epikyklou, "inclination of the epicycle")], namely the Inclination or Declination of the plane of the epicycle to the plane of the eccentric, by which the diameter of the apsides of the epicycle librates this way and that, towards north and south. The third is called in these planets simply [Greek: λόξωσις

(loxōsis, "obliquation")], or Obliquation [Obliquatio] or Reflection [Reflexio], by which the diameter of the mean longitudes of the epicycle is bent transversely from west or east towards north or south. One node Ptolemy, Book 13, ch. 1 and 2, calls the node of the subtracting semicircle, because it lies in that half of the eccentric's semicircle in which the equation of the centre is subtracted from the mean centre, or from the anomaly of the centre; the other node he calls the node of the adding semicircle, because it lies in that half of the eccentric's semicircle in which the equation of the centre is added. So much for the terms.

Deuiationis Leges.

Laws of the Deviation.

V. First, when the centre of the epicycle precedes the apogee of the equant by 90°, it is at the node of the Dragon's Head, or ascending node, and then there is no Deviation of the plane of the eccentric from the plane of the ecliptic; the two lie folded together in one common plane.

[Margin: Deviation in the 1st quadrant.]

Second, when the centre of the epicycle ascends from the node of the Head towards the apogee of the equant eccentric, the Deviation gradually increases until, when the centre of the epicycle occupies the apogee, it becomes greatest: in Venus 10′, and to the north; in Mercury 45′, and to the south.

[Margin: 2nd quadrant.]

Third, when the centre of the epicycle begins to descend from the apogee of the equant, the Deviation begins to diminish, and it decreases continuously until at the node of the Tail it vanishes altogether and the planes are again united in one and the same plane.

[Margin: 3rd quadrant.]

Fourth, when the centre of the epicycle has receded from the node of the Tail towards the perigee of the equant, the Deviation of the eccentric begins to grow, and it increases continuously until at the perigee itself it becomes greatest: in Venus 10′ to the north, in Mercury 45′ to the south. For as soon as the centre of the epicycle passes the descending node, the part of the eccentric in which the epicycle lies begins to verge north in Venus and south in Mercury.

[Margin: 4th quadrant.]

Fifth, once the perigee of the equant has been passed, the centre of the epicycle begins to ascend towards the apogee, and the Deviation to diminish, until it again becomes nil when the centre of the epicycle holds the ascending node. Thus, together with the eccentric revolution, one period of the Deviation is completed.

[Margin: 1st corollary. Situation of the nodes on the eccentric.]

From this you will gather, first, that the nodes of the eccentric and the ecliptic (which we shall call the nodes of the Deviation) lie at the mean longitudes of the eccentric, 90° distant on one side from the apogee and on the other from the perigee of the eccentric; and that the limits of greatest Deviation lie on the

very line of apsides of the eccentric, although these are not the limits of greatest latitude of all.

[Margin: 2nd corollary.]

Second, gather that the centre of the epicycle of Venus is always in that segment of the eccentric which verges to the north, and the centre of the epicycle of Mercury always in that which verges to the south, even though the other part of the eccentric is meanwhile bent to the opposite quarter.

[Margin: 3rd corollary.]

Third, that the axes of the deferents of Venus and Mercury nod this way and that, approaching and receding from the poles of the zodiac, and that the inclination called Deviation, or the inclination of the eccentric to the ecliptic, is not fixed, as in the three superior planets, but inconstant. Regiomontanus adds, Book 13, prop. 5, that while the latitude of Venus is greatest, that of Mercury is least or nil, and vice versa.

Inclinationis & Reflexionis Epicycli leges.

Laws of the Inclination and Reflection of the epicycle.

VI. The Inclination too, by which the plane of the epicycle with its diameter of apsides is inclined to the plane of the eccentric, is wonderfully attuned to the motion in longitude, but in a way exactly opposite to the Deviation.

[Margin: Inclination and Reflection.]

For first, when the centre of the epicycle occupies the apogee of the equant, the diameter of the apsides of the epicycle does not decline at all from the plane of the eccentric; but the diameter of the mean longitudes of the epicycle is twisted transversely, so that its left, or eastern, half is bent with the greatest Reflection, 3° 30′ to the north in Venus and 7° to the south in Mercury, the other half being turned transversely to the opposite quarter.

[Margin: 1st quadrant.]

Second, as the centre of the epicycle recedes from the apogee of the equant, the Reflection begins to diminish and the Inclination of the epicycle to arise, the apogee of the epicycle of Venus being inclined to the north and that of Mercury to the south, and the perigees to the opposite sides. From there the Reflection continuously decreases and the Inclination increases, until the centre of the epicycle comes to the descending node. For there all Reflection vanishes, and the Inclination of the apogee of the epicycle becomes greatest: of Venus 2° 30′ to the north, of Mercury 6° 15′ to the south.

[Margin: 2nd quadrant.]

Third, as the centre of the epicycle descends from the southern node towards the perigee of the equant, the already mentioned Inclination stays on the same sides but gradually diminishes, until it vanishes at the perigee; while the Reflection begins to arise and increase, yet so that the left, or eastern, semidiameter of the mean longitudes is bent transversely to the south in Venus and to the north in Mercury, the other part being bent to the opposite quarter,

until at the perigee itself the Reflection again becomes greatest, and as great as it was at the apogee.

[Margin: 3rd quadrant.]

Fourth, as soon as the centre of the epicycle leaves the perigee of the equant, the Inclination and the diminution of the Reflection begin, but in such a way that the apogee of the epicycle of Venus inclines towards the south and that of Mercury towards the north, with the perigees tilted to the contrary sides, until, when the centre of the epicycle occupies the northern node, the transverse Reflection ceases entirely and the Inclination again becomes greatest, as great as it had been at the southern node.

[Margin: 4th quadrant.]

Fifth and last, as the centre of the epicycle ascends from the northern node towards the apogee of the equant, the diminution of the preceding Inclination begins, and the Reflection, so that the left, or eastern, half of the diameter of the mean longitudes of the epicycle is again twisted to the north in Venus and to the south in Mercury. This Reflection grows until at the apogee of the equant it becomes greatest, but at that same place the whole Inclination of the epicycle ceases.

[Margin: 1st corollary.]

From this is gathered, first, the perpetual accord of the Deviation with the Reflection, and the opposition of both to the Inclination: for where both Deviation and Reflection increase, the Inclination diminishes, and vice versa; and where the Deviation is greatest and the Reflection greatest, there the Inclination is nil, and vice versa.

[Margin: 2nd corollary.]

Second, that the properties of the latitudes of Venus are exactly opposite to the properties or affections of Mercury, in so far as they arise from the position of the centre of the epicycle on the eccentric.

[Margin: 3rd corollary.]

Third, that in the whole upper semicircle of the eccentric, which runs from the ascending node through the apogee of the eccentric to the descending node, the Deviation of the eccentric and the Reflection of the left, or eastern, part of the epicycle are northern in Venus and southern in Mercury; so that if the planet is in the eastern part of the epicycle, the latitude of Venus is necessarily northern and that of Mercury southern. But in the lower semicircle of the eccentric, the opposite of these happens as regards the Reflection.

Speculum varietatis Latitudinum Veneris ac Mercurij.

Mirror of the variation of the latitudes of Venus and Mercury.

VII. Ptolemy, Book 13, ch. 1, al-Farghānī, diff. 18, Regiomontanus, Book 13 of the *Epitome of the Almagest*, prop. 2, and Copernicus, Book 6, ch. 1, did try to distinguish for us the variation of the latitudes of Venus and Mercury; and Reinhold did so somewhat more clearly on Peuerbach, p. 225, adding also a

diagram showing eight principal positions of the eccentric. But it has seemed best to me to serve the imagination and the memory still better, by adding the epicycles, with their semicircles divided into morning and evening, and marking by the letters A the southern latitude and B the northern, with the planet placed at the four cardinal points of the epicycle, so that from these the others may be more easily understood. Consider, then, the following figure, in which T is the centre of the Earth; R the centre of the eccentric, whose line of apsides is GTP, on which the apogee of the eccentric is G and the perigee P; the line ETK is the line of the mean longitudes of the eccentric, passing through the nodes; E is the place of the southern node, 90° distant from the apogee in the order of the signs; while K is the northern node, 270° distant from the apogee in the order of the signs. Now D is the midpoint of the first quadrant of the eccentric; F, of the second; H, of the third; L, of the fourth. From the eight points of the eccentric, namely G, D, E, F, P, H, K, L, as many epicycles have been described, the larger of which is the epicycle of Venus, and the smaller that of Mercury. In the same order, the diameters of the apsides of the epicycle, on which the Inclination depends, are BGB, BDA, BEA, BFA, BPB, AHB, AKB and ALB. These divide each epicycle into a right semicircle, which is called western and preceding, and that of the morning planet, and is therefore marked with a double MM; and a left one, which is called eastern and succeeding, and that of the evening planet, and is therefore marked with a double VV. The diameters of the mean longitudes of the epicycle, to which the Reflexion relates, and which ought to bisect the diameters of the apsides at right angles, are likewise, in the same order, BGA, BDA, OEO, BFA, BPA, BHA, OKO, ALB. Keeping this same order for them, in eight propositions to be set beneath the figure we shall cover every variety of latitude that (unless I am mistaken) belongs to these planets according to Ptolemy, and we shall present it afresh to be contemplated as if at a single glance.

Diagram. A woodcut set in the left column, between the text and proposition 1. A large circle, the eccentric, carries eight double epicycles (an outer and an inner circle on one centre) at eight points spaced around it: G at the top, then L, K, H on the right, P at the bottom, and F, E, D on the left. Inside, a vertical line runs down from the epicycle at G through T to the epicycle at P, and a horizontal line runs from the epicycle at E through R to the epicycle at K; R stands above that horizontal line and T just below it on the vertical. Each epicycle is crossed by two diameters. The letters A, B, M and V stand on or around every epicycle, on both the outer and the inner circle and at the ends of its diameters.

- Top epicycle: centre G.
- Upper right epicycle: centre L.
- Right epicycle: centre K, with the sign ☊ beside it.
- Lower right epicycle: centre H.
- Bottom epicycle: centre P.
- Lower left epicycle: centre F.

- Left epicycle: centre E, with the sign ☋ below it.
- Upper left epicycle: centre D.
- Centre of the figure: R, T.
- Above and below the left epicycle (E), and below the right epicycle (K): O. Above the right epicycle: C [recte: O; the text names this diameter OKO].
- Around each epicycle: A, B, M, V.

[Margin: At the apogee of the eccentric.]

1. Let the centre of the epicycle be at G, the apogee of the eccentric. The Inclination of the diameter BGB is nil. The Deviation of the eccentric is at its greatest: for Venus 10′ northern, but for Mercury 45′ southern; and the latitude too is of this kind and this size, if the planet is at the apogee or perigee of the epicycle. The Reflexion of the diameter BGA, however, is at its greatest: for Venus to the north and for Mercury to the south as regards the left semicircle of the epicycle; but as regards the right, it is southern for Venus and northern for Mercury. And so evening Venus is northern and morning Venus southern, especially around the mean longitudes of the epicycle; but evening Mercury is southern and morning Mercury northern.

[Margin: At the middle of the 1st quadrant.]

2. Let the centre of the epicycle be at D, the middle of the first quadrant. The Inclination grows, the Deviation and Reflexion diminish; and the Inclination and Deviation of Venus are northern, those of Mercury southern. The Reflexion of Venus is likewise northern for the left semicircle, southern for the right; but the Reflexion of Mercury is southern in the left semicircle, northern in the right. Therefore the latitude of Venus, at that time, at the apogee of the epicycle and at the middle of the evening semicircle is northern; at the perigee and at the middle of the morning semicircle it is southern. By contrast, the latitude of Mercury at apogee and at the middle of the evening semicircle is southern, but at perigee and at the middle of the morning semicircle northern.

[Margin: At the end of the 1st quadrant.]

3. Let the centre of the epicycle be at E, the end of the 1st quadrant, or at the node ☋. The Deviation and Reflexion are nil, and the plane of the eccentric lies in the plane of the ecliptic, while the diameter OEO lies in the plane of the eccentric and of the ecliptic. Therefore, if the planet is at O, the mean longitudes of the epicycle, it has no latitude at all. The Inclination of the apogee, however, is at its greatest, for Venus to the north and for Mercury to the south. Therefore Venus in the upper part of the epicycle is northern, and in the lower southern; but Mercury in the upper part is southern, and in the lower northern.

[Margin: At the middle of the 2nd quadrant.]

4. Let the centre of the epicycle be at F, the middle of the 2nd quadrant. The Inclination diminishes, both that of the apogee, northern for Venus

and southern for Mercury, and that of the perigee, southern for Venus and northern for Mercury. The Deviation grows, northern in Venus and southern in Mercury. The Reflexion of the left semicircle is likewise southern for Venus and growing, and northern for Mercury and growing; that of the right semicircle is northern for Venus and southern for Mercury, and growing. And so the latitude of Venus at apogee is northern, at perigee southern; at the mean longitude of the epicycle, morning Venus is northern and evening Venus southern. By contrast, the latitude of Mercury at apogee is southern and at perigee northern; at the mean longitude, morning Mercury is southern and evening Mercury northern.

[Margin: At the perigee of the eccentric.]

5. Let the centre of the epicycle be at P, the perigee of the eccentric. The Inclination of the diameter BPB is nil. The Deviation of the eccentric is at its greatest, for Venus 10′ to the north, for Mercury 45′ to the south; and their latitude too is of this kind and this size, if they are at the apogee or perigee of the epicycle. The Reflexion, however, is at its greatest: that of the semicircle which is left with respect to the Earth looking towards P is southern in Venus and northern in Mercury, but that of the right is northern in Venus and southern in Mercury. Therefore morning Venus is northern and evening Venus southern, but morning Mercury is southern and evening Mercury northern.

[Margin: At the middle of the 3rd quadrant.]

6. Let the centre of the epicycle be at H, the middle of the third quadrant. The Deviation is northern in Venus and southern in Mercury, diminishing in both. The Inclination of the apogee of the epicycle grows, and is southern for Venus and northern for Mercury. The Reflexion of the left semicircle diminishes, and is southern for Venus and northern for Mercury; that of the right is northern for Venus and southern for Mercury. As a result, the latitude of Venus at apogee is southern and at perigee northern, while that of Mercury at apogee is northern and at perigee southern. At the mean longitudes of the epicycle, however, the latitude of evening Venus is southern and of morning Venus northern, whereas that of evening Mercury is northern and of morning Mercury southern.

[Margin: At the end of the 3rd quadrant.]

7. Let the centre of the epicycle be at K, or at the northern node. The Deviation and Reflexion are nil. The Inclination of the apogee is at its greatest, for Venus to the south and for Mercury to the north. For that reason, if they are at the mean longitudes O, they have no latitude at all; but if they are in the upper part of the epicycle, Venus is southern and Mercury northern, and in the lower part Venus is northern and Mercury southern.

[Margin: At the middle of the 4th quadrant.]

8. Let the centre of the epicycle be at L, the middle of the fourth quadrant. The Inclination diminishes, but that of the apogee is still southern for Venus and northern for Mercury. The Deviation grows, northern for Venus and southern for Mercury. The Reflexion also grows: as regards the left semicircle it is northern in Venus and southern in Mercury; as regards the right, southern in Venus and northern in Mercury. Accordingly, the latitude of Venus at apogee is southern and at perigee northern; and at the mean longitudes of the epicycle morning Venus is southern and evening Venus northern. By contrast, the latitude of Mercury at apogee is northern and at perigee southern; at the mean longitudes of the epicycle morning Mercury is northern, but evening Mercury southern.

De Motu Nodorum.

On the Motion of the Nodes.

VIII. According to Ptolemy, Book 13, ch. 6, the motion of the nodes and limits is inferred to be no other than that of the apogees. For the northern limit of Mars is always joined to the apogee of the eccentric, while the northern limit of Saturn always stands 50° from the apogee against the order of the signs, and that of Jupiter 20° in the order of the signs. And so, to obtain the argument of latitude of the planet, or its distance from the limit, for Mars one must use the equated anomaly of the eccentric itself, or the longitude from the apogee; but for Saturn the 50° must be added to the distance from the apogee, and for Jupiter the 20° subtracted. The nodes of Venus and Mercury, however, always stand from the line of apsides, the one 90° and the other 270°, as regards the latitude arising from the Deviation and Reflexion; although as regards the latitude arising from the inclination of the epicycle they lie on the line of apsides. Now follows a synopsis displaying the size of the latitudes and the places of the nodes. But note, from Ptolemy, Book 13, ch. 3, the inclination of the eccentric of Saturn found by him, 2° 26′, and that of Jupiter, 1° 24′;

he adds, however: *In place of these, for convenience's sake, we have used 2° 30′ and 1° 30′*; and therefore we have placed these values in the table along with him. We have followed Ptolemy's text and source, rather than the figures of Reinhold, Wurstisen, Magini and others, which either have been corrupted by printers, or were taken from a faulty text of Ptolemy, or were perhaps adapted by Reinhold and Magini to the Alphonsine or Peuerbachian hypotheses.

Synopſis Latitudinum ex Ptolemæo, & Alijs

Synopsis of the latitudes from Ptolemy and others

Planet	Deviation of the eccentric, or Inclination	Greatest Inclination of the epicycle	Greatest Reflexion of the epicycle
♄	Fixed, 2° 30′	4° 30′	0° 0′
♃	Fixed, 1° 30′	2° 30′	0° 0′
♂	Fixed, 1° 0′	2° 15′	0° 0′
♀	Greatest, 0° 10′	2° 30′	3° 30′

Planet	Deviation of the eccentric, or Inclination	Greatest Inclination of the epicycle	Greatest Reflexion of the epicycle
☿	Greatest, 0° 45′	6° 15′	7° 0′

Latitudo Maxima Trium Superiorum
Greatest latitude of the three superior planets

Planet	Au-thor-ities	Northern, at the apogee of the eccentric: at the apogee of the epicycle	Northern, at the apogee of the eccentric: at the perigee of the epicycle	Southern, at the perigee of the eccentric: at the apogee of the epicycle	Southern, at the perigee of the eccentric: at the perigee of the epicycle
♄	Ptolemy	2° 4′	3° 2′	2° 2′	3° 5′
♄	Rein-hold	2° 3′	3° 3′	2° 1′	3° 5′
♄	Mag-ini	2° 3′	3° 2′	2° 2′	3° 5′
♃	Ptolemy	1° 7′	2° 4′	1° 5′	2° 8′
♃	Rein-hold	1° 6′	2° 5′	1° 4′	2° 8′
♃	Mag-ini	1° 6′	2° 4′	1° 5′	2° 7′
♂	Ptolemy	0° 8′	4° 21′	0° 4′	7° 7′
♂	Rein-hold	0° 5′	4° 21′	0° 2′	7° 30′
♂	Mag-ini	0° 5′	4° 30′	0° 4′	6° 50′

Latitudo Maxima Duorum Inferiorum
Greatest latitude of the two inferior planets

Planet	On the epicycle	Latitude from the Inclination	At the degree of the anomaly of the eccentric
♀	Apogee	1° 2′	90 northern; 270 southern
♀	Perigee	6° 22′	90 southern; 270 northern
☿	Apogee	1° 45′	90 southern; 270 northern
☿	Perigee	4° 5′	90 northern; 270 southern

Latitudo ex Deuiatione Maxima in vtriuſque circuli Abſidibus
Greatest latitude from the Deviation, at the apsides of each circle

Planet	Position	Latitude	Direction
♀	Apogee and perigee	0° 10′	Northern
☿	Apogee and perigee	0° 45′	Southern

Latitudo ex Reflexione maxima
Greatest latitude from the Reflexion

Planet	Latitude	On the eccentric	And at the contact of the epicycle
♀	2° 30′	Apogee	Morning southern; evening northern
♀	2° 30′	Perigee	Morning northern; evening southern
☿	2° 30′	Apogee	Morning northern; evening southern
☿	2° 30′	Perigee	Morning southern; evening northern

Nodorum ac Limitum loca ad Annum CHRISTI 140.
Places of the nodes and limits for the year of Christ 140

Planet	Northern node	Southern node	Northern limit	Southern limit
♄	♋ 3°	♑ 3°	♎ 3°	♈ 3°
♃	♋ 1°	♑ 1°	♎ 1°	♈ 1°
♂	♈ 29½°	♎ 29½°	♋ 29½°	♑ 29½°
♀	♒ 25°	♌ 25°	♉ 25°	♏ 25°
☿	♑ 10°	♋ 10°	♎ 10°	♈ 10°

On the nodes of Venus and Mercury, Kepler and Longomontanus hold otherwise; on this, read Scholium 4. The motion of the nodes is the same as that of the apogees.

SCHOLIA.

Scholia.

[Margin: Whether there is Reflexion in the superior planets?]

I. You will ask whether, in the three superior planets, besides the Deviation of the eccentric from the ecliptic and the Inclination of the epicycle from the eccentric, there is also some Reflexion, as in the inferior ones. Magini will answer, in Book 2 of the *Theoricae*, ch. 4, that it must be admitted, because without it, it cannot come about that, with the centre of the epicycle placed at the nodes, the plane of the epicycle lies in the plane of the ecliptic, and that outside the nodes the axis of the mean longitudes is parallel to the plane of the ecliptic, as is supposed in the preceding hypothesis. However, since that inflexion makes a very slight and scarcely sensible difference in the latitude of the superior planets, it has so far been safely neglected by astronomers. I later found the same thing in Francisco Sarzosa, who in Book 2 of the *Aequator Planetarum*, ch. 21, admits Reflexion in the three superior planets and shows that it was admitted by Ptolemy, Book 13, ch. 1, where he says: "But the diameters of the orbs of revolution, etc., always remain equidistant from the surface of the circle of the signs; and although they are reflected, the reflexion has no quantity worth troubling about." Pedro Nunes remarks the same in annotation 9 on the affections of the planets explained by Peuerbach. He further adds that only twice in one revolution of the centre of the epicycle is the axis on which the epicycle moves in longitude equidistant from the axis of the ecliptic, namely when the centre of the epicycle is at the nodes; and that it is never equidistant from the axis of the eccentric.

[Margin: The Ptolemaic figures here vary from one author to another.]

II. If anyone consults the figures for the Reflexion or the latitude given by al-Battānī, al-Farghānī and Jābir ibn Aflaḥ in the places cited at the beginning of the chapter, he will be amazed at how very different they are, whether this has arisen from a printing fault, or from a difference in the calculation, or in the manuscript of Ptolemy from which they derived them. Therefore our figures are not to be condemned out of hand for disagreeing with those already mentioned; rather, the Ptolemaic text itself should be consulted and attentively considered.

[Margin: Ptolemy's errors concerning latitude.]

III. Ptolemy went less astray regarding latitude in the three superior planets than in the inferior ones, because he set the inclination of the superior planets as fixed and kept their epicycles very nearly parallel to the ecliptic. But he made the inclination of the inferior planets variable, whereas, as will be said in chs. 3, 4 and 7, it is more probably invariable; granted that, since he placed the eccentrics of both and their epicycles below the Sun, he was almost forced to devise so many variations. How far he went astray, however, in equating the motion of the nodes with the motion of the fixed stars and of the apogees was revealed after many centuries by the place of the nodes, which shows that motion to be very different from the motion of the fixed stars and of the apogees, as will be said in ch. 4, no. 6, and in the following chapters. But Ptolemy did not have sufficient observations by the ancients with which to distinguish these motions; and since he saw from rough observations that they were very slow, he judged that no evidently sensible error could be committed if he supposed these three to move with equal slowness, namely the sphere of the fixed stars, the auges of six planets (for he excepts the Moon), and the nodes of the five minor planets. Finally, he went astray in the points of the greatest latitudes, as will be clear from what is to be said in ch. 4, schol. 2.

[Margin: Kepler's apparent contradiction in assessing Ptolemy's opinion.]

IV. But Kepler appears to have erred against Ptolemy when he says, in the *Epitome of Copernican Astronomy*, Book 6, part 3, or p. 770: "Ptolemy set the nodes of Venus in the apsides as he called them; of Venus, that is, the ascending node at 25° ♉, the descending at 25° ♏; so that the northern limit (with a line drawn from the Sun through it) was at 25° ♌.

[Margin: Places of the nodes and limits of ♀ and ☿ according to Ptolemy.]

of Mercury, the nodes likewise in the apsides, the ascending at 10° ♎, the descending at 10° ♈." Longomontanus too, in Book 2 of the *Theorica*, ch. 24, puts their nodes on the line of apsides. But Ptolemy, Book 13, chs. 1 and 2, says explicitly that the nodes of Venus and Mercury stand a quarter of a circle away, on one side from the apogee and on the other from the perigee of the equant eccentric. He places them at the mean longitudes, the one at the middle of the semicircle of the eccentric in which the equation of the centre is subtracted, the other at the middle of the semicircle in which it is added. For that reason he calls the former the node of the subtracting semicircle and

the latter that of the adding one, as Wurstisen noted on Peuerbach's *Theoricae*; and Wurstisen himself also recognises the limits of the greatest latitudes at the apogee and perigee of the equant, along with Peuerbach and the other followers or expounders of the old astronomy. That same point is included in Copernicus's statement, though it is perhaps ambiguous to some, in Book 6, ch. 1, where he says of Venus and Mercury: "At the mean longitudes, namely when the line of the mean motion of the Sun stands a quadrant away from their highest or lowest apse, and the stars themselves are a quadrant of their orbs, evening or morning, away from the same line of the mean motion of the Sun, they found no departure in them from the circle of the signs, by which they understood that they were then at the common section of their orbs and of the zodiac; and this section passes through their apogees and perigees." But from the words that follow it is clear that he is speaking of the apogees and perigees of the epicycle, whereas in the earlier words he speaks of the apse of the eccentric. Magini takes it no differently in the *Theoricae Planetarum*, Book 2, ch. 6, and in Canon 50 of the *Secunda Mobilia*, recognising in both places, as the mind of Ptolemy and of Copernicus, the limits of Venus and Mercury at the apogee and perigee of the equant, and the nodes at the mean longitudes, or a quadrant away from the apogee. But the conflict is removed, because for Kepler and Longomontanus, with the Deviation and reflexion taken away (whose nodes Ptolemy put at the mean longitudes of the eccentric, and its limits at the apsides) and with this attributed to the Earth's approach or to other equivalent causes, there remained only the latitude coming from the orb of the epicycle and its inclination; and the nodes of this Ptolemy would have placed at the apsides of the eccentric. We, however, put the nodes of the Deviation in the little table, as we also indicated above, no. 8.

[Margin: The varied naming of latitude.]

V. Although the latitude of these planets, in the first semicircle counted from the ascending node in the order of the signs, is northern, growing in the first quadrant and diminishing in the second, and in the other semicircle, from the descending node, is southern, growing in its first quadrant and diminishing in the second, Magini nevertheless notes, in Canon 49 of the *Secunda Mobilia*, that latitudes are called ascending as long as the planet is ascending on the epicycle, which for the three superior planets happens from opposition with the Sun until conjunction; and descending as long as the planet is descending on the epicycle, which happens from conjunction to opposition. The inferior planets, however, ascend from the inferior conjunction with the Sun until the superior, and from there onward descend.

VI. To complete the theory of latitude in the Ptolemaic hypothesis, it must be recalled that the figure set out above at no. 7 serves, as it lies, chiefly for Venus, as regards the naming of the nodes; but it is easily carried over to the opposite quarter, towards which the apogee of Mercury, almost opposite the apogee of Venus, was directed. Moreover, the motion of latitude is counted in Venus from the northern node, but in Mercury from the southern. Lastly, various

propositions in Regiomontanus, Book 13 of the *Epitome of the Almagest*, should be read. For he shows in props. 9 and 17 that the Inclination of the epicycle of the inferior planets brings no sensible error into the motion in longitude, since the greatest difference from this does not exceed 2′ in Venus and 3′ in Mercury; and in props. 13, 14, 15, 16 that the greatest angle of this diversity occurs near the points of contact of the epicycle, in Mercury at the very point of contact, but in Venus usually outside the point of contact. Copernicus teaches similar things in Book 6, ch. 6, adding from Ptolemy that the greatest Reflexions occur at the contacts, or around the greatest digressions from the Sun, and that the latitudes arising jointly from the Reflexion and Deviation are in Venus greater in the north than in the south by 20″, but in Mercury greater in the south than in the north by about 1° 30′.

CAPVT II.

Chapter II.

De Copernici & Sectatorum eius Hypotheſi circa Latitudinem Planetarum Minorum.

On the hypothesis of Copernicus and his followers concerning the latitude of the minor planets.

[Margin: Followers or expounders of Copernicus.]

I. Copernicus himself sets out his hypothesis on latitude in Book 6. Rheticus followed it in his first *Narratio*, usually appended to the works of Copernicus, from p. 138 in my copy; Reinhold in the Prutenic Tables, precepts 71 and 72; as regards the figures or measures of latitude, and in part as regards the explanation of the libration, Magini, *Theoricae*, Book 2, especially ch. 7; and Lansbergen in his *Theoricae*, from ch. 15 to ch. 19, although he corrects Copernicus as regards the figures, the measures and the motion of the nodes. Finally, some knowledge of this hypothesis is provided by Longomontanus, Book 2 of the *Theorica*, chs. 14 and 24, and by Hérigone, vol. 5, Book 2 of the *Theorica*, ch. 5.

Copernici Placita de Latitudine trium Superiorum.

Copernicus's tenets on the latitude of the three superior planets.

[Margin: 1st part of the Copernican hypothesis.]

II. First, Copernicus, Book 6, ch. 1, takes as given the alternations of latitude observed by Ptolemy, which we set out in ch. 1, and that the nodes and limits move with the same motion as their apogees. Adducing no observation of his own thereafter, he is wholly occupied in representing Ptolemy's observations in his own hypothesis on the motion of the Earth. Not, he says, that the Earth's great orb, remaining always the same in the plane of the ecliptic, induces any latitude in them of itself, but because their apparent latitude changes with the approach and recession of the Earth. For the three superior planets, at their

acronychal shinings, or when they are seen from the Earth opposite the Sun, appear to recede from the ecliptic by a departure always greater than in any other situation of the Earth: in the northern semicircle of the eccentric they digress to the north, and in the southern to the south.

[Margin: 2nd part.]

Secondly, because the greatest latitudes, even at the acronychal oppositions, let alone around the conjunctions with the Sun, appear different and undergo a greater variation than the Earth's approach or recession requires; and because the three superior planets have no epicycles in the Copernican hypothesis, but in their place there is the great or annual orb of the Earth, whose ecliptic nevertheless always lies in the plane of the celestial ecliptic: for these reasons he lays it down that the inclination of the eccentrics of Saturn, Jupiter and Mars to the ecliptic is not fixed, but movable by a certain libration commensurable with the revolutions of the Earth's great orb. So he says in that ch. 1; and he sets out this libration more fully in ch. 2, with very nearly the following figure. Let A be the centre of the celestial ecliptic, and at the same time of the annual mean motion of the Earth. From it let there be described both the great orb itself, HIKL, and, in the same plane, the celestial ecliptic FCGN, to which let the eccentric BCDM of some superior planet be inclined. Let the already mentioned inclination of the eccentric be midway between the greatest and the least: BF at the northern limit, and GD at the southern limit. Let the ascending or northern node be E, and the descending or southern node C; and let the common section of the ecliptic and of the orbit of the planets be represented by the straight line CAE. And let these nodes and limits shift by no other motion than that by which the apogees of these planets move.

Diagram. A woodcut set into the foot of the right column, with the text running down its left side. An outer circle and an eccentric circle meet at C on the left and E on the right, joined by the straight line CAE through A. A small circle about A stands within them, and a vertical line runs from F at the top through A to D at the foot. Further lines run from the point on the small circle marked O up to the upper part of the circles, and from the rayed point marked P to the right side at m and n. The signs of three planets stand outside the circle at the foot.

- Top, on the outer circle: F.
- Upper left: a ring with a stem and crossbar beneath it, perhaps the sign ♀ [?], and R below it.
- Upper right: N, and M below it.
- On the vertical, below F: B, then H.
- On the small circle, to the right of the vertical: O.
- Left end of the horizontal: C; right end: E.
- On the small circle, on the horizontal: I (left), L (right).
- Centre: A.
- Lower left of the small circle: a rayed star, with P below it.
- On the vertical, below A: K, then G; at the foot: D.

- Right side, lower: m, then n.
- Below the circle, from left to right: ♄, ☋, ♂ (with D standing between ☋ and ♂).

Further, let the angles of inclination, say BEF and GED, vary by a certain libration similar to the libration of the precession of the equinoxes that we explained in Book 3, ch. 29, according to the simple motion of commutation, or according to the mean anomaly of the orb. Thus, whenever the Earth is nearest to the planet — as if the Earth is at H and the planet at B, or the Earth at K and the planet at D, which happens at acronychal oppositions — the apparent latitude of the planet itself is greatest, and the angle of inclination is greatest. But at conjunctions with the Sun, when the Earth at K is most remote from the planet at B, or the Earth at H from the planet at D, the planet's latitude is smallest, and the inclination of the eccentric to the ecliptic is smallest. The measure of the libration is gathered by subtracting the smallest inclination from the greatest. From Copernicus, Book 6, ch. 3, in Saturn the greatest is 2° 44′ and the smallest 2° 16′, and so the whole libration is 28′. In Jupiter the greatest inclination is 1° 42′ and the smallest 1° 18′, and the whole libration 24′. And in Mars the greatest inclination is 1° 51′, the smallest 9′, and the whole libration 1° 42′. Half of the libration serves as the semidiameter of the small circle by which this libration is accounted for.

[Margin: 3rd part.] Third, with these things presupposed, two causes of the varying latitude are now to hand. One is the libration through BF and GD, which, according to the motion of the mean anomaly of the orb, varies the inclination and so the latitude, even if the Earth were always in one place, say at H. The other is the motion of the Earth itself. For since by the laws of optics nearer things look larger, the angle of inclination and the latitude arising from it will certainly appear greater to the Earth when near at H than when remote at I, and smallest to the Earth when most remote at K. So, with the planet placed at B, with the greatest latitude that the libration of the inclination can produce, that greatest northern latitude will nevertheless decrease continuously from there as the Earth goes through the semicircle HIK; then, once K has been passed, that greatest northern latitude will grow continuously as the Earth ascends through the semicircle KLH. Conversely, with the planet placed at D, the limit of greatest southern latitude, this same latitude will diminish continuously while the Earth is carried through the semicircle KLH, and will increase apparently while the Earth goes through the semicircle HIK. Finally, if the planet is at the nodes C or E, then although it is acronychal, with the Earth placed at I or at L, no latitude will appear; for since there is no angle of inclination, it cannot look greater or smaller through the Earth's approach or withdrawal. We shall set out another figure from Copernicus bearing on this in ch. 8, no. 19.

Copernici placita de Latitudine duorum Inferiorum.

Copernicus's tenets on the latitude of the two inferior planets.

[Margin: 4th part, for Venus and Mercury.] III. To demonstrate the varying latitude of Venus and Mercury, in the same ch. 2 he uses the following diagram. In it E is the centre of the Earth's great orb ABCD, set in the plane of the ecliptic, to which let the orb of Venus and of Mercury (which in this hypothesis serves in place of the epicycle) be inclined — the eccentric orb GKF, I say — at an inclination midway between the greatest and the smallest. Let the common section of the annual orb and of the planet's eccentric orb be G and F, and let the line AEC of this section pass through the planet's apogee F and perigee G; and let the nodes of this section move in the order of the signs by the same motion by which the planet's apogee and perigee move. For when both the planet and the Earth are on the same line AEC, there will be no latitude. But when they are at the mean distance from the apogee, the inclination will be greatest; and this inclination is varied by a double libration, commensurable with the Earth's revolution.

Diagram. A woodcut set in the left column, interrupting the sentence at *seruit* | *pro Epicyclo*. A large circle carries a vertical diameter and a horizontal diameter crossing at the centre E. Inside it stand two further circles, shifted against one another so that they overlap and cross: one passes through the points on the vertical above and below the centre (G, F) and the points on the horizontal (K, L); the other passes through T above and H below. A straight line runs obliquely through E from R at upper left to S at lower right.

- Top of the large circle, on the vertical: A.
- On the vertical, above the centre, where the inner circles meet: G.
- Upper left, at the end of the oblique line: R.
- Upper right, on the inner circle: T.
- Left end of the horizontal: B, with O beside it inside the large circle.
- On the horizontal, left of the centre: K.
- Centre: E.
- On the horizontal, right of the centre: L.
- Right end of the horizontal: D.
- Lower left, on the inner circle: H.
- Lower right, at the end of the oblique line: S.
- On the vertical, below the centre, where the inner circles meet: F.
- Foot of the large circle, on the vertical: C.

By the force of the first libration, which occurs twice in one revolution of the Earth with respect to the apsides, the axis, or line of section, is held on the line passing through the apogee and perigee, so that whenever the line of the Sun's mean motion is at the apogee or perigee of these planets, the angle of section becomes greatest, and at the mean longitudes, smallest. By the force of the second libration, a second circle (homocentric in Venus, but eccentreccentric [Eccentrieccentricus] in Mercury), oblique to the first circle GKFL and having its common section with it at R and S, has a movable axis RS, on the condition that while the Earth is at A, the planet is at the extreme limit of the deviation, say at T; and however far the Earth has advanced from A, the planet recedes

that far from the limit T. So if, for example, the Earth, having completed a quadrant of the great orb, comes from the apogee A to B, the mean longitude, the planet too, having completed a quadrant of its orb, comes from the limit T to the node R — the node, I say, of this deviation. When the Earth is at C, the planet is at the limit H; and when the Earth is at D, the planet is at the other node S. Now when the planes of the two orbs coincide at the middle of this libration and at the nodes R and S, and thereafter strain in different directions, the former semicircle of the deviation, STG, which was southern, passes into the north; and on it Venus, leaving the south, makes again for the north, never by this libration alone to enjoy the south. But Mercury, following the contrary parts, remains southern. So this second libration induces the greatest deviation in the planet when by force of the first it ought to have no latitude. The way of demonstrating the species of these latitudes in particular I have decided to reserve for chapter 8, where, especially from Problem 15 to 19, many things bearing on the understanding of this hypothesis can be read; there we shall treat the way of finding the latitudes arising from the Inclination, from the Reflexion and from the Deviation, according to the mind of Copernicus.

Georgij Ioachimi Rhetici Explicatio Copernicanæ hypothesis de Latitudine Veneris ac Mercurij.

The explanation by Georg Joachim Rheticus of the Copernican hypothesis on the latitude of Venus and Mercury.

IV. To the obscurity of Copernicus in this part, however, it has seemed good to add light from the very words of Rheticus, who argues as follows in the *Narratio prima*:

[Margin: Copernicus, the teacher of Rheticus.] *Within the great orb, the sphere of Venus comes first. The Lord Teacher [D. Præceptor] therefore posits that the plane in which Venus moves declines from the plane of the ecliptic, or of the great orb, on a diameter through the proper apsides of the first deferent, so that the eastern half is raised from the plane of the ecliptic's surface to the north, by the angle of inclination that in Ptolemy's hypotheses the plane of the epicycle would make with the plane of the deferent; and the western half to the south. By "eastern" one must understand that half which runs from the place of the highest apsis* in the order of the signs, *etc. By this hypothesis alone, a simple one, it will be easy to see through all the rules of declinations and reflexions, with their causes, from the relation of the Earth's place to the planet's plane. For when by the Earth's annual motion we have arrived at the parts opposite to the highest apsis of the first deferent, where we suppose the orb of Venus to be as an epicycle, and at the apogee of its deferent, then the plane in which Venus is carried will seem to us reflected from the plane of the ecliptic: for in such a position we view it crosswise. And since we observe the same plane from a lower place, the part that projects to the north will be on the left for us, who turn our eyes to the south, and the remaining part, to the south, on the right. But as the Earth proceeds upward toward the highest apsis of the planet, the orb of Venus is believed to descend from the apogee*

of its own orb, and so we begin to look down, as if from a higher place, on the inclined plane itself of the deferent carrying Venus. Therefore the reflexion changes successively into declination, so that at a quadrant's distance from the former place, wherever the planet is seen in the elevated parts, it has declination only from the ecliptic. In such a position, since we, clinging to the Earth, are opposite the half of the deferent that runs from the highest apsis in the order of the signs *and is raised from the plane of the ecliptic to the north, the Ancients said that the epicycle of Venus is at the descending node, and that the apogee of the epicycle declines most to the north, and the perigee to the south. Next, as the annual motion of the Earth carries us aloft toward the place of the highest apsis of Venus, its orb, as if an epicycle, will seem to make for the lowest apsis of its deferent. And the plane of the epicycle (for us, the plane in which the star of Venus is), which before was inclined for us to the plane of the ecliptic, will appear to reflect itself again toward us, and the northern half of the deferent, projecting out of the plane of the ecliptic, will become the right-hand one, because we look on the orb of Venus from above. But when the centre of the Earth has arrived at the place of the highest apsis of Venus, no declination and only reflexion will be seen; and yet the orb of Venus would be believed, in the opinion of the Ancients, to be at the lowest apsis of its deferent. And this is the order of the phenomena* [Greek: τῶν φαινομένων (tōn phainomenōn, "of the phenomena")] *while the centre of the Earth completes a semicircuit, ascending from the place of the lowest apsis of Venus, in the order of the signs, to the place of the highest apsis of Venus. In the same way, as the Earth descends, the reflexion will gradually change into declination in our view. And since the half of the plane of the deferent running from the highest apsis against the order of the signs [in antecedentia] comes opposite to us by such a progress of the Earth, the apogee of the deferent of Venus begins to decline to the south from the plane of the ecliptic; until, with the Earth set at the ninetieth degree from the place of the apsis, both halves are seen declined to the plane of the ecliptic, and the orb of Venus, as an epicycle, is thought to be at the node ascending to the highest apsis. As the Earth withdraws from that place, the declination changes again into reflexion; and, having reached the place of the lowest apsis of Venus, the Earth begins again to produce the same appearances of latitude in Venus. From this it is clear that with the Earth placed at the line of the apsides of Venus, the plane of the deferent carrying the planet appears reflected; at the quadrants from these, declined; and in the intermediate places, mixed latitudes are seen.*

[Margin: The latitude of the deviation of Venus.] V. *But since, besides these latitudes, which the Ancients attributed to the epicycle of Venus, another deviation also, so called by the Ancients and called by Ptolemy the inclination of the eccentric circles* [Greek: τῶν ἐκκέντρων κυκλῶν ἡ ἔγκλισις (tōn ekkentrōn kyklōn hē enklisis, "the inclination of the eccentric circles")], *mingles with them, and since they demonstrated it through the centre of the deferent of the epicycle (which has now been removed), the Lord Teacher [D. Præceptor] has indicated that another method, one more in accord with the observations, is to be entered on. To grasp more easily, no differently from the rest proposed so far, this method of my Lord Doctor Teacher [D. Doctoris Præceptoris mei] for saving the deviation, let us take the plane we have*

just mentioned to be the mean plane and so fixed, from which the true plane wanders now here, now there, by a certain rule. But since all motions are grasped with less labour and expense by reference to the poles, it must be held at the outset that one of the poles of the mean plane is raised to the north from the plane of the ecliptic by the quantity of the angle of inclination, and the other, opposite, is depressed by the same amount to the south; and that what we are going to show happens with the northern pole, or with those things too around it, must be understood of the southern pole in a similar but opposite way. Accordingly, let us take it that around the northern pole of the mean plane there is a movable circle, whose line from the centre corresponds to the greatest obliquities of the mean plane from the true plane; and let the northern pole of the true plane itself describe, by the motion of libration, the diameter of the circle just mentioned. Further, let the movable circle follow the motion of the planet, so that Venus, advancing by its own motion, leaves behind the intersection of any two that follow one another, and on this condition: that when a year is complete it returns at last to the one it left. When a great circle is drawn through the poles of both planes, then, counting 90° on either side from its common intersection with the true plane, when the poles of the true and mean planes differ, the nodes or intersections just mentioned are determined. Meanwhile, while the period of Venus to one or other of the nodes is completed, let the diameter of the movable circle just mentioned be described twice by the pole of the true plane, by the motion of libration. Let these things come about so, that the planet may appear to have made such a pact with the centre of the Earth that whenever the Earth is at the apsides of the deferent, Venus, wherever it is on the true deferent, deviates most to the north from the mean plane, that is, stands furthest outside the mean path. Further, with the Earth a quadrant distant from the apsides of the deferent, let the planet itself, with its whole true plane, lie in the plane of the mean deferent. But while the Earth traverses the remaining intermediate places, let the planet too keep its course in intermediate deviations. That this pact of the Earth and the planet might be perpetual, God ordained that the first small circle of libration (so to speak) should revolve once in the same time in which one return of Venus to one or other of the nodes takes place. To make these things clearer by an example: if, at some beginning of the motion of deviation, the northern pole of the true plane is furthest south of the adjacent pole of the mean plane, and Venus just stands at the greatest limit of the deviation, which is northern, with the centre of the Earth also lingering at one of the apsides of Venus, then in a quarter of a year the Earth by its annual motion will come to the place midway between the apsides, and at the same time the planet to its intersection or movable node. And since the motion of libration is commensurate with the planet's motion to the nodes or intersections, the first small circle of libration will also complete a quadrant, and through the remaining small circle, which is twice as fast as the other, the pole of the true plane will be set beneath the pole of the mean plane; and so the two planes will be joined. But as the planet withdraws from this node, the Earth will proceed to the other apsis of the first eccentric, and the pole of the true plane will be moved forward by the libration from the pole of the mean plane to the north. Thus it will come about that even if Venus is southern, as in our example, the southern latitude nevertheless diminishes; if northern, the same latitude grows.

And when that place has been reached, the pole of the true plane will by the motion of libration touch its greatest limit to the north, and the planet, by its annual motion to the nodes, midway between the two sections, will again have its greatest deviation to the north. So it appears that the motion of the assumed circle has this use: that in a year the revolution of Venus to the nodes takes place; that always, with the Earth placed on the line of the apsides, the planet, wherever it is on its true plane, has its greatest deviation from the mean plane; and that with the Earth set midway between the two apsides, it is at the nodes. Further, by the motion of libration it comes about that when Venus is at one of the nodes the two planes are joined, and that the part of the true plane it enters always departs to the north from the mean plane; so that, as is fitting, this latitude remains perpetually northern.

[Margin: On the latitude of Mercury.] VI. *Just as the plane of Venus that it has pleased us to call mean is intersected by the ecliptic on the line of the apsides of the first eccentric, and the half of that plane running from the highest apsis* in the order of the signs *projects to the north, the remainder, by the law of opposition, tending to the south: so in Mercury, in a similar way, there is a mean plane, which is inclined on either side from the plane of the ecliptic on the line of its apsides, as was fitting, so that conversely the half of the mean plane running from the highest apsis against the order of the signs is northern. Therefore in the annual revolution of the Earth's centre, the declinations and reflexions in Mercury will be found interchanged, namely with respect to those of Venus. But so that this variety might be the more conspicuous, God also arranged the deviation of the true plane of Mercury from the mean so that the half it enters would always depart from the mean plane to the south, and that with the Earth standing at the apsides themselves it would lie, with its true plane, in the mean plane. So it comes about, finally, that in latitude it has no differences from Venus besides those stated, except that this deviation too is greater in Mercury than in Venus; just as it also has a greater angle of inclination. For the rest, the remaining varieties of the latitudes of Mercury will be gathered very easily, not otherwise than in Venus.* Thus far Rheticus, without the aid of any figure.

De Deuiatione Eccentricorum Veneris & Mercurij Copernicana, ex Io. Antonio Magino.

On the Copernican deviation of the eccentrics of Venus and Mercury, from Giovanni Antonio Magini.

VII. To represent this deviation according to the calculation of Copernicus, Magini, *Theoricae* Book 2, ch. 7, assigns it to two small circles placed outside the plane of the ecliptic opposite the apogee and perigee, to the north for Venus and to the south for Mercury; their diameter is 10′ in ♀ and 45′ in ☿. To their circumferences is fixed the orb of deviation, which contains in its own plane the eccentric deferent and takes on, at the motion of those small circles, a libration that is completed twice while the centre of the epicycle completes one period once on the eccentric; and this on the following condition. [Margin: The libration of the deviation, from Magini.] First, when the centre of the epicycle

is 90° from the apogee of the equant, but against the order of the signs, there is no deviation, and the plane of the eccentric coincides with the plane of the ecliptic. Second, when the centre of the epicycle recedes from the place already mentioned, as if from a node, and ascends toward the apogee, the whole plane of the deferent recedes from the plane of the ecliptic, in Venus toward the north, in Mercury to the south, until at the apogee itself it is parallel to the ecliptic and stands furthest from it, namely 10′ in Venus and 45′ in Mercury; and there the deviation becomes greatest. Third, when the centre of the epicycle recedes from the apogee, the deviation decreases, until at the other quasi-node, which is 90° from the apogee in the order of the signs, there is no deviation and the plane of the eccentric lies in the plane of the ecliptic; and thus one entire revolution of the small circles has been completed. Fourth, when the centre of the epicycle recedes from the other quasi-node and passes to the perigee half of the eccentric, the second libration of the small circles begins, and the plane of the eccentric is again separated from the plane of the ecliptic, toward the north in Venus and toward the south in Mercury; and the deviation grows until the centre of the epicycle is at the perigee of the equant, and there the deviation becomes greatest and the plane of the eccentric is parallel to the plane of the ecliptic. Fifth, as the centre of the epicycle recedes from here, the deviation diminishes, until, with the centre of the epicycle 90° distant from the perigee, it comes to nothing; which happens at the place equivalent to the northern node. For I have called the places where there is no deviation quasi-nodes, because in this hypothesis they are not truly nodes, since the plane of the eccentric nowhere intersects the ecliptic, but either coincides with it there or, receding from them, stays wholly outside the plane of the ecliptic, toward the north in Venus and toward the south in Mercury; and to those quarters, outside these quasi-nodes, the centre of the epicycle itself always belongs. But since they are equivalent to nodes in this, that the whole latitude of the deviation ceases there, they can be called quasi-nodes. [Margin: Problems on the Deviation, Inclination and Reflexion indicated.] See now, if you like, the two Problems bearing on this matter below, ch. 8, nos. 23 and 24. There you will also have figures and problems for the latitude arising from the Inclination and the Reflexion, from no. 20 to 23.

De Motu Nodorum.

On the motion of the nodes.

VIII. The nodes and limits of these five planets move by no other motion than the motion of the apsides, that is, the motion by which their apogees move, according to the mind of Copernicus. So it comes about that the nodes and limits of Venus, just as we said of the apogee in Sect. 3, ch. 2, are immobile under the sphere of the fixed stars and are perpetually 48° 21′ distant from the first star of Aries; but they move with an apparent motion, the same motion by which the first star of Aries seems to recede from the section of the vernal

equinox (for in reality Copernicus attributes this motion not to the fixed stars themselves, but to the equinoctial points receding against the order of the signs from the fixed stars). The nodes of the three superior planets and of Mercury, on the other hand, are changeable, following the motion of their apogees. It remains for us to gather into a synopsis the numbers and measures bearing on this hypothesis, which we have taken from Copernicus himself: Book 6, ch. 3, where he treats of the latitude and inclination of the three superior planets; ch. 5, where he treats of the declinations of Venus and Mercury; chs 6 and 7, where he treats of the obliquation or inflexion of their planes; and ch. 8, where he treats of the deviation; and from his tables and the Prutenic Tables.

SYNOPSIS Latitudinum ex Copernico. Latitudo Maxima trium Superiorum

Synopsis of the latitudes from Copernicus. Greatest latitude of the three superior planets

Planet	Latitude	At ♂ with ☉, or at apogee	At ☍ with ☉, or at perigee
♄	North	2° 3′	3° 2′
	South	2° 2′	3° 5′
♃	North	1° 6′	2° 4′
	South	1° 5′	2° 7′
♂	North	0° 6′	4° 30′
	South	0° 45′	6° 50′

Planet	Greatest inclination	Smallest inclination	Whole libration
♄	2° 44′	2° 16′	0° 18′ [recte: 0° 28′ — the row's own figures, 2° 44′ and 2° 16′, differ by 28′, and the text of p. 613 prints 28′]
♃	1° 42′	1° 18′	0° 24′
♂	1° 51′	0° 9′	1° 42′

Planet	Greatest declination	Greatest reflexion	Greatest deviation
♀	2° 30′	3° 29′	0° 10′
☿	6° 15′	7° 0′	0° 45′

Latitudo Maxima conueniens

Greatest latitude corresponding

Planet	Distance	To the greatest inclination	To the greatest reflexion	To the greatest deviation
♀	Apogee	1° 2′	2° 27′	0° 6′
	Mean	4° 30′	2° 30′	0° 10′
	Perigee	6° 22′	2° 34′	0° 15′
☿	Apogee	1° 45′	2° 17′	0° 33′

Planet	Distance	To the greatest inclination	To the greatest reflexion	To the greatest deviation
	Mean	2° 55′	2° 30′	0° 45′
	Perigee	4° 5′	2° 45′	1° 10′

This speaks of the apogee, perigee or mean distance of the centre of the orb from the Earth.

Radix Nodorum ac Limitum ex Copernico ad Annum CHRISTI circiter 1530.

Root of the nodes and limits, from Copernicus, for about the year of Christ 1530.

Planet	Node, north	Node, south	Limit of greatest lat., north	Limit of greatest lat., south
♄	♌ 7°	♒ 7°	♏ 7°	♉ 7°
♃	♋ 27°	♑ 27°	♎ 27°	♈ 27°
♂	♉ 27°	♏ 27°	♌ 27°	♒ 27°
♀	♊ 16°	♐ 16°	♍ 16°	♓ 16°
☿	♏ 28°	♉ 28°	♒ 28°	♌ 28°

The motion of the nodes is the same as the motion of the apogees.

Species Latitudinum Veneris ac Mercurij

The species of the latitudes of Venus and Mercury

[Margin: From Copernicus, Book 6, ch. 9.]

Species	Quadrants of the anomaly: of the eccentric	Quadrants of the anomaly: of commutation	♀	☿
Declination	1 & 2	1 & 4	North	South
	1 & 2	2 & 3	South	North
	3 & 4	1 & 4	South	North
	3 & 4	2 & 3	North	South
Reflexion	1 & 4	1 & 2	North	South
	1 & 4	3 & 4	South	North
	2 & 3	3 & 4	North	South
	2 & 3	1 & 2	South	North

But the latitude of the deviation in Venus is always northern; in Mercury it is always southern. The anomaly of commutation is the motion by which the Earth's mean motion is exceeded by the proper motion of Venus and Mercury, or by which it exceeds the motion of Saturn, Jupiter and Mars. The anomaly of the eccentric orb is that which bears on the Ptolemaic epicycle.

SCHOLIA.

Scholia.

I. *What has been said about the orbs of Venus and Mercury according to the mind of Copernicus can be applied to the epicycles employed by Magini, in whose place Copernicus has the orbs of these planets, which they describe around the Sun, taking their eccentricity from the centre of the Earth's great orb. Likewise, since the Earth's great orb in Copernicus takes the place of the epicycles of the three superior planets, what I said about the latitude fitting them at the Earth's greatest or smallest distance from them holds equally in Magini's hypothesis of the latitude due to them at the apogee or perigee of the epicycle. For although Magini used numbers taken from Copernicus or the Prutenic Tables, he nevertheless transferred them into the schemes of Ptolemy and Peuerbach and into the hypothesis of a resting Earth, constructing for us a kind of Ptolemaic-Copernican hypothesis:*

and adding certain small orbs and small circles which he judged suitable for completing the librations and alternations of the latitudes.

[Margin: On the geometric calculation of latitude.] II. *We have put off the form of the geometric calculation for finding the latitude of these planets at any given time to ch. 8, from no. 16, though we shall give a taste of it in ch. 3, where we shall set out Lansbergen's calculation, which is Copernican in substance and differs only in its numbers and measures, and in ch. 4, where, with Longomontanus, we shall show how to fit the Danish measures and numbers to the Copernican hypothesis as well.* [Margin: The error of Copernicus in the motion of the nodes.] *From that same chapter, moreover [au-dem; recte: autem], it will become clear at no. 6 how far Copernicus erred in assigning to the nodes of these planets the motion of the apogees, and so advancing the places of the nodes too far, especially in Jupiter, where he overshot by a full 20°. And from ch. 5, no. 4, and its Scholia 3, 4 and 5, it will become clear whether and why he went wrong in making the inclinations of Venus and Mercury librate and vary.*

CAPVT III.

Chapter 3.

De Hypothesi Lansbergiana circa Latitudinem Quinque minorum Planetarum.

On Lansbergen's hypothesis concerning the latitude of the five minor planets.

I. Lansbergen's hypothesis of the latitude of the planets differs from the Copernican both in measures and numbers and in the places and motion of the limits and nodes. [Margin: Whether Lansbergen's hypothesis is Copernican.] He thinks that these are in no way moved with the motion of the apogees, as Copernicus, too much attached to Ptolemy, thought, but (except for Jupiter, whose node he makes fixed) by a motion proper and peculiar to them, though very slow, just as he holds the apogees too are driven. For the rest, as regards the theory of the Earth carried around the annual orb, and as regards the inclinations of the orbs to the plane of the ecliptic, in which the Earth's annual orb always lies, it is the very image and offspring of the Copernican hypothesis, as is clear

from Lansbergen's *Theorica motuum cælestium*, from chapter 15 to 19, from which

De Latitudine Trium Superiorum.

On the latitude of the three superior planets.

II. In the following diagram, let A be the centre of the ecliptic FCGE and of the Earth's great orb HIKL, which lies in the same plane of the ecliptic. [Margin: Beware of the error in the first figure of Lansbergen, ch. 15.] To this plane, as also to the ecliptic, let the orb BCDE of Saturn, Jupiter or Mars be inclined, with a fixed inclination and a constant angle BEF and DEG. Let the limit, or end of greatest latitude, be at B on the northern side and at D on the southern; let the common section of the planetary orbit and the ecliptic be CAE; and let the northern or ascending node be E, and the southern or descending node C. But let the nodes and limits of Jupiter not be changed, since they are fixed in the same place: for Jupiter's northern node remains perpetually in Cancer 5° 30′. Those of Saturn and Mars, however, shift in the order of the signs, by a motion to be given in small tables at the end of the chapter. And let the straight line FAD be drawn, cutting the line of sections CAE at right angles and in two equal parts at A. On these assumptions there arises a twofold variety of latitude in these three planets, answering to the twofold anomaly of the motion in longitude. The first is called *Centric*: it is the one that has its angle at A, the centre of the Earth's great orb, and it would be seen by an eye placed there, near the Sun. The second is the one seen from the globe of the Earth, and it has its angle at the centre of the terrestrial globe: for example the angle MON, if the Earth is at O and the planet at M; or the angle QOR, if the planet is at R; or *m*P*n*, if the Earth is at P and the planet at *m*. This latitude is called *True* or *Apparent*, and it differs from the latitude seen from the Earth's surface only as far as parallax in latitude requires. The first depends on the planet's distance from either of the nodes and on the inclination of the orb to the ecliptic. The other depends on the centric latitude and on the planet's distance from the centre of the Earth; and they are worked out by solving a double triangle. Thus if the planet is at M and the Earth at O, one seeks FB, the right sine of the inclination FEB, and the sine of the arc EM by which the planet is distant from the nearer node, according to the motion taken from the tables. When these are found, make: as sine EB, that is, the whole sine, is to sine EM, so sine BF is to sine MN, namely the sine of the planet's centric latitude, which throughout the semicircle EBC is northern. Next, having found the planet's distance from the centre of the Earth, as is done in the geometric calculation of longitude (in our case MO), make: as MO, the distance, is to sine MN of the centric latitude, so OM, taken as radius, is to MN, the sine of the true latitude, or of the angle MON. And the Earth's mean motion, which is always diametrically opposite the Sun's mean motion, will give the Earth's place on the annual orb, on which the angle of true latitude is to be based.

Diagram. Set into the lower left column, with the text running narrowly beside it. Two large tilted curves cross at the two ends of a horizontal line C–A–E: one passes through F at the top and G at the foot, the other through B and D, so that F stands outside B at the top and D outside G at the foot. A vertical line F–B–H–A–K–G–D passes through the centre A. A smaller circle about A carries H at its top, I at its left, L at its right and K at its foot. On it stand O, upper right, and P, lower left, P marked with a small rayed sign. From O straight lines run to M and N at the upper right and to R and Q at the upper left; from P lines run to *m* and *n* at the lower right. Below the lower curve stand three planetary signs, either side of D.

- F (top, on the outer curve): point of the ecliptic
- Q (upper left, outer curve) and N (upper right, outer curve)
- R (upper left, inner curve), B (top, inner curve), M (upper right, inner curve)
- H, I, L, K (top, left, right and foot of the small circle)
- O (upper right of the small circle), P (lower left of the small circle)
- C (left end), A (centre), E (right end)
- *m* and *n* (lower right)
- G (foot, inner curve), D (foot, outer curve)
- ♄ and ♃ (below the curve, left of D); ♂ (below the curve, right of D)

EXEMPLVM.

Example.

Latitudinis ♄, ♃, ac ♂ Geometricè inuestigatæ ex Lansbergio.

Of the latitude of ♄, ♃ and ♂ investigated geometrically, from Lansbergen.

III. *In the preceding diagram, let Saturn be at M and the Earth at O; Jupiter at* m *and the Earth at P; and Mars at R and the Earth at O.* [Margin: The latitudes of the three superior planets, one observed in antiquity for each.] *And let the year of Nabonassar be 519, Tybi 22, on the evening of which, as Ptolemy reports in Book 11, ch. 7, Saturn's northern latitude was observed at Alexandria, as large as the latitude of the star in the southern shoulder of Virgo, that is, 2° 43′. Let the year of Nabonassar be 507, day 17 of Epiphi, 16⅔^h after whose noon Jupiter's southern latitude was observed at Alexandria, according to Ptolemy, Book 11, ch. 3, the same as the latitude of the southern Ass, namely 10′. Finally, let the year of Nabonassar be 476, day 19 of Athyr, 18^h after noon, at which hour, according to Ptolemy, Book 10, ch. 9, the northern latitude of Mars was observed at Alexandria, very nearly the same as the latitude of the uppermost star in the forehead of Scorpius, 1° 15′. For these times, from the calculation of longitude undertaken by Lansbergen in his* Theoricae⋆, ch. 10, their centric longitude is given and their distance from the centre of the Earth, and the other motions from Lansbergen's tables, as below.⋆

Quantity	Planet	Line	Value
Centric longitude [Longitudo centrica]	♄		98° 51′ 57″
	♃		57° 35′ 35″
	♂		111° 57′ 18″
Mean place of ☉ for [Medius Locus ☉ pro]	♄		343° 19′ 16″
	♃		99° 6′ 50″
	♂		292° 58′ 29″
Equal motion of the node E ☊ [Motus æqualis Nodi E ☊]	♄		81° 0′ 0″
	♃		95° 30′ 0″
	♂		26° 28′ 35″
Distance of the planet from the Earth [Distantia Planetæ à Terra], in parts of which the radius AB is 10000 [Qualium Radius AB est 10000.]	♄	OM	9105
	♃	Pm	10916
	♂	RO	8970

[Margin: Step 1.] *Given these, first subtract the motion of the northern node from the planet's centric longitude, and you will have the planet's distance from the northern node* in the order of the signs. In Saturn this will be EM, 77° 51′ 57″, whose sine is 9776. In Jupiter it will be EBCD*m*, 352° 6′, and its complement to the circle, the arc* m*E, 7° 54′, whose sine is 1374. And in Mars it will be EBR, 145° 28′ 43″, whose complement to the semicircle will be the distance RC from the nearer node, 34° 31′ 17″, whose sine is 5666.*[67]

[Margin: Step 2, for the centric latitude.] Second, *find the sine of the given inclination for each planet; once found it remains useful for good, because the inclination is fixed, and it is as follows.*

Planet	Inclination [Inclinatio]	Inclination, value	Sine of the inclination [Sin^9 Inclinationis]	Sine, value
♄	BEF	2° 31′	BF	439
♃	DEG	1° 20′	DG	233
♂	BCF	1° 50′	BF	320

*So make: as the whole sine of quadrant EB, 10000, is to sine BF, 439, so the sine of arc EM, 9776, is to NM, sine 429, of Saturn's centric latitude. And as the whole sine of quadrant ED, 10000, is to sine DG, 233, so sine E*m*, 1374, is to sine* mn*, 32, of Jupiter's centric latitude. And as the whole sine of quadrant CB, 10000, is to sine BF, 320, so sine CR, 5666, is to sine QR, 181, of the centric latitude of Mars.*

[Margin: Step 3, for the true latitude.] Third, *in triangle MON the distance MO, 9105, is given, and sine MN, 429. So make: as MO, 9105, is to MN, 429, so*

[67]As printed, the degrees of these three distances do not follow from the table above, though the minutes and seconds do, within a minute in Jupiter. By subtraction the table gives 17° 51′ 57″ for Saturn, where the text has 77° 51′ 57″; 322° 5′ 35″ for Jupiter, where the text has 352° 6′; and 85° 28′ 43″ for Mars, where the text has 145° 28′ 43″. The printed figures stand in both places.

OM, of 10000 parts, is to MN, 471, the sine of angle MON, namely 2° 42′, the true northern latitude for Saturn. [Margin: Saturn.] *Again, in triangle* mPn *the distance* mP⋆, 10916, is given, and sine⋆ mn⋆, 32. So make: as⋆ mP⋆, 10916, is to⋆ mn⋆, 32, so⋆ mP⋆, 10000, is to⋆ mn⋆, 29, the sine of angle⋆ mPn⋆, 0° 10′, that is, of the true latitude of Jupiter.⋆ [Margin: Jupiter.] *Finally, in triangle QOR the distance RO, 8970, is given, and sine QR, 181. So make: as RO, 8970, is to QR, 181, so RO, the whole sine 10000, is to QR, 202, the sine of angle QOR, 1° 10′, namely the northern latitude of Mars.* [Margin: Mars.]

The true latitude was therefore [Fuit ergo Latitudo Vera]:

Planet	Observed [Obseruata]	Computed [Supputata]
♄	2° 43′ B	2° 42′
♃	0° 10′ A	0° 10′
♂	1° 15′ B	1° 10′

68

[Margin: Drawing the figure for the true latitude.] IV. To draw a suitable figure, moreover: when the motion of Saturn's node was taken from the Sun's mean motion, the remainder was the Sun's distance from the northern node, 262° 19″ [recte: 19′] 16″. Counted on the great orb from L through H and I, these brought the Sun to P, and so the Earth to O, where the visual angle of the true latitude is based. This is not because the Sun in this hypothesis is on the circumference of the great orb, but because it stands over against the Earth, diametrically opposite it; for in fact it is near A, the centre of the great orb. In the same way, when the place of Jupiter's northern node was taken from the Sun's mean motion, there remained the Sun's distance from the northern node, 63° 37′. Counted from L in the order of the signs, these bring the Sun's place to O, and over against it the Earth to P, where the visual angle of the true latitude is. Finally, from the Sun's mean motion and the place of the node of Mars, the Sun's distance from the northern node is gathered as 266° 29′ 54″. Counted from L through H, these bring the Sun's place to P and that of the opposite Earth to O.[69]

De Latitudine Veneris ac Mercurij.

On the latitude of Venus and Mercury.

V. For the theory of the latitudes of Venus and Mercury, let the Earth's great orb HIKL be described from A. In its plane let there be the orb FCGE, and to this let the orb BCDE of Venus or of Mercury be inclined. Let the nodes

[68] B and A stand for Boreal, northern, and Austral, southern; the Computed column prints no letter.

[69] The Saturn and Mars distances here follow from the table on the facing page. Jupiter's does not: 99° 6′ 50″ less the printed 95° 30′ is 3° 36′ 50″, where the text has 63° 37′. The printed figures stand.

be the northern at E and the southern at C, and through them let the straight line of common section CAE pass; produced as far as the great orb, let it be IAL, which HAK cuts at right angles at A, the centre of the great orb. Let the limits of greatest latitude be the northern at B and the southern at D. Let the angles of the inclinations, BEF and DEG, be fixed and unchangeable: in Venus 3° 30′, in Mercury 6° 16′. And let the nodes and limits be carried in the order of the signs by a very slow motion, on which see the tables below. Now imagine the planet at M and the Earth at O, or the planet at S and the Earth at Q. The planet's centric latitude, viewed from A, will then be the arc MN or ST, and the true latitude, viewed from the Earth, will be the angle MON or SQT. Their variation and the finding of them depend, as in the superior planets, on the planet's centric longitude, on the motion of the node and on the planet's distance from the Earth, as will shortly be made clear by examples.

Diagram. Set into the lower left column, with the text running narrowly beside it. A large circle HIKL has H at the top, I at the left, L at the right and K at the foot, with a vertical diameter HAK and a horizontal diameter IAL crossing at the centre A. Rayed solar signs stand on the circle at R, upper left, and at P, lower left. Within the circle, curves cross at C on the left and at a point right of A on the horizontal line, one passing through F at the top and G below, the other through B and D. Two diagonals pass through A: R–A–Q, and O–A–P with Z lying on the lower-left part of it. From O straight lines run in to N and M; from Q straight lines run up to T and S.

- H (top), I (left), L (right), K (foot): the large circle
- R (upper left, with rayed sign), O (upper right), P (lower left, with rayed sign), Q (lower right)
- F, N (upper part, within the circle), B, M, T
- Y (between M and S); S
- C (left), A (centre), E (right of A, on the horizontal line, its middle arm merged with the line)
- G, D (below the centre), Z (lower left), X (lower right)

EXEMPLVM.

Example.

Latitudinis ♀ ac ☿ Geometricè inuestigatæ ex Lansbergio.

Of the latitude of ♀ and ☿ investigated geometrically, from Lansbergen.

VI. *In the preceding figure, let Venus be placed at S and the Earth at Q, but Mercury at M and the Earth at O. For in the year of Nabonassar 476, Mesori 17, Venus as a morning star was seen at Alexandria to cover the leading star of the four that are in the southern wing of Virgo, whose latitude was then 1° 21′ north. And in the year of Nabonassar 484, day 18 of Thoth, Mercury as a morning star was seen in the same place more northerly than the uppermost star of the forehead of Scorpius, which has a latitude of 2° 15′, by two Moons, or about one degree. For these times, from*

Lansbergen's calculation of longitude and from his tables, the following motions are given.

Quantity	Planet	Line	Value
Centric longitude [Longitudo centrica]	♀		195° 5′ 5″
	☿		227° 44′ 15″
Equated anomaly of the orb [Anomalia Orbis æquata]	♀		249° 11′ 32″
	☿		213° 36′ 46″
Motion of the node [Motus Nodi] E ☊	♀		50° 55′ 16″
Motion of the node [Motus Nodi] C ☋	☿		217° 0′ 2″
Distance of the planet from the Earth [Distantia Planetæ à terra]	♀	SQ	9943
	☿	MO	7506

But the distance of ♀ is in parts of which the radius of the great orb is 10000, while that of ☿ is in parts of which the radius of Mercury's orb is 3818.

[Margin: Step 1, for the centric latitude.] *Given these, first, when the motion of the northern node has been taken from the centric longitude of Venus, there remains the Sun's distance from the northern node, for Venus 144° 10′. Counted from L through H, these give the Sun's place at R and the Earth's at Q. For Mercury, when the motion of the southern node has been taken from Mercury's centric longitude, there remains the distance from the southern node, 10° 44′. Counted from I to P, these give the Sun's place at P and the Earth's at O. So we are given arc OL, the complement of arc LHO, and the arc EX equal to it, 35° 50′; and the equated anomaly of the orb, counted from the true apogee V through DS, 249° 12′. When the semicircle is taken away there remains XS, 69° 12′, and when EX is subtracted from this there remains ES, 33° 22′, namely the distance of Venus from the northern node, whose sine is 5500. Similarly for Mercury we are given LO, 10° 44′, to which the arc EY is equal; and the equated anomaly of the orb, 213° 37′, counted from Z through D as far as M, will be the arc ZDM. When the semicircle ZDY is taken away there remains YM, 33° 37′. When EY is added to this, the whole arc EM becomes 44° 21′, which is the amount of Mercury's distance from the northern node; and its sine is 6990.*

[Margin: Step 2, for the latitude of ♀.] Second, *find the sine of the given inclination, which is as follows.*

Planet	Inclination BEF [Inclinatio BEF]	Sine of the inclination [Sinus Inclinationis]	Sine, value
♀	3° 30′	BF	610
☿	6° 16′	BF	1092

So make: as the whole sine of quadrant EB, 10000, is to sine BF, 610, so the sine of arc ES, 5500, is to ST, sine 335, in parts of which AE is 10000. But in parts of which AE, the radius of Venus's orb according to Lansbergen, is 7193, ST is 241 for the centric latitude, since as 10000 is to 335, so 7193 is to 241. Therefore in triangle QST, right-angled at T because the arc ST and its sine are perpendicular, from the base QS, namely the distance of Venus from the Earth, 9943, and the side ST, 241, ST is found to be 242, namely the sine of the angle SQT, 1° 23′, of the northern latitude of Venus.

[Margin: Step 3, for the latitude of ☿.] Third, *make: as the whole sine of quadrant EB, 10000, is to sine BF, 1092, so sine EM, 6990, is to MN, 763, in parts of which radius AE is 10000. But in parts of which radius AE is 3818, MN will be 291. For as 10000 is to 763, so*

3818 is to 291. Therefore in triangle MON, right-angled at N, we are given the base MO, the distance of Mercury from the Earth, 7506, and the side MN, 291. From these the angle MON is gathered trigonometrically as 2° 13′, namely of the northern latitude of Mercury. In this treatment, moreover, the semidiameter of the orb of ☿, already found in the calculation of longitude, is presupposed, according to what was said in Sect. 3, ch. 3, no. 4, since in this hypothesis it is variable.

The latitude *was therefore* [Fuit ergo Latitudo]:

Planet	Observed [Obseruata]	Computed [Supputata]
♀	1° 21′ B	1° 23′
☿	2° 15′ B	2° 13′

[Margin: Šírek, a follower of Lansbergen.] It remains to gather Lansbergen's numbers and measures into a synopsis, supplying the greatest latitudes, which he himself omitted, and which are gathered from the sine of the inclination of the orbs and the greatest or least distance of the planet from the Earth. Lansbergen's measures were adopted by Antonín Maria Šírek in his *Radius Sidereomysticus*, Book 3, ch. 1, as was the motion of the nodes.

Synopsis of the latitudes from Lansbergen [Synopsis Latitudinum ex Lansbergio]

Greatest inclination of the orb [Inclinatio Orbis Maxima]

Planet	Inclination
♄	2° 31′
♃	1° 20′
♂	1° 50′
♀	3° 30′
☿	6° 16′

Greatest latitude of the superior planets [Latitudo Maxima Superiorum]

Planet	Side	At the apogee of the orb [In Apogeo orbis]	At the perigee of the orb [In Perigeo orbis]
♄	South and north [A. & Bor.]	2° 17′	2° 48′
♃	South and north [A. & Bor.]	1° 7′	1° 38′
♂	North [Borealis]	1° 9′	4° 34′
♂	South [Australis]	1° 4′	6° 45′

Greatest latitude of the inferior planets from the declination [Latitudo Maxima Inferiorum ex Declinatione]

Planet	Side	At the apogee of the orb [In Apogeo orbis]	At the perigee of the orb [In Perigeo orbis]
♀	North [Bor.]	1° 25′	8° 54′
♀	South [Austr.]	1° 28′	8° 36′
☿	North [Bor.]	1° 32′	4° 5′
☿	South [Austr.]	1° 32′	4° 5′

Planet	Latitude from the reflexion [Latitudo ex Reflexione]	At anomaly of the orb [In Anomaliæ orbis]
♀	2° 31′	4ˢ 16°
♀	2° 31′	7ˢ 14°
☿	2° 14′	3ˢ 22°
☿	2° 14′	8ˢ 8°

Places of the nodes and limits at the beginning of the year 1 of Christ [Nodorum ac Limitum Loca ad Annum 1. CHRISTI ineuntem]

Planet	Northern node E [Nodus Boreus E]	Southern node C [Nodus Austr. C]	Northern limit of greatest latitude B [Limes max. Latitud. Boreus B]	Southern limit of greatest latitude D [Limes max. Latitud. Austr. D]
♄	♊ 25° 16′	♐ 25° 16′	♍ 25° 16′	♓ 25° 16′
♃	♋ 5° 30′	♑ 5° 30′	♎ 5° 30′	♈ 5° 30′
♂	♈ 29° 30′	♎ 29° 30′	♋ 29° 30′	♑ 29° 30′
♀	♉ 23° 53′	♏ 23° 53′	♌ 23° 53′	♒ 23° 53′
☿	♉ 8° 0′	♏ 8° 0′	♌ 8° 0′	♒ 8° 0′

Daily motion of the nodes [Motus Diurnus Nodorum]

Planet	‴	⁗	V.	VI.
♄	11	0	24	20
♃	0	0	0	0
♂	6	34	31	14
♀	6	26	28	28
☿	2	14	16	39

SCHOLIA.

Scholia.

I. *It must be noted that the motion of Jupiter's node is so slow that, if the Ptolemaic and Tychonic observations are true, about which we shall speak in ch. 4, no. 6, in the 1456 years that elapsed between Ptolemy and Tycho it has not crept forward* in the order of the signs *even by 6°. It is so far from having completed 26° since then, as*

Copernicus believed, assigning it the same motion as the apogee, in the manner of the ancients. [Margin: Criticism of Lansbergen on the immobility of Jupiter's node.] *So the smallness of this motion gave Lansbergen the handle for imagining Jupiter's node perpetually fixed in Cancer 5° 30′, where it was found toward the end of the last century. But if a motion must be eliminated altogether because it is small, made over a great interval of time, how many other motions smaller than the motion of this node would have to be abolished, which Lansbergen nevertheless accepts: for example, that of the obliquity of the ecliptic? Then, if the place of this node had to be set as immovable, it seems a place should have been chosen midway between the place observed by Ptolemy, which was Cancer 1°, and the place observed by Tycho in Cancer 7°, and so it should have been fixed in Cancer 3° or 4°, so that even in this way the observations of both periods would be better satisfied.*

II. *Lansbergen's excessive brevity and the neatness he strove for in his* Theoricae *were the reason that he did not set out the theory of the reflexion of Venus and Mercury, though he nevertheless accepts it in his tables.*

CAPVT IV.

Chapter 4.

De Hypothesi Latitudinis Quinque Minorum Planetarum Danica, seu Longomontanica.

On the Danish, or Longomontanan, hypothesis of the latitude of the five minor planets.

I. Longomontanus sets out the theory of the three superior planets concerning the motion in latitude in the *Astronomia Danica*, Book 2 of the *Theorica*, ch. 14. He first remarks that from the varying latitude, which other things being equal is always greater at a smaller distance of the planet from the Earth, the varying elevation of these planets above the Earth is confirmed a posteriori, since optical reasoning requires that nearer arcs appear larger. [Margin: An argument against the homocentrics from the latitude of the planets.] This the defenders of the homocentrics certainly did not see. He shows it by a figure in which the angle at the Earth, now nearest to the planet and now farthest, subtends the arc of greatest latitude. But one grounded in the elements of optics has no need of another figure, and the matter will become quite plain from this other figure, fitted to Copernicus's hypothesis. In it let E be the centre of the annual orb FHG, which takes the place of the Ptolemaic epicycles. Let two straight lines be drawn: one, AEB, in the plane of the ecliptic and of the annual orb; the other, CED, in the plane of the eccentric of these planets, cutting AB at the centre E. Let C be the northern limit of latitude, and let the greatest northern latitude be measured by the angle CFA, when in the planet's acronychal oppositions with the Sun at G the Earth is at F; but by the angle CGA, when in its conjunctions with the Sun, towards F, the Earth is at G. But let the southern limit be D, and let the greatest southern latitude be measured by the an-

Diagram. Set into the lower right column, with the text running narrowly beside it. A circle about E, with F at its top, H at its left and G at its foot, is crossed by a near-vertical straight line A–F–E–G–B. A second straight line runs through E from C, at the upper left above the circle, to D, at the lower right below it. Further straight lines join C to F and to G, and D to F and to G. The signs ♄, ♃ and ♂ stand one below another inside the circle on its right side.

- C (top left), A (top right)
- F (top of the circle), H (left, inside the circle), E (centre), G (foot of the circle)
- B (foot, left), D (foot, right)
- ♄, ♃, ♂ (right side, inside the circle) gle BGD if the Earth is at G, in the acronychal positions, etc., or by the angle BFD if the Earth is at F. For it is clear that the exterior angle AFC is greater than the interior angle AGC, and the exterior angle BGD greater than the interior angle BFD, by Euclid I.32; and therefore that the same greatest latitude will nevertheless appear greater to an Earth nearby than to one far off.

II. With these things assumed, he presents the places of the limits and nodes observed by Tycho in the acronychal oppositions, in which the latitude appears greatest because of the planet's nearness to the Earth, and the greatest latitude observed on that occasion, which we shall give in our usual way at the end of this chapter. He teaches that to investigate the simple or mean inclination of the orbs to the ecliptic one needs the greatest latitude: in the preceding figure, the angle AFC, measuring the greatest northern latitude, if the Earth moves and is at F; or rather the angle BGD, measuring the greatest southern latitude, which, as I said, is greater than the northern, if the Earth is at G. Next one needs the semidiameter of the annual orb, that is, the mean distance of the Sun from the Earth, namely the side EG; and finally the planet's distance from the centre of the eccentric orb, namely the side DE, or DG, the distance from the Earth if the planet in the acronychal position is at D. For in the triangle DGE, given the sides EG and DE or DG, and the angle EGD which they contain, which is the complement to two right angles of the angle BGD measuring the greatest southern latitude, a trigonometer will easily obtain the angle GED, the inclination of the plane CED to the plane of the ecliptic AEB. [Margin: Longomontanus's foundations for the inclination.] From his own hypothesis on the longitude of the planets, therefore, he sets down, in units of which the radius of the eccentric is 100000, both the semidiameter of the annual orb and the least distance of the three planets from the centre of their own orb when they are in the acronychal position and have the greatest southern latitude, as you see in the following little table.

	Greatest southern latitude	Semidiameter of the annual orb	Distance of the planet from the centre of the orb
♄	2° 49′	10426	97593
♃	1° 40′	19349	95230

	Greatest southern latitude	Semidiameter of the annual orb	Distance of the planet from the centre of the orb
♂	6° 42′	65095	89090

[Margin: The inclination of the three superior planets found.] From these he derives the mean and simple inclination of the plane of the eccentric to the plane of the ecliptic: in Saturn 2° 31′, in Jupiter 1° 19′ 15″, in Mars 1° 48′ 40″. He also confirmed this from the greatest northern latitude, using the triangle CEF and the sides EC and EF. In Saturn and Jupiter he found the same inclination, that is, the angle CEA, equal to the angle BED. But in Mars, using the side CE as 110910 and EF as 65895, according to the correction given in the theory of the longitude of Mars, he found from the greatest northern latitude observed by Tycho, 4° 33″ [recte: 4° 33′], the inclination of the plane of Mars, that is, the angle CEA, to be 1° 50′ 55″. From this he came to suspect that the greatest southern latitude observed by Tycho ought to be corrected somewhat, and increased, because of refractions not sufficiently eliminated in the calculation. So he took the inclination handed down by the ancients, 1° 50′, as a mean between 1° 48′ 40″ and 1° 50′ 55″, and, reversing the demonstration, found the greatest northern latitude of Mars to be 4° 31′ and the southern 6° 47′. [Margin: The inclination of the orbs of the three superior planets invariable.] And so he established that the inclination of the orbs of these three planets to the annual orb, which serves in place of the Ptolemaic epicycles, and hence to the ecliptic, is invariable, contrary to what the ancients held about the epicycles of these planets, and fixed at a constant angle. With this hypothesis made, he gives a method of investigating the latitude of the planets for a given time in the threefold hypothesis, but principally in the Copernican; we shall divide this method into the following problems.

Problema 1. Data Inclinatione &c. Latitudinem Planetæ Superioris ad datum tempus Geometricè inquirere, in Forma Copernicea.

Problem 1. Given the inclination, etc., to investigate geometrically the latitude of a superior planet for a given time, in the Copernican form.

III. With centre A let the annual orb FE, etc., be described, and let the Earth be at F, near the acronychal position E, viewing the planet C, of whose eccentric BC is a portion, and to the planet let the straight line AC be drawn from A. Let BD be a portion of the ecliptic, and let the inclination of the planet's orb to it be the angle CBD. Then let the perpendicular CD be drawn to the ecliptic, and let C and D be joined with the Earth by the straight lines CF and DF, and D with A by the straight line AD. Now let BC be given, the planet's distance from the nearer node B. For from the whole sine, the sine of the arc BC and the angle B, the sine CD will be found, in units of which the radius of the eccentric is, for example, 100000, and also its arc DC. Next, DC

must be reduced to proportion with the planet's given distance CA, previously found from the calculation of the longitude; and also AD, in the triangle ACD, right-angled at D, in which the angle DAC is given, equal to the arc DC that was found, and the side CA. Afterwards, in the triangle DAF, in which AD is now given, the semidiameter AF of the annual orb is taken as given in units of which the planet's radius is known; and so is the angle DAF, because it is the complement to a semicircle of the anomaly of the annual orb, that is, of the distance of the Earth F from the planet's centric place in the ecliptic, which is D. In that triangle, I say, the side DF is derived. Finally, in the triangle CDF, from CD and DF now found and the right angle D, the angle CFD is derived, which determines the latitude of the planet C as seen from the Earth F. In the acronychal position itself, however, the calculation becomes easier.

Diagram. Set into the right column, with the text running narrowly beside it on the left. A circle about A carries E at the top of its circumference and F just to the right of it. From B, at the left outside the circle, two arcs rise to the upper right, one to C and one to D; C and D stand close together above the circle. Straight lines join C to D, C and D to F, and A to C, to D (through E) and to F. A straight line continues from A down to the foot of the circle. The sign ♄ stands inside the circle, left of that line.

- C (top, the upper end of the upper arc), D (top right of C)
- B (left, the lower end of the arcs)
- E (top of the circle), F (circumference, upper right)
- A (centre)
- ♄ (inside the circle, below A, left of the vertical)

Problema 2. Idem Inueſtigare in Tychonica Forma.

Problem 2. To investigate the same in the Tychonic form.

IV. [Margin: Delineation of the scheme in the Tychonic form.] Longomontanus adapts this problem to Mars, because of the particular difficulty in that planet, in roughly this way. From E, the centre of the unmoved Earth, describe the Sun's annual orb AKF, whose diameter is KA. Let the Sun be at F, distant from A, the acronychal position, by the arc AF. Then on the spherical surface let the arcs BC, a portion of the planet's eccentric, and BD, a portion of the ecliptic, be described, whose nearer node is B. Let Mars, for example, be at C; let the perpendicular CD be drawn to the ecliptic; and let D and C be joined with the Sun F by the straight lines CF and DF, so that the line FD, away from the planet's opposition, is parallel to the diameter AK. From the Earth let the straight line EF be drawn to the Sun, the straight line EC to the planet, and the straight line ED to the ecliptic. The measure of the latitude to be investigated will then be the angle CED. [Margin: Step 1.] First, therefore, in the spherical triangle CBD, from the whole sine and the sine of the arc BC, by which the planet is distant from the nearer node B, the right sine CD is found, with its arc, the angle of inclination B being assumed; and to this arc the angle CFD is equal.

But because DC has been found in units of which the radius of the sphere is 100000, it must be reduced to proportion with FC, the planet's distance from the Sun, as to a radius; this distance is here taken as known from the calculation of the planet's longitude. [Margin: Step 2.] Secondly, in the triangle CFD, from the angle at F, or rather from the right angle at D, and the sine DC, obtained in units of the side CF, and the side

Diagram. Set into the lower right column, with the text running narrowly beside it on the left. A circle about E, with K at its left and A at its right joined by a diameter through E, and F on the circumference below A. D and C stand inside the circle below E, to its left. Straight lines join E to A and to K (the diameter), E to F, E to D, E to C, D to F, C to F and D to C. From B, below and left of the circle outside it, one line rises to D, and another rises through C and runs on to E.

- K (left of the circle), A (right of the circle), F (lower right, on the circumference)
- E (centre)
- D (left, inside the circle), C (below D, to its right, inside the circle)
- B (foot, outside the circle)

CF itself, DF is sought. [Margin: Step 3.] Thirdly, in the triangle DFE, ED is sought from the semidiameter EF of the annual orb, in units in which FC, the radius of the planet's orb, was known; from DF, now found; and from the angle EFD, which, because of the parallels AE and FD that the Tychonic hypothesis requires, is equal to the angle AEF, measuring the distance of the Sun F from the planet's opposition with the Sun. From these three givens, I say, ED is sought. [Margin: Step 4.] Finally, in the triangle CDE, right-angled at D, from DC and DE now found, the angle DEC is found, which determines the apparent and true latitude of the planet as seen from the Earth E.

Problema 3. Data inclinatione vniformi Epicycli ad Eclipticam; inuenire Latitudinem Planetæ in forma Ptolemaica.

Problem 3. Given the uniform inclination of the epicycle to the ecliptic, to find the latitude of the planet in the Ptolemaic form.

V. I said "uniform", as the more recent astronomers, with Longomontanus, would have it, asserting that this uniformity of the inclination satisfies the phenomena more correctly. On this assumption, in the accompanying figure, let MAL be the diameter of the ecliptic, and let it be intersected at the centre of the world A by CAB, the diameter of the eccentric orb of some superior planet. From the ends of this diameter, B and C, as centres, let the epicycles FH, to the north, and KG, to the south, be described, whose planes always stand uniformly and equidistantly to the plane of the ecliptic, so that their diameters FH and KG are parallel to the diameter of the ecliptic MAL. Next let the centre A be joined with the point F by the straight line AF, and with H by the straight line AH; then with G and K by the straight lines AG and AK. From all these points

and from B and C let perpendiculars be drawn to ML, namely HL, BN, FQ, GO, CP and KM. And when HF has been produced to E and KG to D, let the straight line ED be drawn through A to their ends, cutting ML at A at right angles.

Diagram. Set across the left column, breaking the paragraph. A long horizontal line M–P–O–A–Q–N–L runs through A. To the upper left, a circle with the diameter K–C–G above that line; to the lower right, a circle with the diameter F–B–H below it. From A straight lines run to K, C and G on the left and to F, B and H on the right. Short perpendiculars drop from K, C and G to M, P and O, and rise from F, B and H to Q, N and L. A dotted line runs from G to D and from F to E, and a dotted vertical joins D and E through A. The signs ♄ ♃ ♂ stand together above the right-hand circle.

- K (left), C (centre of the left circle), G (right end of the left diameter), D (above A, at the top of the dotted vertical)
- M (far left, on the horizontal), P (below C), O (below G)
- A (centre, on the horizontal)
- Q (above F, on the horizontal), N (above B), L (far right, on the horizontal)
- E (below A, at the foot of the dotted vertical), F (left end of the right diameter), B (centre of the right circle), H (right end of the right diameter)
- ♄ ♃ ♂ (above the right-hand circle)

With these designated: if in its conjunctions with the Sun the planet is to the north, at the epicycle's apogee H, the angle of latitude will be HAL; if to the south, at K, it will be KAM. But if in the acronychal oppositions it is at the perigee F, to the north, the angle of latitude will be FAQ; if to the south, at the perigee G, it will be GAO. These angles indeed vary as the sides AB and AH, and likewise AC and AK, will vary, with the planet's distance from the node on the eccentric kept the same, and its arc towards the ecliptic equal to the angles of inclination NAB and PAC. But their right sine, BN and CP, must be reduced to proportion with the planet's distances on the eccentric, AB or AC, just as AN and AP must. So, for example, in the triangle BAN, right-angled at N, from the given AB, the distance of the centre of the epicycle from the centre of the Earth, obtained by the calculation of the longitude, and from the inclination BAN, the sine BN is sought, to be reduced to units of AB, and the side AN. When NQ, equal to the semidiameter FB of the epicycle, is taken from AN, AQ remains in the triangle AFQ, right-angled at Q, in which FQ is given, equal to BN itself. So the angle QAF will not remain hidden, which determines the latitude in such a position. Let it be enough to have indicated this for the other cases.

De Motu Nodorum ac Limitum trium Superiorum Planetarum.

On the motion of the nodes and limits of the three superior planets.

VI. [Margin: Copernicus and Ptolemy criticised by Longomontanus.] About to treat this in Book 2, ch. 15, Longomontanus criticises Copernicus, and indeed Peuerbach and Regiomontanus, because, without consulting the heavens, they affirmed with Ptolemy that the nodes of these planets are moved with the same motion as the apogees, and so assigned them too fast a motion. And although he does not trust Ptolemy much, yet because older foundations are not available, he takes from Ptolemy that the limit of Saturn is 50° short of the apogee, that of Jupiter 20° beyond the apogee, and that of Mars at the apogee itself, about the year of the Lord 136. But he corrects the apogee of Mars from agreement with the greatest northern latitude, and resets it at Cancer 25½°. The places of the apogees of Jupiter and Saturn he corrects by removing 21′ of the precession of the equinoxes, so that they are reckoned from the mean equinox; just as the places of the nodes and apogees recently observed by Tycho about the year 1600 he corrects by adding 7′, to reduce them to the mean equinox. For in this way the mean or equal motion of the nodes is better derived from the interval of time and the motion made in the meantime. Finally, he appends this synopsis.

Years of Christ	Saturn: corrected apogee	Saturn: north node	Jupiter: corrected apogee	Jupiter: north node	Mars: corrected apogee	Mars: north node
136	♏ 23° 50′	♋ 3° 21′	♍ 14° 0′	♋ 1° 21′	♋ 28° 15′	♈ 25° 51′
1600	♐ 26° 27′	♋ 20° 23′	♎ 7° 32′	♋ 6° 53′	♌ 28° 42′	♉ 16° 53′
Difference	32° 37′	17° 2′	23° 32′	5° 32′	30° 27′	21° 2′

Therefore it is clear from these how plainly the followers of Ptolemy and Peuerbach, and Copernicus himself, erred [Margin: The error of the ancient astronomers in the motion of the nodes.] in setting the motion of the nodes and of the apogees to be the same, since in an interval of 1464 years the apogee of Jupiter, for example, has been advanced 23° 32′ and the north node hardly 5° 32′, and so with the rest. Further, from this it is derived by the rule of proportion: if the nodes have advanced so many degrees and minutes in 1464 years, how much they advance with equal motion in single years, or in 20, or in 100, or in 1000, namely:

Equal motion of the nodes [Motus Nodorum Æqualis]

Years	♄ Deg.	′	″	‴	♃ Deg.	′	″	‴	♂ Deg.	′	″	‴
1	0	0	41	53	0	0	13	36	0	0	51	43
20	0	13	57	42	0	4	32	8	0	17	14	26
100	1	9	48	31	0	22	40	39	1	26	12	8
1000	11	38	5	15	3	46	46	33	14	22	1	18

De Latitudine Veneris ac Mercurij.

On the latitude of Venus and Mercury.

VII. [Margin: Proposition 1, on the motion and place of the nodes.] Having completed the latitudes of the three superior planets, Longomontanus treats the latitude of Venus and Mercury in Book 2 of the *Theorica*, chs. 24 and 25. First, he affirms that the ancients wrongly thought the place of the nodes and of the apogees to be the same. For the south node of Mercury does cling perpetually to the apogee; but the north node of Venus, which once was at its apogee, precedes the apogee in this century by 16°, so that the apogee in this century is at the end of ♊ while the north node of Venus is at ♊ 13°. From this he derives that the motion of this node is slower than that of the apogee, and that it completes one degree in about 100 years. [Margin: Proposition 2, on the immutability of the inclination. Fixed in these planets also.] Secondly, he affirms that in the intersections of these nodes the inclination of the latitude is perpetually stable, and that it is invariable in every revolution of the centre of the planet's orb, according to the hypothesis of the unmoved Earth, or of the Earth itself in the hypothesis of the moved Earth; but with the roles exchanged in the first departures from the ecliptic, so that what applies to Venus towards the north applies to Mercury towards the south. And because the angles of the apparent inclinations change regularly with the change in the distance of these planets from the Earth, he affirms that their eccentric is not different from the plane of the ecliptic. [Margin: Assertion 3, on the identity of the inclination and the reflexion.] Thirdly, he asserts that Ptolemy wrongly separated the inclination from the reflexion, since in reality they are the same thing, and that he set it greatest at the point of contact of the epicycle. But this arose from the fact that around the point of contact of the orb, on the occasion of the greatest digressions from the Sun, he always made the angle of inclination smaller by one degree than the inclination observed near the perigee of the epicycle and the quadrants of the eccentric requires; which Ptolemy, however, could scarcely observe in a less oblique sphere. Moreover, in all five planets every variation of latitude depends on the planet's distance from the nodes, at which the angle of perpetual inclination lies, on the planet's motion in the epicycle or its own orb, and on the planet's distance from the Earth. [Margin: Assertion 4, on the superfluity of the Deviation.] Fourthly, he says that the Deviation introduced by Ptolemy, and indeed at its greatest 10′ to the north in Venus and 45′ to the south in Mercury, is superfluous, and has no sufficient foundation in observations properly examined. [Margin: Assertion 5, on the quantity of the inclination.] Fifthly, having compared the observations with one another, he says that he has found the angle of the mean inclination to be 3° 30′ in Venus and 5° 40′ in Mercury, and that by these values the phenomena are satisfied.

Diagramma Latitudinum Veneris ac Mercurij in forma Ptolemaica & Tychonica.

Diagram of the latitudes of Venus and Mercury in the Ptolemaic and Tychonic form.

VIII. From A, the centre of the world, let the eccentric BDFH of Venus or Mercury be described, whose diameters DH and BF intersect each other at right angles at A; and BF is the line of the nodes of the eccentric.

Diagram. Set across the left column, breaking the paragraph. A large circle about A, the eccentric, carries eight small circles, the epicycles, whose centres stand on it. A vertical line runs from the top small circle B through A to the bottom small circle F, and a horizontal line from the left small circle D through A to the right small circle H. In each small circle a vertical diameter RS and a horizontal diameter LK cross at the centre, and a further slanting diameter NM passes through it. The words *Orien* and *Occid* stand on either side of A, read as printed, the first with a stroke over its end; below them, on either side of the vertical, stand the signs ♀ and ☿.

- A (centre), with *Orien* to its left and *Occid* to its right; ♀ and ☿ below
- B (top small circle): R, N, L, K, M, S
- C (upper left small circle): R, N, L, K, M, S (this S stands below the circle)
- D (left small circle): R, N, L, K, M, S
- E (lower left small circle): R, N, L, K, M, S
- F (bottom small circle): R, N, L, K, M, S
- G (lower right small circle): R, N, L, K, M, S
- H (right small circle): R, N, L, K, M, S
- I (upper right small circle): R, N, L, K, M, S

For the present, neglecting the eccentricity, let the centres of the epicycles, with their epicycles, be at the points B, C, D, E, F, G, H and I. In any place on the eccentric the epicycles retain sections similar to the eccentric's, and their parallelism, so that their diameters RS are parallel to the diameter BF itself, and the diameters LK parallel to the diameter DH, at whatever position on the eccentric the epicycle may be. Now, since the orb or epicycle is inclined to the ecliptic, let diameters MN be drawn in every position of the epicycle through the centres of the epicycles, at which there is a common intersection with the diameters LK; and let the angle of inclination NBL or KBM be perpetually 3° 30′ in Venus and 5° 40′ in Mercury. Let the north node be at B, which now coincides with the apogee of Mercury but in Venus precedes the apogee by 16°, and the south node at F. With these things set down, as long as Venus is in the eastern semicircle of the epicycle RNS, it will be in northern latitude, and in the western semicircle of the epicycle SMR it will be in southern latitude. These roles are exchanged in Mercury, so that the eastern semicircle of the epicycle belongs to southern latitude and the western to northern. The transitions from the eastern semicircle to the western and back take place at the epicycle's apogee R and perigee S; and the beginning of the revolution is taken in Venus from the section B, in Mercury from the section F. Notwithstanding this, at the end of ch. 4 he accepts the reflexion of the epicycle at the apogee and perigee of the eccentric, and, imitating Copernicus, carries it into the tables.

Diagramma Latitudinum Veneris ac Mercurij in forma Copernicæa.

Diagram of the latitudes of Venus and Mercury in the Copernican form.

IX. From A, the centre of the annual orb and of the world, let the Earth's annual orb be described, BD, substituted in place of the eccentrics of Venus and Mercury. For the sake of ease, neglecting the eccentricity of the orbs, let the inner orb of Venus or Mercury, KFCG, be concentric with it, substituted for the Ptolemaic epicycles. Although Mercury's large eccentricity does much to vary the latitude, in Venus it makes scarcely a perceptible difference, because it is far smaller and its inclination is small. Now, drawing the line of common section BAD, let it be the same in Mercury as the line of apsides, but in Venus let it precede the apogee by 16°. At right angles to it let FE be drawn, and across FE let HG run, making the angles FAH and GAE equal to the perpetual inclination of these orbs to the annual orb or ecliptic, which angle is 3° 30′ in Venus and 5° 40′ in Mercury. And let there be supposed, as above, an entirely contrary alternation of the latitudes: wherever the Earth may be, the latitude of Venus is northern in the eastern hemicycle KHC and southern in the western CGK; but, on the contrary, the latitude of Mercury is southern in the rising semicircle and northern in the setting one.

Diagram. Set into the right column, with the text running narrowly beside it on the left. Two concentric circles about A. A vertical line runs from B at the top of the outer circle through K, at the top of the inner circle, and A to C, at the foot of the inner circle, and D, at the foot of the outer. A horizontal line runs from F to E on the inner circle through A, and a slightly inclined line from H to G on the inner circle through A. The signs ♀ and ☿ stand in the lower ring between the two circles, on either side of the vertical.

- B (top, outer circle), K (top, inner circle)
- F (left, inner circle), H (just below F), E (right, inner circle), G (just above E)
- A (centre), C (foot, inner circle), D (foot, outer circle)
- ♀ (lower left, between the circles), ☿ (lower right, between the circles)

Latitudinem Veneris Geometricè inquirere in forma Tychonica.

To investigate the latitude of Venus geometrically in the Tychonic form.

X. Let the latitude of Venus be investigated for the year 1585 September 15, Old Style, but 25 New Style, in the morning, at $5\frac{1}{4}^{h}$ after midnight, which was observed by Tycho, after the removal of parallax, as 2° 8′ to the south, with longitude in ♌ 15° 58′. From the Danish tables, moreover, the equated anomaly of the eccentric was 92° 43′ and the equated anomaly of the orb 229° 0′, although in this matter the mean anomalies could be used. [Margin: Delineation of the Tychonic figure.] With these set down, and given the north

node of Venus for that time at 13° of Gemini, that is, anticipating the apogee by 16°, let there be described from A, the centre of the world and of the Earth, at least a semicircle of the concentric BCD, on which is the centre of the great epicycle or orb of Venus. Let the section of the eccentric and the ecliptic be BAD, and let the node ☊ be B, from which the arc BC is counted in the order of the signs; this arc consists of the anomaly of the eccentric and the distance of the node from the apogee, and so is made up of 92° 43′ and 16°, and is therefore 108° 43′. From the centre C let the orb of Venus, EGKN, be described, whose diameter KE is parallel to the line of nodes BD. When ACH is drawn, the arc EH will be, by the law of the motions of Venus, similar to the arc BC, that is, 108° 43′, and the centric place of Venus will be designated by the line ACH. But because the true place of Venus, from the observed or calculated longitude, is found at M, and the arc HKM at 219°,

Diagram. Set into the lower right column, with the text running narrowly beside it on the left. A horizontal base line D–A–B carries a large semicircle above it, the concentric, on which C, the centre of the orb, stands. About C is drawn a circle in a solid line, and a dotted circle of about the same size set a little lower, which runs inside the solid circle at the top and outside it at the foot. A horizontal diameter runs from K through C to E, and a vertical from G through C to F. From A straight lines run through C to H, and to M. C is joined to M; a short vertical drops from the line KE, near E, to M, with P beside it; and a second line, partly dashed, rises from A to I beside M. The sign ♀ and the word *Tycho* stand inside the semicircle at the lower right.

- H and G (top, side by side, H to the left), K (left), E (right)
- C (centre of the circles), P (below E), M and I (lower right, side by side, M to the left), N (lower left, on the solid circle), F (below the circle)
- D (base, left), A (base, centre), B (base, right)
- ♀ and *Tycho* (inside the semicircle, lower right) if to these the arc EH is added, the whole EHKM becomes 327° 43′. Next let the straight line GCF be drawn, perpendicular to KE. The angle MCN, or the arc NM, will be 57° 43′, and EM 32° 17′, provided, that is, that from the arc EHM there is subtracted the arc EKN, or three-quarters of the circle, which is 270°. Since, therefore, Venus is in the western semicircle of the epicycle, its latitude will be southern, according to the alternations set out above. To investigate that latitude, let the orb EKF be described in the plane of the ecliptic, inclined to the orb of Venus, and let the straight line CMI be drawn; and from M, the place of Venus, the perpendicular MP to EK; and from A, the two straight lines AM and AI. And let the distance MA of Venus from the Earth be assumed, from the calculation of longitude, to be 63120 parts, of which the radius of the eccentric is 100000. Let the rest be done as below.

EXEMPLVM. Calculi Geometrici.

Example of the geometrical calculation.

XI. [Margin: Step 1.] First, let it be: as the whole sine 100000 is to PM, the right sine of the arc EM, 32° 17′, which sine is 53411, so is the sine of the angle of inclination MEI, that is, of 3° 30′, which is 6105, to the sine MI, 3261. Next, in parts of which the radius of the orb of Venus is, according to Longomontanus, 72248 of the 100000 of the radius AC, MI will be 2356. [Margin: Step 2.] Secondly, in the triangle MAI, with the side MI now found, the distance MA of Venus from the Earth set at 63120, and the angle at I right, because the arc of latitude is drawn perpendicular to the ecliptic, you will find the angle MAI to be 2° 8′: that is, the apparent latitude of Venus, agreeing entirely with the observed latitude and close to the one the Alphonsine calculation gives, even though the Prutenic calculation falls short at this place by half a degree. [Margin: Error of the Prutenic Tables.]

In his tables, however, he recognized that the reflexion must be applied, just as in Mercury, as we shall soon say, although Longomontanus has not set out the theory of this reflexion in Venus.

De Calculo Latitudinis pro Mercurio.

On the calculation of the latitude for Mercury.

XII. In the same Chapter 24 of Book 2 of the *Theorica*, Longomontanus affirms that the calculation of the latitude of Mercury is similar to the calculation for Venus, provided that the latitude is recognized as southern in the eastern semicircle and as northern in the western, and that nothing is added to the anomaly of the eccentric, but the node is kept on the line of apsides. But because of the great eccentricity and inclination of Mercury, he says there is some difference between its latitude when it is at the apogee and the latitude it has at the perigee of the orb, as was gathered from observations of the years 1585 November 15, in the morning, and 1593 May 11, in the evening. Because of this difference he adopts the Copernican small circle, taken up by him to represent the Ptolemaic deviation, and uses it to vary the inclination, so that the variation of the mean inclination of Mercury, set above at 5° 40′, is 15′ at the apogee and 18′ at the perigee. With these set down, and with the distance of Mercury at the apogee of the eccentric as 106822 and at the perigee as 95452, in parts of which the radius of the eccentric is 100000, and with the semidiameter of the epicycle as 38500 of the same parts, he gathers that the inclination of Mercury near the quadrants of the epicycle is 1° 34′ at the apogee of the eccentric and 3° 33′ at the perigee; and that the obliquation, or greatest reflexion, is 2° 3′ at the apogee of the eccentric and 2° 19′ at the perigee. These are so limited with respect to the inclination of the little small circle [parui circelli] that 2° 18′ remain at the apogee and 2° 1′ at the perigee.

Synopsis of latitudes from Longomontanus [Synopsis Latitudinum ex Longomontano]

Greatest inclination to the ecliptic [Inclinatio ad Eclipticam maxima]

Planet	Greatest inclination
♄	2° 31′ 0″
♃	1° 19′ 15″
♂	1° 50′ 0″
♀	3° 30′ 0″
☿	5° 40′ 0″

Greatest latitude [Latitudo Maxima]

Planet		At the apogee of the epicycle	At the perigee of the epicycle
♄	South & North	2° 17′	2° 49′
♃	South & North	1° 7′	1° 39′
♂	North	1° 9′	4° 31′
♂	South	1° 4′	6° 47′
♀		1° 28′	9° 2′
☿		1° 34′	3° 33′

[Margin: From the declination.]

Greatest latitude from the reflexion near contact, or at the anomaly of the orb written below [Latitudo Maxima ex Reflexione circa contactum seu ad Anomaliam orbis infraſcriptam]

Planet	Greatest latitude from reflexion	Anomaly of the orb
♀	2° 33′	4^{s} 16°
♀	2° 33′	7^{s} 14°
☿	2° 36′	8^{s} 10°

SCHOLIA.

Scholia.

1. Longomontanus reports (Book 2 of the *Theorica*, Chapter 14) that in the year 1593 the latitude and longitude of Mars were observed by Tycho on August 10, Old Style, when Mars appeared to have its greatest southern latitude, 6° 19′, [Margin: On the diminished latitude of Mars as it tends towards opposition with the Sun.]

and that afterwards, on August 25 of the same year, at 17^{h} 30^{m}, when the true opposition of Mars with the Sun took place, the latitude of Mars was observed by the same man to be 6° 5′; and that therefore the latitude decreased while Mars was tending towards acronychal opposition, contrary to the estimation of the ancients and the canons. Because of this diminution a great scruple lodged in Tycho's mind, which was still in suspense. [Margin: The scruple of Tycho and Kepler on this.] Accordingly the following words were written in the book of observations of that same year, and Kepler repeats them in his commentaries on the motion of Mars, Chapter 66: "It is worth considering that Mars, about August 10, had its greatest southern latitude, and afterwards decreased, so that on the 24th, at opposition, it was brought about a quarter of a degree nearer the ecliptic. The canons, however, even with the place of the greatest latitude corrected to the 18th degree of Aquarius, by no means show this, however the greatest latitude is assumed there. The cause of this must be diligently investigated." Therefore Longomontanus, to remove this scruple from himself and the Tychonians, drew the north node of Mars, which he had earlier placed with Tycho at 18° of Taurus, back to the 17th degree, and

likewise the south node to the 17th degree of Scorpio, as we have set it in the table at the end of the chapter. Kepler, moreover, says in that Chapter 66 that he came to Tycho, who was by then living in Bohemia, and often asked him about the theory of the latitudes; and that Tycho answered that the nodes are in opposite places, but that the sections pass through the points of the Sun's mean place, or through the centre of its epicycle, and added: "This is a wonder, that the greatest latitudes occur before or after the oppositions with the Sun, that is, the true ones." [Margin: Tycho's answer on this.]

II. But Kepler, who in Chapter 15 gives the observed southern latitude of Mars for August 25 as 6° 2′, affirms in that Chapter 66 of the Commentaries on Mars that Ptolemy went wrong because of the most intricate motions of the inclinations, deviations and reflexions, and because he was fixed on his notion of the epicycle. [Margin: Kepler's opinion of this diminution.] As soon as he saw the planet at opposition with the Sun digress from the ecliptic towards one quarter, he asserted that at conjunction with the Sun it digresses towards the opposite quarter, so that there would be some compensation, and an equality of restitution and a coherence with the Sun; and therefore he judged that the greatest latitude occurs at the moments of opposition, and the contrary latitude at the moments of conjunction. But the true cause why the greatest latitude occurs now at the moment of true opposition, now before it, now after it, Kepler says, is the proportion of the inclinations to the distance of Mars from the Earth. "For," he says, "the latitude is greatest when the distance of Mars from the Earth grows or shrinks in the same proportion in which the lines of the inclinations of Mars grow or shrink; and the latitude increases when the proportion of the distance decreases more than the proportion of the lines of inclination, or when, as the former decreases, the latter on the contrary grows. Conversely, the latitude diminishes either when the distance of Mars from the Earth grows more than the lines of inclination in their own proportion, whatever it may be, or when, as the distance grows, those lines diminish. These things happen now at opposition, now before it, now after it, according as the opposition falls on the limit, or before it, or after it." What the inclination of the lines of Mars is will be told in the next chapter. Meanwhile Kepler confirms this alternation from the *Ephemerides* of the year 1604, in which the greatest northern latitude of Mars occurred around March 6, although the true opposition followed a whole month later; and on October 7, when its greatest southern latitude occurred, Mars was between quintile and sextile aspect with the Sun. So too at the end of the year 1605 the greatest northern latitude of Mars occurred as the Sun was passing from the quintile to the quadrature of Mars; but in the year 1606, at the end of July, the greatest southern latitude occurred with the Sun placed in trine to Mars; and in the year 1607 its greatest northern latitude came a little after the conjunction of Mars with the Sun. Further, by his own special calculation Kepler, in the same Chapter 66, derives the latitude of Mars observed in the year 1593 on August 10 as 6° 19′ 10″, as nearly as possible the same as the observed one.

III. The latitude of Venus was observed by Tycho in the year 1587, on the evening of February 21, Julian style, and a little later on the morning of the 24th, at 8° 56′ north; that is, much greater than the tables of Ptolemy, Alfonso and Copernicus would allow. [Margin: The latitude of Venus greater than the ancients thought.] So, partly from so great a latitude and partly from the obliquity of the Danish horizon, it came about that Venus could be observed almost at inferior conjunction itself with the Sun and at the perigee of the orb or epicycle, despite the rays of the nearer Sun. Longomontanus recalls having seen this, as a prodigy of observation, among Tycho's records (Book 2 of the *Theorica*, Chapter 18). But Mästlin testifies, in his additions to Rheticus's *Narratio prima*, p. 136, that this same thing was observed by him from the 21st and 24th of February of the year 1587. [Margin: Venus seen almost at the perigee of the epicycle because of its latitude.] That, I believe, is why Kepler states on p. 71 of the Rudolphine Tables that Venus is sometimes seen for two or three days together both morning and evening, emerging in the morning before it is hidden in the evening. This is confirmed even by the fact that in the year 1549[70] we saw Venus through the tube, appearing with the form and size that we showed in this Book 7, Section 1, Chapter 2, Number 4, on June 29, that is, on the 8th day before the perigee conjunction with the Sun, although it had a latitude of only 2°; and we would certainly have seen it nearer the conjunction if it had had the greatest latitude.

CAPVT V.

Chapter 5.

De Hypotheſi Ioannis Kepleri circa Latitudinem Quinque Minorum Planetarum.

On the hypothesis of Johannes Kepler concerning the latitude of the five minor planets.

I. We shall gather Kepler's whole theory of the latitude of these five planets from what he himself says in the *Ephemerides*, p. 14; in the *Epitome of Copernican Astronomy*, Book 4, p. 599, Book 5, p. 674, and Book 6, pp. 753 and 770; in the Rudolphine Tables, Chapters 21 and 24, Precept 108; but above all in the *Commentaries on Mars*, Chapters 12, 13, 14, and the whole of the fifth part, or from Chapter 61 to 70. In the foundations of the *Ephemerides*, however, he has only this: "Each orbit is inclined to the ecliptic at its own constant angle: here there are no circles of deviation, none of obliquation, none of reflexion." In the Rudolphine Tables, besides the tables from which the places and motions of the nodes are gathered, he gives precepts of calculation for the latitude and for telling when the latitude will be greater than the inclination. These precepts are founded on what is said in the *Epitome* and in the *Commentaries on Mars*; and from these Magini too, in his *Supplement to the Ephemerides*, extracted a special

[70] so printed

Canon 11 for finding the true latitude of Mars. Let us see, then, what he teaches in the *Commentaries on Mars* and in the *Epitome*, reducing his whole doctrine on this matter to definite and distinct propositions, and bringing some light to it by the very order and connection of the propositions and by explaining the doubts that arise among them.

II. First, latitude, by Kepler's definition and the common one, is the arc of the circle of latitudes described beneath the fixed stars and intercepted between the ecliptic and the place of the planet as seen from the Earth. [Margin: Definition of latitude.] Its measure is the angle made at the centre of the Earth by two straight lines drawn from this centre, one to the centre of the planet's body, the other to the planet's place in the ecliptic; and it is called the true latitude. For if this angle is considered at an eye placed on the surface of the Earth, it is called the apparent latitude, and its difference from the true is called the parallax in latitude. The inclination, on the other hand, is the angle made at the centre of the planetary system (which for Kepler is the Sun) by two straight lines drawn out from this centre, one to the centre of the planet's body, the other to the place in the ecliptic corresponding to it. [Margin: What the inclination is for Kepler, what for Ptolemy?] But for Ptolemy the inclination is the angle made at the centre of the Earth by two straight lines drawn from it, one through the centre of the epicycle, the other to the centric place of the planet in the ecliptic, speaking of the inclination of the eccentric to the ecliptic. For, speaking of the inclination of the epicycle to the eccentric, it is the greatest angle made at the centre of the epicycle by straight lines drawn from there, one to the centre of the eccentric, the other through the plane of the epicycle towards the centre of the eccentric. From what has been said it follows that the latitude is the inclination of the eccentric, or its arc, as seen from the Earth.

III. Secondly, the latitude that appears to us has two causes, one physical, the other optical. [Margin: Twofold cause of latitude.] The physical cause is the inclination of the planet's orb to the plane of the ecliptic; the optical cause is the withdrawal or approach of the Earth to the planet, or of the planet to the Earth, since by Proposition 56 of Euclid's *Optics* things that are nearer appear larger. Therefore the arc corresponding to the angle of inclination must appear larger when the planet is nearer the Earth, and smaller when it is farther off, whether the Earth by its annual motion approaches it, or the planet itself, because of the motion of its eccentric, approaches the Earth. [Margin: Where, other things being equal, the greatest latitude occurs.] Hence it happens that, other things being equal, the greatest latitudes occur in those acronychal oppositions of the three superior planets in which the centre of the Ptolemaic epicycle is at the perigee of the eccentric, because the planet is also at the perigee of the epicycle and so nearest the Earth; and this nearness would be still greater if the perigee of the Sun lay under the same place of the zodiac. And since the perigees of the three superior planets are in the southern segment of the eccentric, among their greatest latitudes those towards the south are greater than those towards the north. In Venus and Mercury, on the other hand, other

things being equal, the greatest latitudes occur at the perigee of the orb or epicycle, that is, at inferior conjunction with the Sun, because of the same nearness to the Earth, which is greater at that time. I said "other things being equal" because, owing to the differing proportion of the inclinations and the distances, it can happen, and often does, that the greatest latitudes occur away from the moment of opposition of the three superior planets with the Sun, or of the lower conjunction of the inferior planets with it, as will be said in Number 9, and as was already touched on concerning Mars in Scholium 2 of the preceding chapter.

IV. Thirdly, the inclination, which is the physical cause of the latitude of these five planets, is for Kepler always the same, fixed and invariable in itself and with respect to the mean or royal ecliptic [Eclipticæ mediæ ſeu Regiæ]. [Margin: The constancy or immutability of the inclination.] So in one whole revolution of the planet the angle by which the plane of the planetary orb is inclined to the plane of the ecliptic remains of exactly the same size; you will see that size in the little tables at the foot of the chapter. Therefore the planets run out from the ecliptic to the side of the world, towards the north or towards the south, in such a way that the plane they trace with the centre of their body is straight, and inclined to the plane of the ecliptic at a constant inclination. And if the hypothesis of the Keplerian ellipse is transferred to the Ptolemaic eccentrepicycle, the plane of the epicycle, because of the constancy of the inclination already mentioned, would remain perpetually parallel to the plane of the ecliptic. So Kepler teaches in the *Epitome of Astronomy*, pp. 599 and 753, and in the *Commentaries on Mars*, Chapters 13 and 14; and in Chapter 14 he shows that the planes of the eccentrics are [Greek: ἀτάλαντα (atalanta, "not librating")]. [Margin: The planes of the eccentrics free from libration.] He is speaking of the plane of the eccentric ellipse, which for Kepler, single and simple, is equivalent to the Ptolemaic aggregate of eccentric and epicycle. The inclination of this epicycle (which for Copernicus is the orb) Copernicus, to say nothing of Ptolemy, made librating, or variable by libration, with the plane of the epicycle nodding this way and that; even though Ptolemy did make the inclination of the eccentric of the superior planets constant. Speaking, therefore, of the total effect of that Ptolemaic aggregate, just as if it were one eccentric orb, or of the Copernican orb, Kepler affirms that its plane is [Greek: ἀτάλαντον (atalanton)], that is, unlibrating, or immune from the variation of libration.

[Margin: Arguments for the immutability already mentioned.] He shows this from the fact that in Chapter 13, from three positions of observations of Mars in different aspects with the Sun, the greatest inclination was always found to be the same, 1° 50′. How the greatest inclination is gathered from observations we shall teach in the problems of Chapter 8. In the first manner of observation the Sun was about sextile or quintile to Mars, that is, so near conjunction that it cannot be observed any nearer by us; in the second it was in quadrature with Mars; and in the third in opposition itself with Mars; and yet in all these places

the greatest inclination, derived from the latitude, was without perceptible difference an inclination of the plane to the ecliptic of 1° 50′. What he finds in Mars, therefore, he confidently affirms of the remaining minor planets in that Chapter 14, saying: "Let us therefore conclude most firmly (for why should I not conclude in general what has no cause for belonging to one single planet, although I have the same thing demonstrated from observations in Venus and in Mercury too) that the inclination of the planes to the ecliptic does not vary at all; and let him who follows Ptolemy learn from this that the plane of the epicycle is perpetually parallel to the plane of the ecliptic." Understand this of the superior planets. Hence, then, he censures Ptolemy and Copernicus for not having seen that by the parallelism already mentioned and the constant inclination, together with the approach to and withdrawal from the Earth, all the phenomena of the latitudes can be saved. [Margin: Ptolemy, Copernicus and Apian censured by Kepler.] He censures Copernicus the more, because, clinging too closely to the Ptolemaic measures, when he saw that the latitudes increase with the Earth's approach to the planets, but not precisely as much as Ptolemy's measures require, he did not dare to reject these increases, and to furnish them he introduced a libration, not indeed of the epicycles, which Copernicus abolished, but of the eccentric orbs, by which their inclination would vary. From this it has come about that in the calculation of the old astronomy there is no conjunction of Mars and the Sun that is not, as the astrologers call it, corporeal, or through the body, contrary to the end sought by God and Nature in the latitudes, namely that there should not be excessive agitations of the sublunary powers from corporeal conjunctions occurring frequently. [Margin: The end of latitude, introduced by God.] For a conjunction is corporeal when one and the same straight line drawn from the centre of the Earth passes through the centre of the body of each planet as they come together in the same place of the zodiac. He also pities Peter Apian, who in his imperial work [opere Cæſareo] laboured with most ingenious spires, little crowns, helices and volutes to present to us the Ptolemaic fictions of librations for representing the latitudes.

V. Fourthly, however, the inclination of the eccentrics already mentioned to the temporary ecliptic [Eclipticam temporaneā], if the obliquity of the ecliptic varies with the succession of the ages, is different in different ages, as Kepler judges more probable in the *Epitome of Astronomy*, p. 754, and in the *Commentaries on Mars*, Chapter 68. [Margin: The accidental mutability of the inclination, in line with the change of the obliquity of the ecliptic.] For although this variety cannot be shown from the latitudes observed by Ptolemy compared with the observations of our time, because this variety is of a few minutes, which cannot be derived from Ptolemy's coarse observations, since he usually used an instrument having no division of degrees except into tens of minutes, it is nevertheless more probable that the ecliptic to which the planes of the eccentrics keep a constant inclination, or to which, in the reformed Ptolemaic form, the planes of the epicycles remain parallel, is that mean or royal ecliptic along which the Sun or the Earth travels at the mean obliquity

of the ecliptic. And so, when the obliquity of the ecliptic changes, it is more likely that the eccentrics or epicycles of the planets are variously inclined to the temporary ecliptic, so as to follow the Sun, or the Earth travelling along it, with some very small variation; just as the fixed stars appeared to Tycho and others to change their latitude accidentally, because of the change of the temporary ecliptic, about which I spoke in Book 6, Chapter 15. What sort of circle that royal one is, however, to which both the latitudes of the fixed stars and the inclinations of the planetary orbs keep a constant relation, is not yet certainly clear; and so Kepler calls it that blind path in Chapter 68, although he speaks of it more clearly in Book 7 of the *Epitome*, and says that its withdrawal from the equator is more truly called the latitude of the equator from the ecliptic. The variation of this inclination presupposes, in this hypothesis, that the nodes of the planets and of the Earth, that is, the sections which the orbits of the planets make with that blind circle along which the plane of the Earth travels, move with an unequal motion. This accidental variation, then, is the one I indicated when in Number 4, near the beginning, I said that the inclination, in itself and considered over one period, is invariable, but not when the periods of all the ages are considered. This variation seems to be confirmed from the greatest northern latitude of Mars observed with Regulus; for the latitude of Regulus, for Tycho, increased accidentally in line with the change of the obliquity of the ecliptic, and the greatest northern latitude of ♂ also increased, since it was observed by Ptolemy as 4° 20′, but by Tycho as very nearly 4° 32′. But against this stands the greatest southern latitude of Mars, observed with the southern stars of Capricorn, which for Ptolemy was almost 7° and today is 6° 52′. So we are still left in suspense by Ptolemy's observations.

VI. Fifthly, in Kepler's hypothesis the planes of the eccentrics and of the ecliptic are so inclined that they cut one another in one straight line, which passes through the centre of the body of the Sun. [Margin: What the common line of section of the planes is.] In each planet this line extends to places of its own ecliptic that are opposite one another from the centre of the Sun; since in two different revolutions of the same planet, at the places where the planet lacks latitude, those places have been observed to be diametrically opposite with respect to the centre of the world; and Mars, for example, being placed on the ecliptic, or lacking latitude, at 17° of Taurus, returns to the ecliptic and is free of latitude again at 17° of Scorpio. In the Ptolemaic hypothesis, however, that line passes through the centre of the Earth. So Kepler teaches in the *Epitome*, pp. 599 and 753, and in the *Commentaries on Mars*, Chapter 12, where he brings forward observations bearing on this. From these, counting the 687 days of the eccentric revolution of Mars, he finds that Mars was at the north node first in the year 1590 on March 7, then in the year 1592 on January 23, then in the year 1594 on October 28, exactly as the observations of latitude made by Tycho on those or the nearest days demanded. From this, and from the inclination of the eccentric of Mars to the ecliptic, he shows in Chapter 67 that the line of apsides passes through the centre of the Sun as regards its true place, but not through

the centre of the Sun's mean motion, which for Tycho is the centre of the solar epicycle.

VII. *Sixth,* the physical cause of the inclination of the eccentric to the ecliptic and of the latitude itself is, for Kepler, twofold. [Margin: The physical cause of latitude, the final one.] One is final: that the oppositions and corporeal conjunctions of the planets with the Sun should not occur too often, since they stir up the power of sublunary things too much, as I have already indicated in Number 4, from Kepler, *Commentaries on Mars*, Chapter 14; just as the latitude of the Moon also ensures that central eclipses of the Sun and Moon are not frequent. The other, whether efficient or subjective, is the very formation of the planet's body: namely magnetic fibres, rectilinear, whether internal or in the outer crust, or the rotation of the planet about its axis. By the force of these the parallel position is retained for the whole time of the circuit, and the planet is so directed that, when it is itself under the ecliptic, a fibre or arc of gyration touches the orbit, and inclines somewhat to the north with one of its extremities and to the south with the other, and therefore the planet is driven through the other semicircle towards opposite quarters. For once the inclination to the mean or royal ecliptic had been acquired for the purpose already mentioned, it was fitting that the fibres of latitude should always retain the same position with respect to the sides of the world, as was said of the fibres of longitude when dealing with the Moon, in Book 4, Chapter 27, in the Scholia, according to Kepler's thinking. For his notions on this as regards latitude, see the *Epitome* from p. 602 on, and the *Commentaries on Mars*, Chapter 63.

VIII. *Seventh,* the laws of latitude and inclination according to Kepler are these. [Margin: Rules of latitude, and of inclination compared with it.] Latitude always comes with some inclination; for where there is no inclination, as happens at the nodes, there is also no latitude. Whenever the distance between the planet and the Earth is the same as that between the planet and the Sun, and the triangle having those distances as its legs is therefore isosceles, the inclination is equal to the latitude. This happens when the angle of elongation of the planet from the Sun is half the angle of commutation, or when there is less than a quadrant of a circle between the apparent place of the planet and that of the Sun; yet this arc, required for the equality just mentioned, is nearly a quadrant in Saturn, less in Jupiter, and least in Mars. But when the elongation of the planet from the Sun is greater than this arc, or the distance of the planet from the Earth smaller, the latitude exceeds the inclination; conversely, when the elongation of the planet from the Sun is smaller than that arc, or the distance of the planet from the Earth greater, the latitude is exceeded by the inclination. In Venus, however, whose greatest latitude is very great and whose inclination is small, the latitude equals the inclination whenever the angle of elongation together with the angle of commutation makes up two right angles; but whenever the angle of elongation is smaller than the angle of commutation, the latitude is smaller than the inclination; and whenever it is greater, the latitude is also greater. [Margin: The difference between the superior planets and between ♀

and ☿.] But in Mercury, which has a great inclination and a small latitude, the latitude is always smaller than the inclination. So Kepler teaches, partly in the *Epitome*, pp. 755 and 771, partly in the Rudolphine Tables, precept 108.

IX. *Eighth,* the latitude decreases when the distance of the planet from the Earth grows more than the lines of inclination do, each in its own proportion, whatever that may be; or when, as the distance grows, those lines diminish. [Margin: On the decrease and increase of latitude, especially the greatest.] The latitude increases, however, when the proportion of the distance decreases more than the proportion of the lines of inclination, or when, as the former decreases, the latter grows. But the latitude becomes greatest when the distance of the planet from the Earth grows or decreases in the same proportion in which the lines of the planet's inclinations grow or decrease. This happens sometimes at the moments of true opposition with the Sun, sometimes before or after; and indeed in Mars sometimes by a whole month, as we showed in Scholium 2 of Chapter 4. Granted that in Saturn and Jupiter, because of the very slow change of inclination from day to day, the greatest latitude very nearly coincides with the true opposition of the Sun, it nevertheless recedes further from conjunction with the Sun. So in Venus, as also in Mars, around the stations and retrogradations the latitude shows a great variety, one that can scarcely be bound by fixed rules; but in Mercury, because of the very rapid separation of the orbs, the variety there is not so great. This is roughly what Kepler says in the *Epitome*, p. 756, in the *Commentaries on Mars*, Chapter 66, and in the Rudolphine Tables, precept 109.

X. *Ninth,* how great the inclination is can be gathered from the *Epitome of Copernican Astronomy*: for the superior planets on p. 753, [Margin: How great the inclination of the eccentrics is.] for the inferior planets on p. 771; and it will be set out shortly in small tables at the end of the chapter. But Kepler gives the method of deriving it from the latitude in the *Commentaries on Mars*, Chapter 13, where he investigates it for Mars, from afar and close to the truth, in three ways, and finds it to be approximately 1° 50′; and in Chapter 62, bringing it under the file, he finds 1° 50′ 25″ or 1° 50′ 30″. But we reserve those methods for the Problems to be given in Chapter 8, so as not to break the thread of Kepler's teaching too much. How great the greatest latitude of Mars is, however, he investigates in the *Commentaries on Mars*, Chapter 65. [Margin: Likewise how great the greatest latitude is.] The northern one he investigates at the oppositions from the greatest distance of Mars from the Sun, of 166465 parts, and the least distance of the Sun from the Earth, 98200, and from the inclination now established as 1° 50′ 30″; at conjunction, however, from what has been said and the greatest distance of the Sun, 101800, in parts of which the radius of the annual orb is 100000. The southern one he investigates at opposition from the least distance of Mars from the Sun, and that of 138234 parts, and the greatest distance of the Sun from the Earth, 101800; but at conjunction from the least distance of the Sun, 98200. And this first on the supposition that, as was once the case, the apogee of Mars and the aphelion of the Earth

are joined in one line and the ecliptic retains its position among the fixed stars; then on the supposition that the apogee of Mars is joined to the perihelion of the Earth. But because in this century neither conjunction obtains, and the limits of Mars are roughly midway between the apsides of Mars and those of the Sun or Earth, he therefore investigates both latitudes of Mars, at ♂ and ☍ with the Sun, from the distances set out above; all these latitudes I shall give in one view, with the latitudes of the other planets, at the end of the chapter. In the *Epitome*, moreover, pp. 756 and 771, he gives the greatest latitudes of the other planets, noting that the northern latitude of Venus when retrograde runs out in this century to nearly 9°, about as great as the southern will be in other centuries; but that the northern latitude of Mercury is about 2° 30′ and the southern 5°, always smaller than the inclination of Mercury's orbit.

XI. *Tenth,* he gives the places of the nodes in the *Epitome of Copernican Astronomy*, pp. 753 and 770, and in the Rudolphine Tables, in the Epochs of the Nodes; [Margin: On the place and motion of the nodes.] but he teaches the method of finding the places of the nodes and limits in the *Commentaries on Mars*, Chapters 12 and 61, and we shall deal with these more deliberately in Chapter 8, among the common Problems. In those same places of the *Epitome* he notes that the nodes and limits of the three superior planets move with a slower motion than the fixed stars move in the hypothesis of a resting Earth (for in the hypothesis of an Earth moved with annual and diurnal motion, the fixed stars stand truly fixed), and therefore, although they move in the order of the signs with respect to the vernal equinox, with respect to the fixed stars they nevertheless move against the order of the signs. Since this holds true in the four planets already mentioned, judging by the motion of the nodes, which is gathered from their places as handed down by Ptolemy and compared with their places as found by Tycho, it seems likely that it happens also in the motion of the node of Mercury. He therefore holds Ptolemy suspect, who placed the north node of Mercury, together with the apogee, at ♎ 10°; and today it is at 13° 30′ of Scorpio. For it would follow from this that in the 1460 years after Ptolemy this node advanced 33° 30′, that is, much more than the fixed stars, which are found to have advanced by about 27°; so this node would be going in the order of the signs even with respect to the fixed stars. However, because Ptolemy found the node of Venus at the apogee, and the node of Mercury not much farther from the apogee of Mercury, Kepler believes that, lured by the neatness of his hypothesis, Ptolemy drew the node back from the end of Libra to 10° of Libra. And so at last he asserts that the nodes of all five minor planets move more sluggishly than the apparent motion of the fixed stars, and with respect to the fixed stars move against the order of the signs. Further, that the motion of the nodes is unequal, if the obliquity of the ecliptic changes and the eccentrics of the planets vary their inclination with respect to the temporary ecliptic, he shows in the *Commentaries on Mars*, Chapter 68, and in Book 7 of the *Epitome*, p. 931. [Margin: The inequality of the motion of the nodes.] But he shows also that neither this variety nor the most exact inclinations of

the planets can be known, unless posterity, while the world lasts, comes to be more certain whether the obliquity of the ecliptic really changes. Therefore Kepler concludes, in Chapter 68 on Mars, in these words: "Since, therefore, we lack suitable observations from antiquity, the very condition of the matter compels us to leave this discussion of the motion of the nodes, like many other things, to posterity: if, that is, it shall please God to grant the human race a just span of time in this world for learning these remaining things thoroughly." [Margin: Some imperfection of present astronomy still remains.] And on the same occasion and in the same sense he closes Book

7 of the *Epitome of Copernican Astronomy*, saying: "The truest inclinations of the planets to the royal way, therefore, and the causes, quantities and quarters of the motions of the limits and nodes: these, I say, and other such things lie hidden in the Pandects of the age to come; not to be learned before God, the judge of the ages, himself immortal, has opened this book to mortals. To him be praise, honour and glory for ever and ever, Amen." Now follow the small tables so often promised.

Inclination of the plane of the ellipses, eccentric from the Sun, to the ecliptic, at the centre of the Sun, fixed in itself and invariable [Inclinatio Plani Ellipſium à Sole Eccentricarum ad Eclipticam in centro Solis per ſe Fixa & iuuariabilis.]

Planet	Inclination
♄	2° 32′ 0″

SCHOLIA.

Scholia.

I. I did not wish to be more long-winded in explaining the variety of the inclinations and the inequality of the motion of the nodes that would arise if the obliquity of the ecliptic changed. For although Kepler was copious on this in the *Commentaries on Mars*, Chapter 68, and in Book 7 of the *Epitome*, he later taught outright that it is more probable that the obliquity of the ecliptic does not change, as we have pursued more fully in Book 3, Chapter 27. [Margin: The constancy of the inclinations and the equality of the motion of the nodes is more probable.] Accordingly, on his view, not merely on ours, it is more probable that not even the latitudes or inclinations of the planets change accidentally upon a change of the ecliptic. Nor does the latitude of the fixed stars stand in our way, which for the same cause seemed mutable, and indeed for Tycho was changed; for see what we said in Book 6, Chapter 15.

II. A geometrical calculation for the latitude, without any diagram, is given by Kepler in the *Epitome of Copernican Astronomy*, p. 757, in this truly compendious form. [Margin: A compendium of the geometrical calculation for latitude.] For he says: "As the sine of the angle of elongation is to the sine of the angle of commutation, so the tangent of the complement of the inclination is to the tangent of the complement of the latitude." Therefore, he says, let the sine of commutation, increased by 5 ciphers, be divided by the sine of the elongation of the planet from the Sun; let the quotient be multiplied into the tangent of the complement of the inclination; and when the last 5 digits are thrown away, the tangent of the complement of the latitude will come out. Or more expeditiously still: from the logarithm of commutation subtract the logarithm of the elongation of the planet from the Sun, and add the remainder to the mesologarithm of the complement of the inclination; for the sum will be the mesologarithm of the complement of the latitude. Remember, however, that the anomaly of commutation, or the angle at the Sun, is gathered by counting from the place of the Sun to the centric place of the planet, either in the order of the signs or against the order of the signs, so that the arc is always smaller than a semicircle. The elongation of the planet from the Sun, on the other hand, is counted from the place of the Sun to the place of the planet as seen from the Earth, in the order of the signs if it is smaller than 180°, against the order of the signs if greater. So by subtracting the apparent place of the Sun from the eccentric place of the planet, or the latter from the former, so that less than a semicircle remains, you will have the angle of the anomaly of commutation in the first case, but in the second its complement, according to precept 93 of the Rudolphine Tables and p. 750 of the *Epitome*. But by subtracting the true place of the Sun from the true place of the planet, or the latter from the former, you will have the angle of elongation, or the angle at the Earth. Kepler gives a somewhat different rule in the *Commentaries on Mars*, Chapter 62, and Magini gives it after him; I shall speak of it in Chapter 8.

III. Kepler asks, in the *Epitome*, p. 771, why, if the inclination of Venus and Mercury to the ecliptic is fixed, Ptolemy nevertheless introduced two librations of the epicycle; and he answers that this was done because the annual motion of the Earth was unknown and was ascribed to the very centre of the epicycle, carried annually with the Sun. But Ptolemy seems to have done this with little consistency, since he should have set the inclinations of Venus and Mercury to the ecliptic as fixed, just like those of the three superior planets, since every libration of the orbits is absurd in itself, because it produces a tortuous path for the planet; and whatever Ptolemy achieved by those librations is achieved by a fixed inclination and the approach or recession of the Earth, if corrected observations are employed. Therefore, as much probability as the fixed inclination has, so much has the motion of the Earth. [Margin: What the argument for the annual motion of the Earth from the inclination of the planets is worth.] And yet this argument, resting on mere probability, Kepler calls Most Evident for the annual motion of the Earth, there and on p. 543. But is it not enough if, in the Ptolemaic hypothesis, the epicycles are so moved that their planes are parallel to the ecliptic, as it is clear from what was said in this Chapter 5, Number 4, that Kepler taught; or that we remedy the anomaly of latitude, if there is any, in some other way with the Earth at rest, for example by a variation of the semidiameter or of the eccentricity?

IV. Another cause on account of which Ptolemy set two librations in the inferior planets is devised by Kepler [Margin: A second cause of the Ptolemaic libration.]

in the *Epitome*, p. 775: namely, that Venus at perigee, in conjunction with the Sun, should never, thanks to a latitude increased by the libration, be interposed between the Sun and our sight; and that it would thus answer to the older writers who, because Venus was never seen under the Sun, placed it above the Sun. I have already spoken of this argument in this Book, Section 1, Chapter 4. But the more recent astronomers obtain that very thing without that libration.

V. Moreover, Kepler adduces a third cause of the libration of the eccentric introduced by Ptolemy in Venus and Mercury, on p. 773 of the *Epitome*: namely, that in Mercury the southern latitudes should turn out greater than the northern. [Margin: A third cause of the libration.] But he adds that if Ptolemy had set his epicycles unequally disposed around the Sun, for instance by an elliptical figure, or, as we do, by a variation of the semidiameter, he would have had no need of that libration. For the south limit of Mercury is nearer to its aphelion than the north limit is; and the farther it recedes from the Sun, the nearer it comes to the Earth, when Mercury is retrograde, than the north limit does; and therefore the southern latitude of Mercury turns out greater than the northern. The southern latitude of Mars also is greater than the northern, because its south limit is near the perihelion, as Hérigone noted, volume 5, p. 613. In Venus, however, although the north limit is in Virgo, close to the perihelion, the northern latitudes are nevertheless greater than the southern,

because the eccentricity of Venus, much smaller than the eccentricity of the Sun and of Mercury, does in this what the inclination alone cannot do, and does do in Mercury, which has an eccentricity greater than the Sun's. [Margin: What does the small eccentricity of Venus contribute to the latitudes?] This argument seems to undermine our opinion that the eccentricity of Venus is no other than the Sun's. But we do not much fear on this account, because either by a variation of the semidiameter of the epicycle in the first form, or by an elliptical epicycle in the second form of our hypothesis, indicated in its place, we can find a cause for this variety; and otherwise the difference between the northern and southern latitudes of Venus is very small, as Kepler himself grants on p. 775 of the *Epitome*, so that the probability of our hypothesis is not removed on its account.

CAPVT VI.

Chapter 6.

De Iſmaelis Bullialdi Hypotheſi circa Latitudinem Quinque minorum Planetarum.

On the hypothesis of Ismaël Boulliau concerning the latitude of the five minor planets.

I. This most profound astronomer is, as to the substance of the hypothesis, a most faithful follower of Kepler: namely in the elliptical orbit of the planets around the motionless Sun as one umbilicus of the ellipse, the Sun leading around the Earth and these five planets; in the immutability of the inclination of the elliptical orbit to the ecliptic and to the plane of the Earth's annual orb; and in the line of section, by which the planet's orbit cuts the ecliptic, which is to be carried through the centre of the solar globe. Nevertheless, in the places and motion of the nodes, as well as in the quantity of the latitude and inclination, he relies on his own findings; and in each of his books on these planets, after the treatment of longitude, he treats the inclination of the orb and the places and motion of the nodes. Accordingly we too, following the order of his books in the *Astronomia Philolaica*, shall set out distinctly his doctrine concerning the latitude of the planets, while bringing together at the end of the chapter the numbers and measures in a single synopsis, after our custom.

De Saturni Latitudine.

On the latitude of Saturn.

II. *First,* in Book 6, Chapter 3, by a technique not unlike the one by which he usually seeks the place of the aphelion, Boulliau seeks the places of the nodes and the inclination of Saturn's orb to the plane of the Earth's annual orb, or of the ecliptic, an inclination he considers fixed in all the planets. Because this technique is common to all 5 planets, we shall give it in Chapter 8, among the

common Problems; for now we shall present only its foundations in observations, and its conclusions. He therefore assumes three Tychonic observations of the longitude and latitude of Saturn outside the acronychal position, and to these he adds, from the calculation of longitude, the distances of Saturn from the Sun and from the Earth. From these and from the semidiameter of the annual orb he gathers the angles of the latitude to be seen, which he compares with the observed latitudes. [Margin: Boulliau's method indicated.] And first he gathers from afar the place of the ascending node at ♋ 24° 26′ 15″, and from it the inclination, now 2° 11′ 28″, now 2° 18′ 14″, now 2° 29′ 8″; and from this variety he infers some defect in the observation. Therefore, so that those three observations can be reconciled, while the other measures of Saturn's orb and the places of its longitude and of the Earth remain intact, and so that the latitude sought geometrically may be very close to the observed latitude, he assumes the place of the north node at 20° 25′ 24″ of Cancer for the year 1590, and the inclination of Saturn's orbit to the ecliptic as 2° 30′. [Margin: The inclination of ♄.] With these assumed, on going through the calculation again he finds latitudes differing from the observed ones by the smallest difference. He confirms this also by a fourth observation of latitude made by himself, exceeding this hypothesis by scarcely a minute and a half; and therefore he rests content with the assumed place of the node and the inclination. The foundations of the calculation are these, from 3 observations made at Uraniborg and a fourth at Paris, the hours being reckoned from noon in both places.

Of Christ: year, month, day, hour	♄ place as seen from ☉	Observed southern latitude of ♄	Distance of ♄ from the Sun, in parts of the radius 100000	Distance of ♄ from the Earth, in parts of the radius 100000	Latitude of ♄ to be gathered from the given measures, etc.	Latitude gathered from the assumed place of the node and inclination
1587 January 9, 10h	♉ 2° 18′ 51″	2° 28′ A	95596	95628	2° 28′ 4″	2° 26′ 46″
1590 February 8, 8h	♊ 13° 49′ 18″	1° 30′ A	94338	92409	1° 28′ 8″	1° 29′ 12″
1590 September 7, 12h	♊ 21° 46′ 2″	1° 11′ A	94239	94317	1° 11′ 2″	1° 11′ 42″
1640 October 12, 8h	♒ 28° 50′ 2♑″	1° 35½′				1° 36′ 40″

III. *Second,* in Book 6, Chapter 4, from the inclination of Saturn's orbit to the ecliptic already found above, 2° 30′, and from the aphelion and perihelion distances of the Earth and of Saturn, he gathers, by a method to be given in Chapter 8, the greatest possible latitude at oppositions and conjunctions, whether the Earth is at aphelion and Saturn then at aphelion or at perihelion, or

the Earth is at perihelion and Saturn then at aphelion or at perihelion. [Margin: The variety of the greatest latitudes of ♄.] I shall give these latitudes at the end of the chapter in a single synopsis.

IV. *Third,* in the same place, Chapter 6, when about to treat the translation or motion of the nodes of Saturn, which Kepler had gathered from the places of the node observed by Ptolemy and compared with the places observed by Tycho, he tries to refute Kepler from other observations of Walther, from which he says the numbers established in the Rudolphine Tables diverge; and he contends that the motion of Saturn's node is much slower than Kepler supposed. [Margin: The motion of the node of ♄.] The first observation of Bernhard Walther at Nuremberg was made with the armillary spheres, as he himself testifies, in the year 1504, in which, he says, from the third to the sixth day of February he could not see the eighth star of Gemini, since it was covered by the stationary Saturn; but on the 8th Saturn was observed at ♋ 11° 18′, with southern latitude 2′, and the eighth of Gemini appeared at a distance of 4 digits from Saturn, as if in the same latitude, most carefully: so Walther in his observations. Boulliau, however, affirms that that star is not the 8th but the 12th of Gemini, in the groin or belly of the southern Twin, having a latitude of 13′ 30″ south, and he assumes that there took place on February 4 the conjunction of Saturn with [Margin: Boulliau's criticism of the Rudolphine Tables.]

this star, and he gathers from the tables of longitude the place of Saturn at Cancer 10° 49′, whereas, from the observation of the 8th day, it should have been at 11° 33′ on the 4th; but as seen from the Sun, at Cancer 15° 10′ 28″. He suspects, however, a mistake in the noting of the day, and an error of about 10′. Notwithstanding these things, he thinks the place of the north node can be gathered from this ὁλοσχερέστερος [Greek: holoscherésteros, "more in the gross"], that is, approximately, but sufficiently as far as the motion to be derived from it is concerned. He therefore gathers it from the distance of the planet from the Sun and from the Earth, and from the observed latitude of 13′ 30″, and he finds Saturn distant from the north node by 4° 44′ 2″. When these are added to the place of Saturn as seen from the Sun, the place of the north node in the year 1504 comes out at Cancer 19° 54′. But in the years 1587 and 1590 it was found, above in number 2, at Cancer 20° 25′ 24″. Therefore in 86 years the node advanced at most 31′; and yet the Rudolphine Tables put the motion of this node in 86 years at 1° 42′ 24″. [Margin: Error of the Rudolphine Tables.]

The second observation of the same Walther was made in 1504 March 28, at 7^h after noon, when Saturn was seen further west and further north than the eighth star of Gemini, by as much as the space of 2 or 3 fingerbreadths; from which he concludes that the conjunction of Saturn with that star was on March 29 at 7^h, since on the night following the 28th it was seen much nearer that star. From this Boulliau gathers the place of Saturn's north node in that year at ♋ 19° 30′ 30″. He then adds a third observation, made at Athens in the year of Christ 503 February 21, at 9^h 45^m, when Saturn was seen to be occulted by the edge of the Moon, and at 11^h 55^m was seen to be freed from the Moon.

From this, by the motions and place of the Moon, he gathers Saturn's southern latitude of 3′, and from this the place of the north node at ♋ 12° 36′ 21″. Since, then, in the month of May of the year 1588 this node, by the observations of the years 1587 and 1590, was at ♋ 20° 25′ 24″, in 1085 years and 3 months it certainly advanced only 7° 49′ 3″. From this proportion he derives the annual motion of the node of ♄ as 25″ 54‴ 51⁗ 42^{v} 45^{vi} 42^{vii} 5^{viii}. Finally, in Chapter 6, he examines the already mentioned Athenian observation by the Rudolphine Tables, and shows that, with the Rudolphine motion of the node, it would have been impossible for the Moon to occult Saturn. [Margin: Likewise an error of the Rudolphine Tables.] But this could have come about not from the motion of Saturn's node alone, but from many other partial causes.

De Iouis Latitudine.

On the latitude of Jupiter.

V. *First,* the same author, in Book 7, Chapter 4, by the same method he had used for Saturn, derives from three observations, but his own, a fixed inclination of the orbit of Jupiter to the ecliptic. First, from the distances of the planet from the Sun and from the Earth, he finds the north node of Jupiter at 10° 5′ 22″ ♋, and the inclination 1° 20′ 10″. [Margin: Inclination of ♃.] Having assumed these, he tests whether the observed latitudes of Jupiter follow from them; and on finding some disagreement, he corrects the place of the node and the inclination so that latitudes as little removed from the observed ones as possible follow from them at last, and there he rests, namely on an inclination of 1° 21′ 48″ and a node at ♋ 8° 52′ 10″. The observations and the foundations of the calculations are written below; they were made at Paris, with the hours counted from noon. But he omits the latitudes gathered from the repeated calculation.

Year of Christ	Month	Day	Hour	Place of ♃ as seen from ☉	Observed latitude of ♃	Distance of ♃ from the Sun (radius 100000)	Distance of ♃ from the Earth
1634	April	12	8½	♋ 5° 54′ 10″	0° 4′ A	99605	100481
1637	July	16	9	♎ 9° 13′ 25″	1° 18′ B	104854	101685
1639	August	31	8	♐ 8° 55′ 3″	0° 42′ B	102161	100812

VI. After this, in Chapter 5, he places the north limit of Jupiter at ♎ 10° 13′ 25″, and from this he derives the greatest northern and southern latitudes of Jupiter, both at the conjunction of Jupiter with the Sun and at opposition; and he follows through the aphelial and perihelial variation of both in Chapter 6. [Margin: Variety of the latitudes of ♃.] But the limit ought to have been placed at ♎ 8° 52′ 10″, so as to be a quadrant distant from the node, whose place was chosen at ♋ 8° 52′ 10″. Finally, in Chapter 8, in order to find the motion of this node, he takes a latitude of Jupiter observed in the year of Christ 508 by a certain anonymous person and reported in a manuscript of the royal library of

Paris, in which it is said that on the morning of the 30th day of Thoth, that is, September 27, Jupiter was seen so near the Heart of Leo that it stood 3 digits from it toward the north. Boulliau, however, says that the spreading of the light narrowed the true distance for the observer by one digit, and that therefore Jupiter was further north than Regulus by 4 digits, or 10′; that Regulus then had a latitude of 26′ 30″ north; and that therefore Jupiter had 36′ 30″. [Margin: Motion of the node of ♃.] From this, and from the longitude of Jupiter and of the Sun, and the distances of Jupiter from the Sun and from the Earth, he gathers the place of the north node at Cancer 1° 8′ 49″ at the beginning of the year of Christ 509. But at the beginning of the year 1637 it was found at Cancer 8° 52′ 10″. Therefore in 1129 years it advanced 7° 43′ 21″, and in one year 24″ $37'''$ $28''''$ 0^{v} 25^{vi} 30^{vii} 33^{viii}.

De Latitudine Martis.

On the latitude of Mars.

VII. *First,* then, Boulliau, in Book 8, Chapter 7, investigates ὁλοσχερέστερος the place of the node of Mars from a single observation of a northern latitude of Mars of only 45″, made in 1593 December 10, in the evening, when the place of Mars as seen from the Sun was at Taurus 15° 57′ 2″. From this it is gathered that the north node, at which there was no latitude, was at Taurus 15° 30′. Then, from an observation of a northern latitude of 2° 35′, and from the place of Mars as seen from the Sun in 1586 December 15, at 18^{h} 30^{m}, and from the distances of Mars from the Earth and from the Sun, he derives the inclination of the eccentric of Mars to the ecliptic as 1° 53′ 4″. But in Chapter 10 he inquires into these things more accurately from three Tychonic observations, in his usual way, and in the year 1585 he obtains the north node at Taurus 15° 22′ 8″ and the inclination 1° 51′ 4″. [Margin: Inclination of ♂.] The observations, made at Uraniborg, are these.

Year of Christ	Month	Day	Hour	Place of ♂ as seen from ☉	Observed latitude of ♂	Distance of ♂ from the Sun	Distance of ♂ from the Earth
1593	December	10	5	♉ 15° 57′ 2″	0° 0′ 45″ B		
1586	December	15	18	♌ 20° 18′ 5″	2° 35′ 0″ B	109118	64495
1585	January	24	9	♌ 18° 47′ 42″	4° 31′ 0″ B	109069	98627
1585	March	12	10	♍ 9° 25′ 5″	3° 22′ 0″ B	109054	99873
1585	April	26	10	♍ 29° 21′ 51″	1° 49′ 45″ B	107746	101140

VIII. *Second,* in Chapters 11 and 12, he investigates the greatest apparent latitudes of Mars and all their variety at aphelion and perihelion, in conjunctions and oppositions with the Sun, from the inclination found above and from the

greatest and least distances of Mars; these I shall present at the end of the chapter. [Margin: Variety of the latitudes of Mars.] Lastly, in Chapter 14, from a latitude of Mars of 1° 13′, observed in the year of Christ 498, May 1, at 9^{h}, and reported in a manuscript of the Royal Library, and also from the distance at that time of Mars from the Sun, 103492, and of the Earth from the Sun, 101465, he derives the place of the north node at Taurus 0° 48′ 36″, which in the year 1585 was found above to be at Taurus 15° 22′ 8″. [Margin: Motion of the node of ♂.] Therefore in 1087 years, etc., the node of Mars advanced 14° 33′ 32″, and each year 48″ 11‴ 55⁗ 17^{v} 22^{vi} 41^{vii} 35^{viii}.

De Latitudine Veneris.

On the latitude of Venus.

IX. *First,* in his usual way, Boulliau, in Book 9, Chapter 3, inquires into the place of the node of Venus and the inclination of its fixed orbit to the ecliptic, chiefly from two observations, and at last he concludes the place of the north node at ♊ 14° 5′ 39″ and the inclination 3° 22′ 52″. [Margin: Inclination of ♀.] The principal observations were these, which we present in the following table: the former of them, for the inclination, made at Uraniborg by the Tychonians, the latter at Kassel by the Landgrave's people of Hesse, with the hours after noon.

Year of Christ	Month	Day	Hour	Place as seen from ☉	Observed latitude of ♀	Distance of ♀ from the Sun	Distance of the Earth from ☉
1594	December	17	5	♑ 5° 48′ 51″	1° 6′ 35″ A	72077	98216
1595	August	8	16	♊ 11° 41′ 3″	0° 4′ 25″ A	72055	101122

X. *Second,* he examines the variation of the latitudes of Venus at aphelion and perihelion, etc., in Chapter 5; of these below, in the synopsis. [Margin: Variation of the latitude of ♀.] As for the motion of the north node, in Chapter 7, from an observation of the year of Christ 510, August 20, on which, at 7^{h} after noon, at Uraniborg, Venus was seen joined with Jupiter: from this conjunction he gathers the north node of Venus at ♊ 4° 59′ 59″, which in the year 1596 was found at ♊ 14° 5′ 39″. [Margin: Motion of the node of ♀.] Therefore in 1086 years, etc., it completed 9° 5′ 40″, and so each year it completed 30″ 8‴ 37⁗ 29^{v} 40^{vi} 23^{vii}.

De Latitudine Mercurij.

On the latitude of Mercury.

XI. *First,* in this planet too, Boulliau, in Book 10, Chapter 7, hunts for the fixed inclination of the eccentric ellipse to the ecliptic and the place of the nodes, using three observations of Tycho. Applying to them his own measures

of the distances, and arranging the three places of Mercury on one circle, but keeping the proportion and the other things that are to be preserved, from the Rudolphine Tables themselves, which rest on a Tychonic foundation, he finds an error in two Tychonic observations, committed either by the observer or by the printer. For from them the place of the north limit is gathered at ♌ 18° 38′ 15″, and of the north node at ♉ 18° 38′ 15″. From this there follows a northern latitude of Mercury much greater than 47′; and yet, as Longomontanus reports in Book 2 of the *Theorica*, Chapter 20, Mercury is said to have been observed by Tycho in 1592 February 3 with a northern latitude of 47′. Indeed, from those three places compared together, with the measures and the proportion of the Rudolphine motions kept, it follows that Mercury should have been observed as southern, though it is put as northern. For that reason, setting aside the Tychonic observations for the time being, he turns to two observations of Pierre Gassendi, already examined above by him on the occasion of investigating the motion in longitude. [Margin: An error in the Tychonic observations found by Boulliau.] The first was in 1634 January 6, at $6^{h}\ 30^{m}$, when Gassendi observed Mercury as northern with a latitude of 1′ 52″. At that time Mercury as seen from the Sun was at ♉ 12° 42′ 26″ and already northern; therefore the node of Mercury, which is determined by the straight line of the common section of the planes of this orbit and the ecliptic, drawn through the Sun, preceded the 18th degree of Taurus. The same is confirmed by the observation of the conjunction of Mercury with the Sun in 1631 November 7, observed through the telescope by Pierre Gassendi in the morning. For in it the place of Mercury as seen from the Earth was at Scorpio 14° 37′ 42″, and as seen from the Sun at 14° 37′ 33″; but the opposite place of the Earth as seen from the Sun was at Taurus 14° 37′ 42″, and the opposite place of Mercury as seen from the Sun at Taurus 14° 37′ 33″. And when Mercury left from beneath the disc of the Sun, it appeared already northern, by 6′ 20″ from the Earth and by 13′ 50″ from the Sun, having been southern a little before. Therefore the node preceded the 18th degree, of Taurus on that side and of Scorpio on this. With these things set out first, he corrects the second observation of Tycho and draws the north node back to Taurus 11° 20′, so that the proportion may be kept; and from this, in Tycho's first observation, he determines the distance of Mercury from the south node, against the order of the signs, as 66° 37′ 6″, with the latitude of that place seen from the Sun 6° 47′ 42″ (according to the rule often given, especially with the figure in Chapter 5, number 2). So if one takes, as the sine of the distance from the south node is to the given latitude, so the radius to the angle of inclination, the inclination of the orbit of Mercury is found as 7° 24′ 21″; and using the same proportion in the third Tychonic observation, he finds the inclination 6° 21′ 33″. Accordingly, choosing a mean, he sets with Kepler the inclination of Mercury at 6° 54′. [Margin: The Keplerian inclination of ☿ established by Boulliau.] With this assumed, he investigates the node by the following technique, from the conjunction of Mercury with the Sun observed by Gassendi, in which, as above, the latitude seen from the Sun was 0° 13′ 50″.

For he takes: as the tangent of the whole inclination is to the whole sine, so the tangent of the given latitude to the sine of the arc of the distance of Mercury from the north node, which arc is 1° 54′ 12″. Now when the latitude was noted, Mercury was leaving the disc of the Sun at 11^h 16^m Uraniborg time, and its place as seen from the Sun was Taurus 15° 15′ 4″. When therefore the arc of the distance of Mercury from the node in the order of the signs is taken away, there remains the north node of Mercury at Taurus 13° 20′ 52″ in 1631 November 7. [Margin: Place of the node ☊ of ☿.] So at the beginning of the year 1632 it was at ♉ 13° 21′ 5″. The Tychonic observations mentioned above are written below, in Old Style.

Year of Christ	Month	Day	Hour	Place of ☿ from ☉	Observed latitude	Distance of ☿ from the Sun	Distance of ☿ from the Earth
1585	November	14	19	♏ 4° 42′ 53″	2° 18′ B	35912	105881
1587	January	9	5	♉ 11° 47′ 29″	0° 1′ B	31142	96459
1592	February	3	6	♊ 4° 42′ 20″	0° 47′ B	30513	98027

XII. *Second,* Boulliau continues in Book 10, Chapter 8, and from the inclination and the greatest and least distances of Mercury from the Sun at apogee or perigee, that is, with the Earth placed now at aphelion, now at perihelion, he determines the whole possible variety of the greatest latitudes in conjunctions and oppositions with the Sun, which we shall give presently in the synopsis. [Margin: Variety of the greatest latitude of Mercury.] Afterwards, in Chapter 11, for the translation or motion of the node, he uses a very ancient observation, which he had discussed in Chapter 9 and which is reported by Ptolemy, Book 9, Chapter 7. Ptolemy says that in the year of Nabonassar 484, on the day of Thoth following the 19th (this was the year before Christ 265, November 19, with the 20th following), in the morning, Mercury was seen to stand in the order of the signs, by the interval of one Moon, from the line passing through the northern and the middle star of the forehead of Scorpio, and was seen to stand toward the north by two Moons from the northern star of the forehead of Scorpio. By Boulliau's calculation the true place of the Sun at that time was at ♏ 19° 46′ 32″, and that of Mercury as seen from the Sun ♋ 1° 59′ 5″; the distance of the Sun from the Earth was 98292, and that of Mercury from the Earth 76271 and from the Sun 34768, in parts of which the radius of the annual orb is 100000. From these and the fixed inclination of 6° 54′ he gathers the northern latitude of Mercury as 4° 35′ 42″. Then he uses another observation reported by Ptolemy, in the year of Nabonassar

486, Choeac 17, with the 18th following, in the morning, at 16^h 10^m Uraniborg time, when Mercury was observed to stand off from the bright star of the tail of Capricorn, toward the north, by three Moons. That star, by Tycho's reckoning, was at ♑ 21° 40′, with a southern latitude of 2° 29′. At that time,

by Boulliau's calculation, the place of Mercury as seen from the Sun was ♎ 6° 41′ 31″, but from the Earth ♑ 22° 51′ 24″, that is, further advanced than that star by 1° 11″, although Ptolemy says it was at the same longitude, perhaps because that star and Mercury were seen in the same almucantar. For that reason, although Boulliau admits that he is uncertain about the place of Mercury and is at a loss [hærere sibi aquam][71], and that this observation was made only πλατικῶς [Greek: platikōs, "broadly, in general terms"], so that the motion of the nodes cannot be precisely defined from it, he nevertheless, because of the longer longitude of Mercury than of the fixed star, assumes that the latitude of Mercury then was 1° south as seen from the Earth. From this, and from the distance of Mercury from the Sun, 46489, and the place of the Earth at ♌ 19° 32′ 24″, he gathers trigonometrically the latitude of Mercury as seen from the Sun as 1° 37′ 47″ south; from this and from the northern latitude acquired by the preceding observation, the south node is found to have been between Virgo and Libra. When the second observation is used, however, if one takes, as the sine of the angle of inclination of 6° 54′ is to the whole sine, so the sine of the latitude of 1° 37′ 47″ to the sine 23510, there will come out a distance of Mercury, against the order of the signs, of 13° 35′ 52″ from the place of Mercury as seen from the Sun, which we said was at ♎ 6° 41′ 31″. The place of the south node of Mercury therefore falls at ♍ 23° 5′ 41″, and the north node at ♓ 23° 5′ 41″ (which in the year of Christ 1631, November 7, was found above at ♉ 13° 20′ 52″), namely in the year of Nabonassar 2380, Choeac 19. So in 1894 Egyptian years the node advanced 50° 15′ 11″, and each year 1′ 35″ 31‴ 4⁗ 37^{v} 30^{vi} 28^{vii} 30^{viii} 46^{ix}. [Margin: Motion of the node of ☿.]

SCHOLIA.

Scholia.

I. If anyone wants a compendium of the geometrical calculation, let him know that it is the same as the one we gave from Kepler in Chapter 5, scholium 2, although certain figures to be placed in Chapter 8 may throw light on this business. [Margin: On the geometrical calculation.] And though Boulliau, with wonderful candour, as is his way, investigates astronomical truth most acutely, he will not, however, deny that a universal law of motions, especially of the smallest ones, of which kind is the motion of the nodes, is not so certainly gathered from only three observations at a time; and he himself surely knows that, if more observations are used, there will be not a few that resist the measures established above. [Margin: A judgment on Boulliau's method.]

II. Boulliau, in Book 6, Chapter 6, might seem to have acted rashly in deriving, from so short an interval as that between Walther and Tycho, indeed from less than a whole century, the difference in the motion of the nodes of Saturn, and from it so slow a motion. [Margin: On the slowness of the motion of the node of Saturn.] But since he found the same slowness in that same place from an interval of 1085 years, and it agrees closely with the sluggishness of the other motions of Saturn and with the comparison with the motion of the node of Jupiter, it might seem probable. Yet because it follows from it that Ptolemy erred in the place of this node by almost 10°, it seems rather harsh, unless it is softened by the mean of fairness.

CAPVT VII.

Chapter 7.

Noſtra Hypotheſis De Latitudine Quinque minorum Planetarum.

Our hypothesis on the latitude of the five minor planets.

I. Since our hypothesis is the Ptolemaic, but reformed, and supposes many of the things that Ptolemy, or Longomontanus correcting him in this place, posit, and these have already been explained in Chapter 1, number 7, and Chapter 4, number 8, there is no need to repeat them here, but only to indicate in what it differs. *First,* then, we accept, with Longomontanus, Kepler, Lansbergen

and Boulliau, that the inclination of all these planets to the ecliptic is stable and constant; the inclination, I mean, of the eccentric orb in the three superior planets, but of the epicycle in the two remaining ones. [Margin: The constancy of the inclination.] We accept it with that parallelism which we set out above in Chapter 4, numbers 5 and 8, and with the same alternations of the latitude as it changes toward the north or toward the south, that of Venus into the quarter opposite to that of Mercury; and in such a way that, with the centre of the epicycle placed at the apogee of the eccentric, the latitudes are not always northern, and at the perigee southern, as in the three superior planets, but in turn, both in Venus and in Mercury, sometimes northern, sometimes southern. [Margin: The difference between the superior and inferior planets.] Nor also do they remain longer in latitude northern than in southern, as the three superior planets do. For Venus and Mercury allot half of their revolution around the Sun, which in Venus is of 224^{d} and almost 18^{h}, and in Mercury of almost 88^{d}, to the northern semicircle, and the other half to the southern. That is, Venus spends almost 112^{d} in northern latitude, and Mercury 44^{d}, and each spends as many in southern latitude. [Margin: The difference between the superior and inferior planets.] Let the diagram set out in Chapter 1, number 7, but corrected in Chapter 4, number 8, be brought back here.

As for the remaining variations, which Ptolemy sought to defend by means of Deviation or Obliquation, we consider them either as still undiscovered and not resting on clear observations, or, if there are any, as capable of being sufficiently explained away: both from the varying distance of the planets from the Earth, and from the variation of the eccentricity and the change in the semidiameter of the epicycle, and above all from a more correct inclination of the epicycle of Venus and of Mercury to the orbit lying perpetually in the plane of the ecliptic. And this holds until a multitude of observations, to be brought forward and discussed in Volume 3, God willing, either compels us to think otherwise or confirms us in this opinion.

II. As regards the quantity of the inclination: after examining the latitudes dealt with in Chapters 4, 5 and 6, and some others, I judged that the inclination to choose was, for Saturn, $2^{\circ}\ 31'$; for Jupiter, $1^{\circ}\ 25'$; for Mars, $1^{\circ}\ 50'\ 30''$; for Venus, $3^{\circ}\ 24'$; and for Mercury, $6^{\circ}\ 54'$. [Margin: The quantity of the inclinations.] From these, by the method to be given in the Problems of Chapter 8, which follows shortly, the variations of the greatest latitudes are easily derived, provided that our distances of the centre of the epicycle from the centre of the Earth are used, and the semidiameters of the epicycles, variable with that variation which we taught in Sections 2 and 3.

III. As to the ancient and recent places of the nodes, we have no early observations made at the nodes themselves or as close to them as possible, and we are compelled either to believe Ptolemy or not to depart greatly from him on the place of the nodes in that age. For as to the observations that Boulliau brought forward in Chapter 6, number 4, to advance the node of Saturn and to reduce its motion: who, weighing them attentively, would not recognise

either that they are not recorded with such clear marks, or that those of Walther are separated by too short an interval from those of Tycho, that is, not even by a whole century, so that they are on that account unsuited to deriving so slow a motion? Yet, so as not to depart from the third observation, which he adduces in the same place, as far as Ptolemy would wish, we shall choose a kind of middle way, until it becomes possible to seek out firmer foundations for these matters from the observations of Volume 3. In the remaining planets, moreover, by a not dissimilar reasoning we shall choose places and motions of the nodes which seemed to satisfy most of the selected observations, although not all. So, not to detain the reader longer on these matters, we shall set out a synopsis of our hypothesis about them in the small tables below. From the place of the north node, moreover, the Limit of the greatest northern latitude is easily derived, because it stands 90° from the node in the order of the signs. The south node, however, is diametrically opposite the north node, and the southern Limit is diametrically opposite the northern Limit. Further, I considered it pointless to cut up the annual motion as far as the sixth or tenth order of sexagesimal fractions [ſexta vel decima ſcrupula ſcrupulorum], since the whole dispute lies in the minutes and seconds, and it is more than enough to have come closer to the truth in these.

The inclination here, moreover, for the three superior planets, is both that of the eccentric to the ecliptic and that of the epicycle parallel to it, to the eccentric. But in the inferior planets it is that of the epicycle to the ecliptic and to the orbit lying in the plane of the ecliptic, in accordance with what was said in number 1.

Synopsis of our latitudes [SYNOPSIS Noſtra Latitudinum]

Planet	Inclination to the ecliptic	Annual motion of the node ☊
♄	2° 31′ 0″	0′ 50″
♃	1° 25′ 0″	0′ 15″
♂	1° 50′ 30″	0′ 40″
♀	3° 24′ 0″	0′ 40″

CAPVT VIII.

Chapter 8.

De Artificio Inueſtigandi Nodum, Inclinationes Orbitæ, & Latitudines Quinque Planetarum.

On the technique of investigating the node, the inclinations of the orbit, and the latitudes of the five planets.

I. Although in Chapters 3, 4 and 6 we have indicated some problems bearing on this, and have indeed worked some out completely, there still remain others, often promised but deliberately passed over at that point, so that the reader should not be too much distracted, especially in the new and in itself arduous hypothesis of Kepler and Boulliau. I have resolved to set these out collectively, without the lengthiness of diagrams and problems.

Problema 1. Locum Nodi obſeruando inueſtigare.

Problem 1. To investigate the place of the node by observing.

II. This problem is solved by no other technique than observation of the latitude of the planets, made with fine instruments on those days on which, from an ephemeris, it is in some way evident that the planet will lack latitude. The observations are continued on those days, so that from the increments or decrements of the latitude, and from their proportion, the time at which the planet was in the ecliptic can be gathered, with account taken, however, of the correction for parallax and refraction, if any should intervene. Some examples of this kind may be sought from Kepler, in the *Commentaries on Mars*, Chapter 12. Reduced to a synopsis, these are written below, from Tychonic observations made and corrected at Uraniborg.

	In hours after noon: year	Month	Day	Hours after noon	♂ Latitude observed	
1	1590	March	4	$7^h\ 10^m$	0° 3′ 12″	A
2	1592	January	23	$10^h\ 25^m$	0° 0′ 0″	
3	1592	February	6	$10^h\ 25^m$	0° 7′ 0″	B
4	1593	December	10	evening	0° 0′ 45″	B
5	1595	October	27	$12^h\ 22^m$	0° 2′ 20″	A
6	1595	October	28	at night	0° 0′ 25″	B
7	1595	January	4	morning	0° 3′ 0″	A
8	1589	April	15	at night	1° 7′ 0″	B
9	1589	May	9	....	0° 0′ 0″	

Since, then, by the 5th and 6th observations Mars was at the north node, if one counts back from about noon of October 28 the 687 days in which Mars completes its eccentric revolution, it will be found to have been at the north node in 1593 December 10, as observation 4 indicates. Counting another 687 days back again from there, Mars will be found at the north node in 1592 January 23, exactly as observation 2 shows. From this you will gather that, once a planet has been observed at either node, the time at which it will be at the opposite node, or will return to the same node, is easily established without any other ephemeris, so that, if you wish, you can confirm that same time by observation. Therefore the following small table should be consulted for the revolution to the nodes.

Return from node to node [Reditus à Nodo ad Nodum]

Planet	From the node ☊ to ☋	From ☊ to ☊, or from ☋ to ☋
♄	$5379^d\ 14^h\ 29^m$	$10759^d\ 4^h\ 58^m$
♃	$2166^d\ 7^h\ 25^m$	$4332^d\ 14^h\ 50^m$
♂	$343^d\ 12^h\ 0^m$	$687^d\ 0^h\ 0^m$
♀	$112^d\ 8^h\ 53^m$	$224^d\ 17^h\ 46^m$
☿	$43^d\ 41^h\ 37^m$	$87^d\ 23^h\ 14^m$

Having therefore obtained the moment at which the planet was at either node, if the place of the planet in longitude is not established from observation,

it must be derived from the tables, by computing both its mean and its true place in longitude, so that it may appear whether in this return to the nodes, which are diametrically opposite, it follows the mean or the true motion. As for how the time at which the planet falls into the node is gathered from a latitude observed near the nodes, Kepler teaches this by examples on Mars, in Chapter 61, namely from the proportion of the motions. For, as he himself relates there, in 1595 October 28, at 12^h, the southern latitude of Mars was observed as 4′ 30″, and on November 3, at the same hour, a northern latitude of 19′ 45″ was observed by Tycho. [Margin: Place of the node of ♂ in the years 1595 and 1600.] For in 6^d the latitude changed by 24′, and by 4′ daily; therefore it completed 4′ 30″ in 1^d and 4^h, and it was at the node on October 30, at 8^h before noon. At that time, by Kepler's calculation, Mars, and so the place of the north node, was at 16° 45′ 24″ of Taurus. From other observations, however, compared with this one and with one another, he chose for the year 1600 the place of this node at ♉ 16° 44′ 32″, as is clear from the Rudolphine Tables.

Problema 2. Latitudinem Maximam obſeruando inueſtigare.

Problem 2. To investigate the greatest latitude by observing.

III. This too is done by continuing the observations of the latitude on those days on which, from an ephemeris or from elsewhere, there is a suspicion that the planet is approaching the limit of greatest latitude, and by considering the proportion of the increment, and afterwards of the decrement. Further, from the time at which it was at the node, and from a quadrant of the eccentric revolution of the three superior planets, or of the epicyclic revolution of the two inferior planets, a conjecture is formed, though from a distance, about the time of its arrival at the limits. [Margin: 1. A rule for the time of observing the limits.] Thus, for example, if Mars was at the north node in 1595 October 30, then, because a fourth part of its revolution, which is of 687 days, is 172 days, you will gather that it was near the north limit around April 20 of the year 1596. This rule, however, is liable to a difference of some days, but even so it is not wholly useless for scenting out the time. Another rule, for Saturn and Jupiter, is that the observation of the latitude be made around their oppositions with the Sun, near the acronychal shinings; for then their latitude is usually greatest, both northern and southern, but the southern is the greater. In Mars, however, although it often reaches its greatest latitude near opposition with the Sun, it nevertheless sometimes undergoes it many days, and indeed a whole month, before or after the moment of opposition, as we said in Chapter 4, Scholium 2. Venus, when it is retrograde, experiences in this century its greatest northern latitude in Pisces, and its almost greatest southern latitude in Virgo, which is nevertheless less than the northern. In Mercury, by contrast, other things being equal, the southern is greater than the northern, and in this century it usually reaches the former around the middle of Aquarius and the latter around the middle of Leo, if it is retrograde there. On this occasion I point out that

perhaps the greatest southern latitude of Mars observed by Tycho, 6° 42′, as Longomontanus reports in Book 2, Chapter 15, was not in fact yet the greatest, because Tycho believed that it occurs at the moments of opposition. [Margin: The greatest southern latitude of Mars.] It is no wonder, then, if for us it runs out as far as 7⅙°.

Problema 3. Inclinationem totam ſeu maximam Orbitæ ad Eclipticam, Data aut non data Latitudine maxima inquirere, pro tribus Superioribus Planetis in forma Ptolemaica.

Problem 3. To inquire into the whole or greatest inclination of the orbit to the ecliptic, the greatest latitude being given or not given, for the three superior planets in the Ptolemaic form.

IV. In the Ptolemaic hypothesis this procedure is taught by Ptolemy himself, in Book 13, Chapter 3, of the *Almagest*, and on that passage by Regiomontanus in the *Epitome*, Book 13, Propositions 5 and 6; and we showed in Chapter 4, number 3, how it was indicated by Longomontanus. The operation turns out simpler and easier, however, if the epicycles are supposed to be parallel to the ecliptic, or if the greatest latitude is known beforehand. For in the following figure let CBD represent the plane of the ecliptic, and in it let B be its centre and that of the Earth. Through B let MBF be drawn, representing the plane of the orbit of the planet inclined to the ecliptic, with the angle of inclination MBD on one side and FBC on the other. On the same line let BA be the greatest distance, or longer longitude of the epicycle, and BP the least. With centres taken at the apogee A and the perigee P of the eccentric, let the epicycles EFG and HKM be described, whose planes, as well as the diameters of the apsides of the epicycle, namely EG and HK, are to be parallel to the ecliptic CD. For by 29 of Book 1 of the *Elements*, the angle BAG, by which the epicycle is inclined to the eccentric, will be equal to the angle ABC, by which the eccentric is inclined to the ecliptic; just as HPB, too, is equal to MBD. Now let the apogees E and K of the epicycles be joined with the centre B by the straight lines BE and BK, and likewise the perigees G and H by the straight lines BG and BH. And let there be given, as I suppose, the greatest and least distances of the centre of the epicycle, together with the semidiame- ters of the epicycles in the same kind of parts, and the distance of the planet from the centre of the Earth. With these things posited, *first,* let the planet be at the perigee H of the epicycle, when its centre is at the perigee of the eccentric. [Margin: Case 1 of the problem.] In the triangle PBH, in which are given the distance BP, the semidiameter PH, and the distance BH of the planet, let the angle HPB be investigated, which, because of the parallelism supposed, is equal to the angle of inclination MBD. But if HK is not supposed parallel to BD, then the greatest latitude, that is, the angle HBD, must be known beforehand from observation; and in the triangle PHB the angle HBP must be inquired into and subtracted from the latitude HBD, so that the inclination MBD is left known. *Second,* if the planet is at the

apogee K, and the centre of the epicycle at P: from the semidiameter PK and the distances BP and BK, inquire in the triangle BPK into the angle KPB, whose complement to two right angles will be the angle HPB, equal to the inclination MBD, if HK is supposed parallel to BD. [Margin: Case 2.] Otherwise the angle KBP must be investigated and added to the observed greatest latitude KBD, so that the inclination MBD results. *Third,* if the centre of the epicycle is at the apogee A, and the planet at the apogee E: in this case too, in the triangle BAE, from the given distances BA and BE and the semidiameter AE, inquire into the angle BAE. [Margin: Case 3.] For it will be the complement to two right angles of the angle BAG, which is equal to the inclination CBF, if EG is supposed parallel to the ecliptic. Otherwise inquire into the angle EBA, and add it to the observed greatest latitude CBE, so that the inclination CBF results. *Fourth,* if the planet is at G: then in the triangle BAG, with the distances AB and GB and the semidiameter AG, investigate the angle BAG, equal to the inclination CBF, if EG is parallel to CD. [Margin: Case 4.] Otherwise the angle ABG must be investigated and subtracted from the observed greatest latitude CBG, so that what remains is the desired angle of inclination CBF. Therefore either the already mentioned parallelism must be supposed, or the greatest latitude, besides the semidiameter of the epicycle and the distance of the centre of the epicycle and of the planet from the Earth, found by the calculation of longitude, as we taught in the geometrical calculation of longitude in its proper places.

Diagram. Set into the left column, with the text wrapped around its left side. A long vertical line runs from C at the top to D at the foot, and passes through B, at which the other lines of the figure meet. Three circles stand around B. Above and to the right of the vertical line is a circle with centre A, with E at its top, F at its upper right and G at its foot. Below and to the left is a circle with centre P, with H at its top, and M and K at its foot. To the right of B is a smaller circle with centre N, with O at its upper left, L at the right and R at the lower right; Z stands inside it, near the upper edge. Straight lines run from B to the points of each circle, and a line passes from F through B to M. A line joins E and G through the upper circle, and another joins H and K through the lower one.

- C (top of the vertical line): C
- D (foot of the vertical line): D
- B (junction of the lines): B
- A (centre of the upper circle): A
- E (top of the upper circle): E
- F (upper right of the upper circle): F
- G (foot of the upper circle): G
- P (centre of the lower circle): P
- H (top of the lower circle): H
- M (lower left of the lower circle): M
- K (foot of the lower circle): K
- N (centre of the right-hand circle): N

- O (upper left of the right-hand circle): O
- L (right of the right-hand circle): L
- R (lower right of the right-hand circle): R
- Z (inside the right-hand circle): Z

Problema 4 Inclinatiōnem Epicycli ad Eccētricum pro Venere ac Mercurio, Data latitudine maxima, inquirere in forma Ptolemaica.

Problem 4. To inquire into the inclination of the epicycle to the eccentric for Venus and Mercury, the greatest latitude being given, in the Ptolemaic form.

V. According to the teaching of Regiomontanus in Book 13, Proposition 4, of the *Epitome of the Almagest*, let CD in the preceding figure be the line of apsides of the eccentric, and in it the centre of the Earth, B. Let a plane surface be understood, passing through the nodes and falling perpendicularly on the ecliptic, which is to cut the sphere of the epicycle so that the common section is OLR; and let the circle OR be described from N. From B let the line BNL flow, and from the same point the lines BO, to the perigee, and BR, to the apogee of the epicycle. But let us suppose the planet then to be at O, and on BO produced let the perpendicular NZ fall from N. Therefore in the triangle BZN, right-angled at Z, since the greatest latitude, which here is OBN, is given by observation according to what was said in Problem 2, the proportion of the distance BN of the epicycle to NZ will be given. But with the semidiameter NO of the epicycle given, its proportion to the distance BN is also known; therefore the proportion of the same NO to NZ will become known. From these known quantities NO and NZ, the angle NOZ will become known in the right-angled triangle ONZ. By 32 of Book 1 of the *Elements* this angle is equal to the interior angles OBN and ONB. So, with OBN taken away, there will remain the known angle ONB, which is the very inclination sought.

Problema 5. Data Inclinatione Orbitæ ad Eclipticam Inueſtigare latitudines maximas Planetarum; in forma Ptolemaica.

Problem 5. The inclination of the orbit to the ecliptic being given, to investigate the greatest latitudes of the planets, in the Ptolemaic form.

VI. In the same figure of Problems 3 and 4: if the centre of the epicycle is at the apogee A of the eccentric, and the planet at E, the apogee of the epicycle, then the inclination CBF, equal to the angle BAG (the parallelism of the lines EG and CD being supposed), reveals the angle BAE, as being the complement to two right angles of the angle BAG. [Margin: Case 1.] Therefore in the triangle BAE, from the already mentioned angle, from the semidiameter AE of the epicycle, and from the greatest distance AB of the centre of the epicycle, you will investigate the angle EBA, which, taken from the inclination CBF, will leave the greatest latitude of the planet, CBE, in such a position. But if

the planet is at G, then from the distance BA, the semidiameter AG, and the angle BAG, which is equal to the angle of inclination CBF, with the already mentioned parallelism posited, you will obtain the angle ABG, which, added to the inclination, will make up the angle of greatest latitude CBG. [Margin: Case 2.] Now let the centre of the epicycle be at P, the perigee of the eccentric, and the planet at K, the apogee of the epicycle. [Margin: Case 3.] In this case too, in the triangle BPK, the angle KPB will be known, for it is the complement of the angle HPB, which is equal to the inclination MBD. So from the least distance BP of the epicycle and the semidiameter PK of the epicycle you will inquire into the angle PBK, which you will take from the inclination, and the greatest latitude KBD will be left. Finally, if the planet is at the perigee H, then in the triangle HPB, from the semidiameter PH, the distance BP and the angle of inclination HPB, gather the angle PBH. [Margin: Case 4.] Add this to the inclination MBD, and the greatest latitude HBD will result, provided HK and CD are parallel, as is supposed in the reformed hypothesis of Ptolemy. Otherwise one must use the distance of the planet, together with the distance and semidiameter of the epicycle, and inquire into the angle opposite the semidiameter of the epicycle; and this angle, added to the inclination if the planet is in the perigee of the epicycle, or taken away if in the apogee, will make the greatest latitude known, etc.

For ♀ and ☿, however, from the given inclination BNO of the epicycle to the eccentric, from the distance BN, and from the semidiameter NO, you will obtain the latitude NBO, or NBR, etc. [Margin: The problem is applied to ♀ and ☿.]

Problema 6. Data Latitudine maxima Inclinationem Orbis ad Eclipticam, & viciſſim data Inclinatione Latitudinem maximam inquirere in forma Copernicæa.

Problem 6. To inquire, the greatest latitude being given, into the inclination of the orb to the ecliptic, and conversely, the inclination being given, into the greatest latitude, in the Copernican form.

VII. From E, the centre of the annual orb, describe the annual orb FHG. Let AEB be the index of the plane of the ecliptic, and CED that of the plane of the eccentric, inclined to it at the angle AEC or BED. Let the Earth be at F, seeing by the line FC the planet C, at the limit of greatest latitude, opposite the Sun placed near E; or by the line FD let it see the planet D, conjoined with the Sun at the other limit. Or let the Earth be at G, and let it see by the line GD the planet D opposite the Sun, but by the line GC the planet C joined to the Sun.

Diagram. Set into the right column, with the text wrapped around its left side. A circle has its centre at E, marked in a small box, with F at its top, H at its left and G at its foot. Two long straight lines cross at E: one runs from A above the circle to B below it, and the other from C above the circle to D

below it. Lines run from F and G to the points C and D. Inside the circle, to the right of the crossing lines, the signs ♄, ♃ and ♂ are set one below another.

- C (above the circle, upper left): C
- A (above the circle, upper right): A
- F (top of the circle): F
- H (left of the circle): H
- E (centre, in a small box): E
- G (foot of the circle): G
- B (below the circle, left): B
- D (below the circle, right): D
- ♄, ♃, ♂ (inside the circle, on the right, one below another): planetary signs

In the first case, therefore, the triangle EFC must be solved, in which EF, the semidiameter of the annual orb, is supposed known, and the distance of the planet, either EC from the centre E, or CF from the Earth. [Margin: Case 1.] So if the greatest latitude CFA is given, CFE, its complement, will be given; and from these three you will gather the angle of inclination AEC. Conversely, if the inclination CEF is given, you will gather the angle CFE, which is the complement of the greatest latitude CFA. [Margin: Case 2.] In the second case, however, the triangle FED must be solved, in which are given EF, the semidiameter of the annual orb, and, of the planet D, the di- stance, either DE or DF. So if the greatest latitude BFD is given, you will gather the angle FED, which is the complement of the inclination AEC. Conversely, if the inclination is given, and hence its complement, you will inquire into the angle of greatest latitude EFD, that is BFD.

[Margin: Case 3.] In the third case, however, there is the triangle GED, whose sides are, as I suppose, known: EG, the semidiameter of the annual orb, and GD, the planet's distance from the Earth, or ED, its distance from the centre of the annual orb. Therefore, if the greatest latitude BGD is given, and from it its complement, you will find the inclination GED; but if the inclination is given, you will find EGD, which is the complement of the angle BGD, that is, of the greatest latitude.

[Margin: Case 4.] Finally, in the fourth case, look at the triangle GEC, whose sides are likewise known: EG, the semidiameter of the annual orb, that is, the mean distance of the Earth from the Sun, and either EC or GC, the distance of the planet from E or from the Earth at G. So suppose the greatest latitude CGA, that is CGE, is given: you will then inquire into GEC, the complement of the inclination CEA; and, that being known, conversely into the greatest latitude CGA. Therefore, whether the planet attains its greatest latitude in opposition to the Sun or in conjunction with it, the known latitude will show the inclination, or the known inclination the greatest latitude.

Problema 7. Latitudinum Maximarum Viciſſitudines omnes, data Inclinatione orbis Planetæ alicuius ſuperioris ad Eclipticam, & diſtantijs Planetæ à Sole & à terra, inquirere in forma Copernicæa & Philolaica.

Problem 7. To inquire into all the changes of the greatest latitudes, given the inclination of the orb of any superior planet to the ecliptic and the planet's distances from the Sun and from the Earth, in the Copernican and Philolaic form.

VIII. This question could be answered by the preceding problem, by changing the Earth's mean distance from the Sun into its distance, known beforehand, now at aphelion and now at perihelion. Still, to exercise the wits of beginners, I choose to set out and explain more clearly two diagrams of Ismaël Boulliau. He himself presents the first of them in Book 6, chapter 4, for the variation of the greatest latitudes of Saturn; the other in Book 7, chapter 6, and Book 8, chapter 12, for the variation of the latitudes of Jupiter and Mars. But each serves for all three superior planets. So in the first diagram let DA be the diameter of the planet's orb, an orb that it is enough to have indicated by the arcs DR and AV, etc. Let the Sun be at O, and the planet's aphelion at A,

Diagram. A geometric figure set into the left column. A horizontal straight line runs from D at the left to A at the right, passing through O near the centre. Arcs of the planet's orb stand at both ends of it (R below D, V above A). About O are drawn a larger circle, partly dotted, and a smaller dotted circle, with T, I, Y and Z marked on or near the horizontal line. Straight lines run from C at the upper left and from B at the lower right to those points and to D and A; a long line joins C and B through O. Below the figure stand three planetary signs, those of Saturn, Jupiter and Mars.

- C (upper left): point of the perpendicular from D
- V (upper right, on the arc): point of the planet's orb
- D (left end of the horizontal line): the planet's perihelion
- Z (on the line, left of Y): the Earth's position
- Y (on the line, left of O): the Earth's position
- O (centre): the Sun
- I (on the line, right of O): the Earth's position
- T (right of I, at the upper right of the circle): the Earth's position
- A (right end of the horizontal line): the planet's aphelion
- R (lower left, on the arc): point of the planet's orb
- B (lower right): foot of the perpendicular from A
- ♄ ♃ ♂ (below the figure): Saturn, Jupiter, Mars

its perihelion at D; and let its greatest distance from the Sun, AO, and its least, DO, be given. Now let the straight line COB represent the plane of the ecliptic, inclined at the angle COD and AOB. To it from the planet at A or D let a perpendicular be drawn, on one side AB, on the other DC. Next let the Earth at aphelion be at T, seeing the planet at aphelion at A, opposite the Sun, or the planet at perihelion at D, joined to the Sun. Again let the Earth

at aphelion be at Z, seeing the planet at A, at aphelion, in conjunction with the Sun, or the planet at D, at perihelion, opposite the Sun. Conversely, let the Earth at perihelion be at I, and let it see from there the planet at aphelion at A, opposite the Sun, or at D, at perihelion, in conjunction with the Sun. And again let the Earth at perihelion be at Y, seeing the planet at aphelion at A, in conjunction, or at perihelion at D, opposite the Sun. And let these four positions of the Earth be connected by straight lines with the points B and C of the ecliptic. With this laid down:

[Margin: Case 1: if the Earth is at aphelion and the planet is at aphelion and opposite the Sun.] In the first position of the Earth, T, since in the triangle AOB, right-angled at B, there are given AO, the planet's greatest distance from the Sun, and the angle AOB, of the inclination of the orbit to the ecliptic, inquire by trigonometry into the side AB and the angle OAB. Then, when the Earth's greatest distance from the Sun, TO, has been subtracted from AO, just as if OT and TA lay on the same line, AT remains. Therefore in the triangle ABT, with AT and AB and the angle BAT known, you will find ATB, the angle of the greatest latitude seen from the Earth at aphelion when the planet is at aphelion and opposite the Sun.

[Margin: Case 2: if the Earth is at aphelion and the planet is at perihelion and joined to the Sun.] But if the Earth is in the same place, and the planet, at perihelion, is in conjunction with the Sun, then in the triangle DOC, right-angled at C, from the planet's distance from the Sun, DO, and the inclination DOC, you will obtain DC and the angle CDT. Then, on adding together the distances, the planet's at perihelion, DO, and the Earth's at aphelion, TO, DT will be given in the triangle DTC. In that triangle, from the known DC and DT and the angle CDT, you will obtain the angle DTC, which is the measure of the greatest latitude seen from the Earth at aphelion when the planet, at perihelion, is in conjunction with the Sun.

[Margin: Case 3: if the Earth is at aphelion and the planet is at perihelion, opposite the Sun.] Now let the Earth, at aphelion, be at Z, seeing the planet at D. Then in the triangle DCO, right-angled at C, you will obtain, as in the second case, DC and CDO. But when the Earth's greatest distance from the Sun, ZO, has then been subtracted from the planet's least distance from the Sun, DO, DZ will remain known. With it, in the triangle CDZ, and with the DC and CDZ already found, you will find the angle DZC, that is, the greatest latitude of the planet at perihelion and opposite the Sun, seen from the Earth at aphelion.

[Margin: Case 4: if the Earth is at aphelion and the planet is at aphelion and joined to the Sun.] But if the Earth at Z sees the planet at A, then in the triangle AOB you will obtain, as in the first case, AB and the angle OAB. To the planet's greatest distance from the Sun, AO, however, you will add the Earth's greatest distance from the Sun, OZ, so that AZ becomes known in the triangle AZB. And from AB and ZAB you can find the angle AZB, namely

the greatest latitude of the planet at aphelion and joined to the Sun, seen from the Earth at aphelion.

[Margin: Case 5: if the Earth is at perihelion and the planet is at aphelion and opposite the Sun.] Now let the Earth be placed at I and the planet at A. Then in the triangle AOB, right-angled at B, the distance AO and the inclination AOB are given; so seek AB and OAB. Then take the Earth's least distance from the Sun, OI, from the planet's distance at aphelion, AO, and AI will be left, in the triangle AIB, in which AB and the angle at A have been found. So the angle of greatest latitude AIB, seen from the Earth at perihelion with the planet at aphelion and opposite the Sun, will not stay hidden.

[Margin: Case 6: if the Earth is at perihelion and the planet is at perihelion and in conjunction with the Sun.] But if at that time the planet is at D, seek as above, in the right-angled triangle OCD, the side DC and the angle CDO. Next join together the perihelion distances, OI of the Earth and OD of the planet, and in the triangle CDI, with DI, DC and CDI now known, you will obtain the angle of greatest latitude CID, seen from the Earth at perihelion when the planet is in conjunction with the Sun and at perihelion.

[Margin: Case 7: if the Earth is at perihelion and the planet is at aphelion and in conjunction with the Sun.] Now with the Earth placed at its perihelion, Y, and the planet at A, first, in the triangle OAB, right-angled at B, with the planet's distance at aphelion and the inclination O, seek AB and OAB. Then, on joining the distances AO, of the planet at aphelion, and OY, of the Earth at perihelion, the side AY will be known in the triangle AYB. Since AB and the angle at A are given in it, the angle AYB, of greatest latitude, will also become known, when the Earth at perihelion sees the planet at aphelion in conjunction with the Sun.

[Margin: Case 8: if the Earth is at perihelion and the planet is at perihelion and opposite the Sun.] Lastly, with the Earth staying in the same place but seeing the planet at D, first obtain, as above, in the triangle COD, the side DC and the angle CDO, so that with these and with DY (which becomes known by subtracting the Earth's perihelion distance YO from the planet's perihelion distance DO) CYD may become known, the angle of greatest latitude when the Earth at perihelion sees the planet at perihelion opposite the Sun.

The diagram, however, could have been made more easily, and these problems solved more expeditiously, if AD had been placed as the ecliptic and CB in the planet's orbit. For in that way the angle ATB, for example, the measure of the greatest latitude, would become known at once from the adjacent angle OTB, known from the solution of the single triangle TOB, etc.

Secundum Schema Bullialdi.

Boulliau's second diagram.

IX. The other diagram is almost the same, but it has the planet's orb marked MTY, in which the aphelion is M, the perihelion Y, and the mean distance

TS; and the Earth's annual orb GHF, with its aphelion G and perihelion F; the Sun is at S. The perpendiculars drawn to the ecliptic are LN, AO and VZ. The angles of the given inclination are LSM, VST and YSO; but the angles measuring the latitude, for the different positions of the Earth, are LHM, if the Earth is at H; or LKM, if it is at K; or ODY, if at D; or OBY, if at B; or VPT, if at P; or VRT, if it is at R. These vary with the variation in the distances of the Earth and the planet from the Sun, and are inquired into in the same way as in the first diagram; granted that in this one the Earth's line of apsides does not coincide in longitude with the planet's line of apsides, and that for the Earth's aphelion or perihelion distances those must be used which correspond to the Sun's equated anomaly at the time when the Earth is in the place in which it sees the planet joined to the Sun, or opposite it, or at the mean distance T.

Diagram. Boulliau's second diagram, set across the left column at its head. A large outer circle is crossed by a horizontal straight line from Y at the left to M at the right and by a vertical line down to T at the foot. Within it stand a second circle and dotted circles about S, the centre. Straight lines run from L at the upper right and from O at the upper left to points on the horizontal line, and from V at the foot to points near the centre. Beside R, inside the outer circle at the lower right, stand three planetary signs, those of Saturn, Jupiter and Mars.

- G (upper left, on an inner circle): the Earth's aphelion
- O (upper left): a position of the planet
- Y (left end of the horizontal line): the planet's perihelion
- A (on the line, under O): foot of the perpendicular from O
- B (on the line, next to A): a position of the Earth
- D (on the line, right of B): a position of the Earth
- E (above S): not cited in the text of this page
- S (centre): the Sun
- X (on the line, right of S): not cited in the text of this page
- H (on the line, right of X): a position of the Earth
- K (on the line, right of H): a position of the Earth
- N (on the line, right of K): foot of the perpendicular from L
- M (right end of the horizontal line): the planet's aphelion
- L (upper right): a position of the planet
- P (below S): a position of the Earth
- F (lower right of P, on an inner circle): the Earth's perihelion
- R (below P): a position of the Earth
- V (lower left of the vertical line): a position of the planet
- Z (next to V): foot of the perpendicular from V
- T (foot of the outer circle): the mean distance TS is measured to it
- ♄ ♃ ♂ (beside R): Saturn, Jupiter, Mars

Problema 8. Data Inclinatione Orbitæ ad Eclipticam, Inueſtigare viciſſitudines Latitudinum maximarum Veneris ac Mercurij, in forma Copernicæa & Philolaica.

Problem 8. Given the inclination of the orbit to the ecliptic, to investigate the changes of the greatest latitudes of Venus and Mercury, in the Copernican and Philolaic form.

X. From Boulliau, Book 9, chapter 5, let the following diagram serve for the latitudes of Venus. In it let the Sun be at D, and the diameter of the annual orb AI, with the Earth at aphelion at A, its greatest distance from the Sun being AD, but its least ID. Let the plane of Venus's orb be BDH, inclined to the plane of the ecliptic GDK at the angle BDK and HDG. Let Venus at aphelion be now at B, now at H, with the aphelion distances BD and HD; and at perihelion let it be at C or at F, with the perihelion distance FD or CD. From these places of Venus draw to the plane of the ecliptic the perpendiculars BK, CL, GH and FE, and let the four points K, L, E, G of the plane of the ecliptic be connected by their straight lines with the Earth at aphelion and at perihelion. For in this problem there will be eight cases, as in the preceding one.

Diagram. The diagram for Venus, set into the right half of the left column with the text running down beside it. A long spindle of straight lines runs from A at the top, under a short arc, to I at the foot, above a short arc. About D, near its middle, stand a larger circle and a smaller circle, with further straight lines crossing between them. The sign of Venus stands to the right, between the two circles' right edges and outside the spindle.

- A (top): the Earth at aphelion
- B (on the large circle, upper part): Venus at aphelion
- K (right of B): foot of the perpendicular from B
- C (on the small circle, upper part): Venus at perihelion
- L (right of C): foot of the perpendicular from C
- D (centre): the Sun
- E (below D): foot of the perpendicular from F
- F (right of E, on the small circle): Venus at perihelion
- G (left, on the large circle): foot of the perpendicular from H
- H (on the large circle, lower part): Venus at aphelion
- I (foot): the Earth at perihelion
- ♀ (right): Venus

For these: [Margin: Case 1.] First, in the triangle DBK, right-angled at K, from the given inclination BDK and Venus's aphelion distance BD, you will obtain BK and the angle DBK. Its complement ABK must be used in the triangle ABK, in which, besides BK, AB will be known if Venus's aphelion distance is subtracted from the Earth's aphelion distance; and so you will obtain the angle BAK, which measures the greatest latitude of Venus at B, seen from the Earth at aphelion, in the conjunction with the Sun of Venus at perigee and at aphelion. [Margin: Case 2.] Second, in the triangle CDL, right-angled at L, from the inclination CDL and Venus's perihelion distance CD, you will gain

CL and the angle DCL. Using its complement and the sides CL and AC, which is known by subtracting CD from AD, you will find in the triangle ACL the angle CAL, the measure of the greatest latitude when the Earth at aphelion sees Venus, at perihelion, in perigee, joined to the Sun. [Margin: Case 3.] Third, in the triangle DHG, right-angled at G, with DH, Venus's aphelion distance, and the inclination GDH, seek GH and the angle GHD; and with these in the triangle AGH, HD and AD having been joined, gather the angle GAH, that is, the measure of the greatest latitude when the Earth is at aphelion and Venus, at aphelion, in the apogee of its orb, is in conjunction with the Sun. [Margin: Case 4.] Fourth, in the triangle DEF, right-angled at E, with Venus's perihelion distance DF and the inclination FDE, inquire into EF and the angle DFE; and with these in the triangle AEF, AD and DF having first been joined into one line, investigate the angle EAF, namely the greatest latitude of Venus at perihelion and in conjunction with the Sun above it, when the Earth is at aphelion.

From these you readily understand how to proceed in the remaining four cases, with the Earth placed at perihelion at I. [Margin: Case 5.] For Venus is then either joined to the Sun below it, at its aphelion H; and then in the triangle DGH, GH and the angle DHG must be sought, with whose complement GHI, the side GH, and the remainder HI, after DH has been subtracted from ID, you will seek the angle of latitude GIH. [Margin: Case 6.] Or Venus is joined to the Sun below it at its perihelion F, and one must use first the triangle EDF and then the triangle EIF. [Margin: Case 7.] Or Venus, joined to the Sun above it, is at aphelion B, and one must use first the triangle BDK and then the triangle BIK. [Margin: Case 8.] Or finally Venus, joined to the Sun above it, is at perihelion C, and then one must use the triangle CDL and after it the triangle CIL. And in every case the angles at I, subtending the greatest latitudes, must be investigated. In this hypothesis, however, the line of apsides of the Earth and of Venus is supposed to be the same, so that the greatest latitude among those possible may be determined; granted that in this century of ours these lines are not joined.

Schema pro Mercurio.

Diagram for Mercury.

XI. You have this diagram in Boulliau, Book 10, chapter 8. Nor does it in fact differ from the diagram for Venus, except that in this one the angles of inclination of the orbit to the ecliptic are greater, as is fitting. The method of gathering the greatest latitudes of Mercury, in eight cases, is exactly the same as for Venus. So it will be enough to have set out the diagram and indicated those cases. In it, then, there is the annual orb, or great orb of the Earth, AF, with its diameter AF, and the Earth at aphelion at A and at perihelion at F, and the Sun at P.

Diagram. The diagram for Mercury, set into the right half of the right column at its middle, with the text running down beside it. A large outer circle has A at its top and F at its foot; a long spindle of straight lines joins A and F. Within the outer circle stand a second circle and two smaller circles about the region of P. Straight lines join the marked points. The sign of Mercury stands at the upper left, inside the outer circle.

- A (top of the outer circle): the Earth at aphelion
- B (below A): Mercury at aphelion
- M (right of B): not cited in the text of this page
- C (right, on the second circle): foot of the perpendicular from B
- Z (centre line, above D): Mercury at perihelion
- D (right of Z): foot of the perpendicular from Z
- O (left of P): a position of Mercury
- P (centre): the Sun
- Y (below P): Mercury at perihelion, or foot of the perpendicular from O; the text uses Y in both ways
- S (lower left of Y): not cited in the text of this page
- E (left, on the second circle): foot of the perpendicular from G
- G (lower centre): Mercury at aphelion
- F (foot of the outer circle): the Earth at perihelion
- ☿ (upper left): Mercury

The remaining orbs, larger or smaller, within the annual orb, show the path of Mercury, whose aphelion is at B and G and whose perihelion is at Z or Y. The line of apsides BG, which coincides, as is imagined here, with the Earth's line of apsides, also represents the plane of Mercury's orb, inclined to the plane of the ecliptic EPC at angles, on one side EPF, on the other BPC. To that plane perpendiculars are drawn from the four places of Mercury, namely BC, ZD, OY and GE; and the four points of this plane on which those perpendiculars fall are connected by straight lines with the Earth at aphelion, A, and at perihelion, F. With this laid down, by means of the triangles right-angled at C, D, Y, E, with the inclination and Mercury's distances from the Sun, the sizes of those perpendiculars and the angles at Mercury are inquired into; and with these, and the distances of Mercury and the Earth from the Sun, or the remainders of the Earth's distance, the angles at A or I [recte: F] measuring the greatest latitudes are sought. [Margin: 8 cases of the latitudes of Mercury.] For here too there are 8 cases. Either the Earth at aphelion, A, sees Mercury joined to the Sun below it at aphelion B or at perihelion Z, or placed above it at aphelion G or perihelion Y. Or the Earth at perihelion, F, sees Mercury joined to the Sun below it at aphelion G or at perihelion Y, or above it at aphelion B or at perihelion Z. But, as we noted above at the end of no. 8, in these two diagrams too it would be easier to conceive the line AF as the ecliptic, and EC as the line of apsides in the plane of the planetary eccentric; and then the perpendiculars to the ecliptic would have to be drawn from the points C, D, Y, E. But since we are with Boulliau, I choose to indicate the following problem from him.

Problema 9. Inclinationem Orbitæ ad Eclipticam, & ſimul Nodi locum inueſtigare, ex Latitudinibus Planetæ quamuis non maximis, & Diſtantijs ipſius ac terræ, in forma Copernicæa & Philolaica.

Problem 9. To investigate the inclination of the orbit to the ecliptic, and at the same time the place of the node, from latitudes of the planet, even though not the greatest, and from the distances of the planet and the Earth, in the Copernican and Philolaic form.

XII. In the first of the following diagrams let A be the Sun and C the centre of the annual orb LP. Let B be the centre of the orb of a superior planet, its orb being DFKH; the eccentricity from the Sun is BA, and the Earth's eccentricity AC. Let the orb of the ecliptic, lying in the plane of the annual orb, be DIKE, and the nodes D and K. And let the planet have been observed from the Earth at L now at O, now at F, or in any number of other positions, say at G from the Earth at P, etc.

Diagram. The first of the two diagrams for Problem 9, set into the right part of the left column with the text running down beside it. A large circle and a second circle almost coincident with it are cut by a vertical line from D at the top to K at the foot. A smaller circle stands about the region of A and C. Many straight lines run from O, R, I and F at the upper right to L and A, and from G and S at the right to A and P. Three planetary signs, those of Saturn, Jupiter and Mars, stand at the top, just right of the vertical line.

- D (top): a node
- O (upper right, outside the circle): a place of the planet
- R (below O): foot of the perpendicular from O
- I (below R): foot of the perpendicular from F
- F (right): a place of the planet
- L (left of centre, on the small circle): the Earth
- E (far left): on the orb of the ecliptic
- B (centre, upper): centre of the planet's orb
- C (centre, left): centre of the annual orb
- A (centre): the Sun
- H (lower left): on the planet's orb
- S (right, lower): foot of the perpendicular from G
- G (right, lower, outside S): a place of the planet
- P (below A, on the small circle): the Earth
- K (foot): a node
- ♄ ♃ ♂ (top, right of the vertical line): Saturn, Jupiter, Mars

From those places of the eccentric let perpendiculars OR, FI, GS, etc. be drawn to the plane of the ecliptic. Let these points of the plane of the ecliptic, as well as the places of the planet, be connected by straight lines both with the Sun at A and with the Earth at L or P. Let the angles of latitude seen from the Earth be given, such as the angles OLR, ILF, SPG, etc.; and let the planet's

distances also be given, from the Earth, namely OL, FL, GP, and from the Sun, namely OA, FA, GA, etc., together with the places of longitude seen from the Sun and from the Earth. For first, in the right-angled triangles already mentioned, from the given angle of latitude at L or P and the planet's distances OL or PG, the straight lines OR, IF, SG, etc. are given. These are reduced to proportion with the distances from the Sun, so that it may be known how large those perpendiculars are as seen from the Sun at A. But Boulliau inquires into them in a circle concentric with the Sun, so that the diminution of those same lines OR, IF, SG may be established at equal distances from it, and they may be taken as right sines. Next he inquires into the greatest of those that can be set as ordinates at right angles between the planes of the planet's orb and of the ecliptic. To do this he transfers the places of the planet seen from the Sun into the circle IDT, whose diameters LD and IT cut each other at right angles; and on its circumference he considers the arcs intercepted between the places of the planet seen from the Sun, say the arc BC and AB, from the first to the second and from the second to the third observation. From these he drops the perpendiculars AG, BF, CE.

Diagram. The second of the two diagrams for Problem 9, set into the right part of the left column with the text running down beside it. A circle is cut by a vertical diameter from I to T and a horizontal diameter from L to D, crossing at H. Horizontal lines run from the vertical diameter to A, B and C on the circumference at the upper right, and vertical lines fall from A, B and C to the horizontal diameter at G, F and E. Short lines join A, B and C.

- I (top): end of the diameter IT
- Q (below I, on the diameter): level of A; not cited in the text of this page
- S (below that, on the diameter): level of B; not cited in the text of this page
- V (below S, on the diameter): level of C; VC is equal to HE
- A (upper right, on the circumference): a place of the planet
- B (below A, on the circumference): a place of the planet
- R (inside, below B): in the triangle RCB
- C (below B, on the circumference): a place of the planet
- L (left): end of the diameter LD
- H (centre): the centre of the circle
- G, F, E (on the horizontal diameter, right of H): feet of the perpendiculars from A, B and C
- D (right): end of the diameter LD
- P (lower right, on the circumference): end of the arc BCP
- T (foot): end of the diameter IT

When this is done, the ordinates corresponding to the perpendiculars gathered from the observation of the latitudes and seen from the Sun are HE, HF, HG. From the given arcs, namely CB, BA, AC, he inquires into their sines, and from them the angles ACB and BAC, and also the differences of the ordinates GE, GF, FE; and, setting up a proportion, he makes as GE to AC, so FE to

RC. So then, in the triangle RCB, with the sides BC and RC known together with the angle BCR, he investigates the angle CBR and the arc CP; CB added to this makes the arc BCP, and half of it is BD. So if the planet's place in the observation at B is known, going back from there against the order of the signs will give the place D, through which the line of nodes HD passes.

Second, to obtain the greatest of the ordinates between the planes of the ecliptic and of the planet's orbit, which reveals the angle of inclination: from the arc CD given above, and from it CI, and from HE known above, to which VC is equal, he makes, as the sine VC of the arc CI to the radius HD, so HE, or VC, to HD, in parts of which HE was known, in the circle concentric with the Sun. But with the planet's distance from the Sun taken as the radius, if one makes, as the radius of the circle concentric with the Sun, 100000, to the planet's distance, so HD to another quantity, the greatest of the ordinates will be found; it is, namely, the sine of the angle measuring the greatest inclination.

You see, reader, that this technique is like the one by which this author usually investigates the eccentricity and the place of the aphelion, which we have indicated elsewhere. But I did not choose to illustrate it with examples, both because excessive length would too much disturb the series of problems of this chapter, and because it is better to use an observation of the greatest latitude and through it to inquire into the inclination, just as also to deduce the place of the node from an observation of the least latitudes. If anyone, however, wants examples of this treatment [pragmatia], he should consult Boulliau himself, Book 6, chapter 3; Book 7, chapter 4; Book 8, chapter 10; Book 9, chapter 3; and Book 10, chapter 7.

Problema 10. Nodi locum methodo Tychonica inquirere.

Problem 10. To inquire into the place of the node by the Tychonic method.

XIII. Kepler, attributing this method to Tycho, proposes it in the *Commentaries on Mars*, chapter 12, in roughly this way. Let A be the place of the node under the sphere of the fixed stars, and G the Sun, at which, in the Copernican as much as in the Tychonic manner, the orbs of the planets cut the ecliptic. And let E be the ecliptic place of the planet, that is, the point of the ecliptic to which, from the place C of the planet I, seen under the fixed stars from the Earth at H, the perpendicular arc CE is drawn to the ecliptic AB. This is the arc of latitude, but at the same time it determines the planet's longitude, considered not in its orbit but in the ecliptic. Let the Earth be at H when the planet I is in opposition to the Sun, and from the Earth there let one greatest latitude be observed, that is, the arc CE, seen under the angle EHC. For in that case AC will be a quadrant of a great circle, and the latitude, since it is the greatest, will measure the angle CAE. Now let another latitude EC have been observed, but not the greatest, from which nevertheless the place of the node is to be gathered; and at the same moment let the longitude of the planet I, seen from H under the point C of the fixed stars, have been observed. For when the arc CE

is drawn, as before, perpendicular to the ecliptic AB, there arises the spherical triangle CAE, right-angled at E, in which are given the arc of the observed latitude CE and the angle of greatest latitude CAE. So the arc AE, which is the distance of the planet's ecliptic place from the nearer node, will not stay hidden.

Diagram. Set into the right part of the right column with the text running down beside it. Long straight lines fall from A at the upper left, and from C at the right, down to G at the foot, where the Sun's rayed sign stands. An arc runs from A across to C, and an arc from A curves down through E and B; two further arcs cross the lines lower down, one through B and I, the other through H. Short straight lines join E, F, D and C.

- A (upper left): the place of the node
- C (right, end of the arc from A): the planet's place under the fixed stars
- F (on the arc, below C and left): on the inner arc AF
- E (left, below F): the planet's ecliptic place
- D (right of E): not cited in the text of this page
- B (left, below E): end of the ecliptic AB
- I (right of B, at the crossing of lines, marked with a small star): the planet
- H (below B, with a small dark disc): the Earth
- G (foot, with the rayed disc): the Sun

Therefore, since the point E of the ecliptic is known, the place of the node A will also be known; and the practice will be the better, the smaller the arc EC is, and so the nearer the place E is to the node A. So, as Kepler relates, Tycho, from the greatest north latitude CAE of acronychal Mars, 4° 34½′, observed first in the year 1585, and then from the arc EC, of a latitude of 5′ 15″, observed in the year 1595, investigated the distance from the node A of the place E, which was ♉ 17° 56′ 5″. Kepler points out, however, that CAE, strictly speaking, is not as large as the greatest latitude is, because AC is a bent arc; nor is AC the path of the planet as it would be seen from the centre of the Sun, but some inner arc, say AF; and therefore that A is not the very place of the node in this treatment either.

Problema 11. Inclinationem Planorum Eclipticæ & Orbitæ Planetæ inueſtigare tribus modis à Keplero excogitatis.

Problem 11. To investigate the inclination of the planes of the ecliptic and of the planet's orbit in three ways devised by Kepler.

Primus Modus.

First way.

XIV. These ways, not indeed all of them exact, Kepler, in the *Commentaries on Mars*, chapter 13, admits; yet it is useful that posterity should not be cheated of knowing them. The places of the limits and of the nodes must be known beforehand. One must suppose, for example, that in the year 1600 the northern limit of Mars is at ♌ 17° and the southern at ♒ 17°, and one must obtain an

observation of the planet in which it is equally distant from the Sun and from the Earth, and in which a line drawn from the Sun falls on the places of the limits; or, as in the Ptolemaic form, the centre of the epicycle is at the nodes, and the planet and the centre of the epicycle are equally distant from the Earth.

Diagram. Set into the right part of the left column with the text running down beside it. A tall isosceles triangle stands on a horizontal base from B at the left, where the Sun's rayed sign stands, to A at the right, where a small dark disc stands. Its two sides meet at the apex C, and a vertical line falls from C to D on the base. A short line runs up and to the left from C to a star-shaped sign, with E just below it.

- E (top, left of C, under the star-shaped sign): the planet, placed on its orbit
- C (apex): the planet's place in a point of the plane of the ecliptic
- B (lower left, with the rayed disc): the Sun
- D (foot of the vertical line, on the base): the right angle of triangle CDA
- A (lower right, with the dark disc): the Earth

These things supposed, let the Sun be B and the Earth A, and let the straight line BA be drawn, on which there stands the isosceles triangle BCA. Let C be the place of the planet in a point of the plane of the ecliptic, from which the perpendicular CE has been drawn to the orbit of the planet, placed at E. For in this way EC will appear equal whether it is viewed from B or from A. But if it is viewed from the Sun, which is the centre in which, according to Copernicus and Tycho, the orbits of the ecliptic and of the planet are inclined, and through which the line of nodes passes, then EC is the measure of the inclination; whereas if it is viewed from the Earth at A, it is the measure of the latitude. So if the planet is in such a situation that this isosceles triangle is formed, the observed latitude will equal the inclination sought.

For the triangle to be isosceles, however, the place of the Sun seen from the Earth and the eccentric place of the planet must be less than 90° apart; otherwise, if the angle BAC is right or obtuse, ACB will not be equal-legged. To know how great the angle CAB, or the angle of the planet's elongation from the Sun, ought to be, one must know beforehand the distance AB, that is, the semidiameter of the annual orb, and CA, the distance of the planet from the Earth when it is at the place of the limits, and this in parts of which AB is known. For in the triangle CDA, right-angled at D, from AC and half of AB, that is AD, one gathers the angle CAD, the planet's elongation from the Sun, and hence the time at which to observe the latitude of the planet standing at the limits, and in such a way that the apparent latitude equals the inclination. But how difficult it is to have observations endowed with these conditions Kepler shows, with many examples, in the same place.

Secundus Modus.

Second way.

XV. The second way requires an observation that is indeed select and rare, but if one is to be had, it shows the inclination at once, without any labour of calculation. The observation of the latitude must be such that the line drawn through the Sun and the Earth falls on the planet's nodes, already known beforehand, and that at that moment there occurs a perfect quadrature of the planet with the Sun; for then the observed latitude itself will be as great as the greatest inclination of the planet's orbit to the ecliptic. To make this understood, let the Sun be at A and the Earth at B.

Diagram. Set across the left column. A horizontal straight line runs from I at the left to O at the right, passing through A, where the Sun's rayed sign stands, and B, where a small dark disc stands. Above it stand two arcs from I to O, the outer rising to C and D, the inner lying a little below. From A two straight lines rise, one to E and one, vertical, to C, and a short line joins E to C; from B a single vertical line rises to D, with F lying on it. Two sloping lines run up and to the left, from A to H and from B to G. Star-shaped signs stand at E, F, G and H, all four on the inner arc.

- I (far left, on the horizontal line): a node
- H (left, on the inner arc): the point in the plane of the planet's orbit
- G (right of H, on the inner arc): the planet
- C (top of the outer arc): the place of the limit
- E (below C): the planet, at the greatest latitude
- D (right of C, on the outer arc): top of the line from B
- F (below D): the planet in quadrature
- A (on the horizontal line, with the rayed disc): the Sun
- B (right of A, with the dark disc): the Earth
- O (far right, on the horizontal line): a node

Let IEO be the semicircle of the planet's orbit, and ICO that of the plane of the ecliptic. Let the line of nodes IO pass through A and B, and let the place of the limit be at C, so that, with the planet set at E, the angle EAC subtends both the greatest latitude and the inclination. At that moment it is distant from the nodes by the quadrants EAO and EAI, and so AE is perpendicular to IO. Now let another perpendicular BF be erected from the Earth at B. When the planet is at F, it will be in quadrate aspect with the Sun, since from B the Sun and the planet are seen a quadrant apart, that is, at the right angle ABF. In such a case, therefore, with the line AB passing through the nodes, the angle FBD of the observed latitude will be as great as EAC, that is, as great as the greatest inclination. The reason is one that is almost self-evident, and which Kepler therefore does not prove there but assumes:

[Margin: Theorem or axiom of Kepler.] *when two planes cut each other, whichever two lines are drawn in each plane to the same point of the line of section, at right angles to that line, they always enclose one and the same angle.* The occasion for such an observation had arisen on 1584 October 30, but the Tychonians made no observation then, only on the 12th of the following November. On 1585 April 26, however, at $9^{h}\ 42^{m}$, Mars was observed at 21° 26′ of Leo, with a

north latitude of 1° 49′ 15″, the Sun being at 16° of Taurus, that is, very near the north node of Mars. So Mars was a little more than 90° from the place of the Sun and had passed quadrature by a little; therefore the latitude was a little less than the inclination, and this confirms an inclination in Mars of about 1° 50′.

[Margin: Extension of the demonstration to every latitude.] Kepler extends this demonstration to other cases, in which the planet's latitude has been observed even though it is outside quadrature. For the latitude seen from the Earth is as great as the inclination of the point of the orbit that is as far from the node, seen from the Sun, as the planet appears to be from the same node, seen from the Earth. For example, if the planet is at G, seen along BG, and the line AH is drawn parallel to this, then H and G will be seen at the same place among the fixed stars, because of the parallelism of the said straight lines and the immense distance. And so the point H, in the plane of the planet's orbit, will appear as far from the node I, seen from the Sun at A, where the angles of inclination stand, as the planet G appears from the same node I, seen from the Earth at B. Therefore the latitude seen from B and the inclination seen from A will appear equal. [Margin: The same demonstration in the Ptolemaic hypothesis.] Kepler shows in the same place that the first part holds in the Ptolemaic hypothesis, provided that the plane of the epicycle, for the equipollence of the hypotheses, is set always parallel to the plane of the ecliptic.

Tertius Modus.

Third way.

XVI. Kepler uses this way in the *Commentaries on Mars*, chapters 13 and 62. According to it, let the Sun be at A, the Earth at B, and C the place of the planet in its eccentric orbit. For the straight line ABE, passing through the Earth, will fall on the ecliptic, and the straight line from the Sun to C, that is AC, will fall on the planet's orbit, since in this Keplerian hypothesis the planes of the orbs of the five minor planets are taken to cut the ecliptic at the centre of the Sun; hence the inclination of the orbit will be the angle EAC.

Diagram. Set into the right part of the right column with the text running down beside it. A very tall, narrow figure. Straight lines rise from A at the foot to E and to C at the top, E to the left of C; B stands on the line AE, about a third of the way down from the top, and a straight line joins B and C. A further straight line rises from A to the right of AC, passes D, and stops well short of the top; and a straight line falls from C to D.

- E (top left): on the ecliptic, on the line ABE
- C (top right): the planet in the eccentric orbit, or the centre of the epicycle in the Ptolemaic form
- B (left, on the line AE): the Earth in the Keplerian hypothesis
- D (right, on the short line from A): the planet at the perigee of the epicycle
- A (foot): the Sun, or the Earth in the Ptolemaic form

So let the greatest latitude of the planet be observed from the Earth, that is, the angle EBC, so that EAC is the greatest inclination, and let the distance of the planet from the Sun, that is AC, be given in parts of which AB, the distance namely of the Earth from the Sun, is 100000. Then let it be as AC to the angle EBC, so BA to the angle BCA. This, taken from the external angle EBC, by 32 of the first book of the *Elements*, will give the angle of inclination EAC.

In the reformed Ptolemaic form, however, A will be the Earth and C the centre of the planet's epicycle, whose plane CD must be parallel to the ecliptic AE itself. Let the planet be acronychal at the perigee of the epicycle, D, that is, next to the limit. The inclination of the epicycle to the orbit, that is ACD, will be equal to the inclination EAC of the orbit to the ecliptic. And the semidiameter of the epicycle CD is as great as the semidiameter of the annual orb in the other hypothesis, if the equipollence of the hypotheses is to be perfect. Hence the latitude BAD, apparent to the Earth at A, is as great as EBC, apparent to the Earth at B, and the angle of inclination of the epicycle is as great as the inclination of the orbit sought above. But if you cannot observe the greatest latitude, at least observe the one nearest the greatest, around the planet's oppositions to the Sun, so that from its distance from the limit you may scent out the greatest inclination.

Problema 12. Data Inclinatione maxima, & diſtantia Planetæ aut puncti in Eccentrico à propiore Nodo, inuenire Inclinationem tali puncto conuenientem.

Problem 12. Given the greatest inclination and the distance of the planet, or of a point on the eccentric, from the nearer node, to find the inclination belonging to such a point.

XVII. Kepler points out this problem in the *Commentaries on Mars*, chapter 63, and in the *Epitome of Copernican Astronomy*, page 699, from which: let it be as the whole sine to the sine of the greatest inclination, so the sine of the distance of the point on the eccentric from the nearer node to the sine of the inclination sought. So the inclination is sought in the same way as the declination of points of the ecliptic from the equator.

Problema 13. Data Inclinatione, & reliquis mox ponendis; Latitudinem Planetæ ad quoduis tempus determinare.

Problem 13. Given the inclination, and the other things to be set out shortly, to determine the planet's latitude for any time.

XVIII. [Margin: Copernican form, from Lansbergen.] First, in the Copernican form, we gave the solution of this problem, with Lansbergen, in chapter 3, from number 2 to 6. The sum of the rule is this: subtract the motion of the north node from the centric longitude, or centric place, of the planet, to get the planet's distance from the north node, to be counted in the order of the signs; find the sine of this distance or of its complement, and likewise the sine of the

inclination; and let it be as the whole sine to the sine of the inclination, so the sine of the distance from the node, or of its complement, to the sine of the centric latitude. Next, as I taught when discussing the calculation of longitude, the planet's distance from the Earth must be known beforehand; and then let it be as the planet's distance from the Earth to the sine of the centric latitude, so the whole sine to the sine of the latitude sought. For Mercury and Venus, however, see number 6 in the same place.

[Margin: Form of Copernicus or Tycho, from Longomontanus.] Second, likewise in the form of Copernicus or of Tycho, we gave the way of this problem from Longomontanus in chapter 4, numbers 3, 4 and 10; you should reread these if you wish to use that form.

[Margin: In the Copernican form, from Kepler.] Third, from Kepler, in the *Epitome of Copernican Astronomy*, Book 6, at the end of part 2, or page 756, together with what he had taught in the same work from page 688 to 750, the following rule is gathered. First, subtract the planet's true place in longitude from the true place of the Sun, and the elongation from the Sun will be left. The angle of this arc, if the arc is less than a semicircle, is called the angle at the Earth; for if it is greater than a semicircle, the true place of the Sun must be subtracted from the true place of the planet, so that an arc less than a semicircle is left, fit to subtend the angle at the Earth. Further, subtract the true place of the Sun from the centric place of the planet, or the latter from the former, so that the remainder is always less than a semicircle, and you will have the anomaly of commutation, whose angle is called the angle at the Sun. With this prepared, let it be as the sine of the angle of elongation to the sine of the angle of commutation, so the tangent of the complement of the inclination (which is here supposed known) to the tangent of the complement of the latitude desired. So if the sine of the angle of commutation, first increased by five ciphers, is divided by the sine of the elongation, and the quotient is multiplied by the tangent of the complement of the inclination, then, with 5 ciphers thrown away from the total, the tangent of the complement of the latitude will come out. Or, by the shortest method of all, as Kepler says in the same place, subtract the logarithm of the elongation from the logarithm of the commutation, and to the remainder add the mesologarithm of the complement of the inclination; for the total will be the mesologarithm of the complement of the latitude.

[Margin: In the same form, from Magini.] Fourth, from the same Kepler, in the *Commentaries on Mars*, chapters 62 and 66, and from there from Magini in the *Supplement to the Ephemerides*, Canon 11. First, subtract the true place of the Sun from the true place of the planet in the zodiac, and there will remain the angle at the Earth, or the angle of the planet's elongation from the Sun. If this exceeds 90°, you must take its complement to the semicircle; if it has exceeded the semicircle but not 270°, you must take that excess; but if it exceeds 270°, you must take the complement to the circle. For in this way you must use the angle at the Earth in order to have its sine. And when the place of the Sun, true, is subtracted from the eccentric place of the planet, as above, the angle

of commutation will remain. Second, subtract the place of the north node from the eccentric place of the planet, and there will remain the argument of latitude: north, if the argument does not exceed 6^s, but south if it exceeds 6^s. With this argument seek in the Rudolphine Tables the inclination of the orbit to the ecliptic. Third, multiply the sine of the commutation by the sine of the inclination, and divide the total by the sine of the elongation. For the quotient will be the sine of the latitude sought. For Kepler has shown, in the *Commentaries on Mars*, chapter 62, that as the sine of the planet's elongation from the Sun is to the sine of the angle at the Sun, or of commutation, so the sine of the inclination is to the sine of the latitude. Granted, Magini uses this other analogy, namely: as the sine of commutation to the sine of the elongation, or of the angle at the Earth, so the sine of the inclination to the sine of the latitude. On this basis he teaches, for the sake of brevity, that the sine of the elongation is to be multiplied by the sine of the inclination, and the total multiplied by the second secant of the commutation; for the total, he says, is the sine of the latitude sought.

Problema 14. Latitudines trium Superiorum & Inclinationes non maximas Copernicæa methodo inquirere.

Problem 14. To inquire by the Copernican method into the latitudes of the three superior planets, and inclinations that are not the greatest.

XIX. Here one must remember that libration by which, according to what was said in chapter 2, number 2, the inclination of the orbs of Saturn, Jupiter and Mars to the ecliptic varies, by a variation analogous to the simple motion of the anomaly of the orb. With this laid down, let there be understood a great circle of inclination, cutting the plane of the ecliptic at right angles with its own plane, and let the common section be the line AD, etc., passing through the limits of the greatest latitudes, of which let A be the northern limit. Let the straight line CD be the common section by which the planet's orbit cuts the already mentioned circle of inclination, and let it pass through D, the centre of the great orb EF; this orb, however, is to be conceived here as having a common section with DC at D alone. Let the Earth, in the acronychal position, that is, at the planet's mean opposition to the Sun, be at E, and the planet at C; and outside the acronychal position let it be at F; and let the arc FE be known, by which it is distant from the acronychal position.

Diagram. Set into the right part of the right column with the text running down beside it. A circle stands at the foot of the figure, with three planetary signs, those of Saturn, Jupiter and Mars, inside it at the bottom. A horizontal line joins A and C at the top. A vertical line falls from A through E and G to D, the centre of the circle, and on to the bottom of the circle. A straight line runs from C down to D; a line runs from A to F and a line from C to F; a short horizontal line runs from F to G.

- A (top left): the northern limit, on the common section AD

- C (top right): the planet
- E (on the vertical line, at the top of the circle): the Earth in the acronychal position
- F (left, on the circle): the Earth outside the acronychal position
- G (on the vertical line, right of F): foot of the perpendicular from F
- D (on the vertical line, inside the circle): the centre of the great orb

[Margin: From Copernicus, Book 6, chapter 4.] Now from F draw the perpendicular FG to AD, and from C the perpendicular CA; and let A and C be joined to F by the straight lines AF and CF. First, the angle of inclination ADC is sought, which is greatest when the Earth is at E. But since, with the Earth set at F, the inclination decreases, and its libration is commensurate with the mean anomaly, which is known from the given arc EF and its versed sine EG, then if it is made as the whole sine to half the libration, so EG to the difference to be subtracted from the greatest inclination, or to GD, to be added to the mean, the inclination will be known, and its difference from the greatest inclination; and so the angle ADC, in the triangle ACD right-angled at A, will be known for the present. Now let the planet's distance CD from the centre of the great orb be given by the calculation of longitude, and in parts of which the radius DE of the great orb is known or assumed. For from this, by the rules of triangles, AC and AD will be given, and from this the ratio of CD to GD, the second sine of the arc EF. So, when GD is taken away, AG will be known, and at the same time the sine FG, because of the ratio it has with ED and GD. Therefore in the triangle AFG, right-angled at G, the base AF will not stay hidden. Finally, in the triangle CAF, right-angled at A, you will inquire into the angle AFC, which measures the latitude of the planet C, apparent to the Earth placed at F.

Problema 15. Veneris ac Mercurij Latitudines ex Inclinatione ortas inueſtigare ex Copernico, qua occaſione attingitur Reductio.

Problem 15. To investigate, from Copernicus, the latitudes of Venus and Mercury arising from the inclination, on which occasion the reduction is touched on.

XX. [Margin: Latitude of ♀ and ☿ arising from the inclination.] Although Ptolemy teaches this problem in Book 13, chapter 4, and Regiomontanus at the same place in the *Epitome*, proposition 8, it has nevertheless pleased me to take it rather from Copernicus. Copernicus, in Book 6, chapter 5, supposes that the latitude of Venus and Mercury is so entangled in three kinds of wandering from the ecliptic that the latitude of inclination alone is at times separated from the others; and that this greatest latitude was observed by Ptolemy, whether to the south or to the north: in Venus at apogee 1° 2′, at perigee 6° 22′; in Mercury at apogee 1° 45′, at perigee 4° 5′. From this, he says, one gathers the greatest inclination of Venus to be 2° 30′, and of Mercury 6° 15′. [Margin: Explanation of the scheme.] From these he teaches how to demonstrate other, non-greatest latitudes of this kind by the following diagram, in which let there

be understood the plane of the circle of inclinations at right angles to the plane of the ecliptic, and cutting the ecliptic in a common line of section ABC. Let DBE be the common section of the orb of Venus or of Mercury, whose centre is B, and from which the orb CHF has been described; and let the centre of the Earth be A. Let ABE, or CBD, be the angle of inclination of the planetary orbit to the ecliptic. To the diameter of the apsides DBE let the diameter OBF stand at right angles, which he calls the diameter of mean longitudes. In the plane of the ecliptic, of the lines of the plane of the planetary orb, let there be only the diameter OBF. The other straight lines, drawn at right angles to DE, are to be parallel to the plane of the ecliptic, and are to meet at right angles the plane that is at right angles to the ecliptic, that is, the plane of the circle of inclination, to be conceived here in the imagination. For now we are considering only the inclination of the diameter DBE, without any transverse reflexion of the diameter OBF.

Diagram. Set into the right part of the left column at its head, with the text running down beside it. A circle stands at the top. Its diameters cross at B. Inside the circle, below and to the left of B, a small figure of straight lines joins H at the left edge to M, L and K. Long straight lines run down to A at the foot: one from H, at the left edge of the circle, one from C through B, and at least one more, converging on A from the region of E and K. Between them stand two planetary signs, that of Mercury higher and that of Venus lower.

- C (top of the circle): on the line ABC
- D (right of C, on the circle): apogee of the orb
- O (left, on the circle): an end of the diameter of mean longitudes
- H (far left, on the circle): the planet
- B (centre of the circle): centre of the orb
- M (left of B, below it): foot of the perpendicular from H to the plane of the ecliptic
- L (below B, to the right of M): foot of the perpendicular from K to the plane of the ecliptic
- F (right, on the circle): the other end of the diameter of mean longitudes
- K (below M and L): foot of the perpendicular from H to DE
- E (bottom left, on the circle): perigee of the orb
- A (foot): the centre of the Earth

Now let AB be given, the distance of the centre of the epicycle, or rather of the orb, from the Earth; and BC, the semidiameter of the planet's orb, according to what was said in Section 3 when discussing the geometrical calculation of longitude. Let there also be given the angle ABE of the whole inclination, and the planet's distance from the apogee D or the perigee E of the orb, namely the arc HE, if the planet is at H; and let the task be to investigate its latitude in this situation.

[Margin: Step 1.] First, then, let the perpendicular HK be drawn from H to DE, and from these ends let the perpendiculars HM and KL be drawn to the plane of the ecliptic, to which the planet's orbit is inclined; and let them be

joined by the straight line ML. For there will arise the rectangular parallelogram HMLK, and the angle that measures the latitude will be HAM, while the angle LAM will be the measure of the prosthaphaeresis of the orb in longitude. Now since from the arc HE the angle HBE is given (for DBE is to be conceived in the plane of the circle of inclination, represented by CBA, and K and L in the same plane; just as there is to be conceived in the plane of the ecliptic not only CBA but also AM, though not E; and F and O, though not HA), HK will be known as the right sine, and from that BK as the second sine, in parts of which the semidiameter of the orb, EB, is the whole sine. And in the triangle BKL the angle KBL is given, because it is the greatest inclination of the orb, and BLK is right by construction; so the sides KL and BL will not stay hidden.

[Margin: Step 2.] Second, since AB is given in parts of which BE, the semidiameter of the orb, is known, HK will therefore become known in the same parts, and ML, which is equal to it, and KL, to which HM is equal; and when BL is subtracted from AB, AL will be known.

[Margin: Step 3.] Third, in the triangle AML, right-angled at L, since the sides ML and AL are known, the base AM will become known by trigonometry, and the angle MAL, which is the prosthaphaeresis of the orb in longitude.

[Margin: Step 4.] Fourth, in the triangle HAM, right-angled at M, with the sides AM and HM now found, one will find the angle HAM, which is the measure of the latitude sought, and, if one pleases, the planet's distance HA from the Earth.

[Margin: Step 5, for the reduction to the orbit.] Fifth, if it is wished on this occasion to distinguish the difference of the longitude in the orbit from the longitude in the ecliptic, arising from the inclination, let the diameter HL of the parallelogram HMLK be conceived, and let its quantity be investigated from the sides HM and HK, now known. Then in the triangle HAL, in which besides HL there are now known AL and AH from what was said above, let the angle HAL be sought; for this will be the measure of the prosthaphaeresis of the orb in longitude, viewed in the orbit. So this, compared with the prosthaphaeresis MAL found above, will give the difference sought. This difference is usually greatest in the middle of the quadrants OE and FE, that is, at a distance of 45° from the perigee of the orb. And so Copernicus chose his examples of this problem in Venus and Mercury set at H, with HE supposed to be 45°. From his measures of the orbs he found the latitude arising from the inclination alone in this situation to be 1° 47′ for Venus, with a difference of the prosthaphaereses of the orb of 2′; and 2° 16′ for Mercury, with a difference of the prosthaphaereses of the orb of 7′.

So far on the latitudes arising from the inclination alone, when it is without any deviation or reflexion, which happens when the centre of the epicycle (speaking in the Ptolemaic manner) is set at the mean longitude of the eccentric.

Problema 16. In quo loco Epicycli ſeu Orbis contingant maximæ Latitudines Veneris & Mercurij ortæ ex Reflexione, vnde maxima Reductio.

Problem 16. In what place of the epicycle or orb the greatest latitudes of Venus and Mercury arising from reflexion occur, from which comes the greatest reduction.

XXI. This problem too is an old one, found in Ptolemy, Book 13, chapter 4, and in Regiomontanus in his *Epitome*, Book 13, proposition 11, where he teaches that the greatest latitude of reflexion occurs when the planet is at the contact of the epicycle, that is, at the point where the epicycle is touched by a straight line drawn from the centre of the Earth; and in propositions 13, 14, 15 and 16, in which he shows that the greatest difference between the longitude of these planets in their orbit and their longitude viewed in the ecliptic, a difference arising from the latitude of reflexion, comes about near the contact: in Mercury, at that contact itself; in Venus, near the contact indeed, but mostly outside the contact itself. [Margin: Note on the reduction.] But I have preferred to set out this problem from Copernicus, Book 6, chapter 6, with whom we suppose that the greatest latitude arising from reflexion comes about when the centre of the Ptolemaic epicycle is at the apogee or perigee of the eccentric. And indeed Ptolemy, Book 13, chapter 4, says that the greatest latitude of this kind was observed by him at the contacts, that is, where the greatest digressions of Venus and Mercury from the Sun also occur; and he says that at that time the northern latitudes of Venus were found greater than the southern by 20′, and the southern latitudes of Mercury greater than the northern by 1° 30′.

[Margin: Exposition of the scheme.] So first it must be shown that these greatest latitudes occur at the contact of the orb. For this purpose, in the figure added here, let ARC be the line of the common section of the plane of the ecliptic and of the plane of the orb of Venus or Mercury, the orb, I mean, CEB, described from the centre P. Let this line pass through the apogee of the orb, C, and its perigee, G; and let the centre of the orb be at the perigee or apogee with respect to the Earth placed at A. Let the plane of the orb CDB be oblique, or bent crosswise, to the plane of the ecliptic, so that any straight lines drawn perpendicular to the diameter CG, such as DH, ER, FL, enclose angles equal to the whole obliquation, or reflexion; such are the angles DHM, ERN and FLO.

Diagram. Set into the right part of the right column with the text running down beside it. A circle stands at the top, with a vertical diameter from C to G. Inside it a framework of straight lines joins D, M, H, N, E, R, F, O and L. Below the circle, straight lines converge from the lower part of the circle down to A at the foot, with a line of dots running from B to A.

- C (top of the circle): apogee of the orb
- M (below C and left of the diameter): foot of the perpendicular from D
- H (right of M, on the diameter): where DH meets CG
- D (upper left, on the circle): a point of the orb
- N (below D and M): foot of the perpendicular from E

- E (left, on the circle): the contact
- P (right of N, on the diameter): centre of the orb
- K (right, inside the circle): not cited in the text of this page
- R (below P, on the diameter): where ER meets CG
- O (left of R): foot of the perpendicular from F
- F (lower left, on the circle): a point of the orb
- L (below R, on the diameter): where FL meets CG
- B (right, on the circle): on the orb CEB
- G (bottom of the circle): perigee of the orb
- A (foot): the Earth

Let there be understood, drawn from A, the line AE (which the engraver has, however, left out here), touching the orb at E, from which the perpendicular ER was drawn; and AD and AF, cutting the orb. From the points D, E, F let the perpendicular straight lines DM, EN, FO be drawn to the plane of the ecliptic beneath, and let them be joined to the points of the diameter CG by the straight lines MH, NR and OL; and from the angles M, N, O let the straight lines MA, NA, OA be let down to the centre of the Earth, A. For the angles HAM, RAN and LAO will be the measure of the prosthaphaeresis of the orb as to longitude; but the angles of latitude arising from reflexion will be DAM, EAN, FAO.

With this laid down, I say that the angle of latitude EAN, at the contact, is the greatest of all. For the angle EAR is the greatest of all, since it is made by the outermost line, or tangent, AE, and since the side ALRH lies in the common line. And so ER has a greater ratio to EA than HD has to DA, and than LF has to FA. But as ER is to EN, so HD is to DM, and LF to FO; for the angles of reflexion that they subtend are equal, and the angles M, N, O, because of the perpendiculars drawn, FO, EN, DM, are right. So NE has a greater ratio to EA than MD has to DA, and than OF has to FA. Moreover the angles DMA, ENA and FOA are right, since A is in the plane of the ecliptic, to which the perpendiculars were drawn. Therefore the angle EAN, belonging to the contact, is greater than the angle DAM, and than FAO, and than all others whatever constituted in this way.

Problema 17. Inuenire angulum Reflexionis maximæ, & inde maximas Latitudines ad Apogeum & Perigeum Eccentrici ortas ex Reflexione; vnde Reductio ab Ecliptica ad Orbitam colligetur.

Problem 17. To find the angle of greatest reflexion, and from it the greatest latitudes at the apogee and perigee of the eccentric arising from reflexion; from which the reduction from the ecliptic to the orbit will be gathered.

XXII. In the figure immediately preceding, let KAB be the observed angle of greatest latitude, with the planet placed at the contact B, to which let the semidiameter of the orb, PB, be drawn. Let the perpendiculars BL to CG and

BK to the plane of the ecliptic be drawn, and let K and B be joined by the straight line KB; and let the angle of reflexion KLB be the one to be found.

[Margin: Step 1.] First, since the distance of the centre P from the Earth, that is AP, is supposed given in parts of which PB, the semidiameter of the orb, is known, and the angle ABP at the contact is right, the side AB cannot be unknown.

[Margin: Step 2.] Second, since as the base AP is to AB, so the base PB of the triangle PBL is to the side LB, by 8 of the sixth book of the *Elements*, BL will therefore be known. And since the observed or assumed latitude KAB is given, together with AB as found, therefore in the triangle ABK, right-angled at B [recte: K], the side KB can be found.

[Margin: Step 3.] Third, therefore, in the triangle KLB, right-angled at K because of the perpendicular BK drawn to the plane of the ecliptic, since LB and KB are now known, the angle of reflexion KLB becomes known.

See the rest in Copernicus, if you like, Book 6, chapter 7. From this it will not be hard to find the prosthaphaereses of the orb, that is, the angles LAB and KAL, so that their difference may be known and from it the reduction from the ecliptic to the orbit, if the sides AK and AL are found first.

Moreover, Copernicus, Book 6, chapter 7, taking from Ptolemy the latitudes on either side, mean ones, or at the mean longitude of the eccentric, which arise from reflexion, of 2° 30′, gathers the obliquation KLB in Venus to be 3° 29′, and the difference of the equation of the orb only 3′; in Mercury, the obliquation about 7°, and the difference of the equations of the orb about 8′. But with the centre of the epicycle or orb placed at apogee, he gathers the greatest latitude arising from reflexion: of Venus 2° 27′, of Mercury 2° 17′. With it placed at perigee, however, the latitude of Venus is 2° 34′, of Mercury 2° 45′.

[Margin: Part 2 of the Problem.] For once the greatest obliquation has been found, and the distance AP of the centre P, both at apogee and at perigee, he seeks the already mentioned latitudes in this way.

[Margin: Step 1.] First, with the distance AP, at apogee or perigee, given, and the semidiameter PB in parts of the same kind, the side AB is given in the triangle APB, right-angled at the contact B. Hence it comes about that as AP is to AB, so PB is to LB, by 8 of the sixth book of the *Elements*. Therefore in the triangle LKB, right-angled at K, with the side LB now found and the angle of reflexion KLB, the side KB can be found.

[Margin: Step 2.] Second, in the triangle AKB, right-angled at K, with KB and AB now known, the latitude KAB will be found, both at apogee and at perigee.

Problema 18. Inuenire an & quanta ſit Variatio Deuiationis ſecundùm Copernicum.

Problem 18. To find whether there is a variation of the deviation, and how great it is, according to Copernicus.

XXIII. Ptolemy set the deviation of Venus as always to the north and 10′, and that of Mercury as always to the south and 45′. Copernicus, Book 6, chapter 8, raises the doubt whether this is always the same at apogee and at perigee, or whether it undergoes a change, and a sensible one. Afterwards he affirms that it is indeed changeable, but not so that this change produces a sensible error, and this he demonstrates in his hypothesis as follows.

[Margin: Delineation of the scheme.] In the following diagram, let ABC be the line of the common section of a plane at right angles to the ecliptic, and A the centre of the Earth; and let CFE be the orb of the planet, whose centre B is now at its greatest, now at its least distance from the Earth, or, as Ptolemy would say, now at the apogee, now at the perigee of the eccentric, namely when the deviation turns out greatest and the plane of the orb CFE, according to Copernicus, is parallel to the plane of the ecliptic. So let DF be conceived as the diameter of the orb deviating from the plane of the ecliptic, and parallel to the diameter CE; and CDF in the plane CBA, under the common section. Now let DF be bisected at G, so that G is the centre of a circle parallel to the plane of the ecliptic, and let the centres G and B be joined by the perpendicular GB; and let the three points, namely the apogee D, the perigee F and the centre G of that parallel, be joined to A by straight lines.

Next, let the angle of mean deviation BAG be 10′ in Venus and 45′ in Mercury. First, then, in the triangle ABG, right-angled at B, with the mean distance AB given and the angle at A, BG will be given, in parts of which AB is given; and GB is equal to the sine of the arc DC and FE.

Diagram. Set into the right part of the right column with the text running down beside it. A circle stands at the top. A vertical line falls through it from C at the top of the circle, through B, to E at the bottom of the circle, and continues down to A at the foot. A straight line runs from D down through G to F, and a short horizontal line joins G and B inside the circle. D stands at the upper left of the circle and F at its lower left. Straight lines converge from D, from G and from F down to A. Below the circle two planetary signs stand one above the other to the right of the lines, that of Mercury higher and that of Venus lower. A small dark disc stands on the converging lines a little above A.

Second, therefore, conceiving the triangle DAC, right-angled at the point nearest to C, on which the sine drawn from D would fall, from that given sine and the distance AC, nearest to the apogee distance itself, the angle of greatest deviation at apogee is gathered: in Venus 6′, and in Mercury 33′.

[Margin: Greatest and least deviation of ♀ and ☿.] Similarly, conceiving the triangle FAE, right-angled however at a point a little above E, on which the sine drawn from F would fall, from the said sine and the perigee distance

AE, or one a little greater, the angle of greatest deviation at perigee, FAE, is gathered: in Venus about 15′, in Mercury 1° 10′.

Copernicus adds, however, that these differences were unobservable to the ancients, because, since it comes about at the apogee and perigee of the orb, at which the conjunction of these planets with the Sun takes place, the planets lie hidden under the rays of the Sun; and that they therefore followed a deviation observed elsewhere, as simple and unchanging, but that it is in truth variable.

[Margin: Scheme for the libration of the deviation.] This variation he accounts for by a libration through the small circle DF, on whose diameter DF the plane of the orb CBA is carried back and forth, so that it is now in the plane of the ecliptic under F, now at its greatest distance under D, now at the distance of the mean deviation under B; and the libration takes its laws from a motion made along the circumference of the small circle, double the motion of revolution of the centre of the planet's orb, laws that we have already set out in chapter 2, number 7. From the numbers just gathered, of greatest and least deviation, the diameter DF of the small circle is set at 14′ in Venus and 70′ in Mercury.

Diagram. Set into the right part of the right column with the text running down beside it. A small circle stands on two low arcs, which cross each other at C at the lower left and at A at the lower right, each running a little beyond. The upper arc passes through L and crosses the circle between B and E; the lower, flatter arc crosses the lower part of the circle. A short line drops from L to the lower arc. D stands at the top of the circle and F below it, with a vertical line between them on which B and E stand inside the circle, B above E. The planetary sign of Venus stands above and to the left of the circle, and that of Mercury above and to the right. The sign of the ascending node (☊) stands above C and that of the descending node (☋) above A.

Problema 19. Latitudinem Mercurij ac Veneris ex Deuiatione ortam determinare ſecundùm Copernicum.

Problem 19. To determine the latitude of Mercury and Venus arising from the deviation, according to Copernicus.

XXIV. Following Copernicus, Book 6, chapter 8, let ABI be the line in the common section of the planet's orb and the ecliptic, with the Earth A placed at the planet's apogee or perigee; and let us use AB, the quasi-mean distance, of 10000 parts. From the centre C let the orb of the planet DEF be described, parallel to the plane of the ecliptic and at its greatest distance from the ecliptic. Let its diameter DF (which we cannot represent in a plane) be understood under ABI, and its centre C connected with the plane of the ecliptic by the perpendicular line CB.

[Margin: Delineation of the scheme.] Let the planet be at E, distant from F, the perigee of the orb, by the arc EF of 45°. Let perpendiculars be drawn: EG to CF, and, from the ecliptic to the plane of the orb lying beneath it, KE and

HG. Let K and H be joined by the straight line KH, so that the right-angled parallelogram EGHK arises; and finally let E and K be joined to the Earth by the straight lines AE and AK.

With these laid out: [Margin: Step 1.] first, from the greatest deviation the sine CB is given, by the preceding Problem, in parts of which AB is 10000; and in the same kind of parts the semidiameter of the orb, CE, is supposed known. Therefore the second sine BH will be given too, equal to CG; and in the right-angled triangle CEG, EG will be given, equal to KH.

[Margin: Step 2.] Second, with BH subtracted from AB, AH will be given; therefore in the trian- gle KAH, right-angled at H and with the sides AH and KH given, AK will be given.

[Margin: Step 3.] Third, in the triangle AKE, right-angled at K, in which AK is given, and EK, equal to GH, that is, to CB, the angle EAK will be given, which measures the latitude arising from the greatest deviation of the orb, when the planet is at E. From this you will understand how, with the deviation found according to the laws of the libration itself, and given the distance AB of the centre of the orb and the arc by which the planet is distant from the perigee of its orb, you may hunt out the latitude arising from the deviation, according to the mind of Copernicus.

Diagram. Set into the right part of the left column with the text running down beside it. A circle stands at the top, with D and I side by side at its top and F at its foot. A vertical line falls from D through C and G to F, and a second from I through B and H, continuing below the circle down to A. A short horizontal line joins C and B in the upper half of the circle, and a line runs from C down and to the left to E, at the left edge of the circle. In the lower half a small figure of straight lines joins E, K, G and H, H standing at the right edge of the circle. Straight lines run from E and from K down to A at the foot. To the right of them stand two planetary signs one above the other, that of Mercury higher and that of Venus lower.

CAPVT IX.

Chapter 9.

De Reductione loci Planetæ ab Ecliptica ad Orbitam ipſius, & ab Orbita ad Eclipticam, deque Aequatione orta ex Curtatione Interualli.

On the reduction of a planet's place from the ecliptic to its orbit, and from the orbit to the ecliptic, and on the equation arising from the curtation of the interval.

I. *This care*, says Kepler in the *Commentaries on Mars*, chapter 9, *Ptolemy did not think necessary with regard to the planets; Copernicus did not neglect it in the Moon; Tycho Brahe diligently embraced it for the sake of subtlety.* But his memory fails him. [Margin: Authors who have concerned themselves with this reduction.] For Copernicus too, in Book 6, chapters 5 and 7, did not neglect

it in Venus and Mercury, and he taught *the way of weighing what diversity the latitude brings to the longitude*, to use his own words; and so, before him, did Regiomontanus in the *Epitome*, Book 13, propositions 13, 14, 15, 16, 17, 19. Kepler himself, however, was the most diligent in this: in the *Commentaries on Mars*, chapter 9, in the *Epitome of Copernican Astronomy*, Book 5, page 700, and in the Rudolphine Tables, chapter 21. Boulliau, in Book 11 of the *Astronomia Philolaica*, theorem 15, and Book 12, precept 9; and Renieri, in the *Tabulae Mediceae* as reissued, from page 32. Magini, for his part, touches on this lightly in the *Supplement to the Ephemerides*, Canon 10, and Hérigone in volume 5 of the *Cursus Mathematicus*, page 559.

[Margin: The cause of the reduction and the curtation.] It must therefore be understood that when we gather the places of the planets from observation, we estimate their ecliptic place, that is, their place at the point of the ecliptic on which the arc of the circle of latitude drawn through the body of the planet falls. So if we wish to define their place in their own orbit, in which they move, it must be reduced to the orbit, since outside the nodes and the limits of the latitudes it is different. Conversely, when we compute their places from the scheme of the hypothesis and from tables, we consider them in their own orbit; so if we want the ecliptic place, the other reduction is needed in turn. And since the equation of the orb depends on the distance of the planet from the centre of the ecliptic, which distance, with respect to the ecliptic place, is smaller than the distance of the planet itself, that distance must therefore be curtated, and from this curtation the equation of the orb must be corrected, so that the most exact place in longitude may be determined, above all in Mars, Venus and Mercury, in which both the reduction and the curtation would be neglected at greater risk of error. But, beginning from the reduction, I choose to set out first certain definitions and propositions, as foundations of the problems to be added on this subject.

Definitiones ad Reductionem ſpectantes.

Definitions concerning the reduction.

[Margin: What is the ecliptic place?] 1. The place of a planet in the ecliptic *is the point of the ecliptic at which a circle of latitude, at right angles to the ecliptic and passing through the place of the planet's body under the sphere of the fixed stars, cuts the ecliptic.*

[Margin: What is inclination?] 2. The inclination of a planet, or of a point in the planet's orbit, *is the angle at the centre of the ecliptic made by two straight lines, one drawn in the plane of the planet's orbit to the planet, or to a point existing in that orbit, the other in the plane of the ecliptic to the planet's ecliptic place.* For although inclination belongs rather to lines or planes, it is nevertheless attributed to the planets and points that are on those lines. Further, the centre of the ecliptic in the hypothesis of Kepler and of Boulliau is the Sun; for most it is the centre of the Earth.

[Margin: What is the circle of inclination?] 3. The circle of inclination *is a great circle in the sphere of the fixed stars, at right angles to the ecliptic, and described from the centre of the ecliptic.*

[Margin: What is the arc of inclination?] 4. The arc of inclination *is the arc of the circle of inclination intercepted between the eccentric place of the planet and the ecliptic place of the same.*

[Margin: What is the argument of inclination?] 5. The argument of inclination *is the arc of the planet's orbit under the fixed stars, intercepted between the north node and the eccentric place of the planet, counted in the order of the signs.*

[Margin: What is the reduction?] 6. The reduction to the ecliptic *is the small arc by which the argument of inclination and the arc of the ecliptic counted from the common node to the planet's ecliptic place differ from each other.*

[Margin: Why and when the reduction is to be applied.] For by the demonstrations of Theodosius in the *Sphaerics* it is gathered that when the circle of latitude passes through the poles of the ecliptic and of the planetary orbit, the arcs counted from the common section to the circle of latitude are equal, and so no reduction is needed. But when it passes not through the poles of the orbit but only through the poles of the ecliptic, it is indeed at right angles to the ecliptic but oblique to the planet's orbit; and so the arc between the planet's place in its own orbit and the nearer node is greater than that between the planet's ecliptic place and the same node; and therefore the place in the orbit must be reduced to the place in the ecliptic, if the question concerns the planet's place in the ecliptic.

[Margin: Where is the greatest reduction?] 7. The greatest reduction to the ecliptic occurs at about the middle of the quadrants counted from the nodes, just like the greatest difference between the right ascension and the arc of the ecliptic corresponding to it, as Kepler teaches in the *Epitome*, page 700, and Boulliau in Book II, Theorem 15.

Problema 1. Reductionem Loci Planetæ in ſua Orbita ad Eclipticam inueſtigare, & adhibere.

Problem 1. To investigate the reduction of a planet's place in its orbit to the ecliptic, and to apply it.

II. In the spherical triangle DAC, let AD be a quadrant of the ecliptic and AC a quadrant of the planetary orbit, and A their common node. If the planet is at C, distant from the node A by a quadrant, or 90°, it will be at the limit of greatest latitude, and the arc AD will be as great as AC, and therefore no reduction will be needed, just as none is at A either.

Diagram. Set into the right part of the right column with the text running down beside it. A three-sided figure with curved sides. An arc runs from D at the left through E, at its top, to A at the right. A second arc runs from A at the right, through B, down to C at the lower left. A straight side joins D and C, and a further line joins E and B.

Now let the planet be at B, through which let BE be drawn, an arc of latitude at right angles to the ecliptic, so that the spherical triangle AEB arises, right-angled at E. And let the greatest inclination of the planetary orbit to the ecliptic be given, which the angle A measures; let there further be given the argument of inclination, or the arc AB, counted from the nearer node to the place of the planet in the eccentric. For from these three givens, namely the right angle E, the angle A of greatest inclination and the base AB, you will seek, by the doctrine of right-angled spherical triangles, the arc AE, whose difference from the arc AB will be the reduction to the ecliptic.

So multiply the second sine of the greatest inclination by the tangent of the argument of inclination, and divide the total by the whole sine; for there will remain the tangent of the reduced argument, that is, of the arc AE. [Margin: Abridgement of the problem.] Or add the residual of the second logarithm of the greatest inclination to the mesologarithm of the planet's distance from the nearer node; for there will result the mesologa- rithm, the second one, of the distance of the planet's ecliptic place from the same node, whose difference from the argument of inclination is the reduction. From tables, moreover, the reduction is readily gathered, with the argument of latitude, or distance from the node.

[Margin: Use of the reduction.] The use of the reduction is as follows. If the planet is heading from the nodes to the limits, the reduction must be subtracted from the argument of inclination; but if from the limits to the nodes, it must be added. And the remainder in the one case, the sum in the other, added to the place of the preceding node, gives the planet's place in the ecliptic. Or, if the planet is heading to the limits, it must be subtracted from the place computed in the orbit; if to the nodes, it must be added; and the planet's place in the ecliptic will result. Let the contrary be done in the reduction from the ecliptic to the orbit.

Problema 2. Reductionem Planetæ ab Ecliptica ad Orbitam inuenire & adhibere.

Problem 2. To find the reduction of a planet from the ecliptic to the orbit, and to apply it.

III. In the preceding triangle AEB, given the angle A of greatest inclination and the side AE, namely the distance of the ecliptic place from the nearer node, you will seek the base AB by the rules of right-angled spherical triangles; for it will be the distance from the node of the planet considered in its orbit. Its difference from the arc AE will be the reduction sought, but to be applied in the contrary way, namely to be added to the distance of the ecliptic place if the planet is heading from the nodes to the limits, and subtracted if from the limits to the nodes. [Margin: Abridgement of the problem.] Now the second logarithm of the angle A, added to the second mesologarithm of the side AE, will give the second mesologarithm of the base AB.

Problema 3. Reductionem Maximam inuenire.

Problem 3. To find the greatest reduction.

IV. Use the arc AB, taken as about 45°, if you seek the reduction to the ecliptic; or AE, likewise about 45°, if you seek the reduction to the orbit; and do the rest as in problem 1 or 2. I said *about*, because although the greatest reduction occurs around the semiquadrant AB or AE, it does not always occur at the exact limit of 45°.

[Margin: Where the greatest reduction is, from Boulliau.] For Boulliau, in Book II, theorem 15, has demonstrated not only that the reductions viewed from the Earth are greater than those viewed from the Sun, if the Earth is nearer to the planet than the Sun is, as it is at the oppositions of the superior planets to the Sun; but also that they are greater in Mars beyond 45°, namely at 55° of distance from the node, because when it is in opposition the Earth is nearest to it, and the planet's place in its orbit is turned face-on toward us; that they diminish, however, at the quadratures because of the oblique view, and at conjunction with the Sun; but that the greatest reduction at the oppositions exceeds by a few seconds the greatest reduction about 45°, and is found to be unusual [?] [recte: *solitam* for *insolitam*, per the book's errata, giving "the greatest reduction usually found about 45°"]. In Mercury, moreover, the reduction seen from the Sun is always greater than that viewed from the Earth, because it is always nearer to the Sun than to the Earth. In Venus it is sometimes greater, as also in Mars, because of the greater nearness of acronychal Mars to the Earth, and of retrograde Venus likewise to the Earth, when it is about 30° past the node.

De Curtatione Interualli.

On the curtation of the interval.

V. On this, Kepler and Boulliau in the places cited at number 1. From these, note the following. Since the plane of the planetary orbit is inclined to the plane of the ecliptic, and to investigate the planet's latitude a straight line perpendicular to the ecliptic is drawn from the planet's orbit, subtending the angle of inclination, it is necessary that the point of the ecliptic on which that perpendicular falls be nearer to the centre of the world, where the angle of inclination is, than the point of the planetary orbit from which that perpendicular is drawn. And so that ecliptic interval, or the distance of the point in the plane of the ecliptic that terminates that perpendicular, is smaller than the distance of the point or planet set in the planetary orbit. So that shorter distance is called by Kepler and his followers the *curtate distance*; and the excess by which it is surpassed by the greater interval, or the small portion that the curtate distance lacks, is called the *curtation*.

To put this before the eyes, for the superior planets recall the figure set out in chapter 8, number 8. For in it the straight line AD represents the plane of the planetary orbit, and the straight line COB the plane of the ecliptic, on which the perpendiculars AB and DC fall from the planets A or D. So the angles at

B and C are right, and greater than either angle at the base, by 32 of the first book. Therefore the base AO, subtending the angle ABO, that is, the distance of the planet A from O, the centre of the world, is greater, by 19 of the first book of the *Elements*, than the side OB, which is the distance of the point in the ecliptic on which the perpendicular AB falls; and by the same reasoning the distance DO is greater than CO.

For the inferior planets, however, look at the figure placed in chapter 8, number 11, in which BG indicates the plane of the planet's orbit and CE the plane of the ecliptic, to which the perpendiculars BC and ZD are let fall from the planet at B or Z; or, with the planet placed at G or Y, the perpendiculars GE or YO are drawn. So the distance CP from P, the centre of the ecliptic, is shorter than BP, etc. The definitions relevant here are therefore these.

[Margin: What is the curtate distance?] 1. The curtate distance *is the straight line in the plane of the ecliptic intercepted between the centre of the ecliptic (which for Kepler and Boulliau is the Sun) and the perpendicular drawn to the ecliptic from the centre of the planet's body.*

[Margin: What is curtation?] 2. Curtation *is the small portion of the planet's distance from the centre of the world corresponding to the sagitta, or versed sine, of the planet's inclination, in the proportion in which the whole interval corresponds to the whole sine.* So indeed Kepler in the *Epitome of Copernican Astronomy*, page 701. Or, from Hérigone, volume 5, page 559: *it is the excess by which the planet's distance from the centre of the world surpasses its curtate distance.*

In place of the world, however, these authors put the Sun, which they consider to be the centre of the ecliptic, and the point at which the angle of inclination of the orbit to the ecliptic is formed. From the definitions stated there arises this theorem, the foundation of the following problem.

3. *As the whole sine is to the planet's distance from the centre of the ecliptic, so is the second sine of the inclination to the curtate distance.* So let it stand.

Problema 4. Data diſtantia Planetæ à centro Eclipticæ, inuenire diſtantiam Curtatam.

Problem 4. Given the planet's distance from the centre of the ecliptic, to find the curtate distance.

VI. Let it be made: as the radius, or whole sine, to the planet's distance from the centre of the ecliptic, so the second sine of the inclination to the curtate distance. How the planet's distance from the centre of the world is gathered is clear from what was said about the geometrical calculation of longitude. By what method the inclination becomes known, so that its second sine may be known from it, we said in chapter 8, problem 12, or number 17.

[Margin: Where reduction and curtation are nil, where greatest.] Kepler, moreover, teaches on page 701 of the *Epitome* that the distance of the ecliptic point is curtated most around the limits, and still more if the planet is at the limit nearer to the planet's aphelion; understand this of the distance taken from

the centre of the Sun. But in the hypothesis that sets the centre of the ecliptic at the centre of the Earth, it must be understood of the limit nearer to the apogee itself.

But Boulliau, in Book 11, theorem 15, and Book 12, precept 9, teaches that at the oppositions of the three superior planets to the Sun the reduction is greatest and the curtation nil, because the planet's place in the orbit is turned face-on toward us. Conversely, at the quadratures with the Sun the reduction is diminished, because the planet's place in the orbit is viewed obliquely, and the curtation then turns out greatest, and the greater the nearer the planet comes to the limit. He teaches that the curtation of the superior planets is never turned face-on toward us; but that in Venus and Mercury it is turned face-on at the contacts of the orb, where the greatest digressions occur, because the perpendicular falls from the eye on the line drawn from the Sun to Venus or Mercury; and so at the contacts there are no reductions with respect to the Earth, but greatest curtations; conversely, at the conjunctions with the Sun there are no curtations, but greatest reductions.

VII. [Margin: Use of the curtation.] But you will ask what the use of the curtation is. I answer that it serves to correct the equation of the orb, which is usually obtained by means of the planet's distance from the Sun or from the centre of the world. So since the curtation always diminishes the planet's distance from the centre of the world, by its force something must always be subtracted from the equation of the orb. Hence if the equation of the orb was additive, it will add less to the planet's first-equated motion; and if subtractive, it will subtract less. The rules of this practice are of the following kind, supposing tables in which the reduction and the curtation are set out. With the place of the north node subtracted from the place of the planet (the centric place), there remains its distance from the node, with which the greatest prosthaphaeresis of the orb is gathered from the Rudolphine or Philolaic tables or the like, and the curtation in the other small table. Next, in the table of equations of the orb, the equation of the orb belonging to the anomaly of the orb is gathered, as was said in connection with the calculation of longitude. With these prepared, let this proportion be made: as the greatest parallax, or greatest equation of the orb, is to the curtation found in the tables, so is the equation of the orb belonging to the anomaly of the orb to the curtation, which is always to be subtracted from the equation of the orb first found, so that the most exact equation of the orb may be had. The precept of the curtation in the Rudolphine Tables stands somewhat differently; on its use see their precepts 90, 91 and 92, which will be set out more clearly in the precepts of our own tables. [Margin: For which planets the curtation and the reduction are necessary.] The reduction, let alone the curtation, can nevertheless safely be neglected in Saturn and Jupiter; but in Mars, Venus and Mercury it must not be neglected, because neglecting it brings in an error sometimes of 3′ in Mars; just as in Venus and Mercury too, in conjunctions with the Sun, it produces an error not to be despised. According

to Kepler and Boulliau, the greatest reduction and curtation are as you see in the following small table.

Planet	Authority	Greatest reduction	Greatest curtation
♄	Kepler	1′ 41″	
♄	Boulliau	1′ 27″	0′ 20″
♃	Kepler	0′ 29″	
♃	Boulliau	0′ 30″	0′ 11″
♂	·····	0′ 53″	1′ 10″
♀	·····	2′ 59″	5′ 56″
☿	Kepler	12′ 30″	
☿	Boulliau	12′ 45″	10′ 22″

For Copernicus, however, the greatest diversity in longitude, arising from the mere latitude of inclination, does not exceed 2′ in Venus and 7′ in Mercury; and the one arising from the greatest reflexion, when the planet is at the contact of the orb, 3′ in Venus and 8′ in Mercury, as is clear from what we said at chapter 8, Problems 15 and 17.

SCHOLIA.

Scholia.

I. In the reduction of the planets to the ecliptic, or from the ecliptic to the orbit, which Ptolemy neglected, which Copernicus, Lansbergen and Longomontanus applied in the Moon, and which Tycho aimed at in the other planets nearer the Sun, Kepler found two things wanting, in the *Commentaries on Mars*, chapter 9. To understand them, let the scheme set out at chapter 8, number 13 be repeated here. In it A is the place of the node among the fixed stars and AB an arc of the ecliptic, to which let arc AC be equal; let the planet I be seen from the Earth H under the point C of the fixed stars; and let the perpendicular arc CE be drawn from C to the ecliptic, so that the planet's place reduced to the ecliptic is at E.

Diagram. A geometric figure set into the left column of the first scholium, the text running down its left side. From A at the top, a curved arc runs right to C, and further lines descend from A, one of them a curve through E to B, and long straight lines converge downward on a rayed disc at the foot. Lines from C run down and left to E and through F and D towards B and I; arcs cross the figure at B and I and again at H, extending to the right. The planet I is marked by a star-shaped point, H by a dark round point, and G stands beside the rayed disc.

- A (top left, apex): place of the node among the fixed stars
- C (right, end of the upper arc): point of the fixed stars under which the planet is seen
- F (centre, below the upper arc): place where the line from the Sun meets arc CE

- E (left of centre): the planet's place reduced to the ecliptic
- D (centre, just below and right of F): point where the arc from A through F cuts CB
- B (below E): place opposite the Sun in the case the text sets out
- I (below D, at the star-shaped point): the planet
- H (lower, beside the dark round point): the Earth
- G (foot, beside the rayed disc): the Sun

With this set down, some have thought that the planet is not precisely opposite the Sun G except when arc AC, the visible distance of the planet from the node, equals arc AB; or only when the place opposite the Sun is B, namely the point to which arc CB is drawn from C, cutting off arc AB. At that time the planet is indeed seen exactly opposite the Sun, but in reality it is not. For let the straight line GIF be drawn from the Sun G through the planet I as far as arc CE, and let F be the place where it falls; through F let an arc be drawn from A as far as CB, and let CB be cut by it at D. For it is evident that the plane of the eccentric of the planet, seen from H under C, is aligned not under AC but under AF, since these three points G, I, A lie in the same plane; and that when the true opposition with the Sun occurs, the planet will truly be under F, but when the place opposite the Sun is B, the planet will be under D, since in both cases it appears under C. Now AD is shorter than the legs of the isosceles BAC. Therefore B, the place opposite the Sun, is farther removed from A than the place D, under which the planet stands at that moment which some used for obtaining the opposition with the Sun, in order to find the planet stripped of the second inequality; although at that time it was in fact more involved in the second inequality. Since, then, the orbit of the planet free of the second inequality lies under AD, the visible latitude is EAC, and the true inclination of the line GF to the ecliptic is FGE, it comes about that at the opposition the second inequality of latitude is almost at its greatest, and its measure is the angle HIG. And just as the whole latitude EC makes AC longer than arc AE by an excess as great as arc EB, so part of this visible latitude makes that same AC longer than AF, and indeed sometimes by 9′, by which one can go wrong in examining acronychal oppositions. The true method of reducing a planet from the ecliptic to the orbit, therefore, is this: with E known, the planet's place in the ecliptic from observation, let the inclination FGE be sought by the problems given in chapter 8; and in the triangle AFE, right-angled at E, with the distance AE from the node known, and the arc FE, which is the measure of the inclination EGF, let arc AF be sought. Its difference from arc AE will be the difference between the planet's ecliptic place E and its place F in the orbit.

II. If anyone wishes to find by a geometrical route the difference of the equations arising from the mere inclination of the plane of Venus and of Mercury to the ecliptic, let him consult the Copernican problem and its fifth step, which we have already given on another occasion at chapter 8, number 20, which is problem 15; and the one arising from reflexion we taught in the same place, at problem 17. There are, moreover, some notable propositions

in Regiomontanus, Book 13 of the *Epitome of the Almagest*, concerning the reduction and the curtation together: namely prop. 13, which shows that in the Ptolemaic hypothesis of Venus and Mercury the diversity of the longitude reckoned in the ecliptic from the true longitude in the orbit becomes greatest near the point of contact of the epicycle, though not always at the very point of contact; and prop. 14, which shows that in Mercury it occurs when Mercury is at the contact itself; and prop. 15, where he shows that in Venus it mostly occurs outside the contact.

III. [Margin: Reduction of aspects.] What might be wanted here on the reduction of aspects I have preferred to move to the following section, where aspects will be discussed, that is, to section 5, chapter 8, from number 5.

CAPVT X.

Chapter 10.

De Tabulis Latitudinis, earumq. vſu.

On the tables of latitude and their use.

I. By what technique the tables of latitudes are constructed and to be applied is made clear enough by Ptolemy, Book 13, chapters 4, 5 and 6; Regiomontanus in the *Epitome of the Almagest*, prop. 21; Copernicus, Book 6, chapter 9; Wurstisen on Peuerbach, p. 385; Reinhold in the Prutenic Tables, precepts 71 and 72; Magini in the *Secunda Mobilia*, canons 49 and 50, and in the *Supplement to the Ephemerides*, canon 11, and in the *Theoricae*, chapters 5 and 10; Longomontanus, Book 2 of the *Sphaerics*, chapters 15 and 25; Kepler in the Rudolphine Tables, chapter 21, with precepts 108 and 109 added; Lansbergen, precepts 16 and 17; Boulliau, Book 12, precepts 8 and 9; Renieri in the *Tabulae Mediceae*. But the manner of using them belongs to the precepts of the tables, to be given in the practical part of this first volume. The technique of composing them reduces to proportional minutes, the greatest latitudes from apogee to perigee being presupposed; it is like the one by which the tables of equations are made up through proportional minutes, and there is no need for us to dwell on these things any further.

SECTIO QVINTA

Fifth Section

DE PASSIONIBVS QVINQVE PLANETARVM MINORVM SECVNDVM LONGITVDINEM, NON EXCLVSA LATITVDINE.

On the affections of the five minor planets in longitude, latitude not excluded.

PROHEMIVM.

Preface.

[Margin: Enumeration of the passions in longitude.] Now that the affections or affections and accidents that belong to these five planets from their motion in latitude have been dealt with, it follows that we should treat those that befall them from the motion of longitude. Either the planets are compared with themselves, in which way they are called slow and swift, and increased or diminished in number; or direct, as far as speed is concerned, or stationary or retrograde, as far as slowness is concerned. Or they are compared with the quarters of the world, in which way they are called eastern or western, morning or evening. Or they are compared with the light of the Sun and with its motion together, on which account they are called increased or diminished in light, or hypaugi, or rising or setting heliacally. Or, finally, any two planets are compared with each other either as to position, from which come the various aspects, chiefly the great or greatest conjunctions and the revolutions of conjunctions, or as to the harmonic configuration arising from the speed and slowness of motion. We shall have to discuss these in roughly this order. [Margin: Why the digressions of ♀ and ☿ were treated in Section 3.] The greatest digressions of Venus and Mercury from the Sun, which certainly belong to motion in longitude, were more conveniently spoken of in Section 3, on the necessary occasion of investigating their own proper motion. And I said in the title of the section "latitude not excluded" because some variety does nevertheless befall these very affections of longitude from the varying latitude of the planets.

CAPVT I.

Chapter 1.

Planetæ Tardi aut Veloces; Aucti aut Minuti numero quando dicantur?

When are planets called slow or swift, increased or diminished in number?

I. These affections are mentioned by Peuerbach in the *Theoricae*, and there by Reinhold, p. 197, Wurstisen, pp. 251 and 255, and Nonius, p. 278; by Fernel, Book 2 of the *Cosmotheoria*, chapter 9; by Magini, Canon 97, and Book 2 of the *Theoricae*, chapter 13; by Langius in the *Theoricae*, chapter 14; and by Kepler in the *Epitome of Copernican Astronomy*, p. 822. From these:

[Margin: The swift planet.] A planet is called swift, or increased in course, when the line of the planet's true motion moves according to the succession of the signs more quickly than the line of mean motion; or when the apparent motion under the zodiac in the order of the signs is faster from day to day than the mean diurnal motion. This happens to the five minor planets in the upper half of the epicycle, the more so as the superior planets approach conjunction,

or the inferior planets the superior conjunction, or the apogee of the epicycle itself.

[Margin: Slow.] A planet is called slow, or diminished in course, when the line of true motion moves according to the series of the signs more slowly than the line of mean motion, or even moves against the series of the signs, or seems to stand still; or when the apparent daily motion is either nothing, or against the order of the signs, or less than the mean motion. This happens to these five planets in the lower part of the epicycle, especially near the perigee of the epicycle; whereas the Moon, on the contrary, is slower in the upper part of the epicycle and swifter in the lower part.

[Margin: Moderate.] A planet is called moderate in course when the lines of true and of mean motion proceed equally; or when the apparent diurnal motion is equal to the mean motion, which happens to the planets about their passage through the mean longitudes.

[Margin: Increased in number.] A planet is called increased in number, in Greek [Greek: προσθετικὸς (prosthetikos, "additive")] or [Greek: προσθέτης (prosthetēs, "one who adds")], or, as Fernel puts it, increasing the number, when the equation of the argument or of the epicycle is added to the mean motion. This happens to these planets in the first semicircle of the epicycle, that is, from the apogee of the epicycle in the order of the signs as far as the perigee of the epicycle. Or, as Kepler says, when both equations, of the eccentric and of the orb, or at least the greater of them, are additive, which can happen to these planets whether direct or retrograde.

[Margin: Diminished in number.] A planet is called diminished in number, in Greek [Greek: ἀφαιρετικός (aphairetikos, "subtractive")] or [Greek: ἀφαίρετης (aphairetēs, "one who subtracts")], or diminishing the number, when the equation of the argument, or epicyclic equation, is subtracted from the mean motion, which happens to these 5 planets in the latter semicircle of the epicycle. Or a planet is called diminished in number, as Kepler says, when both equations, of the eccentric and of the epicycle, or the greater of them, are subtractive.

[Margin: Corollary.] From this it is clear that a planet can be swift in course and yet diminished in number, as when it is in the fourth quadrant of the epicycle; and on the other hand slow in course and yet increased in number, as when it is towards the end of the second quadrant of the epicycle, whether it is stationary there or retrograde. Granted, in the first quadrant it is at once swift and increased in number, and in that part of the third quadrant which is nearer the perigee it is at once slow in course and diminished in number. It is further clear that the planets are swifter at the apogee of the epicycle than at the perigee, speaking even of the speed of retrogression, for they advance more there than they recede here.

II. [Margin: On tables of the diurnal motion of the planets.] Their apparent or true diurnal motion helps in distinguishing the speed of the planets, whether gathered from ephemerides or from the special tables which Giovanni Antonio

Magini published in Volume 2 of the *Secunda Mobilia*, from page 465 for the true diurnal motion of the Sun and Moon, and from p. 510 to 548 for the other planets. He teaches their construction in Volume 1, Canon 47, and their use in Canon 48, where he corrects Canon 36 of the Prutenic Tables, in which the daily motion near the stations in ♂ ♀ ☿ differs by no negligible difference from the motion deduced from the tables of mean motions and the equations. [Margin: Error of the Prutenic Tables in the daily motion.] In Canon 47 he gives a twofold way of constructing tables of diurnal motion, with examples, but that does not belong to this place, and it is enough to have pointed a finger to the source. From those tables, however, though they are derived from Copernican motions, we shall give a specimen of the diurnal motion of the planets at the principal places of the eccentric and of the epicycle, so that from it the evidence of speed and slowness and the more notable marks may be taken somewhat more accurately than from the small table which Origanus composed from them or from the Prutenic tables, in Volume 1 of the *Ephemerides*, part 2, chapter 2. In this table, then, the greater the direct motion, the greater the speed; but the greater the retrograde motion, the greater the slowness. The greatest speed is at the perigee of the eccentric and the apogee of the epicycle; the greatest slowness, at the perigee of the eccentric and of the epicycle together.

True diurnal motion [DIVRNVS MOTVS VERVS]

Planet	In the epicycle	At the apogee of the eccentric	At the mean longitude of the eccentric	At the perigee of the eccentric	
♄	Apogee	0° 7′ 7″	0° 7′ 35″	0° 8′ 9″	Swiftest
♄	Perigee	0° 4′ 45″	0° 4′ 58″	0° 5′ 13″	Slowest
♃	Apogee	0° 12′ 58″	0° 13′ 38″	0° 14′ 24″	Swiftest
♃	Perigee	0° 7′ 36″	0° 7′ 44″	0° 7′ 57″	Slowest
♂	Apogee	0° 38′ 21″	0° 42′ 3″	0° 47′ 2″	Swiftest
♂	Perigee	0° 24′ 11″	0° 13′ 26″	0° 17′ 32″	Slowest
♀	Apogee	1° 13′ 0″	1° 15′ 0″	1° 16′ 0″	Swiftest
♀	Perigee	0° 38′ 0″	0° 34′ 0″	0° 33′ 0″	Slowest
☿	Apogee	1° 43′ 0″	1° 52′ 0″	1° 54′ 0″	Swiftest
☿	Perigee	0° 35′ 0″	1° 2′ 0″	1° 2′ 0″	Slowest

CAPVT II.

Chapter 2.

De Planetis Directis, ac Retrogradis eorumque Stationibus.

On direct and retrograde planets and their stations.

I. Nothing in the whole planetary system has so strengthened and enlarged, for the five minor planets, the name of wanderers, which the Moon and the Sun share with them, as the heteroclite, so to speak, or at any rate anomalous, not so much variety as a kind of inconstancy and almost self-contradiction in their motion in longitude. For now they hurry in a direct course from west to east, yet striving against the diurnal motion of the primum mobile, as it is considered to be. Now, as if with a hesitant and doubtful step, they stand still and cling for a while to the same place; until, as if they had changed their minds and repented of their former course in the order of the signs, they seem to go back by their own motion from east to west and to retrace their steps against the order of the signs, as though returning to favour with the diurnal motion of the primum mobile and choosing a palinode or palinchorea. But not long after, checking their step again, they halt for a little, and soon, breaking their compact with the diurnal motion, they direct their course once more towards the eastern quarter. This truly wonderful exchange of alternations gave Copernicus his handle for freeing those heavenly lights from these motions, absurd as he at any rate judged them, and for transferring them, from the annual motion of the Earth, to a mere deception of our sight.

[Margin: Authors who treat of station, retrogradation, etc.] The chief authors, moreover, who discuss this subject are Apollonius of Perga; Pliny the Elder, Book 2, chapters 15 and 17; Vitruvius, Book 9, chapter 4; Ptolemy, Book 12 of the *Magna Constructio* or *Almagest*; al-Battānī, chapter 46; al-Farghānī, Difference 15; Jābir ibn Aflaḥ, Book 8 of the *Astronomy*; Proclus in the *Hypotyposes*, chapter 4; Peuerbach in the *Theoricae*, and there Osualdus, Reinhold from p. 135, Wurstisen from p. 231, and Pedro Nunes, annotations 1, 2 and 3 on Peuerbach's theory of the affections of the planets; Regiomontanus in the *Epitome of the Almagest*, Book 12, from prop. 4 to 12; Piccolomini in the *Theoricae*, Book 2, chapter 4; Maurolico, *Cosmographia*, Dialogue 3, p. 95; Barozzi, *Cosmographia*, Book 3, pp. 267 and 274; Magini, Book 2 of the *Theoricae*, chapters 11 and 12, and in the *Secunda Mobilia*, canons 94, 95, 96; Langius in the *Theoricae*, chapter 14; and Longomontanus, Book 1 of the *Theorica*, chapter 1. Of those who ascribe these phenomena to the motion of the Earth: Copernicus, Book 5, chapters 3, 35 and 36; Reinhold in the Prutenic Tables, precepts 68, 69 and 70; Rheticus in his *Narratio prima*, towards the end; Lansbergen, precepts 39 and 40, and in the *Theoricae*, chapter 21; Galileo, Dialogue 3 on the system of the world, p. 253 in my copy; Kepler in the *Mysterium Cosmographicum*, chapter 1, in the *Epitome of Copernican Astronomy*, Book 6, from p. 735 to 750 and 767, and in the Rudolphine Tables, precepts 106, 107; Hérigone, Volume 5 of the *Cursus Mathematicus*, Book 2, *Theorica*, chapter 7, from phenomenon 10 to 17; and Boulliau in the *Philolaus*. From these we shall derive the following theorems and problems in order and distinctly.

Nomina & Definitiones ad Directionem, Stationem, ac Retrogreſſum ſpectantia.

Names and definitions concerning direction, station and retrogression.

II. [Margin: What is a direct planet?] A planet is called direct, or progressing, and in Greek [Greek: ὑπολειπτικὸς (hypoleiptikos, "following behind")], that is, following or proceeding in the order of the signs, when the line of the planet's true or apparent motion (the one, namely, drawn from the centre of the Earth through its body) proceeds in the zodiac according to the succession of the signs; or succeeding to one place of the zodiac after another, the preceding parts being left behind. [Margin: What is direction?] Direction or progression is called in Greek [Greek: ὑπόλειψις (hypoleipsis, "a falling behind")] or motion [Greek: εἰς τὰ ἑπόμενα (eis ta hepomena, "towards what follows")], namely a continuous motion in the consequentia of the signs. This happens to these five planets in the upper part of the epicycle, or in the whole upper semicircle of the epicycle, and besides in that part of the lower semicircle in which the motion in the epicycle seconds the motion of the centre of the epicycle; and that centre perpetually progresses according to the succession of the signs, if it is not burdensome meanwhile to use the Ptolemaic hypothesis for the sake of learning.

[Margin: What is a retrograde planet?] A planet is called retrograde or retroceding, and in Greek [Greek: προηγούμενος (proēgoumenos, "going before")] or [Greek: προηγητικὸς (proēgētikos, "preceding")], that is, receding or preceding against the order of the signs, when the line of the planet's true motion goes back in the zodiac against the order of the signs. [Margin: What is retrogradation?] Retrogradation, or retrocession or regress, is called [Greek: προηγήσις (proēgēsis, "a going before")]. This happens to these five planets in that part of the lower semicircle of the epicycle in which the line of the planet's true motion, or the one drawn from the centre of the Earth through the centre of the planet's body, goes back day by day westward, or against the order of the signs, even if the line of the true motion of the centre of the epicycle proceeds eastward.

[Margin: What is a stationary planet?] A planet is called stationary or stational, and in Greek [Greek: στηρίζων (stērizōn, "standing fixed")], that is, standing or halting, when it seems to stand for some time in the same place of the zodiac, neither proceeding nor retroceding. [Margin: What is a station?] And that station, or in Cicero's word *institio*, is called in Greek [Greek: στήριγμος (stērigmos, "a fixing, a station")]. This happens to the 5 minor planets when the line of the planet's true motion shows the planet on the following day in the same place of the zodiac where it was on the preceding day. This occurs because the progress made by the force of the centre of the epicycle is equally retarded by the beginning and the end of the regress. This happens, however, twice in one revolution of the epicycle to each of these planets, namely at

the boundary of both motions, direct and retrograde; and these boundaries lie below the points of contact of the epicycle, as will be shown later.

[Margin: First station.] The *first station*, in Greek [Greek: στήριγμος πρώτος (stērigmos prōtos, "first station")], is the one that occurs in the left, or eastern, or earlier semicircle of the epicycle, reckoned in the order of the signs from the apogee of the epicycle; or the one that occurs in the passage from direct to retrograde motion; or the planet's stay between the last moment of progress and the first moment of regress. [Margin: Morning and evening station.] In the three superior planets this station is called *morning*, because it follows the planet's morning rising; but in the inferior planets *evening*, because they have the line of mean motion in common with the Sun, and it therefore occurs when they are evening planets.

[Margin: Second station.] The *second station*, in Greek [Greek: στήριγμος δεύτερος (stērigmos deuteros, "second station")], is the name given to the one that occurs in the right, or later, or western semicircle of the epicycle; or the one that occurs in the passage from retrograde to direct motion; or that stay of the planet which falls between the last moment of retrogression and the first moment of progress. In the three superior planets it is called evening, but in the inferior planets morning. So the first station of the superior planets occurs when, after conjunction with the Sun, they are making for opposition, and the second when, after opposition, they are making for conjunction. In the inferior planets, however, the first occurs when, from the upper or apogeal conjunction, they are making for the lower or perigeal one.

[Margin: Points of the stations.] The *points of the stations* are two arcs, both in the epicycle and in the zodiac, in which the planets seem to linger, and which therefore appear to us as if they were points, because the planet seems to remain motionless, with the centre of its body, in the same place of the zodiac and of the epicycle. For an equal position of the epicycle's centre in the eccentric, that is, at an equal distance of the epicycle's centre from the apogee of the eccentric, these points stand equally far on either side from the apogee and the perigee of the epicycle.

[Margin: Arc of direction.] The *arc of direction*, Ptolemy's [Greek: περιφέρεια ὑπολειπτικὴ (periphereia hypoleiptikē, "arc following behind")], is the arc of the epicycle reckoned from the point of the second station through the apogee to the point of the first station.

[Margin: Arc of retrogradation.] The *arc of regression*, Ptolemy's [Greek: περιφέρεια προηγητικὴ (periphereia proēgētikē, "preceding arc")], is the arc of the epicycle continued from the point of the first station, through the perigee, to the point of the second station. This arc is always smaller than the arc of direction, because both stations occur within and below the points of contact of the epicycle.

[Margin: Arcs of the 1st and 2nd station.] The *arc of the first station* is the arc of the epicycle reckoned from the apogee of the epicycle in the order of the signs to the point of the first station; the *arc of the second station* is the one

counted from the apogee, through the 1st station and the perigee of the epicycle, to the point of the second station.

III. [Margin: Definitions in the hypothesis of the moved Earth.] The definitions already mentioned also hold in the hypothesis of the Earth moving with an annual motion, once mention is dropped of the epicycle in the superior planets, in place of which the great orb is to be substituted, and of the Ptolemaic eccentric in the inferior planets, in place of which the great orb is likewise to be substituted. So in this Copernican and Philolaic hypothesis a planet that is superior and slower than the Earth is [Margin: Direct.] *direct* when the visual lines, or lines of apparent motion, of the planet and the Earth on neighbouring days intersect one another between the Earth and the planet, or at the centre of the Earth, or behind the Earth in the quarter away from the planet; [Margin: Stationary, retrograde.] it is *stationary* when the two lines just mentioned are parallel; and it is *retrograde*, finally, when their intersection falls beyond the planet. The planets that are inferior, or interior to the annual orb, are *direct* when the lines already mentioned, which join to each other the termini of the diurnal motions of the planet and the Earth, bend in the order of the signs; and *retrograde* when those lines bend back against the order of the signs and intersect one another behind the Earth, in the quarter turned away from the Sun. The points of the stations are determined in this hypothesis from a distance and somewhat crudely, by drawing from the superior planet to the Earth's great orb, or from the Earth to the inferior or interior orbs of the planets, two straight lines tangent, in the former case to the annual orb, in the latter to the orb of Venus or of Mercury; for the points of the stations lie below the points of contact, though not far from them, except in Mars. [Margin: Arc of retrogradation.] The *arc of retrogradation*, finally, is either the arc of the ecliptic included between two neighbouring apparent stations of the planet; or the arc of the great orb included within the two pairs of parallels that determine the stations; or else the arc of the planet's eccentric which the planet runs through from one station to the next, determined by the two pairs of parallels, etc. So, more or less, Kepler in the *Epitome of Copernican Astronomy*, pp. 743 and 767. For the figure for this hypothesis see below, chapter 4.

Loca in Epicyclo, in quibus fiunt Stationes, seu Quantitas arcuum ad eas spectantium, cum numero & tempore tum earum, tum Directionum ac Retrogressuum.

The places in the epicycle at which the stations occur, or the size of the arcs relating to them, with the number and time both of the stations and of the directions and retrogressions.

IV. [Margin: Aspects with the Sun at which the stations occur.] First, if we want to designate the places of the stations from a distance, Saturn becomes stationary between the square and the trine aspect with the Sun, Jupiter roughly at the trine, and Mars beyond the trine, both before and behind; Venus after

five signs of the argument on one side and after six on the other; Mercury after four on one side and seven signs of the argument, or of the anomaly of the orb, on the other. But if we want to know these places more accurately, then either from the Ptolemaic canon, Book 12, chapter 8, or from the Prutenic tables, which in this matter Magini followed in Book 2 of the *Theoricae*, chapter 12, and Lansbergen in his tables, p. 158, we shall take the arcs of the first and second station. When the arc of the first station is subtracted from the arc of the second, the arc of retrogradation will remain; and this, subtracted from the whole circle, will leave the arc of direction. So, according to the authors mentioned, the size of these arcs is as written below.

Arcs of the stations, etc., from Ptolemy [ARCVS STATIONVM &c. EX PTOLEMÆO.]

Planet	In the eccentric	Arc of station 1	Arc of station 2	Arc of retrogradation	Arc of direction
♄	Apogee	112° 45′	247° 15′	134° 30′	225° 30′
♄	Mean long.	114° 1′	245° 59′	131° 58′	228° 2′
♄	Perigee	115° 29′	244° 31′	129° 2′	230° 58′
♃	Apogee	124° 5′	235° 55′	111° 50′	248° 10′
♃	Mean long.	125° 32′	234° 28′	108° 56′	251° 4′
♃	Perigee	127° 11′	232° 49′	105° 38′	254° 22′
♂	Apogee	157° 28′	202° 32′	45° 4′	314° 56′
♂	Mean long.	162° 18′	197° 42′	35° 24′	324° 36′
♂	Perigee	169° 9′	190° 51′	21° 42′	338° 18′
♀	Apogee	165° 51′	194° 9′	28° 18′	131° 42′ [recte: 331° 42′, per the book's errata; corrected by hand to 331 in this copy]
♀	Mean long.	167° 7′	192° 53′	25° 45′	134° 15′ [recte: 334° 15′, per the book's errata; corrected by hand to 334 in this copy]
♀	Perigee	168° 21′	191° 39′	23° 18′	336° 42′
☿	Apogee	147° 14′	212° 46′	65° 32′	294° 28′
☿	Mean long.	144° 40′	215° 20′	70° 40′	289° 20′
☿	Perigee	144° 40′	215° 20′	70° 40′	289° 20′

Arcs of the stations, etc., from the Prutenic tables, Magini and Lansbergen [ARCVS STATIONVM &c. Ex Prutenicis, Magino & Lansbergio.]

Planet	In the eccentric	Arc of station 1	Arc of station 2	Arc of retrogradation	Arc of direction
♄	Apogee	112° 38′	247° 22′	134° 44′	225° 16′
♄	Mean long.	113° 58′	246° 2′	132° 4′	227° 56′
♄	Perigee	115° 21′	244° 39′	129° 18′	230° 42′

Planet	In the eccentric	Arc of station 1	Arc of station 2	Arc of retrogradation	Arc of direction
☿ [recte: ♃, per the book's errata; corrected by hand to ♃ in this copy]	Apogee	124° 8′	235° 52′	111° 44′	248° 16′
♃	Mean long.	125° 40′	234° 20′	108° 40′	251° 20′
♃	Perigee	127° 19′	232° 41′	105° 22′	254° 36′
♂	Apogee	157° 33′	202° 27′	44° 54′	315° 6′
♂	Mean long.	162° 51′	197° 9′	34° 18′	325° 42′
♂	Perigee	168° 56′	191° 4′	22° 8′	337° 52′
♀	Apogee	166° 1′	193° 59′	27° 58′	332° 2′
♀	Mean long.	167° 7′	192° 53′	25° 46′	334° 14′
♀	Perigee	168° 15′	191° 45′	23° 30′	336° 30′
☿	Apogee	146° 50′	213° 10′	66° 20′	293° 40′
☿	Mean long.	143° 55′	216° 5′	72° 10′	287° 50′
☿	Perigee	146° 0′	214° 0′	68° 0′	292° 0′

On the boundaries of the stations according to Kepler, I shall speak more opportunely at the end of chapter 4.

V. The time, moreover, in which these planets linger in the stations, or run through the arcs already mentioned, varies and differs not only as between the planets but also for the same planet when it is at one time swifter and at another slower. Nevertheless, for anyone who wants to know it roughly, we say that the mean time of a station is about 8 days for Saturn, 4 for Jupiter, 2 for Mars, 1 ½ for Venus and 0 ½ for Mercury. Again, the mean time of the direct course is about 244 days for Saturn, 284 for Jupiter, 705 for Mars, 542 for Venus and 93 for Mercury. The mean time of retrogradation, likewise, is 136 or 140 days for Saturn, 120 or 122 for Jupiter, 73 for Mars, 42 for Venus and 22 for Mercury. Or, if we follow the opinion of Ptolemy in Book 12, from chapter 2 to 6, the mean times of the regressions stand as follows, as also reported by Jābir ibn Aflaḥ in Book 8.

Mean time of the regressions, from Ptolemy [Tempus Mediocre Regressuum ex Ptolemæo]

Planet	At the apogee of the eccentric	At the perigee of the eccentric
♄	$140^{d}\ 16^{h}$	$136^{d}\ 0^{h}$
♃	$122^{d}\ 12^{h}$	$118^{d}\ 0^{h}$
♂	$80^{d}\ 0^{h}$	$64^{d}\ 12^{h}$
♀	$43^{d}\ 0^{h}$	$40^{d}\ 16^{h}$
☿	$22^{d}\ 12^{h}$	$21^{d}\ 0^{h}$

But if you want the true time for each single year, consult the ephemerides, especially if they note these times separately, as Origanus did at the end of each year. The inequality in these is, however, much greater in Mars, Venus and

Mercury. From these and other phenomena, before we investigate their causes from the theory of the Ptolemaic or Copernican hypothesis, we may now take a foretaste of the following propositions, accepted by astronomers as almost axioms.

Proposition 1. *The higher any planet is, or the slower in its own proper motion, the longer it lingers, other things being equal, in either of its stations.*

[Margin: Frequency of stations, progressions and regressions.] Proposition 2. *The higher any of the three superior planets is, the more stations it has; among the inferior planets, however, the nearer it is to the Sun, the more stations it has.* Therefore Saturn makes more stations than Jupiter, and Jupiter more than Mars, just as Mercury makes more than Venus, because the Sun by its motion, or the Earth, overtakes the slower Saturn sooner and therefore more often, and overtakes Jupiter sooner than Mars. Conversely, Mercury completes its period around the Sun in a shorter time, and overtakes the Sun's place or the Earth sooner than Venus does. In this respect, then, the superior and inferior planets behave in opposite ways: the slowest of the superior planets, but the swiftest of the inferior, make the more frequent stations. The same is to be understood of the directions and retrogradations, for they recur as often as both stations do.

[Margin: Duration of direction and of retrogression.] Proposition 3. *The higher any one of the superior planets is, whether than another planet or than itself, or the farther any of the inferior planets is from the Sun, the longer it remains retrograde, but the shorter direct.*

[Margin: Ratio of the intervals and of the time.] Proposition 4. *There is not, however, the same ratio between the durations of the progressions or regressions as between the intervals of the planets.* This is clear to anyone who compares the times of these arcs, given a little earlier, with the distances of the planets from the Earth, set out at the end of the chapters of Sections 2 and 3. For Saturn is nearly twice as high as Jupiter, and Jupiter about three times higher than Mars; and yet the time of Saturn's retrogression is only slightly longer than Jupiter's, and the time of Jupiter's retrogression is no longer than about one and a third times that of Mars.

[Margin: Arc of the ecliptic in the regress.] Proposition 5. *The higher any one of the superior planets is, the smaller the arc of the ecliptic it runs through in its regress.* This proposition seems contrary to the third; but there the discussion concerns the time in which the planet frees itself from the regress.

Proposition 6. *The higher any one of the superior planets is, whether than another or than itself, the greater the arc of retrogradation and the smaller the arc of direction it runs through.*

Proposition 7. *In Saturn, Jupiter, Mars and Venus, the closer the centre of the epicycle is to the perigee of the equant, or to the centre of the world, the nearer the points of the stations are to the perigee of the epicycle.*

Some of the propositions already mentioned are held by Nonius, Magini, Kepler, Hérigone and others listed in chapter 1; on these, however, read the scholia of the following chapter 3.

CAPVT III.

Chapter 3.

Theorica & Causæ Stationum, Directionum, & Retrogradationum ex sententia Antiquorum ac Hypothesi præsertim Ptolemaica.

The theory and causes of the stations, directions and retrogradations, according to the opinion of the ancients and the hypothesis, especially the Ptolemaic.

I. [Margin: Opinion of the Latins on the cause of the stations and retrogradations.] Some of the Latins, not very much skilled in mathematical matters, conjectured that the cause of slowing the motion of these planets, and of quickening, halting or drawing them back, lay in the aspects of the Sun, and judged that the square of the Sun harms Saturn, the trine Jupiter, and Mars something more. *They do not know*, says Kepler in the *Epitome of Copernican Astronomy*, p. 744, *that these aspects, insofar as they can indeed become effective on these lower things, are terrestrial rather than celestial beings: for the aspects are not in the planets themselves, but only here on the Earth. Nor did they consider that aspects are formally beings of reason*, etc.

[Margin: Opinion of Pliny the Elder.] On these matters, however, Pliny the Elder spoke crudely or obscurely enough in Book 2, chapter 15, saying of the three superior planets: *In the triangle, at 120°, they make morning stations, which are also called first; and likewise at 120° from the other side, on its approach, evening stations, which they also call second.* And in chapter 16: *There is no doubt that at their morning risings the number also increases, and that from the first stations the three superior planets decrease down to the second stations. This being so, it will be evident that from the morning rising they climb in latitude, since on that departure the motions first begin to be added more sparingly; and that at the first stations they also go up in altitude, since then the numbers first begin to be subtracted and the stars to go back. The reason for this must be given separately. Struck, in the part we have named and in the triangle, by the ray of the Sun, they are prevented from keeping a straight course, and they are lifted on high by a fiery force. This cannot be perceived at once by our sight, and so they are thought to stand still: from this the station also took its name. The violence of that same ray then advances, and the vapour, beaten back, forces them to go back. This happens much more at their evening rising, with the whole Sun opposite, when they are driven out to the highest apsides and are least seen, because they are at their farthest height and are carried with the least motion, all the smaller when this happens in the highest signs of the apsides. From the morning rising the latitude is descended, with the motion now diminishing itself more sparingly, yet not increasing before the second stations, when the altitude too is descended, as the ray comes over from the other side and by the same force presses back down to the Earth what it raised into the heaven from the former triangle; so much does it matter whether the rays come from below or come over from above. And the same things*

happen much more at the evening setting. This is the account of the superior stars, more difficult than that of the others, and given by no one before us. How much rind there is in these words, and how little kernel? In summary, however, Pliny the Elder judges that from the triangle, or first trine aspect, to the second, the ray of the Sun comes upon the three superior planets from above, and by the force of its fiery vapour draws them back upward as if with a hook; but that in the remaining portion of the orb the ray comes from below and urges the planets on. Not much better is what he adds in chapter 17, as when he says that Mercury stands nearly motionless for four days, and refers its stations or regressions and those of Venus to the Sun. *For those that strain towards the vapour of the Sun also descend with difficulty.* And shortly after: *In the star of Mars, whose course is most unobservable, it never makes a station with the star of Jupiter in the triangle, and very rarely when it is 60° apart, a number that produces the six-angled forms of the world.*

II. Almost the same opinion was held, before Pliny the Elder, by Vitruvius, in Book 9, chapter 4, from whose very many words we have selected these: *The stars of Mercury and Venus, crowning the Sun itself as a centre with their paths around the rays of the Sun, make their regressions backward and their retardations, and by reason of that circling they also linger with stations in the spaces of the signs.* And shortly after: *The star of Mars, in whichever signs it runs through more swiftly when it has made a station, fills out the reckoning of the number of its days.* And, after mentioning the revolution of Jupiter and Saturn: *These, however, which complete their circlings above the path of the Sun, especially when they are in the trine that it has entered, then do not advance, but linger, making regressions, until the same Sun has made its passage from that trine into another sign.* [Margin: A trifling opinion on the cause of the stations.] *Some hold that this comes about because, they say, when the Sun is farther off at a certain distance, the stars wandering through those parts on paths that are not lit are impeded by obscured lingerings. That does not seem so to us. For the splendour of the Sun is visible and open, without any obscurations, throughout the whole world, as it appears even to us when these stars make their regressions and lingerings. So if across such great intervals our sight can perceive this, why do we judge that obscurities can be cast upon the divinities and splendours of the stars?* After this he at once adds his own opinion in these words: [Margin: Opinion of Vitruvius on their cause.] *So this account will rather stand firm for us: that just as heat calls forth all things and draws them to itself (as we also see fruits rising from the ground to a height through warmth, and no less the vapours of water being raised from springs to the clouds through arcs), in the same way the vehement force of the Sun, its rays stretched out in the form of a triangle, draws to itself the stars that follow it, and, as though reining in and holding back those running ahead, does not let them advance but compels them to go back towards itself and to be in the sign of another triangle. Perhaps it will be asked why the Sun, in the fifth sign from itself rather than the second or third, which are nearer, produces retentions in these heats. I shall explain how this seems to happen. Its rays in the world extend in lines, as in the form of a triangle with equal sides, and that is neither more nor less than to the fifth sign from*

it. So if the rays, poured through the whole world, wandered in circlings, and were not extended and drawn out into lines in the form of a triangle, they would scorch nearer things, etc. For the rest, which is certainly obscure amid such frequent mention of rays, see Vitruvius, reader, if you have the time and the inclination.

III. [Margin: Opinion of Apollonius of Perga and of Ptolemy on the cause of the stations and regressions.] But Apollonius of Perga, and Ptolemy following him in Book 12, chapter 1 and those after it, and the whole school of astronomers down to Copernicus, attributed the cause of the stations and retrocessions apparent to us to the motion of the centre of the epicycle and of the planet in the epicycle, both made in consequentia of its own orb, and to a certain commensuration of the epicycle with the deferent. For Apollonius showed that a regress cannot befall any star unless its epicycle is so arranged that its semidiameter has to the straight line drawn from the centre of the world to the perigee of the epicycle a greater ratio than the motion of the centre of the epicycle has to the planet's motion in the epicycle; and that if it has this ratio, the point of the station is bounded by the line which, drawn from the centre of the world, cuts the epicycle so that half of the portion enclosed within the epicycle keeps to the outer portion the ratio that the motion of the centre of the epicycle has to the motion of the planet in the epicycle. And although Apollonius taught this of a concentric deferent, Ptolemy nevertheless adapted it to the eccentric.

Theorem 1. *If the ratio of the semidiameter of the epicycle to the distance of the perigee of the epicycle from the centre of the Earth is not greater than the ratio of the speed of the motion of the centre of the epicycle to the speed of the motion of the planet in the epicycle, the star cannot appear retrograde to us. But if it is greater, then, whether the epicycle moves in a concentric or in an eccentric, and even if both motions, of the epicycle and of the deferent, are according to the succession of the signs, an apparent station and retrogradation about the perigee of the epicycle will be possible, indeed necessary.*

IV. [Margin: Description of the figure for this and certain other propositions.] This theorem is demonstrated, after Apollonius, by Ptolemy in Book 12, chapter 1; Jābir ibn Aflaḥ, Book 8 of the *Astronomy*; Regiomontanus in the *Epitome of the Almagest*, Book 12, propositions 1, 2 and 4 taken together; Nonius, annotation 1 on the Peuerbachian affections of the planets; and Copernicus, Book 5, chapter 35. For this purpose, in the following diagram let E be the centre of the Earth, and ED the distance of the centre D of the epicycle AC from the centre of the world; and, ED being produced to A, let A be the true apogee of the epicycle and C the perigee. With tangents EK and EL drawn from E to the periphery of the epicycle, let the eastern and left contact be at the point L, and the right and western at the point K.

Then, from E, let two lines EGB and EMH be drawn cutting the epicycle, in any way at all, but so that the arcs intercepted by them and the perigee, namely CG and CM, are equal; and let the lower points of intersection be joined to

the centre of the epicycle by the straight lines DG and DM. We shall explain the remaining lines and letters below.

[Margin: 1st part of the theorem.] With these things set down, I say *first* that if the ratio of the semidiameter DC to the distance CE is not greater than the ratio of the speed of the centre D to the speed of the planet in the epicycle, it cannot come about that the planet appears retrograde. For if it can, it can certainly do so most of all near the perigee C, where the motion of the planet in the epicycle, or of the argument, most diminishes the motion in longitude of the centre D. But it cannot, however close the planet G or M may be to the perigee C. For let the arc GC be as small as possible. Because the base of the triangle DGE is divided into two portions, EC and DC, and one of them, DC, is not smaller than the side adjoining it, DG, but equal to it, since each is a semidiameter of the same epicycle, the ratio of the line DC to CE will be greater than that of the angle GED to the angle EDG (by the demonstration of Apollonius, of Ptolemy in Book 12, chapter 1, and of Regiomontanus in Book 12 of the *Epitome*, proposition 3; we assume this demonstration for the moment, and shall bring it in below, so that the order of the present one is not disturbed). Therefore the ratio of the angle DEG to the angle EDG will be smaller than that of the line DC to CE, by Euclid, Book 5 of the *Elements*. But the ratio of DC to CE was laid down as not greater than the ratio of the speed of the centre D to the speed of the planet G in the epicycle. Much smaller, therefore, will be the ratio of the angle DEG to the angle EDG than the ratio of the speed of the centre D to the speed of the planet G. Now the speed of the planet G is determined by the angle CDG; therefore the angle of the speed of the epicycle is greater than the angle CEG. Now let the angle that must be greater than DEG be, I say, DEL. So if D, the centre of the epicycle, were at rest while the planet describes the arc GC, which subtends the visual angle GEC, the planet would seem to go back against the succession of the signs. But because in the same time the centre D has described the arc DL, which subtends the greater angle DEL, in consequentia of the signs, the planet will therefore appear to move directly and in the order of the signs, by a motion as great as the difference, the angle LEG, by which the angle LED exceeds the angle GED. Given, then, what was laid down before, it is not possible for the planet to appear retrograde, however small the arc GC may be. And the same will be shown in like manner by taking the arc CM on the other side. For while, because of the motion of the planet M in the epicycle, the arc CM will seem, under the angle CEM, to have been passed through against the series of the signs, yet in the same time the centre D, from the outer point K, has described the arc DK and the greater angle DEK. And so, since the motion of the centre D in the succession of the signs overcomes the motion of the planet M against the succession, the planet will appear to have advanced directly.

Diagram. Set into the left column, with the text running down its left side. A circle, the epicycle, with a long narrow fan of straight lines running from the single point E at the foot up to the circle and through it. A vertical line runs

from E through C and the centre D to the top of the circle. A nearly horizontal line through the centre joins L at the left to K at the right, the two outermost lines of the fan meeting the circle at those points. Shorter lines join the centre to G and M and to points on the lower arc between them.

- R and A (top of the circle, set side by side and separated by a point): R.A
- F (upper left, on the circle)
- B (upper left, below F, on the circle)
- H (upper right, on the circle)
- S and D (at the centre, S left of the vertical line, D right of it)
- L (far left, at the horizontal line's end)
- P (inside the circle, on the horizontal line, right of L)
- Q (inside the circle, on the horizontal line, immediately right of P)
- O (inside the circle, on the horizontal line, right of centre)
- K (far right, at the horizontal line's end)
- G (lower left, on the circle)
- V (bottom of the circle, right of G)
- T and I (bottom of the circle, right of V, set close together)
- C (bottom of the circle, on the vertical line)
- M (lower right, on the circle)
- E (foot of the figure, where all the lines meet)

[Margin: 2nd part of the theorem.] *Second*, I say that if the ratio of the line DC to CE is greater than the ratio of the speed of the centre D to the speed of the planet in the epicycle, it must be that the planet sometimes appears retrograde. This can be gathered both from the converse method of the preceding demonstration and from what is to be said below. For through the planet, as it approaches the perigee of the epicycle and has passed the point of contact, say through the planet G, a secant EGB can be drawn, such that, with its portion BG inside the epicycle bisected at P, the ratio of the half PG to the outer portion GE is as the ratio of the speed of the centre D to the speed of the planet G in the epicycle; and say the same of the half OM to ME. From this it follows that the planet at G or M is stationary, and within these points, that is, in the arc GCM, retrograde, as will be demonstrated below. For in receding from the line EA, the lines of the secants enclosed within the epicycle gradually diminish, and their outer portion increases. Now what was assumed earlier, in point 1 above, in the parenthesis, must be shown.

Theorem 2. *If the base of a rectilinear triangle is cut into two portions, one of which is not smaller than the side adjoining it, the ratio of that portion to the rest of the base will be greater than the ratio of the angles at the base, with their order interchanged.*

V. [Margin: Lemma of Apollonius.] Apollonius used this as a lemma, as Ptolemy attests in Book 12, chapter 1; Regiomontanus uses the same in Book 12 of the *Epitome*, proposition 3, and Copernicus in Book 5, chapter 35. For this, in the following figure let there be a triangle DAB, whose base AB is cut at I so that one portion, say BI, is not smaller than the side BD adjoining it; for the

ratio of the line BI to IA will be greater than that of the angle DAB to the angle DBA. First let BI be equal to BD; and let a line BG be drawn from B parallel to the dividing line DI, as far as the point E, at which the other side AD, when produced, meets it. Likewise, let a line DG be drawn from D parallel to the line AB. For the two sides BI and GD of the parallelogram IBGD will be equal, just as DI and BG are. Therefore from D, with the semidiameter DG, let an arc of a semicircle be described; for it will pass through B, since DG is equal to BI and so to BD. Therefore the ratio of the triangle EGD to the triangle DGB is greater than the ratio of the sector CDG to the triangle DGB, since the sector CGD is part of the triangle EDG. But the ratio of the sector CDG to the triangle GDB is greater than its ratio to the sector GDB; much greater, therefore, is the ratio of the triangle EDG to the triangle GDB than that of the sector CDG to the sector GDB. Moreover, the ratio of the triangle EDG to the triangle GDB is as the ratio of the line EG to the line GB, since these are bases of triangles of the same height; and EG is to GB as ED to DA, and therefore as BI to IA. Therefore the ratio of the triangle EDG to the triangle GDB is as that of the line BI to IA; and likewise the ratio of the sector CDG to the sector GDB is as the ratio of the angle CDG to the angle GDB; and the two angles DAB and DBA are equal to these angles of the sectors. So the ratio of the sector CDG to the sector GDB is as that of the angle DAB to the angle DBA. But the ratio of the triangle EDG to the triangle GDB was shown to be greater than the ratio of the sector CDG to the sector GDB; therefore also the ratio of the line BI to IA is greater than the ratio of the angle DAB to the angle DBA, which was to be shown. But if BI is greater than DB, it will be possible, with straight lines drawn as before and the arc described, to argue as above.

Diagram. Set into the right column, with the text running down its left side. A tall narrow triangle with E at the apex and A at the foot, the vertical side EA passing through C and D. The side from E runs down through G to B. An arc about D runs from C through G and B towards I. D is joined to G and to B; G is joined to B; B runs to A through I; and D is joined to I.

- E (apex)
- C (on the vertical side, where the arc begins)
- G (on the slanting side, where the arc meets it)
- D (on the vertical side, centre of the arc)
- B (far left of the figure)
- I (on the line from B to A)
- A (foot)

Applying this lemma, therefore, to the preceding theorem: since the triangle EGD is cut at C so that the portion DC is not smaller than, but equal to, the side DG adjoining it, the ratio of the line DC to CE will be greater than the ratio of the angle GED to the angle GDE, which is what was assumed there.

Theorem 3. *Neither the Sun, even if it is supposed to move in a concentrepicycle, nor the Moon is capable of station and retrogradation.*

VI. It is common among astronomers, and above all to Regiomontanus, Book 12 of the *Epitome*, proposition 4, to Maurolico in dialogue 3 of the *Cosmographia*, p. 95, to Wurstisen on the *Theoricae*, p. 248, to Reinhold on the *Theoricae*, p. 143, and to Kepler in the *Epitome of Copernican Astronomy*, p. 749; and it is shown, *first*, of the Sun. [Margin: Why the Sun is incapable of retrogradation.] For if the Sun moves, as we have supposed elsewhere along with most authors, in a simple eccentric, it moves around the centre of the Earth always in consequentia of the signs, and in that hypothesis there is no meeting with another motion that at some time draws it back against the succession of the signs. But if it moves in a concentrepicycle, as Longomontanus would have it, then, to save the phenomena of the Sun, it must move in the epicycle against the order of the signs at the top, and the centre of the epicycle must move in the order of the signs around the centre of the world with equal speed of motion, so that it completes each day as many degrees on the periphery of the concentric as the Sun completes on the circumference of the epicycle; and the semidiameter of the Sun's epicycle must be not sensibly greater than the eccentricity of the Sun usually employed in the other hypothesis, that of the eccentric, as is clear from what was said in Book 3, chapter 19. Now the eccentricity, and hence the semidiameter of the epicycle, does not have to the radius a ratio greater than about 4000 to 100000, as is clear from what was said in Book 3, chapter 24, or as 4 to 100. Therefore in the figure of Theorem 1, DC to the outer portion CE is only as 4 to 96, or as 1 to 24, and so it is much smaller than the ratio of the speed of the centre D to the speed of this planet in the epicycle, since the latter is as 1 to 1, the ratio of equality. Therefore, by Theorem 1, the Sun, with the phenomena saved, cannot appear stationary or retrograde.

[Margin: Why the Moon is incapable of station and regress.] *Second*, the Moon is indeed carried by an eccentrepicycle, so that the epicycle is borne in the order of the signs in its lower part, but against the order of the signs in its upper; yet the speed of the centre of the epicycle is nearly equal to the speed of the Moon in the epicycle. For the mean daily motion of the centre of the Moon's epicycle is $13^\circ\ 10'\ 35''\ 1'''\ 18''''\ 16^{v}$, while the daily motion of the Moon in the epicycle, or of the simple anomaly, is $13^\circ\ 3'\ 53''\ 56'''\ 30''''$, as we said in Book 4, chapter 23. And the semidiameter of the Moon's epicycle is to the radius of the eccentric as 10576 to 100000, or very nearly so, according to what was said in Book 4, chapter 25. Therefore the ratio of DC, the semidiameter of the epicycle, to the outer portion CE of the radius (it is as 10½ to 89½) is much smaller than the ratio of the speed of the centre D to the speed of the Moon in the epicycle, which is almost the ratio of equality. Therefore not even the Moon is capable of station or retrogression.

Theorem 4. *If the luminaries were capable of station and retrogression, this would happen to them in the upper part of the epicycle, that is, at the apogee of the epicycle.*

VII. [Margin: Opinion of Maurolico on the stations of the luminaries.] Maurolico pointed this out to us in dialogue 3 of the *Cosmographia*, p. 93,

saying: *As to the luminaries, whose epicycles are carried in the contrary sense: the semidiameter of the epicycle is to be compared with the whole secant. So if a regress befell the luminaries, the points of the stations would fall in the upper arc of the epicycle; and in place of the outer portion of the line bounding the stationary point, the whole bounding line would have to be taken. We have carried out the demonstration of this matter elsewhere, although it is rather a matter of curiosity than of any usefulness, and was therefore omitted by Apollonius.* But this can easily be made clear, because station and retrogression occur where two motions come together, of which the one, towards one quarter, either equally blunts the other, towards the other quarter, or overcomes it. Since, therefore, the luminaries in the epicycle, with the other phenomena saved, cannot move towards the quarter contrary to the motion of the centre of the epicycle, that is, against the order of the signs, except in the upper part of the epicycle, only in that part would the points of the stations and the arc of regression lie, if these affections were not otherwise incompatible with them.

Theorem 5. *All five minor planets necessarily become stationary and retrograde at some time.*

VIII. This too is accepted by everyone. And even if the experience of observations were lacking, from which it is evident a posteriori that these planets have quite often appeared retrograde, and hence stationary, yet this same thing was demonstrated, from the hypothesis of motion in longitude that uses an eccentrepicycle, by Ptolemy, with Apollonius, in Book 12, chapter 1; Regiomontanus in the *Epitome*, Book 12, proposition 4; Jābir ibn Aflaḥ, Book 8; Pedro Nunes on Peuerbach's theory of the affections, annotation 1; and on the same affections Reinhold, p. 145. The sum of the demonstration is this: those planets necessarily become at some time stationary and retrograde whose semidiameter of the epicycle has to the distance of the perigee of the epicycle from the centre of the Earth a greater ratio than the ratio of the speed of the centre of the epicycle to the speed of the planet in the epicycle, as is clear from Theorem 1. But all five minor planets, at every distance of the centre of the epicycle from the Earth, are of this kind, as is clear from their motions and from the ratios of the orbs set out and proved in this Book 7, Sections 2 and 3. Therefore all are necessarily subject to stations and retrogressions. However, to make the subsumed proposition of the preceding syllogism more readily evident, Reinhold adds two small tables. In one of them, according to the Ptolemaic and almost the Alphonsine and Peuerbachian hypothesis, is contained on the one side the ratio of the semidiameter of the epicycle DC, as in the figure of number 4, to the distance CE of the perigee C from the centre of the Earth E; on the other, the ratio of the speed of the centre of the epicycle to the speed of the planet in the epicycle, the size of the epicycle and the speed of its centre being reduced to the same number 390. In the other is contained the ratio that remains after the ratio of the speed of the centre to the speed of the planet has been subtracted from the greater ratio, that of the semidiameter

DC to the distance CE, the former number being reduced to the same 3367. It seemed good to copy them out here.

[Margin: See the figure of Theorem 1.]

	In the eccentric	Ratio of the line DC to CE, as 390 to	Ratio of the speed of D to the speed of the planet, as 390 to	Residual ratio, after the smaller is subtracted from the greater, is as 3367 to
♄	At apogee	3415	12482	921
	Mean long.	3220	11087	978
	At perigee	3025	9837	1028
♃	At apogee	1738	4665	2156
	Mean long.	1645	4235	1308
	At perigee	1552	3836	1361
♂	At apogee	262	505	1748
	Mean long.	202	343	1980
	At perigee	146	213	2307
♀	At apogee	163	269	2034
	Mean long.	152	244	2097
	At perigee	139	220	2127
☿	At apogee	794	1293	2067
	Mean long.	650	1229	1779
	Nearest the Earth	575	1190	1627
	At perigee	598	1152	1748

Remember that in Ptolemy's hypothesis Mercury comes nearest the Earth not opposite the aux of the epicycle, but about the thirds.

Theorem 6. From this comes a problem for determining the points of the stations. *The planet makes a station at that point of the periphery of the epicycle through which a straight line drawn from the centre of the Earth as far as the concave side of the same periphery has its half-chord in the same ratio to the outer portion as the speed of the centre of the epicycle has to the speed of the planet in the epicycle.*

IX. This is Reinhold's proposition on Peuerbach's *Theoricae*, p. 146, and that of Pedro Nunes in the same place, annotation 1; in the form of a problem

for finding the points of the stations it is demonstrated, with Apollonius and Ptolemy, by Regiomontanus in the *Epitome*, Book 12, proposition 5. For both, therefore, let the figure of the first theorem be repeated here, and besides the lines drawn and set out there, let there also be drawn from the centre of the Earth let two other straight lines be drawn cutting the epicycle and produced as far as the concave periphery; let these be EVF and EIR. And let the points of intersection V and I be joined to the centre of the epicycle by the straight lines DV and DI, and the point F to G and I by the straight lines FG and FI. And of the former secants EB and EH, let the inner portions, or chords, GB and MH be bisected at P and O by the perpendiculars DP and DO drawn from D, just as the chords FV and RI are to be understood as cut in two at Q and S by their respective perpendiculars. With these things set down, I say that if PG, which is half of the inner portion BG, has to the outer portion EG of the secant EB the same ratio that the speed of the centre D has to the speed of the planet in the epicycle, the point of the first station is at the point G; just as the point of the second station is at M, if the half OM of the chord HM has to the outer portion EM of the whole secant EMH the same ratio that the speed of the centre D has to the speed of the planet in the epicycle. We suppose, moreover, that DC has a greater ratio to CE than the speed of D to the speed of the planet, so that the planet is capable of standing and going back. It is further supposed that such a secant can be drawn between EA and the tangents EL and EK; and that the farther the secants stand from the straight line drawn through the centre of the epicycle, the smaller the ratio their inner portion has to their outer.

Diagram. Set into the left column, with the text running down its left side. The figure the text calls the figure of the first theorem, repeated: a circle, the epicycle, with a long narrow fan of straight lines running from the single point E at the foot up to the circle and through it. A vertical line runs from E through C and the centre D to the top of the circle. A nearly horizontal line through the centre joins L at the left to K at the right. Lines join the centre to G and M and to points on the lower arc between them, and lines run from F down to points on the same arc.

- R and A (top of the circle, set side by side and separated by a point): R.A
- F (upper left, on the circle)
- B (upper left, below F, on the circle)
- H (upper right, on the circle)
- S and D (at the centre, S left of the vertical line, D right of it)
- L (far left, at the horizontal line's end)
- P (inside the circle, on the horizontal line, right of L)
- Q (inside the circle, on the horizontal line, immediately right of P)
- O (inside the circle, on the horizontal line, right of centre)
- K (far right, at the horizontal line's end)
- G (lower left, on the circle)
- V (bottom of the circle, right of G)
- T and I (bottom of the circle, right of V, set close together)

- C (bottom of the circle, on the vertical line)
- M (lower right, on the circle)
- E (foot of the figure, where all the lines meet)

[Margin: Lemma of Nunes and Reinhold for the points of the stations.] This, however, Pedro Nunes and Reinhold demonstrate in the places above. For in this same figure the chord RI is smaller than AC, the greatest of the chords; FV is smaller than RI; and BG smaller than FV, by 15 of the third book of the *Elements*; and by 8 of the same, EC is smaller than EI; EI than EV; and EV than EG. Therefore the half DC is greater than the half-chord SI, and this is greater than QV, and this than PG. And therefore, by 8 of the fifth book of the *Elements*, the ratio of DC to CE is greater than that of SI to CE; the ratio of SI to IE greater than that of QV to IE; and finally the ratio of QV to VE greater than that of PG to VE; and by the same proposition SI to CE is greater than to IE. Therefore the ratio of DC to CE is much greater than the ratio of SI to IE; and in the same way it will be proved that the ratio of SI to IE is greater than that of QV to VE; and of QV to VE greater than that of PG to GE; and that the greatest of all is that of DC to CE. With this lemma assumed, let us come to the main demonstration.

X. [Margin: Demonstration of Theorem 6.] So let the portion QV of the secant EF be supposed to have to VE the same ratio that the speed of the centre D has to the speed of the planet; and, taking an arc VG, as small as you please, towards the apogee, and VI towards the perigee, let the remaining lines be drawn as above. For because the base FE of the triangle FGE is divided into two portions, of which VF is greater than the side FG adjoining it, then by Theorem 2 of this chapter the ratio of the line FV to VE will be greater than the ratio of the angle FEG to the angle GFE, and therefore greater than the ratio of double the angle FEG to double the angle GFE. Therefore the ratio of half the line FV, that is, of the line QV, to the line VE is greater than that of the angle FEG to double the angle GFE, that is, to the angle at the centre GDV, which is double the angle GFV or GFE, by 20 of the third book of the *Elements*. But the ratio of the half QV to VE was laid down as equal to the ratio of the speed of D to the speed of the planet in the epicycle; therefore the ratio of the speed of the centre D to the speed of the planet is greater than that of the angle FEG to the same angle GDV. Therefore the angle of the speed of the centre D, corresponding to the angle GDV of the speed of the planet, is greater than the angle FEG, or equal to the angle of the speed of the centre D. For while the planet in the epicycle describes the arc GV, that is, the angle GDV, it will seem at the centre of the world to have described against the succession of the signs, as far as the epicycle's part goes, the angle GEV; but in the same time the centre of the epicycle describes the arc QL in the order of the signs, and the whole epicycle advances by as much as the angle LEV subtends. The epicycle, or the centre D, has therefore advanced more than the planet has gone back, by an excess as great as the angle GEL. Therefore in the whole arc GV the planet appears direct.

[Margin: 2nd part of the theorem.] Now let the arc VI be taken towards the perigee of the epicycle, however slight, and let the lines ordered above be drawn. For the base FVE will be so cut at V that the portion EV is greater than the side EI adjoining it. Therefore, by Theorem 2 of this chapter, the ratio of EV to VF will be greater than that of the angle IFE to the angle IEF; and so, conversely, the ratio of FV to VE will be smaller than that of FEI to the angle IFE, and therefore smaller than that of double the angle FEI to double the angle EFI. From this it comes about that the ratio of the half QV to the line VE is smaller than that of the angle FEI to double the angle IFE, namely to the angle at the centre VDI. But the ratio of the half QV to VE was laid down as equal to the ratio of the speed of the centre D to the speed of the planet. Therefore the ratio of the angle of the speed of the centre D to the angle of the speed of the planet is smaller than the ratio of the angle VEI to the angle VDI. And since the angle VDI is the one that measures the speed of the planet in the epicycle, the angle of the speed of the centre D will be smaller than the angle VDI. So let such a smaller angle be VET. While, then, the planet in the epicycle describes the arc VI, that is, the angle VDI, it seems from the centre of the Earth to have described the angle VEI, against the order of the signs, as far as the part of the motion in the epicycle goes; but in the same time the centre D, according to the succession of the signs, has described an arc subtending the angle VET. Therefore the retrocession of the planet is greater than the progress of the centre D, by an excess as great as TEI, through which the planet will seem to have gone back. [Margin: Conclusion of the theorem.] Now, therefore, since the planet has been shown to be direct in the whole arc GV and retrograde in the whole arc VI, it follows that the point V is the end of direction and the beginning of retrogradation, and therefore is the point of the first station. And the same will be shown in like manner of the point of the second station.

Theorem 7. *The points of the stations are nearer the perigee of the epicycle than the points of contact, that is, they lie within the points of contact.*

XI. If the planet moved with no other motion than its motion in the epicycle, in the order of the signs at the top and against the order of the signs at the bottom, as Capuanus [?] supposes in the *Theoricae*, the first station and the beginning of retrogradation would occur at the left contact of the epicycle, as in the figure of Theorems 1 and 6, at the point L, and the second at the right contact K. But because it moves with the motion of the centre of the epicycle, when it is at the left contact it is therefore still being carried forward towards the east and is still direct; and because of the same motion of the centre D it begins to be direct at M before it has reached the contact K. Then, since to make a station, by Theorem 6, it is required that the inner half-portion of a secant of the epicycle have to the outer portion a ratio equal to the ratio of the speed of the centre of the epicycle to the speed of the planet, whereas a tangent has no portion inside the epicycle, it is clear that the station cannot be at the contacts themselves; nor yet before the contact L or after the contact

K, because there the motion of the planet goes along with the motion of the centre D towards the east. It remains, therefore, that the stations occur within the points of contact, at points nearer the perigee C of the epicycle; and this opinion is indeed common to astronomers.

Theorem 8. *The points of the stations stand equally far from the perigee of the epicycle at an equal distance of the centre of the epicycle from the centre of the Earth.*

XII. This is demonstrated by Pedro Nunes in annotation 2 on the Peuerbachian affections of the planets. For in the figure of Theorem 6 let the point of the first station be at

G, and of the second at M, and let it be supposed that the motion of the centre D keeps the same ratio to the motion of the planet in the epicycle at both places, since the same distance DE of the centre D from the centre of the Earth is posited. Therefore by Theorem 6, as half of the straight line BG is to GE, so will half of the straight line HM be to ME, by 11 of the fifth book of the Elements; and therefore half of the straight line BG will be equal to half of the straight line HM. For if it were greater, then EG would be greater than EM, by 14 of the fifth book, and BG greater than MH; and so the rectangle contained by the whole EB and by EG would be greater than the rectangle contained by EH and by EM, which is impossible and contrary to the corollary of proposition 35 of Book 3 of Euclid. For the same reason half of BG cannot be less than half of HM. Now, as half of BG is to half of HM, so is EG to EM, by alternate proportion; therefore EG and EM will be equal. So when the equal lines DG and DM are drawn, the angles EDG and EDM will be equal by 8 of the first book, and thus by 26 of the third book the two arcs GC and MC, that is, the distances of the stationary points from the perigee C, will be equal.

Theorem 9. *The greater the epicycle, the nearer to the perigee of the epicycle are the points of the stations, if the stations occur at the contact itself.*

XIII. Nonius also touches on this theorem, in annotation 3 on the affections of the planets. In the adjoined diagram, let the greater epicycle KD and the lesser HC be described from the common centre B, and let their common distance from the centre of the Earth A be AB. From A let the tangents AC and AD be drawn, and let the points of contact be joined to B by the straight lines BC and BD; for by 18 of the third book of the Elements the angles at C and D will be right. Finally, let H and K be the perigees of the epicycles. With this laid down, the tangent AD of the greater epicycle cannot fall between AB and the tangent AC of the lesser, or coincide with it. For the triangles ADB and ACB, right-angled at D and C, stand on a common base subtending the right angle, and each singly has its three angles equal to two right angles, by 32 of the first book of the Elements; yet in such a way that the one which lies next to the same end of the base subtends a greater side than the other, namely the angle BAD subtends the side BD, which is the semidiameter of the greater epicycle. Therefore by the scholia to 26 of the first book of the Elements the angle BAD will be greater than the angle BAC; and so by 32 of the first book of the Elements the remaining angle ABD will be less than the remaining angle

ABC. Consequently, if BC is understood to be produced to the periphery of the greater epicycle, it will fall above D and will enclose with BK an arc greater than the arc DK. Now, as the angle ABC is to a right angle, so are the arc HC and the arc KD, etc., bounded by the higher point on which BC produced would fall, to the quadrants of their circles, by the last of the sixth book of the Elements; and so the arcs already mentioned will be proportional, or similar. Accordingly the arc KD will be less in proportion to its circle than the arc HC in proportion to its own, and accordingly the contact D will be nearer to the perigee K of the greater epicycle than the contact C to the perigee H of the lesser. But because the station does not occur at the contact itself, it does not immediately follow that in a greater epicycle the station is nearer the true perigee of the epicycle, unless other causes assist, as they do in fact assist in Saturn, Jupiter, Mars and Venus. Now let us come to the usefulness of selected problems.

Diagram. Set into the left column, with the text running down its left side. A long vertical axis joins two pairs of concentric circles, a larger pair at the top about B and a smaller pair at the foot about E, with A on the axis between them. From A straight lines rise to C on the inner upper circle and D on the outer upper circle; B is joined to C and to D. H stands on the axis at the foot of the inner upper circle and K at the foot of the outer one, with O lower on the axis, above A. In the lower pair, M and L stand on the axis at the top of the outer and inner circles; lines from A reach F on the inner circle and G on the outer, and E is joined to F and to G.

- Labels read, top to bottom: B, C, D, H, K, O, A, M, L, G, F, E. None unread.

Problem 1. *Given the distance of the centre of the epicycle from the apogee of the eccentric, to investigate the speed of the planet and of the centre of the epicycle corresponding to the mean motion.*

XIV. [Margin: Step 1.] First, with the mean distance of the centre of the epicycle from the aux of the eccentric, or with the mean centre, that is, with the mean anomaly of the eccentric, take the equation of the centre from the tables. To that same distance add the arc of mean motion in longitude, and with the sum look up a second equation of the centre; you will then have the difference of the equations, if there is any, which is to be called the centric difference. [Margin: Step 2.] Second, if the centre of the epicycle is between the mean longitudes and the perigee of the eccentric, subtract the centric difference from the mean motion of longitude; if otherwise, add it, provided that both the mean centre and the sum just mentioned place the epicycle in the same quadrant of the eccentric. Otherwise, if by the one it is in the first quadrant and by the other in the fourth quadrant of the eccentric, subtract the sum of the centric equations from the mean motion; but if by the one it is in the 2nd and by the other in the 3rd quadrant, add it. And so you will have the true motion of the centre of the epicycle and its speed. [Margin: Step 3.] Third, for the speed of the planet in the epicycle, take the mean argument or mean anomaly of the

orb corresponding to the proposed mean motion; this will be done easily if it is known to what time the given mean motion corresponds. Then to the mean argument add what you subtracted in order to obtain the speed of the centre of the epicycle (namely either the difference or the sum of the centric equations), or if you added it, subtract it; and you will have the true motion of the planet in the epicycle, and so its speed. So, very nearly, Regiomontanus in Book 12 of the *Epitome of the Almagest*, proposition 7.

Problem 2. *To determine the distance of the points of each station from the true apogee of the epicycle, given the distance of the centre of the epicycle from the apogee of the eccentric.*

Diagram. Set into the right column at its foot, with the text running down its left side. The figure the text calls the figure of the first theorem: a circle, the epicycle, with a long narrow fan of straight lines running up from the single point E at the foot, through the circle, to its upper arc. A vertical line runs from E through C and the centre D to the top of the circle at A. A nearly horizontal line through the centre joins L at the left to K at the right. Lines join the centre to G, M and points on the lower arc between them, and a line drops from F through P towards G.

- Labels read: R and A at the top; F, B and H on the upper arc; S and D at the centre; L, P, Q and K with O on the horizontal line; G, V, T and I set close beside it, C and M on the lower arc; E at the foot.
- Not settled: the second of the two letters set together between V and C, which is I or T; its head is lost in the drawn arc. [?]

XV. Taking up again the figure of the first theorem, let the distance of the centre of the epicycle from the apogee of the eccentric be given, and so, by the preceding problem, let the ratio of its speed to the speed of the planet be known. Let EGB be drawn so that PG, half of the chord GB, has the same ratio to GE as the known speed of the epicycle has to the known speed of the planet; and let the perpendicular DP be drawn from D to BG, and the straight line DG from D to G. For what is sought is the arc ABG, since G is the place of the first station, given the equality of ratios already mentioned, by Theorem 1; just as, if you draw another similar secant EMH, M will be the point of the second station. First, then, since the ratio of PG to GE is given (for it is as great as that of the speed of the epicycle to the speed of the planet), the double ratio of the chord BG to PG will be known, and by composition the ratio of the secant BE to the portion GE will be known; and from the measures of the orbs and the anomaly of the eccentric, the ratio of the semidiameter DC of the epicycle to the distance DE will be known, and therefore also the ratio of the line AC to CE and of AE to CE. So the rectangle contained by the whole AE and EC can also be known, and that contained by the whole EB and the outer part EG, in the same square parts, since they are equal by the corollary to 36 of Book 3 of Euclid. [Margin: By the first of the sixth book of Euclid.] Since the ratio of BE to GE is known, let it be made that as BE is to GE, so is their rectangle to the square on GE, whose root EG will become known in the parts in which the

semidiameter DC, or DG, is given; therefore EB too will be known in the same parts, as will BG and its half PG. Therefore in the triangle PDG, right-angled at P, with the sides PG and DG known, the remaining side DP will become known, and also the angle PDG. Second, because the line PE is also known, in the triangle EPD, right-angled at P, the angle DEP will become known from the known PD and PE; its complement to a right angle is the other angle, EDP. If you take away from this the angle PDG, there will remain the angle GDE, measuring the arc GC; and its remainder GBA, to the semicircle, will be the distance of the planet G, staying in the first station, from the true apogee of the epicycle. Similarly the arc AHM will be found for the planet M, occupying the point of the second station. See Regiomontanus, Book 12, propositions 6 and 8.

Problem 3. *To put the arcs of the stations into tables.*

XVI. Ptolemy gives this problem piecemeal, in Book 12: chapter 2 for ♄, chapter 3 for ♃, chapter 4 for ♂, chapter 5 for ♀ and chapter 6 for ☿, investigating the points of the stations at the greatest, mean and least distance of the centre of the epicycle from the centre of the Earth. Then, in chapter 7, he sets in first place in the Rule of Proportions the difference of the greatest distance from the mean one; in second place the difference of the mean distance from the distance belonging to the centre of the epicycle at the time when the station occurs; and in third place the excess of two stations, of which one belongs to the greatest distance and the other to the mean. Multiplying the third number by the second, he divides the product by the first, and subtracts the quotient from the arc of the station which the mean longitude gives, or adds it, as the case itself requires. He uses the same method for those positions of the epicycle that are between the mean longitude and the perigee of the eccentric, and in this way he extracts the arcs of the stations for every position of the epicycle on the eccentric. In this method, however, it is supposed that the arcs of the stations increase or decrease proportionally by as much as the centre of the epicycle, in receding from the mean longitude towards the apogee or perigee of the eccentric, recedes from the centre of the world or approaches it. As Jābir ibn Aflaḥ notes in Book 8, p. 129, and Regiomontanus in Book 12, proposition 11, this is not necessarily true, if we wish to keep geometric rigour; and so he himself adds a more precise method, at the end of which, however, he admits as follows: *But the neglect of this precision will introduce no perceptible error; and so I judge that Ptolemy's procedure, which, although it is not worked out to the kernel, is nevertheless as convenient as need be, should be followed.* For this reason I have not thought that the reader's application should be burdened with the labour of that precision.

Problem 4. *Given the arc of the first station, to derive from it the arc of the second station, of retrogradation, and of direction.*

XVII. First, subtract the arc of the first station from 360°, and the arc of the second station will be left. Second, subtract the arc of the first station from the arc of the second station, and the arc of retrogradation will be left. Third, subtract the arc of retrogradation from the whole circle, and the arc of direction

will be left. These rules follow from the definitions of the arcs given in chapter 2, and they are used by Peuerbach, Magini, and Reinhold on p. 140.

Problem 5. *Given their arc, to investigate the time of retrogradation and of direction.*

XVIII. In the *Theoricae*, Peuerbach orders these arcs to be divided by the daily motion of the argument, or of the anomaly of the epicycle. Reinhold illustrates this precept there, on p. 140, with the example of Mars. Let, he says, the equated centre of Mars, or its centric place, be 66° 40′; for to this Ptolemy's tables give an arc of the first station of 161°. Therefore if the true argument of Mars at that position of the centre of the epicycle is 161°, Mars will be in its first station, which he says happened about 1542 March 17. So when this is subtracted from the whole circle there remains the arc of the second station, 199°; when the arc of the first station is subtracted from the arc of the second there is left the arc of regression, 38°; and when this is taken from 360° there remains the arc of direction, 322°. Now let the arc of regression be resolved into seconds, 136800″, and let these be divided by the daily motion of the argument, which is 27′ 42″, that is, 1662″. They give 82 days. But this rule, based on the mean motion of the argument, gives only the mean time, which in Mars often departs from the true time by several days; and Reinhold admits in the same place that, from the ephemerides for the year 1542, the true time of retrogradation was only 72 days. He therefore teaches that a correction is to be applied, of the following kind, so that we may come closer to the true time. Since the centre of the epicycle of Mars advances under the zodiac each day by almost half a degree, in 82 days it advances nearly 41°. Add half of these, 20½°, to the equated centre of Mars used before, which was 66° 40′, and the sum is 87° 10′. For this, look up again from the tables the arc of the first station, for it will be 163° 6′. From this, by the rules of Problem 4, the arc of regression is gathered, 33° 48′, which when resolved makes 121680″. If you divide these again by the daily motion of the mean argument, 73 days come out in the quotient, agreeing with the true time of retrogradation or close to it. This rule, says Reinhold, comes closer to the truth because arcs of regression taken for the opposition of Mars to the Sun, or for the middle of the retrogradation, are less deceptive than those taken for its beginning or end.

Problem 6. *To investigate the arc of the zodiac which a planet traverses while it is retrograde.*

XIX. We owe this too to the diligence of Reinhold, on Peuerbach's *Theoricae*, p. 142. According to him, first see what equation of the argument belongs to the arc of retrogress in the epicycle found by Problem 4, and at the same time how far the centre of the epicycle advances in the time in which it traverses the arc of regress. Then subtract this latter arc from the former; the remainder will be the arc of the zodiac which the planet traverses while retrograde. As in the preceding example, in which the centre of Mars was 87° 10′ and the arc of the first station 163° 6′, to which corresponds an equation of the argument of 27° 18′; doubled, this makes the arc of the zodiac corresponding to the arc of regress in the epicycle, namely 54° 36′. The planet would recede through this

whole arc if the centre of the epicycle were not meanwhile advancing in the order of the signs. Further, in the 73 days found above it advances by mean motion very nearly 38° 15′; hence the motion of regress exceeds the motion of progression by 16° 20′. Granted, by the ephemerides for the year 1542 Mars regressed only 16°.

SCHOLIA.

Scholia.

I. [Margin: 1. Cause varying the arcs of the stations.] *The variation of the arcs of the stations and of the retrogressions, etc., depends on three causes, in the opinion of* Peuerbach*, to which* Magini *adds a fourth in his* Theoricae*, Book 2, chapter 12. But these are to be weighed and limited by annotations 2 and 3 of* Pedro Nunes *on the Peuerbachian affections of the planets, by the scholia of* Reinhold *on the same, p. 138, and by* Magini*. The first is the differing distance of the centre of the epicycle from the centre of the Earth; for, other things being equal, the nearer the centre of the epicycle is to the Earth, the nearer the point of the station is to the perigee of the epicycle, as* Reinhold *shows there, and* Nonius *in annotation 2. But this cause does not hold in Mercury, for a reason to be touched on below: for in Mercury, when the centre of the epicycle is placed at the mean longitude of the eccentric, the points of the stations are further from the perigee of the epicycle, but when it is placed at the apogee of the eccentric, less so; and they are furthest from it when the centre of its epicycle is distant from the apogee of the equant by a third. For that distance is, by Ptolemy's reckoning, 32° 56′ at the apogee, and around the mean longitudes*

34° 56′, and at the third 35° 31′, and at the perigee 35° 20′. So if the planet is nearer the Earth anywhere else than at the perigee of the eccentric, the proposition is not verified, as Nonius *shows in that annotation 3.*

[Margin: 2. Cause.] *The second cause is the size of the epicycles in comparison with the eccentric: for the greater the epicycle, the less the points of the stations are distant from the perigee of the epicycle, unless the speed of the planet stands in the way. The greatest of all is the epicycle of Venus; then that of Mars, after that of Mercury, next that of Jupiter, and the least of all that of Saturn, with respect to its own eccentric. And so the points of the stations of Venus and Mars are least of all distant from the perigee of the epicycle; then those of Mercury, after that those of Jupiter, and most of all those of Saturn. In absolute terms, however, the greatest of all is the epicycle of Mars, and the least of all that of Mercury.*

[Margin: 3. Cause.] *The third cause is the varying slowness of the motion of the argument, or of the planet in the epicycle. This is most effective in Mars and in Venus, the centre of whose epicycle traverses the whole zodiac sooner than the planet completes one revolution in the epicycle. This cause, taken not singly but together with the size of the epicycle, brings it about that the points of the stations come nearer to the perigee of the epicycle. But if these two causes are not joined, a planet in an epicycle of any size whatever could complete its period so quickly that the points of the stations*

would come no nearer to the perigee of the epicycle than in another, small epicycle in which the planet's motion was slower. Just as, conversely, unless Venus and Mars had very large epicycles, neither could be retrograde, because of its slower revolution in the epicycle as compared with the motion of the eccentric.

[Margin: 4. Cause.] *The fourth cause is the variation of the eccentricity; but this is reduced to the first, because it varies the distance.*

II. [Margin: Was Pliny the Elder rightly understood by Reinhold on the stations of Mars?] *Reinhold, on Peuerbach, p. 141, thinks it was said by Pliny the Elder in Book 2, chapter 17, that Mars never makes a station. But Pliny the Elder said that it never does so* with the star of Jupiter in trine; *otherwise he would contradict himself in chapter 15, where he says:* The star of Mars, as being nearer, feels the rays even from the quadrate, etc.; the same, when stationary, lingers six months in the signs, otherwise two months, while the others do not fill four months at both stations. *Granted that its station can be observed only with difficulty and scarcely, because, as Reinhold notes in the same place, the periodic time of Mars on the eccentric and in the epicycle is almost the same in quantity, since the daily motion of the epicycle is 31′ 26″ and that of the argument 27′ 42″. So, because of this near equality, the motion of the planet in the epicycle against the order of the signs does not quickly or easily equal or exceed the motion of the centre of the epicycle, and only near the perigee of the epicycle; and once it has equalled it, it is carried against the order of the signs very quickly.* [Margin: Notable points on the stations of Mars and Venus.] *That around the apogee and the mean longitudes of the deferent the arc of the first station is smaller in Mars than in Venus, but on the contrary around the perigee it is somewhat greater in Mars than in Venus, arises from the eccentricity of Mars, which is greater not only in absolute quantity but in proportion to the orbs, as the same Reinhold holds.*

III. [Margin: Stations and regressions in the Danish hypothesis.] *How Tycho and Longomontanus represented the stations* [Sationes] [recte: Stationes] *and retrogressions of the planets in their hypothesis is not clear from their own writings. Tycho indicates, however, in volume 1 of the* Progymnasmata*, p. 478, that these depend on the annual revolution of the centre of the orbs with the Sun, and on two epicycles; but certainly in this hypothesis the demonstration of them is not so simple as in the Ptolemaic one.*

CAPVT IV.

Chapter 4.

Theorica & cauſæ Stationum ac Retrogreſſuum in Hypotheſi Terræ motæ.

The theory and causes of stations and retrogressions in the hypothesis of the moved Earth.

I. In the Copernican hypothesis, that whole alternation of directions, stations and retrogressions has a purely optical cause, in the eyes of the Earth as it goes

round through the annual orb and views these planets from a changing position. We must set this out from what is taught by Copernicus, Book 5, chapters 3, 35 and 36; Rheticus at the end of the *Narratio prima*; Galileo in dialogue 3 of *De Mundi systemate*; Kepler in the *Mysterium Cosmographicum*, chapter 1, in the *Astronomia Optica*, p. 331, and in the *Epitome of Copernican Astronomy*, pp. 735 and 767; Lansbergen in the *Theoricae*, chapter 21; Hérigone in volume 5 of the *Cursus Mathematicus*, p. 604; and Longomontanus, who sets out the same hypothesis but does not follow it, in Book 1 of the *Theorica*, chapter 1.

In brief, then, the cause is the annual motion of the Earth, which overtakes the superior planets more quickly, or moves more slowly than the inferior or inner planets are moved, and so, by parallax or commutation of view, looks up to them or down on them now ahead of itself on the left, now behind it on the right. [Margin: Causes of stations and regressions in the three superior planets.] For in the adjoined scheme let C be the centre of the annual orb, in the Sun or near the Sun, and let the annual orb itself be DE, in which the Earth moves from E to K, etc.; and let the orb of Saturn, Jupiter or Mars be AB, in which the planet moves with a slower motion than the Earth, from A to L, etc. Now let the planet be supposed at A, from which AKL and AHM are drawn, tangent to the annual orb at H and K, and let the common diameter be ACB. For if the Earth is at E, the true motion of the planet A will be in the same line as the Sun C, or as the centre of the mean motion of the Earth, and the planet A will be acronychal and nearest to the Earth. But with the Earth placed at D and the planet at A, it should indeed be seen in the same line ABC, in conjunction with the Sun or the centre of the mean motion of the Earth; but because it then becomes hypaugus on account of the brightness of the Sun, by which it is overwhelmed, it cannot be observed. Outside these cases, because the Earth traverses its great orb in the space of a year, from E through KDH, returning to E, while the superior planet, being slower, meanwhile passes through some part of its orb, the Earth, while traversing the greater arc KDH, approaching through KFD to the point D placed under the apogee B, and receding from there through the arc DGH, will appear, I say, to add to the motion of the planet the angle HAK; but from there through E, which lies under the perigee A of the planet, as far as K, to take the same angle away from the motion of the planet. Accordingly, as long as the subtractive motion of the Earth exceeds the additive motion of the planet, the planet will appear to be abandoned by the Earth and, left behind, to go back against the order of the signs, namely while the Earth is occupied in the whole arc HEK. But when the subtractive motion of the Earth is equal to the additive motion of the planet, the planet will appear neither to advance nor to regress but to stand, which occurs at the point H in the first station and at K in the second. In the remaining arc KDH it will appear to advance directly; and it will appear to retrogress most of all to the Earth arriving at E and viewing the planet acronychal.

Diagram. Set into the right column, with the text running down its left side. A large circle, the orb the text calls AB, with a smaller circle inside it

about the centre C. A vertical diameter runs from B at the top through D, C and E to A at the foot. Straight lines from A pass through H to M at the left and through K to L at the right, H and K standing on the inner circle and M and L at the large circle. Two further lines run down from B on either side, towards G and F on the upper part of the inner circle.

• Labels read: B, A, M, L, D, F, G, C, H, E, K. None unread.

II. [Margin: The same causes for the inferior planets.] For Venus and Mercury, however, whose orbs are like Ptolemaic epicycles but described about the Sun C, and for which the annual orb of the Earth by its motion serves as the Ptolemaic eccentric, let the orbs in the preceding figure be exchanged: let the annual orb of the Earth be BMAL, and the orb of Venus or Mercury the inner one, DHK. Let the Earth be at A, from which two visual lines AKL and AHM are drawn, tangent to the orb of the planet at K and H; and let the motion of the Earth and of the planet be in the order of the signs, towards the same parts, but let the motion of the planet be swifter than that of the Earth. With this supposed, the planet will appear to the Earth A to move in its orb, as in an epicycle, in the order of the signs, through the whole arc KDH, in the middle of which, D, is the apogee; but in the remaining arc HEK it will appear to move against the order of the signs, and in the first case to add the angle HAK to the mean motion of the Earth, in the second to take it away. Accordingly, as soon as the subtractive motion of the planet is equal to the additive motion of the Earth, the planet will appear stationary at H and then at K; but when the subtractive motion of the planet is greater than the additive motion of the Earth, the planet will appear to recede, namely in the arc HEK, but principally at E, the place of perigean conjunction.

III. So far we have outlined the Copernican hypothesis of stations and regressions by means of customary schemes; but some light must be added to these shadows from a new scheme, which we have put together partly from Kepler's *Epitome of Copernican Astronomy*, partly from Galileo, and it is of this kind. From O, the centre of the world, that is, from the Sun, let the annual orb of the Earth BGM be described, and the orb of some superior planet, say Jupiter, which

is to be *bgm*; and let SVY be the arc of the zodiac in the sphere of the fixed stars. Draw the line of opposition OGV: that is, for when, with the Earth at G, Jupiter at *g* appears to us acronychal and opposite the Sun O. On either side of it take any number of equal arcs of the annual orb, for instance BC, DE, FG, GH, HI, IK, KL, LM. To these there correspond in Jupiter's orb dissimilar arcs, smaller in the proportion of the Jovial orb to the annual orb, since while the Earth traverses its whole annual orb once, Jupiter completes only about a twelfth part under the fixed stars. Let those arcs, then, be *bc, cd, de, ef, fg, gh, hi, ik; kl, lm*. And let both the Earth move in the order of the signs from B to D, G, etc., and Jupiter from *b* to *d, g*, etc. With the Earth placed at B, then, and Jupiter at *b*, and the line B*b*P drawn, Jupiter will appear to us under the zodiac at P. But when the Earth has been carried forward to C and Jupiter to *c*, and

the line C*c*Q has been drawn, the planet will appear under Q, having gone direct in the zodiac from P to Q.

Diagram. Set across the left column, interrupting its text. At the top a shallow arc, the zodiac, carries above it, from left to right, the letters S R T, then Q A V P Z, then X N Y. Below stands a large circle, Jupiter's orb in the text, whose upper arc carries the italic letters, from left to right, *m l* K *i h g f e d c b*. Inside it a smaller circle, the annual orb in the text, carries from the lower right round its upper arc to the lower left the letters B, C, D, E, F, G, H, I, K, L, M, with an italic *a* below its foot. A rayed disc with a ringed dot at its centre stands within the smaller circle. A vertical line rises from the rayed disc through G, the large circle and the crossing lines to the zodiac. Straight lines run from the points of the smaller circle through the upper arc of the large circle, cross one another in a narrow waist above it, and fan out to the letters on the zodiac.

- Top arc: S, R, T, Q, A, V, P, Z, X, N, Y
- Large circle, upper arc: *m*, *l*, K, *i*, *h*, *g*, *f*, *e*, *d*, *c*, *b*
- Smaller circle: B, C, D, E, F, G, H, I, K, L, M; *a* at the foot
- Centre: a rayed disc, no letter seen beside it

Now let the Earth advance to D and Jupiter to *d*: for along the visual line D*d*R it will appear still to have gone forward in a direct course from Q to R, following the series of the signs. [Margin: New scheme for the stations and retrogradations of the superior planets, from Galileo and Kepler.] But if the Earth should begin to interpose itself more directly between the Sun and Jupiter, or to approach the opposition G, and, having advanced to E, with Jupiter at *e*, should be so placed that the line D*d*R of the preceding day is almost parallel to the line E*e*S of the following day, Jupiter will appear to have lingered almost under S or the next point R. That is, it will be either stationary [Sationarius; recte: Stationarius] or retrograde from S to R only barely perceptibly, on account, namely, of the immense distance of the fixed stars and the parallelism, or virtual parallelism, of the two neighbouring visual lines. But as the Earth proceeds to F and Jupiter to *f*, Jupiter will appear along the line F*f*T under the point T of the zodiac, and so will appear to have gone back from S to T by the sensible arc ST; granted that earlier, in the time in which the Earth completed the arc EF, Jupiter will have appeared to linger between the points S and T, as if motionless and stationary. Now let the Earth have come from F to G, the place of Jupiter *g*'s true opposition with the Sun O. For along the line OG*g*V Jupiter will appear to us under the point V of the zodiac, and so to have gone back very greatly against the order of the signs from T to V; although in reality, in this hypothesis, Jupiter and the Earth have always proceeded with uniform motion in their orbs and under the zodiac. Now let the Earth have passed the moment of opposition and gone forward from G to H; and similarly, though not by a similar arc, let Jupiter have gone forward from *g* to *h*. For along the visual line H*h*X Jupiter will appear, likewise by a very large arc VX nearly equal to the arc TV, to have gone retrograde from V to X, against the series of the signs.

And when the Earth is at I and Jupiter at *i*, it will appear along the line I*i*Y under the point Y, having regressed a little further from X to Y; and presently, when the visual lines of consecutive days, drawn from the Earth at K through Jupiter at *k*, are parallel or nearly parallel, Jupiter will appear along the line KN either to have lingered motionless between X and Y, or to have begun, barely sensibly, to advance direct from Y to N, towards X, following the series of the signs. Afterwards, as the Earth proceeds to L and Jupiter to *l*, Jupiter along the line L*l*Z will appear under Z, having, that is, directed its course from N to Z with an advance greater as far as appearance goes; and with one greater still each day, when the Earth is at M and Jupiter at *m*; and along the line M*m*A it will appear under A, having advanced, namely, from Z to A. [Margin: Arc of retrogradation.] The whole apparent regression of Jupiter, then, will fill the arc SY, or RN. The same is to be understood likewise of Saturn and Mars; granted that in Saturn the stations and regressions are more frequent, because the Earth catches up with Saturn, which is slower than Jupiter, sooner and more often at the point of opposition than it does Jupiter; and that, conversely, they are rarer in Mars than in Jupiter, for the contrary reasons.

[Margin: On the stations and regression of Venus and Mercury.] IV. Now let the orb of Venus or Mercury be BGM, and let the annual orb of the Earth be *bgm*, and let these planets move in the order of the signs faster than the Earth moves in the order of the signs; for it will be shown proportionally that the appearance of stations and regressions arises not from any real halt or retreat of theirs under the zodiac, but from the motion of the Earth and the optical commutation of the visual lines. For since their orbs lie within the annual orb, and they revolve faster than the Earth, it comes about first, in the part of the eccentric M*a*B in which the apogee *a* lies, with respect to the Earth at *g*, that they appear to go in the order of the signs even if they are supposed to be at rest, and far more so if they move, and that faster than the Earth. But in the part of the eccentric nearer the Earth, such as EGI, they will appear to go retrograde, because opposite parts of circles, viewed from outside, will appear to have opposite motions; and the lines of vision that connect the endpoints of the daily motions will be bent back against the order of the signs, and will cut one another behind the Earth, in the quarter turned away from the Sun. And since the Earth is in the position in which, by the scheme of the preceding number, Jupiter or any other of the superior planets stood, while Venus or Mercury is in the position in which the Earth stood there, it follows that, although they are always in reality advancing, they nevertheless appear at times to stand still and then to go retrograde: to stand still, I say, when the visual lines of consecutive days, drawn from the planet through the Earth, are parallel.

[Margin: Cause of the apparent stations, from the parallelism of the visual lines.] V. From what has been said you will now more easily understand the definitions belonging to this hypothesis that we set out in advance in chapter 2, number 2, among which it is said that planets appear stationary when two visual lines of consecutive days, drawn through the Earth and the planet as far as the

sphere of the fixed stars, are parallel. And the reason is that in this Copernican hypothesis the distance of the fixed stars is so great that, in relation to it, the diameter of the Earth's annual orb vanishes, or produces no sensible parallax. Much less sensible, therefore, will be the distance between two parallels, say DR and ES, since they enclose not the diameter of the annual orb but a far smaller particle, corresponding to the arc of the Earth's daily motion, as the arc ED nearly is. Those parallels, therefore, produced to the sphere of the fixed stars, will appear to fall on the same point of the zodiac, and so the planet will appear, for that day or those consecutive days, to stand in the same place. As for directions and retrogradations: given unequal revolutions of the Earth and the planet in the order of the signs, the intersections of the visual lines of consecutive days must occur in every variety of way, as Kepler shows in the *Epitome of Copernican Astronomy*, p. 740: that is, now between the superior planets and the Earth, now at the centre of the Earth, now behind the Earth in the quarter turned away from the Sun, in which cases they are direct; now beyond the planets, in which case they are retrograde. As regards the inferior planets, however, the lines already mentioned must now bend in the order of the signs, now bend back against the order of the signs, and thus [the planets must be] now direct, now retrograde in appearance. Now some theorems and problems peculiar to this hypothesis are to be indicated; the rest, which it has in common with the Ptolemaic, are not repeated.

Theorem 1. *If the portion of a straight line drawn from our eye and cutting the orb of Venus or Mercury, the portion enclosed by that orb, is bisected in such a way that its half has to the outer portion of the secant the same ratio as the motion of the Earth has to the motion of the planet, the planet will appear to stand still at those points of the planet's circumference which are nearer the perigee and through which the section already mentioned passes; but in the arc intercepted by them, in which the perigee lies, it will appear retrograde, and in the remainder progressive.*

VI. Copernicus demonstrates this in Book 5, chapter 35, having first assumed the lemma of Apollonius, about which we spoke in chapter 3, number 5. To understand this theorem, use our figure set out in chapter 3, number 4; in it, however, the Earth or our eye is to be supposed at E, and the orb of Mercury or Venus to be AGC, described from D. The semidiameter CD of the orb is to be taken as having a greater ratio to CE than the velocity of the Earth has to the velocity of the planet, so that the planet may be capable of station and retrogression. On these assumptions it will be possible to find some line from E cutting the orb AC, say the line EF, whose inner portion VF is so bisected at Q that its half, that is QV, has to VE the same ratio as the motion of the Earth E has to the motion of the planet. For all lines from E cutting the orb AC are so related that the greatest of the inner portions, or chords, is ADC, and the others, not drawn through the centre, become smaller and smaller until they reach the tangent EL, which has no inner portion, and so no ratio of inner portion to outer. Therefore, between a portion having a greater ratio to the outer one and a portion of no ratio, there must be found some portion that has an equal

ratio. If, then, there is such a secant EF on one side, and EH on the other, the planet will appear to stand still at V and at M; to go retrograde in the arc VCM, containing the perigee M, and to go forward in the remainder MAV, as far as the judgement of the eye goes. The demonstration, as to the rest, is plainly the same as those brought forward above in chapter 3, number 10.

Theorem 2. *If a straight line drawn through our eye so cuts the annual orb of the Earth that half of the section enclosed in the annual orb has to the outer portion of the secant lying between our eye, when the Earth is nearer the superior planet, and the planet, the same ratio as the motion of the planet has to the motion of the Earth, the planet will appear to stand still at those points through which the section already mentioned passes; and to go retrograde in the whole arc of the annual orb intercepted within those points and containing the perigee; but to go forward in the remaining circumference of the annual orb.*

VII. This likewise is from Copernicus, Book 5, chapter 35, and it is demonstrated in the same way as the preceding, provided that the annual orb is conceived to be AGC, and one of the superior planets to be at E, and the line EVF, or EMH, to be so cut that the half QV, or OM, has to VE, or ME, the same ratio as the velocity of the planet has to the velocity of the Earth. For on these assumptions the planet will appear to stand still to the Earth placed at V or at M; and in the whole arc MCV, containing the point of opposition C, at which the planet appears nearest the Earth, it will appear to go retrograde, but in the remainder MAV to go forward.

Theorem 3. *If half of the section enclosed by the orb, of a straight line drawn from our eye and cutting the orb of Venus and Mercury, has to the remaining outer segment a greater ratio than the velocity of the Earth has to the velocity of the planet, the planet will appear to advance further in the order of the signs; but if a smaller one, it will appear to go back against the order of the signs.*

Theorem 4. *If half of the section enclosed by the annual orb, of a straight line drawn from our eye and cutting the annual orb of the Earth, has to the remaining outer segment a greater ratio than the velocity of any of the three superior planets has to the velocity of the Earth, the planet will appear to advance in the order of the signs; but if a smaller one, to go back against the order of the signs.*

VIII. Copernicus has both theorems gathered into a single proposition, Book 5, chapter 35, whose demonstration follows from the demonstration of Theorems 1 and 2.

Theorem 5. *If two visual lines of consecutive days, led out from our eye through the planet as far as the sphere of the fixed stars, are parallel, the planet will appear to stand still under the same place of the zodiac; but in the arc that includes the planet's perigee and is included within the two pairs of the parallels already mentioned, it will appear to go retrograde, and to go forward in all the rest.*

IX. This theorem is gathered from what Kepler demonstrated in the *Epitome of Copernican Astronomy*, p. 736 and p. 768, and we have already indicated the reason in number 5.

Problem 1. *To investigate the points of the stations and the arcs of regressions and progressions.*

X. Copernicus teaches this practice in Book 5, chapter 36: that is, by what method, in the figure set out in chapter 3, number 4, and given the half of the line VF, that is QV, having to VE the same ratio as the motion of the Earth has to Venus or Mercury, if their orb is AC and the Earth or our eye at E; or the ratio which the motion of Saturn, Jupiter or Mars has to the annual motion of the Earth, if the annual orb is AC and the planet at E: by what method, I say, from the motions of the Earth and the planet, and from the semidiameter DV (in the one case of the orb of the inferior planets, in the other of the annual orb), and from the distance of the centres ED and the perigeal distance CE, the angle EDV may be found, which measures the arc VC of half the retrogradation. For when this is subtracted from the semicircle AVC, there remains the place of the station computed from the apogee A, or the arc of the first station; adding to this double the arc VC, that is VM, gives the arc ACM of the second station. And when the arc VCM, which is the arc of retrogradation, is taken from the whole circle, there remains the arc MAV of the apparent progression or direction. The demonstration is the same as the one we gave in chapter 3, number 15, with the epicycle of Venus and Mercury changed into an orb about the Sun, and the epicycle of Saturn, Jupiter and Mars into the annual orb, etc.

[Margin: Difficulty of this practice.] Copernicus nevertheless admits in the same chapter 36 that, because the orbs of the planets are not concentric with the great orb of the Earth, and their motions are not equal but anomalous as far as appearance goes, the ratio of their speed to the velocity of our eye with the Earth, which is likewise carried round in an unequal motion, therefore varies from time to time and that this practice is difficult, if we wish to follow geometric rigour. For that reason he closes chapter 35 and Book 5 itself with these words, which Lansbergen almost transcribed in the *Theoricae*, chapter 21: *Nevertheless, since that variable motion of the star according to sight, and the ambiguity of the stations, from which Apollonius's assumption in no way relieves us, bring no small difficulty: I do not know whether someone might not do better by inquiring into the stations simply and from a nearby place, in the way in which we inquire into the conjunction of an acronychal star with the line of the Sun's mean motion, or the meeting of any stars whatever, combining them from the known numbers of their motions; which we leave to each person's pleasure.* Hence Lansbergen concludes above that the surest way is this: having first sought the places of the Earth and the planet in longitude for those times at which we know beforehand, approximately, that there is a risk of stations, we determine by comparing them the time of the stations and of the regressions intercepted between them, as the computers of ephemerides usually do. Let us now hear Kepler.

Problem 2. *To assign to any anomaly of the planet its angles of commutation and its prosthaphaeresis of the orb; or, in the inferior planets, the elongation, at which it becomes stationary.*

XI. Kepler, in the Rudolphine Tables, chapter 24, precept 104, does not indeed claim in this matter geometric [Greek: ἀκριβείαν (akribeian, exactness)], but the nearest approach to it, and a greater one than Apollonius of Perga attained, who touched on very few of the many causes that produce the variety of the stations. Three things, therefore, he presupposes as prepared and known. The *first* is the ratio of the Sun's temporary distance, on the one hand from the planet at the curtate interval, on the other from the Earth. The *second* is the ratio of the daily arcs of the eccentric, both of the planet, which the anomaly itself will indicate, and of the Sun, likewise known approximately from the anomaly. The *third* is that the rays drawn from the Sun to the planet and to the Earth form, with the subtenses of their daily arcs of the eccentric, outward angles greater than a right angle by the amount of each one's semidiurnal arcs; which, however, is not exactly true except in the apsides themselves.

On these assumptions, let S in this small scheme be the Sun, O the Earth, and A one of the superior planets; or, conversely, let A be the Earth and O one of the inferior planets. Let AD be the daily arc of the eccentric of one superior planet, but OP that of the inferior one, and greater; and to the visual line drawn AO let a neighbouring parallel CP be drawn. Now, the ratio is given of the distance AS of the Sun from the superior planet to SO, its distance from the Earth O; or of the Sun's distance SA from the Earth to SO, its distance from the inferior planet. The ratio of the daily arc AD to OP is given besides. So, drawing from A the line AE parallel to SO and AB parallel to OP, as AS is to SO, so will AC be to AE, that is, to OI, which is equal to it; and therefore the ratio of these will be known. In the same way, since AB is equal to OP, therefore the ratio of DA to AB will be known. Finally, since the triangles ASD and OSP are supposed isosceles (since AD is to be conceived as the chord of the arc AD described from S, just as OP is the chord of the arc described from S), and the angle OSP is greater than ASD, therefore the angle SOP is smaller than SAD, and the angle CAD is greater than IOP, or EAB; and each is greater than a right angle by the amount of the semidiurnal arcs. Now, since the angle of commutation is to be sought, through which the planet becomes stationary, and its complement to two right angles is the angle ASO, or CAE, seek therefore from the givens the angle CAE, starting from the position of ACB itself as known.

Diagram. Set into the left column, with the text running down its left side. A long vertical line runs from C at the top through A to S at the foot, ending a little below S. Short lines near the top join A to E, D and B. Two long lines slant down to the right, as the text's parallels AO and CP: one starts above and to the left of A, passes by A and O and runs on past them; the other runs from C through E, D, B and I to P. A line rises from S through O to I, and a short line joins O to P.

- On the vertical line: C (top), A (left of the line), S (foot)
- Near the top of the slanting line from C: E, D, B
- Lower group: I, O, P

Kepler gives an example of this calculation in the same Rudolphine precept 104. To it he adds precept 105, for finding more easily, but approximately, from small tables, both angles of commutation at which, for any one ratio of the distances, the first and second stations occur; and precept 106, for distinguishing the first station from the second, and for recognising whether the daily arc and the distance of the Sun from the Earth have been taken correctly. These precepts bear on the use of the tables. It is now convenient to append from the Rudolphine Tables the angle of commutation determining the points of the stations on either side, at four notable places of the eccentric.

Angle of commutation for the arcs of the stations, from the Rudolphine Tables. Four positions of the eccentric anomaly.

	Stations	0	90	180	270
♄	1	113° 48′	115° 27′	116° 53′	114° 37′
♄	2	113° 57′	114° 47′	116° 50′	115° 24′
♃	1	123° 57′	126° 22′	128° 15′	125° 38′
♃	2	124° 54′	126° 24′	127° 15′	125° 41′
♂	1	157° 40′	164° 0′	170° 8′	162° 46′
♂	2	158° 13′	164° 23′	169° 49′	162° 27′
♀	1	167° 47′	167° 58′	166° 55′	166° 43′

☿	1	153° 48′	144° 58′	136° 46′	145° 19′
☿	2	154° 10′	145° 9′	136° 23′	146° 28′

SCHOLIA.

Scholia.

[Margin: Kepler's encomium of Copernican astronomy in the stations, etc.] I. *On the occasion of the stations and regressions, Kepler extols Copernican astronomy, both in chapter 1 of the* Mysterium Cosmographicum *and in the* Epitome Astronomiæ, *p. 734, because, while the old astronomy multiplies epicycles but is silent, or merely mutters and stands astonished, and does not explain the causes of the stations and regressions, the far simpler Copernican hypothesis so saves all this by the single motion of the Earth about the Sun, added to the eccentric motions, as to state the causes of these variations. But, leaving simplicity aside for now, this way of commending from here the hypothesis of the moved Earth does not seem to me so solid. For either it is judged absurd that these five planets appear stationary and retrograde, and this by no means, since they appear so in any hypothesis, and the undoubted phenomena demand it; or that they so appear as to be so in reality in the heaven, and not only optically, that is, as to our judgement resting on the eyes, and this does not happen even in the Ptolemaic hypothesis, for in it both the centre of the epicycle in the circumference of the eccentric orb and the planet in the circumference of the epicycle move perpetually in the order of the signs. Or, finally, it is absurd that these planets are at times carried in quarters contrary to and different from those towards which the centres of the epicycles tend, and that it comes about from this that, if the lines*

of apparent motion under the zodiac are considered, they at times appear to stand still, at times to go retrograde: this very thing necessarily happens, in its own way, in the Copernican hypothesis, in which whatever is said of the Ptolemaic epicycles is transferred to the annual orb. For Kepler admits in the same Epitome, *p. 738, that the Earth in its annual orb runs with the planet now from the same quarter, now from the opposite one; and that, although both it in its orb and the planet in its own always go on in the order of the signs, nevertheless it is at times carried towards a quarter from which the planets appear to recede; as in the figure of number 3: if the Earth goes from M through a to B, and the superior planet from the point b to m, it will appear to go in the opposite quarter. I would not deny, however, that this discrepancy, such as it is, of the motion of the epicycle from the motion of the planet in the epicycle arises in the Ptolemaic hypothesis from the planet's intrinsic system, but in the Copernican from an extrinsic one, since the annual orb is extrinsic to the system of the other planets.*

[Margin: Euclid's optical theorem for stations and retrogradations.] II. *Since Euclid demonstrated in proposition 54 of the* Optics *that if some things are carried at unequal speed, and among them also the eye, those that are carried with the eye at equal speed appear to sta-*

nd; those that go more slowly than the eye, to fall back in the opposite direction; those that go faster, to run ahead of the eye. This is what happens with ships under way, which appear to stand still to an eye travelling along with them, to fall back from an eye going faster, or to fly past an eye going more slowly. Nevertheless Kepler admits in the *Epitome of Copernican Astronomy*, p. 739, that this cannot be applied so conveniently to setting out the optical causes of the stations and retrogressions that occur on circular courses, on which the planet and the eye sometimes do not go the same way, as Euclid supposes in his theorem.

III. [Margin: Aspects at which stations occur.] To someone asking why Saturn, between the quadrate and the trine aspect of the Sun but nearer the quadrate, Jupiter at about the trine, and Mars beyond the trine, become stationary both before and after, Kepler replies in the *Epitome of Copernican Astronomy*, p. 744. This happens, he says, because if a superior planet made no progress in its eccentric, it would appear to stand at the points of contact with the annual orb, at which a right angle is formed by two lines, one drawn from our sight, or from the centre of the Earth, to the Sun, the other to the planet, and so very nearly at the quadrate aspect itself. But since in its eccentric Saturn nevertheless progresses less than Jupiter, and Jupiter less than Mars, the two parallel visual lines that produce the appearance of a station recede from the points of contact toward the perigee, that is, from the quadrate aspect: less in Saturn, more in Jupiter, and more still in Mars. He adds, however, that if the planet's daily arc were as great as that of the Earth, or of the annual orb, no station would appear except at the very opposition to the Sun.

IV. [Margin: Comparison of the arcs of regression.] But how is it that Saturn runs through the smallest arc of the ecliptic in its regression, Jupiter a moderate one, and Mars the greatest? Copernicus alone (says Kepler in the

Epitome of Copernican Astronomy, p. 747) uncovers the cause of this, while the old astronomy mutters and introduces unequal epicycles with no cause indicated for their size. In Copernicus's hypothesis, however, this comes about because Saturn is very far from the annual orb, Jupiter nearer, and Mars moves closest to it. So if someone on a higher planet were to look down on the arc of the annual orb that bears on the regression, it will seem very small to him, even if the planet were at rest. But into this cause there enters the far swifter motion of the Earth, beyond the motion of the higher planet.

V. [Margin: How conjunctions of the three planets, direct or retrograde, are possible.] Truly astonishing, and most shrewdly tracked down from a comparison of the motions and asserted by Kepler in the *Epitome of Copernican Astronomy*, p. 749, is this: that with Saturn direct, Jupiter and Mars cannot be conjoined to it unless they too are direct; nor can Saturn or Jupiter be conjoined to Mars when it is retrograde, unless they too are retrograde. But with Saturn retrograde, Jupiter and Mars can be conjoined to it while direct; and with Jupiter retrograde, Mars can be conjoined to it while direct.

CAPVT V.

Chapter 5.

De Planetis Orientalibus Occidentalibuſue, Auctis Minutiſue lumine, Hypaugis ſeu Combuſtis, Emerſionibus & Occultationibus, Arcuque viſionis ad has requiſito.

On eastern and western planets, planets increased or diminished in light, hypaugi or combust planets, emersions and occultations, and the arc of vision required for them.

I. Planets are called eastern [ORIENTALES] not because they stand away from the Sun in the order of the signs, but on the contrary when they precede it in the zodiac, because they rise above the horizon at night, that is, between sunset and sunrise. Their setting, however, the day conceals, since the Sun rises before they set. And because they can usually be seen in the morning before the Sun has risen, they are called morning planets [*Matutini*], and in Greek Ἠῷοι or ἑῷοι [Greek: ēōioi, heōioi, "of the dawn, of the morning"]. Conversely, they are called western [*Occidentales*] when they stand away from the Sun in the order of the signs by less than a semicircle, because they set at night and the day hides their rising. At that time they are usually seen above the horizon after the setting of the Sun, [Margin: Which planets are eastern and morning, which western and evening.] and for that reason they are called evening planets [*Vespertini*], and in Greek ἑσπέριοι [Greek: hesperioi, "of the evening"]. More briefly, from Magini, book 2 of the *Theoricae*, ch. 14, and Canon 98 of the *Secunda Mobilia*: they are called eastern and morning when they rise above the horizon in the morning before the Sun, and western and evening when they set or go down below the horizon in the evening after the setting of the Sun. And so all, together with Peuerbach on the affections of the

planets, and especially Magini in the places cited and Kepler in the *Epitome of Copernican Astronomy*, book 6, p. 823.

II. [Margin: Order of these phases in the three superior planets.] The three superior planets, however, like the fixed stars too, because they are slower than the Sun, turn at the middle of direction, that is, at the moment of conjunction with the Sun, from western into eastern, or from evening into morning. They remain so from that moment until the diametrical opposition to the Sun, whether or not they are visible to us because of the nearby brilliance of the Sun; that is, they are such from the time they descend from the apogee of the epicycle to the mean longitudes, and from there to the perigee. By contrast, from the moment of opposition to the Sun and the middle of retrogradation, at which they become ἀκρονύκτοι [Greek: akronyktoi, "acronychal"], that is, shining at both ends of the night and so lasting the whole night, they turn from eastern and morning into western and evening as far as the conjunction, whether or not they appear to us near the conjunction; and this happens while they climb from the perigee of the epicycle to the apogee. [Margin: Order in the inferior planets.] But Venus and Mercury, at the moment of perigee conjunction with the Sun, that is, at the middle of retrogradation, become morning and eastern, and they remain so until the following conjunction with the Sun, which is however an apogee one, that is, until the middle of direction. Then, descending from the apogee of the epicycle, they become western and evening, as far as the perigee of the epicycle. See a synopsis of these in the following little table.

Eastern, morning, and preceding the Sun are:

♄ ♃ ♂ – from ♂ to ☍, with ☉, in the left semicircle of the epicycle.

☿ and ♀ – from perigee ♂ to apogee ♂, with ☉, in the right semicircle of the epicycle.

Western, evening, and following the Sun are called:

♄ ♃ ♂ from ☍ to ♂, with ☉, in the right semicircle of the epicycle.

♀ and ☿ from apogee ♂ to perigee ♂, with ☉, in the left semicircle of the epicycle.

III. [Margin: Increased and diminished in light.] Planets are called increased in light [*Aucti lumine*] when they recede from the Sun, if they are swifter than it, or the Sun from them, if they are slower, by as great a recession as suffices for them to be visible in spite of the Sun's brilliance. They are called diminished in light [*Minuti lumine*] when they approach the Sun, or the Sun approaches them. For this reason Venus and Mercury are at their greatest increase of light when they are at their greatest digressions from the Sun, that is, at the contacts of the visual lines with the epicycle, insofar as this increase depends on remoteness from the Sun; granted that at that time they appear only dichotomous, and that nearer the perigee of the epicycle they show a greater apparent semidiameter but a crescent narrower in breadth, and shine with greater light because of their closer approach to the Earth. But in this increase it is intensity rather than extent that is considered; otherwise the extensive increase of Venus at perigee

is by far the greatest. The three superior planets, however, are most increased in light at their oppositions, both because of their greatest recession from the Sun and because of their nearness to the Earth, since they are at the perigee of the epicycle. And if they are at the perigee of the eccentric and of the epicycle together, which in Mars happens at about the beginning of Aquarius or of Pisces, they become most greatly increased in light, [Margin: Mars taken for a comet or a new star.] so much so that Mars there has more than once been taken for a comet or a new star, as in 1529 in July and August, and in 1561, 1593 and 1608 in the same months. By contrast, at the apogee of the eccentric and of the epicycle together they become most diminished, both because of the brilliance of the Sun, with which they are conjoined beneath the zodiac, and because of their greatest distance from the Earth.

IV. [Margin: Hypaugi.] Planets are hypaugi, in Greek ὑπάυγοι [Greek: hypaugoi, "under the sun's rays"], when they are under the rays of the Sun, that is, under the brightness arising from the Sun's rays, for that is what ἀυγαὶ [Greek: augai, "rays, brightness"] means, with the Sun's brilliance overpowering our eyes so that they do not perceive the light of nearby stars. In this case they are also called combust [*Combusti*], as if the Sun were burning them up; but astronomers use the word in one sense and judicial astrologers in another. [Margin: When planets are combust.] For as Magini teaches in Canon 98 of the *Secunda Mobilia* and in the *Isagoge* to the *Ephemerides*, ch. 28, astronomers call them combust for the whole time they lie hidden under the rays of the Sun, from any occultation whatever, whether morning or evening, until their emersion from under the Sun's rays; astrologers, on the other hand, call them combust when they stand less than half of their orbs away from the Sun, before or after. But hy- paugi are so called when they are elongated from the Sun beyond half of their orbs, yet in such a way that they are enclosed within the space made up of the sum of the two orbs, namely of the Sun and of the planet. [Margin: Conjunction of the body with the ☉.] Finally, they are said to be in the heart of the Sun, or conjoined with the Sun by body, when the centre of their body is less distant from the centre of the body of the Sun than the sum of the semidiameters of the Sun and the planet; which sum does not usually exceed 19′ for the ancients, but more truly 17′. We shall set out the sizes of the orbs, or of the light, below in ch. 7, no. 4.

V. [Margin: Cause of the varying distance between emersion and occultation.] The distance of an emersion from under the Sun's rays from the adjoining occultation varies, moreover, even when the planets are compared with themselves. Kepler enumerates chiefly six causes of this variety in the *Epitome of Copernican Astronomy*, p. 836. The first is the obliquity of the zodiac. For the same star, all else being equal, if it rises in the morning in the signs that ascend straight, that is, those from the beginning of Cancer to the beginning of Capricorn through Libra, can stand much higher above the horizon, or above the circle of position of the Sun, than if it does so in the signs of oblique ascension, which are those from the beginning of Capricorn through Aries

to the beginning of Cancer. So too it stands higher, and is seen longer and better, if it sets in the evening in the signs of right descension, which are those from the beginning of Capricorn through Aries to the beginning of Cancer, than if it sets in the signs descending obliquely. The second is the obliquity of the horizon, with the addition especially of the differing thickness of the air and of refractions. The third is the difference in the motion in longitude both of the Sun and of the planets. From this it comes about that the stay of the fixed stars under the rays of the Sun, all else being equal, is shorter than that of Saturn, and Saturn's than that of Jupiter, and Jupiter's than that of Mars, because the slower a star is in its direct motion, the faster the Sun leaves it. But since Venus and Mercury are swifter than the Sun, their stay under the rays of the Sun is shorter than that of the fixed stars themselves. The Moon too, at its evening emersion, frees itself very quickly from the Sun's rays, Mercury quickly, but Venus more slowly. The fourth cause is the differing latitude of different planets, and indeed of the same planet; for since the variety of the declinations is increased by this, the first and second causes vary sensibly. The fifth is the difference in the apparent magnitude of the stars, which the differing distance from the Earth varies. The sixth is the difference of face in Mercury and Venus, proportionately as in the Moon, since they appear now horned, now gibbous, etc.

De Arcu Viſionis alijſque arcubus ad Emerſionem & Occultationem Planetarum ſpectantibus.

On the arc of vision and the other arcs bearing on the emersion and occultation of the planets.

VI. [Margin: Authors who treat of the occultation and emersion of the planets.] These arcs are treated by Ptolemy in book 13 of the *Almagest*, from ch. 7 to the end of the work, and there by Regiomontanus in the *Epitome*, book 8 from prop. 11 and book 13 from prop. 23; al-Battānī, ch. 48; al-Farghānī, differentia 26; Jābir ibn Aflaḥ, book 9 of the *Astronomia*, at the end; Wurstisen on Peuerbach's *Theoricae*, p. 288; Osualdus in the *Problemata*, prop. 68; Erasmus Reinhold in the Prutenic Tables, precept 73; Copernicus, book 2, ch. 13; Giovanni Antonio Magini in the *Theoricae*, ch. 15, and in the *Secunda Mobilia*, canon 99, and in book 8 of the *Primum Mobile*, problem 22, and in the Tables of Directions of the primum mobile, canons 20, 21 and 22; Kepler in the *Epitome of Copernican Astronomy*, book 3 from p. 369, and in the Rudolphine Tables, precept 101, or p. 75; Lansbergen in his tables, p. 160, where there is a canon of emersion and occultation without any precept; Longomontanus, book 2 of the *Sphaerics*, ch. 4, problem 3; and Denis Pétau, book 1 of the dissertations of the *Uranologion*, ch. 14. From these, after the definitions, we shall select the following problems and precepts.

1. [Margin: What is the arc of vision?] The arc of vision of a star is the arc of the vertical circle intercepted between the horizon and the centre of

the Sun at the time when the star first appears, or ceases to appear, on the horizon.

2. [Margin: Interval of emersion.] The interval of emersion of a star, with respect to the Sun and the horizon, is the arc of the ecliptic lying between the centre of the Sun and the horizon at the moment when the star, touching the horizon, first begins to appear.
3. [Margin: Interval of occultation.] The interval of occultation is the arc of the ecliptic enclosed between the Sun and the horizon at the moment when the star, touching the horizon, begins to be hidden.

In these definitions it is not so much the ascent above the horizon, or the descent below it, that is considered (for those pertain to true rising and setting), as the first and last appearance owing to recession from, or approach to, the rays of the Sun. Now, to determine the emersions and occultations of the planets, we chiefly need the arc of the ecliptic by which a star placed on the ecliptic, or reduced to the ecliptic, is distant from the Sun at the moment when it first begins to appear, or ceases to appear. But this distance varies for the 6 causes enumerated in no. 5; granted that Ptolemy, in book 13, ch. 7, reviews only three as the chief ones, namely the differing apparent magnitude of the star, the differing obliquity of the ecliptic to the horizon, and the differing latitude. These produce an incredible variety in the arcs and times of emersions and occultations in the same star, let alone in different ones. Very wisely, therefore, Ptolemy sought out a kind of mean that would always be the same with respect to the same star and in the same climate. This mean is the arc of vision. Yet to find it he used a certain definite interval of emersion and occultation, so that afterwards, by a demonstrative regress, through the arc of vision once established for each star, he could bring the remaining variety of emersions and occultations back to a geometrical rule. So let this be:

Problema 1. Arcum Viſionis in vnoquoque Climate inueſtigare.

Problem 1. To find the arc of vision in each climate.

VII. [Margin: 1. Precept.] First, following Ptolemy, book 13, ch. 7, and Regiomontanus, book 13, prop. 23, observe the moment of time at which each star first appears on the horizon, when before it did not appear although the sky was clear; or when it first begins to be hidden on the horizon, when before it was visible. For that moment of time compute the true places, both of the Sun and of the star, in longitude and latitude, and collect the distance of the star from the Sun on the ecliptic, that is, the arc of the ecliptic lying between the Sun and the ecliptic place of the star. Keep this, together with the latitude, if there is any. According to the authors already mentioned, it is best to make these observations when the Sun is in the beginning of Cancer, because at that time the air in the northern climates seems thinner and more purged, the vapours having by then been burned off, and the inclinations of

the zodiac to the horizon are moderate. Otherwise, with the horizon beset by thicker vapours, as happens at other times, especially in climates very far from the equator, it is almost impossible to see any star on the horizon itself; rather, when it first appears it is always higher than the physical or sensible horizon itself. And so as not to prepare yourself for observation in vain, consult tables or ephemerides and see whether, with the Sun about the beginning of Cancer, a conjunction of the star with the Sun is impending, at least in that month.

Further, Ptolemy, from his own observations and those of the ancient Chaldeans made in Syria and Phoenicia, that is, at the beginning of climate 4, where the longest day is $14^h\ 15^m$, and in which he says the more certain observations were made by the Chaldeans, Egyptians and Greeks; in that climate, I say, while the Sun was about the beginning of Cancer, he found the arcs of the ecliptic, or intervals, that you see in the little table. Thus with the Sun placed at the beginning of ♋, Saturn would emerge there in the morning from the rays of the Sun when it was distant from the Sun against the order of the signs by 14°, Jupiter by 12° 45′, and Mars by 14° 30′; Venus, however, in the evening by 5° 40′, and Mercury in the evening by 11° 30′.

Distances of the planets from the ☉ placed at the beginning of ♋, for the emersions of the planets in climate 4.

Planet	Distance
♄ morning	14° 0′
♃ morning	12° 45′
♂ morning	14° 30′
♀ evening	5° 40′
☿ evening	11° 30′

[Margin: 2. Precept, in the first case.] Second, look at the following figure, in which let the meridian be HVL, the horizon HCR, and the ecliptic ECL; the Sun below the horizon be at A, to which let the portion VA of a vertical circle be drawn from the vertex V; and let the planet, when it first appears on the horizon lacking all latitude, be at C. In the spherical triangle CAB, then, right-angled at B (although Ptolemy uses rectilinear triangles because of the smallness of the arcs), the arc of vision AB is sought. In that triangle the arc or base CA is given, namely the distance of the planet from the Sun, by the first precept; and from tables of the primum mobile, the angle ACB of the ecliptic with the horizon, corresponding to the place of the planet C. Therefore the side AB, which was being sought, cannot remain unknown.

Diagram. Set in the right part of the left column, with short lines of text running down its left side. A large circle carries V at the top; a small circle at its upper right, with P inside it and K just outside it to the right; E at the upper left; R at the right above the middle; L at the right just below the middle; H at the left; and at its foot a second small circle with M inside it and N just outside it to the left. A line runs from the left-hand H through C to R; a line runs from

E through C to L. An arc falls from V past B to A. From the small circle about P two lines come down close together to the inner letter H, one going on to D and the other to I. From the small circle about M two lines rise close together to G, going on to O and to F. Two letter H stand on the block, one on the large circle at the left and one inside it near B.

- Large circle: V (top), E (upper left), H (left), R (right, upper), L (right)
- Small circle, upper right: P (inside), K (outside)
- Small circle, foot: M (inside), N (outside)
- Interior: O and F (side by side, left of centre), G (below them), C (centre), H (right of centre), B (beside H), I and D (side by side, below H), A (below B)

[Margin: 2. Case.] But if the ecliptic place of the star is D, and the star is at H, having the northern latitude DH, and it is at the beginning of Cancer or Capricorn, then the arc PH, drawn from the arctic pole of the world P, will be an arc set in a straight line with the arc of latitude HD. Then in the spherical triangle PHR, right-angled at R, in which PR is given, the altitude of the pole, as I suppose, and PH, which becomes known by subtracting the obliquity of the ecliptic from the complement of the latitude if the star is at the beginning of ♋, but by adding it to the same complement if the star is at the beginning of ♑, seek the angle PHR, to which the angle CHD is equal, in the small triangle CDH, right-angled at D. In this triangle, from the given latitude DH and the angle CHD just found, seek the side CD, and add it to the observed distance DA; and so in the triangle ACB seek the arc of vision AB as before. The same procedure must be followed if the latitude of the planet appearing at G is southern, say OG, and its ecliptic place is O, but with MGO drawn from the antarctic pole. For from MG, known by subtracting the obliquity of the ecliptic from the complement of the southern latitude, etc., and from the altitude of the southern pole, one must find the angle HGM, equal to the angle CGO; with it, and with the latitude OG, in the triangle GOC, right-angled at O, you will seek the arc of the ecliptic OC, and you will take it away from the distance OCA of the planet from the Sun, so that there remain both the arc CA and the point C of the ecliptic, and from that the angle of the ecliptic and the horizon (which, however, you can gain in solving the said triangle COG), so that with its help and that of the remaining distance CA you may obtain the side AB.

[Margin: 3. Case.] And if the star H, endowed with a northern latitude, is not at the beginning of Cancer or Capricorn, draw from the pole of the ecliptic K the arc KHI through the star, for it will be an arc of a circle of latitude; and connect the poles of the world and of the ecliptic by the arc PK, which is as great as the obliquity of the ecliptic. Further, let the declination of the star be supposed known or found, which in this case will differ from the latitude. With these things laid down, in the triangle PHK, PK is given, as I said, and PH, the complement of the declination of the star, and the angle KPH, which the distance of the true place of the star from the beginning of Cancer or Capricorn

makes plain. Therefore, by the science of oblique spherical triangles, the angle PHK will not remain hidden. Next, in the triangle PHR, right-angled at R, from the given altitude of the pole PR and the complement of the declination PH, you will find the angle PHR; subtract from it the angle PHK, and there remains the known angle KHR, to which the angle IHC is equal, in the small triangle CIH, right-angled at I, in which the latitude IH is given. Therefore the arc CI will not remain hidden; added to the observed distance IA between the star and the Sun, it will make up the arc CA. In this way the point C of the ecliptic, set on the horizon, will be known, and from that the angle RCL of the ecliptic and the horizon; with this and with the arc CA, in the triangle CAB, right-angled at B, seek the arc of vision AB. From this you see how to proceed if the latitude is southern and the star is away from the beginning of Capricorn or Cancer. For in the triangle NGM, from the complement of the declination MG, the arc MN, as great as the obliquity of the ecliptic, and the angle NMG, known from the distance of the star from the beginning of Cancer or Capricorn, you will find the angle NGM. And in the triangle MHG, right-angled at H, from the altitude of the southern pole HM and the complement of the declination MG, you will find the angle MGH, from which you will take away the angle MGN; and there will remain the angle NGH, that is FGC. With this and with the latitude GF, in the triangle GFC, right-angled at F, you will seek the arc FC, which you will subtract from the distance FA, and you will carry out the rest as above. Remember, however, that in all these cases, for the morning emersions of Saturn, Jupiter and Mars, the point C of the ecliptic is rising, but for the evening emersion of Venus and Mercury it is setting, etc.

VIII. In this way Ptolemy, in book 8, ch. 6, from observed emersions of the fixed stars, and in book 13, ch. 7, derived the arcs of vision written below for climate 4, permanently serving for the same star.

Arcs of vision in climate 4, from Ptolemy.

Fixed stars (magnitude of the fixed stars)	Arc	Planets	Arc of vision
1	12° 0′	♄	11° 0′
2	13° 0′	♃	10° 0′
3	14° 0′	♂	11° 30′
4	15° 0′	♀	5° 0′
5	16° 0′	☿	10° 0′
6	17° 0′	☩	
7	18° 0′	☩	

[Margin: Whether the arcs of vision are correct for any climate.] Although the already mentioned arcs hold for the end of the third and the beginning of the fourth climate, Erasmus Reinhold used them at the end of the Prutenic Tables as if they held in every climate, though promising in precept 73 fuller canons for other climates. Magini employed the same arcs both at the end of the *Secunda Mobilia* and in the Tables of Directions from p. 195, for altitudes of

the pole of 43°, 44° and 45°; granted that, by astronomical rigour, the greater the declinations of the fixed stars, the smaller the arc of vision required for them to appear. But planets too, at a greater altitude of the pole, require a smaller arc of vision in order to emerge, because the higher the pole, the greater the ortive amplitude of the stars, and the farther they stand from the Sun while emerging, and so the less the brightness of the horizon harms them. So Kepler observes in the Rudolphine Tables, p. 76, adding that for the morning emersion or evening occultation of Venus and Mercury a far smaller arc of vision is required, because they are then at perigee and appear larger, than for the evening emersion or morning occultation, because they are then at about the apogee of the orb or epicycle and diminished in light. [Margin: Venus and Mercury demand smaller arcs of vision.] So it comes about that Venus is often visible by day too, with the Sun above, let alone below, the horizon. See also Scholium 1. In this part, therefore, astronomy is still defective, because suitable observations of emersions and occultations, made through all climates, are lacking. In the meantime we are forced to use the arcs found by Ptolemy, as not introducing a very sensible difference in other climates.

Problema 2. Dato Arcu Viſionis &c. Inuenire Diſtantiam Stellæ à Sole in Ecliptica requiſitam ad Emerſionem aut Occultationem, ſeu Interuallum emerſionis & occultationis.

Problem 2. Given the arc of vision, etc., to find the distance of a star from the Sun on the ecliptic required for emersion or occultation, that is, the interval of emersion and of occultation.

IX. This problem likewise has been pointed out to us by Ptolemy, book 13, ch. 7; Regiomontanus in the *Epitome of the Almagest*, book 8, props. 13, 14 and 15; Jābir ibn Aflaḥ, book 9; Copernicus, book 2, ch. 13; Magini, book 2 of the *Theoricae*, ch. 15, and in the *Directions*, canon 20; and Daniel Santbech in *On the Observations of Phenomena*, prop. 21. Although we touched on this problem in book 6, ch. 20, at the end of no. 15, on the occasion of the rising and setting of the fixed stars, it still should not have been missing here; indeed, it did not seem good to restrict it to the planets alone. Further, the arc of vision is supposed known, with the Sun placed at the beginning of Cancer, as Ptolemy did, or elsewhere once and definitely, from the then-observed inter-

vals of emersions and occultations: here, however, the same intervals are sought for whatever place of the zodiac the Sun and the other stars occupy. Such a place is supposed given or assumed, and known likewise is the latitude, if there is any, in kind and in quantity, together with the altitude of the pole. On these assumptions, let everything in the preceding figure be as set out there, and [Margin: Case 1.] let the planet first be at C, with no latitude at all: for since its place on the ecliptic is given, there will also be given from the tables of the primum mobile, for the given altitude of the pole, the angle ECH or RCL, namely that of the ecliptic and the horizon. Therefore in triangle ABC,

right-angled at B, from the angle at C and the given arc of vision AB, you will gather by means of trigonometry the base AC, which will be the interval of emersion or occultation, according as the star C is taken to be ascending or descending.

[Margin: Case 2.] Second, let the star be at H, having northern latitude, and let its place on the ecliptic be D or I; for if it is at the beginning of Cancer or Capricorn, the arc of declination will coincide with the arc of latitude, namely the arc PHD. Accordingly, in triangle PHR, right-angled at R, from the given altitude of the pole PR and the complement of declination PH, seek the angle PHR, that is, CHD; with this, and with the latitude DH, in triangle CHD, seek the side CD and the angle HCD. Then with this angle C and with the arc of vision AB, in triangle CAB, right-angled at B, seek the base CA, and subtract from it the arc CD; for the arc DA will be left as the interval of emersion or occultation that was wanted.

[Margin: Case 3.] Third, let the star be at H, possessed of northern latitude, and [?] far from the beginning of Cancer or Capricorn. With the arc PHD of declination and the arc KHI of latitude drawn, first in triangle PHR, right-angled at R, from the pole's altitude PR and the complement PH of the star's declination, find the angle PHR. Then in triangle PHK, in which PK is the distance of the poles, known from the obliquity of the ecliptic, PH is known from the complement of declination, and the angle HPK from the distance of the star's true place from the beginning of Cancer or Capricorn, seek the angle PHK, and subtract it from the angle PHR, so that what remains is KHR, that is, CHI. With this, in triangle CHI, right-angled at I, and with the latitude HI, determine both the side CI and the angle at C. Finally, with this angle and with the arc of vision AB, in triangle CAB, right-angled at B, seek the base AC; take from it the arc CI, and the interval of emersion or occultation IA will be left. You will proceed in the same way if the star's latitude is southern, namely GO or GF, with the arcs MGO drawn from the south pole of the world and NGF from the south pole of the ecliptic.

Problema 3. Idem ope Tabularum adipiſci.

Problem 3. To obtain the same with the aid of tables.

X. By this technique Ptolemy, book 13, ch. 8 and 9, showed us the intervals of emersions and occultations for the five planets, placed at the beginning of the signs, for a pole altitude of about 34°. In imitation of him Reinhold, at the end of the Prutenic Tables, gave a similar small table for the beginnings of the signs, for what may be, I do not know, the pole altitude of Frombork, 54° 22′. Magini transcribed it without any correction in the second volume of the *Secunda Mobilia*, p. 727, but supposing it to hold for the 3rd climate; and so did Lansbergen in his tables, p. 160, although it does not fit so exactly the pole altitude of Goes, which is 51° 31′; and so did Daniel Santbech, prop. 21. The use of these tables is taught by Reinhold in precept 73 and by Magini in the *Secunda*

Mobilia, canon 99. But the same Magini built another table, for pole elevations of 43°, 44° and 45° and for all the degrees of the signs, which is found near the end of the tables they call those of the Directions of the primum mobile, and in the same volume, canons 21 and 22, he taught its notable use. Kepler, however, left out tables of this kind, which take almost no account of latitude and are adapted to only one climate or another. Yet so as not to seem to have despised this precept, he adopts the arc of vision handed down by Ptolemy, and teaches how to find the arcs and times of emersions or occultations through the table of the rising angle [tabulam anguli orientis], in precept III of the Rudolphine Tables. But we reserve these precepts for the practical part of this first volume, in which the already mentioned tables will have to be set out.

Problema 4. Dato Arcu Viſionis Tabulas Interualli emerſionis atque occultationis ad quamcumque Poli eleuationem conſtruere.

Problem 4. Given the arc of vision, to construct tables of the interval of emersion and occultation for any elevation of the pole.

XI. What Reinhold promised at the end of the precepts, and Magini delivered for three pole altitudes, 43°, 44° and 45°, almost at the end of the tables of the primum mobile, you will be able to carry out for any pole altitude, not only at the beginnings of the signs but also at any degrees of the signs, by a very short precept which Regiomontanus (book 8 of the *Epitome of the Almagest*) and Daniel Santbech (*On the Observation of Phenomena*, prop. 21) have pointed out to us. It runs as follows. Multiply the right sine of the arc of vision by the whole sine, and divide the total by the sine of the angle of the ecliptic and the horizon that belongs to the beginning of the given sign or to any degree of it. The quotient will be the sine of the arc of apparition or occultation.

EXEMPLVM.

Example.

Let the Sun be in ♊ 2° 26′. To these, under a pole altitude of 48°, there corresponds an angle of the ecliptic and the horizon of 22° 41′, whose right sine is 38564. Now let the arc of vision of Mercury be 10°, whose sine is 17365. Multiplied by the whole sine, 100000, it makes 1736500000. When this total is divided by 38564, there remains 45028, that is, the sine whose arc, 26° 46′, shows the distance of this planet from the Sun on the ecliptic required for it to be able to appear at rising. But in this precept the planet is supposed to have almost no latitude.

Problema 5. Dato interuallo Emerſionis aut Occultationis, Diem emerſionis aut occultationis coniÿcere, dummodo Digreſſio Planetæ à Sole non ſit minor illo interuallo.

Problem 5. Given the interval of emersion or occultation, to infer the day of emersion or occultation, provided the planet's digression from the Sun is not smaller than that interval.

XII. First, from the true argument, or equated anomaly of the orb, that is, the distance of the planet from the true apogee of the epicycle, gather the kind of emersion or occultation: for if a superior planet is a little after the apogee, a morning emersion is near; if a little before the apogee, an evening occultation. An inferior planet, however, a little after the apogee is nearer to an evening emersion, and a little before the apogee to a morning immersion; but a little before the perigee it is nearer to an evening occultation, and a little after the perigee to a morning emersion. [Margin: Mercury not visible even at its greatest digressions.] Second, from the place of the Sun and of the planet in the zodiac, which the ephemerides supply, draw out the distance between them that answers to the interval of emersion or occultation; for on the day when it is equal to the interval, the planet will first begin to emerge or to be hidden; but as long as it is smaller than that interval, the planet will lie hidden under the Sun's rays. It happens not rarely, moreover, that Mercury's greatest digression from the Sun is smaller than that interval, and for that reason it cannot appear.

For the remaining problems bearing on risings and settings, go back to book 6, ch. 21.

SCHOLIA.

Scholia.

I. It was said above, toward the end of no. 8, that Venus often needs no arc of vision, or depth of the Sun below the horizon, in order to be seen, since she is visible in the daytime, and has rather often been observed by us, even with the naked eye, from about her rising to her setting, especially around her greatest digressions from the Sun; but at those times she is very far from the Sun's rays. We now put forward another marvel peculiar to her, most worthy of note, which befalls her from great latitude, especially northern. [Margin: Venus appearing in the evening and in the morning on the same day.] It is this: on the same natural day she is seen in the evening shortly after sunset, and is Hesperus, and on the following morning she appears in the morning shortly before sunrise, and is soon Lucifer. That this comes about by favour of northern latitude, nearly at the perigee of the epicycle, is taught by Maurolico, dial. 3 of the *Cosmographia*, p. 101, and, following Regiomontanus, by Reinhold on Peuerbach, p. 153, who adds that she is of this kind around the beginning of Aries at the perigee of the epicycle, and awaits an example of this phase from the ephemeris for the year 1547, about the beginning of March. This double

phase is helped, however, by the size of the apparent diameter in altitude, of which we gave a specimen in this book, sect. 1, ch. 2, no. 4. It is helped too by the outstanding brilliance of Venus, on which there is this from Pliny the Elder, book 2, ch. 8: "Now in size it stands beyond all other stars, and it is of such brightness that shadows are cast by the rays of this one star." [Margin: The brilliance of Venus producing a shadow.] From this, I would believe, Martianus Capella, book 8 of the *De Nuptiis Philologiae*, took this encomium of Venus: "Alone of the five stars she casts a shadow, as the Moon does; and alone, long visible, she does not yield to the brightness of the emerging Sun." Granted that Jupiter too may throw some shadow behind opaque bodies. It is no wonder, then, if, with a northern latitude of almost 9°, the greatest apparent size at the perigee of the epicycle, and the brilliance of this star all working together, Venus in the year 1587 was seen from February 21, on which she was an evening star, and on the following days, while on February 24 she was by then a morning star: seen, I say, both by Tycho, as Longomontanus testifies in book 2 of the *Theorica*, ch. 18, and by Mästlin, as he himself states in his additions to the *Narratio prima* of Rheticus, p. 136 in my copy. Kepler had this in view in the Rudolphine Tables, p. 71, where, at the foot of the latitudes of Venus, he says as follows: "At times ♀ is seen in the morning and in the evening together for two or three days, emerging in the morning before she is hidden in the evening." And in the *Epitome of Copernican Astronomy*, p. 838: "Venus, which often lies hidden for a very long time, on other occasions, namely when retrograde in Pisces, does not set in the evening until after conjunction with the Sun in longitude, and rises in the morning before conjunction, and so emerges in the morning before she is hidden in the evening, so that on the same day she is visible in the evening and in the morning, notwithstanding that she is thinned to a horn."

II. [Margin: The twofold emersion and occultation of Mars.] The same author, on the same page of the *Epitome*, observes that Mars sometimes rises twice as a morning star out of the Sun's rays in the intervening time, though after conjunction with the Sun it is hidden again for a while; and that sometimes too it is hidden twice in the rays before conjunction with the Sun, an irregular rising having occurred in between. [Margin: The emersion of Mercury in ♉ or ♏: when and where is it impossible?] He observes also that Mercury in our hemisphere, as a morning star in ♉ and as an evening star in ♏, although digressed very far from the Sun, nevertheless does not emerge from the Sun's rays, and so offers itself to our sight more rarely, while in the southern hemisphere it is then seen very clearly; which Ptolemy too had noted long before, book 13, ch. 8.

III. [Margin: On the arc of vision for the smallest stars, and on refraction.] The arc of vision for the smallest stars is about as great as the depth of the Sun at the beginning of morning twilight and the end of evening twilight, which is not everywhere or always 18°, as is clear from what was said in book 1, ch. 31.

And since the horizontal refraction is about as great in the stars as in the Sun, there is no need to correct the already mentioned arcs on its account.

CAPVT VI.

Chapter 6.

De Ortu & Occaſu Quinque Minorum Planetarum.

On the rising and setting of the five minor planets.

I. We have set out abundantly the Latin and Greek names and the kinds of risings and settings, and of the various configurations pertaining to them, in book 1, ch. 32, but more accurately in book 6, ch. 21, on the occasion given by the fixed stars; though schemes placing those kinds before the eyes are found in book 1, ch. 32. What concerns heliacal risings and settings, that is, emersions from the Sun's rays and occultations made at the horizon, we have already pursued in the preceding chapter, though referring the reader to book 6, ch. 20, for many problems. [Margin: Authors who treat of the rising and setting of the planets.] About the remaining kinds of rising and setting, namely the cosmical and the acronyctal or acronychal, the authors have not been as careful as about occultations and apparitions; those authors I listed in ch. 5, no. 6. The same authors or others who also treat of these kinds of risings and settings belonging to the planets are to be listed, namely: Ptolemy, book 8, ch. 4, and there Regiomontanus, applying that passage to the planets, especially the superior ones; al-Battānī, ch. 48 and 49; al-Farghānī, differentia 24 and 26; Jābir ibn Aflaḥ, book 9; Peuerbach in the *Theoricae Planetarum*, on the affections, and there Reinhold from p. 149 and Wurstisen from p. 282; again Reinhold in the Prutenic Tables, precept 73; Copernicus, book 2, ch. 13; Alessandro Piccolomini in the *Theoricae*, book 2, ch. 6; Magini in the *Theoricae Planetarum*, book 2, ch. 14, and in the *Secunda Mobilia*, canons 98 and 99, and in the Tables of Directions, canons 19, 20, 21 and 22; Kepler in the *Epitome of Copernican Astronomy*, book 6, p. 834; Barozzi in the *Cosmographia*, p. 133; Origanus, part 2 of volume 1 of the *Ephemerides*, ch. 8. Nor are the things Pliny the Elder touches on obscurely, book 2, ch. 15 and 17, without relevance here. From these authors we shall set out briefly which kinds of rising and setting belong to these five planets, in what order, and at what places on the epicycle, and we shall not be reluctant to repeat here some things handed down in book 6, ch. 21.

Species & Ordo Occaſuum & Ortuum, tribus Superioribus Planetis conuenientium.

Kinds and order of the settings and risings belonging to the three superior planets.

For the Greek names see book 6, ch. 21, p. 467; for the schemes see book 1, ch. 32.

II. [Margin: True morning rising and true evening setting.] First. They rise in the morning together with the Sun, by true or cosmical rising, and together with it they set in the evening, likewise by true setting: that is, at the same moment as the Sun they ascend above the horizon in the morning and descend below it in the evening, since they are conjoined with it in the same place of the zodiac. This happens to them at the apogee of the epicycle and in the middle of the course of direction, where they are swiftest, but at that time they lie hidden under the Sun's rays, and so neither of the two is apparent. Once the ♂ with ☉ is complete, they become morning and eastern stars.

[Margin: Heliacal morning rising.] Second. They rise heliacally in the morning, or emerge from the rays of the Sun as it leaves them behind, since they are slower than it. This rising is called the apparent morning or heliacal rising: namely when they first begin to appear on the horizon in the morning before sunrise, which happens a little after the apogee of the epicycle. After this, every day at dawn they appear earlier and earlier, that is, by more moments or even hours before sunrise; and when the Sun rises they stand higher and higher above the horizon, but almost at once they vanish, although Jupiter around the quadrate aspect is visible for nearly a whole quarter of an hour after sunrise. They continue as morning and eastern stars through the whole left semicircle of the epicycle, and appear at each dawn, thereafter higher and higher above the eastern horizon, and finally close to the western horizon.

[Margin: True evening rising and true morning setting.] Third. They rise in the evening acronychally, by true evening rising: that is, they ascend above the horizon as the Sun descends, and on the same natural day they set cosmically, or by true setting in the morning, namely descending below the horizon at the same moment at which the Sun ascends. They are then called [Greek: παννύχιοι (pannychioi, "all-night")] or night-long, and [Greek: ἀκρονύκτοι (akronyktoi, "acronychal")], that is, shining at both ends of the night, or rather from one end to the other, as happens to the full Moon; and Ptolemy in book 10 calls this phase [Greek: ἀκρόνυκτον διάμετρον (akronykton diametron, "acronychal diameter")]. This happens to them in opposition with the Sun, namely when they are at the perigee of the epicycle and in the middle of retrogradation, that is, slowest as to motion in the order of the signs, though swiftest against the order of the signs. Once the ☍ with ☉ is complete, they become evening and western stars, and remain so through the whole right semicircle of the epicycle; every night they appear after sunset in the east, raised higher and higher above the horizon, then on the meridian, and finally in the west.

[Margin: Heliacal evening setting.] Fourth. They set in the evening by apparent or heliacal setting, hiding themselves under the rays of the Sun, which, as they are slower than it, overtakes and forestalls them; and whereas on the preceding days they appeared after sunset on the western horizon, they cease to appear there and lie hidden under its blaze until their morning emersion. This occultation happens a little before conjunction with the Sun and the apogee, as

the emersion does a little after. And at emersion they [Greek: ἐπιτέλλουσιν (epitellousin, "rise")], at occultation they [Greek: κρύπτονται (kryptontai, "are hidden")], as the Greeks say.

They do not have the remaining kinds of apparent rising and setting, that is, the evening heliacal rising and the morning heliacal setting, because they are slower than the Sun and neither free themselves from it nor overtake it, but are rather forestalled by it and uncovered by its departure.

Specis & Ordo Ortuum & Occaſuum Mercurio & Veneri conuenientium.

Kinds and order of the risings and settings belonging to Mercury and Venus.

III. [Margin: The earlier true morning rising and true evening setting.] First. They rise cosmically, or, by true rising in the morning, ascending above the horizon together with the Sun; and on the same day they set with the same Sun in the evening, by true setting, descending below the horizon together with the Sun, since they are conjoined with it above, at the apogee of their epicycle, and so in the middle of their direction and swiftest. But neither their rising nor their setting is apparent, because they lie hidden under the Sun's blaze. Once the apogee ☌ with ☉ is complete, they become evening and western stars.

[Margin: Heliacal evening rising.] Second. They rise heliacally in the evening, or by apparent evening rising, emerging by their own speed, being direct, and a little after the apogee of the epicycle, from the Sun's rays; after its setting they begin to appear on the western horizon. After that they continue as evening and western stars through the whole left semicircle of the epicycle, and as the Sun sets, or when it has set a little before, they are seen each evening higher above the western horizon, up to their greatest digression from the Sun. After this they approach the first station, and then, lower and slower, having become retrograde, they go to meet the Sun, which will at last overtake them.

[Margin: Heliacal evening setting.] Third. They set heliacally in the evening, or by apparent evening setting hide themselves under the Sun's rays, and in turn are hidden by it, which happens to them a little before the perigee of the epicycle, and when retrograde.

[Margin: The later true morning rising and true evening setting.] Fourth. They again rise cosmically in the morning, and by true setting set in the evening, since they are conjoined with the Sun again, but below, at the perigee of the epicycle and in the middle of retrogradation, in which they are slowest as to motion in the order of the signs but swiftest as to motion against the order of the signs. Once the perigee ☌ with ☉ is complete, they at once become morning and eastern stars.

[Margin: Heliacal morning rising.] Fifth. They rise heliacally in the morning, that is, by apparent morning rising, emerging from the Sun's rays, or rather left behind by the Sun as the swifter, since they are themselves retrograde. After that they continue as morning and eastern stars through the whole right

semicircle of the epicycle, and as the Sun rises or is soon to rise they become higher every day, up to the greatest digression from the Sun, which follows the second station. From there, with hurried course, they become every day nearer the horizon, but swifter, and hastening toward the apogee.

[Margin: Heliacal morning setting.] Sixth. They set heliacally in the morning, or by apparent morning setting hide themselves under the rays, a little before the apogee ☌ with ☉; and whereas on the preceding days they appeared at dawn on the horizon, they cease to be seen there, and lie hidden under its splendour until their evening emersion.

[Margin: Corollary.] They do not have the remaining kinds of true rising and setting, that is, the true evening rising and the true morning setting, because they cannot digress from the Sun by a whole semicircle of the heaven, nor come into diametrical opposition with it. Therefore the three superior planets have all four kinds of true rising and setting, but lack two kinds of the apparent; the two inferior planets, by contrast, have all four kinds of apparent rising and setting, but lack two kinds of true rising and setting.

But so that you may have a shorter summary, look at the following small table, in which the letter D signifies a direct planet and R a retrograde one.

Synopsis of the order of the already mentioned phases.

Order	♄ ♃ & ♂	On the epicycle	
1	True morning rising	At apogee and in	D
2	True evening setting	☌ with ☉	D
3	Heliacal morning rising	A little after ☌ ☉	D
4	True evening rising	At perigee and in	R
5	True morning setting	☍ with ☉	R
6	Heliacal evening setting	A little before ☌	D
	They lack the heliacal evening rising and the heliacal morning setting		

Order	♀ & ☿	On the epicycle	
1	True morning rising	At apogee and in	D
2	True evening setting	☌ ☉ above	D
3	Heliacal evening rising	After ☌ ☉ above	D
4	Heliacal evening setting	Before ☌ ☉ below	R
5	Second true morning rising	At perigee and	R
6	Second true evening setting	☌ ☉ below	R
7	Heliacal morning rising	After ☌ ☉ below	R
8	Heliacal morning setting	Before ☌ ☉ above	D

Order	♀ & ☿	On the epicycle
	They lack the true evening rising and the true morning or cosmical setting, regularly and in most climates	

SCHOLIA.

Scholia.

I. [Margin: Notable points on the oppositions [recte: apparitions, per the book's errata] of ♂, ♀ and ☿.] It should be noted with Kepler, in the *Epitome of Copernican Astronomy*, p. 835, that sometimes in Venus when retrograde the order of the apparitions is interchanged, and other changes occur, on which book 6, ch. 21, in the Scholium, where we showed that a true evening rising and a cosmical setting can belong to Venus and Mercury. And in Mars too the order of apparitions can be interchanged. As for Ptolemy's teaching, book 13, ch. 8, that Mercury at perigee in Taurus and at apogee in Scorpio cannot be seen in the fourth climate, this does not hold for much more northerly climates, as Reinhold rightly teaches in the *Theoricae*, p. 153.

II. [Margin: Variation of the seasons from the aspects and apparitions of the planets.] Also from the same Reinhold, in the same place, p. 151, and from Ptolemy, book 1 of the *Apotelesmatica*: just as the Sun makes the four seasons of the year, so proportionally Saturn, Jupiter and Mars moisten notably from the heliacal morning rising to the morning station; from there to opposition with the Sun and the acronychal rising they heat; from there to the second station they parch; and from there to the heliacal evening setting they chill. Similarly Venus and Mercury moisten from the morning rising to the nearest station, from there to the morning setting they heat, and again from the evening rising to the other station they dry, and from there to the evening occultation they rather chill. To this opinion subscribe the author who wrote the isagoge to Abū Maʿshar, and also Pontanus [Giovanni Pontano], *De rebus cælestibus*, although the commentator of the *Quadripartitum* and Guido Bonatus [Guido Bonatti] think otherwise.

III. We gave another small table and an epigram, for distinguishing the kinds of risings and settings belonging to the planets and the fixed stars, in book 1, ch. 32.

CAPVT VII.

Chapter 7.

De Aſpectibus Planetarum cum Sole & inter ſe ſe.

On the aspects of the planets with the Sun and among themselves.

I. Two very notable things happen to the configuration of planets taken two at a time, with one another or with the Sun: one concerning the rays sent down

to the Earth, from which arise aspects or radiations; the other concerning speed or slowness in apparent motion, from which harmony arises. We have already said no little about aspects in book 1, ch. 33, where with two schematisms we instructed the beginner sufficiently. Now, however, we must take up the treatment of them again more accurately. [Margin: Authors who treat of the aspects.] They are dealt with especially by Ptolemy, book 3 of the *Harmonics*, ch. 8, and book 1 of *De Iudiciis Astrorum*, ch. 12; Firmicus, book 2, ch. 29; al-Battānī, ch. 49 and 54; Jābir ibn Aflaḥ, book 6; the author of the isagoge to the *Astrologia* of Abū Maʿshar, book 6, ch. 8; Valentinus Naiboda [Valentin Naboth] on Alcabitius [al-Qabīṣī], that is, in the *Elementa Astrologica*, p. 52 and 324; Reinhold on Peuerbach's *Theoricae* from p. 179; Wurstisen in the same from p. 299; Maurolico in the *Cosmographia*, p. 46; Magini, book 2 of the *Theoricae*, ch. 17, and in the *Isagoge* to the ephemerides, ch. 30 and 31, and in the *Secunda Mobilia*, canon 52, and in the Directions of the primum mobile, from canon 39 to 41; Langius in the *Theoricae*, ch. 15;

Origanus in volume 1 of the *Ephemerides*, part 3, ch. 6; Kepler in the *Ephemerides* from p. 27 to 38, and in the book *De Stella Nova* from ch. 7 to 10, and in the *Epitome of Copernican Astronomy*, p. 840, and in the *Harmonics*, book 4, ch. 6, and in the *Mysterium Cosmographicum*, ch. 12. From these we shall select the things more worth knowing.

Quid ſit Aſpectus, & Quæ illius conditiones.

What an aspect is, and what its conditions are.

II. [Margin: The ancient definition of aspect.] An aspect, as Naiboda defines it, is an arc of the zodiac, or an interval reckoned in the zodiac, from which the stars communicate the greatest force to one another. But by the definition of Magini in the *Directions*, canon 39, an aspect is the radiant mingling of planets and stars with one another, from certain determinate places of the circle or sky, by which their united power flows in and is applied to a certain determinate part of the Earth. But Kepler, in the *Epitome of Copernican Astronomy*, because he denies that rays sent from star to star communicate their power to it, and admits only a union of radiant power made on the Earth, defines aspect in these words: *An aspect is an angle at the Earth formed by the luminous rays of two planets, effective in stimulating sublunary nature.*

[Margin: Kepler's definition corrected.] But neither conjunction nor opposition, which he nevertheless accepts among the principal aspects, forms an angle at the Earth of itself when the conjunctions or oppositions are central, let alone when they are made σωματικῶς [Greek: σωματικῶς (sōmatikōs, "bodily")], that is, by body. Therefore it seems to me that aspect should be defined thus: *An aspect is the concurrence on the Earth of rays sent down straight from two stars, effective in stimulating sublunary nature.*

Now this effectiveness arises from the perfect proportion of the already mentioned angle to the four right angles standing around one point of the

Earth. The perfection of this proportion requires two things. 1. That the terms of the proportions be commensurable; that is, that the angle making the aspect be an aliquot part, or consist of aliquot parts, measuring the whole circle or four right angles. 2. That the arc which is the measure of this angle be cut from its circle geometrically, namely by a straight line that is expressible [effabilem], or at least knowable [scibilem].

Moreover, the regular figures that can be inscribed in a circle and are knowable are infinite, if one considers the continued division of the arcs and the doubling of the sides or chords; yet the radical ones are three, namely the trigon, the tetragon and the pentagon. For the hexagon is the offspring of the trigon with its sides bisected, and the dodecagon of the hexagon, etc.; so too the octagon is the offspring of the tetragon, and the decagon, icosagon [Icoſigonum] etc. of the pentagon. And although the already mentioned perfection is required on the side of geometry, yet physically a certain magnitude of the angle, or incidence of the rays, is required, so that from this and from the already mentioned perfection of proportion there may arise a force effective in stimulating the nature of sublunary things. For in truth the efficacy of aspects is seen on the Earth, not in the stars themselves passively; granted that, by a certain semi-poetic manner of speaking, astrologers attribute many things to the planets, just as if they were all on the very surface of the fixed stars and gazed at one another and by mutual irradiations struck, helped, weakened and fostered one another, etc.

Quot ſint Aſpectus antiqui & Noui, & Quæ illorum ſubdiuiſio.

How many aspects there are, old and new, and what their subdivision is.

III. Old astrology recognised only five, namely conjunction, opposition, the tetragon or quadrate, the trigon or trine, and the hexagon or sextile, for a reason to be stated in ch. 8, no. 6. But Kepler, partly from Mästlin, Fabricius and certain physicians, partly from his own observation and from stimuli found in sublunary nature, added 8 others, whose selection will be discussed in Chapter 8, from number 2 to 5. Their names and quantities are shown in the following table, the new being distinguished from the old by a difference of type. I have added the Greek names for those aspects whose arcs subtend the sides of regular figures inscribed in a circle.

Names of the aspects	Signs	Quantity of the angles	Greek names
1 ☌ Conjunction [Coniunctio]	0	0°	σύνοδος (synodos),
2 *Semisextile* [Semiſextus]	1	30°	δωδεκάγωνος (dōdekagōnos)
3 *Decile* [Decilis]	.	36°	δεκάγωνος (dekagōnos)
4 *Octile* [Octilis]	.	45°	ογδόγωνος (ogdogōnos)
5 Sextile [Sextilis]	2	60°	ἑξάγωνος (hexagōnos)
6 *Quintile* [Quintilis]	.	72°	πεντάγωνος (pentagōnos)
7 Quadrate [Quadratus]	3	90°	τετράγωνος (tetragōnos)

Names of the aspects	Signs	Quantity of the angles	Greek names
8 *Tridecile* [Tridecilis]	.	108°	
9 Trine [Trinus]	4	120°	τριγώνος (trigōnos)
10 *Sesquiquadrate* [Seſquadrus]	.	135°	
11 *Biquintile* [Biquintilis]	.	144°	
12 *Quincunx*	5	150°	
13 Opposition [Oppoſitio]	6	180°	διάμετρος (diametros)

Of these, no other applies to Mercury besides ☌ with ☉, unless perhaps the semisextile, in some hypothesis granting it a digression from the Sun of 30°. To Venus with the Sun, however, only the first four aspects apply; but between Venus and Mercury nearly the first seven can occur; and to the other planets, any two of them, all the aspects apply without distinction.

[Margin: Subdivision of aspect.] Any aspect is further subdivided into true or apparent, and mean, according as the true or mean place or motion is considered in it; but commonly, with the exception of ☌ and ☍, the true ones are considered. Again it is divided into partile and platic. A partile aspect, or perfect and exact one, is when two stars are exactly as many degrees apart as are required for that aspect. A platic aspect, πλάτικος [Greek: πλάτικος (platikos, "broad")], or by orb, or loose, is when between two stars there is not the exact quantity of arc required for that aspect, but it is nevertheless found if the amplitude or light of their orb is considered. But if a planet is so joined to another that it is less distant than the sum of the apparent semidiameters of both, this is called a *bodily conjunction*, or conjunction by body, σύνοδος σωματικὴ [Greek: σύνοδος σωματικὴ (synodos sōmatikē, "bodily conjunction")]. [Margin: Bodily ☌, or by body.] Moreover, the quantity or light of the orbs to which they extend their powers, as determined by the astrologers together with Cardano on book 3 of the *Quadripartitum*, text 63, is set out below.

Quantity or light of the orbs [Quantitas ſeu Lux orbium]

Fixed stars, magnitude	Light of the orbs	Planets	Light of the orbs
1	7° 30′	♄	10° 0′
2	5° 30′	♃	12° 0′
3	3° 30′	♂	7° 30′
4	1° 30′	☉	17° 0′
5	1° 0′	♀	8° 0′
6	0° 30′	☿	7° 0′
		☾	12° 30′

But Origanus holds that the orbs of the planets are spaces of the zodiac within which planets joined to the Sun are hidden for some time; these he confuses with the arcs of vision, although from 3 *Aphorisms* 29 he determines the quantity of the orbs thus: ♄ 9°, ♃ 10°, ♂ 8°, ☉ and ☾ 15°, ♀ 8°, ☿ 7°.

[Margin: Simple and composite aspect.] Next, just as the partile is subdivided into simple and composite, according as longitude alone is considered in the

former, but longitude and latitude in the latter, so the platic is subdivided into application and defluxion [Defluxum] or separation. [Margin: Application and defluxion.] Application occurs when a swifter planet approaches a slower one; when it recedes from it, this is called defluxion, provided the distance is not greater than their rays. And it can happen that a lower planet is heavier, or slower, than some upper one, if one of the lower planets is retrograde or diminished in number.

[Margin: Right and left aspect.] Furthermore, every aspect is divided into left and right. A left aspect is one reckoned, with respect to some determinate point in the sky, according to the succession of the signs; a right aspect against the order of the signs. Of these the right is stronger when compared with the angles of the sky, because the stars are borne towards it by the force of the primum mobile; but the left is judged stronger when compared with other stars, because the planets approach it by the force of their own motion. But the astrologers say more about these things in their introductions to ephemerides.

De Reductione Aſpectuum ad Eclipticam.

On the reduction of aspects to the ecliptic.

IV. [Margin: Authors who treat of this reduction.] On this reduction one should consult Regiomontanus in the Tables of Directions, problem 31; Valentinus Naiboda on Alcabitius, from p. 324; Cyprián Lvovický in the *Method of Directions*, p. 13 before the end; Magini in the Tables of Directions of the primum mobile, canon 39; and Kepler in the *Ephemerides*, p. 37, and in the *Epitome of Copernican Astronomy*, p. 845.

Whether, then, you consider rays sent from one star to the other and from there to the Earth, or rays sent upward from a star to the zodiac (for we suppose that any star diffuses rays of light and of an occult quality spherically, or in every direction), the centres of the stars must nevertheless be regarded just as if they were in the concave of the primum mobile, since it is in that concave that we consider their places; and straight lines are drawn from the points of the highest sky through the centres of the two stars. These lines either meet one another at the centre of the Earth, as happens in opposition, or coincide and stretch towards one another, as in conjunction, or make at the centre of the Earth an angle subtending an arc of a great circle in the highest sky. That great circle will be the ecliptic if neither of the stars has latitude; but it will cut the ecliptic if they have latitude.

Now if they lack latitude, there is no need of reduction. But if one or both of the stars has a rather large latitude, not less than a degree and a half, reduction will be needed, because latitude alters both the strength of the radiations and the intervals of the aspects, since radiations or aspects are judged most effective in the ecliptic itself. It is indeed true that Ptolemy, in book 1 of the *Quadripartitum*, ch. 21, neglected this reduction in the remaining aspects on account of the slight difference, because it rarely happens that two planets placed in sextile or

trine aspect have the greatest or a very great latitude, and because the rays of the stars, from wherever they are sent, make an angle at the centre of the Earth; and Naiboda and the older authors subscribe to Ptolemy.

But in judging the meetings of applications and defluxions, whether or not they are bodily, latitude makes a great difference. For then neither do the lines of conjunctions, to be drawn from the Earth through the centres or bodies of the two stars, coincide, nor do the lines of opposition, drawn from one star through the centre of the Earth to the other, meet one another in a straight line; rather they are inclined to one another and make an angle at the centre of the Earth, unless the south latitude of the one is as great as the north latitude of the other. Therefore account must be taken of latitude, in the mind of Ptolemy. Most of the more recent authors, however, accept the reduction for other aspects, especially the sextile and trine. So let us set out its rules.

[Margin: General rules of the reduction.] 1. Rule. *If the stars lack latitude, or do not have a latitude greater than 1° 30′, the reduction can safely be neglected.*

2. Rule. *The quadrate aspect of any planet with the Sun or with another star devoid of latitude does not need reduction, however great a latitude the planet itself has.*
3. Rule. *The quadrate aspect of two stars, each of which has a great latitude, needs reduction. But if only one has latitude, the place of the quadrate radiation is 90° distant on either side from the star's true longitude and does not need reduction.*
4. Rule. *To an aspect less than a quadrant, if the latitude of the stars making the aspect is of a different species, or notably different in quantity, there corresponds in the ecliptic a smaller arc.*
5. Rule. *To an aspect greater than a quadrant, if the latitude of the stars making the aspect is of a different species, or notably different in quantity, there corresponds in the ecliptic a greater arc.*
6. Rule. *If the latitudes of the configured stars are nearly equal and of the same quarter or species, then greater arcs of the ecliptic correspond to all aspects without distinction.*
7. Rule. *An opposite radiation falls on the point of longitude diametrically opposite, with a latitude of the same quantity but of contrary denomination. Therefore the longitude indeed does not need correction or reduction; but the latitude of the radiation is north if the latitude of the radiating star is south, or south if the latter is north.*

Note that for the fixed stars the reduction arises from latitude alone.

Problema 1. Aſpectum ✶ & △ ad Eclipticam Reducere methodo ac tabulis Regiomontani & Magini.

Problem 1. To reduce the ✶ and △ aspect to the ecliptic by the method and tables of Regiomontanus and Magini.

V. Regiomontanus, in the *Directions* published at Wittenberg in the year 1606, p. 231, gave a small table for equating radiations, but Magini has a larger

table in canon 39 of the *Directions*. It is set out below, and it is founded on the solution of a right-angled spherical triangle whose base is 60° and whose side is the given latitude of the star in the circle of latitude. With the help of these givens, one seeks the arc of the ecliptic that is the longitude due to the sextile aspect reduced to the ecliptic; and the same longitude, subtracted from 180°, will give the longitude due to the trine aspect.

Equation of the aspects or radiations of the stars [Æquatio Aſpectuum ſeu Radiationum Stellarum.]

Latitude or declination	Arc ✶	Arc △	Latitude or declination	Arc ✶	Arc △
1	60° 0′	120° 0′	31	54° 19′	125° 41′
2	59° 59′	120° 1′	32	53° 52′	126° 8′
3	59° 57′	120° 3′	33	53° 24′	126° 36′
4	59° 55′	120° 5′	34	52° 55′	127° 5′
5	59° 52′	120° 8′	35	52° 23′	127° 37′
6	59° 49′	120° 11′	36	51° 50′	128° 10′
7	59° 45′	120° 15′	37	51° 14′	128° 46′
8	59° 40′	120° 20′	38	50° 37′	129° 23′
9	59° 35′	120° 15′	39	49° 57′	130° 3′
10	59° 29′	120° 31′	40	49° 15′	130° 45′
11	59° 22′	120° 38′	41	48° 31′	131° 29′
12	59° 15′	120° 45′	42	47° 43′	132° 17′
13	59° 7′	120° 53′	43	46° 52′	133° 8′
14	58° 59′	121° 1′	44	45° 58′	134° 2′
15	58° 50′	121° 10′	45	45° 0′	135° 0′
16	58° 40′	121° 20′	46	43° 58′	136° 2′
17	58° 29′	121° 31′	47	42° 51′	137° 9′
18	58° 17′	121° 43′	48	41° 39′	138° 21′
19	58° 4′	121° 56′	49	40° 21′	139° 39′
20	57° 51′	122° 9′	50	38° 56′	141° 4′
21	57° 37′	122° 23′	51	37° 23′	142° 37′
22	57° 22′	122° 38′	52	35° 42′	144° 18′
23	57° 6′	122° 54′	53	33° 49′	146° 11′
24	56° 49′	123° 11′	54	31° 43′	148° 17′
25	56° 31′	123° 29′	55	29° 20′	150° 40′
26	56° 12′	123° 48′	56	26° 36′	153° 24′
27	55° 52′	124° 8′	57	23° 22′	156° 28′
28	55° 31′	124° 29′	58	19° 21′	160° 39′
29	55° 8′	124° 52′	59	13° 53′	166° 7′
30	54° 44′	125° 16′	60	0° 0′	180° 0′

The use of the table is as follows. Given the latitude of the star, with it in the first column look in the second for the arc of the sextile aspect, or in the third for the arc of the trine aspect. Reckon this arc according to the order of the signs from the place of the planet's longitude, and you will have the left aspect; but if you count the already mentioned arc from the place of the planet's longitude against the order of the signs, you will have the right aspect. Know, however, that to the left sextile aspect there corresponds, in the diametrically

opposite place, the right trine aspect, and to the right sextile, the left trine; so that when one is known, the other becomes known.

EXEMPLVM.

Example.

Let Venus be at 20° of Gemini with a north latitude of 6°. To this there corresponds in the preceding table, under the ✶ aspect, an arc of 59° 49′, and under the △ aspect, 120° 11′. So add 59° 49′ to the 20th degree of Gemini, and you will find 19° 49′ of Leo, which Venus regards with a left sextile aspect; but on the contrary subtract, or count against the order of the signs, and you will land at 20° 11′ of Aries, a place which Venus regards with a right aspect. Diametrically opposite these stand the trine aspects: to the left one the right trine, at 19° 49′ of Aquarius, and to the right one the left trine, at 20° 11′ of Libra. You would also find these trine aspects if you added 120° 11′ to the 20 degrees of Gemini for the left, and subtracted them for the right. Furthermore, the left quadrate aspect will end at 20° of Virgo and the right at 20° of Pisces, for each is 90° distant from the longitude of Venus; just as the opposite aspect will be at ☍ 20°, but the latitude of the aspect will be 6° south. Thus, then, will the determination of these aspects stand.

Aspects of a planet placed at 20° ♊ with north latitude 6° [Aſpectus Planetæ in Gr. 20. ♊ poſiti cum Latitud. Bor. Gr. 6.]

	Left aspect: sign	Left aspect	Right aspect: sign	Right aspect
✶	♌	19° 49′	♈	20° 11′
□	♍	20° 0′	♓	20° 0′
△	♎	20° 11′	♒	19° 49′
☍	♐	20° 0′	♐	20° 0′
	But to the ☍ aspect assign latitude 6° south.			

Problema 2. Reducere Aſpectus ad Eclipticam priori methodo Kepleri, per tabulam Primi Mobilis.

Problem 2. To reduce aspects to the ecliptic by Kepler's earlier method, by means of the table of the primum mobile.

VI. I call the earlier method the one Kepler gives in the foundations of the *Ephemerides*, p. 37. For it one needs the first table of the primum mobile, or of the first analogy, which he transcribed from Regiomontanus into his Tables of Directions. One enters that table with the complement of the star's latitude at the head of the table, and in the area with the complement of the aspect if it is less than a quadrant, or with its excess over a quadrant if the aspect is greater than a quadrant. For on the same line you will have in the left margin a degree whose difference from the area number will be the equation, to be subtracted from an aspect less than a quadrant but added to an aspect greater than a quadrant. The arc of the aspect thus corrected is to be added to the

planet's longitude for a left aspect, and subtracted for a right one, etc., [Margin: 1. Case, if only one star has latitude.] if only one star has latitude.

EXEMPLVM.

Example.

Let the latitude of Venus on 1617 August 8 be 6° 38′, and suppose you wish to know how far the place of Venus should be from the Sun in the ecliptic for there to be a semisextile aspect, or one of 30°, between these two bodies. Since the aspect is less than a quadrant, apply its complement, which is 60°. Look for this in the area of the already mentioned table, under the complement of the latitude, 83° 22′, found at the head of the table; for on the same line as 60 degrees you will see corresponding in the left margin 60° 41′, if you apply the proportional part when the degrees are not found exactly in the table. So subtract from the semisextile aspect, or 30 degrees, the difference of the marginal number from the area number, which is 41′, and there will remain 29° 19′. So when the Sun is 29° 19′ distant from Venus, the aspect of Venus with the Sun will be semisextile and left.

VII. [Margin: 2. Case for the latitude of both stars, but different in species.] But if each star has latitude of a different species, the already mentioned table is not useful in geometrical rigour, because it is founded on a right-angled triangle, whereas in this case we need an oblique-angled triangle. Yet for the planets, which are always within the zodiac, you will be able to use it with a double entry (overlooking the small errors that lie hidden in this method) and using a combined difference, corresponding to the complement of the arc that arises from the sum of the aspect multiplied by the latitude of each and divided by the sum of the latitudes.

EXEMPLVM.

Example.

Let the latitude of Venus be 10° and of Mars 7°, one north, the other south, and let the distance required between these planets in the ecliptic be sought, so that they regard each other with a semisextile aspect, or one of 30°. The sum of the latitudes is 17°. Let it be, then: as 17 to 30, so the north latitude 10 to 18, whose complement is 72°. Again, let it be: as 17 to 30, so the south latitude 7 to 12, whose complement is 78. Therefore, in the first table of the primum mobile of Regiomontanus or Magini, or of the first analogy, look under 80°, which is the complement of the latitude 10°, and in the area for the number 72, and you will have in the margin 74° 58′, whose difference from the area number is 2° 58′. Again, under 83°, which is the complement of the latitude 7°, look in the area for the number 78; for in the margin you will have 80° 13′, and so the difference from the area number will be 2° 13′. Combining the differences, then, the sum of the differences is 5° 11′. This, taken from the aspect of 30° (because it is less than a quadrant), leaves the corrected aspect 24° 49′. So if Mars and Venus, or

any two planets, endowed with so great and such a latitude, are 24° 49′ apart in the ecliptic, they will regard each other with a semisextile aspect. If, however, you gathered this difference from an oblique-angled triangle, the arc of the ecliptic would be 25° 6′.

VIII. [Margin: 3. Case for the latitude of both planets, but of the same species.] But if the latitudes are of the same species, for either planet take the point opposite it, with a latitude of the contrary quarter; and for the aspect, its complement to a semicircle. Divide this complement according to the proportion of the latitudes, and, having sought the complement of the quotient in the area under the complement of the latitude, find the difference of the marginal number from the area number. Do the same for the other planet. Finally, add the sum of the differences to the aspect if its complement is less than a quadrant; subtract it if greater.

EXEMPLVM.

Example.

Let the biquintile aspect, or 144°, be sought between two planets whose latitude, for each, is 5° north. The complement of the aspect 144 to a semicircle is 36°, and the sum of the latitudes is 10°. Let it be, then: as 10 to 5, so 36 to 18, whose complement is 72. Look for this number in the area of the table, under the complement of the latitude, which is 85, and you will find in the margin 72° 41′. So the difference of the marginal number is 41′. Double this (because to the latitude of the other planet, being equal, there will likewise correspond a difference of 41′), and the sum is 1° 22′, which must be added to the aspect 144. So these planets will not regard each other with a biquintile aspect unless they are 145° 22′ apart in the ecliptic.

Problema 3. Reducere Aſpectus ad Eclipticam poſteriore methodo Kepleri per Antilogarithmos Rudolphinarum.

Problem 3. To reduce aspects to the ecliptic by Kepler's later method, by means of the antilogarithms of the Rudolphine Tables.

IX. This later procedure is given by Kepler in the *Epitome of Copernican Astronomy*, p. 845, for three cases, through the use of the table of antilogarithms in the Rudolphine Tables. [Margin: 1. Case for a single latitude.] The first case is when only one of the planets has latitude. Then from the antilogarithm of the latitude subtract the antilogarithm of the aspect if it is less than a quadrant, or, if it is greater than a quadrant, the antilogarithm of the complement of the aspect to a semicircle; for the remainder will be the antilogarithm of the arc of the ecliptic corresponding in the first case to the aspect, and in the second to the complement of the aspect to a semicircle.

EXEMPLVM.

Example.

Let one of the planets have a latitude of 10°, and let the semisextile aspect be sought in the ecliptic, that is, 30°. From the antilogarithm of 30°, which is 14384, subtract the antilogarithm of 10°, which is 1531; the remainder will be 12853, namely the antilogarithm to which 28° 26′ corresponds. So if the planets are 28° 26′ apart in the ecliptic, then in their own orbit they will regard each other with a semisextile aspect of 30°. But if the biquintile aspect 144 is sought, its complement is 36, from whose antilogarithm 21193 the antilogarithm of 10°, subtracted, leaves 19662, the antilogarithm of 34° 46′. When these are taken from 180°, there remains an arc of the ecliptic of 145° 14′. This distance of the planets shows that the planets in their orbit regard each other with a biquintile aspect of 144°.

X. [Margin: 2. Case of equal latitudes.] The second case is when both planets have equal latitudes; and then, the aspect being bisected, one seeks, as in the first case, the reduction suited to half the aspect, if la- titudes are of different species; or to the complement of half the aspect to a quadrant, if the latitudes are of the same species. The doubled reduction, or arc of the ecliptic, will then be the arc sought. [Margin: 3. Case of unequal latitudes.] The third case is when the latitudes differ in quantity, in the same or in different species; and the method is too laborious, as Kepler admits, who nevertheless gives it somewhat obscurely, by a bare example without rules.

Problema 4. Reducere Aſpectus ad Aequatorem.

Problem 4. To reduce aspects to the equator.

XI. In the *Directions of the Primum Mobile*, canon 40, Magini shows that the aspects of any stars whatever have great force when their distance is considered not only in the ecliptic but also in the equator; and he relies on the authority of Ptolemy, book 3 of *De Astrorum Iudiciis*, ch. 11, and of Cardano on the same book, ch. 14. The method of reducing aspects to the equator is exactly the same as that of reducing them to the ecliptic, given in Problems 1, 2 and 3, provided that the declination of the star or stars is used in place of the latitude, and an arc of the equator in place of the arc of the ecliptic.

Problema 5. Aſpectus Planetarum ad Aequatorem reductos, referre ad Circulos Poſitionum, vel ad circulos Horarios, vel ad Cuſpides Domorum.

Problem 5. To refer the aspects of the planets, once reduced to the equator, to the circles of position, or to the hour circles, or to the cusps of the houses.

XII. In the *Directions of the Primum Mobile*, canon 41, Magini thinks this reduction useful, and thinks that the force of planets is greatly altered by the rays of planets extended on the equator, when those rays fall either on the same

circle of position or on the same hour circle, etc. But since this reduction is less commonly used, I forgo the prolixity of rules and examples. As for you, if you have the leisure to lose better hours, consult Magini there.

Problema 6. Aſpectus Planetarum reducere ad Eclipticam, vel ad Aequatorem ex opinione noſtra.

Problem 6. To reduce the aspects of the planets to the ecliptic, or to the equator, according to our own opinion.

XIII. It certainly seems to me that the aspects of planets on different orbits inclined to the ecliptic are not to be determined with respect to the ecliptic or the equator until they have been reduced to the ecliptic by means of the given latitude, or to the equator by means of the declination, in the way we usually reduce the Moon's place from the lunar orbit to the ecliptic; since they exert their energy on the Earth in the ecliptic, or relatively to the ecliptic or the equator. And so if the places of two stars in the ecliptic are, for example, 60° apart, only then shall I pronounce that to be their ecliptic sextile aspect; or, if they are so apart in the equator, their equatorial one. Therefore, for each planet having latitude or declination, a single right triangle must be solved, in which the latitude or declination is assumed as given, as one side about the right angle, and also either the angle opposite it, that is, the inclination of the orbit to the ecliptic or to the equator, or at any rate the base itself, that is, the distance of the star from the nearer node, according to what will be said in the Problems of the primum mobile.

An & qui ſint Aſpectus Benigni, qui Maligni, Aut validiores, & cur?

Whether there are benign aspects, and which they are; which are malign, or which stronger; and why?

XIV. Among the cardinal or principal aspects, the trine and the sextile are judged by Ptolemy, *De Astrorum Iudiciis* book 1, ch. 12, to be agreeable, or fortunate and benign; but the opposition and the quadrate aspect disagreeable, and unfortunate or malign, because the former embrace like places of the signs, that is, all masculine or all feminine, and the latter unlike ones. Cardano on that passage, and Magini in the *Directions*, canon 39, deny that this reason is sufficient. And so Pontanus on that passage of Ptolemy, and Lucius Bellantius [Lucio Bellanti], question 9, art. 4, say that the opposition is malign because it is made by rays that oppose one another and collide, in nearly the way two contrary winds stir up great discords of storms. The quadrate aspect, on the other hand, is made by rays that do not indeed oppose one another head-on, yet strike each other at the sides; and because they stand at a point equidistant from the most conflicting termini, that is, from the termini of the opposition, they are therefore judged to be of middling enmity. Magini adds that a ray from a star or sign to another sign or star from which it is 90° distant falls in such a

way that it is reflected at an equal angle to the place diametrically opposite the first star or radiating sign, if that on which the radiation falls is taken as a solid body fit for reflecting; but that from the Earth it is reflected back on itself, since it falls perpendicularly, and is thus disturbed; and that for both these reasons it takes on a certain malignity. The trine aspect, however, both through the perfection of a figure that can be inscribed in a circle and does not presuppose others, and because it consists of rays that do not oppose one another but rather assist one another and conspire into one, is judged fortunate and beneficent, as is the sextile also. But Pico della Mirandola, and our own Alessandro de Angelis, and Kepler, *De Stella Nova* ch. 9, do not accept this, but either ridicule and attack it or, like Kepler, limit it. For he denies that any aspect is of itself fortunate or unfortunate; yet he maintains that they are distinguished only by their vehemence in stirring up sublunary nature. [Margin: The force of aspects asserted by experiments.] For it is established by experience that when there are no configurations of aspects, it is then above all that there is great calm in the air; but when the planets are configured in aspects, it is then above all that varieties of meteors are observed, each in its own kind. Kepler thinks, moreover, that what the aspects stir up is a reason [rationem] most natural not to bodies but to spiritual faculties, so that it perceives some harmonic agreement or other. But so far as these matters contain a certain physical speculation, they do not concern this work of ours; so far as that harmonic configuration touches astronomical geometry, however, it must be explained by us in the following chapter, though briefly. From that chapter, at number 6, it will also be clear why among the aspects the most powerful is ☌, next ☍, and after these □ ✶ △.

CAPVT VIII.

Chapter 8.

De Configurationibus Harmonicis, ac de Aſpectuum fundamento in Harmonicis proportionibus.

On harmonic configurations, and on the foundation of the aspects in harmonic proportions.

I. On the connection of the aspects with harmonic proportions, or on the harmony itself among the motions of the planets, one should read first of all Ptolemy, *Harmonics* book 3, ch. 8, and *Quadripartitum* book 1, ch. 12; Firmicus, book 2, ch. 29; Reinhold on Peuerbach's *Theoricae*, p. 182; Magini in the *Directions*, canon 39; but, most accurately and most learnedly of all, Kepler in the *Harmonics*, book 4, ch. 6, and in the *Mysterium Cosmographicum*, ch. 12, and in the book *De Stella Nova*, from ch. 7 to 10, and in the *Dissertatio cum Nuncio Sidereo*, and in the foundations of his *Ephemerides*, from p. 33, and finally in the *Epitome of Copernican Astronomy*, p. 900.

Origo Aſpectuum ex Harmonicis proportionibus, aut cognatio cum illis.

The origin of the aspects from harmonic proportions, or their kinship with them.

II. Sound indeed seems to have nothing in common with light and the rays of the stars; yet the consonances of sounds have in common with the aspects of the heavenly lights their numeration, and a geometrical and cosmopoetic origin. For just as, when the string of a monochord is struck at certain intervals, our ears are roused and struck, so the faculties of sublunary nature, by a certain configuration of the aspects imitating harmonic proportions, are stirred and provoked to exert their powers; so much so that Kepler, in the *Ephemerides*, suspected that God, Best and Greatest [DEVM O. M.], either from harmonic ratios derived the laws for arranging the aspects, or attuned human ears, the judges of concords, to the heavenly aspects. Moreover, out of the seven harmonic divisions of the monochord, made by means of a magadium or saddle [ephippij] placed under the string that is stretched and to be plucked, the older astronomers considered four principal ones in determining the aspects, whether the circle is divided into 360° or the zodiac into 12 signs, as if it were one string; and they assigned to them their harmonic proportions in this way.

[Margin: Proportion of ☍ to □, to △ and to ✶.] The opposition has to the quadrate, that is, 180° to 90°, or 6^s to 3^s, the double proportion, which they call the diapason; to the trine, that is, to 120° or to 4^s, it has the sesquialter proportion, which they call the diapente; and finally to the sextile, that is, to 60° or to 2^s, it has the triple proportion, which is either simple or composed of the diapason and the diapente.

[Margin: Proportion of □ to ✶.] The quadrate aspect has to the sextile, that is, 90° to 60°, or 3^s to 2^s, the sesquialter proportion, which the Greeks call ἡμιόλιον [Greek: ἡμιόλιον (hēmiolion, "one and a half")], and musicians the diapente.

[Margin: Proportion of △ to □.] The trine has to the quadrate the ratio ἐπίτριτον [Greek: ἐπίτριτον (epitriton, "one and a third")] or sesquitertian, as 120 to 90, or 4^s to 3^s, which they call the diatessaron.

III. But Kepler thought that, besides the unison, which corresponds to the conjunction, seven divisions of the circle should be considered, corresponding to as many harmonic divisions of the string. To these divisions of the circle correspond the chords fitted to the circle, or the sides of the notable regular figures inscribed in a circle: namely the side of the sexangle, the side of the quincangle, the side of the quadrangle, the side of the triangle; the chord subtending three eighths, and the chord subtending two fifths, and the diameter. From these arise eight aspects, namely conjunction, sextile, quintile, quadrate, trine, sesquiquadrate [Seſquadrus], biquintile and opposition; just as in music there are, besides the unison, seven other strings concordant with the lowest, and indeed with one another and with the whole string, each arising from one of the divisions of the whole monochord. And since in the following years he

had observed, at the three new aspects of the planets with the Sun, very frequent and notable changes of the air, excepting the sesquiquadrate, which seemed effective more rarely, he therefore, having detected their efficacy, decided that they too should be entered on the roll of aspects; and he says that from that time the prognosticators had vied with one another in using them. That the division of the quintile is harmonic is clear, because it cuts off from the whole circle a fifth part, or 72° of 360°. [Margin: The harmony of the new aspects is shown.] But if you divide the whole string into 5 parts and put the magadium under the first fifth, both the first fifth with the remaining four and either of them with the whole string will be concordant. So too for the harmony of the sesquiquadrate [Seſquiquadri], or sesquadrus, or trioctile (for they are the same): since it cuts off from the circle 135°, that is, three times 45°, which are three parts of eight, since 45 taken three times makes 135, and eight times, 360, let the monochord therefore be divided into 8 parts and the magadium be applied at three eighths. For both the upper part, or segment of 3, with the lower of 5 (which is the major hexachord), and the lower of 5 with the whole string of 8 (which is the minor sixth [ſexta mollis]), will give a harmonious sound. Finally, for the biquintile, which cuts off from the circle twice 72°, that is, 144°, or two fifths: divide the string into 5 parts and put the magadium under at two fifths; for both the segment of 2 with the remaining segment of 3, and the whole string of 5 with the 2 and with the 3, will be in consonance.

IV. [Margin: The origin of the other aspects.] Later on, however, some astrologers, whether by mistake taking in place of the sesquadrus a *Sequadrus* [Sequadrum], that is, half of a quadrate, or an octile of 45°, or otherwise from experiments, were issuing prognostications from this aspect; and Mästlin [Mœſtlinus] had pointed out in a certain disputation that, besides the triangle, the quadrangle and the sexangle, there are other regular and beautiful figures fit for forming aspects, namely the quincangle or quintile of 72°, the octangle or octile of 45°, the decangle or decile or semiquintile of 36°, the sesquiquadrate or trioctile of 135°, the biquintile of 144°, and the sesquiquintile or tridecile of 108°. So the astrologers began to put out prognostications to the public from all of these. Kepler too began to doubt whether other aspects should be introduced besides those seven. The octile indeed did not seem admissible, because it is not perfectly harmonic: it cuts off from the whole circle one eighth part; and although, when the string is divided into 8 parts and the magadium applied at 1, the 1 is in consonance with the 8, yet the 1 is not in consonance with the 7, nor the 7 with the 8. And the same must be said of many other divisions that might seem fit for forming an aspect; as if a semisextile of 30° were formed, a vigintile of 18°, a quindecile of 24°, and a quincunx of 150°, and certain others akin to those already mentioned, which cut off 48°, 54°, 96°, 126°, 162°, 168°. But neither does experiment give clear testimony of efficacy to all the harmonic ones, since rare and not very manifest experiments favour the sesquiquadrate, commended by music. [Margin: Music is not always to be followed in aspects.] On the contrary, although no harmonic division

of the monochord corresponds to either the semisextile or the quincunx, yet a frequent and clear force in stirring up storms has been observed, as Kepler asserts. Accordingly, in the *Ephemerides* and in the book *De Stella Nova*, he concludes that in determining aspects music must sometimes be abandoned, since it draws certain principles of its septenary from the very straightness of the string, and these are not at all suited to a circle returning on itself; nor, as from a division of a string there arises another string, is another circle made from the divisions of the zodiac. For although the kinship between aspects and harmonies is great, and both kinds have the same primary origin, from the notable figures that can be inscribed in a circle, yet the number of the seven divisions of the monochord is formed by certain laws, and the number of the aspects by others: from concurring physical causes not yet fully known a priori, and indeed also from a concurrence of geometrical causes, which make the aspect stronger the more of them there are. Those should be chosen, moreover, which have more prerogatives, and attention must be paid partly to the harmonic ratio and partly to the physical force for changing sublunary things. But when one aspect is too near to another that is more powerful and manifest, as the decile of 36° is very close to the very strong semisextile of 30°, then observation is more difficult because of the nearness of the days, and the observer must be more sharp-eyed. Finally, when Kepler in the *Ephemerides* had pronounced further [amplius] and deferred his last judgement to another time, he brought it out in the *Epitome of Copernican Astronomy*, and from mixed principles of physico-harmony he fixed the number of 13 aspects which we listed in the preceding chapter.

V. So then, to take in all the aspects that deserve consideration according to Kepler, and to give them in one view, we shall distribute them into two classes. One will be called that of possible aspects, though not all of these are either harmonic or proved by physical experiment. The other will be called that of the physico-harmonic [Phyſicharmonicorum], which harmonic division alone, or physical efficacy alone, or both, favour; with the letter H added to those that harmonic division supports together with musical proportion and consonance, and with names attached that are wanting in Kepler.

21 possible aspects according to Kepler [Aſpectus 21. Poſſibiles ſecundùm Keplerum]

Order	Names of the aspects	Degrees of the circle
1	Conjunction [Coniunctio]	0°
2	Vigintile [Vigintilis] / vigintangle [Vigintangulus]	18°
3	Quindecile [Quindecilis] / quindecangle [Quindecangulus]	24°
4	Semisextile [Semiſextus] / dodecangle [Dodecangulus]	30°
5	Decile [Decilis] or semiquintile [Semiquintilis]	36°
6	Octile [Octilis] / semiquadrate [Semiquadratus]	45°
7	Hyperoctile [Hyperoctilis]	48°
8	Subsextile [Subſextilis]	54°

Order	Names of the aspects	Degrees of the circle
9	Sextile [Sextilis] / hexagon [Hexagonus]	60°
10	Quintile [Quintilis] / pentagon [Pentagonus]	72°
11	Quadrate [Quadratus] / tetragon [Tetragonus]	90°
12	Hyperquadrate [Hyperquadrus]	96°
13	Tridecile [Tridecilis] / sesquiquintile [Seſquiquintilis]	108°
14	Trine [Trinus] / trigon [Trigonus]	120°
15	Hypertrine [Hypertrinus]	126°
16	Sesquiquadrate [Seſquadrus] / trioctile [Trioctilis]	135°
17	Biquintile [Biquintilis] / decangle [Decangulus]	144°
18	Quincunx	150°
19	Hyperquincunx	162°
20	Hypodiameter	168°
21	Opposition [Oppoſitio] / diameter [Diameter]	180°

Physico-harmonic aspects chosen by Kepler [Aſpectus Phyſicharmonici à Keplero electi]

Order	Names	Degrees of the circle	
1	☌ Conjunction [Coniunctio]	0°	Uniſon [Vniſonus]
2	Semisextile [Semiſextus]	30°	
3	Decile [Decilis]	36°	
4	Octile [Octilis]	45°	
5	✶ Sextile [Sextilis]	60°	H
6	Quintile [Quintilis]	72°	H
7	□ Quadrate [Quadratus]	90°	H
8	Tridecile [Tridecilis]	108°	
9	△ Trine [Trinus]	120°	H
10	Sesquiquadrate [Seſquadrus]	135°	H

Order	Names	Degrees of the circle	
11	Biquintile [Biquintilis]	144°	H
12	Quincunx	150°	
13	☍ Opposition [Oppoſitus]	180°	H

The letter H marks the harmonic aspects, that is, those concordant with their complement to the circle, as with the remaining segment of the string, and at the same time with the whole circle, as with the whole string.

Proportions of the harmonic aspects to the whole circle, to the remaining segment or complement of the circle, or to one another [Proportiones Harmonicorum Aſpectuum cum toto circulo, cum reliquo ſegmento ſeu Complemento circuli, vel inter ſe ſe]

VI. You now see why, after the conjunction, the opposition has the greatest force of all the aspects: because the conjunction, which contains the revolution of the whole circle, or the whole string, contains all the aspects within itself; next, the opposition is connected with very many, namely with eight, if you count in the whole, or ☌; but the quadrate with six; the sextile with six; the trine with six. The remaining three are connected with fewer. This, then, is the genuine reason why ☌ ☍ □ ✶ △ were once the principal and most accepted aspects, and why ☌ and ☍ prevail over the others. But if anyone preferred to multiply the aspects according to the divisions of the whole circle into whole parts, there would be 16 aspects, and with ☌, 17. For it admits 16 divisions of this kind, which you may see in the following line, with the degrees of the quotient corresponding to each division.

De Harmonicis Proportionibus Motuum.

On the harmonic proportions of motions.

VII. Compound harmonic proportions are infinite, but the simple ones are eight, on whose causes and origin Zerlinus [Gioseffo Zarlino] and other

musicians have much to say, as does Kepler in *Harmonics*, book 3. They are those in the table written below. For although the diapason can be resolved into a third and a sixth, or into a diapente and a diatessaron, and a sixth into a third and a diatessaron, and a diapente into thirds, yet they are not properly called compound, because proportions are properly compound when one or more diapasons are added to one simple proportion. Of this kind is the trisdiapason between 1 and 8, for it is composed of a diapason between 1 and 2, one diapason between 2 and 4, and another diapason between 4 and 8. So too the diapason epidiapente between 3 and 1 consists of a diapente, 3 to 2, and a diapason, 2 to 1. Among the simple proportions, moreover, the first four are judged more perfect, just as among the compound ones the most perfect of all are the triple, between 3 and 1, called the diapason diapente or twelfth, and the quadruple, between 4 and 1, called the disdiapason or fifteenth.

8 simple harmonic proportions [8. Simplices Proportiones Harmonicæ]

As	To	Polyonymy or nomenclature
1	1	Proportion of equality. Unison
2	1	Double. Octave. Diapason Διαπασῶν [Greek: Διαπασῶν (Diapasōn, "through all")]
3	2	Sesquialter. Fifth. Diapente ἡμιόλιος Δια-πέντε [Greek: ἡμιόλιος (hēmiolios, "one and a half"); Διαπέντε (Diapente, "through five")]
4	3	Sesquitertian. Fourth. Diatessaron ἐπίτριτος Διατεσσάρων [Greek: ἐπίτριτος (epitritos, "one and a third"); Διατεσσάρων (Diatessarōn, "through four")]
5	4	Sesquiquartan. Hard or major third [Tertia dura ſeu maior]. Ditone Δίτονος [Greek: Δίτονος (Ditonos, "of two tones")]
6	5	Sesquiquintan. Soft or minor third [Tertia mollis ſeu minor]. Semiditone ἡμιδίτονος [Greek: ἡμιδίτονος (hēmiditonos, "half-ditone")]
5	3	Superbipartient thirds [Superbipartiens tertias]. Hard sixth [Sexta dura]. Major hexachord [Hexachordum maius]
8	5	Supertripartient fifths [Supertripartiēs quintas]. Soft sixth [Sexta mollis]. Minor hexachord [Hexachordum minus]

[Margin: The motions of the planets are suited to these proportions.] Now then, these proportions can be seen in the velocities of the planets, as regards their proper daily or hourly motion, true or apparent. But the proper motion of these five planets is involved in a double inequality: one is that which appears to an eye placed, by a fiction, in the Sun; the other, that which appears to an eye placed on the Earth, but which involves the first. [Margin: Proportions fitting the planets viewed from the Sun.] According to the former consideration, or as they are viewed from the Sun, definite harmonic proportions are assigned to definite planets, but they are merely intellectual and not perceptible by any experience of effects; for the two terms of each are not joined at the same time. Thus the variety of the motions of Saturn reaches the terms of the hard third; of Jupiter, of the soft third; of Mars, roughly of the diapente; of Mercury, nearly of the diapason with a soft third. But Venus viewed from there has no harmonic intervals, since it keeps within the comma of 81 to 80. Nor yet the Earth in motion, since it con- tains itself within the semitone of 16 to 15. And

this holds if one considers the proportions assigned to each planet with respect to the different motions of that same planet. But if one considers the harmonies assigned to pairs of planets next to one another, viewed likewise from the Sun, or to any pairs whatever, then on their variety see Kepler, *Harmonics*, book 4, and in the *Epitome*, p. 902. For we ought rather to speak of those that suit the planets viewed from the Earth, although the following problem also teaches how to compute the harmonies from the Sun.

VIII. [Margin: Proportions suited to the planets viewed from the Earth.] With the planets viewed from the Earth, then, the harmonies of the apparent motions can be perceived not by the intellect only but also by sense, inasmuch as astrologers can attend to the times at which the motions of the planets are harmonically tempered together, and to whether some effect of that tempering appears in the meteors; just as, by attending beforehand to these effects, they have learned in what way and at what time the planets are configured harmonically, or quasi-harmonically, by reason of position or aspects, by which the nature of sublunary things seems to be stirred most of all. And to all the planets so viewed all the harmonic proportions belong, since they become stationary and at times lack all apparent motion. This being laid down, let the following problem be taken from Kepler's *Epitome of Copernican Astronomy*, p. 904.

Problema 1. Inuenire Qualis ſit Harmonia inter Diurnos Planetarum motus veros, ſpectatos ſiue ex Sole, ſiue ex Terra.

Problem 1. To find what harmony there is between the true daily motions of the planets, viewed either from the Sun or from the Earth.

As the greater of the daily motions is to 240, so let the lesser of the daily motions be to something else, and you will have the harmony sought, or the argument of the harmonic proportion, simple or compound, in the following little table, exactly or as nearly as possible. If from the Sun, take the daily motions seen from the Sun; but if from the Earth, take the daily motions viewed from the Earth.

Table indexing the harmonic proportions, with the monochord taken as 240 parts [Tabella Index Proportionum Harmonicarum poſito Monochordo partium 240.]

[Margin: Beware of the errors in Kepler's table.]

Simple proportion [Proport. Simplex.]		Compounded with the diapason [Compoſita cum Diapaſon]						
Diapason	120	60	30	15	7½	3¾	1⅞	15/16
Major sixth [Sexta dura]	144	72	36	18	9	4½	2¼	1⅛
Minor sixth [Sexta mollis]	150	75	37½	18¾	9⅜	4 11/16	2 11/32	1 11/64
Diapente	160	80	40	20	10	5	2½	1¼
Diatessaron	180	90	45	22½	11¼	5⅝	2 13/16	1 13/32

Simple proportion [Proport. Simplex.]		Compounded with the diapason [Compoſita cum Diapaſon]						
Major third [Tertia dura]	192	96	48	24	12	6	3	1½
Minor third [Tertia mollis]	200	100	50	25	12½	6¼	3⅛	1 9/16
Unison [Vniſonus]	240							

EXEMPLVM.

Example.

Let the Sun's true daily motion be 60′ and that of Mars 48′. Multiplying 48′ by 240 gives 11520; dividing these by 60, the quotient is 192. In the preceding table this number indicates the simple harmonic proportion of the major third [Tertiæ duræ], or ditone. Again, let the daily motion of Jupiter be 13′ and that of Venus 1° 42′, or 102′. Multiplying the lesser motion, 13, by 240 then gives 3120. Divide this sum by 102, and the quotient is 30 30/51. This indicates, in the first line, a proportion compounded roughly of the diapason and the disdiapason, that is, from the trisdiapason: for since 120 with respect to 240 is the diapason, and 60 the disdiapason, 30 will be the trisdiapason. So if 80 should come out in the quotient, the proportion would be compounded of the diapente and the diapason; if 40, it would be compounded of the diapente and the disdiapason, and so on.

SCHOLION.

Scholium.

I. [Margin: The speed of the planets in their proper motion.] Aristotle believed that all the planets move of themselves with the same speed, their own orbs being considered. If that were true, the times of the mean motions would be as the orbs and their diameters. But this is utterly false; for the higher each planet is and the more remote from the Sun, the less space it covers in its mean motion in one hour; so much so that, if you assume the Ptolemaic distance of the Sun and the others that depend on it, Saturn in its own mean motion about the Sun, toward the east, covers 960 Italian miles in one hour, Jupiter 1280, Mars 2400, the Earth, if it is supposed to move about the Sun, 2960, Venus 3200, Mercury 4800; although according to Kepler's distance of the Sun from the Earth these numbers are to be roughly tripled throughout, and according to us and certain others are to be increased by much more still, as we shall say in Section 6. For this is an affection arising from altitude, the motions in longitude being assumed. [Margin: The proportion of the motions to the orbs and intervals.] There too we shall explain that notable proposition by which, in book 5 of the *Harmonics*, and book 4 of the *Epitome*, p. 501, and in the Rudolphine Tables, ch. 24, Kepler affirms that in the primary planets the mean distance of one planet from the common centre of the world, which for

him is the Sun, is to the greater distance of another planet in the sesquialter ratio of their periodic times; or that the proportion of the periodic times is sesquialter of the proportion of the orbs, or of the converse proportion of their whole degrees, because whatever has a small number has a large degree. Wendelen extends this proportion also to the periodic motions of Jupiter's satellites about Jupiter, as we shall see in its place. I wanted to point this out here so that no one, on the occasion of the harmonic proportions, should look here for this one as well, which holds between motions and intervals. But how to investigate the absolute proportion of the eccentric daily motions of the Sun and a planet, Kepler teaches in the Rudolphine Tables, precept 103.

CAPVT IX.

Chapter 9.

De Reuolutionibus Planetarum & Coniunctionibus Magnis & Maximis, earumque effectibus.

On the revolutions of the planets and on the Great and Greatest conjunctions, and their effects.

I. Among all the aspects already treated in chapters 7 and 8, the most excellent is the synod or conjunction, for the reason already given in chapter 8, number 6. Among the conjunctions of the planets, moreover, the most celebrated among astronomers and astrologers alike are those called the Greatest and the Great, namely of two or three of the superior planets. For the conjunctions of all the planets, though by far the greatest, or the Greatest of the greatest, have been passed over by the astrologers, because they do not recur exactly within the brief duration of this world. [Margin: Authors who [have written] on the Great conjunctions, etc.] But we must discuss all of these in this place, from what has been taught or pointed out to us by Ptolemy in the *Centiloquium*, aphorisms 50 and 63, and there by Cardano, Pontanus, Georgios Trapezountios and other commentators; Abū Maʿshar in the book *De magnis coniunctionibus*, with an *Isagoge* to it by an unnamed author, and the commentaries on him by Henricus Mechliniensis [Hendrik Bate of Mechelen]; Alcabitius in the treatise *De coniunctionibus planetarum ac revolutionibus*, and in the *Isagogicus ad magisteria stellarum*, differentiae 1 and 4, and there Leopoldus de Austria [Leopold of Austria], tracts 4 and 5, and Valentinus Naiboda, or in the *Enarratio elementorum astrologiae*, from p. 39 and again from p. 352; Māshāʾallāh the Arab, in the book *De coniunctionibus*; Alliacensis [Pierre d'Ailly] in the treatise *De concordia historiae et astrologiae*; Giovanni Pico della Mirandola, *Contra astrologos*, book 5; Lucio Bellanti, book 5 against Pico, and question 11 of *De astrologica veritate*; Reinhold on Peuerbach, from p. 283; Giuntini in the *Speculum Astrologiae*, ch. 8; Origanus in volume 1 of the *Ephemerides*, or in their introduction, part 3, member 2, ch. 1; Cyprianus Leovitius [Cyprián Lvovický], *De magnis coniunctionibus*; Io. Franciscus Spina [?] in two books *De maximis coniunctionibus*; Andrea Argoli

in the *Pandosion Sphaericum*, ch. 73; Kepler in the book *De Stella Nova*, from ch. 6 to 11, and in the *Mysterium Cosmographicum*, the preface and ch. 12, in the notes, and in the *Epitome of Copernican Astronomy*, book 2, p. 189, and book 6, pp. 846 and 854; Gassendi in the *Institutio Astronomica*, book 2, ch. 15.

Quid ſit Apocataſtaſis ſeu Reuolutio, & Quotuplex.

What apocatastasis or revolution is, and of how many kinds.

II. Revolution, in Greek [Greek: ἀποκατάστασις (apokatastasis, "restoration")] or [Greek: ἐξελιγμὸς (exeligmos, "a rolling out")], that is, restitution or reversion, is the return of some star from one and the same term back to the same term to which it was previously joined, whether that term is another star or some notable point of the heaven. This return is the more notable the more conditions concur toward both conjunctions: as when the Sun and the Moon are conjoined again in the same place of the zodiac, or the Sun returns to the same point in which it stood at a person's natal beginning, a revolution customary among astrologers; or when the Moon returns from one node to the same node in the same place of the zodiac; or indeed to ☌ or ☍ with the Sun in the same place of the zodiac and at the same node in which it had stood at the other ☌ or ☍; or when not two only, but three or more stars come together again at once, especially if at the same point of the zodiac. [Margin: Two kinds of revolutions.] The chief kinds of apocatastases [Apocataſtaſeων] are two. One is that of the planets referred to the Sun and to the same place of the zodiac; the other is that of the other planets referred to one another and to the same places of the zodiac. It is of the first kind when one seeks the time in which some planet and the Sun run through the whole zodiac, or are restored to the same place of the zodiac; or within which a planet carries its stations and retrogradations round the whole zodiac; or the Moon likewise leads her phases round the whole zodiac, and so on.

Quantum ſit tempus Reuolutionum cuiuſque Planetæ ad Solem in eodem loco Zodiaci.

How long the time is of the revolutions of each planet with respect to the Sun in the same place of the zodiac.

III. According to Kepler's opinion in the *Epitome of Copernican Astronomy*, p. 848, from which the hypotheses of other astronomers do not notably depart on this point, Saturn and the Sun return together to the same place of the zodiac very nearly within 59 years, so that while the Sun measures out the zodiac 59 times, Saturn measures it out twice. [Margin: ♄ Revolutions to ☉.] Thus, since in 1590 June 9 there was a ☌ of ♄ and ☉ in 18° ♊, we are certain, counting 59 years from then, that Saturn was joined with the Sun in the year 1649 on June 9 in 18° ♊, or at most 19°; just as, since in 1590 on December 17 it was opposed to the Sun standing in 25° ♐, one could declare that in 1649 on December 17 it would return to the same opposition in 25° ♐. [Margin: ♃

Revolutions.] Jupiter, on the other hand, walks round the zodiac seven times within 83 years of the Sun. [Margin: ♂ Revolutions.] Mars, however, keeps its revolutions with the Sun at great intervals. But the longer its apocatastases are taken, the more accurate they are; and the most accurate is held to be the period of 79 years, in which Mars completes 42 revolutions with respect to the Sun to the same place of the zodiac. [Margin: ♀ Revolutions.] Venus returns to the same place fairly exactly within 8 solar years, and is thus joined to the Sun in the upper part of her orb in five places, each two of the five being 72° apart. From these five places the following unions move off at a slow pace, by eights of years, so that those intervening 72° are hardly used up within two half-centuries, and the whole zodiac is frequented by conjunctions of this kind. [Margin: ☿ Revolutions and ☾.] By contrast, Mercury goes round the zodiac 54 times within 13 solar years. Finally the Moon, since she runs through the zodiac somewhat faster than the Sun, needs a greater number of years in order to be restored more accurately with the Sun to the same place of the zodiac, according to the various lunisolar cycles about which enough was said in book 4, ch. 19. The most accurate of these cycles is the one of 3400 years, in which the Moon is restored to the Sun in the same place of the zodiac, and at the same hour, indeed at very nearly the same minute, after 42053 completed synodic months. But here for you is a synopsis of the revolutions of the planets with respect to ☉.

Revolutions of the planets with respect to the Sun in very nearly the same place of the zodiac [Reuolutiones Planetarum ad Solem in eodem proximè loco Zodiaci]

	Solar years [Anni Solares]	Revolutions [Reuolutiones]		Solar years [Anni Solares]	Revolutions [Reuolutiones]
♄	59	2	♀	8	5
♃	83	7	☿	13	54
	15	8		19	235
	17	9		72	940
♂	32	17	☉	257	3055
	47	25		304	3760
	79	42		3400	42053

72

One thing further, I think, should not be passed over: namely that the mean conjunction of Mars with ☉ can differ from the true one by no more than 20 days, and the mean opposition with it by no more than 25 days; but for Saturn and Jupiter the distance of the mean from the true ☌ or ☍ with the Sun is much smaller.

[72] On the page a rule divides the rows under ♃ (and under ☿) from those that follow; ♂ stands centred on the five rows 15 to 79, and ☉ on the five rows 19 to 3400, so each sign governs its whole block.

Quæ ſit Coniunctio Magna & Maxima.

What the Great and the Greatest conjunction is.

IV. Māshāʾallāh the Arab, in the book *De coniunctionibus*, calls it the Greatest when Saturn, Jupiter and Mars are conjoined on the same day or as nearly as possible, wherever in the zodiac they finally come together; and he says that from this conjunction a presumption is to be drawn about the transfer of kingdoms, about the coming of a great prophet, and so on. He calls it the Greater, however, when Saturn and Jupiter are joined; the Middling or Mean when Saturn and Mars; the Great when Jupiter and Mars meet. But Abū Maʿshar, with the whole school of astrologers and almost of astronomers, calls it the Greatest conjunction when Saturn and Jupiter are conjoined at the beginning of Aries, which is the beginning of the fiery triplicity, or in the passage from the end of the watery triplicity, that is, from the end of Pisces, to the fiery triplicity, which begins at the beginning of Aries, especially if it occurs after a revolution of about 800 or 900 years. For they hold that the greatest changes of empires and of sublunary nature are either brought about or foreshadowed from this. The other conjunctions of Saturn and Jupiter they commonly call Great, whether they occur after every 20 years or after 200, when a revolution has been made from the beginning of one triplicity to the beginning of another, namely from the beginning of ♈ to the beginning of ♌, or from the beginning of the latter to the beginning of ♎, or from the beginning of the latter to the beginning of ♒. These two-hundred-year conjunctions some call Greater, others Middle; those of Saturn and Mars, however, they call Lesser. Yet the generic name for all of these is great conjunction, that is, of two superior planets. [Margin: Why they are called Great.] This is because those planets are the heaviest or slowest, and their stay in bodily or platic conjunction lasts much longer than that of the other planets, and the effects or the significations of such conjunctions extend over many years. Those, on the other hand, who with Cardano call the eight-hundred-year conjunctions Great call the twenty-year ones Lesser and the two-hundred-year ones Middle. In this controversy, just as it is easy to discern from the attendant circumstances which conjunction authors are speaking of, so we shall act prudently if we always add some marks by which it is distinctly clear which species of conjunctions we are speaking of. No one, however, would deny that this greatness of conjunctions can be taken either from the dignity and efficacy of the planets, or from the concurrence of several of them in one place of the zodiac on the same or on neighbouring days, or from the greater interval at which they revolve to the same place of the zodiac, or from the dignity of the place of the zodiac itself; and that the more conditions of this kind have marked out some conjunction, the greater the prerogative by which it deserves the name of Great or Greatest conjunction. [Margin: A new ordering of conjunctions.] But speaking of the conjunctions of the three superior planets, it seems to me that three classes should be established, and three degrees in each one. Let the

first class be that of the conjunctions of ♄ and ♃, which may be called in Greek [Greek: κρονοζευτικὰς (kronozeutikas, "Saturn-yoked")], that is, Saturnijovial; the second is the ☌ of ♄ and ♂, which let us name [Greek: κροναρητικὰς (kronarētikas, "Saturn-Martial")], namely Saturnimartial; the third is the ☌ of ♃ and ♂, which we shall call [Greek: ἀρηζευτικὰς (arēzeutikas, "Mars-yoked")], that is, Martijovial. Let the first degree in each class be when the conjunction is periodic, the whole zodiac having been unrolled, but with the revolution made from one cardinal point to the same point, as from the beginning of Aries back to the beginning of Aries; and these we shall call Greatest or Great, each in its own class. Let the second degree be when the places of the conjunctions make a passage from one cardinal point to another immediately following or preceding, or at least to the opposite one, as from the beginning of Aries to the beginning of Capricorn; these we shall call Lesser. This degree shows up more clearly in the Cronozeutic conjunctions; in the Arizeutic, however, the passage to the opposite is to be looked for, as from the beginning of ♈ to the beginning of ♎, as we shall say at number II. Let the third degree be that of conjunctions following one another most nearly and immediately, which we shall call Least. Unless we should prefer to call those of the first class Great, those of the 2nd Middle, those of the 3rd Lesser, and within each one to distinguish not the ☌ themselves but the intervals into least, middle and greatest.

Medianè an Veræ Coniunctiones ſint Conſiderandæ cùm de Magnis aut Maximis agitur?

Whether mean or true conjunctions are to be considered when the Great or Greatest are in question?

V. [Margin: Votes for mean ☌.] The mean conjunction, that is, the one occurring along the lines of mean motion, or, according to Ptolemy's hypothesis, the one by which the centres of the epicycles are conjoined under the same place of the zodiac: this, I say, is what Abū Maʿshar and almost all astrologers considered, as Giovanni Pico affirms, *Contra astrologos*, book 5, ch. 6; and the more recent authors, with Origanus and Kepler, do so too. The reasoning for them seems to be this. First, the ease of defining equal intervals of conjunctions, that is, by equal or mean motions, whereas the intervals of true conjunctions are unequal because of the double inequality, namely of the centre and of the planet on the epicycle. Second, because the mean conjunction is made with respect to the centre of the epicycle, and the conjunction of the epicycle seems more powerful than the conjunction of the planet alone, since the whole epicycle with the planet is nobler than the planet alone, and contains the power of the planet and something more. Third, because there is no point to which the planet is always indifferent except the centre of the epicycle. Fourth, because when conjunctions of this kind are considered in order that a judgement may be formed from them about the great changes of the world, which do not occur

except with some latitude of years, it does not seem that one should proceed more scrupulously in investigating the true conjunctions of these planets.

VI. [Margin: Votes for true ☌.] Bellanti, however, defends the contrary opinion, question 11, art. 3, and book 5 against Pico: namely that true conjunctions are to be preferred to mean ones, though if epicycles really are granted in the heaven, something is to be allowed to the mean ones as well. His first reason is that mean motion is imperfect and needs the perfecting of the equation, whereas true motion is perfect. The second is that the motion of the epicycle on the eccentric exists for the sake of the planet's motion on the epicycle, as a means for the sake of an end. The third is that no diversity is discerned in the orbs of the planets except for the star carried to other parts; and the star is nobler than any unknown part, and therefore the true motion, which belongs to the star, is to be preferred. The fourth is that epicycles and mean motions either have been invented by astronomers for ease of calculation and to help the imagination, or at least it is uncertain whether they really exist in the heaven; and figments or uncertainties ought not to be put before things certain and true and evidently appearing. And although the whole prevails over the part, yet the planet on the epicycle is like a diamond in a ring, which intensively is worth more than the ring alone; or, if you take the whole aggregate, you must conclude that the motion of both is to be attended to, but principally the true motion of the planet.

Giovanni Pico, however, *Contra astrologos*, book 5, ch. 6, teaches that neither mean nor true conjunctions of the planets have force for bringing about or signifying great changes; but if they did, attention would rather have had to be paid to the true ones than to the mean, the latter being fabricated and resting on a fictitious motion, for the convenience of carrying out calculation by mean and equal motions. He confirms this from the conflict with the terms or effects that astrologers have laid down from mean conjunctions. For in the year of grace 1226, by the Alphonsine Tables, Jupiter and Saturn migrated, in their conjunction made in Aquarius, from the earthy triplicity to the airy. Therefore, according to mean motions and Abū Maʿshar's opinion, they were going to remain in that same triplicity for 240 years; and yet after about 140 years, namely in the year of grace 1365, they migrated from the airy triplicity to the watery, and met in Scorpio. Since, however, not all mean conjunctions of Saturn and Jupiter have fallen at the times the astrologers most wished for, and they therefore fled not to the true conjunctions but to another figment, namely by saying that their effects follow neither at once nor quickly, but after many years, or even centuries of years, [Margin: Giovanni Pico's acumen against the slowness of mean ☌.] Pico sharply attacks them with this dilemma: *It is not for a powerful and efficacious cause to begin late what it is going to do, but rather to stop late, and to begin either at once or quickly. Therefore the power of these conjunctions is either efficacious or weak. If efficacious, it cannot long cease so as not to act; if weak, it cannot last long enough to act late indeed, yet at some time. A great force tames what hinders and resists it; a weak one vanishes, and over a longer stretch of*

time dissolves itself by its own thinness. What of the fact that in this interval of time new conjunctions are always supervening, whose nature, as they themselves say, is to erase the earlier ones, since a supervening constellation crushes the preceding one?

VII. [Margin: Our opinion.] But I judge, not absolutely, but on the hypothesis that meetings of this kind are effective in bringing about or signifying notable changes in sublunary things, that attention should be paid principally to the true conjunctions, no differently than to the true synods of the luminaries in eclipses. For if there is any greater force in them than in other lesser conjunctions, it is surely on account of the ponderosity, as they call it, of these two planets, that is, their gravity and slowness, because of which, once conjoined, they last for three or four days, whereas the conjunction of the centres of their two epicycles is momentary. Yet I think that mean motions and mean conjunctions should be employed, not only so that by an easier first computation we may scent out from afar the times of the true conjunctions, but also because, if they precede the true ones, they begin the influx of those by a certain application, and are as it were dispositions toward the impression to be made through the true ones; and if they follow the true ones, by a certain defluxion they retain something of the impression already made, or the planets, thus neighbouring, still persist in the influx once impressed, as long as the mean conjunction lasts.

Quæ ſint loca Zodiaci, in quibus Magnæ aut Maximæ Coniunctiones fiunt, & quid, quot, & quales Triplicitates Signorum, quiſue illarum ordo.

Which are the places of the zodiac in which Great or Greatest conjunctions occur; and what, how many and of what kind the triplicities of the signs are, and what their order is.

VIII. First, the most ancient astrologers before Abū Maʿshar and Alcabitius divided the signs of the zodiac into four classes endowed with the qualities of the elements. The first contains three fiery signs, namely ♈ ♌ ♐; the second three earthy, ♉ ♍ ♑; the third three airy, ♊ ♎ ♒; the fourth three watery, ♋ ♏ ♓. And accordingly they called the first triplicity, that is, one composed of three signs, the Fiery Triplicity; the 2nd the Earthy Triplicity; the 3rd the Airy Triplicity; the 4th the Watery Triplicity. Why they also called the same ones the Fiery, Earthy, etc. triangles or trigons, understand as follows. If Saturn and Jupiter meet at the beginning of Aries, or of the fiery triplicity, after about 20 years another conjunction of theirs will occur, but far from the beginning of Aries against the order of the signs, or backward by about a third of the zodiac, or by nearly 120°; and so it will fall at the beginning of Sagittarius, which is likewise a fiery sign. And the third conjunction, after about another 20 years, will go back through another four signs to the beginning of Leo, a sign equally fiery. Thus, since the places of these nearest conjunctions are about a third of the circle distant from one another, it comes about that in 60 years the places

of three conjunctions form a nearly equilateral triangle inscribed in the zodiac, and regard one another by a quasi-trine or trigon aspect, as can be seen in the figure below: in which are placed the mean synod of Saturn and Jupiter that occurred in the year 1603 in Sagittarius (the true one, however, was on December 24, in 9° 36′ ♐) and the one that occurred in the year 1623

Diagram. A zodiac ring in the right column, a band between two concentric circles divided by radial strokes into twelve compartments, each holding the sign of its zodiac constellation. Within the inner circle, bundles of straight lines, some solid and some dotted, run between three regions of the ring, near ♐, near ♌ and near ♈, so as to form nearly equilateral triangles; dotted lines lead from the dated labels out toward the ring. No lettered points. The sentence the figure illustrates is interrupted by it on the page.

- Ring, top going clockwise: ♎ (top, left of centre); ♍ (top, right of centre); ♌ (upper right); ♋ (right); ♊ (lower right); ♉ (lower right, below ♊); ♈ (bottom, right of centre); ♓ (bottom, left of centre); ♒ (lower left); ♑ (left); ♐ (upper left); ♏ (upper left, near the top).
- Near ♐, set diagonally inside the circle: 1603, 1663, 1723.
- Near ♌, set upside-down inside the circle: [?]743 (the first figure, if one is printed, falls on a line of the figure), 1683, 1623.
- Near ♈, set vertically inside the circle: 1583, 1643, 1703, 1763.

in Leo, and the one that occurred in the year 1643 in Aries. [Margin: Examples of the triplicities.] Since, however, the places of these conjunctions are not exactly a third of a circle apart, but somewhat less, namely 117°, in præcedentia of the signs, it comes about that at every sixtieth year the conjunction passes its initial place by about 9°, and in 180 years by 27°. Therefore in about 200 years, in which 10 conjunctions occur, the vertices of the triangles, having completed each sign of one class, pass over to the signs of another triplicity; so that if the first was Fiery, the second is Earthy, and the second decade of conjunctions stays in these three signs. Hence in about 800 years, that is, 794 years and 332 days, the four triplicities and the whole zodiac are completed, and the conjunction of ♄ and ♃ returns to the beginning of Aries and becomes a Greatest conjunction. You will see, moreover, in the scheme set above, three conjunctions assigned to Sagittarius and three to Leo, each 60 years apart in its own sign, but around the beginning of Aries and the end of Pisces four, 60 years apart from one another, together with the years in which they occurred or will occur, so that by this example one may carry on such transmigrations of the Great conjunctions.

IX. But so that beginners may understand without confusion the backward leap of the mean conjunctions of ♄ and ♃, I have decided to construct for them the following table containing eight great periods, each of which begins from a Greatest conjunction, that is, one occurring in the passage from the end of ♓ to the beginning of ♈; for the explanation of this table, see what follows.

TABVLA MAGNARVM & MAXIMARVM CONIVNCTIONVM Saturni, & Iouis, quarum Maximæ sunt in prima serie sub annorum titulis

Table of the Great and Greatest conjunctions of Saturn and Jupiter, of which the Greatest stand in the first row under the headings of the years

Triplicities	Periods of Great ☌: order	Periods of Great ☌: places	I (years current before Christ)	II (years current before Christ)	III (years current before Christ)	IV (years current before Christ)	V (years current before Christ)	VI (before Christ)	VII (years of Christ)	VIII (years of Christ)	Periods of Great ☌: places	Periods of Great ☌: order	Triplicities
	1 or	♓ 29°; ♈ 0°	3980	3185	2390	1595	801	6 An. Chr.	789	1583	♓ 29°; ♈ 0°	1 or

	35	♓ 11°	3204	2509	1714	920	125	670	1464	2259	♓ 11°	35	
	36	♏ 14°	3284	2489	1694	900	105	690	1484	2279	♏ 14°	36	
	37	♋ 18°	3265	2469	1675	880	85	710	1504	2299	♋ 18°	37	
	38	♓ 21°	3245	2450	1655	860	66	730	1524	2318	♓ 21°	38	
	39	♏ 24°	3225	2430	1635	840	46	750	1544	2338	♏ 24°	39	
	40	♋ 27°	3205	2410	1615	820	26	770	1564	2358	♋ 27°	40	

You should not, however, be scrupulous with this table set out in this way; rather, as Kepler says in the book *De Stella Nova*, ch. 7, all these things are to be taken broadly, especially since there is great diversity among the astronomical tables in the collection of the mean motions, and the mean conjunction often belongs to the class of one triplicity, while the true one belongs to that of another. For example, in the year 7 before the common epoch of Christ the true conjunction of Saturn and Jupiter was in 23° ♓, around June 22; but in the following year, 6, on January 22, the mean one was in 29° 26′ ♓, and, by the more correct tables, readily at the beginning of Aries. So too in the year 1583 their true conjunction was at the end of Pisces; indeed even the mean one, by the Prutenic Tables, was in 28° 14′ ♓, which Cardano nevertheless puts, from the Alphonsine Tables I believe, at the beginning of Aries. So finally in the year 1543 the true union of Saturn and Jupiter was in 26° of Pisces, which Francesco Montebruni nevertheless calls a Greatest conjunction in his *Ephemeris*, because a few months later the mean one followed, in 8° or 9° of Aries. [Margin: 1. A point to note in the table above.] First, then, in the table set out above you will see that in each period, begun from a Greatest conjunction, there are forty Great conjunctions, 20 or 19 years apart from one another, of which the first decade always belongs to the Fiery triplicity, the second to the Earthy, the third

to the Airy and the fourth to the Watery. [Margin: 2. A point to note.] Second, at the head of the table you will see the Greatest conjunctions set opposite the marginal number 1, the oldest of which, near the rising of the world, was in the year 3980 before Christ; the second in the year 3185; the third in the year 2390; the fourth in the year 1595; the fifth in the year 801; the sixth in the year 6 before the birth of the Saviour; the seventh in the year of Christ 789; the eighth in the year 1583, and it will last until the year 2378, if this world lasts so long. [Margin: 3. A point to note.] Third, you will see that the places of the Great conjunctions go back in the zodiac through nearly four signs, or through 117°, so that if the first was in 28° or 29° of Pisces, the second falls in 1° or 2° of Sagittarius, the third in 4° or 5° of Leo, and so on. These places are indicated, not only in the first or eighth period but in the others as well, by the numbers of the left and right margins, set opposite those years. For example, since ♐ 2° corresponds to conjunction 2, and the years 3960, 3165, 2370, 1575, 781, 16[73], 809 and 1603 correspond to the same conjunction, the mean conjunction of Saturn and Jupiter is therefore understood to have occurred in each of those years in 2° ♐, usually without an error of a whole degree; although, if we listen to Andrea Argoli, *Pandosion Sphaericum*, ch. 73, the platic conjunction, or by orb, suffices to name the species of a conjunction. But he is speaking of true conjunctions, for he says that on 1643 January 26 the true meeting of Saturn and Jupiter was in 26° of Pisces, but that since the light of the orb of Saturn is 10° and that of Jupiter 12°, they can be said to have been conjoined at the beginning of Aries, just as also in the year 1583, although the partile conjunction was in 21° of Pisces.

Quanta ſint Interualla Coniunctionum Magnarum ac Maximarum quoad motus medios.

How great the intervals of the Great and Greatest conjunctions are with respect to the mean motions.

X. [Margin: 1. Opinion of the ancients.] The first opinion was that of Aboassar or Abū Maʿshar, *De magnis coniunctionibus*, tract 1, differentia 2, followed by Alcabitius, differentia 4, Alliacensis, Leopoldus and most of the older astrologers: namely, that the interval from one Greatest conjunction to the next is 960 solar years; from the beginning of one triplicity to the beginning of another, 240 years, so that in each of the triplicities 12 Great conjunctions occur, and sometimes 13 or 11; from one great conjunction to the next, 20 years; and from the conjunction of ♄ and ♂, which they call Lesser but restored in Cancer, 30 years. For they suppose that every 20 years the conjunctions of Jupiter and Saturn recur in such a way that they stand 242½°, or 8ˢ 2½°, in the order of the signs from the initial place, so that if the first was at the beginning of Aries, the second, after 20 years, falls in 2° 30′ of Sagittarius, and so on.

[73]the table above prints 15 at this place

[Margin: 2. Opinion of Cardanus and Naiboda.] The second opinion is that of Cardano, *Aphorisms* 1, aph. 65, and of Valentinus Naiboda on Alcabitius, differentia 4, who asserts that from one Greatest conjunction to the next there lie only 794 years, 214^{d}; from the beginning of one trigon to the beginning of another, 198 years and nearly 8 months, or 236^{d}; and from one of the lesser of the Great conjunctions to the next, not 20 years but 19 years, $315^{d}\ 19^{h}$. For the place of the following conjunction, he says, stands 242° 59′ 9″ in the order of the signs from the place of the preceding one. Naiboda adds, however, that a lengthier inquiry into this matter does not pertain to the substance of the true art, since he thinks the force of the Great conjunctions partly erroneous and partly of less moment than some reckon. For Cardano, however, the three already mentioned are called Great, Middle and Lesser, but for Naiboda, Greatest, Great and Lesser.

[Margin: 3. Opinion of Reinhold, Magini, Origanus.] The third opinion is that of Reinhold in the Prutenic Tables, precept 37; of Magini, canon 53 of the *Secunda Mobilia*, and in the tables of the same work, p. 549; and of Origanus, vol. 1, p. 448: that the time from one Lesser conjunction of ♄ and ♃ to the next is 19 Egyptian years and $318^{d}\ 12^{h}\ 59^{m}\ 23^{s}$, in which time the place of the following conjunction stands 242° 58′ 42″ 44‴ in the order of the signs from the place of the preceding one; that from the beginning of one triplicity to the beginning of another it is 198 years, $265^{d}\ 9^{h}\ 53^{m}\ 52^{s}$, on completion of which period the place of the conjunction has advanced 279° 47′ 7″ 25‴; and finally that from one Greatest conjunction to the next there lie 794 years, $331^{d}\ 15^{h}\ 35^{m}\ 28^{s}$, in which almost the whole zodiac is completed and the passage is made from the end of the fourth triplicity to the beginning of the first; that is, the place of the synod comes to stand at 359° 8′ 29″ 41‴. But to reduce these years to Julian solar years, they must be divided by 4, and the quotient subtracted from the number of days.

[Margin: 4. Opinion of Kepler.] The fourth opinion is that of Kepler, *Epitome of Copernican Astronomy*, pp. 189 and 855, who puts 794 years from Greatest to Greatest, nearly 200 years from the beginning of one trigon to the beginning of another, and nearly 20 years from one ☌ to the next nearest. For it is enough for him in that place to use round numbers; in the Rudolphine Tables, however, ch. 33, pr. 180, he teaches a way of defining these times more accurately, should anyone wish to examine them more scrupulously. For us it will be enough to have both the synopsis of the following small table and the problem that will come after it.

☌ ♄ & ♃. **Interualla in Annis ſed Iulianis**

☌ *of* ♄ *and* ♃. *Intervals in years, but Julian years*

☌	Authorities	Interval
Lesser	Abū Maʿshar, Alcabitius, etc.	20 years $0^{d}\ 0^{h}\ 0^{m}\ 0^{s}$
	Cardano, Naiboda	19 years $315^{d}\ 19^{h}\ 0^{m}\ 0^{s}$

☌	Authorities	Interval
	Reinhold, Magini	19 years 314^{d} 12^{h} 59^{m} 23^{s}
	Origanus	
	Kepler	about 20 years
Middle	Abū Maʿshar, Alcabitius	240 years 0^{d} 0^{h} 0^{m} 0^{s}
	Cardano, Naiboda	198 years 236^{d} 0^{h} 0^{m} 0^{s}

Problema 1. Inuenire Interuallum inter duas Medias & proximas Coniunctiones, aut Syzygias binorum Planetarum, ſeu Tempus periodicæ Syzygiæ mediæ binorum quorumuis Planetarum, ſecundùm quaſcumq. tabulas.

Problem 1. To find the interval between two mean and nearest conjunctions or syzygies of two planets, or the time of the periodic mean syzygy of any two planets, according to any tables whatever.

XI. Reinhold, precept 37, and Magini, canon 53, teach this as follows. Subtract the lesser daily mean motion of the centre of the epicycle, or of longitude, that is, that of the slower planet, from the greater daily mean motion, or that of the faster planet; and by the remainder, or excess of the greater, divide the whole circle, first resolved into fractions of the same order as the daily motion. For the quotient will show the time between two mean syzygies, for instance between two ☌ or between two ☍; and the mean motion of the slower planet made in that time will show the place of the syzygy in the zodiac.

EXEMPLVM.

Example.

In the Prutenic Tables the daily motion of Jupiter exceeds the daily motion of Saturn by 2′ 58″ 40‴ 16⁗ 51′′′′′ 25′′′′′′ 2′′′′′′′. When the whole circle, which consists of six sixties of degrees, is reduced to sevenths and divided by the excess already mentioned, likewise reduced to sevenths, there remain 2 second sixties of days, 0 first sixties, 53 days and about 32′ 28″ 28‴ of a day, according to the form of Arabic logistic; but according to the usual form, 7253 days, or 19 Egyptian years, 318^{d} 12^{h} 59^{m} 23^{s} 12‴.

This is the time between one mean ☌ of ♄ and ♃ and the next. If you want Julian years, divide the Egyptian years by 4, and subtract the quotient from the days.

Quæ ſint Interualla & loca mediarum Coniunctionum Maxima Minora, & Minima in tribus ſuperiorib. Planetis.

What the Greatest, Lesser and Least intervals and places of the mean conjunctions are in the three superior planets.

XII. I answer, following the preceding problem and without departing far from the Prutenic Tables, that they are those which the table set below will show. From it you will see that the Greatest or Periodic conjunctions are completed with a more exact revolution in the unions of Saturn and Jupiter than in the unions of Jupiter and Mars, since the period of the latter, when the circle is finished, passes the initial place by 6° 9′; or than in the conjunctions of Saturn and Mars, since, when the circle is completed, the last ☌ occurs 8° 24′ beyond the former place. You will see further that the Middle intervals of the conjunctions of Saturn with Jupiter occur with a passage from the beginning of one triplicity to the beginning of another, as nearly as possible; but that in the conjunctions of Mars and Saturn the nearest cardinal point is passed by 8° 24′; while in the Middle intervals of Jupiter and Mars this passage cannot be considered. For if Jupiter and Mars have been joined at the beginning of Aries, they will be joined in the following conjunction at the beginning of Gemini, then at the beginning of Leo, after that at the beginning of Libra, etc. Therefore the Middle interval of these must be determined from the passage from one cardinal point to the opposite one, namely from the beginning of ♈ to the beginning of ♎, or from the beginning of ♋ to the beginning of ♑. Finally you will observe that in one period of the conjunctions of ♄ and ♃, 40 ☌ occur; but in one of ♄ and ♂, 15 ☌; and in one of ♃ and ♂, 6.

Interualla ☌ Trium Superiorum Planetarum

Intervals of the ☌ of the three superior planets

Planets	Intervals	Julian years	Arc of the zodiac	Number of ☌
♄ & ♃	Min.	19 years 314^{d} 12^{h} 59^{m}	8^{s} 2° 59′	1
	Med.	198 years 216^{d} 9^{h} 54^{m}	8^{s} 29° 47′	10
	Max.	794 years 133^{d} 15^{h} 35^{m}	11^{s} 29° 8′	40
♄ & ♂	Min.	2 years 3^{d} 20^{h} 52^{m}	0^{s} 24° 36′	1
	Med.	6 years 15^{d} 11^{h} 29^{m}	3^{s} 8° 24′	4
	Max.	24 years 68^{d} 1^{h} 4^{m}	12^{s} 9° 0′	15
♃ & ♂	Min.	2 years 86^{d} 10^{h} 26^{m}	2^{s} 0° 41′	1
	Med.	6 years 259^{d} 7^{h} 18^{m}	6^{s} 2° 3′	3
	Max.	13 years 153^{d} 14^{h} 36^{m}	12^{s} 6° 9′	6

[Margin: Time of the revolution of a ☌, roughly.] More roughly, however, Argoli, *Pandosion Sphaericum*, ch. 73, says that the conjunction of ♄ and ♃ occurs in the 20th year; of ♄ and ♂ every 25th month; of ♃ and ♂ every 27th

month; of ♄ and ☉ every 13th month; of ♃ and ☉ every 14th month; of ♂ and ☉ every 27th month; of ☉ and ♀ in the 10th month; of ☿ and ☉ every two months.

Quæ ſint Interualla Verarum ſeu apparentium Coniunctionum, & quæ diſtantia illarum à medijs.

What the intervals of the true or apparent conjunctions are, and what their distance from the mean ones is.

XIII. This question, indeed, asks too much, because of the excessive inequality of the motions of these planets, which does not allow a certain and precise rule to be determined. Between the true conjunctions themselves, however, so short a time can sometimes intervene, because of the condition of direct and retrograde motion and the position of the apsides, that three conjunctions of Saturn and Jupiter take place within one year, as happened in the year 5 before the birth of Christ the Lord and in the years 1563 and 1564, as will be clear from the history of notable conjunctions to be given in the next chapter.

CAPVT X.

Chapter 10.

Hiſtoria Coniunctionum Inſignium, & Mutationum Generalium in Mundo cum eis connexarum. Qua occaſione Diſceptatur an Coniunctiones huiuſmodi, aut aliæ magnæ Reuolutiones ſint cauſæ vel Signa magnarum mutationum in Mundo ſublunari.

History of notable conjunctions and of the general changes in the world connected with them. On which occasion it is debated whether conjunctions of this kind, or other great revolutions, are causes or signs of great changes in the sublunary world.

I. To proceed in order in this celebrated controversy, we shall first set out a history of certain more notable conjunctions of the three superior planets, drawn from the astronomical tables; and we shall add a synopsis of the mean conjunctions occurring at the cardinal points of each triplicity, with the more notable effects or events that stand at a nearer interval of time from them, so that it may better appear from this whether, and how great, a connection there can be between these conjunctions and those changes.

Coniunctiones Corporales quinque Planetarum.

Bodily conjunctions of the five planets.

II. [Margin: Almost bodily ♂ of ♄ and ♃.] That Jupiter should cover Saturn wholly or in part, and that their conjunction should occur [Greek: σωματικῶς (sōmatikōs, "bodily")], or by body, can hardly happen once within many

centuries, says Kepler in the *Optics*, p. 305. It seems to Kepler, however, to have happened in the year 1563 (for so the passage of the *Optics* is to be emended from Kepler himself, *De Stella Nova Serpentarii*, p. 184), since it is established from the ephemerides of that year that on September 27 Jupiter, direct, was conjoined in ♌ 4° 12′ to Saturn, direct, while each had ascending north latitude, the former 10′, the latter 14′. But since the sum of the visual semidiameters is not 4′ in these planets, either the latitude must be corrected, or, because of the expansion of the rays, it can be reduced to the bodily conjunctions. But from the observation of Giuntini, of which I shall speak shortly at no. 4, it appears that the latitude must be corrected, and that Saturn was truly covered by Jupiter. This conjunction was, however, notable, because in the following year, 1564, Jupiter, retrograde, was conjoined to Saturn, likewise retrograde, in ♌ 0° 56′ on January 26. Kepler points out, moreover, in the book *De Stella Nova*, p. 184, that the conjunctions of these planets that occur in Leo and Cancer are the more important, because the raising nodes [nodi euehentes] of both are in Leo, while in Cancer they ascend toward the apogee, and the altitude of this sign in our hemisphere favours a closer conjunction, that is, a bodily or quasi-bodily one. [Margin: Bodily ☌ of ♃ and ♂, of ♀ and ♂.] Mästlin saw Jupiter covered and wholly eclipsed by Mars at Tübingen on 1591 January 9, for the ruddy and fiery colour of the covering planet showed that Mars was the lower; and he saw Mars covered by the whiter Venus on 1590 October 3, at 5^{h} in the morning, as Kepler reports in the *Optics*, p. 305, [Margin: Mutual eclipses of ♀ and ☿.] adding that mutual occultations of Venus and Mercury can occur; and he suspects from his own observation that Mercury was occulted by Venus on 1599 June 8. [Margin: ♀ under the Sun.] He says further that no part of the Sun can be covered by Venus in this century, but that it was possible, and will be in other centuries. [Margin: ☿ under the Sun.] For about Mercury seen under the Sun enough has been said in book 3, ch. 3, scholium 3.

Coniunctiones ♄ ♃ & ♂ Insignes.

Notable conjunctions of ♄, ♃ *and* ♂.

III. [Margin: Greatest conjunction of ♄ ♃ ♂ shortly before the birth of Christ.] Although the mean conjunction of Saturn and Jupiter usually lasts until Mars overtakes them and completes their conjunction with its own true or mean one, we shall nevertheless report here three above the others. The first was in the Julian year 40, or 6 before the common epoch of Christ, in which, on January 22, in

Pisces at 29° 26′, Saturn and Jupiter came together in mean motion; and shortly afterwards, on February 25, there followed the mean conjunction of Mars and Saturn in 3° of Aries, and on March 1 the mean conjunction of Mars and Jupiter in 5° of Aries. But the true conjunction was more remarkable. For in the Julian year 39, or 7 before Christ, around June 22, there had been a true conjunction of Saturn and Jupiter in 23° of Pisces; and when, shortly

afterwards, each had become stationary and soon retrograde, in the month of August Jupiter at last overtook Saturn again as it crept against the order of the signs, at about 21° of Pisces. Finally, in the month of December, Jupiter overtook Saturn for the third time in 17° of Pisces. But Mars had joined them in the Julian year 40, in February, at the end of Pisces or the beginning of Aries. Therefore within six or seven months three true Greatest conjunctions of Saturn and Jupiter took place at the end of the watery triplicity and toward the beginning of the fiery; and about four months afterwards they were followed by a twofold conjunction of Mars, one with Saturn, the other with Jupiter.

Since this conjunction, then, was close to the birth of our Saviour and to the Star that announced him to the Magi, it gave Kepler occasion to believe, in the book *De Stella Nova in Serpentario*, ch. 26, and in the book *De Iesu Christi Servatoris nostri vero anno natalitio*, that the opinion of Laurentius Suslyga [Wawrzyniec Suślyga] the Pole was most probable. Suslyga adds four years to our customary epoch and asserts that Christ was in truth born not in the Julian year 45, as the common epoch of the Christian world and the Roman calendar suppose, but in the Julian year 41, that is, two years after the true and Greatest conjunction of the superior planets; and that the star which shone on the Magi began to shine in the very place of the Greatest conjunction, [Margin: The Star of the Magi arose under a Greatest conjunction.] in which respect it was like the new star that arose in Serpentarius in the year 1603 under the great conjunction of the three superior planets. Kepler therefore says that God himself, to accommodate himself for the time being to the rules of the Chaldeans, who at the passage of the conjunctions from the watery to the fiery triplicity expected the greatest changes in the world and universal renewals, kindled that star at the very moment of that conjunction; indeed, perhaps in the same place, so that the Magi, who were watching that conjunction, might more easily catch the new star with their eyes; and that he so ordered the times of that conjunction that it would serve to announce the coming of his Son, who was soon to appear in the flesh. He adds, moreover, that two years passed between the first shining of the star and the arrival of the Magi and the cradle of Christ. He therefore concludes that the year in which he was writing, if truth be regarded, is to be counted not 1606 but 1610, if not 1611; although he admits that the epoch in use for so many centuries is not to be changed, and that it is enough to know that its beginning is taken from the year 5 of Christ. I, however, in my chronological book have shown by solid arguments, unless I am mistaken, that our common era lacks either no year at all or at most one only.

As for this conjunction: although I do not deny that God could have used it to announce the birth of Christ that was to follow shortly after, just as he used the rainbow, a natural sign of fair weather, to signify his perpetual covenant with Noah and his pact not to destroy the human race any more by a universal flood, I nevertheless judge it safer and more pious to hold that the Star had no dependence on, or subordination to, that conjunction in what it signified, as

the Holy Fathers everywhere teach in their homilies and treatises on the Most Holy Epiphany. Indeed, I judge that God deliberately kindled it some years afterwards, so that this independence might be recognised, and so that by the miracle and by his illumination, inner and outer, the Magi might discern the renewal of the world and the birth of the great Prophet and King of Kings, which that Greatest conjunction could only foreshadow and stammer out.

IV. [Margin: ♂ ♄ ♃ ♂ ☉ ☾ and ☿ in the year 1524.] In the year of Christ 1524, in the month of February, Saturn, Jupiter and Mars appeared conjoined on almost the same day in 10° of Pisces, with Venus preceding by a few degrees, and with a conjunction of the Sun and Mercury going before them a little earlier at the end of Aquarius, and with the Moon passing through all of them in the space of thirty hours; so that, given the meeting of so many planets, perhaps no conjunction since the founding of the world has been more celebrated, as Kepler judges in the book *De Stella Nova*, ch. 29.

Again, on 1563 September 27 Saturn and Jupiter were conjoined in ♌ 4° 8′ by the Alphonsine calculation, but on August 26 at 10^{h} in 29° of Cancer according to the Prutenic Tables, [Margin: Three ♂ of ♄ and ♃ in 1563 and 1564.] with very nearly the same latitude toward the same side, that is, in an almost bodily conjunction; and when they had become retrograde, ♄ on November 6 and ♃ on the 14th, they were again truly conjoined on 1564 January 26 in 0° 56′ of Leo. Afterwards, in the same year, they became direct again, ♃ on the 14th and ♄ on the 21st of March. For the third time they appeared joined on April 14 in ♋ 28° 56′; and this conjunction was followed in the same year 1564 by a true conjunction of Mars and Saturn on June 6 in ♌ 3° 15′, and of Mars with Jupiter on June 15 in ♌ 9°. The conjunction was therefore notable, both because it was in a sign of the fiery triplicity, and because it was tripled within seven months, and because it was of the three superior planets very close together. So, at any rate, the ephemerides of Carelli have it; although Kepler, in the book *De Stella Nova*, ch. 29, calls the conjunction of 1563 conspicuous only in such a way as to assert that what was granted in the age of Christ has been wholly denied to these times of ours and to the 250 years around us: namely, that around opposition to the Sun, Saturn and Mars, having met and being retrograde, can be joined twice or three times in the same year. As for the day, however, all the tables erred. For Francesco Giuntini, in the preface to his astronomical tables, says that he observed the conjunction of Saturn and Jupiter at Orange [Aurangæ] on August 24 at 14^{h} 30^{m} after noon, when Jupiter, more to the north, covered almost the whole of Saturn. To this seems to belong the Great or Greatest conjunction of the three superior planets at the end of Cancer, from which, Henricus Mechliniensis [Hendrik Bate of Mechelen] taught in his commentary on Abū Maʿshar, the Flood issued; and Petrus Alliacensis [Pierre d'Ailly] followed him in his questions on Genesis, interpreting these planets conjoined in the watery signs as the cataracts of heaven. But to the pious ears of the sacred interpreters this origin of the Flood cannot but seem absurd.

Coniunctiones aliæ ♄ & ♃ inſignes, & de Cauſa nouæ Stellæ Anni 1603.

Other notable conjunctions of ♄ and ♃, and on the cause of the new star of the year 1603.

V. [Margin: ☌ of ♄ and ♃ in the year 1603.] Besides the mean conjunctions that took place at the beginning of the fiery triplicity, or the end of the watery, which we have already listed, namely in the years before Christ 3980, 3185, 2390, 1595, 801, 6, and in the years of Christ 789 and 1583, the most celebrated proved to be the one that occurred in the year 1603, when, after the mean conjunction held in 1° 7′ of Sagittarius, the true conjunction of Saturn and Jupiter took place in 8½° of Sagittarius on December 17, though with Mars absent in Libra; Mars afterwards overtook Saturn in 10° of Sagittarius on 1604 September 29, and Jupiter on October 8 or 9. Magini and Origanus, however, place the true conjunction of Saturn and Jupiter on December 24 in 9° 36′ ♐. This synod, moreover, was held to be notable by Kepler in the book *De Stella Nova in Serpentario*, and by Io. Francisco Spina [?], book 2 of *De maximis coniunctionibus*, ch. 2, because of that very new star which appeared in Serpentarius in the year 1604, on October 8 or 9, in ♐ 17° 43′ with north latitude 1° 56′; and because it fell shortly after the beginning of the fiery triplicity, namely in 8½° ♐ as to the true conjunction but in 1° as to the mean, although, more exactly, this triplicity began from the immediately preceding mean conjunction of Saturn and Jupiter, which took place in the year 1583, either in 29° of Pisces, as the Prutenic Tables will have it, or in 1° of Aries, as the Alphonsine do, and was the eighth since the founding of the world; the true conjunction, however, was in 21° of Pisces. But Kepler admits there, in ch. 7, that all these beginnings must be taken in a broad sense. [Margin: Kepler's opinion on the efficient cause of new stars.] Finally, in ch. 27, he concludes that this star was created anew by God, whether using nature as his minister or not, and associated with a great conjunction, and by special providence, so that, marked by so many prerogatives, it might the more clearly rouse mortals to understand the things of which he wished them to be forewarned. The prerogatives were these: that the rising of the Star fell in the year [recte: after the year, per the book's errata] of a Greatest conjunction of Saturn and Jupiter; that it fell on the very day of the conjunction of Mars with Jupiter, and 8 or 10 days after the conjunction of Mars with Saturn; and that it stood close to the very place of those conjunctions, namely in 18° of Sagittarius. If, however, this prodigy had to be attributed to any natural cause, he thinks it should be attributed to an animal faculty, which he makes similar to the animal faculty of sublunary nature, which forms little animals out of rotting matter, such as bees, flies and butterflies, or certain shapes of plants, flowers, etc.; a faculty which he says is endowed with a certain sense, by which it perceives the place and time for doing these things; and which is roused and moved by the rays of the stars and their aspects, not passively, by receiving something that compels it to act so, but objectively, that is, it is stimulated in

the manner of an object, here and now, to act accordingly. In this way, then, that animal faculty which presides over the heavens, and whose task it is to preserve the transparency of the ether, therefore forms anew, out of impure and superfluous bodies diffused through the ethereal air and gathered into one, new stars in the immobile heaven of the fixed stars, and mobile comets in the mobile heaven of the planets; especially if it senses that this is fitting to be done at such a conjunction of the planets, or because of some other aspect by which it is objectively moved. But, as I said, he thinks outright that this star was kindled by God himself to signify something great to the inhabitants of the terrestrial globe, to whom the conjunction of the planets appeared. For although in the same book, p. 195, he grants other inhabitants, of a species different from men, to other celestial globes, nevertheless the conjoined superior planets appeared not to them but to the dwellers on Earth.

Auctoritates ac Rationes pro vi Maximarum Coniunctionum ad excitandas vel ſignificandas inſignes ac generales mutationes in Mundo.

Authorities and reasons for the power of the Greatest conjunctions to rouse or to signify notable and general changes in the world.

VI. There is no need to list the authors of this opinion, who after Abū Maʿshar and Alcabitius have so multiplied that very few astrologers have not stood by it. Among them, however, the chief have seemed to be Alliacensis, who for that reason wrote a book on the concord of history and astrology, confirming from great events the great force of these Great conjunctions, although later, in the *Elucidarium*, he corrected himself in large part; and Cyprián Lvovický, Io. Franciscus Spina [?], Origanus, Argoli and the others adduced at the beginning of ch. 9; and countless others who, either foreseeing the great conjunction of the year 1603 or on seeing the new star then kindled, spread innumerable prognostications of great future changes in pamphlets issued throughout Europe. Kepler, in the book on that new star, is to be counted among them. [Margin: Kepler's view on the vanity of astrology.] For although he says in ch. 2: *Although astrology has much vanity in it, and is for the greater part unworthy that good hours should be spent on it; yet because this disease belongs to not a few, but pervades the greatest part of the human race, so that whoever teaches the mathematical arts without mentioning it seems to speak too little to common use, I cannot refrain from beginning the explanation of the history of the new star, already given, with a mention of the astrological traditions.* Nevertheless, in ch. 7, considering the ages of the world and the principal epochs, which fell almost at the very moments of the Greatest conjunctions at the beginnings of the fiery triplicity, he says that *he takes very great delight in this series of trigons, and in what is, so to speak, a compendium most useful for helping the memory.* And in ch. 8, 9 and 10 he teaches that by the aspects of the planets sublunary nature is not indeed compelled but is roused, in the way the senses are roused by objects, to set new things in motion,

above all by the Greatest conjunctions; and that around the time of the Great conjunctions there were such great commotions of natures, and of their natural effects and instincts, that they gave astrologers a handle for attributing them to the conjunctions themselves, or to the planets so conjoined, as to efficient causes. Finally, in ch. 26, 27 and 39 he teaches that God, not by chance but by special providence, at the moment of the Greatest conjunction that took place in the Julian year 40, kindled the star for the Magi, and in the year 1603 the new star in Serpentarius for us, in order to support the power of signifying that astrologers believed the conjunctions to have, and to illustrate it by a new portent. This is, in the end, to concede that they are taken up by God as a sign at will, or, as they say, *ad placitum*, at least so that he may accommodate himself to the opinions of the astrologers, who at any rate use them as signs of great changes.

VII. But the strongest and most particular reason, passing over those usually brought forward in general for the efficacy of any aspect and syzygy of the planets, is the connection of notable vicissitudes and changes on the globe of the Earth with these Greatest conjunctions. Alliacensis draws this connection from chronology; so do Argoli, *Pandosion Sphaericum*, ch. 73; Io. Franc. Spina [?], book 2, ch. 2; Origanus, vol. 1, p. 449; and Kepler in the *Epitome of Copernican Astronomy*, p. 855, and in the book *De Stella Nova*, ch. 7, though using round numbers of 800 years for the revolution of the Greatest conjunction. To these we shall add more exact numbers from what was said in ch. 9, no. 9. Here, then, is a chronological table from these authors, who however leave out the reform of the calendar. Argoli adds that the law of idolatry began from the earthly trigon under Belus, about 1420 years before Christ; the Jewish law from the airy trigon, the Christian from the fiery, the Mahometan from the watery, whose triplicity, he says, began in the year of the Lord 591 and lasted until 789.

Order of the triplicities	Greatest ☌, years before CHRSTVM [recte: CHRISTVM]: Kepler	Greatest ☌, years before CHRSTVM [recte: CHRISTVM]: ours	Notable events and changes
1	4000	3980 Adam	The beginning of the world or the fall of Adam.
2	3200	3185 Enoch	Brigandage, then the building of cities. The invention of the arts.
3	2400	2390 Noah	The universal Flood, the restoration of the world.
4	1600	1595 Moses	The plagues of Egypt. The Exodus. The written Law.
5	800 Isaiah	801 Romulus	The beginning of the Olympiads; Rome founded. The new era of Nabonassar.
6	Christ	6 Augustus	The monarchy of Augustus flourishing. The description of the world. The birth of Christ.
7	800 Charlemagne	789	The transfer of the Roman Empire to the Franks.

Order of the triplicities	Greatest ☌, years before CHRSTVM [recte: CHRISTVM]: Kepler	Greatest ☌, years before CHRSTVM [recte: CHRISTVM]: ours	Notable events and changes
8	1600 or Gregory XIII	1583, 1603	The reform of the calendar; the embassy of the kings of Japan to the supreme pontiff. Three new stars in the heavens.

Since, then, by using round numbers of 800 years the times of the events already mentioned are easily committed to memory, as Kepler pointed out, I could not restrain myself, or hold back our Urania (who is, after all, the highest of the Muses), from pouring out the following verses, stirred by a kind of poetic surge rather than by the frenzy of empty prophecy.

The FIERY TRIPLICITY, called the Greatest conjunction of Saturn and Jupiter, returns every eight hundred years. The FIRST holds the fall of Adam and the beginnings of the world; savage brigandage, then cities and arts, the SECOND. The THIRD, the Flood, and the seeds of a renewed race. The FOURTH calls Moses, and writes the Law in marble; and the FIFTH, the Olympiads, Rome, and the era of Babylon. The SIXTH stands astonished at CHRIST GOD, and at Augustus the monarch. The SIXTH triumphs for CHRIST GOD, more than you, Augustus. With the Empire transferred, the SEVENTH gives Charles the Great. The EIGHTH reforms the sacred rites and the cycles of the calendar, subjecting to Gregory the Japanese, the furthest kingdoms of the earth, and three times renews portents with new stars on Olympus. What if the threatening NINTH, thrice threefold, should blaze for the world extinguishing the kindled supreme lamp of life, after seven decades of ages and the Sabbaths of the great Week, and should call back the beginnings of a new Kingdom, so that the pious ages may merit a perpetual Sun, and the impious ages be damned to eternal night?

[Margin: Mark 13.] However, lest, with the Gospel protesting and Christ sounding in our ears that saying, *But of that day or hour no one knows, neither the angels in heaven, nor the Son, but the Father alone*, we should seem to want to prophesy, since this saying, as Augustine acutely said, loosens the fingers of all who calculate: we reject and condemn all dependence of that last day on the influences of the stars, and all force of certain signification. And if it should be thought best that not even a suspicion of doubt be raised, let the censure of the sacred sponge, with my free consent, delete the last six verses that my pen poured out.

Auctoritates ac Rationes contra Maximarum Coniunctionum vim significandi, nedum efficiendi prædictos euentus & mutationes.

Authorities and reasons against the power of the Greatest conjunctions to signify, let alone to bring about, the events and changes already mentioned.

VIII. This is not the place for refuting the rashness of judicial astrology, long since proscribed and infamous for its very frequent lies among sensible men learned in astronomy itself, let alone among those learned in the sacred codes and canons. For although that class of men will always be forbidden in the City, and indeed in the world, and yet will always be retained, nevertheless, once the *Almagest* is finished, if it so please God, I will, so far as in me lies, shake and undermine the foundations of this Babylonian citadel from the innermost recesses of astronomy. But now I must indicate what tells against the excessive power, urged by so many, of the Greatest conjunctions in changing sublunary nature and human polities, or in certainly signifying their changes.

[Margin: 1st argument, and the opinion of Ptolemy discussed.] *First.* Ptolemy says in the *Centiloquium*, aphorism 50: *Do not overlook the one hundred and nineteen conjunctions: for in them lies the knowledge of the things that come to be in the world, both of generation and of corruption*; and in aphorism 63: *When Saturn and Jupiter are joined, see which of them is higher, and pronounce according to its nature. Do the same also with the other stars.* In the former he speaks of the 119 comparisons of conjunctions that can occur among the seven planets, and in the latter of the height of a planet at the apogee of the epicycle, as if reigning on a highest throne, as Pontanus [Giovanni Pontano] explains there. Yet notwithstanding these passages, Valentinus Naiboda, otherwise a great teacher and patron of astrology, on Alcabitius, differentia 4, and Argoli, *Pandosion Sphaericum*, ch. 74, maintain that Ptolemy attributed the power of signifying great events either solely or chiefly to eclipses of the luminaries, not neglecting the stations and heliacal risings of the three superior planets, or even their conjunctions, provided these fall at the time of an eclipse. He tries to show this from book 2 of the *Apotelesmatica* and from other passages and arguments, [Margin: The opinion of Valentinus Naiboda.] adding: *And if you should wish above all to pursue the conjunctions of the heavy planets in the way in which Ptolemy treats eclipses of the luminaries, the very difficulty of the matter will easily drive you from your purpose, since human understanding does not grasp the exact time of a conjunction of the superior planets.* From this my second argument now arises.

[Margin: 2nd argument.] *Second*, then. Either a Greatest conjunction has the power of certainly signifying the greatest events insofar as it is a conjunction of Saturn and Jupiter, whenever and wherever at length it happens; and this the astrologers neither say nor can say, because the events signified would always be of the same kind. Or it has that power insofar as it happens in such a degree of the zodiac and at such a moment; and this no tables have yet delivered with all misgiving excluded, [Margin: Note the disagreement of the Alphonsine and Prutenic tables.] since the ☌ of ♄ and ♃ of the year 1563 was carried forward by the Alphonsine tables to September 27 and to the 4th degree of Leo, whereas the Prutenic tables drew it back to August 26 and the 29th degree of Cancer. So one would have had to judge in one way from the nature of Leo, a fiery sign, as they will have it, and in another from that of Cancer, a watery sign: that is, in an entirely opposite manner. In reality it took place on August 24 at

14^h 30^m after noon at Orange, as Giuntini observed and reported in the preface to his astronomical tables, adding: *Jupiter, on the north side, as it were covered Saturn, which was on the south side, and both of these stars were found at the end of the 28th degree of Cancer.* We have reported similar errors in the conjunction of Saturn and Mars in this Book 7, sect. 1, ch. 6, no. 5; they arise from the slowness of the motions, especially of Saturn, which does not make its progress manifest except after many days.

[Margin: 3rd argument.] *Third.* It is more just to use true rather than mean conjunctions in this judgement, for the reasons brought forward in ch. 9, no. 5; and yet Abū Maʿshar and almost all his followers used mean ones, which not rarely occurred in signs of the opposite triplicity, as we have shown above more than once. It is therefore plain that, if the properties of events depended on the conjunctions, at least as to signification, they should have been assigned differently from these men's decrees; and that what was ascribed, for example, to the watery triplicity belonged to the fiery. That art is therefore uncertain and vain which rests on false or inconstant principles; indeed, it does not even deserve the name of art.

[Margin: 4th argument.] *Fourth.* That very division of the signs into fiery, earthly, airy and watery, and the naming of the trigons after the elements, does not come from the nature of things but from the mere choice of men, as Kepler shows in *De Stella Nova*, ch. 6; and it is founded on a mere analogy with the images of the signs. For because Cancer, Scorpio and Pisces are aquatic animals, the signs in which such stars once stood have been called watery. But why should Aquarius not rather be called watery, and Taurus and Scorpio fiery, since the largest stars in them, Aldebaran [Palilicium] and Antares, rival the fires of Mars with their redness? That is, if the naming was indeed taken from the stars once conjoined with those signs.

[Margin: 5th argument.] *Fifth.* The fictions of Abū Maʿshar and of many Arabs founded on these and similar conjunctions are so ridiculous, and so much at odds with the events that actually followed, that they surpass cabalistic trifles and the fables of the Koran in levity and futility; and I almost regret having turned my eyes to them, however much with the intention of attacking them. So when he says, in book 1, differentia 4, that if at the time the conjunction changes some other one of the planets is lord of the fourth of the ascendant, that planet is the significator of the mounts and the garments that the greatest part of the new sect will use. *If it is* ♄, he says, *it signifies that the greatest part of the mounts of the citizens of that sect will be nags; and if it is* ♂*, horses; and if it is* ☿*, asses; and if it is* ♀*, camels; and if it is* ☾*, oxen or cows.* But what has slowest Saturn to do with nags? What has most learned and most shrewd Mercury to do with the braying and stupidity of asses? What has loveliest Venus to do with the hump and the foul gape of camels? And if a young bull or heifer imitates the horns of the Moon with its own horns, Venus seen through the telescope appears no less horned all the same. But away from our pages with the other ravings with which this author teems.

[Margin: 6th argument.] *Sixth.* The chronology of events, on which our opponents have built many dogmas in order to win great dignity for the Greatest or Great conjunctions, is either false or not rarely so disputed that it cannot suffice for founding an art. So when Abū Maʿshar says, tract. 1, diff. 1, that between the creation of Adam and the night of Friday on which the Flood occurred there were 2226 years, 1 month, 24^{d} 4^{h}, whereas by our chronology, confirmed by clear proofs, there were only 1685. But it would be endless to pursue these things, and I see that they can defend themselves by the credit of the historians they have followed. We shall, however, shortly sample some other things in the following argument.

[Margin: 7th argument.] *Seventh.* The deceptiveness of the predictions about the rise or fall of sects, deduced from these conjunctions or from the position of the stars, shows their shameful vanity. [Margin: False predictions of the astrologers about the end of the Christian religion, etc.] Once the mathematicians, says St Augustine, *De Civitate Dei*, book 18, ch. 53, and Io. Picus [Giovanni Pico della Mirandola], book 5 of *Adversus Astrologos*, ch. 1, when the faith of Christ began to sprout, kept saying that it would last not more than 365 years; and yet the one thousand six hundred and almost fiftieth year now rolls by since his Church flourished like a lily among thorns, and it will flourish until the consummation of the age. That same Abū Maʿshar, tr. 2, last differentia, said that this same religion of ours would last only 1460 years, because that, of course, is the number of years they call the greatest years of the Sun, or the great canicular year, on which see what was said in book 3, ch. 13, scholium 4; and that the sect of the Arabs would last 544 years. Those 1460 years have passed, and not yet has our religion passed away, because heaven and earth will pass away, but the words of our Lord Jesus Christ, who promises it perpetuity, will not pass away. Nor was Abū Maʿshar more truthful about the duration of his own sect: since it began in the year 622, it should have perished in the year 1166. Abū Maʿshar was still living in that century, and he likewise added that the time of that change was near.

Abraham the Jew had predicted that the Messiah would come in the year of Christ 1464, from a position of the stars like the one that obtained when Moses, having led the people out of bondage, gave the law he had received from God. "I," says Pico in the place cited above, "born in the year just before it, and now in my thirtieth year, have learned the falsity of that prediction by experience." Arnaldus Hispanus [?], a distinguished physician but far too steeped in this superstition, threatened that the Antichrist would come in the year of grace 1345, because of the conjunction of the three superior planets in Aquarius. More than 300 years have flowed by since that time, and no other Antichrists have come except such as there were in apostolic times too, that is, heresiarchs.

Cardinal Petrus Alliacensis, whose purple was, alas, all too deeply stained with this Arabic ink, believed the astrologers in the year the General Council of Constance was held, when they were predicting the ruin or monstrous

destruction of the Catholic religion, and he feared that after that schism, which the council nevertheless removed, the Antichrist was at hand. Nicolaus Cusanus, in his book *De diebus nouiss.*, judged that the end of the world would come in the year 1700 or 1734. Cardano (*De varietate rerum*, book 2, ch. 2) and Iacobus Naclantus [Giacomo Nacchianti] (in the *Prælud.* of his *Medulla*, ch. 4) held that it would come in the year 1800, from the position of the stars. Others, according to Nausea [Friedrich Nausea] in his book *De consumatione sæculi*, predicted from the conjunction of so many planets in the year 1524, discussed above, a flood over the whole globe or the greatest part of it, and they struck such fear into some people that these withdrew to live in the mountains, or raised up buildings, or made ready enormous ships. Others predicted the end of the law of Christ for the year 1048, from the conjunction of ♄ and ♃ in July of the year 1044, as Abulensis [Alonso Tostado] has it on Matthew ch. 22, question 231. Ridiculous too is that astrologer of Toulouse who, fearing from a similar aspect a flood on a fixed day, built himself a citadel; yet Florimundus [?], in his book *De extremo Iudicio*, reports that the day was perfectly clear. Mercurius historicus [?] relates that Regiomontanus asserted the end of the world for the year 1588. But Petrus Alliacensis, in his book *De concordia Astr. & Histor.*, ch. 60 and 61, extends it to the year 1789.

For other opinions or conjectures about the end of the world, but taken from elsewhere than the stars, see St Irenaeus, *Adversus Haereses*, book 5, ch. 28; St Ambrose on Matthew ch. 17; St Augustine, *De Civitate Dei*, book 20, ch. 7, and Vives [Juan Luis Vives] on that place; Georgius Venetus [Francesco Giorgi], *De harmonia mundi*, Canticle 3, tome 7, ch. 7; Hadrianus Finus, *Flagellum contra Iudæos*, book 4, ch. 20; Galatinus [Pietro Galatino], book 9, ch. 11; Sixtus Senensis [Sisto da Siena], book 5, annotation 190; Hieronymus Maggius [Girolamo Magi], in his book *De exustione Mundi*; Henricus Emstius [?], *De fine mundi*; and Florimundus, *De extremo Iudicio*.

The astrologer Valens too, as Scaliger reports in book 5 of *De emendatione temporum*, had predicted that Constantinople, restored by Constantine, would last only 696 years. Would that the prophecy of Io. Franciscus Spina (book 2, ch. 3) were true, though it is built on an empty foundation. From the great conjunction of Saturn and Jupiter of the year 1603 he gathers that the sect of the Turks is to be exterminated in this century or at the beginning of the next. For the origin of this extermination, he says, sprouted in that conjunction, flowered in the second, of the year 1623, will yield fruit in the third, of the year 1643, and the fourth or the fifth will complete the fruit; and so the superstition of Muhammad will perish in the year 1663 or 1683, or at the very latest in the year 1702. On this occasion I go on to the 8th argument.

[Margin: 8th argument.] *Eighth.* Either a greatest or a great conjunction generates or signifies events that are to follow immediately, and this the astrologers neither dare to say nor can, with history protesting on every side; or it does so only after some notable time, so much so that Abū Maʿshar (tr. 1, differ. 1) grants that 279 years intervened between the conjunction that

signified the Flood and the Flood itself. If that is so, then, as even Bellanti himself teaches (*Against Pico*, book 5), those effects can no more be attributed to great conjunctions than to other syzygies of the stars formed at a nearer time: say, the eclipses of that year, and six hundred other configurations of the wandering and unwandering stars. Bellanti does add that in this matter the opinion of Alliacensis and of others, who in such a case attribute those effects to great conjunctions, can be neither proved nor disproved. For he says: "It seems to me most evident that it cannot be proved or disproved that these or those changes in the affairs of the world come from these or those constellations, unless we diligently keep before our eyes the great conjunctions and the others we have called necessary, and the effects corresponding to those times. For in the first place the astrologers would be proving lightly that these or those effects proceeded from great conjunctions, on the ground that they occurred in the intervening times, etc." But because he considers that an effect which a great conjunction has begun grows little by little, in the course of time, through other syzygies of the planets, and at last matures, he therefore judges that this opinion cannot even be disproved.

[Margin: 9th argument.] *Ninth* and finally: if only the greatest conjunctions are considered, those formed at the beginning of the fiery triplicity, or at least at the beginning of any triplicity, many events of the greatest moment and notable changes in affairs nevertheless happened before them, so that they could not have been foreshadowed by conjunctions that came after. But if appeal is made to the conjunction immediately preceding, it often belongs to a triplicity of a different kind, and one less suited to those effects than the great or greatest conjunction that followed. Consult our *Chronology*, or any other you reckon more exact, and compare the times of the changes and more notable events with the great or greatest conjunctions entered in the table at ch. 9, no. 9, and you will see a very great discrepancy throughout.

Finally, there has been no century, indeed scarcely a half-century, without some notable events in the world: for instance wars between nations, or new monarchies, or barbarian invasions, or persecutions of the Church, or schisms, or heresiarchs, or founders of new sects, or pestilences, famines, earthquakes, floods. So there is no reason why these should be foreshadowed to us from heaven, from afar and confusedly, by the conjunction of two planets; for we know from another source, from the history of all the centuries, that no century will be immune from vicissitudes of this kind. But God granted the particular and distinct signification of events to his prophets, not to astrologers.

SCHOLIA.

Scholia.

I. [Margin: Changes in the world from the change of the apsides.] With the same vanity with which astrologers derive, from great conjunctions, general changes and catastrophes of affairs in this world, they suppose that these

same things depend on the change of the obliquity of the ecliptic and of the eccentricity, and also of the apogees, a change which, because their motion is slow, works or signifies effects that are slow but notable. Foremost among such people is Cardano, in book 1 of the Ptolemaic *Centiloquium*, aph. 37, who says: "Changes of the apsides change kingdoms, regions and religions"; and in book 5, aph. 129, speaking of the change of the solar apogee, he dares to say: "The apsis of the ☉, travelling from ♈ to ♋, renders the southern part uninhabitable, but makes the northern habitable; from ♋ to ♎, it makes the northern well habitable and dominant over the southern; from ♎ to ♑, it makes the southern habitable, but by no means ruling over the northern part; from ♑ to ♈, it makes the southern ruling over a desolate northern part."

[Margin: Cardanus's opinion is empty.] Yet since the motion of the Sun's apogee, from the beginning of the world, has barely completed the first quadrant of the ecliptic, and even now is around the beginning of the second, as is clear from what was said in book 3, ch. 25, by what experience did Cardano learn what is to happen in later times? In past times, that is, from the founding of the world down to the present time, during which the Sun's apogee has passed from the beginning of ♈ to the beginning of ♋, the southern part of the globe has not been rendered more and more uninhabitable. Granted that, with the Sun at apogee in Cancer and at perigee in Capricorn, winter and summer are more moderate than if it were at apogee in Capricorn and at perigee in Cancer, while conversely both seasons of the year are less moderate for those in the south; still, other causes concur that diminish that excess. So farewell to Cardano, and to Origanus, who subscribes to his view (vol. 1, part 3, member 2, ch. 1). Nor is the foundation much greater in the apogees of the other planets: how great the uncertainty is about their place and motion is clear from what was said in Sections 2 and 3. On the change of monarchies according to the change of the solar eccentricity and of the obliquity of the ecliptic, against Rheticus, [Margin: Change of the obliquity and of the eccentricity of the ☉.] I said enough in book 3, ch. 26, schol. 1, especially since it is more probable that the Sun's eccentricity and the obliquity of the zodiac are always the same, from what was said in book 3, ch. 27; and Argoli is with us on this in the *Pandosion*, ch. 73.

II. [Margin: The Platonic Great Year.] The Platonic Great Year is very celebrated among writers: when it has come round, the planets and stars are all believed to return to the same point and the same goal from which, as if from the starting gates, they once began to run. Hence that passage of Cicero in the *Dream of Scipio*, or rather of Scipio in the dream of Cicero: "For people commonly measure the year only by the return of the Sun, that is, of one star. But when all the stars have returned to the same place from which they once set out, and after long intervals have brought back the same configuration of the whole heaven, then that can truly be called a revolving year, etc."

Yet this year seems fictitious rather than real. For even the revolution of the Moon to the Sun alone, with all the circumstances that attended some one

syzygy with it in the past, has not yet been demonstrated to be possible: for who has ever demonstrated, says Boulliau (book 3, ch. 3), that the motions of the Moon are commensurable with the motions of the Sun? [Margin: The incommensurability of the celestial motions.] As for the rest, hear Kepler in the *Mysterium Cosmographicum*, who from one postulate shows that there will be no Platonic year. "For let it be granted," he says, "that the eccentricity has a rational proportion to the orb; for the radii of the orbs will be irrational, because they are related as those inscribed in and circumscribed about the bodies, which are irrational, because they follow from the ratio of the subtense in a square and of the section according to extreme and mean ratio, which are two examples of irrational proportions in geometry. But the motions have a proportion to the radii; therefore the motions are irrational to one another. And so, even if they should last for infinite ages, they will never return to the same beginning and goal of the Platonic year, because not even in an infinite division of time can a common measure be found which, repeated often enough, would equal the whole."

SECTIO SEXTA

Section Six

DE PASSIONIBVS PLANETARVM SECVNDVM ALTITVDINEM.

On the affections of the planets according to altitude.

PROHEMIVM.

Preface.

The affections that befall the planets according to altitude are: 1. The variation of their distance from the centre of the Earth or of the world. 2. The proportion of these intervals among themselves and with the motions, whether it is harmonic or not. 3. Their order in the system of the world. 4. Parallax, or variation of view. 5. Speed in motion, whether common or proper, insofar as it varies with greater or lesser distance from the centre of the universe. 6. The variation of apparent magnitude, if they are viewed from the Earth. 7. The diversity of apparent magnitude, if they are imagined to be viewed from some other place in the world. 8. Their true magnitude in three dimensions. 9. The length and thickness of the shadows they cast. 10. Eclipses, by which, either with their shadow or by the interposition of their body, they can hide the other planets or the fixed stars from us. All these things must therefore be discussed, with God's help, in the same order, and an end at last put to this seventh book.

CAPVT I.

Chapter 1.

An varietur Diſtantia Planetarum à centro Terræ vel Mundi.

Whether the distance of the planets from the centre of the Earth or of the world varies.

I. [Margin: On the varying distance of the ☉.] I taught in book 3, ch. 7, from eclipses and parallaxes, and in ch. 10, from the diversity of the apparent semidiameter, that the distance of the Sun from the centre of the Earth varies, as being much more probable; although in ch. 8, schol. 2, and more expressly in ch. 10, schol. 2, I taught that the variation of the Sun's distance cannot be demonstrated. [Margin: On the varying distance of the ☾.] That the Moon's distance is variable we showed against the Homocentrists, not only from eclipses but much more evidently from the diversity of parallaxes and of the apparent semidiameter, in book 4, ch. 13 and 14 (reread the scholia of the latter) and ch. 16.

What is now to be said of the other five planets could be called into doubt, especially since the defenders of the homocentrics, namely Girolamo Fracastoro, Giovanni Battista Amico and Io. Antonius Delphinus [Giovanni Antonio Delfino], reported in the scholia already mentioned, try to refer all the apparent diversity in their diameters to various vapours, or to parts of the heaven of different density and transparency; when these come between, varied refraction of the rays is supposed to produce that diversity in apparent magnitude. These things could indeed seem probable at first sight, especially if the diminution of the diameter or disc near the Sun were attributed to the Sun's brilliance overwhelming the smaller lights of the minor planets, so that accordingly at their greatest distances from the Sun they could appear larger, as is actually observed, than when they come nearer to heliacal setting. And to me, formerly, when I was younger and not yet admitted to the inner sanctum of astronomy, there seemed no necessity to introduce a differing distance for these planets. But much stronger reasons for this diversity of intervals stand in the way, reasons which, taken together, come as close as possible to evidence.

II. [Margin: 1st argument for the change of distance of the 5 planets from the Earth.] For first, they sometimes appear very tiny and sometimes much larger than themselves, not only when one compares their visible magnitude at the horizon, or as seen among vapours or clouds, with that seen farthest from the horizon or in a clear and cloudless sky; not only in different parts of the heaven; and not only with the Sun's light or the brightness of twilight close by or present; but even when they are viewed in the same part of the heaven, in the same degree of serenity of the sky or clearness of the air, and at the same depth of the absent Sun below the horizon. For let Jupiter or Mars, for example, be observed at mid-heaven when, having become acronychal, it stands diametrically opposite the Sun, especially when the equation of the centre, which a few days before had been subtractive, has turned additive; then let it be observed around the quadrate aspect with the Sun; and finally let it be observed when it is so far from conjunction with the Sun that the Sun is nevertheless below the horizon, and morning or evening twilight is not present,

that is, before the first or after the second sextile aspect, or even around the semisextile. For it will appear much larger in opposition than in quadrature, and in quadrature larger than in the sextile or semisextile aspect; and this not only to the naked eye but also through the telescope, so much so that the bright disc of Mars is seen larger in opposition than near conjunction with the Sun: five times larger to the naked eye, but through the telescope sixty or fifty times as regards area, and seven times larger as regards diameter, as Galileo also notes in dialogue 3 of *De Mundi systemate* and in the *Trutinator* [*Il Saggiatore*], p. 217. And more than once, when near opposition it became [Greek: περιγειότατος (perigeiotatos, "nearest to the Earth")] in Aquarius and Pisces, it was believed to be a comet or a new star, so increased in light did it seem. Nor can the whole of so great a decrease around the sextile or semisextile be attributed to the brilliance of the absent Sun, since fixed stars viewed in the same aspect with the Sun do not appear smaller than themselves as seen around opposition to it.

III. [Margin: 2nd argument.] *Second.* Venus most manifestly, and also Mercury and Mars, are carried around the Sun in such a way that they are illuminated by it in the manner of the Moon, as the spyglass [Tubospicillum] attests; so that this diversity of phases and faces cannot be fittingly explained except by asserting that they run around now above and now below the Sun, which is itself an argument for a varied distance. Then Venus, especially when retrograde in the middle of its regression, or around conjunction with the Sun, when from an evening star it is about to become a morning star, or when it has recently become a morning star, appears with a horn very narrow in breadth but very long in height. Observed with the best telescopes, it thus seems forty times larger than itself as regards area than when, direct at the other conjunction, it offers itself to be viewed with a disc that is round indeed but very slender, as Galileo notes in the *Trutinator*, p. 217, and in Dialogue 3 of *De Systemate Mundi*. And again, when it is retrograde and stands about 15 degrees from the nearer conjunction with the Sun, it shines with a far ampler disc and a greater lamp than when, direct, it stands 15 degrees from the other conjunction. That diversity therefore arises not from the vicinity of the Sun, which is equally absent in both cases, but from the differing interval between Venus and our view; for by prop. 56 of Euclid's *Optics* it is necessary that the same true magnitudes appear larger when nearer the eye and smaller when more remote. See, please, a specimen of these phases in Section 1 of this book, ch. 2.

IV. [Margin: 3rd argument.] *Third.* The latitude of the planets, especially of the superior ones, that is, their departure from the ecliptic, appears, other things being equal, much greater when they are around the middle of their retrograde course than when they are around the middle of their direction; and greater still if, when retrograde, they pass from the subtractive equation of the centre to the additive. Their latitude is also greater in opposition to the Sun than around conjunction, and, other things being equal, the southern is greater than the northern. By these arguments it was almost evident to astronomers

that these planets sometimes become perigean and approach closer to the Earth, and sometimes recede from it and become apogean; and accordingly that the same arc of the circle of latitude, or of inclination to the ecliptic, is nevertheless seen now under a greater angle and now under a smaller, so much so that the southern latitude of Mars when acronychal and retrograde is 7° 9′, but the northern only 4° 32′; and so for the rest, according to what was said in sect. 3, ch. 7. Practitioners have therefore rightly established that the apogees of the eccentrics of Saturn, Jupiter and Mars always incline to the north, and the perigees always to the south.

V. [Margin: 4th argument.] *Fourth.* Neither anomaly, or inequality, in the motion of longitude, which is most manifest in these five planets, can be accounted for and represented more conveniently and simply than by eccentric circles, or else eccentrepicycles or epicepicycles, as is clear from the hypotheses of the most famous astronomers set out in sections 2 and 3. But with these posited, or with spirals and whorls, or ellipses that yield the equipollence of the motions and prosthaphaereses, the planets must necessarily be now raised on high and now pressed down toward the centre of the world; and this diversity is far more simply explained by one circle or another than by the innumerable *circitores*, *anticircitores*, *vecti* and *contravecti* by which the Homocentrists, and the haters of a varied distance, are compelled to defend the diversity of the motions. It is accordingly much more likely than concentric orbs and the immutability of the intervals. But no one who has attentively considered the arguments already mentioned, and the harmony of the motions, will be of so childish a mind as to say that the planets, or the parts of the heaven between them and the ecliptic, now swell and expand, and now subside and contract.

CAPVT II.

Chapter 2.

Quanta & Quàm varia ſit Diſtantia Planetarum Minorum à centro Terræ, & à Sole.

How great and how varying is the distance of the minor planets from the centre of the Earth and from the Sun.

I. [Margin: The distance of the ☉ and the ☾.] Enough has been said about the distances of the Sun in book 3, ch. 7, at the end of which there is a table showing the threefold distance, that is, the greatest, mean and least, according to the opinion of 26 authors. About the Moon's distances from the Earth too, it was said at length in book 4, ch. 14; at the end of it we likewise gave a table of these from the opinion of nearly 15 different authors. The scholia of these chapters, full of uncommon learning, should be reread at this point. We therefore want those tables to be consulted just as if they were added to the following distances of the five minor planets. For these too I could have sent the reader off to the distances placed at the end of the chapters of sections 2

and 3 of this book. But those are bound up with the other proportions of the orbs, for instance the eccentricities and the semidiameters of orbs, epicycles, etc., and they are moreover given in parts of which the radius of the annual orb of the Sun or Earth, or the radius of the planet's orb, is 100000, let alone in semidiameters of the Earth. So it seemed best in this place to separate the distances of these planets from the Earth, to examine them more carefully, and to represent them only in semidiameters of the Earth: both because I know that such distances are generally what is sought, and because these will be of more use to us for determining the other properties of the planets according to altitude, since the other proportions of the orbs to the radius serve rather for the geometrical calculation of the motion in longitude and its theory. Whoever desires those proportions is free to fetch them from there: the solar ones from book 3, ch. 7, and its scholium; the lunar from book 4, ch. 14, and its scholium; those of the three superior planets from this book 7, sect. 2; and those of the two inferior from book 7 and sect. 3, by consulting the tables placed at the end of each chapter.

If anyone wishes to look at these distances in larger figures and put them before his eyes, perhaps at the end of this section or in book 9 I will supply them or the method of drawing them.

De Planetarum Diſtantijs Ptolemaicis & Alphonſinis à Sole & à Terra.

On the Ptolemaic and Alphonsine distances of the planets from the Sun and from the Earth.

II. Apart from the distances of the luminaries, neither Ptolemy nor Alfonso expressed for us the distances of the other planets. From their hypothesis, however, various authors derived them, in various ways, though omitting the distances from the Sun that we have had to add. The chief of these were: al-Battānī, ch. 50; al-Farghānī, diff. 16 and 21; Jean Fernel, *Cosmotheoria*, book 1; Maurolico, at the end of the dialogues of his *Cosmographia*; Clavius on the *Sphere*, p. 215, and at the end of the *Sphere*, nearly following Maurolico; Mauro Fiorentino and Francesco Giuntini in their *Spheres*, from which Baranzanus drew in part 1 of the *Uranoscopia*; Barozzi, *Cosmographia*, book 1, p. 48, following al-Farghānī; Copernicus, as given by Kepler in the *Epitome of Copernican Astronomy*, p. 494, correcting the Ptolemaic ones; Mästlin, on Kepler's *Prodromus*, p. 92, gathering Saturn's greatest distance from data given by Reinhold; Tycho, *Progymnasmata*, vol. 1, p. 468, reporting those of al-Battānī from his own manuscript; and Lansbergen, *Uranometria*, book 3. Among these Maurolico, a truly diligent man, declares that in the Sun's eccentricity and the semidiameter of the lunar epicycle he adhered to Alfonso, as being more truthful in those matters; but in deriving the distances of Venus and Mercury from the solar ones, he chose the Ptolemaic ones, as being more convenient; in the rest he kept to al-Farghānī, al-Battānī and Thābit.

Now the universal rules for gathering or understanding the distances in this hypothesis must be given, though only after first setting out some measures that bear on the matter.

Measures in semidiameters of the Earth, Ptolemaic or Alphonsine

Regulæ Pro Diſtantijs Ptolemaicis vel Alphonſinis Planetarum à Terra & à Sole.

Rules for the Ptolemaic or Alphonsine distances of the planets from the Earth and from the Sun.

[Margin: Mean distance.] 1. Rule. The mean distance of a planet, whether from the Earth (always understand: from the centre of the Earth) or from the Sun (that is, from the centre of the Sun's body), is of the same quantity as the radius of the eccentric, or the semidiameter of the deferent. The mean distance occurs a little below the mean longitudes of the eccentric and the epicycle.

[Margin: Greatest distance from the Earth.] 2. Rule. The greatest distance of a planet from the Earth is made up of the eccentricity of the deferent and the semidiameters of the eccentric and the epicycle. It occurs when the planet, at apogee in both eccentric and epicycle, is joined to the Sun.

[Margin: Least distance from the Earth.] 3. Rule. The least distance of a planet from the Earth is obtained by subtracting from the semidiameter of the

eccentric the sum made of the semidiameter of the epicycle and the eccentricity of the deferent. It comes out least when a superior planet, at perigee in eccentric and epicycle, is opposed to the Sun, while an inferior planet, at perigee in eccentric and epicycle, is joined to the Sun, if these distances are regarded in the line of apsides. Otherwise Mercury, with the centre of its epicycle at a third of the eccentric [in triente Eccentrici] on either side of the eccentric's apogee, can come nearer to the Earth, at the perigee of the epicycle, than anywhere else.

[Margin: Greatest distance of ♄ ♃ ♂ from the ☉.] 4. Rule. The greatest distance of a superior planet from the Sun, among all the great or greatest ones, occurs if the apsides are turned about, that is, if the planet's apogee lies under the place of the zodiac opposite to the one under which the Sun's apogee lies: namely when the planet, at apogee in both places, is joined to the Sun at perigee. It is therefore found by subtracting the Sun's least distance from the Earth from the planet's greatest distance from the Earth; and this is the greatest of the greatest. But if the apogees coincide, the greatest is then obtained by subtracting the Sun's greatest distance from the Earth from the superior planet's greatest distance from the Earth.

[Margin: Least distance of ♄ ♃ ♂ from the ☉.] 5. Rule. The least distance of a superior planet from the Sun occurs at its opposition with the Sun if the apogees are set opposite to each other, that is, it occurs when the planet, at perigee in both places, is opposed to the Sun at perigee. It will therefore be found by adding the Sun's least distance from the Earth to the planet's least distance from the Earth; and this is the least of the least. But if the apogees coincide, the least is obtained by adding the Sun's greatest distance to the planet's least distance from the Earth. But this will not be the least of the least.

[Margin: Greatest distance of ♀ and ☿ from the ☉.] 6. Rule. The greatest distance of an inferior planet from the Sun occurs if the apogees of these planets are opposed to the Sun's apogee, and the planet is then joined to the Sun at apogee in the lower position, that is, at the perigee of its epicycle. It is therefore found by subtracting the inferior planet's least distance from the centre of the Earth from the Sun's greatest distance from the Earth. And this will be the greatest of the greatest. But if the apogees coincide, the greatest distance from the Sun will be obtained by subtracting the planet's greatest distance from the centre of the Earth from the Sun's greatest distance from the Earth; but to the remainder must be added the diameter of the inferior planet's epicycle.

[Margin: Least distance of ♀ and ☿ from the ☉.] 7. Rule. The least distance of an inferior planet from the Sun occurs if the apogees of these planets are opposed to the Sun's apogee, and the inferior planet is then joined to the Sun at perigee in the upper position, that is, at the apogee of its epicycle. It is therefore found by subtracting the inferior planet's greatest distance from the Earth from the Sun's least distance from the Earth. But if the apogees coincide, it will be obtained by subtracting the planet's greatest distance from the Earth from the Sun's greatest distance from the Earth. But this will not be the least of the least.

These already-mentioned distances, however, do not in fact occur, nor can they occur in these ages, because the Sun's line of apsides does not coincide with the line of apsides of these planets. But we are seeking those that are possible in this hypothesis, if the world had lasted, or were going to last, long enough for the lines of apsides of the Sun and of each of the planets to coincide in the same line.

[Margin: Extent of the planetary heaven.] 8. Rule. Add the true semidiameter of the planet's body to the planet's greatest distance from the Earth, or subtract it from the least, and you will have, in the former case, the semidiameter of the convexity and, in the latter, that of the concavity; that is, the radius of the convex and of the concave surface of the heaven within which the planet ascends and descends. The difference of the semidiameters will be the thickness of that planet's heaven.

De Diſtantijs Planetarum Minorum à Sole & à Terra ex Copernici, Mæſtlini, & Lansbergij Hypotheſi.

On the distances of the minor planets from the Sun and from the Earth, from the hypothesis of Copernicus, Mästlin and Lansbergen.

III. From what sources I elsewhere derived the Copernican, Mästlinian and Lansbergian distances and measures of the orbs is clear from sect. 2, ch. 2, no. 7, and ch. 4, no. 4, and from sect. 3, ch. 2, no. 11, and ch. 3, no. 5. But there, either following the reckoning in parts of the radius of the planet's orb or of the annual orb, taken from Mästlin or Copernicus, and sometimes disregarding the eccentricity of the Earth, we indicated the distances of the planets from the Sun or from the Earth only from afar; and those distances also suffer from several errors, whether of the pen or of the printer. In this place we shall make good those slips with interest. And we shall consider the distances of the planets both in the case in which (if the world lasted so long) the apogees of these planets would coincide with the Sun's apogee under the same point of the zodiac, and in the case in which they would be diametrically opposed to it. Moreover, in the distances from the Sun, we shall take account of both the greatest and the least eccentricity of the Sun, so that the greatest differences of the intervals possible in this hypothesis may appear.

[Margin: Summary of the Copernican hypothesis for the distances.] We shall set out the rules for deriving these distances using, of the three forms of the Copernican hypothesis, the one that consists of an eccentre of the eccentric [Eccentro Eccentrici], that is, in which the eccentric varies its eccentricity, taken from the centre of the annual orb, by means of a small circle, whose schemes we set out in the chapters already mentioned. That was the reason why we have joined Lansbergen, who uses the same form here, with Copernicus and Mästlin. We therefore suppose that the superior planets, whenever they are at the apogee or perigee of their eccentric, have the least eccentricity, that is, half of the whole eccentricity, which Ptolemy would call the eccentricity of

the deferent. So too, whenever the Earth falls on the line of apsides of Venus and Mercury, Venus has its least but Mercury its greatest eccentricity, and then too Mercury has the least semidiameter of its orb, by force of the librating small circle. Further, the annual orb of the Earth is equivalent to the Ptolemaic epicycles of the three superior planets, and to the eccentrics of the two inferior ones. Finally, from the chapters already mentioned, I take as a foundation the measures written below, with the letter M set against the least eccentricity of Venus, which is to be used with the Sun's greatest eccentricity. Although it seems this should be done for Mars as well, there is no danger of great error because of its larger eccentricity, and so we have chosen the middle one among its least eccentricities.

Measures in semidiameters of the Earth

Regulæ Pro Diſtantijs Planetarum à Sole & à Terra Determinandis in prædicta Hypotheſi.

Rules for determining the distances of the planets from the Sun and from the Earth in the hypothesis already mentioned.

[Margin: Mean distance.] IV. First rule. The mean distance from the centre of the Earth, in any one of the minor planets, is always as great as the radius or semidiameter of the eccentric. In Venus and Mercury, therefore, it is as great as the radius of the annual orb, that is, as the Sun's mean distance from the Earth. The mean distance from the Sun, by contrast, is as great as the radius of the eccentric of the three superior planets and of the lesser orb of the two inferior ones.

[Margin: Greatest distance of ♄ ♃ ♂ from the Earth.] 2. Rule. The greatest distance of the three superior planets from the centre of the Earth occurs only at their conjunction with the Sun. For it, join together the semidiameters of the annual orb and of the planet's orb, and the planet's least eccentricity.

[Margin: Least distance of the same from the Earth.] 3. Rule. The least distance of the three superior planets from the centre of the Earth occurs only at opposition with the Sun. For it, subtract from the semidiameter of the planet's orb the sum made of the semidiameter of the annual orb and of the planet's least eccentricity.

[Margin: Greatest distance of the same from the ☉.] 4. Rule. The greatest distance of the three superior planets from the Sun occurs only at conjunction with the Sun. For it, from the sum made of the semidiameter of the orb and the planet's least eccentricity subtract, if the apogees coincide with the Sun's apogee, but add, if they are opposed to it, whichever eccentricity of the Sun you prefer: namely either the greatest, of Ptolemy's time, or the least, of our times. This is to be understood below, whenever the Sun's eccentricity is mentioned. But if you want the greatest of the greatest possible, subtract the Sun's least distance from the Earth from the greatest distance of the superior planets from the Earth.

[Margin: Least distance of the same from the ☉.] 5. Rule. The least distance of the three superior planets from the Sun occurs only at opposition with the Sun. For it, subtract from the semidiameter of the planet's orb, if the apogees coincide, the difference between the solar eccentricity and the planet's least eccentricity; but if the apogees are opposed, the sum of those eccentricities. But if you want absolutely the least of the least possible, add to the Sun's least distance from the Earth the least distance of the superior planets from the Earth.

[Margin: Greatest distance of ♀ and ☿ from the Earth.] 6. Rule. The greatest distance of Venus and Mercury from the centre of the Earth occurs only at their conjunction in the highest part of the orb. For it, add to the semidiameter of the annual orb the semidiameter and the least eccentricity of the orb of Venus; but the least semidiameter and the total eccentricity of the orb of Mercury.

[Margin: Least distance of the same from the Earth.] 7. Rule. The least distance of Venus and Mercury from the centre of the Earth occurs only at their conjunction with the Sun in the lowest part of the orb. For it, subtract from the semidiameter of the annual orb the sum made of the semidiameter and the least eccentricity of the orb of Venus, or of the least semidiameter and the total eccentricity of the orb of Mercury.

[Margin: Greatest distance of the same from the ☉.] 8. Rule. The greatest distance of Venus and Mercury from the Sun occurs if their apogees are opposed to the Sun's apogee, and these planets are joined either in the lower position to the Sun at apogee, or in the upper position to the Sun at perigee. Therefore add to the semidiameter of the orb of Venus the sum made of the total eccentricity of the Sun and the least eccentricity of Venus; but to the least semidiameter of the orb of Mercury add the sum made of the total eccentricity of both the Sun and Mercury. In this way you will have their greatest distance from the Sun possible in this hypothesis. But if their apogees coincide with the Sun's apogee, then to the least semidiameter of the orb of Mercury, or the ordinary semidiameter of Venus, add the difference between the total eccentricity of

Mercury or of Venus and the total eccentricity of the Sun. But this will not be the greatest of the greatest, as the former was.

[Margin: Least distance of the same from the ☉.] 9. Rule. The least distance of Venus and Mercury from the Sun occurs if their apogees are opposed to the Sun's apogee, and these planets are joined either in the upper position to the Sun at apogee, or in the lower position to the Sun at perigee. Therefore subtract from the semidiameter of the orb of Venus the aggregate made of the total eccentricity of the Sun and the least eccentricity of Venus; but from the least semidiameter of Mercury subtract the aggregate made of the total eccentricity of both the Sun and Mercury. And this will be the least of the least. But if their apogees coincide with the Sun's apogee, the least will be obtained by subtracting from the semidiameter of the orb of Venus the difference between the Sun's total eccentricity and Venus's least eccentricity; and from the least semidiameter of the orb of Mercury subtract the difference between the total eccentricity of Mercury and that of the Sun. But this will not be the least of the least.

De Diſtantijs Planetarum Minorum à Sole & à Terra ex Tychonis & Longomontani Hypotheſi.

On the distances of the minor planets from the Sun and from the Earth, from the hypothesis of Tycho and Longomontanus.

V. We have already reviewed the places from which we derive these distances, at sect. 2, ch. 3, no. 8, and sect. 3, ch. 4, no. 5, and in the scholia of those chapters, where we also exposed the errors of Baranzanus and others in reviewing the Tychonic distances. Now, as is our way, these must be treated more accurately. For there we did not cover all the cases, and, with Tycho (*Progymnasmata*, vol. 1, p. 476), we assumed the Sun's mean distance from the Earth in determining the greatest and least distances from the Earth, neglecting the Sun's eccentricity, which we shall not neglect now.

[Margin: Why the variation of the eccentricity is neglected here.] Granted, it may have seemed right to disregard the variation possible from the variation of this eccentricity, because Tycho (*Progymnasmata*, vol. 1, pp. 32 and 33), although he admitted it, did not determine how great it is in any given age, on account of the disagreement between the observations of al-Zarqālī and al-Battānī on the change of the solar apogee, and their agreement on the eccentricity; while Longomontanus (*Theorica*, book 1, ch. 2, in the commentary on the Sun) denies that it varies, as many others also do, as I said in book 3, ch. 26. Moreover, since the eccentricities of the planets in this hypothesis have been transformed into semidiameters of epicycles, keeping the same quantity everywhere, there is no reason to vary the distances from the Sun because of the concurrence or opposition of the apogees. We must, however, change the distances from the Earth, because of the Sun's eccentricity; for they stand one way if the apogees of these planets coincide with the Sun's apogee, and another if they are opposed

to it. Meanwhile, look at the foundations or elements of these distances in the following small table. In it we have, however, supplied the Tychonic ones for Jupiter and Mars, since Tycho left us only their mean distance from the Earth (*Progymnasmata*, vol. 1, p. 476). But since at p. 479 of the same place he nearly follows Copernicus, applying a moderate increase and dividing the whole Copernican eccentricity into 4 equal parts, three parts to the semidiameter of the greater, and

[Margin: See the table at sect. 2, ch. 2, no. 7.] the fourth to the semidiameter of the lesser epicycle in his distribution, we have, by a conjecture that is surely probable, determined the epicycles of Jupiter and Mars as well, according to Tycho's mind. Therefore, as the whole Copernican eccentricity of ♄, of 1394 semidiameters of the Earth, is to the whole Tychonic, 1200 (of which three parts are 900 and the fourth 300), so the whole Copernican eccentricity of Mars, 334, is to the whole Tychonic eccentricity of Mars, about 290; and the whole Copernican eccentricity of Jupiter, 542, to the whole Tychonic eccentricity of Jupiter, 472. Therefore, by dividing the whole eccentricity of ♃ and ♂ into 4 portions, and giving one to the lesser and the rest to the greater epicycle, the semidiameter of the lesser and of the greater epicycle comes out as large as you see in the small table.

Measures in semidiameters of the Earth

			From Tycho	From Longomontanus
Eccentricity		☉	40	46
	Total	☿	☩	74
	Half	♀	☩	21

		☉	1150	1288

Regulæ pro determinandis Diſtantijs in Hypotheſi Danica à Sole & à Terra.

Rules for determining the distances from the Sun and from the Earth in the Danish hypothesis.

[Margin: Mean distance.] VI. First rule. The mean distance of ♄ ♃ and ♂ from the Earth or from the Sun is as great as the radius or semidiameter of the

orb concentric with the Sun. But in ♀ and ☿ it is obtained by adding to the least distance half the difference between the least and the greatest.

[Margin: Greatest distance of ♄ ♃ ♂ from the ☉.] 2. Rule. The greatest distance of the three superior planets from the Sun occurs if you add to the radius of the planet's orb the semidiameter of the greater epicycle, and take away from the sum the semidiameter of the lesser epicycle.

[Margin: Least distance of the same from the ☉.] 3. Rule. The least distance of the three superior planets from the Sun is obtained if you subtract from the radius of the planet's orb the semidiameter of the greater epicycle, and add to the remainder the semidiameter of the lesser.

[Margin: Greatest distance of the same from the Earth.] 4. Rule. The greatest distance of the three superior planets from the centre of the Earth, if their apogees coincide with the Sun's apogee, would occur when a conjunction came about between those planets, placed at apogee, and the Sun, which is of course at apogee; and it is obtained if you add the Sun's greatest distance from the Earth to their greatest distance from the Sun. But if the apogees are opposed, it would occur when they, at apogee, were joined with the Sun at perigee; and it is obtained by adding the least distance of the ☉ from the Earth to their greatest distance from the ☉. But this is not the greatest of all, as the former was.

[Margin: Least distance of the same from the Earth.] 5. Rule. The least distance of the three superior planets from the centre of the Earth, when the apogees coincide, would occur if they, at perigee, were opposed to the Sun at apogee; and it is obtained if the Sun's greatest distance from the Earth is subtracted from their least distance from the Sun. But if the apogees are opposed, it would occur when they, at perigee, were opposed to the Sun at perigee; and then it would be obtained by subtracting the Sun's least distance from the Earth from their least distance from the Sun. But this is not the least of all.

[Margin: Greatest distance of ♀ ☿ from the ☉.] 6. Rule. The greatest distance of Venus and Mercury from the Sun is made by adding to the semidiameter of the planet's greatest epicycle half the eccentricity of Venus, or the total eccentricity of Mercury.

[Margin: Least from the ☉.] 7. Rule. The least distance of Venus and Mercury from the Sun is obtained by subtracting from the semidiameter of the planet's greatest epicycle the half-eccentricity of Venus or the total eccentricity of Mercury, when the Sun is at its greatest distance from the Earth; for if it is at its least, then only the least eccentricity of Mercury is to be taken away from the semidiameter of the epicycle.

[Margin: Greatest distance of the same from the Earth.] 8. Rule. The greatest distance of Venus and Mercury from the Earth, when their apogee coincides with the Sun's apogee: if the Sun is at its greatest distance from the Earth, it is made by adding the Sun's greatest distance from the Earth to their greatest distance from the Sun; but if the Sun is at its least distance from the Earth, their least eccentricity must be taken from the semidiameter of the epicycle, and the

remainder added to the Sun's least distance from the Earth. When, however, the apogees are opposed: if the Sun is at its greatest distance from the Earth, it is made by taking their least eccentricity from the semidiameter of the epicycle and adding the remainder to the Sun's greatest distance from the Earth. But if the Sun is at its least distance from the Earth, there must be added to the Sun's least distance from the Earth the semidiameter of the epicycle and, besides that, the half eccentricity of Venus, but the total eccentricity of Mercury.

[Margin: Least distance of the same from the Earth.] 9. Rule. The least distance of Venus and Mercury from the Earth, when the apogees coincide: if the Sun is at its greatest distance from the Earth, it is made by subtracting the semidiameter of the greatest epicycle from the Sun's greatest distance from the Earth; but to the remainder must be added the half eccentricity of Venus, but the total eccentricity of Mercury. But if the Sun is at its least distance from the Earth, then from the Sun's least distance from the Earth must be subtracted the sum made of the semidiameter of the epicycle and the least eccentricity of either planet. When, however, their apogees are opposed to the Sun's apogee: if the Sun is at its greatest distance from the Earth, from the Sun's greatest distance from the Earth must be subtracted the sum made of the semidiameter of the epicycle and the least eccentricity of either star. But if the Sun is at its least distance from the Earth, then there must be subtracted from the semidiameter of the epicycle the half eccentricity of Venus, but the total eccentricity of Mercury, and the remainder must be subtracted from the Sun's least distance from the Earth.

10. Rule. In all five minor planets, Mercury excepted, the difference between the greatest and the least distance in the same kind of comparison is always of the same quantity; thus, for example, in Venus it is always 931 semidiameters of the Earth.

De Diſtantijs Planetarum Minorum à Sole & à Terra ex Kepleri & Bullialdi Hypotheſi.

On the distances of the minor planets from the Sun and from the Earth, from the hypothesis of Kepler and Boulliau.

VII. We gave the distances of the planets that fit this hypothesis at sect. 2, ch. 5, no. 20, and sect. 3, ch. 5, no. 5. There, in the measures that depend on the distance of the Sun, we showed a double column in the table: one relying on the solar distances that Kepler set down in the *Commentaries on Mars* and in the *Ephemerides*, the other on the distances given in the *Epitome of Copernican Astronomy* and in the Rudolphine Tables. Since these latter are of later care, they will be chosen by us in this place; and they will be carried over to other cases possible in this hypothesis, different from those we devised there for the distances from the Earth, so that we may learn the possible extremes.

Measures in semidiameters of the Earth

Greatest distance	☉	3469	1486

In this hypothesis there is no variation of the Sun's eccentricity, and the greatest and least distances from the Sun are the same whether the aphelia coincide with the Earth's aphelion or are opposed to it. The distances from the Earth, however, vary in many ways. The foundations of the possible distances in both cases, namely the concurrence or the opposition of the aphelia, are in the table given above. Kepler's foundations, taken from the analogy of the intervals and of the bodies of the world, will be explained below in Chapter 7, from number 11.

Regulæ pro Diſtantijs à Sole & à Terra in hac Hypotheſi

Rules for the distances from the Sun and from the Earth in this hypothesis

[Margin: Distance from the ☉, greatest and least.] VIII. First Rule. The greatest distance of the five minor planets from the Sun is made up of the greater semidiameter of the ellipse and the eccentricity of the centre of the ellipse from the Sun, which is one of the foci. The least is obtained by subtracting, from the greater semidiameter of the ellipse assigned to any planet, the eccentricity of the centre of the ellipse from the Sun.

[Margin: Greatest distance of ♄ ♃ ♂ from the Earth.] 2. Rule. The greatest distance of the three planets from the centre of the Earth, if their aphelia coincide with the Earth's aphelion, is made up of their greatest distance from the Sun and the Earth's least distance from the Sun. But if the apsides are turned about, that is, if their aphelia are opposed to the Earth's aphelion, it is made up of their greatest distance and the Earth's greatest distance from the Sun. It therefore becomes known when these are joined.

[Margin: Least distance of the same from the Earth.] 3. Rule. The least distance of the three superior planets from the centre of the Earth is obtained by subtracting, from the greater diameter of the planet's ellipse, the sum made of the planet's greatest distance from the Sun and the Earth's least, if the aphelia coincide, or the Earth's greatest distance from the Sun, if they are opposed.

[Margin: Greatest distance of ♀ and ☿ from the Earth.] 4. Rule. The greatest distance of Venus and Mercury from the centre of the Earth. When their aphelion coincides with the Earth's aphelion: if the Earth is at its greatest distance from the Sun, it is obtained by adding the greater semidiameter of the ellipse to the Earth's greatest distance from the Sun, but subtracting from the sum the eccentricity of the centre of the ellipse, of Venus and of Mercury alike. But if the Earth is least distant from the Sun, it is obtained by adding to the Earth's least distance from the Sun the sum made of the semidiameter of the ellipse and the eccentricity of the centre of the ellipse. When, however, the aphelia are opposed: [Margin: In 4 cases.] if the Earth is most distant from the Sun, it is obtained by adding together the Earth's greatest distance from the Sun, the semidiameter of the ellipse and the eccentricity of the centre of the ellipse; but if the Earth is least distant from the Sun, it is obtained by adding the semidiameter of the ellipse to the Earth's least distance from the Sun, and subtracting from the sum the eccentricity of the centre of the ellipse.

[Margin: Least distance of the same from the Earth.] 5. Rule. The least distance of Venus and Mercury from the centre of the Earth. When the aphelia coincide: if the Earth is most distant from the Sun, it is obtained by subtracting from the Earth's greatest distance from the Sun the sum made of the semidiameter and the eccentricity of the centre of the ellipse. But if the Earth is least distant from the Sun, it is obtained by subtracting the semidiameter of the ellipse from the Earth's least distance from the Sun, but the eccentricity of the centre of the ellipse must be added to the remainder. When, however, the aphelia are opposed: [Margin: In 4 cases.] if the Earth is most distant from the Sun, it is obtained by subtracting the semidiameter of the ellipse from the Earth's greatest distance from the Sun, but the eccentricity of the centre of the ellipse must be added to the remainder. But if the Earth is least distant from the Sun, the sum made of the semidiameter and the eccentricity of the centre of the ellipse must be subtracted from the Earth's least distance from the Sun.

De Diſtantijs Quinque Minorum Planetarum à Terra & à Sole ex noſtra Hypotheſi.

On the distances of the five minor planets from the Earth and from the Sun according to our hypothesis.

IX. We come at last to the intervals of these planets according to our own hypothesis, derived partly in Section 2, Chapter 6, number 13, and Section 3, Chapter 6, number 7, and partly to be derived in this place, by considering both the conjunction of the apogee of these planets with the Sun's apogee and the

diametrical opposition of the apogees. Let no one be surprised if the intervals that depend on the Sun's distance from the Earth are much greater with us than with many others; for they have as much probability as the distances of the Sun from the Earth established in Book 3, Chapter 7, and the proportions of the intervals to that distance, which are to be indicated in Scholium 1. The remaining foundations for the rules and distances about to be set down may be seen in the following table, the Sun's mean distance being not the round 7300 but, more precisely, 7327.

Measures in semidiameters of the Earth

		Greatest	Least
Eccentricity	☉	253	253
	♀	253	253
	☿	730	584
	♂	2200	1900
	♃	3635	3321
	♄	8906	7884
Semidiameter of the epicycle	♀	5339	5157
	☿	3322	2811
	♂	7805	6727
	♃	7417	6738
	♄	8249	7373
Radius of the eccentric	☿ ♀ ☉	7327	
	♂	11000	
	♃	36500	
	♄	73000	

Regulæ pro Diſtantijs Planetarum à Sole & à Terra in Noſtra Hypotheſi.

Rules for the distances of the planets from the Sun and from the Earth in our hypothesis.

X. The rules for deriving the distances of the three superior planets from the Earth and from the Sun are the same as the rules for the Ptolemaic hypothesis given at number 2. For the inferior planets, which we arrange not below the Sun but around it, they are the following. In these we suppose that Venus has the same eccentricity as the Sun, and the greatest semidiameter of the epicycle at the apogee of the eccentric and the least at the perigee; [Margin: Summary of the hypothesis for the distances.] that Mercury, on the other hand, has the greatest eccentricity at the apogee of the eccentric and the least at the perigee, but in both places the least semidiameter of the epicycle; and that the semidiameter of the eccentric of each is the same as the radius of the Sun's annual orb. In the three superior planets, however, we set the greatest eccentricity and semidiameter of the epicycle at apogee, and both of them least at perigee.

[Margin: ♀ and ☿: greatest distance from the Earth.] 1. Rule for the greatest distance of Venus and Mercury from the Earth. When their apogees

coincide with the Sun's apogee: if the centres of the epicycles are at the apogee of the eccentric, add to the Sun's mean distance from the Earth the greatest semidiameter of the epicycle of ♀ and the least of ☿, and in addition the whole eccentricity for each. [Margin: In 4 cases.] But if the centres of the epicycles are at the perigee of the eccentric, add to the Sun's mean distance from the Earth the least semidiameter of the epicycle, but from the sum subtract the whole eccentricity of Venus and the least of Mercury. Likewise, when the apogees are opposed to the Sun's apogee: if the centre of the epicycle is at the apogee of the eccentric, add to the Sun's mean distance from the Earth the greatest semidiameter of the epicycle of ♀ and the least of ☿, and the whole eccentricity of the planet. But if the centre of the epicycle is at the perigee of the eccentric, add to the Sun's mean distance from the Earth the least semidiameter of the epicycle, but from the sum subtract the whole eccentricity of Venus and the least of Mercury.

[Margin: Least distance of the same from the Earth.] 2. Rule for the least distance of Venus and Mercury from the Earth. When the apogees coincide: if the centre of the epicycle is at the apogee of the eccentric, subtract from the Sun's mean distance from the Earth the greatest semidiameter of the epicycle of ♀ and the least of ☿, but to the remainder add the whole eccentricity of ♀ or ☿. But if the centre of the epicycle is at the perigee of the eccentric, [Margin: In 4 cases.] subtract from the Sun's mean distance from the Earth the least semidiameter of the epicycle, and in addition the whole eccentricity of ♀ but the least of ☿. Similarly, when the apogees are opposed: if the centre of the epicycle is at the apogee of the eccentric, subtract from the Sun's mean distance from the Earth the greatest semidiameter of the epicycle of ♀ and the least of ☿, but to the remainder add the whole eccentricity for each. But if it is at perigee, subtract from the Sun's mean distance from the Earth the least semidiameter of the epicycle, but from the remainder subtract further the whole eccentricity of Venus and the least of Mercury.

3. Rule for the greatest distance of Venus and Mercury from the

[Margin: ♀ and ☿: greatest distance from the ☉.] Sun. When the apogees coincide: if the centre of the epicycle is at the apogee of the eccentric, use the greatest semidiameter of the epicycle of Venus; but to the least semidiameter of the epicycle of Mercury add the difference between its whole eccentricity and that of the Sun. But if the centre of the epicycle is at the perigee of the eccentric, use the least semidiameter of the epicycle of Venus; [Margin: In 4 cases.] but to the least semidiameter of the epicycle of Mercury add the difference between its least eccentricity and the Sun's whole eccentricity. When, however, the apogees are opposed: if the centre of the epicycle is at the apogee of the eccentric, add to the greatest semidiameter of the epicycle of ♀ and the least of ☿ the sum made of the whole eccentricity of the planet and of the Sun. But if the centre of the epicycle is at the perigee of the eccentric, add to the least semidiameter of the epicycle the sum made of the eccentricity of the Sun and the whole eccentricity of Venus, but the least of Mercury.

[Margin: Least distance of the same from the ☉.] 4. Rule for the least distance of Venus and Mercury from the Sun. When the apogees coincide: if the centre of the epicycle is at the apogee of the eccentric, use the greatest semidiameter of the epicycle of Venus; but from the least semidiameter of the epicycle of Mercury subtract the difference between its whole eccentricity and that of the Sun. But if the centre of the epicycle is at the perigee of the eccentric, use the least semidiameter of the epicycle of Venus, but from the least semidiameter of the epicycle of Mercury subtract the difference between its least eccentricity and the Sun's whole eccentricity. When, however, the apogees are opposed: [Margin: In 4 cases.] if the centre of the epicycle is at the apogee of the eccentric, from the greatest semidiameter of the epicycle of ♀ and the least of ☿ subtract the sum made of the eccentricity of the Sun and the whole eccentricity of the planet. But if the centre of the epicycle is at the perigee of the eccentric, from the least semidiameter of the epicycle subtract the sum made of the eccentricity of the Sun and the whole eccentricity of Venus, but the least of Mercury. Which distances are the greatest of all, and so on, the following tables will show.

[Margin: Quantity of the greatest digressions from the ☉.] As for the semidiameters of the Earth contained in the greatest digression of these planets from the Sun, we shall speak of them in Chapter 12, number 4.

Monitum Pro Sequentibus Tabulis.

Notice concerning the following tables.

XI. From the authors already listed above, or from others soon to be reviewed, we have collected the following tables, or have constructed some of them from the foundations and rules already set out. In these we decided to include the greatest and least distances of these planets from the Earth and from the Sun, not as large as they actually turn out at this time, but as large as each author's hypothesis can allow, if the apogees of the minor planets either coincided under the same place of the zodiac with the Sun's apogee or, conversely, were diametrically opposed to it; so that, when all have been computed, the absolutely greatest and least distance can be chosen, if anyone wishes to use it. Besides these we decided to add the distances given by Giuseppe Biancani at the end of his *Sphaera* (but he gives only the mean ones, from Tycho, as does Andrea Argoli in the *Pandosion Sphaericum* from Chapter 52 on), by Athanasius Kircher in the *Ars Magna Lucis et Umbrae*, p. 762, by Antonín Maria Šírek in his *Radius Sidereomysticus*, Book 4, Chapter 2, member 5, and by Gassendi in the *Institutio Astronomica*, Book 3, Chapter 11, where he gives the Tychonic and Lansbergian ones, but middling ones [mediocres]. I have also added the distances of Govaert Wendelen, from his own letter written to me, and those of Posidonius, from the distance of the Sun from the Earth that he set (Book 3, Chapter 7), on the supposition, as the prosthaphaereses require, that Saturn's mean distance from the Earth is ten times the Sun's distance from the Earth, Jupiter's five times,

Mars's one and a half times, Venus's three-quarters, and Mercury's one-third, approximately.

Anyone who wants the following distances in miles or leagues should consult the foot of Table 4 of Chapter 4, or multiply them by the miles or leagues contained in the semidiameter of the Earth, according to whichever opinion he prefers to follow among those reported in Book 2, Chapter 7. [Margin: On reducing the distances to miles.]

If you want the measures set out in the preceding tables in Italian miles, see the rule to be given at the foot of the last table of Chapter 4; or, for Kepler's, consult our Athanasius Kircher in *Magnes*, p. 561.

SCHOLIA.

Scholia.

[Margin: On the size of our distances.] I. If the distance of these planets from the Earth or from the Sun that arises from our hypothesis seems excessive to anyone, let him call two foundations to mind. One is the distance of the Sun itself from the Earth, which, from what was said in Book 3, Chapter 7, is for us nearly midway between the extremes asserted by astronomers, since there has been no lack of those who extended it to about 15000 semidiameters of the Earth. The other is the proportion of the mean distance of these planets to the

distance of the Sun from the Earth. This proportion is gathered from the commensurations of their orbs with the annual orb, through the prosthaphaereses of the orb, since the motion of these planets is tied to the motion of the Sun, as all astronomy agrees. Now the distance of Venus and Mercury is smaller among the more ancient authors, because they placed those planets below the Sun; but all after Copernicus arrange them around the Sun, so that their mean distance from the Earth is about as great as the Sun's as well. The proportion of the remaining planets, derived from the distance of the Sun (on which see Book 3, Chapter 7) and from the mean distances just reported in Tables 1 and 2, stands as you see in the following small table, the fractions in Saturn and Jupiter having been reduced to the nearest round numbers. Speaking, moreover, of the distance from the Sun, that too, according to Copernicus, Kepler in the *Epitome of Copernican Astronomy*, p. 455, and many others, is about tenfold in Saturn, fivefold in Jupiter and one-and-a-half-fold in Mars, relative to the distance of the Earth from the Sun. Therefore we have done nothing incongruous if, following in the footsteps of more recent astronomy, we have made the distance of ♄ from the Earth tenfold, Jupiter's fivefold and Mars's one-and-a-half-fold of the distance of the Sun. From this there results for us a mean distance of Saturn of 73000 terrestrial semidiameters, that is, almost twice as great as Kepler's, just as Kepler's is almost twice as great as Tycho's; for if we had listened to Posidonius and Wendelen, it would be twice as great again as ours.

The proportion of the mean distance from the Earth of the superior planets to the mean distance of the Sun from the Earth, taken as 1, is as below.

[Margin: On harmonic intervals, etc.] II. The question of the archetypal and harmonic intervals of the planets would certainly seem to belong here: namely, whether they should be so limited as to keep harmonic proportions among themselves, and with the whole distance of the fixed stars or of the outermost heaven, or with the diameters of the regular bodies that can be inscribed in a sphere. But that question concerns the general constitution of the world-system, and it also takes in the intervals of the fixed stars and of the

luminaries; a fuller exposition and examination of it is therefore reserved by us for Book 9, where, among other matters, the harmonic system will be treated. Meanwhile one may consult both what we have already indicated in Book 3, Chapter 7, in the scholia, and in Book 4, Chapter 14, likewise in the scholia, and in Book 6, Chapter 7, and in this Book 7, Chapter 1, and what will be said below in Chapter 8, from number 11; and also what Kepler teaches in the *Mysterium Cosmographicum*, Chapters 14, 20 and 21, in *De Stella Nova*, Chapter 16, in the *Harmonics*, Book 5, Chapter 4, and in the *Epitome of Copernican Astronomy*, Book 4, from p. 452 to 483, and 501, and in the Rudolphine Tables, p. 71; Pierre Hérigone in Volume 5 of the *Cursus Mathematicus*, from p. 570; and Wendelen in a most learned letter written to me, if he allows me to publish it. From these I shall indicate here some selected propositions, to be examined elsewhere.

[Margin: Proportion of the intervals from the 5 regular bodies.] The first is that the intervals of the five minor planets among themselves were defined by God according to the ratio of the five regular bodies. For, as Kepler says in the preface to the *Mysterium Cosmographicum*, the Earth is the circle that measures all the others, that is, the Earth's annual orb, because it lies midway between the convexities of the three superior spheres and of the two inferior ones, which he thinks are so proportioned that the five regular bodies can be inscribed in them in this order: the cube or hexahedron, the tetrahedron, the dodecahedron, the icosahedron and the octahedron. For around the Earth's annual orb circumscribe a dodecahedron, and around this dodecahedron circumscribe an orb: it will be the concave of the sphere of Mars. Around the convex of Mars circumscribe a tetrahedron, and around this circumscribe an orb: it will be the concave of the sphere of Jupiter. Around its convex circumscribe a cube, and around the cube an orb: it will be the concave of the sphere of Saturn. Then in the concave of the annual orb inscribe an icosahedron, and in this inscribe an orb: it will be the convex of the sphere of Venus. In its concave inscribe an octahedron, and in the octahedron inscribe an orb: it will be the convex of the sphere of Mercury. To fill out the interval of Jupiter, however, the circuits of the four satellites around Jupiter contribute, just as the Moon's circuit around the Earth contributes to the size of the annual orb. From this Kepler thinks it is shown why there are six orbs in the Copernican system, namely those of the five minor planets, and a sixth of the Earth with the Moon: because, just as the four intervals of the hand require 5 fingers, so the intervals of the five regular bodies require 6 orbs. For the Sun has no heaven of its own in that system, since it rests at the centre of the world.

[Margin: Harmonic intervals and their proportion with the periodic times.] The second proposition is that the intervals of the primary planets approach the proportions of the five regular bodies in such a way that they still differ from them somewhat, on account of the harmonic proportions which GOD, as Regulator [Harmoſtam] of this music of the world, was obliged, or it was fitting for him, to keep with the periodic motions of the same planets. Accordingly, the already mentioned authors say that the distances of the planets and of the

Earth from the Sun, the centre of the world, are in the sesquialteral ratio of their periodic times. So, for example, if the periodic time of Saturn is 30 years and that of Jupiter 12, and you take the cube roots of these and multiply them by themselves, then whatever the proportion between the square numbers, such will it be between the distance of Saturn and that of Jupiter from the Sun. They say this holds even if you do not compare neighbouring planets with each other. Thus, since the time of Saturn is 30 years, whose cube root is 3 11/100, while the periodic time of the Earth's annual motion is 1, whose cube root is 1, then multiplying the numbers 3 11/100 by themselves gives 9 672/1000, and 1 multiplied by 1 gives 1. Therefore the distance of Saturn from the Sun is to the distance of the Earth from the Sun as 9 672/1000 to 1, or as 9672 to 1000; and this ratio will come out the more exactly, the more precise and accurate the times assumed. By this method it was found that, relative to the distance of the Earth from the Sun, the distance of Saturn is nearly tenfold, Jupiter's fivefold, Mars's one-and-a-half-fold, Venus's in the ratio of 3 to 4, and Mercury's one third, approximately. [Margin: Proportion of motions and distances, from Wendelen.] Or, if you want finer numbers, and reduce the periodic times of the planets to small fractions of hours, and take the distance of the Earth from the Sun as 100000, the proportion of the intervals was found by Wendelen as you see in the present small table.

♄	953153
♃	519966
♂	152366
The Earth	100000
☿	72336
♀	38710

74

The third proposition is Kepler's in the *Epitome of Copernican Astronomy*, p. 154, and that of Wendelen himself in the letter to me already mentioned. [Margin: Proportion between the motions and intervals of the satellites of Jupiter.] They observe that the distances of Jupiter's satellites from Jupiter are in the sesquialteral ratio of the periodic times in which they circle Jupiter. I gave a foretaste of this proportion in Section 1, Chapter 3, Scholium 3. On the proportion of the spheres and of the planetary bodies there will be discussion below in Chapter 8, from number 11, where certain matters relating to the intervals as well will be explained from Kepler's analogies.

CAPVT III.

Chapter 3.

[74] the signs of the last two rows stand as the leaf sets them; the text just above gives Venus about 3 to 4 and Mercury about one third of the Earth's distance.

De Planetarum Diſtantijs inter ſeſe, vel à Fixis ſtellis, Maximis ac Minimis.

On the greatest and least distances of the planets from one another, or from the fixed stars.

I. There is no less danger of error here than in the greatest and least distances from the Earth; indeed the danger is greater, unless certain rules are set out first for beginners, and on these we have built the double table that follows. So let this be

[Margin: 1. Rule, for planets and fixed stars.] First Rule. From the distance of the lowest fixed stars from the centre of the world subtract the planet's least distance from the centre of the world, and you will have the Greatest Distance of the planet from fixed stars placed on the same side. But if you subtract the planet's greatest distance from the distance of the fixed stars, you will have the Least Distance of the planet from the fixed stars. I said *lowest* because it is about these that the question is usually raised, whether Saturn's shadow reaches them, and whether the space between them and Saturn is sufficient for the ascent and descent of comets or new stars; I am not speaking of those supposed to be higher, in the depth of the Firmament.

[Margin: 2. Rule, for the greatest distance of ♄ ♃ ♂ from one another.] Second Rule. You will obtain the greatest distance of the three superior planets from one another as follows. In the hypothesis of Copernicus, Lansbergen, Kepler and Boulliau, add together the greatest distance from the Earth of the higher planet, the least distance from the Earth of the lower, and also twice the least eccentricity of the lower. In the hypothesis of Tycho and Longomontanus, on the other hand, join the greatest distances from the Earth of each planet, and take away the diameter of the Sun's annual orb and also twice the Sun's eccentricity. We are speaking here, moreover, of the greatest distance of the greatest, and of the least of the least. In the Ptolemaic hypothesis and in ours, however, join the greatest distances of the two planets from the Earth, but from the sum subtract the diameter of the epicycle of the lower planet, the greatest in ours, the ordinary one in Ptolemy's. But take care not to think that the greatest can arise from the sum of two greatest, say those of Saturn and Jupiter: they cannot each attain their own greatest from the centre of the Earth except in conjunction with the Sun, and then any two of the superior planets tend toward the same quarter and rather approach one another. One must therefore use, on one side, the greatest of the higher planet conjoined with the Sun, and on the other the distance of the lower, not indeed the absolutely greatest, but the greatest compatible with its opposition to the Sun.

[Margin: 3. Rule, for the least distance of ♄ ♃ ♂ from one another.] Third Rule. You will obtain the least distance of the three superior planets from one another as follows. To the least distance from the Earth of the higher planet add, in the hypothesis of Ptolemy and in ours, the diameter of the epicycle of that same higher planet, which for us is then at its least; in the

hypothesis of Copernicus, Lansbergen, Kepler and Boulliau, add the diameter of the annual orb; but in the hypothesis of Tycho and Longomontanus, add, besides the diameter of the annual orb, twice the Sun's eccentricity. Then from this aggregate subtract the greatest distance from the Earth of the lower planet in each hypothesis.

[Margin: 4. Rule, for the greatest distance of the superior planets from the inferior.] Fourth Rule. To the greatest distance from the Sun of any of the three superior planets add the greatest distance from the Sun of either of the two inferior planets, and the greatest distance between a superior and an inferior planet will be made up, in any hypothesis. Conversely, join the least distances from the Earth, of the superior planet on one side and of the inferior on the other, but in the hypothesis of Longomontanus add, further, to the aggregate of the already mentioned least planetary distances, twice the Sun's eccentricity, and the least distance between them will result. [Margin: For the least.] For neither the greatest nor the least distance of the inferior planet should be subtracted from the least of the superior: when the superior planets attain their least distance they are opposed to the Sun, and then Venus and Mercury are toward the opposite quarter, and so are more distant from any of the superior planets than when each of the planets attains its least distance (in such a case) from the Earth, but with the two opposed to each other.

[Margin: 5. Rule, for the greatest distance of ♀ and ☿ from one another.] Fourth Rule [recte: Fifth]. You will obtain the greatest distance between Venus and Mercury as follows. In the Ptolemaic hypothesis of al-Farghānī, and in those of Copernicus, Longomontanus and Boulliau, from the greatest distance of Venus from the Earth subtract the least distance of Mercury from the Earth; but in the hypothesis of Kepler, of Lansbergen and our own, from the greatest distance of Mercury from the Earth subtract the least of Venus. For we are speaking of the greatest possible distance, deduced from the measures of these hypotheses. [Margin: For the least.] The least distance between Venus and Mercury, on the other hand, you will obtain thus. In the Ptolemaic hypothesis of al-Farghānī, etc., subtract the greatest of Mercury from the least distance of Venus from the Earth; but in the Danish hypothesis of Longomontanus, the least of Venus from the least of Mercury; and in ours, subtract the greatest of Mercury from the greatest distance of Venus from the Earth. But in the hypothesis of Copernicus, Lansbergen, Kepler and Boulliau, add to the least distance of Venus from the Earth twice the greatest eccentricity of Venus, and subtract this aggregate from the least distance of Mercury from the Earth.

[Margin: 6. Rule, for the distance of ☾ from the others.] Sixth Rule. The greatest distance of the Moon from any planet whatever is made up of the greatest distance of the Moon on one side, the Moon however being opposed to the Sun, and the greatest distance of any planet from the Earth on the other. The least, however, is obtained by subtracting the greatest distance from the Earth of the Moon opposed to the Sun from the least distance of whichever superior planet the comparison is made with; but by subtracting the greatest of

the Moon conjoined with the Sun, if it is compared with one of the inferior planets.

[Margin: 7. Rule, for the distance of the planets from the ☉.] We have already given a Seventh Rule, for the distance from the Sun, adapted to each hypothesis, in Chapter 2.

There now follows the table of such distances, in which for the Ptolemaic ones we have used those of al-Farghānī, which Maurolico, Clavius and Barozzi generally chose. Where little crosses stand, it is a sign that the distances of the fixed stars from the Earth, or the least or greatest distances of Venus and Mercury, were not determined by the authors. Remember, moreover, that this table gives the extreme distances among those possible, if the world had lasted so long or were going to last so long; and that in looking them up, the planet that is higher is always to be sought in the former column, and in the latter the fixed stars or the lower planet which is being compared with the higher.

Table I. Greatest distance of the planets from one another, or from the fixed stars. In semidiameters of the Earth.

Vſus Tabulæ præcedentis & ſequentis.

Use of the preceding and following table.

Suppose the first thing to be looked up is the greatest distance of Venus from Jupiter. If you look for ♀ in the first column, you will seek ♃ in the second column in vain, and so the greatest distance between these planets will seem to have been omitted. But it is not so: in order not to multiply the series of numbers needlessly, it seemed best to give these distances once only, in such a way that the higher star is first to be looked up in the former column and compared with the lower star, which is to be noted in the second column. Since ♃, then, is higher than Venus, look for ♃ in the first column and ♀ in the second: for opposite Venus ♀ you will find the greatest distance between these planets, according to the Ptolemaic hypothesis as found in al-Farghānī, to be 14289 terrestrial semidiameters. According to Copernicus, however, it is 7163; according to Lansbergen, 9688; according to Tycho, not indeed none, as if Tycho had thought there was none, but not yet determined by Tycho, who was forestalled by death. In its place there follows the distance according to the view of Longomontanus, 7873 semidiameters of the Earth. For Kepler, however, it is 20881; for Boulliau, 9063; and for us, 46323. In the same way the other greatest distances in the preceding table, or least distances in the following one, will be looked up.

Table II. Least distance of the planets from one another, or from the fixed stars. In semidiameters of the Earth.

Expoſitio Tabulæ III. Sequentis.

Explanation of Table III, which follows.

However, for recognising or rejecting eclipses of the planets by means of their shadows, besides their least distances from one another, for which Table II is to be consulted, certain other distances are useful. These are not, to be sure, least absolutely, but least nevertheless in the case in which an eclipse can be feared for one planet from the shadow of another, because the shadow of the planet casting its shadow toward the other also comes out both broader and longer, owing to the caster's greatest distance from the Sun. It therefore seemed best to append a third small table. In its first column is set the planet from whose shadow a shadow is feared, and in the second the planet for which it is feared from the other's shadow, with the conditions required for the position that comes closest to such eclipses. In the remaining columns is set the least distance of those two planets under such conditions. Where a little cross stands, it is a sign either that the comparison is impossible or inept in that hypothesis, or that those distances are lacking, as in Tycho's, who did not leave us the extreme distances of Venus and Mercury.

Table III. Least distance of the planets from one another, in the cases indicated in columns 1 and 2, for distinguishing eclipses from the shadow of the planets, etc. In semidiameters of the Earth.

CAPVT IV.

Chapter 4.

De Cælorum, intra quos Planetæ vagantur, Altitudine, Craſſitie, & Ambitu; cum Milliaribus debitis Circumferentiæ toti, aut vni Gradui.

On the height, thickness and circuit of the heavens within which the planets wander, with the miles due to the whole circumference or to one degree.

I. The thickness of each heaven, that is, the space within which the planet's whole excursion with its orbs is contained, is easily found if the semidiameter of the concave surface is subtracted from the semidiameter of the convex surface: the remainder will be the thickness. But how large the semidiameter of each surface is cannot be found precisely from the greatest and least distance of the planet itself; different rules must be followed according to the difference of hypotheses. Always, however, the greatest of the greatest and the least of the least distances possible in each hypothesis are to be used.

[Margin: 1. Rule, for the Ptolemaic hypothesis and our own.] *First Rule.* In the hypothesis of Ptolemy, al-Battānī, al-Farghānī and our own, the semidiameter of the convexity of any heaven is made up of the planet's greatest distance from the centre of the Earth and the planet's true semidiameter. But in our hypothesis, for Jupiter, there must be added the semidiameter of the epicycle which the outermost satellite describes around Jupiter, increased by one unit, so that the body of the satellite itself may amply have its place in the heaven of Jupiter; of this semidiameter we shall speak below, in Chapter 12. The semidiameter of the concavity of the heaven, on the other hand, is found by subtracting the true semidiameter of the planet's body from its least distance from the Earth; and besides, in our hypothesis, for Jupiter, there must further be subtracted the semidiameter of the greatest epicycle, that of the outermost of the satellites, and one unit more. And where fractions of numbers occur here and in what follows, a whole unit can be put in their place; for it is not necessary that the planet's heaven be bounded exactly by the planet itself, but some little space above and below can be admitted. The true semidiameter, moreover, we shall take from Table 2 of Chapter 9 for the 5 planets, for we gave those of the ☉ and ☾ in Books 3 and 4.

[Margin: 2. Rule, for the Danish hypothesis.] *Second Rule.* In the hypothesis of Tycho and Longomontanus, the semidiameter of the convexity of the heaven of the three superior planets and of the Moon is made up of the planet's greatest distance from the centre of the Earth and the diameter of the lesser epicycle. The semidiameter of the concavity is found by taking the diameter of the lesser epicycle from the planet's least distance from the Earth. When these are observed, sufficient room is left for the epicycles of Jupiter's satellites, and indeed for the satellites themselves. But the semidiameter of the convexity of the heaven of the Sun, of Venus and of Mercury is made up of their greatest distance from the Earth and the true semidiameter of the planet's body; that semidiameter, subtracted from the least distance, will leave the semidiameter of the concavity.

[Margin: 3. Rule, for the hypothesis of the moving Earth.] *Third Rule.* In the hypothesis of the Earth going annually around the Sun at the centre of the world, with the Moon as its attendant, and using simple orbs without epicycles, of which kind is one of the three forms of Copernicus, and those of Lansbergen, Kepler and Boulliau, the distances from the centre of the Sun are to be used, and the heaven of the Moon is not distinguished from the heaven of the Earth; rather, the Moon's distance is to be reckoned with the Sun's distance from the Earth, since the Moon is a companion, as it were, of the Earth, just as the Medicean Stars are of Jupiter. Therefore the semidiameter of the convexity of the Earth-Moon heaven [cæli Terrilunaris] is made up of the Earth's greatest distance from the centre of the Sun, the greatest distance from the centre of the Earth of the Moon opposed to the Sun, and the true semidiameter of the Moon's body. The semidiameter of the concavity of this heaven, on the other hand, is found by subtracting from the Earth's least distance from the centre of the Sun the sum of the greatest distance from the Earth of the Moon joined to the Sun and the true semidiameter of the Moon's body. But for the remaining planetary heavens, add to the planet's greatest distance from the centre of the Sun the planet's true semidiameter, and besides, for Jupiter, the semidiameter of the greatest epicycle of the satellites, increased by one unit for the body of the satellite itself, and you will have the semidiameter of the convexity of the heaven. Subtract, on the other hand, from the planet's least distance from the centre of the Sun the true semidiameter of the planet's body, and for Jupiter further the semidiameter of the greatest epicycle of the satellites increased by one unit, and you will have the semidiameter of the concavity of the heaven. And yet these authors recognise a single planetary heaven, liquid and permeable, as do the Tychonians too. Indeed, among them neither the Sun nor Mercury nor Venus is in the heaven above, but below.

[Margin: Authors of the following tables.] II. With these things laid down, here, reader, are the tables which were compiled or handed down to us by Fernel in Book 1 of the *Cosmotheoria*, and following him Egnazio Danti, from Table 22 of the *Mathematical Tables*; Maurolico at the end of the *Cosmographia*; Clavius on Chapter 1 of the *Sphere*, p. 214 in my copy; and Barozzi in Book 1 of

the *Cosmographia*, p. 49. Although these follow al-Farghānī in the number of terrestrial semidiameters, nevertheless in the number of miles corresponding to one semidiameter of the Earth, Maurolico follows al-Farghānī, while Clavius and Barozzi follow Ptolemy, as does Baranzano in Part 1 of the *Uranoscopia*, although in the number of semidiameters he reports the opinion of Giuntini and Mauro Fiorentino derived from al-Battānī, and then that of Tycho. The remaining tables I constructed myself, and Table 4 in particular with the diameter of the convexity made to the circumference as 100 to 314, according to the teaching of Book 1, Chapter 4. Where the small spaces are empty, it is a sign that the measures from which the height of these heavens could be gathered were not handed down by the authors.

One semidiameter of the Earth contains, in Italian miles: according to Ptolemy, Clavius, Barozzi and Giuntini, 3580; according to al-Battānī, 4868; according to al-Farghānī and Maurolico, 3894; according to Copernicus, Tycho, Longomontanus and Kepler, 3440; according to Lansbergen, perhaps following Snel, 3919; according to Fernel, 3900; according to Boulliau, perhaps following Gassendi, 4177; and according to ourselves, 4139, in keeping with what was said in Book 2, Chapter 7. Choose, therefore, whichever opinion you like, and multiply the semidiameters of the Earth set out in the preceding small tables, and you will have the same measures in Italian miles.

SCHOLIA.

Scholia.

In Quibus præcipuè attinguntur digniſſima ſcitu pro Syſtemate Mundi.

In which the matters most worth knowing for the system of the world are chiefly touched on.

I. If anyone wants the semidiameters of the epicycles, or of the deferents, or of the equants, or even the eccentricities, in semidiameters of the Earth, he has them partly in Sections 2 and 3, in the tables at the end of each chapter, and partly in Chapter 2 of this section. If anyone wants the same reduced to miles, we have indeed judged that superfluous; he may nevertheless consult Fernel in Book 1 of the *Cosmotheoria*, and Egnazio Danti, who follows him, in his *Mathematical Tables* from Table 22. From these, however, it is our pleasure, in order to illustrate the Ptolemaic hypothesis that they follow, to add the Fernelian miles due to the semidiameter both of the deferent and of the epicycle of the planets.

Italian miles corresponding to the semidiameter of the Ptolemaic deferent and epicycle, according to Fernel and Egnazio Danti.

	Semidiameter of the deferent	Semidiameter of the epicycle
☾	190515	20150
☿	456430	171145
♀	2687071	1933199
☉	4903756	has no epicycle
♂	22003197	14485437
♃	51009409	9788504
♄	75665295	8197074

[Margin: On the height and circuit of the elementary sphere and of the eighth.] II. There will also be someone who might more reasonably want, at this place too, for conceiving the extreme measures of the world-system, the diameter and circuit of the elementary sphere, and the semidiameter of the convexity of the firmament, and the circuit of each. But he has the semidiameter of the convexity of the elementary sphere in Tables 1 and 2 of the preceding chapter, for it is the same as the semidiameter of the concavity of the heaven of the Moon. So if that is doubled, the diameter will be had; and if one makes, as 7 to 22, or rather as 100 to 314, so the already mentioned diameter to another quantity, the circumference or circuit of the elementary sphere will be known. For the sphere of the firmament, or the eighth, which is that of the fixed stars, either the table we gave in Book 6, Chapter 7, no. 14 must be consulted, or the greatest distance of the fixed stars must be doubled to obtain the diameter, and one must make, as 100 to 314, so that diameter to the circumference of the fixed stars.

[Margin: The imperfection of the Ptolemaic heavens.] III. In the Ptolemaic intervals of the heavens, this above all is to be noted: there is a danger that a superior planet at perigee may touch or even strike an inferior one at apogee,

especially Mercury against the Moon; further, that the heaven of Jupiter lacks a space able to hold the satellites of Jupiter; and that Venus and Mercury are always below the Sun, while Mars is always farther from the Earth than the Sun. [Margin: Mercury, Venus and Mars pass through the heaven of the Sun.] These things are contrary to the evident phenomena of recent astronomy. But some natural philosophers or theologians, who have never put hand or eye to celestial observations, fearing from this for the solidity of the heavens or for the older system, peddle the claim that the discoveries and observations of recent astronomers are uncertain. Let them therefore go back over what I said in Section 2, Chapter 3, Scholium 4, and what is to be said in Chapter 7, no. 3, on the parallaxes of Mars. [Margin: Arguments for which ♂ in ☍ with ☉ becomes nearer the Earth than the Sun.] For the prosthaphaereses, or equations of the motions, that are necessary if the mean motion of Mars is to be brought to the apparent motion observed in the acronychal oppositions with the Sun, and to agree with it, establish that a parallax somewhat greater than the parallax of the Sun is required. Those observations, carefully taken with Tycho's instruments, cannot be brought to rule unless the radius of the eccentric of Mars, that is, its mean distance from the Sun, is one and a half times [sesquipla] the radius of the annual orb, that is, the mean distance of the Sun from the Earth, and unless the radius of the epicycle of Mars is equal to, or very slightly less than, the radius of the annual orb. From this it follows by geometric necessity that Mars in opposition with the Sun, when it is found at the perigee of the epicycle, especially if it is then also at the perigee of the eccentric, becomes much nearer to the Earth than the Sun itself at perigee. And this very thing is confirmed by the unusual increase of the apparent diameter in that position, on which see what is to be said in Chapter 10, Scholium 1. Thus Kepler, a most diligent examiner of Tycho's observations of acronychal Mars, was at last compelled to acknowledge that the parallax of Mars was then somewhat greater than the parallax of the Sun. [Margin: Testimonies of astronomers for the nearness of Mars.] So long, then, as the opposite is not established from other, more certain observations, we must stand in this with Tycho and Kepler, and indeed with Copernicus, from whose intervals the same thing follows, and with Lansbergen and Boulliau and Wendelen and Galileo, that is, with the most illustrious lights of astronomy. I add also Giovanni Antonio Magini. For although in a letter to Tycho dated 1590 September 13 [Idibus Septembris], which is found towards the end of Tycho's *Mechanica Astronomica*, he had said: "I cannot but greatly approve the system of the universe you have devised, although I should wish that the orb of the Sun and that of Mars did not intersect at all", he nevertheless at once added: "But if, as I have learned from that student, you have observed that acronychal Mars comes nearer to the Earth than the Sun does, an intersection of this kind must certainly be admitted." To this doubt and to the whole letter Tycho replied in a most learned letter on 1590 December 1 [Calendis Decembribus], which I have in Magini's *Tables of Directions of the Primum Mobile*, p. 80, affirming among other things the following: "That the

orb of Mars does not wholly encircle the Sun's, but crosses it in two places, affects you somewhat, and perhaps others also, and keeps you in two minds; with me no scruple at all remains on this. [Margin: Fragments of letters of Magini and Tycho on the approach of Mars to the Earth.] For what has been believed until now, with Aristotle's authority thus persuading in vain, that the heaven consists of an impenetrable and adamantine material and is packed with real and solid orbs that turn the stars fixed in them, has no foundation and is utterly foreign to the truth of the matter, as is sufficiently clear from the comets themselves at least, if not from elsewhere too." And shortly after: "Indeed, the point of which our often-mentioned Gellius [Gellius Sascerides] reminded you, that Mars in its acronychal position is brought nearer to the Earth than the Sun itself, has been continually investigated by us with close inquiry and found to be so, especially about the end of 1582, when, high in ♋, with its north latitude too raising it further, it was in opposition to the Sun. For I discovered at that time, from many accurate observations made in various positions and carefully compared with one another, that it admitted a parallax somewhat greater than the Sun's, which could by no means happen if its whole revolution were completed in orbs standing above the sphere of the Sun, as the Ptolemaic arrangement holds. I also often attended to its retrograde passages when it was acronychal, and after an interval of some days found them to become somewhat swifter than the Ptolemaic reckoning allows; the Copernican calculation agrees better here, especially if the application is made of the truer apogee and of the opposition with the Sun's mean motion. And from this it was plain, not obscurely and with sufficient certainty, that Mars, when passing through the part of the heaven turned away from the Sun, is brought nearer to the Earth than the Sun itself." In these things, and in Kepler's commentaries on the motion of Mars, Magini so far acquiesced in the *Supplement to the Ephemerides* that on these foundations he composed new tables for finding the place of Mars. Nor is it an obstacle that Kepler examined the opposition of Mars with reference to the true rather than the mean place of the Sun: for through these too he found a parallax of Mars that was indeed smaller than Tycho's, but still greater than the Sun's.

[Margin: Authors opposed to Tycho on this.] IV. This being so, I could indeed wish that certain members of our Society, too much attached to the solidity of the heavens, had not taken a stand against this Tychonic doctrine with arguments that are truly weak. Among them Charles Malapert, in his short work on the *Austrian Stars*, said that Tycho seemed to have done good work, if he had not made his violent Mars, breaking through the orbit of the Sun against all right and law. So too Adam Tanner, in the *Dissertation on the Heavens*, q. 7, paragraph 6, and, subscribing to him, Bartholomæus Amicus [Bartolomeo Amico], Treatise 5, *De caelo*, q. 5, art. 5. Their reasons reduce to this single one: that Tycho at times erred, either in observing or in the conclusions to be drawn from observation, or was not so exact, as he himself admits somewhere. But this is to abuse his admission. For if he is to be abandoned on that account even

when he affirms, as happens in our case, that he worked most diligently and most subtly, neither he nor any of the astronomers would have to be believed in anything; which not even Tanner would dare to assert. Tanner nevertheless indicates that, by multiplying epicycles in a single heaven common to the Sun, Mercury, Venus and Mars, these new phenomena can be defended with the solidity of the heavens intact; of this we shall have to speak in Book 9. Further, the fact that Rothmann long disagreed with Tycho, and wrote in a letter to Tycho, which stands among Tycho's letters on p. 129, that the Tychonic system introduces confusion into the spheres of the planets, and that one planet enters the heaven of another, is not of such weight that it can prevail with us against the already mentioned observations. Lastly, Mercury and Venus must necessarily pass through various places of the heaven of the Sun, through which the Sun itself at times travels. If, therefore, it is not absurd for Mercury and Venus to intersect parts of the Sun's heaven, it ought not to seem absurd either that Mars in its body should pass through a place through which the Sun at times passes, and be, as it were, a satellite of the Sun; and so that all these three planets, Mars, Venus and Mercury, belong with the Sun to a single heaven.

[Margin: Our new system of the world.] V. Hence, then, there arose for me the occasion of confirming my old opinion on the new semi-Tychonic system, which I indicated with its own scheme in Book 3, Chapter 6, no. 5, and shall explain more fully in Book 9. For in the Ptolemaic system there are those imperfections and absurdities that I indicated at the beginning of Scholium 3. In the Tychonic system, that confusion of the heavens seems to offend many. In the Copernican, the Sun has no heaven but rests at the centre of the world, and with respect to it the Earth, with the Moon as companion, is not down but up in the heaven, having below and beneath itself the heaven of Venus and Mercury, and the Sun; and above itself Saturn, Jupiter, and Mars, which in its acronychal shinings is nearer to it than the Sun: a system that we cannot uphold, for many reasons. So, in order that all things may be reconciled, and that we may lay down a system of the world complete in every respect and without any absurdity, we say that seven huge and major bodies of it were divinely founded. The first is the Earth at the centre with the elementary sphere, and the Moon, most closely joined to it by kinship of nature and, as it were, the immediate vehicle of the influences that it receives from the superior bodies and pours back into the elementary region. The second is the heaven assigned to the Sun and its companions, namely Mercury, Venus and Mars; and Mars, as the outermost of the Sun's satellites, shares in the properties of Venus and Mercury on one side and of Saturn and Jupiter on the other, and goes round the Sun in such a way as to embrace the Earth too within its circuit. The third is the heaven allotted to Jupiter and its satellites. The fourth is the heaven serving Saturn and its circumambulators. The fifth is the heaven set apart for the new stars and for very many comets going up and down, as intermediate between the wandering and the unwandering stars. The sixth is the huge sphere of the fixed stars. The seventh, finally, is the Empyrean, the seat of the blessed

minds. Hence it has come about that no satellites have been assigned to Mars, or Venus, or Mercury, since these are not primary lights of the world, nor were they to exercise their own monarchy in a heaven of their own; whereas the Sun, as by far the greatest of all the planets and the source of planetary light, was given larger satellites of wider circuit; and that the heaven of Saturn and of Jupiter is to be ordered not around the Sun, as Tycho does, but around the Earth, as you see in our scheme. Granted that all the planets depend both on the Sun, as the efficient cause of their light and the ideal cause of one of their two motions, and on the Earth as their final cause, the orbs of all the planets had to be eccentric to both. But more of this, God willing, in Book 9.

[Margin: A correction to be applied to what was said in Book 3, Chapter 6, no. 5.] VI. I said in Book 3, Chapter 6, no. 5, that if we saw Jupiter from as great a distance as that from which we see the Sun, Jupiter would appear to us a little smaller than the Sun now appears. For at that time, when I was teaching philosophy at Parma, I followed the Tychonic distances with Biancani; so that if Jupiter were seen from 1150 terrestrial semidiameters, which is the Tychonic mean distance of the Sun, and has 4 semidiameters of the Earth in its own semidiameter, as Kepler holds, Jupiter would appear to us under an angle of about 26′, while the Sun appears under an angle of about 30′. Afterwards, however, with the distances and the true semidiameters of the planets corrected, one will have to speak differently, in keeping with what is to be said in Chapter 13, Table 5.

CAPVT V.

Chapter 5.

De Tempore, quo Mobile vniformi aut difformi motu deſcenderet ex ſupremo cuiuſque Planetæ Cælo, aut ex Fixis.

On the time in which a moving body, in uniform or difform motion, would descend from the highest heaven of each planet, or from the fixed stars.

I. I have elsewhere read in treatises on the heaven, and have heard from some people, that in order to explain the almost immeasurable height of the heavens they usually employ the time in which some moving body, travelling through the heaven, would traverse the whole height of the heaven, if nothing obstructed its descent and it were preserved in its integrity from the beginning to the end of the motion. Some, indeed, apply uniform motion to this computation, others uniformly difform motion, and in either case they require a great number of years. A specimen of this in uniform motion comes from Simon Maiolus [Simone Maioli] in the *Dies Caniculares*, Colloquy 1, p. 63 in my copy, where he imagines a man riding at top speed and covering 60 Italian miles every day. On this assumption he assigns to each heaven the years and days required to traverse its height down to the Earth, as can be seen in the following small table, which agrees with the Ptolemaic hypothesis.

If a uniform moving body covers 60 Italian miles daily, it will reach the Earth from the top of the heaven in years and days:

	Years	Days		Years	Days
☾	5	2	♂	184	5
☿	10	0	♃	1291	2
♀	26	0	♄	2065	11
☉	160	9	✶	2754	6

II. But someone might want a specimen of this height for some much swifter moving body, for instance couriers riding the fastest horses, or ships driven by the strongest wind, or birds, or even lightning, and so the question would become endless. Yet so that we may not seem to have done nothing here for the curious, let us imagine some moving body covering 1000 Italian miles every day, which is about as many as there are in the long stretch of Italy from the Alps to the far end of Sicily, and let us use the height of the heavens from our own hypothesis. On these assumptions, here is a second small table.

If a uniform moving body covers 1000 Italian miles daily, it will reach the Earth from the top of the heaven in years and days:

	Years	Days		Years	Days
☾	0	265	♂	238	10
☉	87	231	♃	539	130
☿	128	141	♄	1050	0
♀	149	18	✶	23819	70

De Tempore, quo Graue aliquod deſcenderet à maxima Lunæ, Solis, Saturni, ac Fixarum altitudine ad Terram.

On the time in which some heavy body would descend from the greatest height of the Moon, the Sun, Saturn and the fixed stars to the Earth.

II. In this controversy too, extreme opinions, but born of inexperience, are read or heard again and again. Some, to exalt the height of the heavens, boast that a millstone would not descend from the eighth sphere all the way to the Earth even after many thousands of years. Others, by contrast, could not bear to wait without anxiety even for the space of a single hour for such a stone, let fall perpendicularly from there onto their own heads, without dreading the fate of Aeschylus; for they report that the bald head of Aeschylus looked to an eagle like a rock, onto which it dropped a tortoise, to break it and devour it. [Margin: Galileo's opinion on the descent of heavy bodies from the Moon to the Earth.] Nearer to the truth came both that author who, in Galileo's Dialogue 2 *De Mundi systemate*, said that a cannonball would not reach the Earth from the Moon except in 6^h, and Galileo himself, who says that an iron ball of 100 pounds would fall from the Moon to the Earth within 4^h. Read again

what I taught more fully on this matter in the whole of Book 2, Chapter 21. From it I assume, first, from the most certain experiments of ours and of Father Francesco Maria Grimaldi cited there, that the spaces which a heavy moving body traverses in natural descent are to one another as the squares of the times, which Galileo above and Giovanni Battista Baliani, in his short work on the natural motion of heavy bodies, also asserted. Second, from many experiments of ours reported there, a ball of chalk of 8 ounces, let alone one of iron of one pound (for we used very many chalk balls of equal weight, so that by often repeated drops from many towers the proportion of the increase of velocity, and the time required to traverse a determinate space, might be more evident), I assume, I say, that a ball of this kind, in 2^s of time, measured with a most exact pendulum applied for the purpose, traversed 60 Roman feet, and in 4^s, 240 feet. If, therefore, one makes, as the square of the time of 4^s, which is 16, to the square of a given greater time, so the space of 240 feet to another space, one will have the space that a ball of this kind can traverse in the given time, if it were not worn away, or dispersed by the heat it had taken on; but if it descended naturally, under the impulse of its own weight, through a medium of equal density and fluidity such as the air around the Earth. In the space of one hour, then, it would traverse 38880000 Roman paces of 5 feet each, that is, 7 39/50 terrestrial semidiameters, and in the space of 2^h, 31 terrestrial semidiameters. If therefore one makes, as the space of 31 terrestrial semidiameters to another given space, say to the distance of the Moon, the Sun, Saturn or the fixed stars, so the square number of 2^h, which is 4, to another number, one will have a square number whose square root will be the time in which a chalk ball of 8 ounces, and much more an iron ball of one pound, would pass through the given distance in its descent. Take, for example, the Sun's greatest distance as 7580 terrestrial semidiameters, as I judge it to be. If one makes, as 31 to 7580, so 4 to another number, the number 978 2/31 will result, whose nearest square root, choosing the nearer round number, is 31. So in 31^h, that is, in $1^d\ 7^h$, that ball will pass through the interval of 7580 or 7600 terrestrial semidiameters.

By this method, then, as a courtesy to our readers, I have decided to set out in the following table the time in which an iron ball of this kind would most certainly traverse the intervals of the Moon, the Sun, Saturn and the fixed stars. I have, however, taken round numbers for the intervals and added the authors who assert that interval or one very close to it, so that in a problem of such moment we may not bind our readers to our own opinion on these intervals. Since, however, the substance of the ether and of the most liquid heaven is much thinner than the thick air around the Earth, there is no doubt that that iron ball, unless it melted and were dispersed by fire caught from the friction, would fall to the Earth much faster still. Further, in reducing semidiameters of the Earth to German miles, each of which contains four Italian miles, we shall use the round number 1000, which is very nearly how many are contained in one semidiameter of the Earth. For there is no need to proceed more scrupulously in this place: to estimate the time already mentioned it is enough to have noted

the intervals close to the truth, and likewise the days and hours, with no hunting after the minutest fractions.

The approximately true time for an iron ball of one pound to descend by natural descent to the Earth from the Moon, or the Sun, or Saturn, or the sphere of the fixed stars.

Distance of the star	Authors or foundations or calculations of the distances	Distance of the stars, in the nearer round numbers of the distance from the Earth asserted by the authors listed below: semidiameters of the Earth	The same: German miles	Time of descent: days and hours
☾ Of the Moon	Most astronomers	64	64000	0^{d} 2 7/9^{h}

	Kepler himself	37000	37000000	2^{d} 21^{h}
	We	90000	90000000	4^{d} 12^{h}
✶ Of the fixed stars	Tycho	14000	14000000	1^{d} 18½^{h}
	al-Battānī	19000	19000000	2^{d} 1½^{h}
	Francesco Maurolico	20000	20000000	2^{d} 2⅘^{h}

Distance of the star	Authors or foundations or calculations of the distances	Distance of the stars, in the nearer round numbers of the distance from the Earth asserted by the authors listed below: semidiameters of the Earth	The same: German miles	Time of descent: days and hours
	al-Farghānī, Magini	40000	40000000	3d 0h
	Jean Fernel, Clavius	45000	45000000	3d 4h
	We, for the present	100000	100000000	4d 18h
	or	125000	125000000	5d 8h
✶ Of the fixed stars in the Copernican hypothesis, from calculation	Of Tycho and Longomontanus	7900000	790000000	22d 1h
	Of Galileo	12000000	1200000000	31d 20h
	Of Scheiner	13000000	1300000000	39d 23h
	Of Kepler	34000000	3400000000	87d 6h
	Of Antonín Maria Šírek	42000000	4200000000	97d 0h
	Our own	47000000	4700000000	122d 18h
	Of Martinus Hortensius	68000000	6800000000	177d 23h
	Of Lansbergen	14000000000	1400000000000	17666d 16h

Note that the time recorded here is not entirely required for the descent of an iron ball of one pound. For it would suffice for a chalk ball of 8 ounces, and so much more for an iron ball of 8 ounces; and therefore much more still it suffices for an iron ball of one pound, which we chose for good measure.

CAPVT VI.

Chapter 6.

De Velocitate Quinque minorum Planetarum.

On the speed of the five minor planets.

I. We have, if I am not mistaken, set out well enough the speed of the Sun's motion in Book 3, Chapter 12, that of the Moon in Book 4, Chapter 18, and finally that of the fixed stars in Book 6, Chapter 7, number 18. It now remains to examine the speed of the five minor planets. I do not mean their speed in degrees and minutes, which each of them runs through daily in the zodiac by its own proper motion; of this enough has been said in Section 5, Chapter 1, and it is not an affection following from height or distance from the Earth. I mean their speed as regards the part of a determinate space, say the leagues or miles that a planet traverses in a given time, or as regards the time that would be required for some moving body of known speed to cover as much space as any of these planets covers in so much time. Very few treat of this speed;

yet it is set before us by Fernel in Book 1 of the *Cosmotheoria*, by Egnazio Danti, following him, from Mathematical Table 22, by Kepler in the book *De Stella Nova*, Chapter 16, and by Pierre Hérigone in volume 5 of the *Cursus Mathematicus*, pp. 581 and 583. These authors, however, consider the speed of these planets only in their proper motion from west towards east, although the speed of the diurnal motion, by which they complete the whole circumference of their heaven in 24^h, is far greater. But Kepler and Hérigone abstained from this speed, because in their hypothesis there is no motion of the primum mobile in these planets; rather, its appearance arises from the libration and rotation of the Earth about its own centre and axis. Lansbergen, for his part, grants the fixed stars a proper motion but denies them the common motion of the primum mobile.

Further, the speed of either motion depends on the arc of a great circle that the planets describe as they move, either with the topmost point of their body or with its centre. The determinate size of this arc depends on the varying circuit, that is, on the varying size of the circumference, which takes its variety from the differing distance of the planet at apogee. On the size of the whole circuit we have already set out Table 4 above, in Chapter 3. It serves for the highest point of the planet's body, or, in the hypothesis of Tycho and Longomontanus, for the apogee of the smaller epicycle, where we can imagine the planet to be without any great difference as regards the business at hand, just as, in the case of Jupiter, we can assign to Jupiter the path of its outermost satellite as regards the motion of the primum mobile. On these suppositions we shall construct a table for the diurnal motion of the primum mobile in the hypothesis of a resting Earth. As a more common and more convenient measure we shall use semidiameters of the Earth, which the planets or the highest points of the heavens traverse in one hour, or in one minute or second of time, rather than miles, paces or feet, which vary too much among different authors or peoples. If anyone nevertheless wants Italian miles, let him use the rule given at the end of the last table of Chapter 4. For the speed of the planets' proper motion towards the east, we shall give a few things in the following Scholia.

The speed of the minor planets in the motion of the primum mobile, expressed in semidiameters of the Earth, those which their highest points, at both apogees, cover in one hour, or in one minute, or in one second of time.

From the data of the authors	Parts of time	☿ (semid. of the Earth)	♀ (semid. of the Earth)	♂ (semid. of the Earth)	♃ with its companions (semid. of the Earth)	♄ with its companions (semid. of the Earth)

	1^m	0 44/60	4 53/60	38 1/2	62 2/3	98 3/5
	1^s	0	0 5/60	0 38/60	1 3/60	1 39/60
Of al-Farghānī, for Barozzi	1^h	43 17/24	293 1/12	2322 1/2	3769 7/24	5290 5/6
	1^m	0 44/60	4 53/60	38 2/3	62 49/60	88 1/6
	1^s	0	0 5/60	0 39/60	1 3/60	1 28/60
Of Longomontanus	1^h	494 1/3	598 5/12	902 3/4	2207 1/6	3863
	1^m	6 1/4	9 58/60	15	36 47/60	64 23/60
	1^s	0 1/10	0 1/6	0 1/4	0 37/60	1 4/60
For us	1^h	2839 7/8	3381 1/4	5496 5/6	12477 7/12	23595 5/24
	1^m	47 1/3	56 1/3	91 3/5	207 57/60	393 1/4
	1^s	0 47/60	0 56/60	1 32/60	3 1/2	6 33/60

For the speed of the Sun see Book 3, Chapter 12; for that of the Moon, Book 4, Chapter 18; for that of the fixed stars, Book 6, Chapter 7, number 18.

SCHOLIA.

Scholia.

I. The speed set out in the tables above is that of the motion of the planet itself when placed at the apogee of its eccentric and, at the same time [?], of its epicycle, or of a circle or ellipse equivalent to them. But Fernel, in Book 1 of the *Cosmotheoria*, and Egnazio Danti, from Mathematical Table 22, have set it out for us both as regards the motion of the centre of the epicycle towards the east and as regards the motion of the planet in the epicycle, taken separately, as can be seen in the following small table.

[Margin: The speed of the motion of the centre of the epicycle, and of the planet in the epicycle.]

The Ptolemaic speed of motion of the 6 minor planets, from Jean Fernel and Egnazio Danti, in 1 hour.

Motion	Of the centre of the epicycle: Italian miles	Of the planet in the epicycle: Italian miles
♄	1826 and 910 paces	5678 and 124 paces
♃	3084 and 704	6425 and 747
♂	8388 and 283	4863 and 860
♀	1926 and 772	867 and 75
☿	327 and 386	9283 and 816
☾	1834 and 609	191 and 525

[Margin: The speed of the planets' proper motion, from Hérigone.]

II. Pierre Hérigone, in volume 5 of the *Cursus Mathematicus*, p. 582, investigates the speed of the planets' proper motion by this method. First he supposes that one degree of a great circle of the Earth contains 60 Italian miles, and the whole circumference 21600 miles. The 24th part of these, which belongs to one hour, is 900, and this divided by 60 gives 15 miles, which a point of the Earth placed on the equator traverses in one minute of time, while the Earth, as he himself posits, turns about its own centre daily.

[Margin: The speed of the Earth's motion according to Hérigone.]

Since, however, the ratio of the Earth's semidiameter to the mean distance of the Earth's centre from the Sun is, for him, as 1 to 1142, he says that the motion of the Earth about its own centre is to the motion of the Earth's centre about the Sun as 365 1/4 to 1142, or as 15 to 47; and that therefore the motion by which the centre of the Earth advances eastward in one minute of time is 47 Italian miles. From this it follows that the motion, in a minute of time, of the Earth's surface about the Earth's centre is exceeded by the motion of the centre; and that the part of the surface illuminated by the noon Sun covers 32 Italian miles, 15 being subtracted from 47 because of the motion of rotation in the opposite direction, while the part opposite to it covers 62 Italian miles, 47 and 15 being added because that motion seconds the other. From this difference of motions Galileo judged that the flux and reflux of the sea arises, like water shaken to and fro in a vessel.

Secondly he says that, because the Earth's semidiameter is to the mean distance of the Moon as 1 to 56, and the Moon completes its period around the Earth in about 28 days, the ratio of the motion of the Earth about its own centre to the Moon's motion is therefore as 28 to 56, that is, as 1 to 2, or as 15 to 30; and so the Moon advances in the order of the signs around the Earth 30 Italian miles in one minute of an hour, and 1800 in one hour, as regards the motion of the centre of the epicycle. Hence, because this motion is exceeded by the motion of the Earth's centre, the Moon too, with respect to one looking from the Sun, proceeds according to the succession of the signs. But at full Moons, he says, it covers 77 Italian miles in one minute of time, and at new Moons only 17. These agree with Kepler, according to what we said in Book 3, Chapter 12, in the Scholium on the speed of the Earth, and in Book 4, Chapter 18, in the Scholia on the speed of the Moon. I have decided to repeat them here, since by the same method, from the intervals of the planets and their periodic

motions around the Sun, he gathers the Italian miles that each planet traverses in its orb around the Sun in the mean motion of one minute of time, as is clear from the following list. In it the first column of numbers contains the ratio of the paths covered in the same time, so that if the Earth covers 60 spaces in one hour, Saturn covers 19 200/10000 such spaces, Jupiter 25 9825/1000 [recte: 9825/10000, as in the table that follows], and so on; the second contains the Italian miles covered in one minute of time.

The speed of the planets' proper motion according to Pierre Hérigone.

	Ratio of the motions	Italian miles in one minute of time: min.	Med.	Max.
♄	19 200/10000		15	
♃	25 9825/10000		20	
♂	45 7050/10000		36	
The Earth	60 0	32	47	62
♀	65 1600/10000		51	
☿	93 1344/10000		72	
☾	38 2978/10000	17 ♂	30	☍ 77

III. But Kepler, in the book *De Stella Nova*, Chapter 16, first gives the speed of the hourly proper motion of the planets in German miles, but according to the intervals and periodic motions of Copernicus; then he gives the speed of the motion of the Earth around the Sun and of the Moon around the Earth. Although I indicated this in Book 4, Chapter 18, it is worth while here to give it in a single view with the speed of the other planets, in the following small table, with our addition of the motion they complete in one minute of an hour, in both German and Italian miles.

[Margin: The speed of the planets' proper motion according to Kepler.]

The speed of the proper motion of the planets around the Sun, or of the Moon around the Earth, in the Copernican hypothesis, from Kepler.

	1 hour: German miles	1 hour: Italian miles	1 minute: German miles	1 minute: Italian miles
♄	300	1200	5	20
♃	400	1600	6 2/3	27
♂	600	2400	10	40
The Earth	740	2960	12 1/3	49
♀	800	3200	13 1/3	53

CAPVT VII.

Chapter 7.

De Parallaxi Quinque Minorum Planetarum.

On the parallax of the five minor planets.

I. The skill of the astronomers could not investigate the heights of the planets by any more certain method than by means of the lunar parallaxes. For once these had first been found in the way I taught in Book 4, Chapters 13 and 14, the distances of the Moon from the centre of the Earth were sought; from there a step was made to all but demonstrating the distances of the Sun, in the manner I taught at length in Book 3, Chapter 7; and from these the Sun's parallaxes at once became clear, through the problems given in the same place, Chapter 8.

[Margin: The astronomers' order in investigating parallaxes and distances.]

Since, however, the other five planets have the measures of their intervals bound and connected, by a wonderful tempering and harmony, no less to the interval between the Sun and the Earth than their motions to the motion of the Sun or of the Earth, a more certain method therefore first seeks their distances from the Earth from the commensuration of the orbs that compose the planetary system with the radius of the annual orb of the Sun or the Earth, as we have done so far; and then from those distances it gathers the parallaxes by the following problem. For although some conjecture about the parallaxes of the planets, especially of Mars and Venus when they come closest to the Earth, can be drawn from their apparent motions and the analogy of these, that conjecture is nevertheless very weak, and always carries the suspicion that the variation arises rather from some small deception in the observations, or from uncertainty in the things assumed in deducing the place from observations, than from a variation of view arising from sheer distance.

II. Since, therefore, we are now clear about the opinion of the distances from what was said in Chapter 2, it will not be difficult to deduce the horizontal parallaxes of these planets from the mean, or least, or greatest distance. These are the foundation of the others, by the problem and scheme set out in Book 3, Chapter 8, which you should reread here just as if it were inserted. The sum of the rule is this: if the distance of the planet is known in parts of which the Earth's semidiameter is one, you are to find the residual of the logarithm of the distance [Reſiduum logarithmi]; for that, when looked up and used as a logarithm, will show the angle of horizontal parallax.

[Margin: Summary of the rule.]

Or let one make, as the given distance to the radius or whole sine, so one semidiameter of the Earth to the sine of the angle measuring the horizontal parallax. By this technique, then, the following table of parallaxes has been constructed for the greatest and least distances; from these it will be easy to judge the parallaxes belonging to the mean distance, although in Venus and Mercury the mean parallaxes are equal to the parallaxes of the Sun placed at its mean distance from the Earth.

Table of the horizontal parallaxes for the five minor planets, at greatest and least distance from the Earth.

In the distance: / Authors of the distance	♄ great- est	♄ least	♃ great- est	♃ least	♂ great- est	♂ least	♀ great- est	♀ least	☿ great- est	☿ least

III. Much would have to be said here about the parallaxes of Mars, especially of acronychal Mars, that the learning of astronomers requires; but we have set this out generously in Section 2, Chapter 3, Scholium 4, all of which we wish to apply to this chapter as well. From what was said there, I recall to memory two points especially worth noting. The first is that the parallax of acronychal Mars, that is, in its oppositions with the Sun, is greater than the solar parallax, and that Mars then, especially in Aquarius in these centuries, comes nearly twice as close to the Earth as the Sun does. This is established from the commensuration of its orbs and the Sun's, deduced through the prosthaphaereses, and from the striking increase in its visible diameter. The second is that this same parallax is hardly 2′; indeed, Kepler says in the *Epitome of Copernican Astronomy*, p. 479: "But I have observed that the parallax of Mars is by no means sensible." From this Kepler and we have drawn a powerful argument for diminishing the solar parallax and increasing the Sun's distance from the Earth. So let Tycho take his leave here, who forced on us an excessive parallax of Mars, just as he did of the Sun, and too small a distance for each; granted that he boasts, in volume 1 of the *Progymnasmata*, p. 414, that he has "precisely measured" the parallaxes of acronychal Mars.

[Margin: The parallax of Mars hardly sensible, though greater than the solar.]

In the parallaxes of Venus too he went wrong, though by an error consistent with those in the solar parallaxes. Kepler said, no less candidly than correctly, in the foundations of his *Ephemerides*, p. 15: "In Venus there occur Brahean observations which the nearness of the Sun, the inequality of the air, and the star's position nearest the Earth, that is, its parallax, bring under suspicion of error, so that they sustain credit by nothing except the authority of a most diligent craftsman. Relying on these observations (because they seemed very opportune in establishing the annual commutation), I fear that, through the votes of many others collated, I may be found guilty of some minutes. This most laborious examination of the witnesses, and perilous sifting of the reliable from the unreliable, requires another time."

[Margin: The parallaxes of Venus.]

And he immediately adds these further words: "No small labour also remains in separating the observations of Venus by day, very frequently made by Brahe, from those by night, and those demonstrated from both, which I had unwittingly mixed together, at no small risk of error. For there remains, undecided between the Landgrave and Brahe, the dispute about 6′ of the Sun's motion from the fixed stars, and the testimonies waver this way and that.

[Margin: Tycho's excess in the parallaxes of Venus.]

For the parallax of Venus cannot be as great as the one Brahe assumed in the *Progymnasmata*, fitted to the parallax of the Sun handed down by the Ancients, which is without doubt smaller."

[Margin: Vol. 1 of the *Progymnasmata*, from p. 157.]

IV. As regards Saturn and Jupiter, Tycho admits that their parallaxes are hardly sensible with any instrument, for in volume 1 of the *Progymnasmata*, p. 414, he says: "Although this measurement of parallaxes and distances finds hardly any place in the three superior planets, because of their huge remoteness from the Earth, which makes this variation very small, especially in Saturn, where it scarcely exceeds a third of 1′, nevertheless, by applying a most exact instrument which finely divides aliquot parts of 1′, it will be possible to try these parallaxes too, as far as can be done; especially in Mars when it is acronychal, whose parallaxes I have several times, around that time, carefully and precisely measured, so as to establish whether, having become all-night, it was brought nearer the Earth than the Sun itself, as the Copernican and also our own hypothesis demands."

[Margin: Tycho's opinion on the parallaxes of Saturn and Jupiter.]

Then, on p. 661, he criticises Thomas Digges, who had said: "If the parallaxes of the three most remote planets can truly be detected by any art, they can be found either by his own Problems or by no geometrical precepts at all." In these Problems, however, he assumed that the phenomenon moved by no other motion than the motion of the universe. But since these planets move by a proper motion, "which even in slowest Saturn" (the words are Tycho's) "readily exhausts the smallest parallax, how, I ask, will he unravel the parallaxes of these planets from them? If he hopes to accomplish this at their stations, those do not last long, especially in Mars; and neither are their times known so precisely that the parallaxes can then be examined accurately enough. I pass over the fact that the variation of latitude presents some impediment, etc." And finally Tycho concludes thus: "Intermediate examinations are less discriminable, so that perceiving the parallaxes of the three superior planets seems all too inaccessible. We, however, have not left it untried to test this in acronychal Mars by some other method and, as we hope, to attain it with sufficient certainty." Rashly, therefore, do some who only sip astronomy with the very tips of their lips boast that the parallaxes of Saturn and Jupiter are sensible.

[Margin: Thomas Digges's excessive confidence regarding the parallaxes of the three superior planets.]

V. Further, Tycho must be forgiven those words in volume 1 of the *Progymnasmata*, p. 415: "Nor would it be altogether superfluous to attempt this in Mercury and Venus when they approach the Earth, if, being then very close to the Sun, they did not close off the opportunity for this observation." He is speaking there of parallaxes to be investigated by observation. But Venus at perigee, when it has a great latitude, can be observed, and was in fact observed by Tycho, as we said in Section 3, Chapter 4, Scholium 2, and Section 5, Chapter 5; and we ourselves observed it around perigee, as we said in Section 1, Chapter 2, number 4. At that time, therefore, its parallax can also be observed, by comparing the visible place with the true place.

[Margin: Tycho's error about the parallax of Venus at perigee as unobservable.]

SCHOLIA.

Scholia.

I. From what was said in the preceding chapter it is gathered that, in computing motions, the parallaxes of Mars, Venus and Mercury cannot be disregarded without risk of sensible error when, having passed the mean distance, they approach perigee. When they are above the Sun, however, the risk of erring is not so great, and much less in Saturn and Jupiter. This risk vanishes altogether in our hypothesis, and far more so in that of Posidonius and Wendelen, who place the Sun, and consequently these planets, still twice as high above the Earth as we do.

[Margin: In which planets and when parallax may be disregarded.]

II. That excess in the parallaxes of Venus which Tycho adopted in volume 1 of the *Progymnasmata* was the reason why the places of the fixed stars too, determined from their distance from Venus and from Venus's distance from the Sun, contain some fault. This is what Kepler meant to indicate in the words quoted above, in number 3. Let no one wonder, therefore, if the distances of the fixed stars from one another, and the Tychonic places in longitude and latitude, sometimes differ from ours by 1′, or even by 2′.

[Margin: The Tychonic places of the fixed stars vitiated by the parallax of Venus.]

CAPVT VIII.

Chapter 8.

Præmittuntur Problemata ad Apparentem ac Veram Magnitudinem Quinque Minorum Planetarum pertinentia, & ea occaſione Explicantur Analogiæ interuallorum & Corporum cæleſtium Keplerianæ.

Problems relating to the apparent and true size of the five minor planets are set out first, and on that occasion Kepler's analogies of the intervals and of the celestial bodies are explained.

It is evident that the variation in the apparent and true diameter of the planets depends on their distance from the Earth. Before we report the opinions on these matters, both those of others and our own, I think that general problems concerning them should be set out first, so that recourse to them may afterwards be readier. Let there be, therefore:

Problema 1. Data diſtantia Planetæ à terra, & ſemidiametro ipſius apparenti in illa diſtantia, Inquirere veram eiuſdem Semidiametrum ac Diametrum.

Problem 1. Given the distance of a planet from the Earth and its apparent semidiameter at that distance, to find its true semidiameter and diameter.

I. In the attached diagram, let the centre of the Earth be at C and the distance of the planet's centre AC or PC. From the centre of the planet's spherical body let a circle be described with equal semidiameter AB and DP, one from A, the other from P, representing a great circle on the globe of the planet. To this circle let two straight lines be drawn from the centre of the Earth: one, CD, touching the planet at D, when it is nearer the Earth; the other, CB, touching it at B, when it is more remote. For two triangles will arise, PCD and ACB, right-angled at the contacts D and B, by 18 of Book 3 of Euclid. Therefore, if the planet is at A, and the distance AC and the angle ACB are given, namely the angle measuring its apparent semidiameter at the time when the planet is at that distance, then by the first rule of our rectilinear right-angled triangles the side AB will easily be gathered, that is, the true semidiameter, in the kind of parts in which the distance AC was given. In the same way, if the planet is at P, then with the distance PC and the apparent semidiameter, that is, the angle PCD, the true semidiameter DP will be gathered. And when the semidiameter is doubled, the diameter will be known. In short, then, let it be made: as the whole sine or radius to the given distance, so the sine of the given angle, or of the apparent semidiameter, to something else, and the true semidiameter will come out. Or, more briefly, add to the logarithm of the distance the logarithm of the apparent semidiameter; the sum will be the logarithm of the true semidiameter.

[Margin: Summary of the problem.]

Diagram. A small geometric figure set into the right side of the left column. Two equal circles stand one above the other, with a point C well below them. Straight lines run up from C past the lower circle to the upper circle. In the

upper circle a short radius joins its centre A to the point B on its left edge; in the lower circle a short radius joins its centre P to the point D on its left edge. Labels read off the block, all five: A, B, P, D, C. None unread.

- A (centre of the upper circle)
- B (left edge of the upper circle)
- P (centre of the lower circle)
- D (left edge of the lower circle)
- C (foot of the figure, where the lines meet)

Problema 2. Data Vera ſemidiametro Planetæ, inuenire Apparentem ſemidiametrum ipſius, cuiuis datæ diſtantiæ conuenientem.

Problem 2. Given the true semidiameter of a planet, to find its apparent semidiameter, suited to any given distance.

II. In the preceding scheme already set out, let the planet be at A, holding its greatest distance from the Earth, now known, and let the side AB be given, that is, the true semidiameter in the same kind of parts. Then by Rule 2 of our plane and right-angled triangles the angle ACB, opposite the given side, can be found; and this is the angle under which the apparent semidiameter is seen and which measures it. Again, let the planet be at P, that is, at a lesser distance, whether that be the mean, or the least, or any other, which distance is known either in itself or by subtracting the difference AP from the greatest distance AC. For since the true semidiameter DP is given, by the same rule the angle DCP will certainly become known, measuring the planet's apparent semidiameter in that position. In short, then, let it be made: as the given distance to the radius, so the true semidiameter to the sine of the angle determining the apparent semidiameter. Or add to the logarithm of the true semidiameter the residual of the logarithm of the given distance: for the sum will be the logarithm of the angle measuring the planet's semidiameter as it appears, or as it would appear at that distance of the planet if its appearance were not otherwise prevented, for example by the rays of the Sun. By doubling the visual [?] semidiameter, the whole diameter will be known.

[Margin: Summary of the problem.]

Gather from what has been said that the distances required by the hypothesis of any astronomer must agree with the variation or difference of the apparent diameter, and vice versa; otherwise, if they do not agree, the hypothesis will be convicted of falsity in one or the other.

[Margin: Corollary.]

Problema 3. Aliter ſed Mechanicè abſoluere 1. & 2. Problema.

Problem 3. To solve Problems 1 and 2 in another way, but mechanically.

III. Our Giuseppe Biancani, not so much to avoid the labour of solving triangles by sines as to entice the young to astronomy by an easy and more

evident method of measuring on Earth stars that exist in the heavens, directed that on some plane, say on a huge sheet or board, a straight line be drawn and divided into as many small equal parts as there are in the distance of the planet from the Earth; indeed, that one of those small parts be subdivided into some smaller equal parts, say into 10 or 100. Then, from one end of the line, as from a centre, an arc of 60° was to be described with the help of a compass, or of a ruler equivalent to a compass, at an interval matching the distance, and it was to be divided into degrees, and 1° into 60′. In this way, either from the given arc of the apparent diameter the ratio of the chord, that is, of the planet's true diameter, to the distance would be established with the help of the compass; or from the true diameter, taken as a chord, the doubled sine and the arc determining the visual angle, that is, the angle measuring the apparent diameter. But at great distances this rather crude procedure certainly proves inconvenient.

Problema 4. Data Diametro Vera, Planetæ, Inquirere Circumferentiam circuli in ipſius corpore maximi, & è conuerſo.

Problem 4. Given the true diameter of a planet, to find the circumference of the greatest circle in its body, and conversely.

IV. Let it be made: as 7 to 22, so the given or found diameter to something else; or (more exactly) let it be made: as 100 to 314, so the diameter to something else, and the circumference will come out in the same kind of parts in which the diameter was known. You have the basis of this precept in Book 1, Chapter 4. Conversely, if it is made: as 314 to 100, so the circumference to something else, the diameter will become known.

Problema 5. Datis Diametro & Circumferentia Planetæ inuenire, tum Aream ſeu capacitatem circuli in eo maximi, tum ſuperficiem ipſius in menſuris quadratis.

Problem 5. Given the diameter and circumference of a planet, to find both the area or capacity of the greatest circle in it, and its surface, in square measures.

V. First, take, that is, multiply, the semicircumference by the semidiameter, or a fourth part of the circumference by the diameter, and the area of the greatest circle will result, known in square measures: so that if the measure of the diameter was in feet as to length, the total made by the already mentioned multiplication will be in square feet, that is, small areas each of whose sides equals 1 foot.

[Margin: Part 1 of the problem.]

Second, multiply the diameter by the circumference, or quadruple the area found by the first precept; for either way the number of square measures will result which equal the convex surface of the spherical planet, as is supposed here. I laid the foundations of these precepts in Book 1, Chapters 4 and 6.

[Margin: Part 2 of the problem.]

Problema 6. Datis Diametris veris ducrum [recte: duorum] Planetarum, & vnius Circumferentia vel Area, Inuenire alterius Circumferentiam vel Aream.

Problem 6. Given the true diameters of two planets and the circumference or area of one, to find the circumference or area of the other.

VI. First, if the circumference of one is given, let it be made: as the diameter of the planet whose circumference is known to the diameter of the other, so the known circumference to the one sought. For the latter will likewise turn out known, because the diameters of different circles are to one another as their circumferences, and conversely, as Pappus of Alexandria demonstrated in Book 11 of the *Collection*, Theorem 5.

[Margin: Part 1 of the problem.]

Second, if the area of one is given, let it be made: as the square number of the diameter of the planet whose area is known to the square of the diameter of the other planet, so the given area to the area sought. For circles are to one another as the squares of their diameters, by 2 of the twelfth book of Euclid's *Elements*.

[Margin: Part 2 of the problem.]

Problema 7. Datis Diametro vera Planetæ & ſuperficie conuexa; Inquirere ſoliditatem corporis Planetæ in menſuris cubicis.

Problem 7. Given the true diameter of a planet and its convex surface, to find the solidity of the planet's body in cubic measures.

VII. Multiply a sixth part of the surface by the diameter, or a third part of the surface by the semidiameter; either way a number will result containing as many cubes as equal the whole solidity of the planet's spherical body.

Problema 8. Data proportione inter veras Diametros binorum Planetarum, vel Planetæ & Terræ; Inuenire proportionem corporis Planetæ ad corpus Planetæ, vel ad ſoliditatem Terræ; ſeu quot vicibus maior minorem contineat.

Problem 8. Given the proportion between the true diameters of two planets, or of a planet and the Earth, to find the proportion of the body of one planet to the body of another, or to the solidity of the Earth; that is, how many times the greater contains the lesser.

VIII. It is certain that the globe or sphere with the greater diameter is the greater. To find, therefore, the proportion of the lesser sphere to the greater, one must seek the triplicate ratio of the lesser diameter to the greater diameter;

or each diameter must be multiplied cubically, and the proportion of those cubes sought. "For cubes are in the triplicate ratio of their sides," by 12 of Book 8 of Euclid's *Elements*; and "spheres are to one another in the triplicate ratio of their diameters," by 18 of Book 12 of Euclid's *Elements*, "or of their semidiameters," by 19 of the Fifth. Therefore, taking the diameters as the sides of cubes, spheres are to one another as the cubes of their diameters. This is indeed a most beautiful analogy: just as circles are to one another as the squares of their diameters, by 2 of the twelfth book of the *Elements*, so spheres are to one another as the cubes of their diameters.

[Margin: The proportion of sphere to sphere.]

Now by Definition 10 of Book 5 of the *Elements*, if there are several quantities in continued proportion, the first has to the second a simple ratio, but the first to the third a duplicate, the first to the fourth a triplicate, the first to the fifth a quadruplicate, and so on to infinity. Thus, if the proportion of doubleness is taken and continued in these numbers, 2, 4, 8, 16, 32, between 2 and 4 there will be a simple proportion of doubleness, but between 2 and 8 a duplicate, between 2 and 16 a triplicate, and between 2 and 32 a quadruplicate. A square number is one generated by multiplying a given number into itself; a cubic number, one generated by multiplying a square number by the root of the square. Thus, if 2 is given and multiplied by 2, 4 results, which is a square number whose side or root is 2. If 4 is multiplied again, by 2, 8 will result, which will be the cube of the number 2, and 2 will be the side of the cube, or the cube root, of the number 8. On these premises two rules arise for solving the problem.

[Margin: What is a triplicate ratio?]

The first rests on Proposition 18 of Book 12 of Euclid, in which it is said that "spheres are to one another in the triplicate ratio of their diameters." Therefore, if the proportion between the lesser and the greater diameter is continued as far as the fourth term, the triplicate ratio of the first to the fourth will be obtained, and just such and so great will be the proportion of that lesser sphere to the greater.

[Margin: Rule 1 for solving the problem.]

EXEMPLVM.

Example.

Let there be two spheres, one having a diameter of 2 palms, the other of 4 palms, that is, as 2 to 4. Let it be made, then: as 2 to 4, so 4 to 8; then, as 4 to 8, so 8 to 16. For the lesser sphere will be to the greater as 2 to 16; that is, the sphere of 2-palm diameter will be contained, as to solidity, 8 times in the sphere of 4-palm diameter.

The second rule rests on Proposition 12 of Book 8 of the *Elements*, in which it is said that "spheres are to one another as the cubes of their diameters." So let the diameters be multiplied cubically, each separately; for whatever proportion

holds between the cubic numbers of the diameters, the same will hold between those spheres.

[Margin: Rule 2 of the same problem.]

EXEMPLVM.

Example.

Let the spheres be the same as above, one of 2 palms, the other of 4 palms as to diameter. For when 2 is multiplied by 2, 4 results, and again, when 4 is multiplied by 2, 8 results; and this is the cube of the number 2. On the other side, when 4 is multiplied by 4, 16 results; and when 16 is multiplied by 4, 64 results, which is the cube of the number 4. Therefore, as 8 to 64, so the 2-palm sphere to the 4-palm sphere; and 8 is contained in 64 8 times, therefore that sphere too is contained in this one 8 times.

I have chosen to give these two rules separately, so that they do not seem to conflict if you should happen to find one used by some authors and the other by others, and at the same time for testing one by the other, because of their equivalence. Since the cube of unity is unity itself, if some sphere and its diameter are taken as 1, as the common measure of the proportion of the others, and if its proportion to the diameter of another is continued to the fourth term, it will at once be had how many times the lesser sphere is contained in the greater. But when the true diameter of a star does not contain one whole diameter of the Earth, but a fraction of unity, it is expedient to reduce the denominator of the fraction to a hundred or a thousand and to find the numerator proportional to it; and then the Earth's diameter is to be taken as of 100 or 1000 parts. For in this way the fourth term of the triplicate ratio, or the cubic numbers both of the terrestrial diameter and of the number that was the numerator of the fraction, now taken as whole, will be found more easily.

[Margin: A caution on the use of this rule.]

Problema 9. Data Semidiametro, atque adeò Diametro conuexitatis cuiuſuis cæli, inuenire tum Circumferentiam ſeu ambitum eius, tum Aream circuli maximi, tum ſuperficiem Conuexam, tum Soliditatem illius Cæli.

Problem 9. Given the semidiameter, and therefore the diameter, of the convexity of any heaven, to find its circumference or circuit, the area of its greatest circle, its convex surface, and the solidity of that heaven.

IX. This problem is contained in the problems set out above, from 4 to 8, if what was said there about the globes of the planets is applied to the globes of the heavens. But if the interior and lower heavens are wholly distinct from the upper ones, yet from those that immediately contain them, the solidity of the lesser must be taken away from the solidity of the greater, so that the solidity of the greater alone remains, not as a sphere but as an orb or spherical vessel; just

as from the least of the heavens, that is, from the lunar solidity, the elementary sphere will have to be subtracted.

Problema 10. Data Diſtantia duorum quorumuis Planetarum à Sole, vel periodo motuum, & vnius ſoliditate; inuenire alterius ſoliditatem, ex hypotheſi Kepleriana.

Problem 10. Given the distance of any two planets from the Sun, or the period of their motions, and the solidity of one, to find the solidity of the other, from the Keplerian hypothesis.

X. I have not proposed this problem absolutely, because it is not established that it is absolutely true, or equally applicable to every hypothesis, especially since in this hypothesis the Earth is supposed to be one of the planets going round the Sun, as the Moon is a planet going round the Earth. The solution of this problem, however, rests on certain propositions which, because of their beauty and their great probability in that hypothesis, as if axioms

Kepler calls them in the *Epitome of Copernican Astronomy*, Book 4; and he explains their foundations from p. 474 to p. 499. But from among them Pierre Hérigone chose three, in volume 5 of his *Cursus Mathematicus*, and stated them absolutely in Book 2, Chapter 3, Axioms 18, 19 and 20. They are the following; of these, however, Kepler abandoned the second and held to the first.

[Margin: 1st Keplerian axiom.]

Axiom 1. *The bodies of the planets have among themselves the same proportion as the semidiameters of their orbs, or their mean distances from the Sun.*

[Margin: 2nd axiom.]

Axiom 2. *The times of the periodic motions are in the sesquialteral proportion of the proportion of their bodies and of their mean distances from the Sun.*

[Margin: 3rd axiom.]

Axiom 3. *The proportion between the bodies of the planets is the duplicate of the proportion of their weights, or of the quantity of matter enclosed in the bodies.*

From these axioms, if they are accepted, the rules written below follow.

[Margin: 1st rule.]

First Rule: Let it be made, as the distance of the planet whose solidity is known is to the distance of the other planet whose solidity is sought, so the known solidity to the solidity sought. Thus, since the mean distance of the Earth from the Sun according to Kepler is 3469 semidiameters of the Earth (this is what he chose in the *Epitome*, so that these proportions might be preserved, although he had earlier made it 1800 in the *Commentaries on Mars* [in Marte] and in the *Ephemerides*), and that of Saturn from the Sun is 32256, if the solidity of the Earth is taken as 1, and it is made as 3469 to 32256, so 1 to another number, there will come out in the quotient approximately the number 9. Therefore the solidity of the Earth will be to the solidity of Saturn as 1 to 9.

[Margin: 2nd rule.]

Second Rule, from Axiom 3: Given the periodic times of two planets, seek two numbers that are mean proportionals between those two times. For the smallest term, taken to the next greater, will give the ratio of the matter they possess; but compared to the third, it will give the ratio both of the solidity of the bodies and of the mean distances from the Sun. For example, since the periodic time of the Earth round the ☉ is 1 year, and that of Saturn about 29, and the mean proportionals between these numbers are 3 and 9, fractions being left aside, the matter of the Earth will be to the matter of Saturn as 1 to 3, but the solidity of the Earth to the solidity, or distance to distance, as 1 to 9. Therefore, when the Earth's mean distance from the Sun, which for Kepler is 3469, is multiplied by 9, the result will be approximately the mean distance of Saturn from the Sun, namely 31221. We do not set down a third rule, because Kepler did not afterwards accept Axiom 2.

Doctrina Kepleri de Præcipuorum Mundi Corporum Proportionibus.

Kepler's doctrine of the proportions of the principal bodies of the world.

XI. Let us consult Kepler, then, and see by what indications he hunted down the analogies already mentioned. In Book 4 of the *Epitome of Copernican Astronomy*, Part 1, no. 4, he reasons as follows. The globe of the Sun, since it is the chief among the bodies of the world (and perhaps the first in the order of creation, if by the name of the light made on the first day one understands the Sun), ought not to receive its proportion from other bodies, but rather the others from it; and first of all the Earth, since it was to be the home of the creature that contemplates the works of GOD and measures them by means of sight. And the first ratio of measuring ought to be taken from the first visible thing, that is, from the visible quantity of the Sun. Now the visible quantity of the Sun, or its apparent diameter, is according to Aristarchus and all astronomers the seven hundred and twentieth part of the circle described from the Earth through the Sun, that is, it is 30′.

[Margin: Kepler's most ingenious reasoning on the proportion of the bodies of the world.]

This number 720, moreover, arises from harmonic ratios; for the smallest number that offers itself for determining all the parts of the monochord, so as to constitute the system of the double diapason, or of the soft and hard *cantus* [mollis & duri cantûs], is 720, as the same Kepler shows in the *Harmonics*, Book 3, Chapter 6. Since, then, the motions of the planets were to be accommodated to the harmonic system of the soft and hard *cantus*, as Kepler thinks he has demonstrated in Book 5 of the *Harmonics*, it was fitting that the first body, which was to lead the chorus of this harmony, should, by the appearance of its diameter with respect to the Earth that was to perceive this harmony, divide the circle for the Earth-dwellers in such a way that this division would be the index and measure of the appearance of the harmonic motions, by the very

division of the monochord, that is, into 720 parts. These contain 360 twice, 240 three times, 180 four times, 124 [recte: 144] five times, 120 six times, 90 eight times, 80 nine times, 72 ten times, 60 twelve times, 48 fifteen times, 45 sixteen times, 40 eighteen times, 36 twenty times, 30 twenty-four times; and this is the most fertile form of division into aliquot parts.

Now, if the Sun had to appear to the Earth at its greatest distance under an angle of 30′, that is, under the 720th part of the circle, the Earth must necessarily then have been a little more than 229 semidiameters of the body of the Sun distant from the Sun, as geometry teaches. But if the Earth, being the home of the contemplating creature, had to be the first to perceive these proportions and to measure with a measure best known to itself, then it too had to be, by its own semidiameter, as by the line best known to it of all lines, the measure of the intervals, and by its own body the measure of the principal bodies of the world. And so the first proportion had to be between the semidiameter of the Earth and its interval from the Sun, just as the first also between the body of the Earth and the body of the Sun. And no simpler, better known or more suitable proportion could be set up than an equality of proportions, that is, that the semidiameter of the Earth should be to the distance of the Sun, or of itself from the Sun, as the body of the Earth is to the body of the Sun.

These foundations laid, he sets the semidiameter of the Sun at 100000 parts, so that the interval between Sun and Earth is 22918166 parts; and he divides the cube of the number 100000, which is 100000,00000,00000, by 22918166. Of the quotient (which he says is, that is, approximately, the sine of 15′, or of the apparent semidiameter of the Sun), namely of the number 43631764, he says that the nearest square root, 6606, is the semidiameter of the Earth. For as 6606 is contained in 22918166, the interval of Sun and Earth, 3469 ⅓ times, so the cube of the number 6606 is contained in the cube of the number 100000, of which numbers the former has been assigned to the semidiameter of the Earth, the latter to that of the Sun. For we have already said that sphere is to sphere as the cubes of the diameters are, that is, the cubes in which the globes are inscribed. Hence it comes about that the semidiameter of the Sun contains the semidiameter of the Earth fifteen times, or a little more; but the body of the Sun contains the body of the Earth about 3469 times, that is, as many times as the interval of the Sun contains the semidiameter of the Earth; in strictness, however, the triplicate ratio of the diameters requires 3375. For as 1 to 15, so 15 to 225, and as 15 to 225, so 225 to 3375.

[Margin: Determination of the true distance of the ☉ from the Earth and of the Sun's semidiameter.]

That this distance of the Sun from the Earth is nearly three times greater than the one set by the ancient astronomers he confirms, first, from the parallax of Mars at perigee, which in the acronychal position ought to be greater than the parallax of the Sun; and yet Kepler says: *"But I have observed that the parallax of Mars is by no means sensible."* Therefore, if the parallax of Mars, even when it is nearest the Earth, is not sensible, the parallax of the Sun is much less sensible,

since the Sun is further from the Earth than acronychal Mars. But if the Sun were distant from the Earth only 1200, as much as the ancients supposed, the horizontal parallax of the Sun would be sensible, namely 3′; therefore the Sun is much further from the Earth than 1200 semidiameters of the Earth.

[Margin: 1st confirmation of the great distance of the Sun, from the insensible parallax.]

Second, because otherwise Mars would come too close to the Earth, and from its apparent diameter observed through the Belgian telescope it would be concluded that Mars is smaller than the Earth. This conflicts with the analogy due between the size of the bodies of the world and the order of their position, for that analogy requires that a higher planet also be larger; and in the Copernican system Mars is higher than the Earth.

[Margin: 2nd confirmation, from the size due to Mars.]

Third, as the parallax of the Sun decreases, and so as the distance increases, the parallax of the Moon from the Sun increases, which serves outstandingly for correcting the calculation of eclipses.

[Margin: 3rd confirmation, from eclipses.]

Fourth, if the distance of the Sun from the Earth is increased at least in this way, the body of the Sun turns out larger than all the bodies of the planets fused into one, which is very congruous with the physical cause of the celestial motions: namely, that the Sun, which according to Kepler's opinion leads all the planets round and imparts motion to them, should also be larger than all the moving bodies taken together.

[Margin: 4th confirmation, from the size due to the Sun.]

And this is Kepler's first step for determining the proportion between the body of the Earth and the body of the Sun, and between the distance of the eye contemplating the stars from the centre of the Earth and the distance of the Earth from the centre of the world, which is the Sun. But since Father Paulus Casatus [Paolo Casati], while reading these things, was in doubt how the square root 6606 rather than the cube root was to be applied according to Kepler, he himself later resolved his own doubt by a theorem and a problem, which I have chosen to insert here; and they are the following.

Theorema. Si numerus Cubus ad alium Cubum eam habeat rationem, quam datus quipiam numerus habet ad ſecundi Cubi radicem cubicam; Radix quadrata primi cubi ſumpti vt quadrati, eſt media proportionalis inter datum numerum & datæ radicis cubicæ quadratum.

Theorem. If a cube number has to another cube the same ratio that some given number has to the cube root of the second cube, then the square root of the first cube, taken as a square, is the mean proportional between the given number and the square of the given cube root.

Let the given first cube be S, the second cube A, and let its cube root be C. Let there be given a number D that has to C the same ratio as the cube S to the cube A. And let B be taken, the square of the root C. I say that the square root of S itself is the mean proportional between D and B.

S.	A.	D.	C.
		B.	

For since, as S to A, so D to C, therefore S times C is equal to A times D. But the cube A is equal to C times B; therefore S times C is equal to D times B times C. So, when each term of the equation is divided by C, there remains S equal to D times B. Therefore D, and the square root of S itself, and B, the square of the given root C, are continued proportionals. From this arises

Problema. Dato numero Cubo, & alio quopiam non cubo, inuenire cubum, ad quem datus cubus eam habeat rationem, quam datus non cubus habet ad quæſiti cubi radicem cubicam.

Problem. Given a cube number and some other number that is not a cube, to find a cube to which the given cube has the same ratio that the given non-cube has to the cube root of the cube sought.

Let the given cube be S, the given non-cube D. The cube A is sought, and its cube root C, such that the ratio S has to A is the ratio D has to C. Since, then, by the theorem above, the square root of S itself is the mean proportional between the given D and B, the square of the root C, divide the number S by the given D, and B, the square of the root C, will result. When B has thus been found, the square root C extracted from it will be the cube root sought; and if this is multiplied by B, the square that was found, A will be generated, the cube sought. Which was to be done.

De Proportione Interuallorum & Corporum Lunæ ac Telluris iuxta Keplerum.

On the proportion of the intervals and bodies of the Moon and the Earth according to Kepler.

XII. Kepler thinks that the second place among the bodies of the world is owed to the Moon, as a star owed to the Earth, to assist the growth of terrestrial things; and to the contemplating creature, so that it might begin its observations of the other stars from the Moon, and especially of eclipses, by which we are instructed first and most evidently about the course of the stars. It is plain that this comes about most correctly if, at the greatest remoteness from the Earth, the apparent diameter of each is equal, and the Moon can exactly hide the Sun. So the diameter of the Moon, like that of the Sun, had to occupy the 720th

part of the circle, that is, half a degree. And since the Moon is an earthly and secondary planet, and made for obscuring the Sun, it had also to follow the pattern of the proportions of the Sun and the Earth, both as to the interval and as to the mass of the body. It was fitting, then, that just as the body of the Earth is to the body of the Sun as the semidiameter of the Earth is to the interval of the Earth from the centre of the world, so likewise the body of the Earth should be to the body of the Moon as the distance of the Moon from the Earth is to the semidiameter of the Earth. Nor does this conflict with observations; for Tycho found the greatest distance of the Moon in the quadratures to be greater than 59 and a little less than 60 semidiameters of the Earth. From what has been set out, then, it follows that the semidiameter of the lunar orbit, or the distance of the Moon from the Earth, is the mean proportional between the semidiameter of the Earth and the semidiameter of the annual orb, or the distance of the Earth from the Sun. For as 1 to 59, so 59 to 3481, that is, very nearly 3469, which is the distance of the Earth from the Sun. So by seeking the square root of the Earth's distance from the Sun, we have the distance of the Moon from the Earth. And when the cube of the Earth's semidiameter is divided by 59, and the cube root of the quotient is sought, the semidiameter of the lunar body results. Accordingly, the semidiameter of the Earth contains the semidiameter of the Moon a little less than four times, and the body of the Earth contains the body of the Moon a little less than 59 times. Therefore the body of the Sun, which contains the body of the Earth 3469 times, will contain the body of the Moon, when 3469 is multiplied by 59, 204671 times. Kepler therefore says that these proportions, by a wonderful agreement of likelihoods, have their own dignity, and are so worthy of belief in themselves that they can be used in the place of an axiom.

De Proportione Interuallorum & Corporum Quinque reliquorum Planetarum, iuxta Keplerum.

On the proportion of the intervals and bodies of the five remaining planets, according to Kepler.

XIII. Nothing, says Kepler in the *Epitome of Copernican Astronomy*, Book 4, p. 484, is more in keeping with nature than that the order of sizes should be the same as that of the spheres. And so, of the six primary planets (for he makes the Moon a secondary, and a planet of the Earth rather than of the world), the one that is nearer and innermost of all and describes the smallest orb round the Sun, namely Mercury, should be the smallest of the planets; next larger Venus, then the Earth, then Mars, then Jupiter; and largest of all Saturn. Nor was it right that the bodies of the planets should be adjusted to the body of the Sun by the same laws as the Earth; otherwise size would be contrary to the order of the spheres, and Mercury would turn out largest and Saturn smallest, which conflicts with archetypal reasons and with the observation of the apparent diameters. Further, the dimension of bodies is threefold: one according to diameters, the second

by surfaces, the third according to bulk [corpulentiam]. Spherical surfaces are in the duplicate ratio of their diameters, but bulks in the triplicate.

[Margin: A threefold ratio in the proportion of the intervals and bodies, from a threefold disagreement [trina diſſenſione].]

Either, then, the proportion of the intervals and bodies had to be taken according to the diameters, so that, as the interval of Saturn from the Sun is ten times greater than the interval of the Earth, so the diameter of Saturn would be ten times greater than the diameter of the Earth; and this conflicts with the observations of the diameters made with the Belgian telescope. Or it had to be taken according to the surfaces: that is, as the interval of Saturn is tenfold of the interval of the Earth from the Sun, so the surface of the body of Saturn would be tenfold of the surface of the Earth. This once seemed more probable to Kepler, because from it there follows a proportion of the bodies that is the sesquialteral of the proportion of the intervals, and Saturn is thirty times greater than the Earth, as it is thirty times slower; while the proportion of the diameters is at least half the proportion of the intervals: analogies that favour archetypal reasons. Or finally it had to be taken according to the bulks directly, so that Saturn is ten times greater than the Earth, as it is ten times higher from the Sun than the Earth, and so with the others. This Johannes Remus Quietanus [Ioannes Remus Quietanus] chose, because, as Kepler admits above, on p. 485, the observations of the apparent diameters favour it, and so do the true sizes collected from those observations and the distances. And so Kepler yields to Remus and to the observations, especially since it is not at odds with archetypal reasons that, just as earlier the proportion of the bodies of the Sun and the Earth, and of the Earth and the Moon, was made the same as that between the semidiameter of the Earth and the semidiameters of the lunar orbit and of the Earth's annual orb, so the proportion between the bodies of the planets should be the same as that between the semidiameters of their orbs, or between their mean distances from the Sun.

So Saturn will be nearly ten times greater than the Earth, Jupiter five times, Mars one and a half times; but Venus will be a little greater than three-quarters [dodrante], or 9 parts of 12, of the Earth's body, and Mercury a little greater than a third of the same body; that is, it will contain nearly a third part of the Earth.

[Margin: The proportion between the bodies and the intervals of the 5 planets is established.]

A further reason for yielding to the observations was that Kepler admits that acronychal Jupiter has often been seen by him, at the perigee of the eccentric, to occupy about 50″, where Saturn, by the testimony of Remus, occupies 30″. Acronychal Mars at perigee in Aquarius, moreover, is somewhat larger than Jupiter, but not by much. But about these appearances the reader will judge more surely from our observations, to be presented below in Chapter 10.

De Proportione inter Molem & Denſitatem Corporum Planetariorum, iuxta Keplerum.

On the proportion between the mass and the density of the planetary bodies, according to Kepler.

XIV. On p. 487 of the *Epitome*, Kepler lays down the following about this proportion. First, that the same density, or quantity of matter, does not suit these 6 principal bodies of the world, since the dissimilarity of the periodic times is an argument for dissimilar density.

[Margin: 1st proposition, on dissimilar density.]

Second, that the Sun is the densest of all the bodies of the whole world, because its immense light and active force cannot exist without a proportionate subject, that is, a very great quantity of matter compressed into a small mass. Thus in the *Astronomia Optica*, Chapter 6, he had said that as much matter was once heaped together by God into the one Sun as there is in the rest of the universe. It is fitting, then, that the closer a body is to the Sun, the denser it should be.

[Margin: 2nd proposition: the Sun, for Kepler, the densest of all bodies.]

Third, that the proportion between the densities of these bodies is not the same as that between their intervals or masses; for this would offend against the law of variety, and the quantity of matter would be the same in all the planets. For if, for example, the density of Saturn were to the density of Jupiter as 10 to 5, as its distance and mass are to the distance and mass of Jupiter, then, when the mass of Saturn, 10, is multiplied by the density of Jupiter, 5, a density of 50 would come out, as much as would result if the mass of Jupiter, 5, were multiplied by the density of Saturn, 10. But it seems more congruous that the density should be different, as I said in the first place, and that in the same order in which they recede from the densest centre of the world, in that same order, but not in the same proportion, they should vary in density.

[Margin: 3rd proposition, on the proportion of densities and masses, to be rejected.]

Fourth, therefore, he affirms that the proportion of density is exactly half the proportion both of the intervals and of the masses, and one and a half times that of the diameters, which are in the globes, and three-quarters that of the surfaces. For in this way it comes about that Saturn, which is twice as high as Jupiter, is one and a half times heavier or slower, and one and a half times rarer than Jupiter. There is added another geometrical elegance, namely that the density or quantity of matter is the mean proportional between the mean distances of two planets from the Sun, or the semidiameters of their orbits, or is taken from the mean proportional.

[Margin: 4th proposition, on the proportion of densities and masses, to be chosen.]

On this basis, both here, on p. 490 of the *Epitome*, and in his book in the German language on weights and measures, he presents the following small

table, as an index of the proportion of density among the principal bodies of the world, with metals or stones added that are similar to them in density.

Proportion of density among the bodies, from Kepler.

♄	324	*Hardest gem*
♃	438	*Lodestone*
♂	810	*Iron*
Earth	1000	*Silver*
♀	1175	*Lead*
☿	1605	*Mercury* [Hydrargyrum]
☉	1800	*Gold*
or	1900	*Gold*

De Proportione Magnitudinis & Interualli inter tres præcipuas Mundi Regiones.

On the proportion of size and interval among the three principal regions of the world.

XV. At the centre of the world, as Kepler would have it, is the Sun; and the space occupied by the body of the Sun Kepler calls the first region of the world. Around this is the space extending to the greatest distance of Saturn from the Sun, which is the second region, called the region of the moving bodies [Mobilium]; so the sphere of the whole planetary system embraces the Sun and this space. The remaining space, as far as the outermost surface of the fixed stars, is the third region, containing in itself the two preceding, and it is called the sphere of the fixed stars. That space, however, which extends from the Sun, the Sun excluded, to the concave surface of the sphere of the fixed stars, he calls the ethereal air [Auram ętheriam]; the remaining space, which lies between the concave and the convex surface of the sphere of the fixed stars, he calls the walls of the world, or its skin, or its tunic, or the crystalline orb.

He distributes the intervals of these from p. 491 on, as follows. From the centre to the surface of the body of the Sun there are 15 semidiameters of the Earth; from the surface of the Sun to the centre of the Earth, 229 semidiameters of the body of the Sun; and from the centre of the Sun to the distance of Saturn from the Sun, nearly ten times this interval, that is, 2290 semidiameters of the Sun, or at any rate 2000, because the mean distance of Saturn is not exactly tenfold, but nearly tenfold, the interval of the Earth from the Sun. From the Sun to the fixed stars, moreover, he sets 4000,000 semidiameters of the Sun, or forty times a hundred thousand semidiameters of the Sun. So, when 229 is multiplied by 15, there result from the Sun to the Earth 3454 terrestrial semidiameters; if you add to these 15 for the semidiameter of the Sun, there result from the centre of the Sun to the Earth 3469 semidiameters of the Earth. And when 2000 is multiplied by 15, there result 30000 semidiameters of the Earth from the Sun to Saturn. Finally, when 4000,000 is multiplied by 15, there result 60,000,000 terrestrial semidiameters from the Sun to the fixed stars, that is, six hundred

times a hundred thousand terrestrial semidiameters. And the same reasoning holds for whole diameters of the Earth with respect to the diameter of the sphere of the moving bodies, or of Saturn, or to the diameter of the sphere of the immovable bodies, or of the fixed stars.

The foundation of these intervals is that he thinks it fitting that, just as the distance of the Moon from the Earth is the mean proportional between the semidiameter of the Earth and the semidiameter of the Earth's annual orb, and the orb of the Moon is the mean proportional between the orb or body of the Earth and the annual orb of the Earth itself, so the semidiameter of the sphere of the moving bodies, or the distance of Saturn from the Sun, should be the mean proportional between the semidiameter of the body of the Sun, which is the centre of the world and the source of motion, and the semidiameter of the sphere of the immovable fixed stars, which is the place containing all things; and by the same reasoning, the sphere of the moving bodies, or of the planetary system, should be a mean proportional between the body of the Sun and the body of the sphere of the fixed stars.

[Margin: The foundation of these intervals.]

He had said above, moreover, that the distance of Saturn from the Sun is nearly tenfold the distance of the Earth from the Sun, and so contains the Earth's distance, which is 229 solar semidiameters, ten times, that is, nearly 2290, or in round and more exact terms 2000. So, when the proportion is made, as 1 semidiameter of the Sun to the 2000 semidiameters of the Sun contained in the semidiameter of the sphere of Saturn, so 2000 to another number, there result 4000,000 semidiameters of the Sun for the semidiameter of the sphere of the fixed stars. These, multiplied as I said by 15, give 60,000,000 semidiameters of the Earth. Thus it comes about that the semidiameter of the sphere of the fixed stars contains the semidiameter of the orb of Saturn two thousand times, and this is its square root. But since spheres are to one another in the triplicate ratio of their diameters, it follows that the body of the Sun is to the body of the sphere of the fixed stars as 1 Sun to 64000,000,000,000,000,000 bodies equal to the Sun, and to the sphere of Saturn as 1 to 8000,000,000. Further, from this distance of the fixed stars and the whole diameter of the Earth's annual orb, it comes about that the parallax of the annual orb turns out for him to be 12″. But we have shown in Book 6, Chapter 9, no. 11, that he erred in this very thing.

De Proportione Denſitatis ſeu Copiæ Materiæ cum Interuallo & Magnitudine Trium præcipuarum Mundi Regionum, & de Craſſitie tum Sphæræ ſolius Fixarum, tum Cæli Cryſtallini, iuxta Keplerum

On the proportion of density, or quantity of matter, with the interval and size of the three principal regions of the world, and on the thickness both of the sphere of the fixed stars alone and of the crystalline heaven, according to Kepler.

XVI. Since for Kepler the Sun is the centre of the world, he therefore thinks that from the founding of the world the whole matter of the world's machine was divided into three parts. One of them was compacted into the body of the Sun, so that there should be as much matter in it alone as there is in all the rest of the ethereal air. Another third part was likewise thinned out and spread through the immense space of the world, which extends from the Sun to the concave surface of the sphere of the fixed stars. The remaining third part was expanded into an orb and placed around the world on the outside like walls, or a skin; its thickness runs from the concave to the convex sphere of the fixed stars, and this he calls the crystalline heaven. He assigns it no greater thickness than about two German miles, or 8 Italian miles. Its density he makes a mean proportional between the density of the body of the Sun and the density of the whole ethereal air; and so also the space occupied by it, or the mass of the body contained between the concave and convex sphere of the fixed stars, he makes a mean proportional between the space occupied by the body of the Sun and the space occupied by the ethereal air. Above, moreover, the proportion of the body of the Sun, as regards space or mass, to the body of the ethereal air, or of the sphere of the fixed stars up to its concave surface, was set out as the proportion between 1 and 64000,000,000,000,000,000. Between these numbers or terms the mean proportional is 8000,000,000. That, therefore, is how great the mass of that crystalline heaven is, or the thickness of the heaven containing the fixed stars; and so from it there could be made 8000,000,000 bodies equal to the Sun in mass. If this were reduced and coagulated into one spherical lump, it would make a sphere whose semidiameter would be greater than the Sun's semidiameter 2000 times, that is, greater than 30000 semidiameters of the Earth, granted that, spread out as it is, it is no thicker than one six-thousandth part of one solar semidiameter, or about two German miles. For the cube root of the compound number 64000,000,008,000,000,001 is 4000,000 1/6000.

Summa Propoſitionum & quaſi Axiomatum Kepleri.

Summary of Kepler's propositions and, as it were, axioms.

1. Proposition. *As one semidiameter of the Earth is to the interval of the Earth from the Sun, so is the one mass or body of the Earth to the body of the Sun; and conversely: or, as many times as the Earth's semidiameter is contained in the Earth's distance from the Sun, so many times is the body of the Earth contained in the body of the Sun.* Kepler, p. 478 of the *Epitome*.
2. Proposition. *As the Moon's distance from the Earth is to the Earth's semidiameter, so is the body of the Earth to the body of the Moon.* Kepler, p. 478 of the *Epitome*.
3. Proposition. *The Moon's distance from the Earth, or the semidiameter of the Moon's orbit, is a mean proportional between the semidiameter of the body of the Sun and the semidiameter of the annual orb, or the distance of the Earth from*

the Sun. Kepler, p. 482 of the *Epitome*. Therefore the Moon's distance from the Earth is the square root of the Earth's distance from the Sun.

4. Proposition. *The Moon's orbit, in its mass, is a mean proportional between the body of the Earth and the body of the Earth's annual orb.* Kepler, p. 491 of the *Epitome*.
5. Proposition. *If the surfaces of the bodies of two primary planets were to one another as their intervals from the Sun are to one another, the ratio of the bodies would turn out sesquialteral to the ratio of the intervals.* And so Saturn would be thirty times greater than the Earth and Jupiter twelve times, just as it is also slower. Kepler, p. 484 of the *Epitome*. Outright, however, he chose the following analogy.
6. Proposition. *As the intervals of two primary planets from the Sun are to one another, or as the semidiameters of their orbits are to one another, so is the body or mass of the one to the body or mass of the other.* And so Saturn is nearly ten times greater than the Earth, Jupiter five times, Mars one and a half times; and Venus has 3/4, Mercury 1/3, of the Earth. Kepler, p. 485 of the *Epitome*.
7. Proposition. *The semidiameter of the sphere of the moving bodies, or Saturn's distance from the Sun, is a mean proportional between the semidiameter of the body of the Sun, taken as the centre, and the semidiameter of the sphere of the immovable bodies, or fixed stars; therefore Saturn's distance from the Sun is the square root of the distance of the fixed stars from the Sun.* Kepler, p. 491 of the *Epitome*.
8. Proposition. *The body of the region of the moving bodies, or of the planetary system, is a mean proportional between the body of the Sun and the body of the sphere of the fixed stars, or of the whole world.* Kepler, p. 491 of the *Epitome*.
9. Proposition. *The nearer each of the planets is to the Sun, the densest of all bodies, the denser it is, in the same order but not in the same proportion of the interval; and the farther from it, the rarer.* Kepler, p. 487 of the *Epitome*.
10. Proposition. *The ratio of density between the bodies of two planets is half the ratio of their masses, and one and a half times the ratio of their diameters, and three-quarters of the ratio of their surfaces.* Kepler, p. 488 of the *Epitome*.
11. Proposition. *There is as much of the world's matter in the Sun alone as in the whole ethereal air, and just as much again in the thickness of the crystalline heaven containing the fixed stars.* Kepler, p. 495 of the *Epitome*.
12. Proposition. *Just as the density of the crystalline, or star-fixing [ſtellifixeri], heaven is a mean proportional between the density of the Sun and the density of the ethereal air, so the thickness or mass of the crystalline is a mean proportional between the mass of the Sun and the mass of the ethereal air.* Kepler, p. 496 of the *Epitome*.

Keplerian numbers, rounded however, or derived from Kepler's, and bearing on the intervals or the mass of the bodies of the world.

SCHOLIA.

Scholia.

[Margin: Our distance is confirmed from Kepler's doctrine.]

I. *The arguments of Kepler, discussed in the preceding chapter toward the end of number 11, for raising the Sun three times more than the ancients did, tell more in favour of our distance of the Sun and of the planets that depend on it in this. For if the Sun is distant from the Earth by only 3469 semidiameters, and acronychal Mars by about 1400 or 1500, as follows from his hypothesis, the Sun will certainly have a horizontal parallax of 1′ and Mars of 2′, each of which is perceptible. But if they are removed from the Earth twice as far and more, as we do, it is much truer that the parallax of the Sun and of Mars is imperceptible, or scarcely perceptible. Nor on that*

account will that property collapse, that the Sun is distant from the Earth by about 229 semidiameters of its own body because it is seen by us under an angle of about 30′, or occupying an arc that is the 720th part of the circle of the Sun's orb. For as the distance grows, with that angle preserved, the quantity of the Sun's true semidiameter grows in like manner. So from that reasoning the distance of the Sun from the Earth does not yet come out determined, since with that reasoning preserved the distance could be increased indefinitely. But that distance was chosen by Kepler so that the Moon's distance should be a mean proportional between the semidiameter of the Earth and the distance of the Sun from the Earth.

[Margin: Critique of the Keplerian analogies.]

II. *Although Kepler's analogies display their own beauty and their author's ingenuity, yet they rest for the most part on the hypothesis of the Sun at rest in the centre of the world, of the Earth going round the Sun as a primary planet, and of the Moon relegated among the secondary planets; and they savour of nothing but a certain material elegance of bare geometry and arithmetic, with no mention or account taken of the end and the effects that divine Providence chiefly laid down in determining the mass and the intervals of the planets. They therefore lose a great part of their likelihood, at least among those who both hold to the hypothesis of the Earth at rest and measure the proportion of intervals and sizes chiefly from the end. And if the mass of the planets constructed from these analogies conflicts with the more certain observations of the planets' apparent diameter, to be presented in Chapter 10, those otherwise beautiful analogies will collapse much more. That they do conflict we shall show in that chapter, scholia 1 and 2.*

[Margin: The proportion of the planetary masses, from Šírek.]

III. *Antonín Maria Šírek, in his* Radius Sidereomysticus*, gathers by another analogy the proportion that the masses of the planets have to one another. For in Book 4, chapter 2, member 4, he affirms that the masses of the planets other than the Sun are to one another as the square roots of their revolutions. Accordingly, having resolved the periodic times into hours, he seeks their square roots and compares them with one another. Thus, because Saturn's periodic time is 10747 hours and Jupiter's 4330, and the square root of the first is 107 and of the second 66, he says that the mass of Saturn is to the mass of Jupiter's body as 107 to 66; and so of the others, as you see in the following small table. From elsewhere, however, he takes the proportion of the mass of the Sun's body, which he makes 190 to the mass of the Earth; and so, since he compares the Sun with the remaining planets in that ratio, the result is that the mass itself of the planets is obtained if the square root of the periodic time is sought.*

Proportion of mass to mass	
☉	190
♄	107
♃	66
♂	26

Proportion of mass to mass

CAPVT IX.

Chapter 9.

Indicantur Modi, quibus obſeruatæ ſunt aut obſeruabiles Planetarum Minorum Diametri, & afferuntur Auctorum loca, & opiniones ipſorum de Apparenti ſimul ac Vera horum Magnitudine.

The methods are set out by which the diameters of the minor planets have been observed or can be observed, and passages of the authors are brought forward, with their opinions on both the apparent and the true size of these planets.

I. In Book 6, chapter 9, we have already set out eight methods used by others or by us for observing the apparent diameters of the smaller stars. After first giving six general causes of the eyes' deception in this matter, we then taught one by one how much deceptiveness or clarity there is in each of those methods. You must therefore read that whole chapter again, just as if it had been inserted here as well. On that assumption we shall only indicate those methods, and which of those 8 methods were used by the authors to be reviewed in the following tables.

[Margin: Method 1, deceptive.]

The *first* method, then, works by estimation with the eye, comparing the star's visible diameter with a portion of the Moon or with the distance of two fixed stars close to each other, for instance two of the Pleiades or of the Hyades. It is deceptive above all because of the adventitious rays that the naked eye, by itself or through the interposition of the medium, places around the stars, increasing their discs by a certain spurious surround of rays and taking just as much away from their distances from one another.

[Margin: Method 2, deceptive.]

The *second* method works by the slits or holes of sights and their distance from the eye. It is deceptive both for other reasons and chiefly because the visual angle is formed not at the surface of the eye, from which the distance to the sights is taken, but at the bottom of the eye. And so both the diameters of stars taken in this way and distances taken with a radius, whether Greek or Latin, are foisted on us larger than is right. All astronomers to whom the use of the telescope was unknown, that is, down to Tycho inclusive, are reckoned to have used one or other of these two methods; so it is no wonder if they erred so greatly, increasing the diameters of these planets.

[Margin: Method 3, deceptive.]

The *third* method, by a thread hung perpendicularly whose thickness is known and by the withdrawal of the eye from it until the star is exactly covered by the thread, which Galileo used on occasion, has already been rejected or corrected by us in Book 6, chapter 9, number 3.

[Margin: Method 4, good.]

The *fourth* method works with the help of the telescope, which strips the stars of their adventitious hair-like fringe [capillamentum]. The capacity of the tube must first have been determined, whether by the method that *Galileo* gives in the *Sidereus Nuncius*, p. 7, though it is little suited to celestial objects, or from what fraction of the Moon it takes in, or from a known distance of two fixed stars taken in by it. One then observes what part of that capacity the apparent diameter of the fixed stars occupies. This method was used by *Martinus Hortensius*, *Galileo*, *Gassendi*, *Scheiner*, *Kepler*, and in his work *Io. Remus Quietanus* [Johannes Remus Quietanus]; and by us too, especially on Venus and Saturn, but after first dividing the diameter of the tube's capacity into 4 parts and comparing the planet's diameter with that, for in this way, as *Father Grimaldi* advises, the estimate is clearer. Our telescope, moreover, using a lens convex on both faces at each end, when tested on the Moon, takes in 30′.

[Margin: Method 5, suspected of deceptiveness.]

The *fifth* method works by receiving the bright image of Jupiter or Venus through one or more glasses of the telescope on clean paper, measuring the diameter of that image and comparing it with the diameter of the Sun's image, received with the same glasses and at the same distance of the paper from the glass and divided into very small particles. Hortensius used this method on Jupiter and Scheiner on Venus. But *Pierre Gassendi*, together with the image of the Sun, caught on paper the black image, or little shadow, of Mercury seen under the Sun, and from comparing it with the Sun's diameter he defined its apparent quantity: see the examples below in chapter 10, scholia 4 and 5.

[Margin: Method 6, ours.]

The *sixth* method is carried out with our two radii, the triangular and the scalar, on which see Book 6, chapter 9, number 6; and it serves at least for judging within what nearest limits the quantity of the apparent diameter of stars smaller than the luminaries lies.

[Margin: Method 7, ours, the best.]

The *seventh* method requires the approach of Saturn or Jupiter to some fixed star with so small a difference of latitude that not only can the planet be taken in with the fixed star in the same view through the spyglass, but it also comes as close to the star as possible. How the quantity of the apparent diameter is deduced with the greatest certainty from the planet's true daily or hourly motion, and from its distance from the fixed star on the day immediately before or after its conjunction with that star, we shall teach better by example than by a longer precept in the next chapter, numbers 2 and 8. We used this method on ♄ and ♃, and D. Vicenç Mut on ♃.

[Margin: Method 8, very good.]

The *eighth* method, by various little circles prepared on paper and the comparison with them of the discs of stars viewed through the telescope, so that the little circle is chosen that of all of them appears to fit the star's disc most closely, and is compared by compasses with the diameter of Jupiter or Saturn already known by method 4 or 7, has been used by us, with the attestation and help of the eyes of several people, to whom the same circle appeared, among the others, most nearly equal to the star's disc. The planets' apparent diameters established by these methods we have therefore put into tables, deducing from them the true size by the problems of chapter 8.

To this method or to the fifth can be reduced the comparison of a star's disc copied onto paper and then compared with one of the smaller spots of the Moon, the apparent quantity of which spot is known from our *Selenographia*, Book 4, chapter 7, and from the Appendix bearing on that chapter, from its proportion to the Moon's apparent diameter. But if we want to rely on spots of the Moon already drawn elsewhere, the observation turns out more deceptive, since those spots vary in apparent size with the varying libration, latitude and altitude of the Moon and with the varying illumination from the Sun according to the Moon's various phases. And if, at the same time as we compare the star with the spots, the proportion of the spot to the Moon's diameter has to be determined exactly anew, too much labour is laid on astronomers and the opportunity will be rarer. For these reasons, when I had tried some observations of this kind, I set them below the others, which are much more certain. But just as this leaf was to go under the press, there at last reached our hands the *Selenographia* of Johannes Hevelius, who in chapter 55, p. 447, prefers this method to all others, but older ones (for our others he has not yet seen), and from it brings out the diameters of certain stars. On this occasion he advises that a perforated metal leaf, whose hole is as wide as a pea, be placed over the lens farther from the eye, so that the stars may in this way be better stripped of their adventitious rays and appear rounder or bounded by a more certain edge, especially those that radiate a more vivid light, like Venus, Mercury and Sirius.

The observations of Gassendi, Hortensius and Scheiner, moreover, we shall report in chapter 10, scholia 4 and 5, and our own in chapter 10.

Auctores ex quibus ſequentes Tabulæ collectæ ſunt.

The authors from whom the following tables have been gathered.

II. The authors from whom we have gathered the following tables, with the utmost good faith, are: *al-Battānī*, chapter 50; *al-Farghānī*, section [differentia] 22; *Jean Fernel*, Book 1 of the *Cosmotheoria*, and, following him closely, *Egnazio Danti* in his mathematical tables, from table 22; *Wurstisen* on Peuerbach's *Theoricae*, p. 355, and, reporting the same numbers, *Giovanni Antonio Magini* in the *Theoricae Planetarum*, Book 3, chapter 19; *Francesco Maurolico*, in the small tables added to dialogue 3 of his *Cosmographia*, following al-Farghānī closely; *Clavius* on chapter 1 of Sacrobosco's *Sphere*, p. 186 in my copy, mostly following

Maurolico and adding some things of his own; *Francesco Barozzi*, Book 1 of the *Cosmographia*, p. 50, and Book 4, p. 337; *Tycho*, volume 1 of the *Progymnasmata*, from p. 468 to 475; *Redento Baranzano*, *Uranoscopia*, part 1, p. 123, and part 2, p. 116, following now Clavius, now Tycho; *Giuseppe Biancani* in his *Sphaera*, in the several books on the planets and in the tables at the end of the *Sphaera*, following Tycho; *Scheiner* in the *Sol Ellipticus*, p. 25, in the *Disquisitiones Mathematicae*, number 42, and in Letter 1 to Markus Welser; *Galileo*, dialogue 3 of the *De Mundi systemate* and *De Maculis solaribus*, p. 110; *Kepler* in the *Epitome of Copernican Astronomy*, volume 2, p. 485, reporting the opinion of *Johannes Remus*, in the *Optics*, p. 333, and in the Rudolphine Tables, precept 110; *Lansbergen*, Book 3 of the *Uranometria*; *Martinus Hortensius* in the *Dissertatio* with Pierre Gassendi, *De Mercurio sub Sole viso & Venere inuisa*; *Pierre Gassendi* in the *Life of Nicolas-Claude Fabri de Peiresc*, and in the *Institutio Astronomica*, Book 2, chapter 14, where he also reports the opinions of the ancients, and Book 3, chapter 11, where he brings forward those of Lansbergen and Hortensius; *Andrea Argoli* in the *Pandosion Sphaericum*, from chapter 52 to 59, following Tycho and Biancani; *Pierre Hérigone*, volume 4 of the *Cursus Mathematicus*, pp. 60 and 62, where, though borrowing the apparent semidiameters from Hortensius, he took the true sizes from elsewhere, and volume 5, p. 573, where he follows the Keplerian proportions; *Antonín Maria Šírek* in his *Radius Sidereomysticus*, Book 4, chapter 2, members 4 and 5; *Athanasius Kircher* in the *Ars Magna Lucis et Umbrae*, volume 2, after p. 761; and *D. Vicenç Mut* in a letter written to me on the diameter of Jupiter, a fragment of which I shall quote in the next chapter.

[Margin: Praise of Hortensius and Mut, and Lansbergen's boasting.]

Among these no one came closer to the truth than *Hortensius* and *Mut*. Yet Hortensius erred greatly on Saturn at perigee and likewise on Venus at perigee, perhaps because he did not have the chance of observing both at perigee, as we did, according to what is to be said in chapter 10. And that *Lansbergen* too pronounces in this place that there is no doubting his numbers arose from excessive confidence, which he did not think could be blunted by plain observations.

[Margin: On the tables of the sizes of the ☾, the ☉ and the fixed stars.]

Further, I have given tables and authors for the size of the Sun in Book 3, chapter 10, number 12, and chapter 11, number 1; for that of the Moon in Book 4, chapters 16 and 17; and for the size of the fixed stars in Book 6, chapter 9. From these, assuming with al-Battānī and al-Farghānī that the Sun's apparent diameter at mean distance is 31′ 20″, it is easy to gather the apparent diameters of the five minor planets. For they say that the diameter of Saturn, as regards appearance, is the eighteenth part of the Sun's diameter, Jupiter's the twelfth and Mars's the twentieth. But on Venus and Mercury they disagree: al-Battānī makes Venus's diameter the tenth part and Mercury's the fifteenth part of the Sun's diameter, whereas al-Farghānī makes Venus's the twentieth and Mercury's the twenty-fifth.

Table 1. Apparent diameters of the minor planets: mean, at the planet's mean distance from the Earth; or minimum at apogee and maximum at perigee.

We, but ♄ without its companions	891	0	685	0	0	14/100	1	1/2	0	1/256

In using the preceding table, when only fractional numbers are given, the numerator of the fraction indicates what part the planet holds in the body of the Earth; the denominator of the fraction, that is, the number below the little line, signifies the times that the Earth contains the planet. For example, according to *al-Battānī* the body of Mercury holds only one single part of 19000 parts of the Earth; and conversely the Earth contains 19000 bodies equal to Mercury.

Table 4. Proportion of the diameter of the planets to the diameter of the Earth.

Authors	♄ as	to	♃ as	to	♂ as	to	♀ as	to	☿ as	to
Clavius and *Barozzi*	9	2	32	7	7	6	3	10	1	28
Pierre Hérigone	31	11	12	5	5	12	6	11	3	8
Athanasius Kircher	31	11	12	5	6	11	6	11	3	8

Table 5. Proportion of the solidity of the planets to the solidity of the Earth.

Authors	♄ as	to	♃ as	to	♂ as	to	♀ as	to	☿ as	to
Clavius	729	8	32768	643	343	216	127	1000	1	21952
Baranzano	729	8	32768	343	343	216	27	2000	1	21952
Pierre Hérigone	22	1	14	1	1	13	1	6	1	19

You see opinions mixed together, and Clavius's figures corrupted by Baranzano.

Table 6. Proportion of the solidity of the planets to the solidity of the Sun or ☾.

Authors	To	♄ as	to	♃ as	to	♂ as	to	♀ as	to	☿ as	to
Biancani	☉	1	6 4/21	1	10	1	1820	1	840	1	2918
Biancani	☾	180	1	560	1	40	13	7	1	40	19
Šírek	☉	107	190	66	190	26	190	19	190	9	190

III. Add to the preceding tables the small Keplerian tables set at the end of chapter 7. And if you wish to have the solidity of the planets in cubic miles, see in Book 2, chapter 7, how many cubic miles one single Earth contains, and multiply that number by the number of times by which the planet contains the Earth; or, if the planet is smaller than the Earth, divide the Earth's cubic miles by the number by which the Earth contains the planet. If you wish to have the true diameter of the planets, see likewise in Book 2, chapter 7, how many miles are contained in the Earth's diameter, etc. I am pleased, however, to set here the Italian miles to which Father Athanasius Kircher reduced Kepler's measures, in his *Magnes*, p. 561.

The Keplerian size of the bodies of the world in Italian miles, from Father Athanasius Kircher.

	Diameter in Italian miles	Body in cubic Italian miles
Earth	7000	343,000,000,000
☾	2281	11867,954,041
☿	377	21253,933
♀	3766	41637,598,696
☉	42900	78,953,589,000,000
♂	9100	753,571,000,000
♃	35620	45194,100,328,000
♄	15100	43243,551,000,000

CAPVT X.

Chapter 10.

Noſtræ & Aliorum Obſeruationes Diametrorum Apparentium Quinque Minorum Planetarum cum vera Magnitudine, tam ſecundùm noſtras, quàm ſecundùm aliorum Diſtantias.

Observations, our own and others', of the apparent diameters of the five minor planets, with their true size, according both to our distances and to those of others.

I. Just as I once lamented that recent astronomers had hunted the Sun's distance from the Earth in no other way than through conjectures from eclipses, a method I showed in Book 3, chapter 7, to be most uncertain; and just as, therefore, still unaware of Wendelen's attempt, I searched by another, more certain inquiry for the solar distance, on which the distance of the five minor planets depends, and found it proportional, at almost the middle position, between the distance that Kepler finally raised in the *Epitome of Copernican Astronomy* to 3469 semidiameters of the Earth (driven to it by the parallax of Mars at its acronychal position, scarcely perceptible and yet then exceeding the solar parallax) and the one that Wendelen carried up to 14905, for the reasons adduced in that same Book 3, chapter 7; and just as I was no less concerned to investigate the apparent diameter of the luminaries in several ways, as is clear from Book 3, chapter 9, and Book 4, chapter 16: so too I was long concerned about the diameters of the remaining planets and of the fixed stars. For I saw that the ancients, with great and gross errors, had obscured astronomy on this matter rather than illuminated it, while more recent writers, who were not ignorant of the use of the telescope, do come closer to the truth, yet still disagree among themselves; and I did not want to depart from anyone's opinion without grounds. Yet I could not rest content with the observations taken with our radii, set out in Book 6, chapter 9, number 6, nor with others made by the telescope and by projecting the images of each planet onto paper, because no occasion had yet presented itself of determining without misgiving the diameter of one of these planets, and by its standard the diameters of the rest. Later, however, GOD granted that occasion to *Father Francesco Maria Grimaldi* and to us; and so we now go on with a livelier spirit to advance astronomy in this area, making our start from Jupiter, and having selected from among a good many observations the clearest of all.

Obſeruatio Diametri Iouis.

Observation of the diameter of Jupiter.

II. In the year of Christ 1649, while Father Francesco Maria Grimaldi of our Society was observing the zones of Jupiter with a truly excellent telescope 11 Roman feet long, he noticed, when June had already begun, that Jupiter was drawing daily closer to that star of the fourth magnitude which is the leading

one of the four stars in the left wing of Virgo, and the sixth among the stars of the constellation of the Virgin in the Ptolemaic, Tychonic and Rudolphine catalogues. According to the same catalogue, that star has a northern latitude of 1° 25′ and at that time a longitude, that is, an ecliptic place, in ♍ 29° 56′ 25″. Jupiter too was at that time, according to Montebruni's Lansbergian ephemeris, at the end of Virgo, with a northern latitude of about 1° 25′. He therefore had no doubt that Jupiter, in conjunction with that star, or on the day immediately before and the day after that conjunction, could be seen together with that star at a single glance within the compass of the telescope, and that from its distance from the star and its daily motion one could pronounce with the greatest certainty on its apparent diameter. When he had told me of this opportunity, so that I might be present to assist in and test the observation, he was thereafter, on those days, wholly intent on this observation, which we shall set out more clearly with the schematism attached.

Diagram. Two equal circles, each a disc of Jupiter, stand at left and right in the right column, with a single sign for Jupiter above each. A horizontal straight line runs from K on the left circle through its centre C, then through D at the mid-point of the figure, to R on the right circle, passing through that circle's centre B. In each circle a hatched band lies above the horizontal line and parallel to it: NL in the left circle, PM in the right. A star-shaped point A stands at the foot of the figure; a vertical line rises from A to D, a straight line runs from A to C, and a straight line runs from A through G, H and B to F at the top right of the right circle. The four quarters of the sky are engraved in italic: Septentrio (North) above, Meridies (South) below A, Oriens (East) at lower left, Occidens (West) at lower right.

- N, L (left circle, ends of the upper edge of the band): point labels
- K (left circle, left end of the horizontal line): point label
- C (left circle, centre): point label
- D (on the horizontal line, above A): point label
- P, M (right circle, ends of the band): point labels
- R (right circle, right end of the horizontal line): point label
- F (right circle, upper right, end of the line from A): point label
- B (right circle, centre, on the line from A): point label
- H (right circle, on the line from A between G and B): point label
- G (right circle, lower left limb, on the line from A): point label
- A (foot of the figure, at the star): point label
- ♃ (above each circle): the sign of Jupiter
- Septentrio, Meridies, Oriens, Occidens: North, South, East, West

All labels read; none unread.

[Margin: The scheme of the observation is set out.]

Let A be the leading star of the four in the left wing of Virgo. Let B be the centre of Jupiter when it was more westerly than that star, that is, the centre of the disc or circle of apparent Jupiter, FPG; and let C be the centre of the same when it had become more easterly. Let PM and NL be its bands, parallel to the

line RBCK drawn through the centres BC; these bands, as is established from several other observations, are sensibly parallel to the ecliptic, as is also the path of the Jovian satellites, and so RDC too was parallel to the ecliptic. Then from A, a star more southerly than Jupiter was, let a perpendicular arc AD be drawn to RK; and let the centres of both Jovian discs be joined to A by the straight lines AC and AB, with AB produced as far as F, so that GBF is the diameter of Jupiter. Let this diameter be understood as divided not only into two at B, but also into four at H, so that GH is a fourth part of it. This is how Father Grimaldi chose to have it, for a finer measure of the interval between the limb G and the star A.

[Margin: The observation itself is set out.]

III. On June 9, then, in the first hour after sunset, Jupiter appeared at B, more westerly and more northerly than the star A. The distance of the limb G from the star A, that is, the straight line AG, was plainly 7 parts of which GH was one, or 3½ of which GB, that is, Jupiter's semidiameter, was one; and the whole AB was 9 parts of which GH was one, or 4½ of which GB will be one. For by all these comparisons the size of the interval AB was confirmed. And since the spyglass showed Jupiter most brightly round and stripped of all adventitious hair of rays, and represented it far larger than you see it in this schematism (for there the proportion of the lines is represented, not the size of the true image), and since it was very close to the star A, the eye measured that space with as much clearness as if a hand were defining it with compasses on a paper laid beneath. Straightway on June 10, in the same first hour of the night, Jupiter appeared at C, more easterly and more northerly than the star A, but somewhat less distant from it than on the 9th: for the distance AC was exactly 8 parts of which GH was one, or 4 parts of which GB is one. Moreover, with the straight line BC drawn by estimation on each of the two days, which both to the bands of Jupiter and to the path of the four little Jovian planets and finally to the ecliptic was sensibly parallel, and with the perpendicular AD drawn to it, Jupiter, when with its centre it was at D, in conjunction with the star A, stood away from it towards the north, that is, was more northerly than it, by the line AD, which, all things considered, was estimated with certainty at 4⅓ parts of which GH was one.

[Margin: 1. Step for the size of the chord BC.]

First, then, by the doctrine of triangles, in the triangle ABD, right-angled at D, given the side AD of 4⅓ parts and the base AB of 9 parts, the side BD is gathered to be very nearly 8 parts, an imperceptible difference being disregarded. Again, in the triangle ACD, right-angled at D, given the side AD of 4⅓ parts and the base AC of 8 parts, CD is deduced to be as nearly as possible 6 parts. And so the chord, that is, the whole daily path of Jupiter, BC, was 14 parts of which GH, a fourth part of Jupiter's diameter, was one; or 7 parts of which the semidiameter BG is one; or equal to 3½ apparent diameters of Jupiter's disc.

[Margin: 2. Step for the apparent diameter of ♃.]

Second, the true motion of Jupiter from noon of the 9th to noon of the 10th was 2′ 30″; but from the first hour of the night of the 9th to the first hour of the night of the 10th it was 2′ 40″, that is, 160″. Let it be, then, as 3½ to 160″, so 1 to 46″. Therefore Jupiter's apparent diameter in that position was exactly 46″, and its semidiameter 23″. Again, let it be as CB of 14 parts to CB of 160″, so AD of 4⅓ parts to 49″. Jupiter was therefore more northerly than that star by 49″; and so, if the star's northern latitude is 1° 25′, Jupiter's northern latitude was 1° 25′ 49″ at the moment of conjunction, which fell on the 9th at 21^h after noon, and Jupiter's true longitude then was ♍ 29° 56′ 25″.

[Margin: The disagreement of the tables with the sky.]

Granted that the Prutenic tables then set the longitude of ♃ in ♍ 29° 40′, with a latitude of 1° 36′; the Danish tables in ♎ 0° 1′, with a latitude of 1° 33′; and the Lansbergian tables in ♍ 30°, that is, ♎ 0° 0′, with a latitude of 1° 24′; yet all of them set Jupiter's daily motion at 2′ 40″, or 2′ 42″, or 2′ 38″.

[Margin: 3. Step for the true diameter of Jupiter.]

Third, because the anomaly of the eccentric of Jupiter was 1° 55′ and the equated anomaly of the orb very nearly 248½°, Jupiter's distance from the Earth, by our hypothesis, was 39500 semidiameters of the Earth; and it was very nearly at the apogee of the eccentric and a little below the mean longitude of the epicycle. So from that distance, and from the angle of the apparent semidiameter, 23″, there is gathered by Problem 1 of chapter 8 a true semidiameter of Jupiter of 4 42/100 of which the Earth's semidiameter is one.

[Margin: The apparent semidiameter of Jupiter at the greatest, mean and least distances.]

And from this, by Problem 2 of the same chapter, from Jupiter's distances, the greatest 47552, the mean 36500 and the least 26441 semidiameters of the Earth, there is deduced an apparent semidiameter at the apogee of the eccentric and of the epicycle of 19″ 9‴, at the mean distance of 24″ 53‴, and at both perigees of 34″ 23‴. These numbers will result from any other hypothesis that preserves the proportion of the intervals to the Sun's distance, that is, to the radius of the annual orb.

[Margin: Observation of the diameter of Jupiter by D. Vicenç Mut.]

IV. When these things had already been most certainly established among us, there was brought to me, behold, a letter from the most illustrious D. Vicenç Mut, a truly outstanding astronomer, celebrated too for the *Sol Alphonsinus* he recently published, dated 1649 June 30, from Majorca. In it he reported to me, in exactly these words, that on the very same days as we, and yet suspecting nothing of our observation, he had observed the diameter of Jupiter. *I observed Jupiter with the leading star of the left 4 in the wing of* ♍*, on the 9th of this month, at* 10^h*. Jupiter was more westerly than the said leading star of the 4 in the left wing, and this star stood from its limb by, most exactly, one diameter of Jupiter itself. Moreover the star was more southerly than the line of the satellites by scarcely more than Jupiter's semidiameter, and seemed about to meet it, grazing the limb. On the following day at the same hour* ♃ *was already more easterly, and between those 24 hours Jupiter,*

by comparison with the star, was seen to have run through three diameters of its body, weighed with the highest precision. So Martinus Hortensius is not far wrong on Jupiter's diameter in this position, 48″. This I observed on the 9th and 10th of this month of June; but on May 11 Jupiter had been more easterly than the said star by almost 2′ or 1′ 30″, and they stood from each other a little less than the two contiguous stars in the second of the Hyades. For it had then been retrograde. So he wrote; I wrote back to him about our observation, and it is not easy to say with what joy we were filled at so happy an accord and an agreement so very close, down to the seconds of this diameter, although for just reasons I was compelled to follow our own observation instead.

[Margin: Šírek's error on the diameter of Jupiter.]

Compare also with ours the observations of Hortensius and Gassendi, on which see scholium 4 below, and you will see how false is the opinion of Antonín Maria Šírek, who says in Book 4 of his *Radius Sidereomysticus* that the diameter of Jupiter, from his own observation, is 3′.

Obſeruatio Diametri Martis.

Observation of the diameter of Mars.

V. Of all the observations of this diameter, the clearest of all seemed to us the one made in 1649 on July 22, when Mars, viewed with our very large telescope, appeared with a diameter exactly half as great as Jupiter's. This was evident when the image of each was at once copied onto paper, each planet was examined again and often, and the diameter of each circle was divided into equal small parts. Jupiter was then, as to the anomaly of the eccentric, at 5°, and as to the anomaly of the epicycle at 287°; so its distance from the Earth, by our hypothesis, was 43100 semidiameters of the Earth. From this, and from its true semidiameter found in number 3 above, 4 42/100 semidiameters of the Earth, there is deduced by Problem 2 of chapter 8 an apparent semidiameter of Jupiter of 21″ 5‴. Half of that, 10″ 32‴, was therefore the apparent semidiameter of Mars in that position.

[Margin: The true diameter of Mars.]

At the same time Mars stood 86° in the order of the signs from the apogee of the eccentric, and 255° from the apogee of the epicycle. Its distance from the Earth, according to us, was accordingly 11200 semidiameters of the Earth. From this, with the angle 10″ 32‴, there is gathered by Problem 1 of chapter 8 its true semidiameter, 0 516/1000 of which the Earth's semidiameter is one.

[Margin: And the apparent one at three distances.]

From this, by Problem 2 of the same chapter, and from our distances of Mars from the Earth, the greatest 21005, the mean 11000 and the least 2373 semidiameters of the Earth, is derived its apparent semidiameter at both apogees, 5″ 3‴; at the mean distance, 11″; and at both perigees, 46″.

Obſeruatio Diametri Veneris.

Observation of the diameter of Venus.

VI. In that same year 1649, on July 26, the day dedicated to St Anne, in the morning, with the telescope turned on the Moon, it was confirmed that its field, from the eastern limb near the Lake of Posidonius as far as the eastern shore of the Caspian Sea, took in 30′, a crystal convex on both sides being used near the eye. The telescope was then turned at once on sickle-shaped Venus; and when a fourth part of the diameter of the circle taken in by the telescope was considered, it appeared again and often that the interval from horn to horn of Venus equalled a fourth part of that fourth, that is, was contained 18 times in the telescope's whole field, and so was 1′ 40″. Comparing its image with the image of the same planet seen on June 29 of the same year, whose scheme we gave in Section 1 of this book, chapter 2, it seemed half as great as on June 29, namely 3′ 20″; for on June 29 it had been close to the perigee of the epicycle. Also on June 24, Venus, compared with Jupiter by means of the telescope, contained Jupiter 3⅔ times; Jupiter then, by the principles established in number 3, occupied 42″, and so Venus 2′ 34″; and with the image of Venus set against the image close to perigee of which I spoke above, it seemed as 3 to 4. From all these things, then, it is confirmed that at the perigee of the epicycle, on July 7, it was 3′ 20″. Finally, on 1650 January 2, when Jupiter by our reckonings was 43″ in apparent diameter, Venus, seen through the telescope, was about as 4 to 5 to Jupiter, that is, 34″ 24‴.

[Margin: The true semidiameter of Venus.]

First, then, using the diameter of 3′ 20″, or the semidiameter of 1′ 40″, which was very nearly its size on July 7, when it was at the perigee of the epicycle but at an anomaly of the eccentric of 15°, and so stood only 2400 semidiameters of the Earth from the Earth by our hypothesis, there follows by Problem 1 of chapter 8 a true semidiameter of Venus of 1 15/100 of which the Earth's semidiameter is one.

[Margin: And the apparent one at three distances.]

Second, from this true semidiameter and from our distances of Venus from the Earth, the greatest 12919, the mean 7418 and the least among the possible ones 1917 semidiameters of the Earth, we shall gather the apparent semidiameter of Venus at both apogees, 16″ 45‴; at the mean distance, 32″ 6‴; and at both perigees, 2′ 4″. See now the observations of Scheiner in scholium 5 below, and compare them with ours.

Obſeruatio Diametri Mercurij.

Observation of the diameter of Mercury.

VII. In 1650, on January 2, with the horizon perfectly clear, Mercury was seen close to its greatest digression from the Sun, and with its image copied onto paper, after it had first been examined long and much through the telescope, and the same done with Jupiter's image, and in this way Mercury's diameter was found to be to Jupiter's diameter as 2 to 5. Now Jupiter's apparent diameter at that time, from the principles established above, was 44″, as we shall show

shortly in number 8. Mercury's diameter in that position, therefore, was 17″ 36‴, or at most 18″.

[Margin: True diameter of Mercury.]

First, the anomaly of Mercury's centre was then 42° and the equated anomaly of the orb 149°; hence its distance from the centre of the Earth, by our reckoning, was 5800 semidiameters of the Earth. From this, and from the apparent semidiameter of 9″, by Problem 1 of chapter 8, Mercury's true semidiameter is derived as 0 25/100, in parts of which the Earth's semidiameter is one.

[Margin: And its apparent diameter at three distances.]

Second, from our greatest distance of Mercury, 10868, the mean, 7473, and the least, 4078 semidiameters of the Earth, there is deduced by Problem 2 of chapter 8 its apparent semidiameter at both apogees, 4″ 40‴; at the mean distance, 6″ 54‴; and at both perigees, 12″ 36‴. I pass over the remaining observations, which are less certain than this one. See also the observations of Gassendi and Hortensius below, in scholium 4.

Obſeruationes Diametri Saturni.

Observations of the diameter of Saturn.

VIII. We have deliberately put off the highest of the planets to this last place, because its diameter is entangled in several inequalities, owing to the varied figure that it presents to our gaze together with its flanking attendants [Collateronibus], a figure that quite often departs from the circular or spherical. Among the other times at which we observed it, the most opportune was that very recent one when, having become acronychal at both perigees, namely of the eccentric and of the epicycle, it came down as far as it could toward the Earth and, spending the night with us, granted the fullest view of itself for contemplation, at our complete leisure. For in 1649 it was at the perigee of the epicycle about December 18, and around the 27th at the perigee of the eccentric; on those days, and indeed from December 12 until January 10 of the year 1650, its diameter was observed often and in many ways, both when it was taken alone and when taken with its attendants [lateronibus].

[Margin: 1. Observation of the diameter of Saturn.]

First, Saturn at perigee was viewed together with Jupiter through the same very large telescope of ours, both by direct and careful inspection of each and by copying the image of each onto paper at once; the visible diameters of each were divided, in the inspection by estimation, in the image by compasses. Saturn's whole composite diameter AB was to Jupiter's diameter BZ as 13 to 8. But the interior or simple diameter, that of Saturn taken alone, namely FG, was to Jupiter's diameter as 6¼ to 8, and the remaining diameter CD as 5¾ to 8. At that time the anomaly of Jupiter's eccentric was 18° and the equated anomaly of its epicycle 65°; and so by our hypotheses its distance from the Earth was about 44000 semidiameters of the Earth. From this, and from its true semidiameter found in number 3, 4 42/100 semidiameters of the Earth, Jupiter's apparent semidiameter at this time is gathered, by Problem 2 of chapter 8, as 22″, and its

whole diameter as 44″. If, therefore, one makes as 8 to 13, so 44″ to another, the diameter AB will come out as 71″ 30‴. If as 8 to 6¼, so 44″ to another, FG will result as 34″ 22‴. Finally, if as 8 to 5¾, so 44″ to another, CD will be 31″ 38‴.

Diagram. A full-width figure across both columns. At left, a large horizontal ellipse represents Saturn with its companions, with a dark crescent inside it toward each end, the crescents' hollow sides facing the centre, and the ellipse's interior between them left white. At right, immediately beyond the ellipse, stands a circle, Jupiter, crossed by a slanting hatched band that runs down from its upper left limb to its right limb. To the left of the ellipse, a vertical dotted line descends from the star at H to L, and a horizontal dotted line runs from L to A at the ellipse's left end. A second vertical dotted line descends from the star at P to the top of the ellipse, and resumes below it to R.

[Margin: 2. Observation of the diameter of Saturn.]

Second, over the same days, two stars observed among the Hyades occupied almost a fourth part of the circle that equalled the telescope's field, that is, 6½′ or a little more, while Saturn's diameter AB seemed to be contained 5½ times in that space between the stars. Again, from Saturn's more distant end to a certain star of Gemini near Propus (a star that is not in the catalogues of the fixed stars and is visible only with the telescope, but was chosen by us because it lay on the straight line drawn through AB, which is usually parallel to the equator), the interval was equal to 5½ Saturnian diameters AB. The space from the end B to the same star, however, was of 4½ such diameters, most evidently to me. Now the interval from the end A to that star, compared often with the already mentioned interval in the Hyades, seemed entirely equal to it; and so the diameter AB was, by every method, 71″ 30‴ or 72″.

[Margin: 3. Observation of the diameter of Saturn.]

IX. Third, in 1650, on the night following January 2, at hour 1 after sunset, Saturn stood, with its diameter AB, very nearly on the same straight line as the

already mentioned star lying west of it; and from other observations, as we said in Section 1, chapter 2, number 7, the line AB, that is, the line passing through the centres of Saturn and of the Saturnian companions, is parallel to the equator. But on the night following January 3, at the 2nd hour of the night, because Saturn was still moving retrograde along its orbit, which was not parallel to the equator, it had already become both more southerly and more westerly than the already mentioned star. And, as Father Francesco Maria Grimaldi observed most accurately, a straight line drawn perpendicularly from the star P to the line AB fell as nearly as possible through F, at R, cutting off exactly a fourth part of the diameter AB. Then, at 5¼ hours of the night, with Saturn moving back toward the west and leaving that little star behind, the star appeared on the perpendicular HL, so that the interval AL was exactly equal to the space AF, that is, to a fourth part of Saturn. (Here, however, F is taken for a point scarcely distant from Saturn's central disc, toward K, and placed in that dark interval, whether of aether or of some other body, which divides the companion AK from the body of Saturn itself, FG.) That moment of time was awaited and chosen because of the equality just mentioned, since before hour 5¼ LA was not yet equal to AF, and afterwards it was manifestly greater. Now the true daily motion of Saturn on that day was 4′ 30″, from the more accurate tables; therefore the hourly motion was 11″ 15‴; therefore from hour 2 to hour 5¼ the centre of Saturn, O, completed 36″ 34‴, that is, a space equal to its semidiameter AO. For when the perpendicular from the star P fell at R, AF was a fourth part of the whole AB; and when the perpendicular fell from H at L, LA was equal to AF; therefore LF was equal to the semidiameter AO. So the whole AB, from this observation, was 73″ 8‴. But above, from the earlier observations, it was 71″ 30‴ or 72″: the difference between such different ways of observing is plainly negligible, or rather the agreement is altogether marvellous, and it is reported in scrupulous good faith.

[Margin: The true diameter of Saturn is established.]

We shall therefore take Saturn's perigee diameter as 72″, or 1′ 12″, and FG as 34″ 30‴. From these, by Problem 1 of chapter 8, with Saturn's least distance from the Earth of 57743 semidiameters of the Earth, we shall gather its true semidiameter: the simple one, FO, 4⅘, and the composite one, AO, 10 8/100, in parts of which the Earth's semidiameter is one.

[Margin: And its apparent diameter at three distances.]

From the mean distance, 73000, and from the greatest, 90155, by Problem 2 of chapter 8, we shall deduce the apparent semidiameter: at the mean distance, the simple one FO, 13″ 20‴, and the composite one AO, 28″ 30‴; but at the greatest distance, FO, 11″, and AO, 23″; provided it is supposed that Saturn with its companions in its various phases keep the proportion of apparent size that arises from the variation of distance. Compare now with our observations the observation of Hortensius, to be given below in scholium 4.

Monitum Pro tabulis ſequentibus.

Notice for the following tables.

X. In the first table I have set out the apparent sizes of these five planets, and the true sizes derived from our distances by the geometrical problems of chapter 8. If, however, there is anyone who wishes to use the apparent diameters observed by us but the distances of others, and to gather the true size from these, so as to know within what limits we are certain of the size of these planets, according to the extreme opinions of the most celebrated astronomers, then to satisfy that person I have also constructed a second table. In it I have taken four of the more notable classes of distances, namely: that of Wendelen, and nearly that of Posidonius, derived from their distance of the Sun from the Earth; our own; the Keplerian; and the Tychonic, to which the Ptolemaic, al-Battānī's, the Copernican and that of a good many more recent writers are reduced with a small difference (as far as this business goes). Here, then, in the first table is collected what we think about these matters from our own observations.

I. TAB. MAGNITVDO APPARENS, ET VERA QVINQVE PLANETARVM Minorum ex obſeruatione noſtra Diametrorum, noſtriſque Diſtantijs.

Table 1. The apparent and true size of the five minor planets, from the diameters as we observed them and from our distances.

SCHOLIA.

Scholia.

I. There is a great dispute, or rumour, about the variation in the apparent size of Mars, since the prosthaphaereses necessary to recent astronomy, in its acronychal position, prove that it comes much closer to our Earth than the Sun does, as I said in Section 2, chapter 3, scholium 4, and in this Section 6, chapter 4, scholia 3 and 4, and chapter 7, number 3. Granting this, it seems necessary that it should appear very notably greater in its acronychal position, especially when it is at perigee in Aquarius in respect of both the eccentric and the epicycle, than near its apogeal conjunction with the Sun.

[Margin: The size of Mars as seen at perigee.]

As to the proportion, Galileo, in dialogue 3 on the World System, introduces Salviati inveighing against the Copernican system and objecting that, if Copernicus's hypothesis were true, Mars in opposition to the Sun would be seen with a disc sixty times greater than when it is most remote, whereas it does not turn out even four or five times greater than itself as it hastens to conjunction with the Sun. He then has the same man reply to himself and to Sagredo and Simplicio: namely, that if Mars is viewed with the naked eyes, near conjunction it appears larger than it is because of the adventitious rays that either the deception of our eye or that of the medium places around it, like a mane or curls; and so it then appears not much smaller than when it is nearest the Earth. But if it is viewed in both positions through a large telescope, which strips Mars of that adventitious hair, it is seen in opposition sixty or fifty times greater than near conjunction with the Sun: understand this of the disc, or area of the apparent circle; and so as to the diameter it is seen eight or seven times greater in ☍ than in ☌ with ☉, for circles are to one another as the squares of their diameters, by 2 of Book 12 of the *Elements*. But by our reckonings Mars at its least distance from the Earth appears 92″ in diameter, and at its greatest 10″ 6‴; that is, nine times greater. And so, as to the circle of its disc, it appears in perigee ☍, compared with itself in ☌, as 8464 to 101, that is, greater as to area by 84⅗ times.

[Margin: Mars believed to be a new star.]

Nor is support from experience lacking. For Kepler reports in the *Astronomia Optica*, p. 333, from Philipp Melanchthon, that in 1529, in the months of July and August, Mars was seen with so prodigious an appearance that it was believed to be a new star; and the same, he says, must have happened in 1561 in August, in 1593 likewise in August, and in 1608 in July. As for Gassendi's assertion, however, in Book 2 of the *Institutio Astronomica*, chapter 9, that Mars at apogee scarcely equals stars of the second magnitude, and at perigee rivals the size of Venus and Jupiter, that must be taken to mean that it then surpasses Jupiter but is surpassed by Venus. But what are you to do with Kepler? In the *Epitome of Copernican Astronomy*, p. 485, he had said: "Mars, acronychal and at perigee in Aquarius, does appear greater than Jupiter, yet not by much", asserting in the same place that Jupiter at perigee had often seemed to him to be 50″. Afterwards,

in the Rudolphine Tables, precept 110, he errs first (if he is speaking of ♄ with its companions) in saying that ♄ never appears greater than about 30″; and presently he says that through the telescope the semidiameter of Mars, when it approaches the Earth, ought to be seen as 3′ 15″, and therefore its diameter as 6′ 30″, which he says is grounded on the equal proportion between the intervals from the Sun and the bodies of the planets, treated in the *Epitome*.

[Margin: The apparent size of Venus at perigee.]

II. Venus too is remarkable in this variation. For it Kepler, in the same place of the Rudolphine Tables, gathers from his own hypotheses a semidiameter of 3′ 33″ at perigee, and so a diameter of 7′ 6″, and that as seen through the telescope.

[Margin: Venus believed to be a new star.]

For although it is true, as he says in the *Optics*, p. 333, that Venus has quite often been believed to be a new star, as in 1603 in February and March, because, as is said in the same place, it was seen through clouds and horizontal refractions, and other optical causes concur toward this sort of quasi-prodigy (so much so that once at Parma Doctor Claudius Achillinus [Claudio Achillini], and later at Bologna others on three occasions, likewise appealed to me to indicate whether a star of unusual size, seen by chance at that time in the public square, was one of the comets; and I answered them, and not wrongly, that it was Venus), yet it is plainly false, what he says in the Rudolphine Tables, that it ought to be seen through the telescope as 7′ 6″ in diameter, since we, with an excellent spyglass, saw it close to the perigee of the epicycle as no greater than 3′ 30″. Truer, however, is what Galileo asserts in dialogue 3 on the World System: namely, that Venus to the naked eye does not appear much smaller at apogee than itself at perigee, but that if it is viewed with the telescope, and its adventitious hair is taken away, it appears forty times smaller at the apogee of its epicycle or orb than at perigee. For by our reckoning it would appear there 33″ 30‴ and here 4′ 8″; therefore, with the diameters squared, the disc there is 860″ and here 48325; therefore the area of the apogeal circle is smaller than the perigeal by 56 times, granted that as to the diameter it may appear only seven times smaller there than here.

[Margin: Kepler's analogy between the intervals and masses of the planets is false.]

III. From our observations and those of Hortensius concerning the diameters of the planets, those Keplerian analogies between the masses of the planets and their intervals, otherwise sought out with so much ingenuity and expounded by us in chapter 7 from number 7, now manifestly collapse. He had set up an analogy between the surfaces of the bodies and the intervals, judging that the surfaces of the planets are to the surface of the Earth as their interval from the Sun to the Earth's interval from the Sun, from which it followed that the proportion of the bodies is sesquialteral of the proportion of the intervals. Just as he abandoned that analogy, and on seeing a few observations of Johannes Remus Quietanus on the apparent diameters of the planets said on p. 485 of the *Epitome*:

"I yield place, however, to Remus, I yield to the observations"; and just as in the Rudolphine Tables, at the end of precept 110, which concerns the investigation of the planets' apparent semidiameters, he added: "I assume, however, in the foundations of this precept, from the *Epitome of Copernican Astronomy*, that the bodies of all the planets are in the proportion of the intervals between them and the Sun, and therefore their diameters in the subtriplicate. Let judgement and censure rest with whoever shows a more probable proportion": so, without doubt, if he had seen the observations of Hortensius, Gassendi, Vicenç Mut, Father Grimaldi and our own, he would with the same candour and love of truth have yielded place to them and have abandoned that very analogy. He would indeed have looked for another, so that the Copernican hypothesis and the *Mysterium Cosmographicum* might not be undermined, but in vain. For I shall teach more lucidly, God granting, in Book 9, where the system of the world is treated, that GOD did not geometrize so materially that he begged the proportions of bodies from the mere intervals themselves, or sought no other praise for his works than from geometry of this purely mathematical kind.

[Margin: A specimen of the observations of Hortensius and Gassendi.]

IV. Further, let us draw a specimen of Hortensius's observations from his dissertation with Gassendi. He had found the field of his tube to be 42′, because it took in exactly both the space between the two Kids [Hœdos], which for Tycho are 42′ apart, and one and a quarter times the Moon when the Moon was 33′ 30″. He saw two contiguous stars in the following horn of Capricorn distant from each other by an eighth part of the tube's field, that is, 5¼′, and two contiguous stars of the Hyades distant from each other by very nearly the same amount; and a fifth part of this small space was occupied, as he saw in 1632, by the diameter of acronychal Jupiter, that is, 1′, the size at which Gassendi too estimated the diameter of Jupiter, inspected through a tube, in 1630.

[Margin: The diameter of Jupiter observed by Hortensius and Gassendi.]

Again, in the same year 1632, on November 13, the day on which Jupiter was opposite the Sun, he received Jupiter's image on paper through the glasses of the telescope. Though it appeared with faint edges, it yet seemed round to a keen effort of the eyes, and its diameter was of 4 parts of which the Sun's diameter, taken the day before with the same telescope on a small board, had been 130. And again on another day he found that the diameter of the Jovian image equalled 6 parts of which the solar diameter was 195. So, since the Sun's diameter was then 34′, he concluded that Jupiter's diameter was 1′ in its acronychal position.

[Margin: The diameter of Venus and of Mercury observed by Hortensius.]

He determined the diameter of the remaining planets by observing them by direct sight through the telescope and comparing them both with the interval of the contiguous Hyades and with Jupiter's diameter as received on the board, when it was of the size A———B and, compared with the Sun's diameter, was 48″. At that time Venus's diameter was seen to be to AB as ⅓ to 1, and Mercury's to Venus's diameter as ⅔ to 1, when both were approaching their

apogeal conjunction with the Sun. Hence he inferred that the apogeal diameter of Venus is 15″ 20‴ and that of Mercury 10″. From Lansbergen's distances he deduced the perigeal diameter of Venus as 1′ 40″ and of Mercury as 28″; but he erred, because he did not see Venus at perigee in the appearance in which we did.

[Margin: The diameter of Mars observed by Hortensius and Gassendi.]

Mars too, in 1632 on February 9, in its acronychal position and joined to the Moon, he observed in some fashion through the tube, and he saw that its distance from the Moon's limb did not take up one lunar digit, and that Mars's diameter was contained about four times in that distance. The lunar digit was then 2′ 42″; so for him the diameter of Mars was then not much greater than 36″. This agrees with Gassendi, for whom it then stood between 30″ and 40″. Mars was then near the apogee of its eccentric. Accordingly, from Lansbergen's distances he concluded that the diameter of Mars at both apogees is 9″ and at perigee 1′ 4″: an error not indeed to be wondered at, from so slippery an observation.

[Margin: The diameter of Saturn observed by Hortensius.]

Finally he relates that in 1625, in February, Saturn at perigee in ♌ and round was seen very nearly equal to Jupiter, which had 40″ in diameter; but that in 1632 Saturn alone was seen as 36″ of the measure in which Jupiter was 40″, while with its appendages of little globes, which did not wholly stand out, it was seen as one minute, 1′. Accordingly, from the distances he gathers Saturn's apogeal diameter without companions as 31″ and the perigeal as 42″ 40‴. But if he had seen Saturn at both perigees, and with our larger telescope, he would have come closer to the truth.

[Margin: The diameter of Mercury observed by Gassendi.]

As for Gassendi, as he himself reports in Book 2 of the *Institutio Astronomica*, chapter 14, he observed Mercury under the Sun in 1631, on the morning of November 7, when, he says, it painted itself on the disc of the Sun with its own little shadow, on paper on this side of the telescope, and its diameter could be compared with the Sun's diameter, and it was found to be 20″ or at most 23″. This wonderfully favours our observations, by which Mercury at both perigees is 25″ 36‴; for it was then indeed at the perigee of the epicycle, but near the apogee of the eccentric.

[Margin: A dispute between Scheiner and Galileo about the diameter of Venus.]

V. Our Scheiner had said, in his letters to Markus Welser of the year 1611, that Venus at perigee, unless latitude prevents it, can be seen when it is under the Sun; but that on December 11, from Magini's Prutenic tables and ephemeris, Venus was in conjunction with the Sun with a latitude of 9′ and yet was by no means seen, although it should have been seen like a large spot, since its apparent diameter, by the assertion of Tycho and Clavius, is to the solar in subdecuple proportion, and so of at least 3′, and it lacks its own light. Therefore, since it was not seen by him when he observed this most attentively with a Dutch tube [tubo

Belgico], he concluded that Venus, then at apogee, had been above the Sun. But Galileo, in his letters to the same Welser, especially p. 110 and following, reproves these authors for having observed Venus by night, gleaming all round with adventitious hair, rather than by day or with the telescope, when its genuine size appears, and for having pronounced indifferently that the diameter of Venus is a tenth part of the solar, since at apogee and in morning conjunction, in which Venus was on that December 11, it is not a two-hundredth part of the solar diameter, that is, it is scarcely 10″; and he says that those opposed to the motion of Venus around the Sun can therefore say that it was not seen under the Sun either because of the smallness of its diameter, or because it is always above the Sun, or because it shines with some light of its own. Afterwards Scheiner, in the *Sol Ellipticus*, p. 25, reports that the diameter of Venus was observed by him in 1612, its radiant image being received on paper through the glasses of an optical tube, with the same separation of the lenses and distance of the paper by which it held the Sun's image, then 34′. And compared with the Sun's diameter with the help of a compass, the diameter of Venus was found on October 23 to be 2′ 40″, but on November 27 and 29 to be 2′ 12″, and on December 26 to be 2′ 0″. He admits, however, that that observation was a shadowy one, and reserves a complete treatment of this matter for another time. Venus had by then risen far from the lowest apsis of the epicycle. He therefore concludes, and confirms what he had said in the *Apelles post tabulam*: namely, that it would have come about that Venus was seen under the Sun because of the size of its diameter.

[Margin: Criticism of Scheiner.]

But in truth this is concluded only on the hypothesis that the opponents should grant that the conjunction took place at the perigee of the epicycle. For though Scheiner is a friend to me, truth is a greater friend. Hortensius, moreover, from this observation of Scheiner's and from Lansbergen's distances, concludes, not absolutely but hypothetically, that Venus's apogee diameter is 34″ and its perigee diameter 3′ 42″. This supports our observations wonderfully. And Scheiner rightly refutes Tycho, who assigns Venus a diameter of 3′ 15″ at mean distance.

[Margin: Earlier and rougher observations of Johannes Hevelius.]

VI. It remains for us, in the last place, to point out the observations of Johannes Hevelius, the last to become known to us, from his *Selenographia*. In chapter 3 of that work he rightly advises that, to strip the discs of stars, especially those of livelier light, of their adventitious rays, the convex lens of the telescope that is farther from the eye should be covered with a small perforated metal leaf [bracteola], whose hole should be about the size of a pea. In this way, he says, Arcturus appeared to him larger than Aldebaran [Palilicium], and Aldebaran larger than Regulus.

[Margin: Diameter of Venus and Jupiter.]

And on 1644 March 22, at 7^{h} in the evening, Venus, very close to Jupiter, was seen to be smaller than Jupiter, although to the naked eye it had appeared

much larger; we too have observed this about Venus more than once. And in chapter 4 he affirms that on 1645 January 13 Venus appeared to him to be of about 10 digits, but on 1646 April 21 of less than one digit. Then he relates that on 1644 November 22, at 7^h in the morning, Mercury appeared to him smaller than Mars and than 1½′ [ſeſquiminuto].

[Margin: Diameter of Mercury.]

And on 1645 May 16, at $8½^h$ in the evening, Mercury, still sickle-shaped, appeared to him larger than fixed stars of the first magnitude through a tube fitted with the leaf mentioned above. He admits, however, that even in this way Mercury is not stripped of all its adventitious rays, because of its very close neighbourhood to the Sun, which prevents it from being seen by day; whereas Venus, visible by day at its great digressions from the Sun, is denuded of that borrowed head of hair by the prevailing light of day itself, and much more so if the already mentioned leaf is applied.

[Margin: Somewhat better observations by the same man.]

So much for Hevelius's rougher observations. For later, in chapter 55, he teaches a way of estimating the diameters of stars by comparison with the spots of the Moon; on this see our judgement above, chapter 9, at the end of Method 8.

[Margin: Diameter of Jupiter and Venus.]

Yet by that method Jupiter appeared to him, on 1646 April 22, to have a diameter of 1′ 2″. And in chapter 56 he reports that on 1647 January 20 the diameter of Jupiter, compared with the spots of the perigee Moon, appeared to him to be 1′, or 55″, if the Moon's diameter was then 34′ or 31′. Earlier, however, in chapter 55, he had said that on 1646 April 22 Venus, observed by him in the same way, at the perigee of the epicycle, was 1′ 22″, and that in 1644, about the morning □, it appeared to him to be 46″: understand quadrature, when it appears dichotomous. Therefore the 10 digits mentioned above are to be understood of the phase of Venus, showing 10 of its 12 parts illuminated.

CAPVT XI.

Chapter 11.

Noſtræ & Aliorum Obſeruationes circa Diametros Apparentes Fixarum, ex Planetarum Diametris deductas, cum Vera Fixarum Magnitudine, tam ſecundùm noſtras, quàm ſecundùm aliorum diſtantiam Fixarum à terra vel aſſertam vel aſſerendam.

Observations, our own and others', on the apparent diameters of the fixed stars, derived from the diameters of the planets, with the true size of the fixed stars, according both to our distance of the fixed stars from the Earth and to the distance that others assert or must assert.

I. In Book 6, chapter 9, because of the dependence that the observation of the diameter of the fixed stars has on the observation of the diameter of the planets, and because of the affinity of the evidence, we put off to this place the observations of the fixed stars made on their apparent diameters and then finally confirmed from here, after the firm determination of the diameters of Jupiter and Saturn. The principal method, and the most evident of all, was this. On white paper we drew various images, circular ones for the disc of Jupiter and egg-shaped ones for Saturn with its companions. And having inspected both planets long and often through a large telescope, we chose from the many that figure which, as the eye was brought at once and repeatedly from the telescope to the paper, seemed of all the most closely matching the size of the planet's disc as it then appeared. But so as not to trust our own eyes alone, Father Grimaldi and I, both together and separately, brought in the eyes of several others as co-witnesses, who, forewarned of nothing about the figure chosen by us, were themselves to choose the one that seemed the closest match.

[Margin: See the figures in chapter 10, number 8.]

And so at the end of 1649 and the beginning of 1650 that figure of Saturn and of Jupiter was chosen which we showed in chapter 10, number 8. At that time, from what was said there, the apparent diameter of Saturn was 34″ 30‴ and that of Jupiter 44″. We divided the diameter BZ of Jupiter's disc into 200 small parts, of which an uncia of the Roman foot is 100; and of such parts the inner diameter, that of Saturn alone, FG, was 160. With these prepared, we again drew on paper a number of small circles of larger and smaller diameter; and having inspected through the same telescope the fixed stars discussed below, and frequently turning the eye back to those small circles, we chose the one that seemed most nearly equal of all to the size of the fixed star. Then others were brought in separately, above all Father Paulo Casato [Paolo Casati] and Father Matthęo Tauerna [?], outstanding professors, the former of philosophy and the latter of sacred oratory, and most fit to discern such things for the sharpness of their eye and mind and the keenness of their judgement. Using the same telescope, each of them, with a truly wonderful agreement, chose those very figures that Father Grimaldi and I had chosen. And so, with all the anxiety and suspense that had held us until then removed, and rejoicing, as it were, over stars caught in so noble a fishing, we took the diameters of those small circles with a very sharp compass and applied them to the diameter of Jupiter and of Saturn; and from the proportion they had to these we drew out the apparent size of the diameter of the fixed stars listed below, and rested in it with complete confidence. Nor do we doubt that, if all the experiments mentioned are repeated by skilled men who are not steeped in others' opinions on the size of the planets or the distance of the fixed stars, and who use a suitable spyglass and suitable witnesses, they will agree with us without any perceptible difference.

[Margin: Why Hortensius's opinion on the diameters of the fixed stars is suspect.]

II. For we know, certainly, that Hortensius, in his dissertation with Gassendi, greatly reduced the diameters of the fixed stars, so far as to allow only 10″ to Sirius and 8″ to the other stars of the first rank. But he did so for two reasons. First, because in comparing their diameter with Jupiter's he used a telescope showing too small an image of Jupiter, as is clear from the schematism of the image he gave, which we discussed in scholium 4 of chapter 10. For its diameter was only 60 parts, of which the diameter of our Jupiter, close to apogee, was 200; so that in working out the proportion itself the danger of error lay more readily in the smaller measure than in the larger. Second, because he was wholly given over to defending the Copernican hypothesis as regards the distance of the fixed stars required in it, so that the parallax of the fixed stars arising from the Earth's annual motion should not prove perceptible. But since from so great a distance there follows a size of the fixed stars that is excessive and has seemed monstrous to most people, he thought, in order to water down that charge, that the diameters and sizes of the fixed stars should be watered down. I gather this both because he concludes: "It does not follow, then, from the Copernican motion of the Earth that the size of the fixed stars is increased beyond measure, since we see that they are much smaller than the Earth's annual orb, against certain people"; and from that very quasi-cunning by which both he and Lansbergen expressed the size of the fixed stars compared not with the globe of the Earth, lest it seem excessive, but with the sphere of the Earth's annual orb.

[Margin: Lansbergen's false opinion on the same diameters.]

And yet Lansbergen, in the *Uranometria*, Book 3, element 20, following neither Hortensius nor others, sets a rather larger diameter of the fixed stars at his mere discretion, in these words: "Al-Battānī defines the apparent semidiameter of the non-wandering stars of the first magnitude as 45″, and Tycho Brahe as 1′; we, as ½′. For through the optical tube it appears much smaller still." As if, indeed, more trust were not to be placed in the tube, which strips the discs of the stars bare and scrapes away their adventitious curls of rays, than in the naked eye or the mere judgement of an arbitrary estimate.

[Margin: Galileo's false opinion on the same diameters.]

III. Galileo and Kepler labour, in our view, under a suspicion similar to that under which Hortensius labours. For Galileo, in Dialogue 3 on the world system [de ſyſtemate Coſmico], replying to those who had objected to the Copernican hypothesis the immensity of the fixed stars that arises from it, does rightly teach that before the use of the Dutch glass [ſpecilli Belgici] astronomers went much too far in the size of the apparent diameter of the minor planets and of the fixed stars. Yet he himself falls too far short of it when he denies that stars of the first magnitude exceed 5″, and says that it therefore does not follow that they are larger than the Earth's annual orb. For he can easily be convicted of falsehood by anyone who uses a telescope larger and more perfect than Galileo's tubes. And how deceptive the method of observing these diameters

by a suspended thread is, we have shown sufficiently in Book 6, chapter 9, number 3.

[Margin: Kepler's twofold opinion on the diameter of the fixed stars.]

Kepler too, in the book *De Stella Nova*, chapters 16 and 21, before the use of the telescope, had allowed 4′ to Sirius and at least 2′ to any star of Orion's belt. Afterwards, in the *Epitome of Copernican Astronomy*, p. 498, to the small question "How large do the fixed stars appear, seen from the Earth?" he answers: "Skilled craftsmen deny that any size, as of a round body, is detected by inspection through the telescope, because rather, the more perfect the instrument, the more the fixed stars are represented as mere points, from which bright rays go out in the form of hair and are scattered." In the same place he also judges that the Sun is larger in bulk of body than the fixed stars. But leaving these matters aside, we shall follow the evidence of the observations carried out by us with a large and very powerful telescope, and we shall append the following tables, with the true size derived from various distances, so that they may be ready for every outcome of the dispute, especially on behalf of the Copernican hypothesis.

[Margin: How the stars may appear round and without rays.]

That the skilled craftsmen of whom Kepler has just spoken saw the fixed stars as radiant points must be thought to have come about, if not from imperfection of the eyes, then at least from the way the telescope was used. For if they had laid over the lens farther from the eye a leaf or plate [bracteam ſeu laminam] pierced in the middle, with a hole whose diameter equals about a quarter of an uncia of the Roman foot, they would have seen the fixed stars so shorn of adventitious rays that they both appeared perfectly round, and, not as points but as small discs so enlarged by the power of the telescope, showed a definite size to one comparing them with the disc of Jupiter or Saturn, whose size is known in the manner we stated above. I said "about" because that hole should be somewhat larger for the smaller stars and smaller for the larger ones, as will be clear to anyone who tries it.

I. TABVLA. OBSERVATIONES DIAMETRI Apparentis Fixarum, comparatæ cum Diſco Saturni ſolius quando erat 35″. & Iouis quando 44″. ſed illius diametro diuiſâ in 160. huius in 200. particulas

Table 1. Observations of the apparent diameter of the fixed stars, compared with the disc of Saturn alone when it was 35″, and of Jupiter when it was 44″, the diameter of the former being divided into 160 small parts and that of the latter into 200.

Fixed stars	In parts of which the diameter of ♄ is 160, of ♃ 200	Hence the apparent diameter is	Old order of magnitude
Sirius	82	18″ 0‴	1
Bright star of Lyra	79	17″ 24‴	1
Arcturus	76	16″ 42‴	1
Capella	73	16″ 8‴	1

Fixed stars	In parts of which the diameter of ♄ is 160, of ♃ 200	Hence the apparent diameter is	Old order of magnitude
Aldebaran	70	15″ 24‴	1
Spica	68	15″ 5‴	1
Regulus	64	14″ 5‴	1
Regel	62	13″ 40‴	1

For the foundations of these distances see Book 6, chapter 7, number 15.

CAPVT XII.

Chapter 12.

De Quantitate Maximarum Digreſſionum tum Iouialium Satellitum à Ioue; tum Veneris ac Mercurij à Sole.

On the amount of the greatest digressions, both of Jupiter's satellites from Jupiter and of Venus and Mercury from the Sun.

I. If you remember, in this book, section 1, chapter 3, number 5, we promised an exact determination of the greatest digression of the Medicean planets from Jupiter in minutes and seconds, once Jupiter's diameter had been established, since nearly all who have measured those digressions with the telescope use as their measure the diameter of Jupiter itself. So Galileo in the *Sidereus Nuncius*; Simon Marius in his *Mundus Iovialis*; Kepler in the *Dissertatio cum Nuncio Sidereo* and in the *Epitome of Copernican Astronomy*, p. 554; Scheiner in the *Disquisitiones Mathematicae*, number 39; Hérigone in volume 5 of the *Cursus Mathematicus*, p. 580; and Antonín Maria Šírek in the *Radius Sidereomysticus*, Book 4, chapter 4, who adds their greatest distance from Jupiter in semidiameters of the Earth, but supposing Jupiter's diameter to be 3′. Further, Kepler, and Wendelen in a letter given to me, subscribe to the digressions determined by Galileo and Marius, because it follows from them that the periodic motions around Jupiter are in the sesquialteral ratio of the ratio of their intervals from Jupiter. Hérigone, moreover, judges that these digressions were determined from Jupiter's mean distance from the Earth. Yet Hevelius, in chapter 4 of the *Selenographia*, assigns to the innermost satellite 3′, to the next-to-innermost 5′, to the next-to-outermost 8′, and to the outermost 13′ or 14′, as regards digression from Jupiter: as if, when Galileo and Marius observed these digressions and rated them at just as many Jupiters, Jupiter appeared to be of 1′. Their opinions, then, are in the following small table.

Digreſſio Maxima Satellitum ♃ à Ioue

Greatest digression of the satellites of ♃ from Jupiter.

	Diameters of Jupiter			Semidiameters of the Earth
Satellites	Galileo and Marius	Scheiner	Šírek	Šírek
1	3	3	3	20¾
2	5	4	4	27
3	8	5	6	41
4	Mar. 13; Galil. 14	10	10	69½

Kepler, Hérigone, Wendelen and Hevelius side with Galileo and Marius.

II. But to determine this distance we need, besides the number of Jupiter diameters by which they have been seen to digress most from Jupiter (a number that is perhaps variable because of the narrower or wider circuits that the same satellite describes around Jupiter), both the apparent diameter, as observed by us, and Jupiter's mean distance from the Earth. For from these, by the problem to be brought forward in number 5, we shall easily determine that digression in semidiameters of the Earth, not only from our distance of Jupiter from the Earth but also from that of others, so that readers may be better satisfied. Here, then, is the table we constructed for this purpose.

DIGRESSIONES MAXIMÆ SATELLITVM IOVIS A IOVE In Minutijs reſpondentibus Iouis diametro in Media ipſius Diſtantia per nos obſeruatæ, iuxta numerum diametrorum Iouis, digreſſionibus attributum, & in Semidiametris Terræ.

Greatest digressions of Jupiter's satellites from Jupiter, in minutes corresponding to Jupiter's diameter as observed by us at its mean distance, according to the number of Jupiter diameters assigned to the digressions, and in semidiameters of the Earth.

Diameters of Jupiter		3	4	5	6	8	10	13 [?]	14
Minutes for the diameters of ♃		2′ 30″	3′ 20″	4′ 10″	5′ 0″	6′ 40″	8′ 20″	10′ 50″	11′ 40″[75]
Authors of the distance of ♃	Mean distance of ♃, in semidiameters of the Earth	Semid. of the Earth	Semid. of the Earth	Semid. of the Earth	Semid. of the Earth	Semid. of the Earth	Semid. of the Earth	Semid. of the Earth	Semid. of the Earth

We	36500	24	36	44	53	71	89	115	124

[Margin: Use of the preceding table.]

III. The table is used as follows. First choose, in the earlier small table, the opinion you prefer on the number of Jupiter's diameters contained in the greatest digression of any one of the satellites from Jupiter, and look for that number at the head of this table. Under it you will have how many minutes and seconds are comprised, in the heaven of Jupiter, by the angle made by lines drawn from our eye, one to the centre of Jupiter's body, the other to the centre of the satellite at its greatest digression from Jupiter. In the same column you will also have the semidiameters of the Earth corresponding to that digression, opposite the mean distance of Jupiter from the Earth according to whichever author you have chosen. For example, if you think with Galileo that the remotest or outermost satellite digresses from Jupiter as far as 14 diameters of Jupiter, you will see under 14, in the last column, 11′ 40″ set below, and at the foot of the column 124 semidiameters of the Earth corresponding to our distance of Jupiter, which we judge the truer. And this same value is the semidiameter of the epicycle the satellites are thought to describe around Jupiter.

[Margin: How large Jupiter appears when viewed from the satellites.]

Anyone who wishes to know how large Jupiter appears when viewed from its satellites should consult small table 3 of chapter 13 below.

De Quantitate Digreſſionum Veneris ac Mercurij à Sole ipſo vel à linea medij loci Solis.

On the size of the digressions of Venus and Mercury from the Sun itself or from the line of the Sun's mean place.

IV. Venus and Mercury too are, as it were, satellites of the Sun. On Tychonic principles Biancani, in his *Sphaera*, Books 11 and 12, and after him Andrea Argoli in the *Pandosion Sphaericum*, chapters 58 and 59, define their greatest elongations from the Sun as 855 semidiameters of the Earth for Venus and 585 for Mercury, and they think that the semidiameter of the epicycle these planets describe around the Sun is just as large. In the opinion of other astronomers, however, this measure varies, both because of the varying distance of the Sun from the Earth that each posits from his own hypothesis, and because of the varying angle they attribute to the greatest digression, and the distance of these planets

from the Earth, which varies by reason of the eccentric. To resolve the small astronomical questions that could be raised on this point, it will be enough for us to take the mean distance of the Sun and of these planets as the same, and the angle of greatest digression, already known from Section 3, chapter 7; and from these data, according to the better-known opinions, to reduce the size of these elongations to semidiameters of the Earth. By the old astronomy these are to be understood with respect to the line of the Sun's mean place; by the recent astronomy, with respect to the centre of the Sun's body. Let this therefore be the

Problema. Data Solis Diſtantia mediocri à Terra, & arcu vel angulo maximæ Digreſſionis à Sole ♀, ac ☿, vel Satellitum Iouis à Ioue, Inuenire quantitatem Digreſſionis in ſemidiametris terræ.

Problem. Given the Sun's mean distance from the Earth, and the arc or angle of greatest digression of ♀ and ☿ from the Sun, or of the satellites of Jupiter from Jupiter, to find the size of the digression in semidiameters of the Earth.

V. In their greatest digressions from the Sun, just like the satellites in theirs from Jupiter, these planets stand (if you consult the figure given in Book 3, chapter 11, number 3) at M or F, the point of their epicycle at which the straight line BM or BF, drawn from our eye B, touches the epicycle QDF. By Euclid 3.18 it therefore makes a right angle at M and F with the epicycle's semidiameter AM or AF, and the right triangle AFB or AMB arises. If the angle ABM or ABF is given, solving this triangle readily gives the size of the side AM or AF, in measures of the same kind as those in which the distance of the centre A, of the Sun or of Jupiter, from the Earth B is known. In short, then, make: as the radius is to the distance of the Sun or Jupiter from the Earth, so the sine of the angle measuring the greatest digression is to the side AM or AF. Or more briefly: to the logarithm of the distance AB add the logarithm of the angle just mentioned, and the result will be the logarithm of the side AM or AF, that is, of the distance sought.

But if, from the measures of the hypothesis itself, the size of the greatest semidiameter of the epicycle, or of the orb equivalent to an epicycle, is already known in semidiameters of the Earth, that value, with no further computation, will be the distance we are seeking here. Consult, therefore, the following small table.

MAXIMÆ DIGRESSIONES ♀ ac ☿ à ☉ vel à linea medij loci Solis; in ſemidiametris Terræ.

Greatest digressions of ♀ and ☿ from the ☉ or from the line of the Sun's mean place, in semidiameters of the Earth.

Measured	According to the authors	♀, semid. of the Earth	☿, semid. of the Earth
From the line of the mean ☉	Ptol. Maur. Clau.	461 41′	43 31′
From the line of the mean ☉	Jean Fernel	495 42′	43 53′
From the line of the mean ☉	Copernicus	821 0′	451 0′
From the line of the mean ☉	Michael Mästlin	834 0′	459 0′
From the line of the mean ☉	Lansbergen	1077 0′	708 0′
From the ☉ itself	Tycho and Biancani	855 0′	585 0′
From the ☉ itself	Longomontanus	931 0′	496 0′

From the ☉ itself	Boulliau	1057 0′	563 0′
From the ☉ itself	Ourselves	5339 0′	3322 0′

CAPVT XIII.

Chapter 13.

De Magnitudine Apparenti Planetarum, Fixarum, Telluris, ac Orbium aliquorum, ſi aliunde ſpectentur, quàm ex Terra.

On the apparent size of the planets, the fixed stars, the Earth and certain orbs, if they are viewed from somewhere other than the Earth.

I. Long ago, in Book 2, chapter 6, scholia 4 and 5, we inquired whether this Earth of ours, which seems and is so large to us, would look like a point when viewed from some heaven, and we brought forward no contemptible learning from Cleomedes and Maurolico, even though we did not complete the whole problem there but offered only a specimen of it. Then in Book 3, chapter 10, scholium 4, we showed how large the Sun would appear to a spectator placed on each other planet, from the calculation of Boulliau and of Antonín Maria Šírek, assuming Kepler's intervals. Now, however, a more universal treatment must be given, since in the preceding chapter we have completed our discussion of the intervals of the planets and the fixed stars from each other, and the true diameter of the stars, according to the opinions of the more distinguished astronomers, is already established. We need these two elements to solve the following problems. But before them I will give a foretaste of what certain others, besides the four authors already mentioned and just listed, have indicated to us on this matter.

[Margin: Scheiner's statement on various moons.]

Scheiner, then, in the *Disquisitiones Mathematicae*, towards the end, number 43, says: *But if a person were stationed on Saturn, he would see absolutely all the planets like moons; and from their number the sunspots are not to be excepted either, if they are stars or enduring bodies.* For it is assumed that they and the planets have

their primary light from the Sun. Therefore, with the eye placed on Saturn, all the other planets would go around the Sun, with respect to that eye, in the way Venus and Mercury now do; and similar phases would also appear on Saturn if the eye were above Saturn at some moderate distance, and on the little planets of Jupiter with the eye outside their epicycles but placed not far away.

[Margin: Kepler's teaching on the Moon and on the Moon's digressions from the Earth when viewed from the heaven.]

So Kepler too observes in the *Dissertatio cum Nuncio Sidereo*, p. 11 ½, where he also says that the diameter of the Moon's orbit, since it is scarcely the thirtieth part of the diameter of the Earth's own great orbit around the Sun, seems less than 2° when viewed from the Sun; and since the height of Saturn is about tenfold, and that of Jupiter about fivefold, the distance of the Earth from the Sun, the Moon viewed from Saturn cannot therefore digress from the Earth beyond 18′ or 12′, and viewed from Jupiter not beyond 36′ or 24′. He then adds: *Let the Sun's parallax be 3′, even though I think it much smaller. The Earth viewed from the Sun will then have 6′, the Moon 1½′. Indeed a much smaller Earth will also leave less to the Moon, namely not 1′. And this, viewed from Saturn, perhaps 6″ secon- ds will be seen; and from Jupiter, 12″. It is plainly so, then: what the Moon is to us on our Earth, it is not to the other globes,* that is, it does not appear either so large or with so evident a change of phases. *And what those four little moons are to Jupiter, they are not to us; and in turn each of the globes of the planets, and its inhabitants, are served by circulators of their own.*

[Margin: Inhabitants on Jupiter, posited by Kepler.]

From this consideration we conclude about inhabitants of Jupiter with the highest probability; and this indeed seemed equally so to Tycho, from the consideration of the vastness of those globes alone.

[Margin: How large the Sun or the annual orbit appears from Saturn, or the orb of Saturn and of the Earth viewed from the fixed stars, according to Kepler?]

The same author, in the book *De Stella Nova Serpentarii*, chapter 16, assumes that, since the Sun's semidiameter seen from the Earth is 15′ and Saturn is ten times higher, the Sun's semidiameter viewed from Saturn seems ten times smaller, namely 1′ ½. And because he posits the semidiameter of Saturn's sphere as a mean proportional between the semidiameter of the Sun and the distance of the fixed stars, the semidiameter of Saturn's sphere viewed from the Sun therefore appears as 1′ ½. Hence, since the semidiameter of the annual orb is the tenth part of the diameter of the orb of ♄, he infers that the semidiameter of the Earth's annual orb seen from the fixed stars appears as no more than a tenth part of 1½′, that is, 9″, and that the parallax of the fixed stars produced by the semidiameter of the annual orb is that large. On this, however, see what I said in Book 6, chapter 7, number 11.

[Margin: How large some fixed stars would be if viewed from other fixed stars?]

II. In chapter 21, moreover, he asserts that the three stars in the belt of Orion, of the second magnitude, have at least 2′ in diameter and are 81′ apart from each other. Hence, if they lie on the same spherical surface, of which we are the centre, then with the eye placed on one of those stars, another will appear under an angle of about 2 ¾°, an amount that five Suns set in a row and touching one another would not occupy for us on the Earth. Finally, in the *Epitome of Copernican Astronomy*, p. 497, he asks how large the Sun appears when seen from the fixed stars, and answers that it is seen under an angle of 6‴, which is the six-hundredth part of 1′: for he had already posited that they are 60,000,000 semidiameters of the Earth distant.

[Margin: The Earth viewed from Jupiter.]

Hérigone, however, in volume 5 of the *Cursus Mathematicus*, p. 665, affirms that the apparent conjunctions of the satellites of Jupiter occur at almost the same moment everywhere on the Earth, because the Earth viewed from Jupiter is smaller than 1′, since Jupiter, which is larger than the Earth, does not appear larger than 1′ when seen from the Earth. If you join these points with what we said in Book 2, chapter 6, scholium 5, and Book 3, chapter 10, scholium 4, then besides the varied learning that will delight you, you will see how important are the problems we are going to give in this chapter.

Problema 1. Quanta ſit apparitura Tellus viſa ex Planetis vel Fixis Stellis?

Problem 1. How large will the Earth appear when seen from the planets or the fixed stars?

[Margin: First way of solving the problem.]

III. First, take the horizontal parallax of the Sun from Book 3, chapter 8, and of the Moon from Book 4, chapter 14; that of the other planets from chapter 7 of this Section, and that of the fixed stars from Book 6, chapter 7; and double it. In this way you will obtain the apparent diameter of the Earth viewed from the planets or from the fixed stars.

[Margin: Second way.]

Second, another way: in the figure added here, solve triangle CAB, right-angled at the contact B, or triangle CDP, right-angled at the contact D, if the base CA or CP is given, as is assumed, that is, the distance of the planet or fixed star C from the centre of the Earth placed at A or at P, in parts of which the Earth's semidiameter AB or PD is one; and find the angle ACB or DCP. Its double will be the measure of the diameter of the Earth as it will appear to the eye placed at C.

Diagram. Woodcut set in the left column beside number III. Two circles of equal size stand one above the other, with a point below them from which three lines rise: one to the upper circle's centre through the lower circle's centre, and one to each circle's left edge, where a radius meets it.

- A (centre of upper circle, right of the vertical line): centre of the Earth, as the text says
- B (left edge of upper circle): contact of the line from C; AB is the Earth's semidiameter
- P (centre of lower circle): centre of the Earth in the second position
- D (left edge of lower circle): contact of the line from C; PD is the Earth's semidiameter
- C (foot, where the lines meet): the planet or fixed star; the eye

Problema 2. Quanta ſit apparitura Stella quæuis ſiue Errans ſiue Inerrans, ſpectata ex aliquo Planetarum, aut ex Fixis in maxima aut minima ab ipſis diſtantia.

Problem 2. How large will any star, wandering or non-wandering, appear when viewed from one of the planets or from the fixed stars, at its greatest or least distance from them?

IV. Take from table 1 or 2 of chapter 3 the greatest or least distance, as needed, of the star from the planet or from the fixed stars in question, and from table 2 of chapter 9, or from tables 2, 3 and 4 of chapter 11 of this Section, the true semidiameter of the planet or fixed star to be viewed. For in the figure just given that semidiameter will be AB and the distance AC, or the semidiameter DP and the distance PC. Therefore, by solving triangle ACB or DCP, right-angled at the contacts B and D, you will be able to find the angle C, whose double is the measure of the apparent diameter under which the planet or fixed star A or P would appear to the eye C placed on another star.

Problema 3. Quanta diſtantia requiratur, vt Stella videatur ſub dato angulo, ſeu datæ quantitatis apparentis.

Problem 3. What distance is required for a star to be seen under a given angle, or at a given apparent size?

V. You will solve the present problem by the same right triangles we have been discussing, if the true semidiameter of the star in question is known from the tables mentioned in Problem 2. From this, as the side AB or DP, and from the angle C, you will find by trigonometry the required distance AC or PC.

Problema 4. Quantus appareat Orbis Annuus Solis aut Terræ, vel quiuis orbis Planetarius, viſus ex Saturno, vel ex Fixis.

Problem 4. How large the annual orb of the Sun or the Earth, or any planetary orb, appears when seen from Saturn or from the fixed stars.

VI. You will carry out this problem by the same scheme, given, as I assume, the semidiameter of the sphere of the annual orb of the Sun or the Earth, which semidiameter is the mean distance of the Sun from the Earth; or, if the discussion concerns another sphere, given its semidiameter, or the mean distance of the

planet from the Earth, from table 1 of chapter 2 of this Section; and given besides the distance of Saturn or of the fixed stars from which the annual orb, or any other, is supposed to be viewable. For in the figure above, the semidiameter of the sphere to be viewed will be either AB or DP, and the distance from which the orb is imagined to be viewed either AC or PC. Therefore, by analysing the right triangle ABC or PDC, you will learn the angle ACB or DCP, whose double will be the measure of the diameter of the sphere as it appears to the eye C placed on Saturn or on the fixed stars. We have, however, said much that bears on this about the parallax of the annual orb in Book 6, chapter 7. On the hypothesis of the Copernicans it is useful to reduce to unity the Earth's semidiameters contained in the semidiameter of the sphere to be viewed, and to use the distance AC or PC in parts of which the semidiameter of the sphere to be viewed is one.

[Margin: Šírek's advice on the planets viewed from Saturn, etc.]

VII. It is fitting to add here what Antonín Maria Šírek observes in his *Radius Sidereomysticus*, Book 3, chapter 2, member 3. There he says that, with the eye supposed to be on the planets, it will be seen as a most delightful spectacle how far one of them, with respect to another, is going to retrograde, stand still and digress from the Sun. *For*, he says from his own measures, *Saturn would see Jupiter never straying beyond about 75° from the Sun; Mars about 24°; Venus 12; Mercury scarcely 5°.* These and similar things will not be difficult to determine from the mutual distances of the planets from one another and from the Sun, according to the hypothesis of each astronomer. Accordingly, an eye placed on Saturn, and much more on one of the fixed stars, would judge not only Mercury and Venus, as we now judge from the Earth, but also Mars and Jupiter to be satellites of the Sun, since they do not digress from it by a whole semicircle.

VIII. On these foundations, then, we have constructed the following tables, restricting however a question in itself almost infinite to the more notable cases, which will serve us later, in Book 9, for a fuller knowledge of the system of the world. Granted, the horizontal parallax itself, doubled, can satisfy the question.

I. TABVLA. DIAMETER APPARENS TERRESTRIS GLOBI Spectati ex Fixis aut Planetis in Maxima aut Minima ipſorum à Terra diſtantia.

CAPVT XIV.

Chapter 14.

De Mutuis vel non mutuis Eclipſib. Planetarum vel interpoſitu Corporum, vel Vmbrar: vbi de Prolixitate harum Vmbrarū.

On the mutual or non-mutual eclipses of the planets, by the interposition of bodies or of shadows; where also on the length of these shadows.

I. As for the first kind of eclipse, which arises from the interposition of an opaque body between our sight and a star otherwise visible, there is no doubt that the lower planets can hide from us any star higher than themselves, if they are in conjunction at the same place of the zodiac and a large latitude does not prevent it, that is, a latitude greater than the sum of the semidiameters of the occulting star and the star to be occulted. Kepler discusses these occultations and gives examples in the *Astronomia Optica*, p. 304. He notes, moreover, that part of the Sun can be hidden by Mercury in this century and at almost all times, but not by Venus in this century, although it could once have been and at some time will be, as its latitude permits. But I wish to set down here some examples of occultations of this kind, beginning with the Moon.

Catalogus Stellarum à Stellis occultatarum.

Catalogue of stars occulted by stars.

[Margin: ☾ covers ♂.] II. The Moon covered Mars, as Aristotle observed and attests in *De caelo*, Book 2, chapter 12; and Kepler says, in the *Astronomia Optica*, p. 305, that this happened only in 357 BC, April 4. [Margin: ☾ covers ♃.] The Moon also covered Jupiter in 807, in January, with a certain monk watching, about whom see Kepler in the same place; and in 1646, on December 24, in the evening before 8^{h}, it covered Jupiter, which emerged at Danzig at 8^{h} $39½^{m}$, with Hevelius observing. [Margin: ☾ covers ♄.] And in 1482, January 12, in the morning, it occulted Saturn, as Bernhard Walther reports in his observations and as Kepler weighs in the *Optics*, p. 409. [Margin: ☾ covers ♀.] It also occulted Venus, in 1529, March 12, in the evening, as Copernicus saw and reports in Book 5, chapter 23. [Margin: ☾ covers the Heart of Leo and of Scorpius.] More often, however, it has covered fixed stars that lie within the zodiac: as when, in 1486, October 21, in the morning, it covered Regulus, with Bernhard Walther observing, in his observations; and in 1637, September 23, on the following night, it occulted the Heart of Scorpius, as D. Vincenzo Renieri observed and reports near the beginning of the *Tabulae Mediceae*.

[Margin: ☾ covers Aldebaran.] In 1644, moreover, on November 15, in the morning, the Moon began to occult Aldebaran at 3^h 5^m, with Hevelius observing at Danzig. And in 1645, on October 8, it began to obscure Aldebaran at 1^h 43^m after midnight, again with Hevelius observing at Danzig. He says that this star emerged from the Moon at 2^h 57^m, and from this he gathers that the middle of the obscuration was at 2^h 20^m and that the duration of this eclipse was 1^h 14^m.

[Margin: ♃ covers ♄.] Among the minor planets said to have occulted one another, the first was Jupiter, which in 1563 occulted Saturn, as Kepler reports in the *Optics*, p. 305. [Margin: ♂ covers ♃.] Then Mars, which in 1591, January 9, covered Jupiter while Mästlin watched, as Kepler says in the same place. [Margin: ♀ covers ♂.] And Venus, which in 1590, October 3, at 5^h in the morning, occulted Mars; [Margin: ♀ covers ☿.] and in 1599, June 8, covered Mercury, on the testimony of Kepler in the same place. [Margin: ☿ covers ☉.] I say nothing of Mercury occulting a small part of the Sun, for enough has been said on this in Book 3, chapter 3, scholium 3.

[Margin: ♃ covers fixed stars.] Finally, the minor planets have not rarely covered some one of the fixed stars. For Jupiter occulted the Southern Ass in 241 BC, September 4, in the morning, according to Ptolemy, Book 11, chapter 3; twice it occulted another star, which is in the feet of Gemini, on the testimony of Aristotle, *De caelo*, Book 2, chapter 12; and it occulted Propus, the star before the feet of Gemini, in the year of Christ 1633, December 19, in the morning, as Pierre Gassendi, who observed it, reports in his *Life of Peiresc*.

[Margin: ♂ covers fixed stars.] Mars, moreover, was seen to occult the northern star in the forehead of Scorpius, in the year 272 before our Saviour, January 18, in the morning, according to Ptolemy, Book 10, chapter 9; and the outermost star, which is in the wing of Virgo, as Gassendi observed and recounted in the *Life of Peiresc*. [Margin: Whether ♀ covered Regulus.] But whether Venus covered Regulus in 1574, September 16, at 4^h in the morning, with Mästlin observing, and in 1598, September 25, at 3^h in the morning, on the testimony of Kepler in the *Optics*, p. 305, some affirm and others deny.

De Vmbris Planetarum.

On the shadows of the planets.

[Margin: Authors who have written on these shadows.] III. No astronomer, so far as I know, has discussed the shadows of the minor planets except our own Biancani, in his *Sphaera*, both towards the end and in the individual treatises on these planets. From him Andrea Argoli took the same measures in the *Pandosion Sphaericum*, from chapter 51 to 59, though he suppressed his name; and Father Athanasius Kircher, at the end of volume 2 of the *Ars Magna Lucis et Umbrae*, did not depart far from Biancani. The shadow of Jupiter darkening its satellites, however, has been treated by nearly all who have treated its four companions, as I reported in Section 1, chapter 3 of this Book. The Moon's shadow has been

dealt with sufficiently in Book 4, chapter 17, from Problem 5 on, and in Book 5, chapters 8 and 9, where the Moon's shadow is treated as bounded by the Sun's rays, both unrefracted and refracted in the air round the Moon, if such air is admitted.

[Margin: 3. Assumptions for measuring the shadows.] To come now to the measure of the shadows cast by the opaque bodies of the remaining planets, we first assume three things. First, that the bodies of the planets are opaque and spherical or globular, which many think of Saturn too when taken alone; though for the shadow it casts together with its attendants [lateronibus], let it suffice to use the composite diameter of Saturn, whether it is then spherical or not. Second, that all the planets are in reality smaller than the Sun, as is now clear from Table 3 of chapter 9 and Table 2 of chapter 10 of this Section; from which it follows that if they cast a shadow, it is not calathoid or cylindroid but conoid or quasi-pyramidal, from what was said in Book 5, chapter 3. One thing, however, must be noted: the shadow that Saturn casts together with its companions is not always of the same shape, just as it does not always turn its face toward us with the same appearance, according to what has been said elsewhere and will be said in the following Scholia. Hence it also follows that a diameter of one constant size is not to be used to find the measure of the shadow that Saturn with its companions extends onto another star. Third, that all the planets receive either all or nearly all of their light from the Sun, according to what was said in Section 1, chapter 5. From this it follows that they cast, into the part turned away from the Sun, a pointed shadow that finally ends in some point. With these laid down, let this be

Problema 1. Inuenire Axem ſeu altitudinem Vmbræ Planetæ, tam maximæ, data maxima; quam minimæ, data minima ipſius à Sole diſtantia; & differentia veræ ſemidiametri Solis ac Planetæ à Sole illuſtrati.

Problem 1. To find the axis or height of a planet's shadow, both the greatest, given the planet's greatest distance from the Sun, and the least, given its least distance, and given the difference between the true semidiameters of the Sun and of the planet lit by the Sun.

IV. We gave the greatest and least distances of the planets from the Sun in chapter 2, Tables 3 and 4, and in chapter 3, Tables 1 and 2; their true diameter in chapter 9, Table 2, and in chapter 10, Table 2; and finally the true diameter of the Sun in Book 3, chapter 11. Now since as diameter is to diameter, so is semidiameter to semidiameter, if you subtract the semidiameter of the minor planet from the semidiameter of the Sun, there will remain the difference of the semidiameters that we need here. This Problem, moreover, is solved in four ways.

[Margin: 1. Method.] The first method, used by Boulliau in Book 4, chapter 3, is this. In this first scheme, let AB be the known semidiameter of the Sun and

CD that of the minor planet; and from the Sun's centre A, through the centre C of the minor planet, let the straight line AC be drawn, to be produced until at E it meets the straight line BDE, which touches the Sun at B and the minor planet at D. For the height of the shadow sought will be CE. To find it, cut off from AB a portion AF equal to the semidiameter CD of the minor planet; for FB will be the difference or excess by which the semidiameter exceeds the semidiameter of the other planet. And finally, from the point of section F, draw a parallel to the end D of the diameter, which, with an imperceptible difference, coincides with the point of contact of the line BDE. This produces two similar triangles, FDB and AEB, and the parallel FD cuts the sides AB and BE proportionally, by proposition 2 of the sixth book of the *Elements*. Therefore, since AF is known, being equal to CD, and FB, the difference of the semidiameters, and FD, which is equal to AC, the distance of the planets, by proposition 33 of the first book of the *Elements*: let it be made, as the difference BF is to the whole BA, so FD to the whole AE. In this way the whole AE will be known, in the parts in which the distance AC was known; and when the distance AC is subtracted from the whole AE, there will remain the known height CE of the shadow. Because, however, the point of contact D lies somewhat lower than the end of the semidiameter CD, that is why this comes about.

Diagram. The first scheme, a small woodcut set into the right column. A straight line along the top is lettered A F B, with a large semicircle hanging below it, the Sun's hemisphere. Two lines run from its ends down to a vertex at the foot, forming a tall narrow cone. A vertical line runs from A to the vertex, and a second vertical runs from F to the right-hand tangent at D. On the axis a small circle stands inside the cone, its upper half white and its lower half solid black, the diameter between the halves ending at D on the right. Below it a short cross-line is lettered L N M, and beneath this the point of the cone is hatched.

- A (top, on the line, at the foot of the axis): centre of the Sun
- F (top, between A and B): the point of section
- B (top right): the Sun's tangent point
- C (centre of the small circle): centre of the minor planet
- D (right end of the small circle's diameter): point of contact
- L (left end of the cross-line), N (on the axis), M (right end of the cross-line): not cited in the text of this page
- [?] (a small mark inside the hatched cone, just right of the axis below N, perhaps a letter T; not resolved)
- E (below the vertex): the point of the shadow

[Margin: 2. Method] The second method is the one familiar to us. For it, in this second scheme, let EMF be the hemisphere of the Sun and ABCD the globe of a planet smaller than it; and from the Sun's centre K, through the planet's centre H, let the straight line KH be drawn and extended until at G it meets the straight lines EAG and FCG, which touch the Sun at the points E and F and the minor planet at A and C. To these points of contact let the radii KE,

KF and HA, HC be drawn from the centre of each planet. By proposition 18 of the third book of the *Elements*, these will make right angles with the tangents at the points of contact E, A, etc.

Finally, from EK let EL be cut off, equal to the semidiameter AH, and from H let the straight line HL be drawn. For it will be perpendicular to EK, making right angles at L on both sides, and at the same time parallel to EAG, by proposition 33 of the first book of the *Elements*. Hence the triangle KHL, right-angled at L, will be similar to the triangle KGE, right-angled at E, by proposition 4 of the sixth book; and by proposition 2 of the sixth book of the *Elements*, as the side KL is to KE, so is the side KH to KG. Now the side KL is known, because it is the excess of the Sun's semidiameter over the semidiameter of the minor planet; the distance KH of the planets is also known. Therefore, if it is made, as KL is to the whole semidiameter KE, so the distance KH to KG, the straight line KG will be known in the same kind of parts; and when the distance KH is subtracted from it, there will remain the known HG, which is the height or axis of the shadow AGC that was sought. Or, since the triangles KHL and AHG are similar, let it be made, as KL is to KH, so AH to HG.

Diagram. The second scheme, a small woodcut set into the left column. A straight line along the top carries K at its centre and E and F at its ends, with a large semicircle hanging below it, the Sun's hemisphere. Two straight lines descend from E and F to a vertex G at the foot, forming a tall narrow cone. A vertical axis runs from K to G. A small circle stands on the axis inside the cone, touching the two lines at A and C, with radii drawn from its centre H to A and C. A slanting line runs from L, near the top on the left, down to H.

- K (top centre): centre of the Sun
- E (top left), F (top right): the points where the lines touch the Sun
- L (inside the cone, near the top left): foot of the perpendicular from H
- M (on the axis, just below the semicircle)
- I (left of B, where the slanting line meets the small circle): not cited in the text of this page
- B (on the axis, top of the small circle)
- H (centre of the small circle)
- A (left), C (right): the points of contact on the small circle
- D (on the axis, bottom of the small circle)
- G (below the vertex): the point of the shadow

[Margin: 3. Method] The third method is carried out by means of the same second figure, but not without trigonometric labour. For first, in the triangle KHL, right-angled at L, the angle KHL is found from the given distance KH and the difference KL of the semidiameters. Because of the parallelism of the lines HL and EG, on which the straight line KG falls, this angle is equal to the interior angle AGH, by proposition 29 of the first book of the *Elements*. Then, in the triangle AGH, right-angled at the contact A, the base GH, namely the height of the shadow, is found from the angle AGH just obtained and the semidiameter AH.

[Margin: 4. Method.] The fourth method, which Biancani suggests after the second in Book 4 of his *Sphaera*, chapter 3, is mechanical and is carried out with the help of compasses. On some very large plane you draw the preceding figure, keeping the proportions that have to be kept, so that on KH you can mark off by division the individual equal parts, each representing one semidiameter of the Earth, with the semidiameters KE and HA proportional to it. For compasses spanning HG and laid along KH will show the size of HG itself. But the operation is a slippery one.

Problema 2. Diſcernere an & cuius Planetæ Vmbra poſſit, aut non poſſit alterum Planetam inumbrare, ſi Latitudo hanc Eclipſim permittat.

Problem 2. To determine whether, and whose, planet's shadow can or cannot darken another planet, if the latitude allows this eclipse.

[Margin: 3. Conditions required for an eclipse of the planets by a shadow.] V. Three things are required for this test: namely, the order itself of position among the planets, the distance between them, and the size of shadow belonging to them at such a distance. As regards position, no planet can darken another unless it can be interposed between that other and the Sun. And no higher planet can be interposed before a lower one, that is, one nearer the Earth, except ♀ and ☿, which can be interposed between the Sun and the Moon, and Mercury, which can pass between the Sun and Venus even when Venus comes nearer to the Earth than Mercury does. Conversely, every lower planet can be interposed before a higher planet, except Venus compared with Mercury: even when perigean, Venus cannot pass between Mercury and the Sun, for it is certain that both are carried around the Sun in such a way that Venus surrounds it in a wider circle than Mercury does.

[Margin: Mercury immune from the shadow of the others by reason of position.] From what has been said it follows that Mercury alone, by reason of position, cannot be darkened by any planet, being the innermost of all to the Sun, and that Hermes forever enjoys the light of Apollo's face. As regards the mutual distance of the planets, it is certain that, other things being equal, a greater risk of being darkened by another threatens a planet when they are least or less distant from one another than when they are most or more distant. As regards the size of the shadow: the conical shadow of globes is both longer and wider, or both more drawn out and thicker, when they are farther from the greater illuminating body (in our case, from the Sun) than when they are less far from it. Therefore there is also a greater risk of darkening from that lower planet which, and when it, is interposed at its greatest or a greater distance from the Sun, than from the one which, or when it, is at its least or a lesser distance from the Sun. With these things indicated beforehand, the distances and the shadows must be compared, but only those that can meet in the same quarter; for if the shadow exceeds the distance, one planet can be darkened by

the other, but it cannot if the distance exceeds the shadow. We shall therefore first set out a table of shadows, and then settle this matter very quickly with a second small table.

I. TABVLA. VMBRÆ ALTITVDO MAXIMA ET MINIMA In Semidiametris Terræ.

II. TABVLA. VMBRÆ ALTITVDO MAXIMA ex Tychonicis principijs.

Table 2. Greatest height of the shadow, from Tychonic principles.

Authors	♄	♃	♂	♀	☿	☾	Earth
Biancani and Argoli	12527	859	147	102	43	67	254
Athanasius Kircher	12532	869	147	102	43	68	264

VI. Our Biancani rightly concluded, at the end of his *Sphaera*, from Tychonic principles, that apart from the eclipse of the Moon by the Earth's shadow, the eclipse of the Earth by the Moon's shadow and the eclipse of some fixed stars by Saturn's shadow, no other eclipse by the shadow of the planets can occur (the Jovian satellites excepted), because their greatest shadows are shorter than the distances between the nearer planets. But what is to be said under other hypotheses will be clear from the following propositions, which are proved from the size of the shadows, given in the preceding small table, and from the distances of the planets from the Earth or from one another, already set out in the tables of chapters 2 and 3. Because of the affinity of the hypotheses and the proportion of the measures, one can safely decide about the Copernican hypothesis from that of Lansbergen, about the Danish hypothesis of Longomontanus from the Tychonic, and about the Philolaic hypothesis of Boulliau from the Keplerian: granted that neither Copernicus nor Longomontanus nor Boulliau has left us the apparent or true size of the five minor planets, on which, however, the determination of the size of the shadow depends.

Theoremata de Eclipſibus Poſſibilibus, vel non poſſibilibus ab Vmbra Terræ vel Planetarum.

Theorems on eclipses that are possible or not possible by the shadow of the Earth or of the planets.

1. Theorem. *In any hypothesis whatever, the Earth's shadow can obscure the Moon, and the Moon's shadow the Earth.* This is clear from what was said in Book 5, chapters 3, 8 and 9.
2. Theorem. *In the Ptolemaic hypothesis, especially that of al-Farghānī, Mercury can darken the Moon, and Venus Mercury, and Jupiter Saturn and the fixed stars, and Saturn the fixed stars; but the remaining eclipses of planets by the shadows of the others are impossible.*
3. Theorem. *In every other hypothesis of a more celebrated astronomer, neither can the Earth darken any planet except the Moon, nor can any planet darken any planet that is not its own companion or satellite.*
4. Theorem. *In every other hypothesis, neither the Earth nor any planet can darken the fixed stars, except in the Tychonic, in which Saturn alone can darken some fixed stars; yet it cannot obscure them, if the fixed stars have their own light, but can only, by a kind of penumbra, deprive them of that secondary light which they would otherwise have from the Sun.* The same would have had to be said in our own hypothesis, had we not, in Book 6, chapter 7, raised the fixed stars as far as 210000 semidiameters of the Earth precisely in order to avoid this shadow. For although, as we said in the same place, there is no danger of an absolute eclipse of the fixed stars by the shadow of the planets, since they have their primary light from themselves, yet because the Sun, by the magnitude of its brilliance, does in the end add some light to them, then if they were not at a distance exceeding the length of the shadow of Saturn taken with its attendants, some of those in the zodiac could be deprived of that secondary light and suffer a semi-eclipse.

But it is more probable that, just as GOD has allowed only the Moon, as a terrestrial planet, to be subject to the alternations of eclipses that arise from the Earth's shadow, and the satellites of Jupiter to the shadow of Jupiter, because they are its companions, while in every hypothesis of the more recent astronomers He has exempted all the remaining planets from these shadowings, so too, and much more, He willed the non-wandering stars to be exempt. Thus from this too they would earn the name of fixed stars, being unchangeable even with respect to that very addition of light received from outside, which they receive from the Sun. And in this too they would be a symbol, either of the Blessed, who, walking in the light of the divine countenance, will shine like the stars of the firmament for perpetual eternities, or else some sort of trace of the divine immutability itself, with which there is no shadow of change. Besides which, a great space between the fixed stars and Saturn suits both comets and new stars and the symmetry of the world system, so that the interval from Saturn and

the last sphere of the planets to the fixed stars is at least as great as that from the centre of the world to Saturn.

SCHOLIA.

Scholia.

De Vmbra & Figura Saturni & Comitum.

On the shadow and figure of Saturn and of its companions.

[Margin: Examination of Saturn's shadow and of the spots appearing on it.] I. In Section 1, chapter 2, number 7, above, I said it is almost established that both Saturn's companions and Saturn itself likewise lack light of their own, from the shadow Saturn throws onto them; and in chapter 5, number 5, I hinted at this same opinion of mine, which I used to hear commonly asserted on all sides. For I had not yet noticed that, with our eye on this side of Saturn, the caster of that shadow, and lying almost between Saturn and the Sun, it is impossible for that shadow to spread out to the sides, and so to show us its companions darkened on both sides, unless it were calathoid, and Saturn were therefore not a little but much larger than the body of the Sun that illuminates it. I came to this suspicion while debating the matter with the Lord Antonio Rocca, my Uranian friend, a man most learned above all and most worthy of the friendship of any of the wise. At that time, since we had not yet found a way of determining Saturn's apparent diameter evidently, I kept turning over in my mind, and was in doubt, whether, with other evident phenomena preserved, a Saturn larger than the Sun could be upheld, so that with its shadow calathoid the phenomena of its attendants, which we depicted in Section 1, chapter 2, in figures 3, 4 and 5, could be more easily explained.

But when the observation of the diameter had been made, on which see chapter 10 of this Section, that whole suspicion vanished; and we were made certain that Saturn is much smaller than the Sun, and therefore that, if it has its primary light from the Sun, its shadow is conical and does not suffice to explain the cause of both those obscurities or blacknesses that are seen equally, at the same time, between Saturn and its companions. It may be, then, that Saturn, shining of itself, is prevented from being able to illuminate its attendants entirely by some other body distinct from it, or by some part at its back protruding in the form of a mountain; or that it has caverns devoid of light, which, by the varied libration or rotation of its body, it displays to us at different times in different figures; or rather that it is itself lit by its attendants; or that, as in the Moon, however full, there are certain larger spots, that is, parts not so suited as the others to reflect the Sun's light toward us, and these therefore appear to us darker, especially at so great a distance; or that it is something else, which will be made manifest to us or to our posterity after many experiments with the phenomena.

[Margin: The new and multiform figure of Saturn.] Meanwhile nothing occurs to me that satisfies altogether, especially since not only Fontana, in 1644 and 1645, but also some of the Fathers of our Society, and above all Father Mattheus Tauerna [?], attest that they saw through the telescope Saturn having the appearance of the figure set down at the end of these scholia, and showing several bodies, partly spherical, partly egg-shaped. This, however, it has not yet been granted us to see, but only under the figures shown in Section 1, chapter 2, and in this Section, chapter 10, number 8. To this last figure seen by us, the one most closely similar is that which I later saw in Hevelius's *Selenographia*, chapter 4, in figure G and letter C, seen by him in 1645, in September, October and November.

II. Hevelius adds, moreover, that in 1642, in September and October, Saturn was seen by him on separate occasions as quite round. Gassendi attests that it was seen so by him in the same year, in the month of August, in the *Judgement on the 9 Stars Seen around Jupiter*, p. 14, affirming that Saturn was likewise seen round by Galileo 30 years before. From this Hevelius gathers that Saturn's companions lie hidden behind it at definite times. But what if either both of them or one of them, being no larger than Saturn, passes between it and our eye on the same line at the time when Saturn appears round, and, in receding from it on both sides, casts a shadow onto it? But more observations and periods are needed for the causes of this phenomenon to become known.

[Margin: Hevelius's error on the line of the companions of ♄.] Meanwhile it is certain that in these years the line drawn through the centres of Saturn and the satellites lengthwise is not parallel to the ecliptic, as Hevelius thinks in chapter 4 of the *Selenographia*, I believe from an argument drawn from the line of Jupiter's satellites, but parallel to the equator. This is clear from what was said in Section 1, chapter 2, number 7, and in this Section 6, chapter 10, numbers 8 and 9, and it is confirmed by the very recent observation of Father Francesco Maria Grimaldi of 1650 March 18. For on the same straight line there appeared the centres of Saturn and its companions and a certain small star (unnamed, because it can be observed only with the telescope), distant from the nearest attendant toward the east by about half the Moon. On the night following the 23rd, however, Saturn overtook the small star, leaving it lower down toward the south, at an interval as large as about 4 greater diameters of Saturn would fill. From this it was plain that the line of Saturn and its companions is neither in the ecliptic nor parallel to the ecliptic; otherwise, by its motion in longitude, it would on the 23rd have covered that small star or grazed it, whatever variation by reason of latitude it had undergone in the space of 5 days.

[Margin: Opinions of Antonín Maria Šírek on the figure, light and shadow of Saturn and its companions.] III. But to return to the figure and shadow of Saturn: we must not pass over what Antonín Maria Šírek devised in his *Radius Sidereomysticus*, Book 4, chapter 4. For he says [?] that certain people think that the two handle-stars revolve around Saturn and are therefore hidden in the evening or in the morning; yet he denies that this has ever been observed

by him. But if this should happen, he says that this motion is very slow and observable only after many years; and that at their conjunction with Saturn, evening for the one and morning for the other, Saturn, being alone, must necessarily appear round, and at their quadratures three-bodied. Šírek goes on to say: if it is granted that the attendants already mentioned circle Saturn, and that because of their motion it sometimes appears solitary and round, it must also be granted that it can at times be hidden and eclipsed by the attendants; or, since this has never been seen, one of two things must necessarily be granted;

that is, that the attendants just mentioned revolve on the near side of Saturn; or, if this is so, that they are necessarily endowed with their own light and are to Saturn as luminaries, by whose light, being destitute of its own, it is refreshed and illuminated. He then at once teaches that Saturn cannot be sufficiently illuminated by the Sun because of its huge distance, so great that Saturn does not see the Sun's disc except under an angle of 3′ 11″; and that the Earth is therefore illuminated at least 100 times more strongly and intensely than Saturn. From this he draws the following conclusion: "We therefore think it most probable, indeed necessary, that Saturn obtains light sufficient for itself from somewhere altogether other than the very remote Sun; and since its two attendant stars are seen to be very bright, it surely seems necessary that Saturn borrows from them, on either side, the chief rays of its light."

From this, and from the rotation of Saturn about its own axis, which he sets as completed in $29^{d}\ 10^{h}\ 1^{m}$ (we have already set out the basis of this motion in Book 3, chapter 4), and having assumed, following the opinion of Cardinal Cusanus, inhabitants on Saturn, he reasons that such inhabitants will have most delightful and almost perpetual days, and will experience the alternations of summer, winter, spring and autumn, according as the hemispheres of the attendants turn toward Saturn a part more or less hot or bright. For he had invented something similar about two hemispheres of the Sun's body, as we said in the same chapter 4. He then adds: "One might also perhaps suspect whether the middle globe, luminous by its nature, does not perhaps illuminate the two opaque attendants, all other things, however, being understood to be equal, as has been said." So much for this author's inventions.

[Margin: Šírek's statements are weighed.] IV. For the rest, although much of what has been said displays the man's talent and acumen, certain things cannot at all win my approval. First, from the fact that the attendants, when in conjunction with Saturn, bring no eclipse, it does not necessarily follow either that they revolve on the near side of Saturn or that Saturn, lacking its own light, is illuminated by them. For it can fail to be eclipsed for this reason: that they revolve beyond Saturn; or, if they revolve between us and Saturn, that both they and Saturn have their light from the Sun; or that they have their own light, but Saturn has its light from the Sun. For although Saturn is ten times further from the Sun than the Sun is from the Earth, Saturn can still be illuminated by the Sun with that languid and leaden light which we see in it, especially since the quality of the surface, and the very matter of the body of

Saturn and its companions, assist the reception and reflexion of the light. And certainly that a privation of its own light in Saturn does not necessarily follow from what he said, Šírek himself has admitted, either contradicting himself or correcting himself, when he says that one may suspect that Saturn, luminous by its nature, illuminates its attendants.

I would have preferred him to give a reason why that twin blackness or darkness on either side, which very frequently appears around Saturn, does not come from its companions (for he says that Saturn has never been seen hidden by them), or else where it does come from. Moreover, from the fact that Saturn sometimes appears solitary, it is not a necessary consequence that it appears round: for it can appear egg-shaped, as it sometimes does appear, even when the attendants are visible on both sides, as has been noticed more than once with the telescope, and as may be seen from the figure shown at chapter 10 of this Section.

We therefore do not reject the probability of Šírek's arguments, but the necessity of the consequences, which he draws without evident reason. In the same way we also do not approve that what the same man ingeniously invented about the rotation of Saturn and the other minor planets about their own axes, in his Book 4, chapter 2, member 3, should be thrust upon us as secrets communicated to him almost by divine means. For he says there: "Now as to the time of the rotation of the planets, hear an astounding secret, known until now, so far as I know, to no one": namely, that each of the planets named turns 365 times on its own axis within one of its periodic revolutions, just as the Sun rolls itself 365 times yearly over the Earth. And meeting an unspoken question, he says: "You will ask from where we have taken these secrets, and on what foundations they rest. I answer with the Archangel Raphael, Tobit 12: It is good for now to hide the secret and sacrament of the King, but to reveal and confess the works of God is honourable. Let this answer suffice for the wise reader for now." Relying on his authority, however, our own Father Athanasius Kircher, not absolutely but on a hypothesis, has ingeniously carried certain things over to the harmony of the world and of the planets, in volume 2 of his *Musurgia*, Book 10, p. 380; on these, see below, Book 9, in the discussion of the harmonic system.

It remains for us to close this seventh Book with the scheme, already promised, of the seventh of the planets, as with a seal.

Diagram. Saturn as seen, set across both columns: a large central circle with a smaller circle standing clear of it on either side along the horizontal. Between the central circle and each small circle lies a dark, closely hatched region, broad against the central circle and narrowing to a point against the small circle. A single curved outline passes over the top and under the bottom of the central circle and meets each small circle, enclosing the whole in an elongated oval. Caption: *Saturn as seen in the year 1645, in December, and sometimes also in the year 1644, at Rome and Naples.*

- Labels read: none. The figure carries no letters.

• Labels not read: none.
End of the Seventh Book. [FINIS LIBRI SEPTIMI.]

APPENDIX AD I. PARTEM TOMI I.

Appendix to Part I of Volume I.

PROHOEMIVM.

Preface.

[Margin: 3 reasons for adding this Appendix.] I had three reasons for this Appendix. The first: to add in their proper places certain things that became known to me afterwards, either from books not read before or from letters of astronomers or of others sent to me, or that had slipped away while I was writing. The second: that the teaching on one and the same subject, given for just reasons in different places of this work, may be gathered into one by those who perhaps would not easily manage this from the indexes of both volumes. The third: to explain and complete certain things said rather obscurely or imperfectly and, if anything seemed to need correcting, to correct and retract it myself, of my own accord. In this I believe that no one will be of so severe a brow as to abuse the sincerity of my confession and want me reproved twice: because I have erred somewhere, namely, or nodded when I ought not to have done, and because I was not ashamed to disclose errors or blemishes. The former of these belongs to man; the latter to one who candidly prefers truth and the benefit of others to his own reputation. If, however, any censor of this kind should arise, I shall answer him with no other words than those of St Augustine, from the prologue to Book 1 of the *Retractationes*. [Margin: St Augustine's sincerity and modesty.] "For no one but an imprudent man will dare to reprove me because I reprove my own errors. But if he says that those things which afterwards displeased even me ought not to have been said by me, he speaks the truth and is on my side: for he reproves the same things as I do. For I ought not to reprove them if I ought to have said them. But let him who could not hold the first part, that of wisdom, hold the second, that of modesty: so that he who was not able to say everything without cause for repentance may at least repent of what he has come to know should not have been said."

Ad Præfationem.

On the Preface.

[Margin: Miracles for the Roman calendar.] Article 2, p. 5, where the miracles done for the Roman calendar or for the correct celebration of Easter are treated: add what Paschasius relates in the Letter to St Leo the Pope, which is number 65 among the letters of St Leo; and Cassiodorus, *Variae* Book 8, chapter 33; and Baronius [Cesare Baronio] at the year 417, and from him Odoricus Rinaldus [Odorico Rinaldi] in the *Annales*. [Margin: Roundness of the heavens.]

IN CHRONICO.

In the Chronicle.

Add Ecphantus the Pythagorean, who held, as Philolaus also did, that the Earth moves; although his period is not yet established. To what has been said of Girolamo Cardano, add that he was born with hair, already covered with black, very long and thick hair; that he was pulled by force from his mother's womb and revived in a bath of wine; some say he was born 1501 August 24 [9. Kal. Sept.]. Add likewise Johannes Stadius, born in Loehnoutio, a village of the Brabant country, author of the Bergen tables, and very dear, because of his astrological divinations, to the prince of the Allobroges and to Henry III, King of the French, by whom he was made Royal Professor of Mathematics. He died in the year 1579, June 17 [15. Kalend. Iulij], aged 52 years and almost 2 months. Add also Valentinus Naiboda, born at Cologne, and dead at Padua in his house and found torn with wounds, having once predicted for himself death by iron.

AD LIBRVM I.

On Book I.

Chapter I, column 2. I promised a trigonometry, that is, a fuller one; yet it seemed good to give its Epitome beforehand in Book 10, Section 1. Anyone who does not have from elsewhere the rules for solving triangles by logarithms may have recourse to it meanwhile.

Chapter II, Scholium 7. What I touched on concerning the opinion of the Fathers on the roundness of the heavens must be understood and illustrated from what is said in Book 9, Section 4, chapter 5, number 2.

[Margin: Solidity of spheres.] Chapter VI, Problem 3. Join to it the related problems on the solidity of spheres compared with one another, given later in Book 7, Section 6, chapter 8, from Problem 8.

[Margin: Finding the meridian.] Chapter X. I have added other ways of finding the meridian line, though more recondite ones, in Book 10, Section 4, from Problem 49 to 66.

[Margin: Days of the Sun and of the primum mobile.] Chapter XI. I give a specimen of the double table named here in Book 10, Section 3, Problem 1, and earlier in Book 3, chapter 31; these are to be reconciled together. You have the authors of the tables converting hours into degrees, and conversely, in Book 10, Section 3, Problem 3.

[Margin: Finding the altitude of the pole.] Chapter XII. The remaining ways of either finding or confirming the altitude of the pole, which I judged out of place here, I teach more suitably in Book 10, Section 4, from Problem 67 to 103.

[Margin: Difference of geographical longitude.] Chapter XIII. On finding the difference of geographical longitude, or the distance of the meridians, I propose several other methods to the now better-instructed reader in Book 10,

Section 4, from Problem 104 to 120. What I advised in Scholium 3 about the start of longitude differing among different authors, and from where it is better taken, I discuss more fully in my *Geographical Book*. Meanwhile it is enough to have added the chief opinions. The start of the meridians, then, was made as follows.

[Margin: The start of the meridians varies.] Eratosthenes from the Pillars of Hercules, namely from Abyla and Calpe, as is found in Strabo, Book 1.

Ptolemy and Marinus of Tyre, and the greatest part of the older geographers, from the westernmost of the Fortunate Isles, although many enter on it from the Fortunate Isles indiscriminately. See Ptolemy, *Geography* Book 1, chapter 11, and there his interpreters Werner, Magini, Moletti, Bencius [?].

Ismaël Abilfedea [Abū al-Fidā], the most celebrated geographer of the Arabs, from Cadiz [Gadibus], namely from the island of the Strait of Hercules.

Gerard Mercator and his son Rumoldus [Rumold Mercator] from the island of Palma, which is now the westernmost of the Fortunate Isles; although in the year 1634 the King of France ordered the cosmographers of his kingdom to establish the first meridian on the island of Ferro, as

Fournier relates in Book 12 of the *Hydrographie*, chapter 2.

Gulielmus Iansonius [?] in the 4 maps of the world published in the year 1624; Iosephus Rosaccius [Giuseppe Rosaccio], Simon Stevin, and Willem and Joan Blaeu in the new Atlas: from the island of Tenerife, about the middle of the Fortunate Isles, because of the height of Mount Pico, of which we shall speak in Book 10, Section 4, Problem 30 and Section 6, Problem 50.

Gulielmus Iansonius in the plane hemispheres, Gerard Mercator the younger, Ortelius in the world map, Magini in the table of Africa, Petrus Bercius [Pieter de Bert] in the abridged Europe: from the Island of Fire, which is one of the Hesperides, because on it the magnetic needle declines in neither direction from the meridian line, and the meridian of that island passes through Thule, the furthest of the lands known to the ancients.

The same Iansonius in the world map of the years 1604 and 1607, Gerard Mercator in the description of the polar land, Nicolaus Piscatorius [?] and Franciscus Hoeius [?]: from the island of Corvo [Corui], which is one of the Azores, where most people have thought that the magnetic needle does not decline at all, although Robert Dudley asserts that it declines a little.

Arnoldus de Arnoldis [?] in the world map and Jodocus Hondius in his globe: from the island of St Vincent, both because the magnet does not decline at all there, and because that island and Thule have a common meridian.

Astronomers: from the place to which they fix the roots of the astronomical tables, on which see Book 3, chapter 33, the last table. But Govaert Wendelen begins the Atlantic tables from that meridian of the Atlantic Ocean which passes through Hola and Schaltola, towns of Iceland, formerly Thule.

What if someone were to begin from the meridian from which the first day of the world began, according to the differing opinions on that first day that we have given in Book 9, Section 1, chapter 1, question 8 and chapter 4,

question 6? Or rather from the line which Alexander VI, Supreme Pontiff, in the year 1493 ordered drawn 100 leagues beyond the Hesperides, as the limit of Portuguese navigation from there eastward and of Castilian navigation from there westward, the parties themselves thus seeking his arbitration? Yet in the year 1524 John, King of Portugal, obtained that this line be moved forward by 300 leagues beyond the Canaries, so that it would then pass through the Land of Smokes and over the Cape of Good Appearance; and so it came about that the Moluccas turned out to be western, as Don Francisco López de Gómara and Don Jerónimo Girava relate in the description of the West Indies. Maffeius [Giovanni Pietro Maffei], however, in Book 1 of the *History of the Indies*, and Giovanni Botero in the *Relations*, say that this line was once drawn 140 leagues beyond the Hesperides and afterwards 580; and Fournier, in Book 12 of the *Hydrographie*, chapter 2, says it was drawn 370 leagues beyond the island of St Anthony, the westernmost of the Hesperides.

[Margin: Our opinion.] I, however, began my Table of Longitudes from the island of Palma, whose meridian passes through the eastern part of Iceland or Thule, and very close to Cape Verde, and through the island of St Mary. I did so both in order not to depart without great cause (and none yet exists) from the chief and more common opinion of geographers, and because nearly everyone grants that whatever lies on the near side of that meridian, and within the equator, belongs to the old world, and whatever lies beyond it to the new.

[Margin: Two zodiacs, and the varied naming of the signs.] Chapter XIV. You have the Arabic, Chaldean, Hebrew and Egyptian names of the signs of the zodiac in Book 6, chapter 3, in the Scholia. There I also computed the year before Christ in which the first star of the constellation naming each Sign stood at the beginning of the dodecatemorion [Dodecatemorij], and the longitude and latitude of these constellations. See also what I insisted upon in Book 3, chapter 14, in the Scholia, about distinguishing two zodiacs. [Margin: Greatest latitude of the zodiac and of the planets.] What I said in Scholium 1 of this chapter about determining the latitude of the zodiac from the greatest latitude of the planets must be illustrated or even corrected from what is said later in Book 7, Section 3, chapters 5, 6 and 7, according to the differing opinions on this latitude. Yet, when other ages are considered, the latitude of Mars can be 7° and that of Venus 10°, as Kepler admits in the *Epitome of Copernican Astronomy*, Book 2, p. 150, where he adds that therefore the latitude of the zodiac must be extended not only to 14° but also to 20°. At the end of Scholium 5 I said, following Pliny the Elder, that the obliquity of the ecliptic was discovered by Anaximander; but Plutarch, *De placitis philosophorum* Book 2, chapter 12, attributes this to Pythagoras, while Theon ascribes it to Oenopides.

Chapter XVI. What I said in chapter 14, number 6, and in this chapter on divine Providence in distinguishing the five zones by the obliquity of the ecliptic, Kepler pursues broadly and learnedly in the *Epitome of Copernican Astronomy*, Book 3, from p. 330. [Margin: Reason for the number and latitude of the zones.] For if the ecliptic were not inclined to the equator, but the Sun

ran perpetually along the equator, there would be no variety of seasons and no alternation of the quarters of the year. Conversely, if it were inclined to the equator at a right angle, and the Sun always travelled along some fixed meridian of the movable heaven, the properties of all the zones that now exist would be confounded. For all climes would share in the conditions of the torrid, the temperate and the frigid; but in the zones that are now frigid and temperate, that is, in the greatest part of the globe, there would be excessive cold because of the total recession of the Sun, and excessive heat because of its approach to the zenith [verticem]. As it is, the alternation of these qualities is so distributed that the variety in the nature of living things and animals, suited to their heterogeneous parts and humours, is preserved, and the unbearable long duration of cold and heat is removed; and the extreme regions, torrid and frigid, are joined by the temperate ones between them, and not immediately.

[Margin: Proportion of the parallels to the equator.] Chapter XVIII. On the proportion that the parallels and their degrees have to the equator and to a degree of the equator, see Book 10, Section 4, Problem 1.

[Margin: The mediation of the heaven, taken equivocally among astronomers.] Chapter XXII. In Definition 35, with Copernicus, Book 2, chapter 3, and most others, I defined the mediation of the heaven [Mediationem cęli] as the point of the ecliptic that crosses the meridian at the moment some star crosses it; and with this meaning Magini assigned mediations of the heaven to the chief fixed stars in the introduction to the Ephemerides, part 4, chapter 5, as Montebruni also did later at the end of his Ephemerides. Yet the same Magini, in the Directions of the primum mobile, Canon 8, and in their tables, p. 54, just as Regiomontanus once did in the Directions, Problems 3 and 4 and pp. 16 and 40, used the mediation of the heaven for the point of the equator crossing the meridian together with the point of the ecliptic or the star; that is, for right ascension.

[Margin: Increase of the artificial day from refractions and from the rising of the Sun's limb.] Chapter XXVI. On artificial days lengthened by the refraction of the ray, which apparently raises the Sun, see Book 10, Section 3, Problems 12 and 13, if anyone is hurrying to that learning. But the day is also lengthened, if you reckon it from the rising of the upper limb to its setting, by as much as the time required for the whole disc of the Sun to rise; on this see the small table in the Appendix to Book 3, chapter 10.

Chapter XXVII. If anyone wants the authors of tables of the semidiurnal arc or time, let him consult Book 10, Section 2, Problem 10, where I also teach other ways of composing them, from Problem 7.

[Margin: Altitude of the twilight exhalations.] Chapter XXXI. To complete the teaching of this chapter, two problems are needed first, to be sought from Book 10: one in Section 3, Problem 25, for deducing the moment of time from the fixed stars; the other in Section 2, Problem 221, for finding geometrically the depth of the Sun at that moment. What I promised in this chapter 31, number 3, about correcting this altitude by refracted rays, I chose to perform in Book

8, chapter 14, from Problem 4, where I refuted the opinion of Gassendi, who thinks that it comes out twice as small because of refractions, and I recast a new table for this altitude. Nor did I follow Kepler in the *Epitome of Copernican Astronomy*, Book 1, p. 73, where he thinks that a ray of the Sun, refracted at its first entry, before it goes out of the refracting air and is refracted, is thrown back inward repeatedly within this air, from its surface as from a mirror; for I do not think this air is so bounded that it has the smoothness necessary for a mirror.

[Margin: Kinds of risings and settings, and their definition.] Chapter XXXII. On the kinds of rising and setting of the stars, I have set out many things for the now better-instructed reader in Book 6, chapters 20, 21 and 22, from which very many examples can be sought, and from chapter 21 several kinds as well as definitions and rules; and anything said obscurely or less exactly in this chapter 32 can be illustrated or corrected from there. But let him who instructs beginners beware lest with too abstruse learning he deter them from the study of astronomy rather than attract them.

[Margin: Aspects of the stars.] Chapter XXXIII. Some things about the aspects had to be given as a foretaste in this place; but a fuller treatment was to be put off to Book 7, Section 5, chapter 9, as has been done. Let the reader fly ahead to it, however, if, impatient of delay, he wants to survey together all the material on the same subject.

[Margin: Parallaxes.] Chapter XXXV. A few things about parallaxes are indicated here for novices; more are said elsewhere: namely, on the parallaxes of the Sun in Book 3, chapter 8; of the Moon in Book 4, chapters 13 and 14; of both, for use in eclipses of the Sun, in Book 5, chapter 10; and of the remaining planets in Book 7, Section 6, chapter 7. The complete treatise, however, and all the problems of parallaxes I deliberately reserved for Book 10, Section 5; nor do I yet regret having discussed them in different places, as the proper subject of each book required.

[Margin: Refractions.] Chapter XXXVI. Likewise the candidate in astronomy had to be advised about refractions in this place; but their effects had to be treated afterwards, as the occasion varied, in Book 3, chapter 2, number 10, and chapter 9, and in Book 4, chapter 15, and Book 5, chapter 5. The truly subtler problems, however, had to be reserved for an entire section on them, which is the sixth of Book 10.

AD LIBRVM II.

To Book II.

[Margin: The height of mountains does no harm to the roundness of the Earth.] Chapter I. If you are loath to await the edition of volume 2, in which my *Geographical Book* stands, you may still take the argument from this Book 2 of the work now appearing, chapter 7, where the Earth's diameter is treated, and from Book 10, Section 4, Problem 30, and Section 6, Problem 50, where the

height of mountains is treated. For we know that the highest of the mountains on which history and evidence give any certainty is the Caucasus, and it does not exceed 50 Italian miles, of which there are 8278 in the diameter of the Earth and 4139 in the semidiameter; and in this figure the number 50 is contained 83 times. Take, then, even a wooden sphere whose semidiameter is 83 equal small parts, and place on it some grains or little mounds of wax, their height equal to a single one of the 83 parts; and you will see by experiment with your own eyes that their tiny size does no harm to the physical roundness of the sphere, especially when it is viewed from a distance.

[Margin: The Earth's position in the middle of the world.] Chapter II. In Number 1, where it is said that according to the Copernicans the Earth moves in that annual orb in which the others hold that the Sun moves, this must be understood of that orbit as regards the orbit's size and the manner and speed of the motion, not as though the Earth stood in the same position in the space of the world. To argument 6 of the same chapter a seventh can be added, from Kepler's *Epitome of Copernican Astronomy* [Epitome Aſtronomiæ], Book 1, p. 38, taken from the appearance of the Milky Way, which the Germans call St James's path. For it divides the sphere of the fixed stars into two apparent hemispheres in such a way that, although it is not of great breadth, nowhere on Earth is anything but half of it seen, that is, an arc of nearly 180°. But if the Earth were outside the middle of the world, withdrawn to one side, it would see the whole milky circle at once, as a circle of the sphere that is not a great circle but a small one. If it lay indeed in the plane of the milky circle, but came nearer to it on one side, a smaller part of the Milky Way than 180° would be seen by it, while the antipodes would see many more degrees of it than 180.

Chapter III. In Scholium 1 of this chapter, the arguments from the parallax of the annual orb and from refractions that I brought against the Copernicans, partly in Book 6, chapter 7, and partly in Book 9, Section 4, have force only against the measures of some Copernicans, not absolutely against Copernicus. Against him, however, there are other arguments, physico-mathematically evident, on which see the same Section 4 of Book 9.

[Margin: Whether the centre of heavy bodies is the same as that of the universe.] Chapter IV. In this place I discussed the common centre of gravity of all bodies according to the opinion more received in the schools, that of the Earth's rest. But whether, with the Earth moved through the annual orb, its centre turns out to be the centre of all heavy bodies, which heavy bodies seek in order to have and keep a fixed place in the world, or whether they tend to it so that parts may be joined to their whole, must be discussed in Book 9, Section 4, chapters 8 and 25. The error of the geometers in measuring mountains, indicated in this same chapter at number 8, I repeat in Book 10, Section 4, Problem 32, but there I bring the remedy.

[Margin: The size of the Earth compared with the heaven.] Chapter VI. Scholium 2. If you are in a great hurry here and are eager to know how large the Earth is relative to the Sun, Saturn, etc., see Book 3, chapter 11, Problem 1,

and Book 7, Section 6, chapters 9 and 10. But if you want to know how large it would appear if viewed from the planets or fixed stars, see Book 7, Section 6, chapter 13.

[Margin: The Earth's diameter and circumference.] Chapter VII. I admit that in this chapter, on account of the beauty and necessity of the problem, I reported the opinions of others in such a way that I did not then intend to set them out geometrically in this first volume with figures of their own. But in Book 10, Section 4, from Problem 2, I chose to carry this out, lest, if volume 2 should perhaps never see the light, cosmography should be left incomplete in this part. Let the reader therefore join together, if he pleases, what is said there and here, so as to have a fuller learning on these matters. Moreover, compare the former method, which I reviewed from Father Casati in Number 4, with the one I brought from Clavius in Book 10, Section 4, Problems 5, 6 and 7: for they seem the same, but they are different. Add to these, besides, the opinion of Bartolomeo Crescenzio in Book 2 of the *Nautica Mediterranea*, where he says that ship-masters [Naucleris] have found 87½ miles in each degree of the meridian circle. This is nearly true of the older Roman miles, and Alessandro Piccolomini had said it before him in his work on the sphere. I also remember having read somewhere of 100 English miles attributed to one degree by Francis Drake. Marin Mersenne, on Genesis, p. 111, gives the Earth's semidiameter 3436 Italian miles and the circumference 21600, or 7200 leagues.

Chapter X. Besides the table placed here, see another, constructed by me, in Book 10, Section 4, Problem 39, running up to an eye height of 50 Italian miles of Bologna, or 63 ancient Roman miles, which I take to be the greatest height of mountains. Beneath that one I have placed a third as well, from Kepler. [Margin: Distance of sight.] From all of these, however, Crescenzio stands refuted. [Margin: Crescenzio's error.] In Book 1 of the *Nautica Mediterranea* he had said that the greatest distance from which lookouts on the ship's top lookout post see other ships and their sails is 20 miles, a distance which the eyes of those looking from the bottom of the ship nevertheless do not reach; and he had added that according to most ship-masters the cause of this difference is the roundness of the sea's surface. Yet he dares to pronounce this openly false, because at a distance of 18 miles the sea does not fall away from the straightness of the horizontal line by more than two paces. He himself therefore puts the cause in the thickness of the vapours that lie between the object and the eyes of those looking from the bottom of the ship, whereas those looking from the masthead enjoy purer air. But he errs badly in geometry: for at a distance of 18 Italian miles the sea, because of its roundness, falls away from the horizontal straight line by more than 30 paces, as you see in the table of this chapter. Therefore, if the top of a ship's mast is seen from the top of another's 20 miles away, either both masts must be 15 paces high, so that a height of 30 paces rises from the two together, or whatever one lacks of 15 the other must have to spare. That is, unless perhaps refractions of the denser air help somewhat in seeing

an object otherwise not to be seen from so great a distance, according to what will be said in Book 10, Section 6, Problem 50.

Our Georges Fournier treats this problem learnedly in Book 19 of the *Hydrographie*, chapter 8. Taking from Tycho a diameter of the Earth of 1718 German miles, he shows that a man 6 feet tall cannot see from the surface of the sea beyond a French league, that is, beyond 15000 feet or 3000 paces. He attributes to Eratosthenes the same opinion that Macrobius held, namely that of 180 stadia; but if this is true, he teaches that the place from which the sensible horizon was being viewed was 368 ⅓ feet high, or 73 ⅗ [?] paces; that the place from which Proclus and Geminus estimated the distance of sight was 2274 paces high, if that distance was 125000 paces or 1000 stadia; and that Lilybaeum too is 7358 paces high, if, as Cicero relates in Book 4 of the *Academic Questions*, Strabo from its summit counted ships still lying in the harbour of Carthage, namely from a distance of 1800 stadia or 225 miles, although Pliny the Elder, Book 7, chapter 21, restricts that distance to 125 [CXXV] miles, unless 225 [CCXXV] is to be read. Finally, if what Patrizi relates and the French ship-masters assert is true, [Margin: Fournier's opinion on the distance of sight.] that the mountains of the island of Corsica are seen from as far away as Toulon, namely from a distance of 100 leagues or 300 miles, they must rise 5807 geometric paces. He does not, however, think that any mountain is really found 7358 paces high in the perpendicular; on this we are compelled to disagree with him, because of what was said in Book 1, chapter 11. Yet he rightly concludes that the distance of sight varies with the height of the eye, or of the visible object, or of both.

[Margin: Kepler's opinion on the view of the sea from mountains.] But Kepler too, in the *Epitome of Copernican Astronomy*, p. 26, says that the reason why intervening seas and the circles of visible land look flat is that the highest mountains are no taller than half a German mile, and from that height an object does not appear to be depressed below the horizontal line by more than two degrees. Yet, he says, there is scarcely any mountain so great from which a free view over the sea lies open and is not obstructed by other mountains, forests and so on, unless perhaps the mountains of Chile are of that kind. But on the height of mountains he is mistaken, as I said in chapter 11.

[Margin: Whether the sea is higher than the land.] Chapter XIV. The question could have been added whether the sea is higher than the land of its shores, as it commonly appears to be and as seems to be gathered from Sacred Scripture; but Ascanio Martinengo has already treated this learnedly in the *Glossa Magna*, p. 736. Kepler touched on the optical cause in Book 1 of the *Epitome of Copernican Astronomy*: the eye sees the more remote parts of a floor by a more elevated ray.

[Margin: The depth of the sea.] Georges Fournier, in Book 18 of the *Hydrographie*, chapter 13, lists various depths of the seas. He says that near the Cimbric Chersonese, or Jutland, the bottom of the water has been found with the sounding-lead [bolide] at 24 ells, each of which consists of 6 feet; near Frisia at 18; near Zeeland at 26. Those going from Cape Finisterre toward Ireland on

a north-north-east course [per Nord Nordest], at a distance of 24 leagues from the shore, find the water 60 ells deep; toward Picardy 20 or 24; near the shores of Bordeaux, at the distance at which the eye discovers land, the depth is found to be 40 ells; 22 leagues south of Belle-Île [Inſula Bella], 70 ells; and between England and the Surlingas [the Scilly Isles], 70. He adds, moreover, that unless the lead of the sounding line is proportioned to the length and weight of the rope, it floats and does not descend to the bottom, and that this is why the sea seems in some places to have no bottom. Posidonius, in Strabo, Book 1 of the *Geography*, asserted that the sea had been found 1000 ells deep; although ship-masters, where they have reached a depth of 100 or 120 ells, do not care about the rest, being confident that they are then far from the shore and from shoals. Finally he censures the method of Leon Battista Alberti for measuring the depth of the sea, as I also did in Book 2, chapter 5, number 10. Robert Dudley [Robertus Dudlæus] lists several other depths in the *Arcana of the Sea*; and in Book 2, chapter 8, Rule 34, he concludes that a whitish colour of the sea is a sign of a nearby shore and little depth, a bluish colour of moderate depth, and a deep blue of great depth.

[Margin: The equilibrium of seas.] I return to Fournier, who in the same Book 18, chapter 9, asserts that it is impossible for seas that communicate with one another by their waters, at least through some strait, to be higher one than another. He therefore considers groundless the reason for the fear of the kings of Egypt, that if they joined the Arabian Gulf to the Mediterranean by removing the isthmus, the gulf would overwhelm Egypt. Nor does he believe, as some allege, that the sea at the port of Nombre de Dios [Nominis Dei] is higher than the sea at the port of Panama, or that because of this height there would have been anything to fear if that isthmus of 7 leagues were dug through, as certain Spaniards wished.

[Margin: The tide of the sea.] Chapter XV. Below, in Book 9, Section 4, chapter 14, there will be occasion to go over the history and rules of the tide of the sea again, more accurately and at greater length, against Galileo's fictions.

As for the currents [Currentes] of the waters of the ocean, on which see here at number 1, consult Fournier, Book 9 of the *Hydrographie*, chapters 22, 23 and 31, and Robert Dudley, Book 2, chapter 21, of the *Arcana of the Sea*, where there is very much learning about them; the same author, p. 66, adds rules of flow and ebb. See also what I shall add in Book 9, Section 4, chapter 14, number 13, and the history of the tides in the Cimbric Sea in Heinrich Rantzau, in the *Calendar* [Kalendario], from p. 489.

Chapter XVI. On ships, their kinds and parts, Fournier should be read in the whole of Book 1 of the *Hydrographie*. On the speed of sailing westward I shall speak in the Appendix at chapter 17, and in Book 9, Section 4, chapter 14, number 13.

Chapter XVII. On the winds, for nautical use, no one I have read treats more accurately than our Fournier in the whole of Book 15 of the *Hydrographie*;

yet Robert Dudley adds many things in Book 2 of the *Arcana of the Sea*, from chapter 20, from which I have chosen to indicate the choicer points.

[Margin: Winds of the sea and of the land.] First, winds risen from the vapours of the sea are moister, warmer, more even, more easily raised by the heat of the stars, purer of the fumes of exhalations, and for the most part more violent than those of the land, if you believe Fournier; and the branches of trees near the sea-coasts are for the most part bent by the breeze toward the mainland, which is a sign that winds from the sea are more frequent and stronger. Second, east winds blow chiefly in the morning and west winds in the evening, and east winds are usually stronger and drier. North winds in Europe, on the other hand, blow violently downward from on high and are cold and dry, the opposite of south winds; yet not rarely the same wind is moist and unhealthy in one region and dry and healthy in another, of which Fournier brings examples in chapter 16.

[Margin: General and fixed winds.] Third, general and fixed winds, or those that are lasting, regular and tempered, are those that in the cold zones and the torrid, within the tropics, are carried from rising to setting, following the daily motion of the Sun. Sailing westward is therefore, other things being equal, healthier and faster, so much so that on the return from the East Indies toward the island of St Helena one comes back almost twice as fast as one went. For this reason the Spaniards, to sail more quickly through the Pacific to the Philippines, China and Japan, set out from Acapulco and go down as far as the 10th parallel; there, having caught the east winds, they cover 3000 miles in 85 days. When they have reached the Islands of Thieves [Insulas latronum], they go up to the 13th degree to find the mouths of the Archipelago and from there reach Manila. But on the return from there to Acapulco, to avoid the force of the east winds opposing them, they must turn north as far as the 40th degree. In the same way, those heading from Seville to New Spain sail nearer the Tropic of Cancer; but on the return, after the passage near the Bahama, which is at 18° of latitude, they withdraw from the equator toward Florida and Virginia, as far as the 40th degree, to avoid contrary winds and gain favourable ones, so as to return to Seville by way of the region of the Azores. Granted, the currents of the sea-water toward the west are no slight cause of this difference. Besides these there are other, regular winds, those which ordinarily prevail in some regions at fixed times of the year; Fournier lists them in chapter 13.

[Margin: Free and variable winds.] Fourth, other winds are called free and variable. Most of those that prevail in the temperate zones are of this kind, if they are compared with those that prevail in the cold or torrid zones; they blow more often in the morning or evening than at noon, are less healthy, more violent, and contend with one another, especially beyond the Tropic of Capricorn. [Margin: Stormy winds.] Among these the stormiest of all, called hurricanes [Oricani] or typhoons [Typhones], arise near the tropics when the Sun reaches the tropics, but outside the torrid zone; and they are more violent near the shores or among islands than on the high sea, or where continents

run out crosswise toward the poles and struggle with their own winds against the fixed winds. In the West Indies, in the months of July and August and part of September, the fixed winds cease and hurricanes and the most violent storms rage, called *Spouff* by the English, especially on the Mexican coast and in the Gulf of Bahama. In those months, therefore, few larger vessels trust themselves to the ocean; these storms also breed most pestilent fevers, which kill within 24 hours. In the same months, in the Gulf of the Ganges, on the coast of Natal and along the Cape of Good Hope, typhoons prevail, no milder than hurricanes. [Margin: The violence of typhoons.] But a storm becomes more dangerous when currents of water are carried against the wind, for from this conflict the waves swell excessively. The whirlwinds of typhoons are dangerous, especially to those sailing toward Japan in the Chinese Ocean, so much so that they sometimes snatch away yards and sails and dash them through the air against crags and cliffs, in the way that griffins in Muscovy and Tartary carry off armoured horsemen with their horses. [Margin: Siphons.] In the Mediterranean, more often than in the ocean, there arise Trumpets [Tubæ] or Siphons [Syphones], namely winds enclosed in a cloud, which suck water back from the sea, discharge it onto ships, and sink them. Storms from subterranean winds that swell the waters must also sometimes be feared, even if the air is calm and the sky clear, as Fournier teaches by examples in chapter 18. He also treats most learnedly of St Elmo's Fire, or the flames of the Tyndarids, in chapter 20; of the cause of winds in chapters 22 and 23; and of the signs of storms in chapters 31 and 32; as does Dudley in Book 2 of the *Arcana of the Sea*. Let it be enough to have indicated these.

[Margin: Magnetic declination.] Chapter XVIII. I promised a longer and better table for magnetic declination; but if anyone does not expect it, or cannot wait, let him consult for these matters Robert Dudley, Book 2 of the *Arcana of the Sea*, chapter 8; Fournier, Book 11 of the *Hydrographie*; Pierre Hérigone, volume 4 of the *Cursus Mathematicus*, from p. 426; and Crescenzio, Book 2 of the *Nautica Mediterranea*, chapters 8 and 9.

De Altitudine Regionum Aeris.

On the Height of the Regions of the Air.

Chapter XIX. Number 1. On the height of the refractive air I have given more, but for those further advanced in astronomy, in Book 10, Section 6, from Problem 43 to 51, where I established that it is in some places, namely above the Euxine and Caspian, no less than 18 or 20 miles.

[Margin: The third region of the air.] Number 2. What I said about the height of the twilight exhalations will be treated again, on the occasion of comets, in Book 8, Section 1, chapter 14, where I shall confirm my opinion on this height. I said, moreover, that the uppermost region of the air is as great as that of the exhalations [halituum seu exhalationum]. Understand this to mean that it is not smaller, but not that it is precisely as great as that of the

twilight exhalations; for other exhalations, subtler than these and less opaque, can rise higher than the twilight fumes. And certainly it is fair to leave some place for the purest air, as Cabeo observes on Book 1 of the *Meteorologica*, text 10, question 1. In addition, the height of some sublunary comets urges the same. Besides, this was said according to the opinion of the Peripatetics, who place fire above the air; for those who deny an element of fire distinct from the heaven and the remaining three elements, whom I shall list in Book 9, Section 1, chapter 1, questions 4 and 5, are divided into four classes. The first teaches that fire does indeed exist, but that it extends from the air all the way to the firmament and does not differ from the ethereal or celestial substance; I shall list these in Book 9, Section 1, chapter 1, question 4, and chapter 5, question 3; and add Paracelsus to them. The second, akin to this, places nothing between the air and the firmament but an ethereal breeze, though they do not say that it is fire: so Kepler, here and there in his works. The third places air from the Earth all the way to the firmament: so Froidmont, Book 1 of the *Meteorologica*, chapter 2, with Thomas Fienus [Thomas Fyens] in *The Comet of the Year 1618*, and before him Rothmann, in Tycho's *Letters*, from p. 106 to 112, from 121 to 124, and from 137 to 139, contending from the likeness of their transparency that pure air and ether are one substance and of the same species, while impure air, which produces the refractions, is watery. The fourth places air up to the Moon, and that substantially distinct from the ether or heaven. I shall list its authors in Book 9, Section 1, chapter 1, question 4, and above all Tycho in the places cited, and in volume 1 of the *Progymnasmata*, p. 92; add to them Cabeo on Book 1 of the *Meteorologica*, text 15, question 1, and Franciscus Resta [Francesco Resta], Book 2 of the *Meteorologica*, chapter 2. Let this be said on the occasion of the third region of the air.

[Margin: The second region of the air.] Number 3. What I said about the second or middle region of the air depends on a double controversy, one about the height of clouds, the other about the height of mountains. On both there is great diversity of opinion and uncertainty, and far greater if anyone should wish to determine one from the other, namely the height of clouds from the greatest height of mountains, or the height of mountains from the height of clouds. On the height of clouds I have said enough here; I add, however, the following. Suppose that, as Pliny the Elder, Book 2, chapter 23, reports from the opinion of many, some clouds rise to 900 stadia, or 112 Italian miles; and what Father Emmanuel Maignanus [Emmanuel Maignan] reports in his *Perspectiva Horaria* as observed by himself and others supports this: small clouds around midnight at the interlunar time lit by the Sun, and therefore lying outside the shadow of the Earth at a great height. If these things, I say, are true, the height of mountains is badly estimated from the height of clouds, for I said in chapter 11 that mountains scarcely reach 51 Italian miles in perpendicular height. [Margin: The fallacy of the argument for the height of the air from mountains.] But the argument Cabeo touches on, Book 1 of the *Meteorologica*, text 15, question 2, about Mount Olympus, once immune from winds, clouds and rain and yet not

higher than 10 or 11 stadia, is most fallacious and most unsuited to determining the height of the second region of the air. [Margin: First reason for the fallacy.] First, because the height of Olympus was not taken as a perpendicular above the sea, but in the way I have taught to be fallacious in Book 2, chapter 4, number 8, and Book 10, Section 4, Problem 32. For Plutarch, in the *Aemilius Paulus* [in Paulo Æmylio], relates that Xenagoras measured it from the Temple of Pythian Apollo; so Olympus was much higher above the surface of the sea than 10 stadia, as Maioli too judges in Colloquy 16. [Margin: Second reason.] Second, what St Augustine, Book 1 of *On Genesis against the Manichaeans* and *On Genesis Literally*, Book 1, chapter 14, and Book 3, chapter 2; Solinus, chapter 13; and St Isidore, Book 14 of the *Origins*, chapter 4, relate about the ashes of the sacrifices left untouched by wind and rain on the summit of Olympus: [Margin: The excess of Olympus above the clouds and winds called into doubt.] granted that this is not to be referred to the power divinely permitted to demons, who, to entice the heathen and to win authority for those sacrifices, kept those ashes intact, as Aversa reports, Question 42 of the *Philosophy*, Section 9, it can still be traced to a peculiar property of that region. Because of the quality of its soil, no doubt, it would not supply vapours and exhalations fit for so great an elevation or for strong winds, but only for light breezes. Cardano held this in Book 2 of *De subtilitate*, and held that for the contrary reason some mountains higher than Olympus can yet be subject to winds, snows and rains and have clouds above them, especially if there are lakes not far from the peak from which vapours can rise, and if they are not so rocky, pumiceous or ashy that exhalations can hardly be drawn from them.

[Margin: Third reason for the fallacy.] Third, many call the excess of Olympus above the clouds into doubt for this very reason, that with Aristotle they think the middle region of the air is bounded by the tops of the highest mountains, and that therefore there is no mountain that exceeds the clouds. Among them are Vives and Coquæus [Leonard Coqueau] on St Augustine, *De Civitate Dei* Book 15, chapter 27; Pererius on Genesis, Book 12, disputation [d.] 9; Fernandez on Genesis chapter 7, section 4; and Salianus in volume 1 of the *Annals*, at the year of the world 1656, numbers 34 and 35. The reason being, of course, that Francesco Filelfo [Franciscus Philelphus], as Mazzoni reports on Dante, Book 3, chapter 12, and Maioli in Colloquy 16, climbed Olympus and yet saw clouds not below him but above (which, however, one could attribute, with Francesco Resta, Book 2, chapter 2 of the *Meteorologica*, to the height of Olympus now diminished by the floods of so many centuries, floods being sufficient for this around the middle of the mountain and undermining the foundations of the summit). Or at any rate the Olympus Filelfo explored was a different one, as Mazzoni and Maioli think. But Genesis 7 says of the Flood: *And all the high mountains under the whole heaven were covered. The water was 15 cubits higher over all the mountains it had covered*; and at the end of the Flood it rained from the clouds. Much more, then, did the clouds from which those rains came exceed Olympus and all the mountains; which, however, one might

attribute, not without a miracle, to an extraordinary elevation of the clouds, rising with the increase of the waters that burst from the abyss. And Froidmont rightly denies, Book 2 of the *Meteorologica*, chapter 6, article 5, that the water of the Flood, or its clouds, should be judged by the common laws of meteorology. [Margin: St Augustine's excellent opinion on the height of mountains.] And so St Augustine, *De Civitate Dei* Book 15, last chapter, and in the *Questions on Genesis*, question 10, said shrewdly: *On the height of the mountains, all of which, it is written, the water overtopped by 15 cubits, some wrongly have doubts because of the story of Mount Olympus. For if earth could invade the space of that calm air, where it is said that neither clouds are seen nor winds felt, why not water too, by rising?* By the name of earth he means the summit of Olympus.

Now who would not hiss off Caietanus, who, on Genesis chapter 7, preferred to deny, against the plain and universal sense of Holy Scripture, that absolutely all mountains were covered by the waters of the Flood? For he says that only those were covered which are under the airy heaven, or under the second region of the air, in order, of course, to except those mountains that are said to lift their peak above the clouds. But Sacred Scripture says that all the high mountains under the whole heaven, etc., were covered: what more universal could be said? Or if Holy Scripture is not to be taken so universally, why does Caietanus take with such rigour the Apostle's saying about Adam, *In whom all have sinned*, so that by no reason and no authority of the Doctors [Margin: Caietanus is censured in his exposition of Holy Scripture.] can it be removed from including the Blessed Virgin MARY under the common stain of original sin? Must Olympus, then, on the authority of two or three men, be exempted from the waters of the universal Flood, while the Most Holy MOTHER OF GOD [DEIPARA], exempted by GOD with so many other privileges from the common condition of mankind, could not by the sublimity of her dignity and merits, and by the prerogative of divine munificence toward her, rise above the flood of original guilt as if by the loftiness of a summit: she, I say, of whom it is said in Psalm 86, *Its foundations are in the holy mountains*? But this in passing. Salianus's other reason, for which he thinks fabulous what is told of Olympus, and which Pererius too had adduced, is that on the one hand Olympus, by Xenagoras's measurement, was no higher than 10 ⅙ stadia, and on the other vapours rise to 52 or at least 43 miles, as from the twilights de- monstrate Nonius and Clavius; at which point Salianus and Pererius confuse twilight exhalations with rain clouds, but wrongly, and so they are rightly censured by Francesco Resta in Book 2 of his *Meteorologica*, chapter 2.

[Margin: Pererius and Salianus confuses [confundit] twilight exhalations with clouds.]

[Margin: 4. Reason.]

Fourth. From history it seems certain that there are several mountains which are higher than the clouds and beyond the common hazard of rainstorms, winds and snows. For Geminus, in his *Elements of Astronomy*, chapter 14, affirms of Mount Cyllene too what is said of the untouched ashes of Olympus, and

adds that Satabyrium rises above all clouds. Aristotle, section 26, problem 38, affirms the same of Mount Athos, as do Solinus, chapter 16, and Pomponius Mela, Book 2, chapter 2, who add as evidence the untouched ashes; and for that reason, they say, there was on its summit a town called Acroton, and later Uranopolis and Apollonia, so healthful that people there lived twice as long, and were therefore called Macrobii; and Pliny the Elder, Book 4, chapter 10, subscribes to these authors. And Aelian, in the *Varia Historia*, relates that when physicians advised Plato to leave the unhealthy site of the Academy and move to the Lyceum for his health, he replied: *I would not move even to the upper parts of Athos, which are most healthful, in order to live longer.* On Atlas lifting its head above the clouds, see Solinus, chapter 27; Mela, Book 3, at the end; and Martianus Capella, Book 6, the chapter on Africa, even though Pliny the Elder, Book 5, chapter 22, says that its summit is covered with deep snows in summer too, and Virgil sings of it in *Aeneid* 4:

whose pine-bearing head, with black clouds, is beaten both by winds and by rain.

Franciscus Aluarez [Francisco Álvares], chapter 35 of his *Ethiopian Affairs*, relates that in a province of Ethiopia called Temei there are mountains like pyramids, of no great circuit at the base but so steep that they are higher than the clouds. And Father Alphonsus Oualius [Alonso de Ovalle], chapter 5 of his *Account of Chile*, asserts that the mountains of Chile are so high that the air is scarcely fit for breathing because of its thinness, and that frequent panting has to be tempered with small linen cloths held to the mouth; that not rarely falling stars have clung to the feet and ears of many people and frightened them; that perpetual clouds are looked down on below, the sky in the upper parts being always clear, and that the rainbow is seen underneath like a footstool; and that while it rains and hails below, travellers meanwhile tread those rocks dry and parched, and that the rocks are white and very bright, and the rays of the Sun are thrown back from them as from mirrors; yet in winter they are covered with snows; so that even from this you may notice that the domain of the snows is much higher than that of rainstorms and rains,

[Margin: 5. Reason.]

Fifth. The reason why Aristotle drew the boundary of the second region of the air, assigned to snows and clouds, a little below the summits of the highest mountains was that clouds are not carried along by the motion of the primum mobile, whereas he thought that comets are carried along by that motion and come to be in the highest region of the air. But since that carrying-along [raptus] does not reach below the Moon, the heaven of the planets being of course fluid, as we shall say in Book 9, section 1, chapter 7, he feared in vain for clouds carried above the mountains. Then too, even if that carrying-along were granted, it could not be impeded by the summits of the highest mountains, which are very rare. So the division of the air handed down by Plato in the *Timaeus* seemed sufficient, to which St Damascene [John of Damascus] later subscribed in his *Physics*, chapter 13: namely, into a purest aether, dry and hot, and into a turbulent air, more humid and colder. Pererius, however, in Book

12 on Genesis, disputation 10, places the middle region of the air so far above all the mountains that the Flood either did not reach it, or reached only its lower part.

CONCLVSIO.

Conclusion.

It is therefore established from what has been said that the height of the whole air, or of its regions, is uncertain, since it is uncertain whether below the Moon there is an element of Fire distinct from the aether; and, if there is, how far the air reaches, both the air which is the seat only of the subtler and hotter exhalations, and the air which is the seat of snows, winds, clouds and rains: for twilight exhalations do not exceed 100 Italian miles, as I taught in Book 1, chapter 31, and shall teach in Book 8, section 1, chapter 14; and yet some very light small clouds may have risen beyond this limit. In some places, moreover, and at some times, clouds and winds stay below mountains that are not the highest; and conversely, in other places and at other times, much higher mountains have their heads exposed to snows and clouds, especially if there are lakes around their middle parts, from which vapours can be raised above their summits. Finally, it is wrong to infer either the greatest height of mountains from the greatest height of clouds, or the greatest height of clouds from the greatest height of mountains; or the greatest height of some clouds or some mountains from the greatest height of other clouds or other mountains. In general, however, it seems certain that no mountains are much higher than 50 miles, that no small clouds or twilight exhalations are much higher than a hundred or a hundred and twenty Italian miles, and that air dense enough to be suited to sensible refractions of the rays of the stars is not raised much beyond 20 Italian miles. The first is clear from what was said in Book 2, chapter 11; the second from what was said in Book 2, chapter 19, and in this appendix to that chapter; the third from what will be said in Book 10, section 6, problem 51.

[Margin: 3. Certain things about the height of these.]

CAP. XX. Gassendi, in Letter 1 *De motu impresso*, p. 64, holds with Galileo in Dialogue 2 *On the Systems* that the reason why the arcs of vibration of one and the same pendulum become smaller and smaller, and why the pendulum finally comes to rest, is twofold: namely, the resistance of the air, and the weight of the cord or chain and of all its parts. For the parts nearer the vertex of the motion strive to swing back and forth more often, just as if they were partial and separate pendulums, while the more remote parts do so less often; and from this a certain resistance arises. From this Gassendi infers that if this motion took place in a vacuum, and the hanging weight were suspended from a radius of no heaviness, the motion of the pendulum to and fro would be perpetual.

[Margin: Cause of the pendulum's rest.]

Hydrargyric or mercurial clocks, which Tycho finally abandoned in astronomy and found unreliable (volume 1 of the *Progymnasmata*, p. 149), were taken

up by Robert Dudley, Book 1 of the *Arcana of the Sea*, for measuring a sea voyage, and he teaches their construction and use. He recommends using six clocks full of quicksilver, and gives their measure as set out below.

[Margin: Clocks of water or of quicksilver.]

For the time of the primum mobile (hours, minutes)	Pounds of quicksilver
0^h 1^m	1
0^h 5^m	3
0^h 30^m	4
1^h 0^m	6
6^h 0^m	12
24^h 0^m	24

And he rightly warns that a whole clock, and not a part of it, contains a correct time; and that if the liquid of one entire clock is allowed to run out, sea water can be used in place of quicksilver. For he says he found by experience that from one sunrise to the next 1800 pounds of water often flowed out of his glass vessel, and that he never found a greater difference in weight than half an ounce, to which 30″ correspond, since 1800 pounds, that is, 21600 ounces, correspond to 24 hours, that is, to 1296000 seconds of the hours, and so one ounce corresponds to 60″. But in astronomical observations we cannot use only whole clocks: the count of time has to be ended the moment a star has arrived at the meridian or at another vertical circle, or an eclipse has ended, or the whole diameter of a luminary has passed, and so on. The use of the pendulum is therefore better suited to astronomical observations.

What I said about the pulses of the artery, from the observation of Cardano, of Wendelen and our own, stands somewhat differently in Fromondus, from his own observation, Book 2 of the *Meteorologica*, article 10. For he says that his own healthy artery beats 4450 times in one hour; and that thunder, after the flash of lightning, is heard scarcely one beat later, whereas between the sound of a larger firearm and its flash 10 beats of the artery intervene, which I think too many.

[Margin: How many beats does the human artery make in one hour?]

CAP. XXI. The experiments on the speed of naturally descending heavy bodies will have to be illustrated by many others in Book 9, section 4, chapter 16, since arguments against the Copernicans will be drawn from them. Having considered these, I hope that D. Vicenç Mut will not assert that all heavy bodies, even of unequal weight, fall in equal time, as he did in his *Sol Alphonsinus*, no. 50.

AD LIBRVM III.

On Book 3.

[Margin: The substance of the Sun, and encomia of it.]

CAP. I. Auersa [Raffaele Aversa] thinks the Sun is liquid, and so does Aristarchus of Samos brought back to life, in the *Systema mundi*, p. 23, as Hevelius reports without refuting it, chapter 5 of the *Selenographia*. Moreover, I have not seen fit to gather more encomia of the Sun from elsewhere. Yet on this subject St Gregory Nazianzen, Oration 2 on Theology, St Cyril of Jerusalem, Catechesis 9, and St Ambrose, Book 4 of the *Hexaemeron*, chapter 1, stand in place of all the Fathers; add to these, if you please, Julian's oration on the Sun. On the substance and production of the Sun, there is more from Sacred Scripture and the Fathers in Book 9, section 1, chapters 4 and 5; to these add Francesco Resta, Book 1 of his *Meteorologica*, chapter 3, who suspects that the Sun is an aggregate of many stars, and Caussinus [Nicolas Caussin], Book 2 of *De Domo Dei*, from chapter 2.

[Margin: The magnetism of the Sun rejected.]

CAP. II. In no. 6 a few things are touched on here about the motive force of the Sun; they are treated more fully in their own place, on the movers, namely Book 9, section 2, chapter 1. What is touched on here in no. 7 about the magnetic force of the Sun, Father Niccolò Zucchi rejects in his *New Philosophy of Machines*, part 5, section 12, especially as regards the Moon, whose monthly or half-monthly libration about its own centre does not follow the laws of the annual or half-yearly libration of the Sun about its centre, detected from its spots by Scheiner, and to be explained in Book 9, section 4, chapter 12.

To Scholium 1 of this chapter add what we shall say about the ellipse of the Sun, from Diodorus Siculus, Book 17, in the appendix to chapter 10, near the end.

CAP. III. Do not be surprised that little has been said here about the spots of the Sun. For since the argument taken up here from Galileo, and boasted as evident against the rest of the Earth and for the motion of the Sun, had to be refuted in Book 9, section 4, chapter 12, it seemed best to discuss this matter there more carefully than elsewhere, so that the subtlety of this argument and the solidity of the reply might be more manifest. To the opinions on the substance of sunspots indicated at no. 10, add the opinion of our Adam Tanner, in his dissertation on the heavens, question 7, paragraph 5. There he says that in 1611, from October 21 to the end of the year, and through almost the whole of the following year, he observed spots on the Sun with a spyglass and pointed them out to others; that they are above the Moon and very close to the Sun; but that their phenomena can be defended without corruptibility and without fluidity of the solar heaven, if they are said to be moved like planets on their own eccentrics and epicycles around the Sun. Lessius also taught this, Book 1 of *De Providentia*, chapter 2, and Tanner repeats the same in volume 1 of his *Theological Summa*, disputation 6, question 5 on the heaven, assertion 2. But Ouiedus [Francisco de Oviedo] too, in the single controversy on the heaven, point 2, no. 20, or p. 468, and Arriaga, in the single disputation on the heaven, section 5, no. 42, or p. 443, think that these spots can be explained by local motion, without generation and corruption. But against these authors see

what will be said in Book 9, section 4, chapter 12, nos. 19 and 20. Further, Johannes Hevelius, chapter 5 of the *Selenographia*, judges that these spots are soots expelled from the mass of the Sun by the force of its heat, and faculae brighter parts of the Sun; and he says that the Sun was without spots in 1642 on October 26 and November 18, and in 1642 on October 12. Caussinus, however, Book 2 of *De Domo Dei*, chapter 8, thinks they are circumsolar stars.

[Margin: The substance of sunspots.]

[Margin: The Sun without spots.]

[Margin: Our System.]

[Margin: And D. Baliani's.]

CAP. VI. Our System, proposed here in no. 6, is put forward only as probable, provided that the eccentricities of the planets from the Earth and from the Sun are made so great that the phenomena of the motions are saved without evident error: we shall speak of it in Book 7, section 6, chapter 4, scholium 4, and in Book 9, section 3, chapter 9. What I likewise suspected here about Baliani's system, I explain later, from a letter the author sent me, in Book 9, section 4, chapter 15.

[Margin: Tycho's error, *facundus*, in the parallax of the Sun.]

CAP. VII. No. 3. It seemed that the reader should be forewarned here that Tycho, because he assumed too great a parallax of the Sun, also made the horizontal refraction too great by about 2′, and the greatest declination of the Sun, or the obliquity of the ecliptic, greater by 1½′ than it should have been; and that this error overflowed into the whole hypothesis of the Sun, and indeed into the distances and parallaxes of Venus and Mercury, as well as of Mars, and also into the right ascensions of the fixed stars, which he measured from Venus. But it would have been untimely to press this on a reader not yet instructed in these matters, so we have reserved these things for their own places, where they are more timely. Moreover, that Tycho did not investigate the parallax and distance of the Sun from any other source, but took them over from Ptolemy and Copernicus, is clear from volume 1 of his *Progymnasmata*, p. 97, where he says that parallaxes are sought from the distances, and adds: *We shall therefore assume here the semidiameter of the eccentric of the Sun, as it was traced out by Copernicus from eclipses; namely, of 1142 semidiameters of the Earth.* Then, on p. 99, from the remaining distances of the Sun, investigated through the eccentricity, he gathers the parallaxes for each degree of altitude.

[Margin: D. Vicenç Mut's foundations for the parallax of the Sun.]

But what shall I set against my very dear friend, the most learned D. Vicenç Mut? In a most erudite little work entitled *De Sole Alphonsino Restituto*, published in 1649 and very generously sent to me, he sets, in marginal number 30, the horizontal parallax of the Sun at apogee at 4′ 37″, and at mean distance 4′ 46″; and in no. 45 he sets the distance of the Sun at apogee at only 744 terrestrial semidiameters. But his foundations are 5. The *first* is that the apparent semidiameter of the Sun is equal to the half-angle of the cone of the Earth's shadow and the horizontal parallax of the Sun taken together, which differs

insensibly from the truth. The *second* is that the semidiameter of the Sun at apogee, as observed by himself, is 15′ 39″. The *third* is that the Moon at apogee, at full moons, is 62 terrestrial semidiameters from the centre of the Earth. The *fourth* is that the semidiameter of the Earth's shadow, at the place where the Moon passes at apogee, is 44′ 22″ from Kepler's observations. The *fifth*, which he demonstrates from 3 and 4 by a geometrical figure and proof, is that the half-angle of the cone of the Earth's shadow, with the Sun at apogee, is 11′ 2″; and when these are subtracted from the apparent semidiameter of the Sun, there remains the horizontal parallax of the Sun at apogee, of 4′ 37″.

[Margin: The falsity of the foundations already mentioned indicated.]

But in truth foundations 2, 3 and 4 are uncertain and, from my observations, false. On the second, that is, on the semidiameter of the Sun, see what was said in Book 3, chapter 10, and what will be said in this Appendix on chapter 10 of this book. On the third, see what was said in Book 4, chapter 14, and what will be said in the appendix on chapter 14 of Book 4. Finally, on the fourth, see what was said in Book 5, chapter 4, and you will see how slippery the observation of the semidiameter of the Earth's shadow is, and that it is gathered more surely either from the parallax of the luminaries and the semidiameter of the Sun, or from the distance of the Sun and its semidiameter and the half-angle of the cone of the Earth's shadow, than the parallax is from the semidiameter of the shadow. Besides, the solar distance that D. Mut deduced from this parallax is manifestly contradicted by the distance deduced from the lunar dichotomy, even if the smallest distance compatible with such a phase is granted: as I said in Book 3, chapter 7, Problem 3, and shall soon teach in the next part of the Appendix to this chapter. It is also contradicted by the parallax of acronychal Mars, which ought at times to be 9′ or 10′ if the parallax of the Sun were nearly 5′, as D. Giovanni Antonio Rocca also wrote to me in his judgement on D. Mut's *Sol Alphonsinus*.

De Distantia Solis per Dichotomiam Lunæ Inuestiganda.

On Investigating the Distance of the Sun by the Dichotomy of the Moon.

[Margin: D. Vicenç Mut's doubts about the dichotomy of ☾.]

In 1650, when I had asked D. Vicenç Mut by letter to turn his attention to the lunar dichotomy and, by the Aristarchean Problem, to deduce the distance of the Sun and from it the parallax, he replied in a letter dated from Majorca on March 5 of the same year that this method seemed to him as doubtful as the one which relies for this purpose on eclipses, from the Earth's shadow: especially since Reinhold and Athanasius Kircher, in the *Ars Magna Lucis et Umbrae*, Book 9, fol. 751, put the digression of the dichotomized Moon from the Sun at 87°, whereas I put it at about 89° 30′, and Wendelen at 89° 45′ ½. Yet at that time he declared nothing certain. In a letter dated August 20, however, he advises that he could not determine the dichotomy of the Moon exactly, because to the naked eye it still appeared concave at 9^{h} 30^{m} after noon, but when seen through

the tube it was less concave, and dichotomized around its middle parts; and that the Moon cannot always show the same face in the quadratures, because of the reciprocal motion of the Moon about its own centre, which the variable distance of the spots from the limb shows. But how much this Problem is to be valued, and by how much more surely the distance and parallax of the Sun are gathered from this than from the shadow of the Earth and eclipses, I taught in Book 3, chapter 7, both by comparing the two and by the authority of Kepler, Wendelen and van Langren, cited in this chapter. Please read again Kepler's words cited there at no. 10, where he says that the distance and parallax of the Sun have until now *depended on the unreliable shadow of the Earth*; and in the *Astronomia Optica*, p. 237, he says: *But when the Moon is dichotomos, from a careful view of the section of the Moon's face you may within a few hours pass judgement on the true quadrature.* Yet he adds that on 1602 December 21, in the evening, at the half-sixth hour after noon [hora dimidia sexta post merid.], the Moon was seen by him still concave, when it had already come to the limit [Greek: τῆς διχατομίας [recte: διχοτομίας] (tēs dichotomias, "of the dichotomy")].

[Margin: On the use of dichotomy, the judgement of Kepler, Wendelen and D. Giovanni Antonio Rocca.]

But D. Giovanni Antonio Rocca too, most expert in astronomy, and indeed in the whole of mathematics, when asked by me in a letter to observe the time of the dichotomy with his own tube as well, replied at last after several observations, on 1651 May 19. He says that scarcely any sensible time intervenes between the first quadrature and the appearance of the dichotomy, and that the distance of the Sun from the Earth must therefore be much greater than most astronomers have so far put it; and he urged me earnestly to advance this problem, from which the distances of the Sun and of the five other planets, and many other things, can be determined better than from parallaxes that are in any case unobservable. And he concludes that this is the most excellent among the physico-astronomical Problems, and that even if all the labours of one astronomer and the cares of a whole life had to be spent on it, his effort would be excellently invested. So he writes. But for the observation of the dichotomy to be made properly, the following Rules must be kept.

[Margin: Rule 1.]

The *first* is that the observation be made not with the naked eye only, but with telescopes, and those of the best and very large. For to the naked eye the Moon generally still appears falcate when it is in itself dichotomized, because the parts lying between the horns are illuminated not continuously but discretely, and among them are many lower parts, like valleys or seas, not yet lit by the Sun; while those peaks of which only the tips are illuminated do not appear to the naked eye, because of their smallness. So in the present figure (which indicates the intended point after a fashion) there are the peaks of rocks or of mountains C, D, E, F, G, H, and between them and the curve A Q L M N P B lie unilluminated parts. Therefore, while the telescope sees the section of illumination along the straight line A E F B, the naked eye sees only the curve

A Q M N B. Furthermore, the telescope should be used in such a way, however, that the whole horns are not compared with the intermediate parts: for the horns AQ and BP, since they are parts of the Moon resembling continents and are moreover full of more prominent parts, are lit by a greater and more continuous light than the lower and interrupted parts; so that if the former were compared with the latter, the intermediate parts would still look too concave beside them. And so the time to observe is that at which the intermediate parts C, D, E, F, G, H, set in one and the same straight line, begin to be illuminated together in such a way that this line bisects the disc of the Moon, and the line EA and EK appear equal, cutting off the quadrant AEK. If this cannot be discerned at once, a time must be chosen between two doubtful moments: namely, one at which the Moon begins to appear bisected, but with hesitation in the estimate; the other at which it now appears plainly bisected, with gibbosity almost beginning if it is the first quadrature, or concavity if the second. If you use an excellent and very large telescope, this time will never exceed half an hour, and will indeed stay well within it, provided the Moon is far from the horizon. And if you use the naked eye, for this reason it will not rarely seem concave to you even after the first and before the second quadrature, which Kepler too admits happened to him, in the *Astronomia Optica*, p. 237. It also helps to apply to the eye a lens convex on both sides, which makes the telescope, however long and powerful, still take in the whole Moon, visible in one view, as is usual with us. But then great care must be taken that the line of dichotomy not be viewed outside the middle of the already mentioned lens; otherwise it would appear by no means straight, even when it is so, but curved toward one part or another, according as the eye is applied to this or that part of the lens.

Diagram. Woodcut of the half-illuminated Moon, set in the left column with the text running beside it. The right edge is the smooth convex limb, from A at the top to B at the bottom; the left edge is an irregular terminator with small detached peaks standing beyond it. Hatched dark patches and small round craters mark the face. A straight line runs across the disc from E on the left to K on the right limb.

- A (top of the limb): label
- B (bottom of the limb): label
- C, D, E, F, G, H (down the left side, each beside a small detached peak): labels
- M (just inside the terminator, below the line from E): label
- N (at the terminator, below G): label
- P (at the terminator, near B): label
- K (right limb, at the end of the line from E): label
- Q (just below A, inside the edge): label
- L (at the terminator, just below C): label

[Margin: Rule 2.]

Secondly. Let those lunar quadratures be chosen whose dichotomy can appear with the Moon not only above the horizon, but also placed in the nonagesimal

degree of the ecliptic, or as close to it as possible. For if it is in the nonagesimal, the same plane which divides on the Moon the shining hemisphere from the dark, and which passes through the horns and centre of the Moon, passes at the same time through the centre of the Earth and through the centre of an eye placed on the surface of the Earth; and so there will be no difference between the time of the dichotomy occurring with respect to an eye imagined at the centre of the Earth and the time of the dichotomy observed on the surface of the Earth, whether the Moon has no latitude or not. And the less it is distant from the nonagesimal, the smaller will be the difference of those times; and moreover the diversity which varied refractions could produce will be avoided. But since this will be very rare, of all the dichotomies occurring outside the nonagesimal, the best for our business is the one in which the Moon has no latitude or the greatest; for then the circle of latitude, drawn through the centre of the Moon, will pass through both horns of the Moon, and not so many things will be needed to find the time of the true dichotomy, as we shall soon teach. The altitude of the Moon, however, must have been taken at the moment of the dichotomy, although it can be found by calculation from the given time and place of the Moon.

[Margin: Rule 3.]

Thirdly. If the dichotomy has been observed outside the nonagesimal degree of the ecliptic, it will be necessary to seek the difference of time between the true dichotomy, that is, as reckoned from the centre of the Earth, and the one observed from the surface of the Earth; for which two or three of the following Problems are needed.

1. Probl. Angulum circuli Verticalis, & Latitudinis in centro Lunæ factum inuestigare, Datis Lunæ longitudine ac Latitudine, Nonagesimo Eclipticæ, & vel Altitudine Lunæ, vel Altitudine Nonagesimi, seu Angulo puncti Eclipticæ Orientis cum Horizonte.

Problem 1. To find the angle of the vertical circle and of the circle of latitude made at the centre of the Moon, given the longitude and latitude of the Moon, the nonagesimal of the ecliptic, and either the altitude of the Moon, or the altitude of the nonagesimal, or the angle of the rising point of the ecliptic with the horizon.

[Margin: Case 1, if the Moon has no latitude.]

In the following figure, let ABC be the semicircle of the meridian and AFC that of the horizon; and let DIE be the portion of the ecliptic in which the nonagesimal degree of the ecliptic is N; and let the arc NE of the ecliptic be a quadrant, and the Moon, with no latitude, be at I, through which let the quadrant BIF of the vertical circle be drawn; and let FI be the altitude of the Moon. Then for the moment of the observed dichotomy, let there be sought, by the Problems of the primum mobile to be given in Book 10, section 2, the point E of the ecliptic, ascending or descending, and from it the point N,

which is the nonagesimal, and the angle of the ecliptic and the horizon, namely IEF. For the same moment, let I, the place of the Moon in the ecliptic, also be known; for from it and from the nonagesimal point N the difference NI will be known, and from that the remainder to the quadrant NE, that is, the base IE. Therefore in the triangle FIE, right-angled at F, with the base IE and either the altitude FI, observed but corrected in the usual way by adding the parallax and subtracting the refraction, or, if you have not observed it, with the angle FEI of the rising or setting point, find the angle FIE. Join it to the right angle EIO, which the circle of latitude LI makes with the ecliptic, and subtract the sum from two right angles; for there will remain the angle BIO that was sought.

Diagram. Geometric figure set in the right column with the text running beside it: a semicircular arc from A over B to C, with a shallow arc along the base from A through H, F, K and E to C. Straight lines run from B down to the base at or near H, F and K; a line runs from D through N and I to E; a line runs from L through O toward G; further lines join G and O to E; the line from B to K passes through O.

- A (left end of the base): label
- B (top of the arc): label
- C (right end of the base): label
- D (upper left on the arc): label
- L (upper right on the arc): label
- N (inside, below D, beside a dot): label
- O (inside, below L): label
- I (centre, where the lines cross): label
- G (inside, left of I): label
- H, F, K, E (along the base, left to right): labels

[Margin: Case 2, for northern latitude.]

Now let the Moon be at O, having northern latitude IO, and let the vertical BOK be drawn through it: and first, in the triangle IOE, right-angled at I, from the given IE, as above, and the latitude IO computed for the time of the observed dichotomy, find the base EO and the angle IOE. Next, in the triangle KOE, right-angled at K, with the altitude KO and the base OE, find the angle KOE; subtract it from the angle IOE already found, and there will remain the angle KOI, equal to the angle sought, BOL. But if the altitude KO is unknown, it will be necessary in the triangle IOE to find also the angle IEO, and to add it to the angle DEA of the rising or setting point, so that the angle KEO becomes known; with this and with OE the angle KOE is to be found.

[Margin: Case 3, for southern latitude.]

Finally, let the Moon be at G, with southern latitude IG, and with the vertical BGH drawn. In the triangle GIE, right-angled at I, with IE known as before and the latitude GI, find the base GE and the angle IGE. Next, in the triangle HGE, right-angled at H, with the base GE and the altitude HG of the Moon, find the angle HGE; add it to the angle IGE and subtract the sum from two right angles, for the angle sought, BGL, will remain. But if the altitude HG is

not known, in the triangle GIE find also the angle GEI; subtract it from the angle DEA of the rising or setting point of the ecliptic, and there will remain the angle GEH; with this and with the base GE you will then find the angle HGE.

2. Probl. Inclinationem Cornuum Lunarium ad Verticalem circulum per Lunæ centrum ductum, inuestigare: Dato Angulo Verticalis huius, & circuli Latitudinis per centrū Lunæ ducti; datisq. Latitudine Lunæ, & Distantia loci Ecliptici Lunæ à loco Solis.

Problem 2. To find the inclination of the horns of the Moon to the vertical circle drawn through the centre of the Moon, given the angle of this vertical and of the circle of latitude drawn through the centre of the Moon; and given the latitude of the Moon and the distance of the Moon's place in the ecliptic from the place of the Sun.

If the Moon has no latitude, or its greatest, the plane of the ecliptic or of the lunar orbit will make right angles at the centre of the Moon with the plane of the circle of latitude, drawn likewise through the centre of the Moon; and a straight line drawn from the centre of the solar globe to the centre of the lunar globe will lie very nearly in the plane of the ecliptic or of the lunar orbit. Therefore, since this line makes right angles with the plane passing through the horns of the Moon and separating the illuminated part of the Moon from the dark, the circle of latitude will pass through the horns of the Moon. And so the angle of the vertical circle and of the circle of latitude, given or found by Problem 1, will itself be the inclination of the horns of the Moon to the vertical.

But if the Moon had a sensible latitude, though not its greatest, someone used to proceed to the following scheme. In it, let AS be the arc of the ecliptic between the Sun, S, and the Moon's place in the ecliptic, A, intercepted and known, the places of the Sun and of the Moon being of course known for the moment of the observed dichotomy. And let the Moon's circle of latitude be PL, making right angles with the ecliptic at A, and passing through the centre of the Moon, O if it has northern latitude, or G if southern. To these points let the straight lines SO and SG be drawn from the Sun, and to those lines, through the centres O and G, let the perpendiculars or orthogonals COK and FGM be drawn, representing the plane drawn through the horns of the Moon and separating the illuminated part, CEK or FHM, from the dark.

Diagram. Geometric figure set into the foot of the left column, with narrow text running beside it. A horizontal line runs from P to L through G, M, A, C and O. A vertical line falls from A to S at the foot, and two straight lines run from S up to G and to O, passing through H and E respectively. At G a half-circle hangs below a straight side F–G–M, with its lowest point near H; at O a half-circle hangs below a straight side C–O–K, with its lowest point near E. From G a curved line rises to R; from O a curved line rises to B.

- P (left end of the horizontal line): label

- G, M, A, C, O (along the horizontal line, left to right): labels
- L (right end of the horizontal line): label
- R (above, from G): label
- B (upper right, from O): label
- F (left end of the left half-circle's side): label
- K (right end of the right half-circle's side): label
- H (bottom of the left half-circle): label
- E (bottom of the right half-circle): label
- S (foot, meeting point of the lines): label

[Margin: Case 1, for northern latitude.]

With this laid down, if the Moon is at O, he used the triangle ASO, treated however as spherical and right-angled at A; in it, with the distance AS of the luminaries along the ecliptic and the latitude AO, he sought the angle AOS. For its complement to a right angle would be KOL, since SOK is a right angle and the three angles AOS, SOK and KOL equal two right angles. Further, adding the angle KOL to the angle BOL, given or found by Problem 1, he obtained the angle BOK, by which he would measure the inclination of the Moon's horns to the vertical circle.

[Margin: Case 2, for southern latitude.]

But if the Moon is at G, he used the triangle AGS, right-angled at A, and with the distance AS along the ecliptic and the latitude AG he sought the angle AGS. Subtracting its complement MGA to the right angle SGM from the angle RGA, given or found by Problem 1, he obtained the angle RGM, which measures the inclination of the horns of the Moon to the vertical.

But there is no need of this scheme or of its use. For even if the Moon has a latitude that is not its greatest, the angle of inclination of the circle of latitude to the vertical at the time of the dichotomy is nevertheless the same as when it has either no latitude or its greatest; and what is said of the orbit of the Moon having its greatest latitude must be said likewise of any great circle in which the centre of the Sun and of the Moon lies, and consequently the line drawn from one centre to the other. Here, however, that insensible difference is disregarded which could arise from the Moon's being less than a quadrant distant from ⊙.

3. Probl. Data Inclinatione Cornuum Lunariū ad Verticalem circulum, & Parallaxi altitudinis Lunaris, ac mensis Lunaris veri Duratione; Inuenire Tēpus addendum aut demendum tempori Dichotomiæ obseruatæ, vt notum sit momentum veræ dichotomiæ.

Problem 3. Given the inclination of the horns of the Moon to the vertical circle, the parallax of the Moon's altitude, and the duration of the true lunar month, to find the time to be added to or subtracted from the time of the observed dichotomy, so that the moment of the true dichotomy may be known.

In the third scheme, appended here, let the Moon be beyond the nonagesimal at O, in the western quadrant. Let AOB be the plane of the circle drawn through the horns of the Moon and separating the illuminated part from the dark; let B be the horn that is northern for us in the north, A the southern, and O the centre of the Moon, through which let the portion POK of a vertical circle be drawn. Let ADB be the illuminated limb of the Moon, and let there be drawn the curve AEB through the tips of the horns, and the straight line CED, making right angles with AOB at O and representing a quadrant of the circle of monthly illumination, that is, of the circle which is illuminated successively as a whole from one new moon to the next; for in this way, in the same surface, OE will be the arc and portion of the illumination already mentioned.

Diagram. Two schemes side by side, set into the right column with narrow text running beside them. Each is a semicircle with its round side outward. The left scheme has its arc to the left, from B round through F to A, the arc broken near B; a vertical line runs from R down through G and S and past the arc; a line runs from B to G and on toward A, and a curved line runs from B to A through Q; a straight line runs from G to F. The right scheme has its arc to the right, from B round through D to A; a vertical line runs from P down through O and K and ends in a short foot stroke; a straight line runs from A through O to B, and a curved line runs from B to A through E and K; a straight line runs from O to D.

- B, R (top of the left scheme, left to right): labels
- G (left scheme, centre): label
- Q (left scheme, below G): label
- F (left scheme, left end of the line from G): label
- S (left scheme, below Q, on the vertical): label

- O (right scheme, centre): label
- E (right scheme, right of O): label
- K (right scheme, below O, on the vertical): label
- D (right scheme, right end of the line from O): label
- A (right scheme, foot, left): label

Now when the first and true dichotomy takes place with respect to the centre of the Earth, and an eye placed there would see the half Moon AOBDA shining, and the section AOB as a straight line, yet to an eye on the surface of the Earth all points of the straight line AOB are apparently depressed because of the parallax of altitude, except the points of the horns. They are depressed, I say, comparatively, with respect to the Moon's straight line AOB; for with respect to the fixed stars and the highest heaven we do not deny that all points, even those of the horns, are depressed, but we have no need of this depression. And so the point O is depressed to K, and other points likewise, but always less and less the nearer the points of the straight line AOB are to the tips of the horns, which on the face of the Moon differ insensibly from those seen from the centre

of the Earth. Hence it comes about that, because of the parallax of altitude, in the true dichotomy of the first quadrature the straight line AOB appears to us curved and concave, even when we use a very large telescope; and conversely, when the Moon has been seen as dichotomous on the surface of the Earth, it would already appear gibbous to an eye placed at the centre of the Earth. And the parallax of longitude, considered in the circle of illumination, becomes the arc OE. Therefore, from the time of a dichotomy observed beyond the nonagesimal in the western quadrant, the time corresponding to the arc OE must be subtracted. Thus in the dichotomy of the second quadrature, beyond the nonagesimal in the eastern quadrant, or in the left scheme, when from the centre of the Earth there would be seen the straight line AGB of the true dichotomy, dividing the bright from the dark, then, because the points within AB are apparently depressed for an eye placed on the surface of the Earth, as the point G is to S, and so on, the Moon already appears sickle-shaped along the arc BQA, and so the time of the dichotomy appears already to have passed, although it has not passed. When therefore it previously appeared dichotomous to us, it was not yet so, and therefore the time corresponding to the arc GQ is to be added to the time from noon at which the dichotomy was observed.

Therefore, with the altitude of the Moon given, or found by Problem 1, let there be sought the parallax of the Moon's altitude suited to that altitude at the known position in the anomaly; for as great as that is, so great will the arc OK, or GS, be, in the triangle OKE, or GQS, to be treated as spherical and right-angled at E, or at Q. In this triangle the angle KOE is also known, in the right-hand figure, being the complement to the right angle AOE of the angle AOK, or POB, which is known by Problem 2, since it is the western inclination of the Moon's horns. Likewise the angle SGQ, in the left-hand figure, is the complement to the right angle AGQ of the angle AGS, or BGR, known from the eastern inclination of the horns; therefore the arc OE, or GQ, will not remain hidden. Next, from the ephemeris let there be sought the days and hours of the true lunation within which the dichotomy falls, and let the whole lunation be resolved into hours; and let it be that as the 360° of the whole circle of illumination are to the hours of the whole lunation, so is the arc OE, or GQ, to the hours and fractions of hours that correspond to the arc OE, or GQ. Let this time be subtracted from the time of the first observed dichotomy, or added to the time of the second, and the time of the true dichotomy, as reckoned from the centre of the Earth, will be had.

[Margin: Rule 4.]

Fourth and last, from the ephemeris or astronomical tables let there be sought the moment of the quadrature of ☾ with the Sun; for the difference between it and the moment of the true dichotomy will be the difference of the quadrature and the dichotomy. Let there be sought therefore the true hourly motion of the Moon from the Sun, and let it be that as 1 hour is to the hourly motion of the Moon from the Sun, so is the time of the difference between the quadrature and the dichotomy to the arc of the ecliptic by which the Moon is distant from

the place of the quadrature. This arc is equal to the angle TSL (in the figure placed in Book 5 [recte: Book 3], chapter 7, no. 9, or p. 108), which we need in the Aristarchean problem, set out in this Book, chapter 7, for finding the distance of the Sun from the Earth.

Nor should anyone have doubts about this method because we have transferred the angles made at the centre of the Moon, and found in Problems 1 and 2, to the surface of the lunar globe in Problem 3: for it is enough that they are made by planes intersecting one another in a common section through the centre of the Moon. And since the globe of the Moon appears to us as a disc, if anyone wishes to examine their tiny difference, including that which arises in the angle of inclination of the horns to the same vertical if the disc of the Moon is viewed now from the centre of the Earth, now from its surface, he will find it insensible, and will recognize that he has wasted his time on empty subtlety. Finally, in this way the angle of inclination already mentioned will be found more surely than if it were observed directly with some instrument: we too have devised such an instrument, but it is not worth the effort to describe it here. But the Rules and Problems will be illustrated by an example, and indeed by the most outstanding of 15 dichotomies, more select than the others, observed here at Bologna.

EXEMPLVM.

Example.

On the evening of 1651 April 27, the Moon before the apparent setting of the Sun was, even when viewed with the largest telescope, too concave; but at sunset or a little after, some doubt began as to whether it was still concave. At 34^m after sunset, however, it already appeared dichotomous in the same telescope, and 6^m later, that is, 40^m after sunset, it was so without any further misgiving. At that time it stood 65° high and had passed the nonagesimal by a few degrees, with the northern horn now inclined from the vertical toward the west. Then, 1½ hours after sunset, it plainly appeared gibbous in the largest telescope, although in a small telescope it still seemed dichotomous, and to the naked eye still sickle-shaped and concave. The Sun's place at noon had been ♉ 6° 59′. Therefore at Bologna, where the pole is elevated 44° 29½′, the semidiurnal time and true setting of the Sun was $6^h\ 56^m$ after noon, but because of refractions $6^h\ 58^m$. Adding therefore 40^m, the moment of the dichotomy first observed becomes $7^h\ 38^m$ after noon; but with only 34^m added, the first moment of the dichotomy was at $7^h\ 32^m$ after noon. Since, however, the distance was taken at $7^h\ 38^m$, let us examine the Moon for this moment. Now for that moment the prerequisites for our Problems stood as follows.

[Margin: By Book 5, chapter 10, Problem 1.]

[Margin: By Problem 1 here.]

[Margin: By Problem 3.]

At Bologna, at pole altitude 44° 30′, at 7^h 38^m after noon	Sign, degrees, minutes, seconds
True place of ☉ in the ecliptic	♉ 7° 16′ 0″
Ascending point of the ecliptic	♏ 15° 0′ 0″
Descending	♉ 15° 0′ 0″
Nonagesimal degree of the ecliptic from the horizon	♌ 15° 0′ 0″
Place of the Moon in the ecliptic	♌ 6° 40′ 0″
IE: distance of the Moon from the descending point of the ecliptic	81° 40′ 0″
IO: northern latitude of ☾	5° 13′ 0″
Therefore in the right-angled triangle IOE, the base OE	81° 42′ 9″
And the angle IOE	89° 13′ 30″
And in the right-angled triangle KOE, the altitude KO, true	65° 24′ 10″
And the angle KOE	71° 35′ 21″
Therefore KOI, or BOL	17° 38′ 9″
—	—
Anomaly of ☾ at that time	2^s 10° 0′ 0″
Parallax suited [?] to the altitude of 65°, or OK in the third scheme	0° 24′ 10″
The angle POB, that is, AOK	17° 38′ 9″
Therefore in the right-angled triangle KOE — the angle KOE	72° 21′ 51″
Therefore the arc OE	0° 7′ 19″

[Margin: By Rule 4.]

That lunation was of 29^d 49^m [Dier.29.49′.], or 745 hours. Therefore, if the 360° of the whole circle of monthly illumination take 745 hours, then surely 7′ 19″ of that circle require 14^m 58^s of time. Subtracting these from 7^h 38^m after noon, the hour of the observed dichotomy, the true dichotomy was at 7^h 23^m 2^s. But the true time of the quadrature was 8^h 15^m; therefore the interval between the true dichotomy and the quadrature was very nearly 52^m of time, to which, at the Moon's true hourly motion from the Sun, which was then 29′ 2″, there correspond 25′ 10″.

[Margin: By Book 3, chapter 7, Problem 3.]

And the angle TSL is of this size (in the figure placed in Book 3, chapter 7, no. 9, or p. 108). In this triangle the distance of the Moon from the centre of the Earth, or TL, was for us 61 semidiameters of the Earth; therefore TS, the distance of the Sun, was about 8333 semidiameters of the Earth. But from the hour 7^h 32^m after noon, the distance of the Sun would come out as 7480.

But if, as that someone supposed in the second part of Problem 2, you were to correct the angle BOL by his scheme, which in the third problem is POB, it would come out here as 17° 41′ 28″, from which the arc OE would follow as 7′ 20″, and hence the remaining quantities we found without it, with a difference of one or another second, surely rightly negligible in this subtlety, however great it may be.

COROLLARIVM De Distantia Solis.

Corollary: on the distance of the Sun.

From this dichotomy, and from several others observed with a very large and excellent telescope, it is certain to us that between the true dichotomy and the quadrature there never intervenes a time notably greater than one hour, and so that the angle at the Sun is greater or less than 30′ by a very few minutes; from which it follows that the distance of the Sun is never less than 7000 terrestrial semidiameters. But if opponents want us to abide by an observation of the dichotomy made with the naked eye, or observed indeed with a telescope, but when the lower-lying parts on the Moon are also filled with light, so that half of the Moon's disc appears exactly and continuously illuminated, either course will carry the Sun much higher. For to the naked eye the Moon for the most part appears concave right at the very point of the first quadrature, and sometimes even after; and in a telescope that continuous filling takes place after the first quadrature has already been passed. So that angle would vanish, or come out so slender that it would carry the Sun much higher than Posidonius and Wendelen did, who advanced it beyond 14000 semidiameters of the Earth. The remaining observations of very many dichotomies we shall, God willing, bring forward in volume 3, and we shall confirm this distance of the Sun.

In this same chapter I set out the Tychonic distances of the Sun, such as he himself finally chose; but how from this there arises an eccentricity other than the one he himself laid down, I shall say in the appendix to Chapter 24; and in the same place see the remaining distances of D. Vicenç Mut.

[Margin: Disagreement of the distances and eccentricity of the Sun in Tycho.]

[Margin: Refractions of the Sun.]

CAP. IX. If anyone wants other ways of gathering refractions, and an examination of solar refractions, let him consult Book 10, section 6, from Problem 20 to 30, and see the tables to be placed at the end of the same section. And what is said here in scholium 8 about the Dutch is to be understood according to what will be said in Book 10, section 3, Problem 14.

[Margin: The diameter of the Sun observed by telescope: how certain it is.]

CAP. X. In no. 3, among the ways of observing the diameter of the Sun, I did not list the one done by means of a telescope, receiving the bright image of the Sun on paper or on a white board, because, with the intervening refraction of the crystal lenses, it was not evident to me that this image was correct, and not too contracted or enlarged. Later there appeared the *Sol Alphonsinus* of D. Vicenç Mut, in which this method is handed down. Let the telescope, he says, be of the best lenses, and let its machine, especially the reeds, be immune from every alteration of the weather, and let the rings of the lenses be exactly round, and so fitted that the image of the Sun admitted through the convex lens is not larger than the image projected onto the paper through the concave lens; or let the board and paper EG be at such a distance from the concave lens that the bright image of the Sun is received through a clean circle with a very sharp edge, and let it be orthogonal to the axis HV of the tube. Thus in a very dark room, with a very serene sky, and at the very time of noon, when, that is,

the image of the Sun runs across the paper not obliquely but straight, let the diameter CF of the solar image be taken off with a compass, in the vertical line AB (which you will learn by means of a plumb line), and let it be transferred to another paper KD, and be divided into equal parts as small as possible; and let the extremes C and F be marked. Then, with the instrument left entirely unmoved,

Diagram. Woodcut set across the left column, between the lines ending *immo-* and beginning *to prorsus*. At the upper left, three overlapping circles lie along an oblique straight line, marked P, M and N from lower left to upper right. Dotted rays run from the circles down to the end of a tube marked H. The tube is held by two cross brackets on a long inclined board, shaded on its under side. From the lower end of the tube dotted rays continue to a shaded rectangular board at the foot of the inclined board, carrying an oval image with overlapping outlines. To the left of the lower part stand two separate short scale lines, O–T above and K–D below.

- P, M, N (along the oblique line, lower left to upper right): labels
- H (at the upper end of the tube): label
- G (top corner of the receiving board): label
- B (right edge of the receiving board): label
- R (on the board, within or beside the oval image, upper right): label
- F (within the oval image): label
- V (within the oval image): label
- C (at the lower left of the oval image): label
- A (on the left edge of the receiving board): label
- E (bottom corner, where the two boards meet): label
- O, T (ends of the upper scale line): labels
- K, D (ends of the lower scale line): labels

on the following days, if the Sun's meridian altitude decreases, the bright image will be raised and will be, for example, in the position VR. Let its extremity V therefore be noted, and let the interval CV be measured in parts of the line KD, and let its portion be OT. And from the table of the Sun's declination let there be taken the declination suited both to the noon at which the extremity C was noted and CF taken, and to the noon at which the extremity V was noted; for when the smaller declination is subtracted from the greater, the difference of the declinations will be known. Now let it be that as the difference or interval OT, that is, CV, is to the whole diameter KD of the image, that is, CF, so is the difference of the declinations PM to the whole diameter PN of the Sun; for these are analogous, as is clear. It is useful, moreover, that the difference of the declinations be not less than 15′, or about the semidiameter of the Sun.

[Margin: How great is the diameter of the Sun for D. Mut?]

By this reasoning D. Mut affirms that the diameter of the Sun at apogee was found by him to be 31′ 18″. For on 1648 June 11 and 20 (the difference of declination of those days being 18′ 46″) he noted the portion OT as 2395

particles, of which the whole KD had been 4000. Therefore as 2395 is to 4000, so is 18′ 46″ to 31′ 21″. But between the 21st and the 30th of the same month the difference of declination was 18′ 18″, and OT was 2338 particles; therefore as 2338 is to 4000, so is 18′ 18″ to 31′ 18″. Moreover in the following year too he found the diameter of the Sun at apogee to be 31′ 18″, and for that reason chose this value.

[Margin: How, and how great, was the diameter of the Moon found by D. Mut?]

He likewise took the diameter of the Moon on paper by comparison with the image of the Sun, and found it at an apogee full moon to be 29′ 40″: for he found its image to be of 3791 particles, of which the image of the Sun had been 4000, and he made it that as 4000 is to 31′ 18″, so is 3791 to 29′ 40″. And in no. 51 he says that the diameter of the Sun at perigee was found by him to be 32′ 46″, and that of the Moon at perigee 33′ 10″.

Iudicium de Diametro Luminarium inuenta à D. Vincentio Muto, & de ipsius in hoc artificio.

Judgement on the diameter of the luminaries found by D. Vicenç Mut, and on his [?] in this technique.

The technique just mentioned is without doubt outstanding, and worthy of the genius of this most ingenious astronomer, but very difficult in practice, because it requires observation over several days, during which we cannot have evident assurance that no slight disturbance has occurred in the instrument; and so small a one is enough to introduce into the observation an error greater than 1′, as he himself admits. So I should believe it better, on the same day, to count the transit of the bright image received by such a telescope, with a pendulum showing the time exactly, and to carry out the rest as I taught in this Book 3, chapter 10, provided we were certain that the refraction of the Sun's rays, which takes place from the perpendicular in the lens nearer the paper, does not dilate the image of the Sun more than would be proper for this practice. Because this is uncertain, I therefore praise the diligence of so great a man, but hold as suspect the semidiameter of the Sun derived from it.

For the rest, although these methods show a diameter close to the true one, they are not sufficient for their exact measurement unless those things are reconciled which I said here, in scholium 1, are to be reconciled, and above all the total eclipses of the Moon and of the Sun and the annular eclipses of the Sun, on which see our careful work in Book 4, chapter 16, from no. 15 to 18. For on account of eclipses I was compelled to extend the diameter of the Sun at apogee, which I had obtained from direct observations of it at about 30′ 30″, to 30′ 50″, and that at perigee to 33′ 8″. Otherwise there will be as many opinions about these minutes as there are observers and observations.

[Margin: In how much time does the Sun rise?]

Likewise in this chapter, at no. 6, on the time in which the whole disc of the Sun rises or sets, I said certain things from the method of the ancients, but I did not include our observations, made with the aid of a pendulum (on which see Book 2, chapter 20), which shows very exactly with each vibration one second of time of the primum mobile. It seemed good, therefore, to insert some selected ones here for the reader's instruction. The first small table contains those made with a sky not only cloudless but also with a very bright and very serene horizon; the second small table contains those made with a horizon that was indeed cloudless, but full of reddish vapours and showing an ellipse of the solar image far larger than at other times.

Of the time from the rising of the Sun's upper limb to the rising of its lower limb, observed at Bologna.

Table I. With a very serene horizon.

Year	Month	Day	Vibrations of the pendulum	Time
1641	September	24	184	$3^m\ 4^s$
		28	186	$3^m\ 6^s$
1642	March	27	185	$3^m\ 5^s$
	June	21	321	$5^m\ 21^s$
		22	320	$5^m\ 20^s$
		30	300	$5^m\ 0^s$
	July	16	310	$5^m\ 10^s$
	September	23	186	$3^m\ 6^s$
	October	12	246	$4^m\ 6^s$
		19	247	$4^m\ 7^s$

Remainder of the Preceding Table.

Part	Year	Month	Day	Vibrations of the pendulum	Time
Remainder of Table I	1643	May	20	195	$3^m\ 15^s$
		June	22	328	$5^m\ 28^s$
			26	330	$5^m\ 30^s$
		December	20	380	$6^m\ 20^s$
	1644	March	20	186	$3^m\ 6^s$
Table II	1642	September	14	250	$4^m\ 10^s$
		October	21	350	$5^m\ 50^s$
	1643	January	25	390	$6^m\ 30^s$
	1646	July	4	365	$6^m\ 5^s$

From these it is gathered that the variation of the air and of the refractions, together with the obliquity of the ascensions and with the variation of the arc of the altitude circle intercepted between the Sun about to rise and the horizon, is the cause of the variation in the time in which the Sun's whole disc, or transverse diameter, rises. For the arc already mentioned is smaller at the solstices than at the equinoxes, but the obliquity of the ascensions etc. is

greater; and the refractions, speaking of them in themselves, are greater at the winter solstice than at the equinoxes, and at these than at the summer solstice. Yet when the horizon is most serene and cloudless, we can state generally that at Bologna the Sun's whole diameter rises at the equinoxes in a time of 3^m and 5^s or 6^s, at the summer solstice in 5^m 20^s, at the winter solstice in 6^m 20^s. So if you begin the day from the rising of the Sun's limb and run it to the setting, and add what refraction adds, the artificial day at Bologna comes out at the summer solstice as 15^h 29^m, at midwinter as 8^h 52^m, at the equinoxes as 12^h 9^m. For refraction adds to the semidiurnal arc about 2^m at the solstice, 4^m at midwinter, and 3^m at the equinox.

[Margin: The apparent size of the Sun at the horizon.]

[Margin: The height of Mount Ida.]

What I said about the apparent size of the Sun at the horizon is to be understood, or even corrected, from what was said in Book 10, section 6, chapter 1, question 13. Add to these what historians relate of Mount Ida: that it does not wholly hide the rising Sun from the eyes it stands in front of, because of the vastness of the transverse diameter of the ellipse. But Diodorus Siculus ascribes this to the Ida that is in Phrygia, in Book 17, saying: *Mount Ida is the most eminent of all the mountains around the Hellespont; for on Ida something very rare, and beyond human belief, is found. About the rising of the Dog Star, on the very summit of the mountain, the air, utterly still on every side, ensures that no blast of the winds is felt there; and there, while night still lasts, the Sun is seen to send out its rays, not indeed so that its circular form appears, but rather so that its brightness is seen far and wide, as if a fire had seized the horizon over a great stretch of land.* Here he indicates the elliptical vastness of the Sun rising prematurely for the summit of Ida. But Pliny the Elder does so more clearly, in Book 2, chapter 11, though he ascribes it to the Ida of the island of Crete, and concludes that the Sun is larger than the Earth *because in rising it exceeds Mount Ida in breadth, embracing it amply to right and left, especially at so great a distance.* Strabo relates in Book 10 that this is the highest of the mountains of the Cretans and takes in 600 stadia in circumference; and Solinus says, in chapter 16, that the Sun is seen from it before its rising.

[Margin: The size of the Sun as seen from the planets.]

In Scholium 4 a small table is set out from the opinion and calculations of others, but I gave another, more accurate one in Book 7, section 6, chapter 13.

[Margin: The semiangle of the cone of the Earth's shadow.]

CAP. XI. In Problem 5 of this chapter I derived the semiangle of the cone of the Earth's shadow, with the Sun at apogee, as $14' 52''$, from an apparent semidiameter of the Sun of $15' 19''$. But since I was later forced, because of eclipses, to make the semidiameter of the Sun at apogee $15' 25''$, if you subtract from this my parallax, which is then $27''$, this semiangle would come out as $14' 58''$, that is, larger by $6''$. But in the same Book 3, chapter 11, no. 7, I taught that it is not necessary for the sum of the Sun's parallax and the semiangle of the cone

of the Earth's shadow to be exactly equal to the Sun's apparent semidiameter, and that it suffices if there is no perceptible difference.

[Margin: Where does the increase of the artificial day come from?]

Further, from the fact that the Sun illuminates more than a hemisphere of the Earth, it does not follow that the artificial day comes out longer on this account, for its quantity does not depend on the illuminated terrestrial arc, but on the motion of the Sun's centre on the equator or on a parallel cut by the horizon more or less obliquely. The day is, however, increased if you begin it from the rising not of the Sun's centre but of its limb.

[Margin: Anaximander's error on the size of the Sun.]

[Margin: And Lucretius's.]

Anaximander, in Plutarch, Book 2 of *De placitis philosophorum*, chapter 2, and Theodoret, in Book 4 of *De Græc.*, taught that the Sun is larger than the Earth by only 27 times; so crude was astronomy then. Add this, however, to the scholia of this chapter. But in Scholium 1, among the Epicureans who affirm that the Sun and Moon are truly a foot across, just as they appear, include Lucretius, and copy out his verses from Book 5 of *De rerum natura*, beginning from the line:

Nor can the Sun's wheel be much larger, nor its heat much smaller, than it seems to our senses to be.

For at last, after 24 lines, he concludes universally:

Lastly, whatever fires of the ether you see from here, you may know that they can be smaller by only a very little, or larger by a tiny and brief part.

[Margin: Look at the figure placed in Book 3, chapter 14, no. 3, or p. 132.]

CAP. XIV. No. 1. I described the great Bologna gnomon here in very few words, reserving the rest for the *Liber Organicus*. Yet if anyone wishes to know the other distances on the line AN corresponding to the middle of the ellipse which the Sun's image makes on it at the beginnings of the signs, here they are for him, from measurements taken not only by us but also by DD. Carlo Antonio Manzini and Bartholomæus Provalius [?]. Let him read the letters in the figure set there, and then compare those lines with the following small table. Now, however, the angle XAN is not right, but because of the wear and constant treading of those walking over the threshold A, it is acute: not indeed like XAV, but still so that XA has come out longer by 3⅔ inches, with respect to the eye N looking along the horizontal.

Beginnings of the signs	Line and source	Bolognese feet	Inches	Fraction
♑	AN: Manzini	170	0	0
	Provalius	169	1	20/24
	Myself	169	2	½
♎ ♈	AG: Manzini	65	1	0
	Provalius	64	7	0
	Myself	64	7	22/24
♋	AC: Manzini	26	0	0
	Provalius	25	6	0

Beginnings of the signs	Line and source	Bolognese feet	Inches	Fraction
	Myself	25	6	17/24
♊ ♌	AD: Manzini	30	8	0
	Myself	30	8	3/5
♉ ♍	AE: Manzini	43	10	0
	Myself	43	10	4/5
♓ ♏	AK: Manzini	100	7	0
	Myself	100	8	½
♒ ♐	AI: Manzini	141	7	0
	Myself	141	8	3/5
	AM: Manzini	167	7	0
	Myself	166	8	7/12
	AL: Myself	164	3	0
	For LN	4	11	½

[Margin: Whether the length of the year has been adequately confirmed by D. Mut.]

CAP. XV. No. 6. D. Vicenç Mut, in his *Sol Alphonsinus*, no. 38, tries to confirm the Alphonsine quantity of the equinoctial year, of $365^{d}\ 5^{h}\ 49^{m}\ 16^{s}$. But in this he uses a solar parallax of 4′ 37″ at apogee, which I showed to be false in the appendix to chapter 8. He supposes, besides, that Alexandria is further east than Toledo by $2^{h}\ 54^{m}$, whereas from our *Geographical Book* it is more truly $2^{h}\ 58⅓^{m}$. Finally, he uses the morning equinox of Hipparchus, which is faulty because of refractions, according to what was said in Book 3, chapter 14, no. 9.

CAP. XVIII. D. Vicenç Mut, in the *Sol Alphonsinus*, nos. 32 and 33, affirms that from the vernal equinox to the autumnal equinox the interval is $186^{d}\ 23^{h}\ 54^{m}$, and from the autumnal to the vernal $178^{d}\ 5^{h}\ 55^{m}\ 16^{s}$. But at the equinoxes he uses an excessive parallax, about which I spoke in the appendix to chapter 8.

[Margin: Boulliau's solar hypothesis.]

CAP. XXIII. In no. 10 I indicated too sparingly Boulliau's hypothesis and his way of resolving the ellipse into two circles, but at this place one can see what I later taught in Book 7, section 2, chapter 5, no. 13.

[Margin: Inconsistency between the distances of the Sun and the Tychonic eccentricity.]

CAP. XXIV. No. 8. In Tycho, vol. 1 of the *Progymnasmata*, pp. 30, 31, 60 and 98, the Sun's eccentricity is 3584 parts, of which the radius of the orb, or semidiameter of the Sun's eccentric, is 100000. But on pp. 97, 98 and 423 he puts the Sun's greatest distance at 1182 56/60 semidiameters of the Earth, the mean at 1142, and the least at 1101 4/60; so the eccentricity is 40 55/60, or 41, semidiameters of the Earth. Later, however, on p. 472, he chose a mean distance of the Sun of 1150 semidiameters of the Earth. Therefore if he wanted to maintain the same eccentricity, he ought to have made the Sun's greatest distance 1192 and the least 1108 semidiameters of the Earth, as is clear from adding the eccentricity in the one case and subtracting it in the other; or if he wanted to keep the greatest distance of the Sun at 1182 56/60, or 1183, and the

mean at 1150, he ought to have made the least 1117 and reduced the eccentricity to 33 semidiameters of the Earth. Yet I should think that, had he lived longer, he would rather have increased the Sun's distances than diminished the eccentricity. For that reason I kept the Tychonic eccentricity here, although in Book 3, chapter 7 I did not dare to vary the Tychonic distances on its account. But in this table too I placed the mean distance later chosen by Tycho, so that from this at least there would be an indication that if the eccentricity of 41 were added to it the greatest distance would come out as 1191, and if subtracted from it the least would be 1109.

[Margin: The Sun's eccentricity, apogee and greatest equation, according to D. Mut.]

But D. Vicenç Mut, in the *Sol Alphonsinus*, nos. 32, 33 and 34, puts the Sun's eccentricity at 378122 parts, of which the radius of the orb is 10000000, that is, 29⅕ semidiameters of the Earth; the Sun's greatest prosthaphaeresis at 2° 10′; and the Sun's apogee at 5° 53′ 5″ of Cancer, about the year of Christ 1648. But since he says that he used an interval between the vernal and autumnal equinoxes of $186^{d}\ 23^{h}\ 54^{m}$, and a stay of the Sun in Aries of $30^{d}\ 14^{h}\ 48^{m}$, adding to the Sun's meridian altitudes his own parallax, which I showed in the appendix to Book 3, chapter 8 to be 4′ greater than the true parallax of the Sun, there is no reason for us to discuss further his disagreement with others and with us on this. Moreover, since he puts the Sun's least distance at 744 semidiameters of the Earth, if you subtract the eccentricity 378122 from the radius 10000000, the least distance remaining will be 9621878; but if you add it, the greatest will be 10378122. So in semidiameters of the Earth the mean distance of the ☉ will be 773⅕ and the greatest 802⅖.

CAP. XXV. What I said in no. 4 about the fabrication of those Jews who presided over the arranging of the Alphonsine Tables, I drove home again on another occasion in chapter 28, no. 16, and in Book 6, chapter 16, nos. 3 and 4. This fabrication about the motion of the auxes and of the fixed stars, derived by Kabbalists from the period of the Jubilee, is excellently refuted, and from the same sources as ours, by D. Vicenç Mut in his *Sol Alphonsinus*, nos. 39 and 40. He adds that the Alphonsine Tables published by the Jews in the year 1252 are judged spurious by Scaliger and Mulerius, and also by Stadius in the Bergen tables and by Arguello [?] in his *Ephemerides*, and that in their place are to be used those which Alfonso himself published in the year 1256.

[Margin: The time of the least eccentricity, for Tycho.]

[Margin: The vanity of judicial astrology.]

[Margin: The error of Melanchthon and Cardano about the Sun's approach to the Earth.]

CAP. XXVI. Tycho too rejects the vanity of Rheticus, which we mocked here in Scholium 1, in a letter to Rothmann dated 1588 September 19 [13. Cal. Octobris], p. 131, where this is found: *As to your view, toward the end of the Röslin refutation, that the Sun's least eccentricity has passed, I hold the same myself; for I refer the least eccentricity and obliquity of the Sun to Peuerbach. Nor is Rheticus*

to be listened to either, who, while he writes that al-Battānī abuses the mysteries of astrology too freely, himself falls into that same fault here. For how can a change in the Sun's eccentricity bring about a change of empires? Nor do you unjustly censure this too, which Philipp Melanchthon first introduced, namely that the Sun has now come closer to the Earth; although Cardano too, in Book 3 of the Subtleties, mistakenly states the same. For they have not grasped Copernicus's meaning on this matter. Yet Cardano, in Book 3 of *De Subtilitate*, p. 144 in my copy, reports in Melanchthon's opinion that in the age of Ptolemy or Hipparchus the centre of the Sun's orb stood from the centre of the Earth at 24⅕ diameters of the Earth, that is, 48⅖ semidiameters; but in his own century at only 18⅖ diameters, or 36⅘ semidiameters. So you now see which of the two have erred.

[Margin: The obliquity of the ecliptic, 23° 30′, confirmed from Kepler's thinking.]

CAP. XXVII. Kepler admits, in the Rudolphine Tables, chapter 34, that the Tychonic obliquity of the ecliptic, 23° 31′ 30″, is faulty because of the excessive parallax Tycho assumed. For at the summer solstices Tycho used a solar parallax of 1′ 33″; adding this to the Sun's visible meridian altitude of 57° 35′ 27″, he made the true altitude 57° 37′; and subtracting from this the equator's altitude at Uraniborg, 34° 5′ 30″, he held the obliquity to be 23° 31′ 30″. But Kepler there, since he assumes a much smaller parallax for the Sun at apogee, makes the obliquity of the ecliptic 23° 30′ 30″. So if he had applied our parallax, which is still twice as small, not of one minute but of about half a minute, or 27″, he would surely have acknowledged and accepted an obliquity of only 23° 30′. Further, we found the Sun's parallax and distance, twice as small as Kepler's, by means of the lunar dichotomy, according to what was said in Book 3, chapter 7, with Kepler himself urging us to it.

AD LIBRVM IV.

On Book IV.

[Margin: The tide of the sea from the Moon.]

CAP. I. I said more about the Moon's dominion over the tide of the sea in Book 9, section 4, chapter 14; see also Caussin, Book 2 of *De Domo Dei*, chapter 15.

[Margin: Antichthones.]

CAP. II. Those who in no. 4 are called Antichthones can also be called Antipodes on our own Earth; and I see the word so used for the same people by not a few.

[Margin: The Laconians called lunar, the Arcadians antelunar.]

CAP. III. In no. 4, or at the end of the chapter, add from Pindar that the Olympic contest used in former times to be held at the full Moon, and that the Laconians were called [Greek: σελήνας (selēnas, "moons")], as if lunatics, because they held it a religious scruple to begin anything great before an impending new or full Moon. By contrast the Arcadians, who used to begin

wars and great undertakings before the imminent new or full Moon, were called by their neighbours [Greek: προσελήνοι (proselēnoi, "before the Moon")], as if antelunar; but they themselves turned this to the praise of their antiquity, as if they were older than the Moon herself. On the phases of the Moon see Caussin, Book 2 of *De Domo Dei*, chapter 12.

[Margin: The time of the dichotomy.]

CAP. IV. Problem 7 is to be understood of the dichotomy reckoned from the centre of the Earth; for from the Earth's surface the dichotomy of the first quadrature appears noticeably later, and that of the second earlier, than it should, because of the Moon's parallax, unless the Moon is then in the nonagesimal. On the difference between the dichotomy reckoned from the centre of the Earth and that observed from its surface, see what was said in the appendix to Book 3, chapter 7.

[Margin: The Moon deprived of light in a total eclipse.]

CAP. VI. That the Moon in its total eclipses is sometimes wholly deprived of light is confirmed by Johannes Hevelius, *Selenographia*, chapter 6, from Vitruvius, Book 9, chapter 4, and from an observation of the eclipse of 1642 April 14 made by himself. Johannes Phocylides Holwarda affirms the same about the same eclipse in the *Epitome Astronomiae reformatae*, p. 65, and Kepler about the eclipse of 1620 June 15 in the *Epitome of Copernican Astronomy*, Book 6, p. 825.

[Margin: An inconsistency of Tycho's in the hypothesis of the Moon with the Sun, shown by D. Vicenç Mut.]

CAP. XIV. D. Vicenç Mut, in his *Sol Alphonsinus*, no. 16, shows that it follows from the Tychonic observations and hypotheses that the distance of the Moon, at apogee and full, from the centre of the Earth is 62 23′ semidiameters of the Earth, not 58 8′ as Tycho has it. He shows this, I say, from the data given by Tycho: the semidiameter of the Sun at apogee, 15′; its horizontal parallax at that time, 2′ 54″; and the semidiameter of the Earth's shadow at the place where the Moon at apogee passes through, 43′. Now recall here the figure placed in Book 3, chapter 11, Problem 6, or p. 124. For in it the Sun's apparent semidiameter, that is, the angle BND (as great, because of the Sun's enormous distance, as BAD), is equal to the two interior angles ABN, that is, the Sun's horizontal parallax, and AEN, that is, the semiangle of the cone of the Earth's shadow, taken together, by Euclid I.32. So with the parallax of 2′ 54″ subtracted from the semidiameter of 15′, the angle AEN is left as 12′ 6″, to which because of the parallelism of the lines AG and LK, NLK is equal; but because of the same parallelism the angle GAL, which measures the shadow's semidiameter, is equal to the angle ALK. Therefore, when this, that is 43′, is joined with NLK, 12′ 6″, the whole ALN comes to 55′ 6″. And LAN, the complement to a right angle of the angle GAL, is 89° 17′; so the third angle, ANL, is 89° 47′ 54″. Therefore, with all the angles given in the triangle ALN, and the side AN, which is one semidiameter of the Earth, LN is found to be 62 39/100 semidiameters of the Earth; and with this and the angle LNK, in the right-angled triangle LNK, LK,

that is AG, is found, namely the Moon's distance, of 62 38/100 semidiameters of the Earth.

[Margin: The Moon's parallax and distance as observed by D. Vicenç Mut.]

Further, Mut himself relates in no. 20 that in 1646 June 27, about midnight, he observed at Majorca, where the elevation of the equator is 50° 25′, the meridian altitude of the Moon, full and at apogee, as 28° 27′. He says that it then underwent no refraction, and that it was close to the Tropic of Capricorn, namely according to the Danish tables at 5° 21′ 46″ of Capricorn, with north latitude 2° 15′ 18″ and declination 21° 9′ 12″; but according to Lansbergen at 5° 7′ 20″ of ♑, with latitude 2° 17′ and declination 21° 8′ 30″; and according to Kepler at 5° 21′ 35″, with latitude 2° 15′ and declination 21° 9′ 30″; and finally by Boulliau at 5° 12′ 44″, with latitude 2° 15′ 20″ and declination 21° 9′ 30″. When these declinations are subtracted from the altitude of the equator, there remain the true altitudes of the Moon, and the differences from the visible altitude, that is, the parallaxes, and the lunar distances, as you see in the following small table.

Visible altitude of ☾, 28° 27′.

	True altitude	Parallax	Distance of ☾ in semidiameters
By the Danish tables	29° 15′ 48″	48′ 48″	62
By Lansbergen	29° 16′ 30″	49′ 30″	61
By Kepler	29° 15′ 30″	48′ 30″	about 62
By Boulliau	29° 15′ 30″	48′ 30″	about 62

Yet Tycho gives the lunar altitude of 28° 27′ a refraction of 2′ 11″, and it seems astonishing that at Majorca, which is surrounded on all sides by so great a sea, there are no refractions at that altitude. Certainly, as I observed, the parallax came out for me much smaller and the distance greater because of refractions, as can be seen in the observations reviewed in this chapter; which, however, favours the Alphonsine hypothesis more, as D. Mut himself admits.

Hevelius, moreover, on p. 97 of the *Selenographia*, gives the parallaxes of the Moon written below.

☾ in	Aspect	Parallax, apogee	Parallax, perigee	Distance in semidiameters of the Earth, apogee	Distance in semidiameters of the Earth, perigee
	☌ & ☍	59′ 9″	61′ 39″	58 8′	54 52′
	□	56′ 44″	65′ 36″	60 36′	52 14′

[Margin: Whether the Moon's refraction is less than the Sun's.]

CAP. XV. The reason why Tycho in his tables showed the Moon's refraction as smaller than the Sun's was the excessive parallax of the Sun added to the solar refraction; but more on this in Book 10, section 6, Problems 24 and 27. For it is certain that, with equal density of the air and equal inclination of the star, or visible altitude, the star that is less distant from the Earth has the greater refraction, as will be shown in the same section, chapter 2; and in section 5,

from Problem 73, we shall show how great the greatest refraction and parallax of the Moon and Sun can be supposed to be, and at the end of the section we shall give the refractions of the Moon. Further, Hevelius attests on p. 198 of the *Selenographia* that by the force of refraction the full Moon was seen above the horizon together with the Sun in 1642 at Stettin by Laurentius Eichstadius [Lorenz Eichstaedt].

[Margin: The Moon's diameter according to D. Vicenç Mut.]

CAP. XVI. How D. Vicenç Mut used to observe the Sun's apparent diameter through its bright image received by telescope on paper, I set out from his own *Sol Alphonsinus* in the appendix to Book 3, chapter 10. In nos. 15 and 51 he says, further, that he compared the bright image of the Moon at apogee, received by telescope, with the image of the Sun at apogee, and found it to be of 3791 parts, and that of the Moon at perigee of 4239, of which the Sun's had been 4000. And he had defined the Sun's diameter as 31′ 18″; therefore that of the full Moon at apogee is 29′ 40″ and at perigee 33′ 10″. But I think that for a twofold reason he gathered it larger than he should have: first, because the Sun's diameter in itself was shown to him somewhat larger by the telescope, which dilates the image; then, because the image of the Moon too is larger from the same cause. But one or another observation does not suffice, unless it satisfies all the eclipses.

What I said in no. 8 of this chapter, against the equation of the lunar diameter introduced by Longomontanus, has seemed to some too far-fetched; but I have neither the time nor the wish here to haul on a contentious rope.

CAP. XVII. To Problem 7 another can be added, about which Kepler inquires in the *Dissertatio cum Nuncio Sidereo*, p. 11½: for he asks how large the Moon appears as seen from the Sun and from the other planets. And because he supposes the Sun's distance to be thirtyfold the Moon's distance, Saturn's to be tenfold the Sun's, and Jupiter's about fivefold, he therefore says that the Moon seen from the Sun subtends an angle of about 6′, from Jupiter 12″, from Saturn 6″.

[Margin: The Moon seen from the planets.]

Similar to this table are those we set out in Book 7, section 6, chapter 13, on the apparent diameter of the Earth, the Sun, Saturn, Jupiter and Sirius seen from the planets.

[Margin: The Earth seen from the Moon.]

The table here in Problem 7, set out only from our own opinion, can be illustrated from the opinion of others and from Table 1 of Book 7, section 6, chapter 13, expounded and composed by us. Further, the table of this problem is more accurate, being made with geometric rigour, than the one set out by us from Kepler's method in Book 5, chapter 12, Problem 3. For there the disc of the Earth seen from the Moon at apogee is 53′ 20″ taken twice, that is, 1° 46′ 40″, and at perigee 63′ 45″ twice, that is, 2° 7′ 30″; but here it is 1° 47′ 0″ and 2° 7′ 50″.

[Margin: The Alphonsine size of the Moon's orbs, according to Mut.]

CAP. XXV. No. 3. I supposed the Alphonsine lunar hypothesis to be similar to the Ptolemaic in the form of its theory; as for the numbers of the motions, their difference is easily gathered from what was said in chapter 23. As for the measures, D. Vicenç Mut, in his *Sol Alphonsinus*, no. 52, puts the whole diameter of the orb of the ☾ at 117 28′ semidiameters of the Earth, the semidiameter or radius at 58 44′, and the lunar eccentricity at 3 16′ semidiameters of the Earth; and so the least distance of the Moon in syzygies at 55 28′ semidiameters of the Earth and the greatest at 62, which he had also given in no. 16.

[Margin: Proportional minutes.]

[Margin: How the measures of the Moon's orbs are investigated.]

What I said here on p. 260, very sparingly, about proportional minutes can be illustrated from the figure and from what was said in Book 7, section 2, last chapter. Moreover, the method of investigating geometrically, from three eclipses, the ratio of the semidiameter of the deferent carrying the Moon to the semidiameter of the epicycle, and also the eccentricity, is the same as for the three superior planets, whose three places each have been observed in the zodiac; consult, therefore, Book 7, section 2, chapter 8, and supply from there what is lacking here. I now wish to set out at least one figure for the geometric calculation of the Moon, from Ptolemy, Book 5 of the *Almagest*, and from Regiomontanus in his *Epitome*, from Proposition 8 to 11, which I omitted through a [Greek: μνημόνικον ἀμάρθημα (mnēmonikon amarthēma, "slip of memory")]. From the centre D let there be the semicircle ABG of the lunar deferent, and on it the centre of the epicycle B, and the epicycle PLN, on which let the Moon's globe be at L. Let the eccentricity of the deferent be DE, and let the centre of the Earth and of the ecliptic be E, and let EZ be equal to that DE. And let the centre B be joined by straight lines with the points D, E, Z, these being BD, BE, BZ, and also with the Moon by the straight line BL, which is the semidiameter of the epicycle. Let BE be produced as far as M, until it meets the perpendicular DM drawn to it from D; and with BZ produced to O, let O be the mean apogee of the epicycle, and N the perigee. Further, from Z let another perpendicular ZT be drawn to BM; and finally from the point E let the straight line EL be drawn to the Moon. With these set, you will complete or understand the following propositions,

Diagram. A geometric figure at the foot of the right column, set into the text at the right of the lines from "Ex centro D" downward. A large arc, part of a semicircle, runs from the top of a vertical straight line down the left side to the foot of that line; the line carries, from top to bottom, A, D, E, Z, G. A small circle, the epicycle, stands on the arc at the lower left. Straight lines run from a point at the epicycle's centre up to D and to E, and on past E to a point at the upper right, joined to D by a short line; another line runs to Z. Further lines run from that centre to the circumference at the lower left and on through the circle to the right.

- A (top of the vertical line): A
- D (on the vertical line, below A): D

- M (right of D): M
- T (on the line rising to the right, left of E): T
- E (on the vertical line, below D): E
- Z (below E; the sort stands turned): Z
- G (foot of the vertical line): G
- N (right side of the small circle): N
- L (foot of the small circle): L
- P (lower left of the small circle): P
- C (left of the small circle, outside it): C
- B (centre of the small circle, crossed by a line): B
- Small round letter, lower-case size, on the line at the small circle's upper right; its right side is lost in the line crossing it: c or o [?]

1. Proposition. *The diameter of the Moon's epicycle passing through the mean aux of the epicycle and through its opposite looks toward a point opposite the centre of the eccentric, as far from the centre of the Earth as the centre of the eccentric stands from that same centre of the Earth.*

Regiomontanus demonstrated this in the *Epitome of the Almagest*, Book 5, Proposition 8. Now that point is Z, through which passes the epicycle's diameter OBN, drawn through the mean apogee O and the perigee of the epicycle N; passes through it, I say, if it is produced outside the epicycle as far as the diameter of the eccentric.

2. Proposition. *Given the elongation of the epicycle from the aux of the eccentric, the eccentricity of the Moon and the semidiameter of the eccentric, to find how large the arc of the epicycle is between its two auxes.*

In the preceding figure the line AEG is the line of the aux of the eccentric, and EDA is the longer longitude [longitudo longior]. So if the elongation of the centre B from the apogee, or from the aux, of the eccentric is given, the arc AB will be given, and so the angle ADB, and therefore also BDE. With this, and with the radius BD and the eccentricity DE, *first* let BED be sought, so that DEM may be known. Now the angle EBZ is sought, equal to the angle PBO, which measures the arc PO by which the mean apogee of the epicycle, O, stands from the true apogee P. *Second*, therefore, in the triangle EMD, right-angled at M, the angle DEM is given, and the side DE, which is the lunar eccentricity; so EM will become known, and also the side DM, in the right-angled triangle BDM, in which another side, BD, is given, which is the semidiameter of the eccentric; so the side BM will not remain hidden. Similarly, in the triangle TEZ, right-angled at T, EZ is given, because it is equal to the eccentricity DE, and the angle TEZ, because it is equal to the angle DEM, known as above; so the sides TZ and TE will become known. TE, together with EM, taken away from the side BM already found, will make known the side BT; with this, and with TZ, in the triangle BTZ, right-angled at T, you will find the angle TBZ that was sought.

3. Proposition. *Given the mean motion of the Moon both in longitude and in anomaly, and its mean distance from the Sun, to demonstrate its true place.*

In the preceding figure let the Moon be at L, and let the line of its true place be EL; let the given mean distance of the Moon from the Sun, doubled, be AEB, and let the given longitude of the Moon be the arc AB, or the angle ADB; and finally let the given anomaly be the arc OPL. Therefore by Proposition 2 the line BE is known, in the parts in which the semidiameter of the epicycle BL and that of the eccentric BD are known, and the arc OP is known too. OP, taken from the anomalistic arc OPL, leaves the arc PL, that is, the angle PBL. Subtract this from a semicircle, or from two right angles, for the angle LBE will then be left, in the triangle LBE. Since in this triangle BL and BE are given, as above, you will seek out the angle LEB, that is, the equation to be added to the mean longitude in this position of the eccentric and epicycle (for in the other it would have to be subtracted), so that you may have the true place of the Moon. Thus by Proposition 2 you will obtain the equations of the centre, and by this Proposition 3, though dependently on the second, you will obtain the equations of the epicycle.

CAP. XXVI. Besides the scheme and paradigm of the Tychonic lunar theory, I wish to set out yet a twin to it, from Longomontanus's *Astronomia Danica*, Book 1 of the *Theorica*, chapter 6, and it is as follows. In the following figure let A be the centre of the small circle CQB, which carries C, the centre of the eccentric IDM, whose diameter MI is to be always parallel to the diameter BF of the small circle. Let the eccentric carry D, the centre of the greater epicycle GL, and let this greater epicycle bear along K, the centre of the lesser epicycle HN; and let us suppose the Moon to be at E. To E, from the centres of the epicycles, let the straight lines DE and KE be drawn; and from the same E let the straight line EC be drawn to the centre of the deferent, and EB to the perigee of the small circle FB; and from the same centre C let the straight line CDG be drawn through the centre of the greater epicycle, and from C to B another straight line, which AQ is to cut orthogonally.

Diagram. A geometric figure at the head of the right column, set into the text at the right of the lines from "K, fingamusque" downward. A vertical straight line runs from I at the top to M at the foot, with a large arc, the eccentric, running from its top round the left side to its foot, bowing past D. On the arc at the upper left stands the circle of the greater epicycle about D, and within its upper part a smaller circle about K. A small circle about A stands low at the right of the vertical line, which passes through C on its rim. Straight lines run from C, at the top of the small circle, up to R, I, E and D, and from E down to B at the foot of the small circle.

- N (top of the smallest circle): N
- K (inside the smallest circle): K
- H (foot of the smallest circle, below K): H
- E (right of the smallest circle): E
- R (upper right, on the arc rising to the vertical line): R
- I (head of the vertical line): I

- C (inside the small circle, at its top): C
- A (right of centre in the small circle): A
- Q (left of the small circle, at the end of a short line): Q
- B (foot of the small circle): B
- M (foot of the vertical line): M
- P (just left of A, inside the small circle; not cited in the prose on this page): P

Methodus Calculi Lunæ Geometrici ex Longomontano, exemplo illustrata anni 1587. Augusti 17. H.17. 25′. post merid.

The method of the Moon's geometric calculation from Longomontanus, illustrated by an example of the year 1587 August 17, 17^h 25^m after noon.

[Margin: Step 1.]

With these set, *first*, from the Moon's mean anomaly let the arc ID be given, 45° 37′ 21″; similar to it, or of as many degrees, is the arc GK. This anomaly doubled will give the arc HE, 91° 14′ 42″. Thus in the triangle DKE, besides the sides KD, of 5800 parts, and KE, of 2900 parts, of which the radius CD is 100,000, these being the semidiameters of the epicycles, the included angle DKE will be given, which measures the arc HE. By means of trigonometry, therefore, the angle KDE becomes known, 26° 18′ 43″, and the side DE, 6541.

[Margin: Step 2.]

Second, in the triangle DCE there are given the side DE, just found; CD, the semidiameter of the eccentric, of 100000 parts; and the angle EDC. For when the arc GK, known above from the simple anomaly, is taken from the semicircle GKL, there remains KL, that is, the angle KDL; and if from this you again take the KDE already found, the angle EDC is left, 108° 3′ 56″. So the angle DCE will become known, 3° 29′ 16″, which is the epicyclic prosthaphaeresis, and the side CE, 102217, which is the distance of the Moon from the centre of the deferent. Now if to the mean motion of the Sun, which was 5^s 5° 42′ 16″, there is added the mean longitude of the Moon from the Sun, which was 9^s 25° 12′ 6″, then with a whole circle cast off there remains the Moon's simple motion from the mean vernal equinox, 3^s 0° 54′ 22″. If from this you subtract the epicyclic equation just found, there remains the equated longitude of the Moon, 2^s 27° 25′ 6″; and if the same equation is taken from the Moon's anomaly, which was 1^s 15° 37′ 21″, the equated anomaly will remain, 1^s 12° 8′ 5″, which, that is to say, the angle ICE measures. Next, from the equated longitude of the Moon subtract the true place of the Sun from the mean equinox, which was 5^s 3° 57′ 30″, and there remains the distance of the luminaries, 9^s 23° 27′ 36″. Its double, with a whole circle cast off from the sum, is 7^s 16° 55′ 12″, and it measures, on

the small circle of the eccentricity, the motion of the centre C from the Earth B, in the order of the signs, that is, the arc BFC.

[Margin: Step 3.]

Third, with the semidiameter AC of the small circle drawn, and the straight line BC, an isosceles triangle BAC will arise, whose angle BAC is the complement, to two right angles, of the angle CAF, known from the excess of the arc CF above a semicircle; and so in our case BAC is 133° 4′ 48″. The semidiameters AB and AC are each of 2174 parts, so the side BC will be of 3988 parts. The angle FBC, moreover, by *Elements* III.20, is half the angle FAC, and so is 23° 27′ 36″. Equal to it is the angle ICR, which, subtracted from the Moon's anomaly once equated, leaves it equated a second time, 18° 40′ 29″, namely the angle RCE.

[Margin: Step 4.]

Fourth, therefore, in the triangle ECB, in which there are given CE, by Step 2, BC, by Step 3, and the angle BCE, which is the complement to two right angles of the anomaly equated a second time, and so is 161° 19′ 31″, you will find the angle BEC, 0° 41′ 25″. Add this to the earlier equation of the epicycle, found above as 3° 29′ 16″, and the whole epicyclic equation becomes 4° 10′ 41″, in this case subtractive.

[Margin: Step 5.]

Fifth, for the libration and variation of the Moon one proceeds thus. The doubled longitude of the luminaries, with a circle cast off, was 7^{s} 16° 55′ 12″, and its excess above a semicircle is 46° 55′ 12″, whose sine is 7304007; and the greatest equation of this Tychonic variation is 40′ 30″. Let it be, therefore: as the radius of the small circle of libration, 10000000, is to 40′ 30″, so is the sine 7304007 to another; and there will come out the equation of 29′ 35″, subtractive in this case. Added to the epicyclic equation found the second time, it makes up the whole equation, 4° 40′ 16″. So subtract this from the simple mean longitude from the mean equinox, which was 3^{s} 0° 54′ 22″, and there remains the equated longitude, 2^{s} 26° 14′ 6″. If to these you add the prosthaphaeresis of the equinoxes, 7′ 13″, the Moon's true longitude from the true vernal equinox comes out at Gemini ♊ 26° 21′ 20″. But Tycho observed it at Uraniborg at Gemini 26° 21′ 30″, namely in the year 1587 August 17, at 19^{h} 25^{m} after noon.

Altera Lunæ Hypothesis à Longomontano inuenta, & dicta Secundaria.

A second hypothesis of the Moon, devised by Longomontanus and called the Secondary.

On the straight line FM conceive two points, A and B, of which let B be the centre of the Earth, and A the centre of the small circle LK, which varies the eccentricity, and on which, as in the earlier example, is C, the centre of the deferent FDM. Through C draw the straight line ICO, parallel to the straight line FM, for at I will be the mean apogee of the eccentric orb. Further, from the centre D describe the equant, or epicycle, NH, on which the Moon is at E;

since by the law of the revolutions, when D is conjoined with the apogee I, the Moon occupies the lowest part of the epicycle, H. And because the motion HE is as great as ID, the angles ICD and HDE are therefore always equal; and indeed ICD measures the Moon's simple anomaly from the mean apogee, while HDE measures the Moon's motion on the epicycle, made from the perigee in the order of the signs. Now AB is the mean eccentricity; and the centre of the orb moves on the small circle KLC in the order of the signs, from K through L to C, with a motion as great as twice the distance of the Moon from the Sun. So at the direct syzygies of the luminaries, that is, at true ☌ and ☍, the centre of the lunar orbit is at the perigee K and nearest the centre of the Earth B; at the quadratures, however, it is found at the apogee L. With the straight line BG drawn, therefore, through C, in our case the straight line BC will be the true eccentricity, G the place of the true apogee, and the angle ABC, or arc IG, the subtractive equation of the anomaly; for the external angle GCI is equal to the internal CBA, because of the parallelism of the lines FM and IO, on which the straight line GCB falls. Now the Moon in its motions is configured to the true opposition or conjunction of the Sun; so to save its phenomena one prosthaphaeresis suffices, gathered from two angles, EKD (to which ECD is always equal) and KEB. Supply here in the figure the lines EB and EC, omitted by the engraver. Besides the third equation, of the variation, about which enough was said above. It suffices to have indicated this secondary theory, which Longomontanus illustrates by an example in Book 1 of the *Theorica*, chapter 6, before the tables of the lunar prosthaphaereses.

Diagram. A geometric figure in the left column, set into the text at the right of the lines from "tur in the order of the signs" down to "tur in apogeo". A vertical straight line runs from F at the top to M at the foot; a second vertical line, parallel to it, runs from I at the top to O at the foot. A large arc runs from the top round the left side to the foot, with a small circle standing on it at the upper left. A small circle stands low at the right, on the line FM. Straight lines run from G at the top down through C, on the left rim of the right-hand small circle, to B; from D to C; and from C to A, the centre of that small circle. Dotted lines run from E to L, and from H and from D to K.

- G (top, left of I): G
- I (top of the second vertical line): I
- F (top of the first vertical line): F
- N (left edge of the small circle at the upper left): N
- E (inside the small circle, upper right): E
- D (inside the small circle, centre): D
- H (inside the small circle, lower right): H
- L (head of the small circle at the right): L
- C (on the left rim of the small circle at the right, on the line IO): C
- A (centre of the small circle at the right): A
- K (foot of the small circle at the right): K
- B (below K, on the first vertical line): B

- O (foot of the second vertical line): O
- M (foot of the first vertical line): M

CAP. XXVIII. In no. 2 I rejected the other focus in the ellipse as idle. For although its authors use it as the point of mean motion, they do not in fact use it as the centre of a circle described around the ellipse, but use a circle described from the centre of the ellipse, etc.

[Margin: The limitation of our hypothesis of the Moon.]

My hypothesis of the Moon, however, I proposed neither as containing in itself the physical cause of the motions nor as perfect. I was content to teach an easier way by which the monthly equation, or second, proceeding from the eccentricity, could be found; for there is no such great difficulty about the calculation of the epicyclic equation. But when the manner of the variation, or third equation, has been established through observations, then, as I hope, I shall present the hypothesis perfect. Among the epicyclic hypotheses, moreover, I see that one comes very close to the truth, which Giovanni Antonio Magini, in the *Supplement to the Ephemerides*, reduced to a new form from the observations of Tycho; provided, however, that it is proportionally corrected so that the greatest equation at the conjunctions [in Copulis] is 5° 1′, and not merely 4° 58′ 27″.

AD LIBRVM V.

To Book V.

CAP. II. To this chapter or to its scholia can be attached rules for the effects of eclipses, which Proclus gives, and from him Pierio Valeriano at the end of his *Sphere*.

CAP. IV. No. 12. You will correct the scheme, badly cut by the engraver, by producing the little straight line KI to the left as far as the line AV, placing at its end the letter N, and drawing to it the line TN, so that the triangle NTK comes out isosceles and resting on the base KN.

[Margin: The quantity of the Earth's shadow.]

As to what I said here in Scholium 1 about the altitude of the refracting air being very small in respect of the Earth's semidiameter, it is confirmed from what is said in Book 10, section 6, Problem 51, where I teach that in the temperate zones it is not much greater than 20 Italian miles; so that the quantity of the shadow is not, for this reason, sensibly varied by the Sun's rays tangent to this air.

[Margin: The portion of the Earth illuminated by the Sun.]

CAP. V. No. 8. To enlarge the arc of the Earth illuminated by the Sun's refracted rays, I used the Sun's Tychonic horizontal refraction of 34′. But it is not so great everywhere or always, as can be seen from my table of refractions, to be placed at the end of Book 10, section 6. Indeed, even for Tycho it was not so great, except on the supposition of a parallax of the Sun at apogee of

2′ 54″, which however is smaller; so from this increase must be taken away as much as the Sun's horizontal parallax is smaller.

[Margin: The Moon's light extinguished in an eclipse.]

That the Moon is wholly extinguished in a total eclipse, as I said here in no. 13, Hevelius confirms in chapter 6 of the *Selenographia*, from Vitruvius, Book 9, chapter 4, and from the eclipse of 1642 April 14 observed by himself and by Phocylides; and Kepler in the *Epitome of Copernican Astronomy*, p. 825, from the eclipse of 1620 June 15.

CAP. X. No. 15. On other ways of gathering the parallax of longitude and of latitude, see Book 10, section 5, chapter 7.

[Margin: Are the extremes of eclipses better observed with less powerful telescopes?]

CAP. XV. In nos. 3, 7 and 14, on observing the beginning and end of an eclipse, especially a lunar one, I recommended the use of the telescope, sometimes a larger one, sometimes a smaller. For smaller telescopes, by taking in the whole luminary and not so rarefying the species, help in discerning whether anything of the disc's roundness has been nibbled away. Larger ones, however, separate the shade [vmbraginem] from the penumbra and the shadow, and by enlarging the black lentil of the shadow at the edges of eclipses they make it possible to estimate its quantity better, by comparison with the Moon's nearer spots of known quantity; so that from this and from the Moon's hourly motion the time to be added or subtracted can be gathered, and the beginning of the eclipse be had more justly.

[Margin: Scheiner's opinion on the telescope in observing eclipses.]

Yet our Scheiner, in the *Rosa Ursina*, Book 4, Part 2, chapter 16, teaches that, absolutely speaking, both the black spots of the Moon and the lentils of the Earth's shadow or penumbra at the extremes of eclipses are discerned with more evident distinction if you use telescopes of less power, that is, shorter, but clear nevertheless. He says: *For if anyone scans the Moon with a shorter tube, he will distinguish its ancient spots well; but if you attack it with a longer and more powerful telescope, that appearance of the spots, through refraction by the lenses, being enlarged and apparently rarefied, will not be seen so easily distinct, but will tire the sight. In lunar eclipses the edges of the Earth's shadow suffer the same; for with more powerful telescopes they are not discerned precisely from the illuminated parts; they are discerned best with weak or short ones.*

But Wendelen says still more, in his preface to the *Eclipses*. For although on p. 4 he said that the durations of eclipses were shown too great by Tycho and the ancients, because they counted the shade and smoke preceding the legitimate beginning of eclipses as part of the legitimate eclipse, since the use of the telescope had not yet become known, yet on p. 8 he warns astronomers:

[Margin: Wendelen's opinion on the use of the telescope in observing eclipses.]

Let them not apply themselves to eclipse observations gapingly or perfunctorily, and let them not allow themselves to be deceived, whether by the Earth's penumbra,

or by the Moon's spurious light, or finally also by telescopes, which need caution no less than those. For the eclipse that has already been noted by the naked eyes, and pronounced by everyone's judgement, is, if a telescope is applied, judged to begin at about the tenth minute after: since, that is, the telescope sees through, even within the darkness, the limb of the Moon still glowing red with some light, and so much the later decides the beginnings of eclipses. So that I do not at all know whether this too lynx-eyed tube has brought us more advantage than danger. Certainly I have always found all the phases of eclipses, the beginnings, digits, immersions, emersions and ends, no less certainly and definitely indicated by the naked eyes than if they were helped by a telescope; nor, if several spectators were present, do I remember the votes ever differing even within the narrow limits of one, or at most a second, minute of an hour. So whenever I prepare to observe, I take diligent care to have with me several youths, or young men of keen sight, and while some handle the telescopes, I attend to what others pronounce on the faith and confidence of their own eyes too. And I would advise all who are curious about these things to pursue the same, since I know that I have never been deceived by it even in the least.

But with all due respect to this most learned and most friendly man, how do these statements of his cohere? For if, through lack of the use of the telescope, Tycho and the older astronomers pronounced on the beginning of an eclipse too soon, how is it that those using the telescope pronounce about ten minutes later than they should on a beginning already made? Or if this second is true, how is it all the same to use it and not to use it, and how was he equally certain in either way about the beginning of an eclipse, within the narrow limits of one or another minute of an hour? Finally, from what source was he certain of the true beginning, so as to be able to judge from it whether in this the naked eye or rather the telescope should be trusted?

[Margin: D. Vicenç Mut's opinion on the same.]

Yet D. Vicenç Mut, in his *Sol Alphonsinus*, nos. 27 and 55, subscribed to Wendelen and Scheiner, asserting that when tubes are used, especially the more powerful, the beginnings of eclipses are observed later and the ends earlier than they should be, and so the durations smaller than is right; and Hevelius holds the same in chapter 56 of the *Selenographia*, p. 451. But a distinction had to be drawn, as we have already indicated. For with the naked eye or with short tubes the small portion of the Earth's shadow or penumbra making the extremity of the eclipse is more easily and evidently distinguished, and by a survey of the whole disc of the luminaries, seen at once, it is more easily recognized whether anything has been nibbled away from its perfect roundness. But that very small portion of shadow has some quantity; and so that it can be known how great a portion of the disc or diameter of the luminary is darkened, and how much time of the Moon's hourly motion from the Sun answers to it, this is better discerned with a strong telescope, if that small portion is compared with some small spot on the Moon.

[Margin: Our opinion on the telescope in observing eclipses of the Moon.]

And besides, with such a telescope the danger of confusing the shade with the legitimate eclipse is better avoided. And if, as is our practice, a lens convex on both sides, of almost a finger's thickness, excellently made, is applied to the eye, or four convex lenses arranged at set intervals, then the telescope, however powerful, takes in the whole disc of the Moon or Sun.

[Margin: The eclipse at the death of Christ.]

CAP. XVIII. On this eclipse, Georgios Kedrenos, in the *Annals of Constantinople*, under the year 19 of the Emperor Tiberius, p. 155: *There was an eclipse of the Sun, the greatest of all that had occurred before, and night fell at the sixth hour of the day, so that stars appeared in the sky. A huge earthquake too occurred around Bithynia, which laid low a great part of Nicaea. So Phlegon relates, and Africanus also.* He goes on, moreover, to teach that this was not a natural eclipse of the Sun, because it was full Moon. Add to these Origen, Book 2 of *Contra Celsum*, arguing from this eclipse; and our Jacob Gretser, Book 1 of *De Cruce*, chapter 31, page 102; and Iansenius [Cornelius Jansen the Elder] in the *Concordia Evangelica*, chapter 143. Scheiner, moreover, in the *Rosa Ursina*, Book 4, Part 2, chapter 13, since he thinks that the lunar shadow covers with its diameter only 70 great German miles, that is, as he himself explains, 350 Italian, therefore thinks it more probable that the miracle lay in this: *that so much and so dense a matter of spots was massed together as to snatch the whole Sun from the sight of mortals, like one spot.* From this he infers that the Moon too altogether, and all the other stars that were accustomed to receive light from the Sun, were then deprived of light, and that this is the darkness which St Dionysius the Areopagite indicates. Georgius Polaccus [Giorgio Polacco], moreover, subscribes to Scheiner in the *Anticopernicus Catholicus*, assertion 108. Add also our Pétau, Book 12 of *De doctrina temporum*, chapter 21. Now Giovanni Battista Capuano, at the end of his exposition of the *Sphere* of Sacrobosco, says that St Dionysius the Areopagite, after the portent of this eclipse, set up in the temple of Pallas an altar to the suffering God unknown to him, about which it is said in Acts 17, and that as a result he more easily believed the Apostle preaching the Gospel, etc.

Ad CAPVT XIX. libri 5. Seu ad Catalogum Eclipsium Appendix.

Appendix to Chapter XIX of Book 5, or to the catalogue of eclipses.

[Margin: Years before Christ]

Denis Pétau of the Society of Jesus, a man learned in every way, in Books 8, 11 and 12 of *De doctrina temporum* reports about 116 eclipses, and enters upon the calculation of all of them from principles partly Tychonic, partly Prutenic or Lansbergian. Since I had once gone through this work, but when chapter 19 of our Book 5 was soon to go to press had at hand only the catalogue of these eclipses once made by me, and since I later had the opportunity of reading that work again, I decided to reread my catalogue and, if anything was to be added

or corrected, to indicate it in this place. This I shall do following the order of time, as I did in that catalogue.

[Margin: 772]

Pétau, Book 8 of *De doctrina temporum*, p. 771: because he enters upon the calculation for July 24 of this year, he finds no eclipse of the Sun, from his Parisian tables. [Margin: 720] The eclipse between the 15th and 16th of the month Phamenoth, however, was on September 1, at 9^h 35^m after noon at Alexandria.

[Margin: 715]

The eclipse of the Sun at the death of Romulus was, for Pétau, of 8 digits 38′, and its duration 1^h 54^m; although later, in Book 10, chapter 21, he puts 9 3/11 digits and a duration of 1^h 46^m, and in the same place adds much to the learning of this chronology.

[Margin: 597 & 585]

The eclipse of the Sun in the year of the Julian Period 4117, or 597 before Christ, if you believe Pétau, *De doctrina temporum*, Book 10, chapter 1, is the one of which Herodotus speaks in Book 1, whose words I reported in Book 5, chapter 2, no. 8; where he sets out and pursues at length the opinions of others on the eclipse predicted by Thales. But why it seems to me it should be brought down to the year 585, I said in the catalogue of eclipses.

[Margin: 582]

[Margin: 581]

Pétau, Book 8, pp. 782 and 793, weighs two other eclipses of the Sun from calculation, not from ancient observation: one in the year 4132 of the Julian Period, that is, 582 before Christ, on October 2 at 5^h 57^m at Rome, of 6¾ digits, whose beginning could be seen at Sardis in Lydia, and it lasted 1^h 34^m. The other he puts on September 21 around noon at Sardis, but he shows from the parallax that there was none, namely in the year 581, in order to refute Scaliger.

[Margin: 580]

Pétau, Book 8 of *De doctrina temporum*, p. 788, computes from his tables an eclipse of the Sun in the year 580 before Christ, or 4234 of the Julian Period, which he says was of 7 digits 14′ and lasted 2^h 51^m, and that the apparent new Moon was at 1^h 50^m after noon at Athens. But it cannot be the one which terrified Xerxes as he moved from Sardis into Greece; for that one occurred when the Olympic contest was imminent, which was celebrated at the summer solstice. Yet what I said on p. 363, at the end, must be corrected, that in this year there was no eclipse of the Sun visible in western Asia; for this is to be understood of the time of this year at which Xerxes set out into Greece.

[Margin: 394]

This eclipse, as Pétau says in Book 8, p. 798, Buntingus [Heinrich Bünting] assigns to the year of the world 3574, and he makes it of only 2 digits.

[Margin: YEARS Before Christ.]

[Margin: 383]

Pétau, in Book 8, p. 800, computes the lunar eclipse of this year from various tables, so as to show how far they disagree with the observation. You may examine this in the small table set out below.

The eclipsing full Moon occurred at Alexandria after midnight at $6^h\ 30^m$.

But from the tables	**It was at**	**Excess**
Alphonsine	$8^h\ 26^m$	$1^h\ 56^m$
Prutenic	$7^h\ 19^m$	$0^h\ 49^m$
Danish	$7^h\ 12^m$	$0^h\ 42^m$
Parisian	$7^h\ 3^m$	$0^h\ 33^m$

Pétau says a great deal against Herwart in *De doctrina temporum*, Book 12, Ch. 37, denying that an eclipse can be inferred from the words of Livy in Book 7 of Decade 1.

[Margin: 343]

[Margin: 337]

Insert here, at this year, the eclipse of the Sun which took place in the year of the Julian Period 4377, or 337 before Christ, on July 14 near sunset. Herwart writes of it in his *Nova Chronologia*, and Pétau in *De doctrina temporum*, Book 12, Ch. 37. This is the one which Herwart thinks Livy described, in Book 7 of Decade 1, in these words: *night seemed to be falling during the day* [noctem interdiu visam intendi]. But, says Pétau in Book 12, Ch. 37, that prodigy, as Livy adds, was soon followed by the dedication of the temple of Moneta, which on Macrobius's testimony took place on June 1 [Kalendis Iunij]. So Herwart is wrong when, in order to show a metachronism of 8 years in the Fasti, he takes Livy to mean the eclipse of the Sun that took place in the year 337 before Christ, on July 14.

[Margin: 331]

The eclipse made famous by the victory of Alexander the Great began, Bünting says in his *Chronicle*, at Arbela at $8^h\ 45^m$ after noon, and in Sicily at $5^h\ 29^m$. But that would have been 31^m before sunset, which agrees less well with Pliny the Elder's account. On this eclipse, however, Pétau, in *De doctrina temporum*, Book 10, Ch. 36, defends Plutarch against Scaliger's slander: Plutarch did not say that this eclipse fell on day 20 of the month of Boëdromion, for his words in the *Alexander* are these: *And the Moon was eclipsed in the month of Boëdromion about the time when they enter on the Mysteries at Athens. On the eleventh night after the eclipse, with the two camps set in sight of each other*, etc.

[Margin: The year Alexandria was founded.]

Moreover, since the foundations of Alexandria in Egypt were laid by Alexander as this same year was running out, as is clear from Diodorus, Plutarch, Curtius and Arrian, it is plain that three authors are wrong: Livy (Decade 1, Book 8), Solinus (Ch. 38) and Cassiodorus in his *Chronicle*. They say Alexandria was founded in the year when C. Poetelius and L. Papirius Mugilanus were consuls; for according to Varro this is the year of the City 428, which falls

in the year 326 before Christ, and so they are out by 5 years. Worse still is Eutropius in Book 2, who says it was founded in the Varronian year of the City 416, anticipating by 7 years. Eusebius, finally, puts its founding one year later. See Pétau, Book 10, Ch. 36.

On the eclipse of the year 219 and of 217, against Herwart, see Pétau, Book 12, Ch. 37.

[Margin: 219]

[Margin: 217]

[Margin: 202]

Bünting makes the eclipse of the year 202 a solar one, small indeed but of 2 digits 38′, in the year of the World 3767. Pétau, however, in Book 8, Ch. 13, p. 810, admits that if he had followed the lunar diameter assigned to full Moons, the eclipse would have been of 2 digits 25′. But he says: *It is better to follow Tycho*.

[Margin: Pétau's error on the lunar diameter.]

Tycho, of course, wrongly believed that at new Moons the lunar diameter is always smaller than the solar, and therefore admitted no total eclipse of the Sun. Enough was said of his error in Book 5, Ch. 20, so that on these matters Pétau too must be corrected.

[Margin: 201]

[Margin: 200]

An uncorrected codex of Ptolemy puts this eclipse in year 52 of the Callippic period; but it must be corrected and read as 54, as Georgios Trapezountios translates and as our Pétau has it in Book 10, Ch. 37. The following eclipse, of the year 200 before Christ, was according to Pétau at $0^h\ 42^m$ after midnight of March 20, a day he begins from that midnight, and of 17 digits 20′.

[Margin: 190]

[Margin: &]

[Margin: 188]

[Margin: &]

[Margin: 168]

Against Herwart's misuse of these eclipses, see Pétau, Book 12, Ch. 37. But Herwart erred above all on the eclipse of the year 618 [recte: 168], which he draws back to the year 160, with the Sun in Aquarius. For that eclipse took place in the year of the City 586, with the Sun not in Aquarius but in Gemini, since Livy, in Book 4 of Decade 5, says that it came *after the solstice had passed, in the most blazing heat*, and Plutarch in the *Paulus* says it was *when the summer was already waning*: evidently because he had read that it fell on September 4 [pridie nonas Septembris], but of the Roman year, which was then out of joint.

[Margin: YEARS Before Christ.]

On the eclipse of the year 188, moreover, Bünting also erred, in the year of the World 3781, making it of only 3 digits and recording it at 3^h after noon at Rome, although Livy, in Book 8 of Decade 4, says that *in daylight, between the*

third and fourth hour of the day, darkness arose. So Pétau does better; see him also at Book 12, Ch. 37.

[Margin: 51]

Before the eclipse of the year 44, put the eclipse of the Sun of the year 51 before Christ, from the calculation of Pétau in Book 8, Ch. 13, p. 819. He says that it took place on March 7, a Wednesday [feria 4], that the apparent new Moon was at Rome at $12^h\ 21^m$ after midnight, and that the eclipse was of 10 ½ digits and lasted $2^h\ 42^m$. In Book 10, Ch. 58, moreover, he contends that this was the eclipse mentioned by Cassius Dio in Book 41, which occurred shortly before the beginning of the Civil War, which fell in the year of the City 705. Read him there.

Eclipses in Annis CHRISTI.

Eclipses in the Years of Christ.

[Margin: YEARS of Christ.]

[Margin: 291]

[Margin: &]

[Margin: 316]

In recording these eclipses an error crept into Pétau's numbers, in *De doctrina temporum*, Book 8, Ch. 13, pp. 831 and 833, where 391 is put for the year 291, and 318 for 316. But they must be corrected from the same Pétau's *Rationarium temporum*, as we have done in the catalogue.

[Margin: 334]

The words of Julius Firmicus must be continued and this added: *That in the consulship of Optatus and Paulinus (to speak of more recent events) the keen application of the mathematicians foretold what would come upon all men.* Further, Mulerius (Ch. 11 of the *Isagoge*) and Pétau (*De doctrina temporum*, Book 8, Ch. 13, p. 836) point out that this eclipse cannot be worked out from the Prutenic Tables.

[Margin: A defect of the Prutenic Tables.]

For by Reinhold's Canon 10 the time of emersion would have been $0^h\ 40^m$ after midnight, when in fact the eclipse was seen from $10^h\ 19^m$ to $13^h\ 14^m$ after midnight. And perhaps for that reason neither Bünting nor Mercator mentions this eclipse.

[Margin: 1573]

[Margin: to]

[Margin: 1612]

Denis Pétau, in *De doctrina temporum*, Book 8, Ch. 13, from p. 753 to p. 769, gives the calculation from his Parisian tables of nearly all the eclipses observed from 1573 to 1612. At the eclipse of 1596, moreover, he notes that the calculation from the Parisian tables differs from the observation by 13^m of time, but from the Danish by 5^m and from the Frisian by 6^m.

[Margin: 1596]

[Margin: 1612]

[Margin: &]

[Margin: 1616]

Father Ioannes Vremanus [?], in a letter to Father Grienberger written from the East Indies, concludes, from eclipses observed there and compared with those that Origanus computed in 1612 and 1616, that Goa lies further east than Frankfurt on the Oder by $4^h\ 2^m$, Macau by $6^h\ 48^m$, Beijing [Pachinum] by $7^h\ 5^m$ and Nanjing [Nanchinum] by $7^h\ 11^m$; our Georges Fournier also reports this, in Book 13 of the *Hydrographie*, Ch. 14.

[Margin: 1621]

On the eclipse of the Sun of May 21 observed at Aix by Gassendi, I took the observation from his letters sent to Rome. But Father Georges Fournier, in Book 12 of the *Hydrographie*, Ch. 14, p. 578, relates that it began there with the Sun at an altitude of 35° 30′, and at $19^h\ 5^m\ 20^s$ after noon of the preceding day; the end after $2^h\ 3^m\ 12^s$, with the Sun at an altitude of 51° 17′; and that therefore the time midway between these was $20^h\ 18^m\ 20^s$, the incidence was of $1^h\ 12^m\ 52^s$, the duration of $2^h\ 25^m\ 14^s$, and the digits 9 23′.

[Margin: 1621]

In the same place, on the eclipse of the Moon of November 28 of the same year, he agrees with us about Gassendi's observation, but adds that the incidence was 59^m and the middle at $14^h\ 53^m$.

[Margin: 1625]

I recorded the eclipse of the Moon under March 24, but I put the hours after noon of the 23rd. Granted, because the eclipse had passed midnight, it may seem to belong to the 24th.

[Margin: 1628]

The observation of the eclipse made by Gassendi, Mydorge [Middorgio] and Bainbridge [Baindbrigio] is also related by Fournier, in the same way as by me, in Book 12 of the *Hydrographie*, Ch. 6. But in Ch. 13, p. 579, he adds another eclipse, of the Moon, on June 14 of the same year, observed at Aix, whose beginning, he says, was observed by Gassendi at $11^h\ 15^m$, the total obscuration at $12^h\ 17^m$ and the emersion at $14^h\ 0^m$.

[Margin: 1629]

In 1629, on June 21, an eclipse of the Sun was observed by Father Rhodes [Alexandre de Rhodes] of the Society of Jesus in the Kingdom of Tonkin, in the city of Rum, which is about 80 leagues, or 240 Italian miles, from the royal seat of Tonkin, has a pole altitude of 18°, and is

[Margin: YEARS of Christ.]

from the Fortunate Isles by about 133°. There, then, he says, the eclipse began about two hours before noon, was of about six digits, and ended about one hour after noon.

[Margin: 1631]

In 1631, on November 8, the eclipse of the Moon at Oxford, with Bainbridge observing, began with Aldebaran at an altitude of 28° 50′, or at 9^h 4^m. It emerged from the shadow with the right shoulder of Orion at an altitude of 34° 30′, that is, at 11^h 58^m, and ended with the same shoulder at an altitude of 41° 20′, or at 13^h 4^m. So Fournier relates, in Book 12 of the *Hydrographie*, Ch. 6.

[Margin: 1632]

In 1632, on October 27, the eclipse of the Moon which I said was observed by four astronomers was also observed by Bainbridge at Oxford, at a pole altitude of 51° 46′, with the Moon at an altitude of 44° 50′. So says Fournier, in Book 12 of the *Hydrographie*, Ch. 6, deducing from this and Gassendi's observation a difference of $31\frac{1}{2}^m$ of time, or 7° 52′, between Oxford and Lyon in France.

[Margin: 1633]

In 1633, on April 8, an eclipse of the Sun was observed at Paris by Master Beaugrand; there it began with the Sun at an altitude of 31° 27′, that is, at 3^h 18^m 8^s after noon, and it ended with the Sun at an altitude of 12° 6½′, that is, at 5^h 23^m 12^s. The digits, so far as could be seen through the clouds, were more than 6. At Digne, however, with Gassendi observing, it was of 8 digits 18′; it began at 4^h $42\frac{1}{2}^m$ and ended at 5^h 45^m. At Aix, with Claudius Fabricius [Nicolas-Claude Fabri de Peiresc] and Garterius [?] observing, it was of 8 digits 48′, starting with the Sun at an altitude of 32°, or at 3^h 29^m, and ending with the Sun at an altitude of 8° 40′, or at 5^h 41^m. But at Oxford Bainbridge observed it entering with the Sun at an altitude of 31° 10′, namely at 3^h 4^m, and ending with the Sun at an altitude of 14° 55′, or at 5^h 58^m, or about to end a little later. So Fournier relates, in Book 12 of the *Hydrographie*, Ch. 17.

[Margin: 1634]

In 1634, on March 14, the beginning of a lunar eclipse was observed by Master Toriduto [?] at Avignon at 9^h $7\frac{1}{2}^m$ after noon, the end at 11^h. But at Tübingen Schikardus [Wilhelm Schickard] observed the beginning at 7^h 40^m, the middle at 9^h 17^m 45^s and the end at 10^h $56\frac{1}{2}^m$, as Fournier reports in Book 12 of the *Hydrographie*, Ch. 7.

[Margin: 1635]

In 1635, on March 3 new style, the eclipse of the Moon is said to have been observed by Gassendi, not at Marseille, as had been written to me, but at Aix. There, the beginning of the eclipse was with Regulus at an altitude of 50° 25′, or at 6^h 47^m; the total obscuration with Regulus at an altitude of 42° 10′, or at 7^h $55\frac{1}{2}^m$; the emersion at 9^h $32\frac{1}{2}^m$; and the end at 10^h 38^m. But the umbrago lasted until 11^h 2^m, and the semidiameter of the shadow appeared three times greater than the lunar semidiameter. So Georges Fournier has it, in Book 12 of the *Hydrographie*, Ch. 8.

He adds that at Paris Boulliau observed the beginning of the total obscuration at 7^h 37^m, the emersion at 9^h 9^m, and therefore the middle at 8^h 23^m. At Digne, D. Bollon Chatoini [?] observed the total obscuration at 8^h 2^m and the end at

10^h $40½^m$. At Amsterdam Hortensius observed the beginning with Regulus at an altitude of 27° 8′, or at 6^h 46^m, the total obscuration at 7^h 51^m, the emersion at 9^h 30^m and the end at 10^h $34½^m$. But at Danzig, with Crüger observing, the beginning was at 7^h 39^m, the total obscuration at 8^h 47^m, the emersion at 10^h 30^m and the end at 11^h 39^m, unless there is some defect in the calculation of the last time. At London, again, Master Gellibrandus [Henry Gellibrand] observed the beginning at 6^h 20^m, the total obscuration at 7^h 37^m, the emersion at 9^h 9^m and the end at 10^h 11^m. At Tübingen, further, Schickard observed the middle at 8^h 43^m. So Fournier, in the place cited above.

Albert Linemann himself, in the short work entitled *Memoria Secularis*, relates what he observed at Königsberg in Prussia. He did not observe the beginning, because clouds were in the way; but when nearly six digits were obscured, Jupiter stood at an altitude of 56° 50′ in the east, that is, at 8^h 19^m. The beginning of the stay was with Procyon at an altitude of 41° 0′ in the west, or at 8^h 54^m; half a digit was recovered with Jupiter at an altitude of 51° 40′ in the west, namely at 10^h 34^m; and the end of the eclipse was with Jupiter at an altitude of 44° 40′, or at 11^h 35^m. But he assumes the places of the Sun, Jupiter and Procyon from the Rudolphine Tables. He adds, from Crüger's letters to him, and confirms, what we gave above from Fournier; and he adds that at Stettin in Pomerania D. Eichstaedt, Doctor of Medicine, observed the beginning of the total obscuration with Regulus at an altitude of 41° 13′, or at 8^h 27^m, as that author himself has it in his *Pædia Astron.*, p. 128. At Franeker, however, Metius observed the middle of the eclipse, from the extremes, at 8^h 41^m, as Phocylides [Johannes Phocylides Holwarda] reports in his *Examen Astronomiæ*, p. 108.

[Margin: 1635]

In the same year, on August 28, Albert Linemann, as he himself reports in his second *Memoria Secularis*, observed the lunar eclipse at Königsberg in Prussia as follows.

[Margin: YEARS of Christ.]

	Altitude of Aldebaran in the east	After midnight
BEGINNING	35° 40′	2^h 33^m
3 digits obscured	37° 25′	2^h 46^m
5 digits obscured	38° 25′	2^h 54^m
6 digits obscured	39° 20′	3^h 2^m
9½ digits obscured	40° 40′	3^h 13^m
Total obscuration	42° 30′	3^h 30^m

He adds that the Moon, while still high above the horizon, vanished entirely around the middle of the total obscuration, both to the naked eye and to the telescope.

[Margin: 1636]

In 1636, on February 20, Albert Linemann, as he himself relates in his third *Memoria Secularis*, observed at Königsberg in Prussia the exact beginning of the lunar eclipse, through the tube, at $10^h\ 45^m$, when Arcturus was at an altitude of 26° in the east. With Arcturus at an altitude of 30° 20′, or at $11^h\ 15^m$, fewer than 3 digits and more than 2½ were obscured, and that was then the middle of the eclipse.

Fournier, however, in Book 12 of the *Hydrographie*, Ch. 10, relates that at Traona [Trahone] in the Valtellina Monsieur Petit, Professor of Mathematics, observed the beginning at $10^h\ 8^m$, the middle at $11^h\ 1^m$ and the end at $11^h\ 54^m$, using the altitude of Aldebaran and of Sirius, and the pole altitude there, observed exactly from the altitude of the Sun at the summer solstice, 46° 10′. He adds an observation of the same eclipse made at Aix by Master Gerardo [?], as in the following small table.

	Altitude of Arcturus	After noon
Beginning	15° 30′	$9^h\ 49½^m$
Digit obscured	16° 30′	$9^h\ 57^m$
Two digits	18° 30′	$10^h\ 6½^m$
2 and ½ digits	19° 20′	$11^h\ 9^m$
End	21° 0′	$11^h\ 33½^m$

At Amsterdam, however, Hortensius observed the end with Arcturus at an altitude of 33° 7′, or at $11^h\ 32^m$.

[Margin: 1637]

In 1637, near the Hurons in New France, Father Castelanus [?] of the Society of Jesus observed, on December 31, the middle of a lunar eclipse at $6^h\ 15^m$, as Fournier has it in Book 12 of the *Hydrographie*, Ch. 14.

[Margin: 1638]

In 1638, on December 20, Gassendi observed the phases of a lunar eclipse, as Fournier reports in Book 12 of the *Hydrographie*, Ch. 11, as you see in the following small table.

Phases		Altitude of Aldebaran in the west	After noon
Umbrago or smoke		52° 46′	$12^h\ 12½^m$
Beginning of the true eclipse		49° 18′	$12^h\ 26½^m$
	1	48° 29′	$12^h\ 42^m$
	2	47° 32′	$12^h\ 48^m$
	3	46° 46′	$12^h\ 53^m$
	4	46° 1′	$12^h\ 58^m$
	5	45° 17′	$13^h\ 2^m$
	6	44° 25′	$13^h\ 7½^m$
Digits obscured	7	43° 41′	$13^h\ 12^m$
	8	42° 51′	$13^h\ 17^m$
	9	41° 59′	$13^h\ 22^m$
	10	41° 1′	$13^h\ 28^m$

Phases		Altitude of Aldebaran in the west	After noon
	11	40° 12′	13^h 33^m
Total obscuration	12	39° 21′	13^h 38^m
		Altitude of the right shoulder of Orion	
Emersion		30° 32′	15^h $13½^m$
	1	29° 41′	15^h 17^m
	2	28° 49′	15^h 24^m
Digits recovered	3	28° 9′	15^h 28^m
	4	27° 15′	15^h 33^m

[Margin: YEARS of Christ.]
The remainder of the preceding observations.

Phases		Altitude of the right shoulder of Orion	Time
	5	26° 20′	15^h $37½^m$
Digits recovered	6	25° 24′	15^h 44^m
	7	24° 42′	15^h 48^m
	8	23° 59′	15^h 52^m
	9	23° 2′	15^h 57^m
	10	22° 3′	16^h 3^m
	11	21° 3′	16^h $8½^m$
End	12	20° 3′	16^h 14^m
End of the umbrago		15° 54′	16^h 37^m

In the same chapter Fournier relates an observation made at Aix by Master Garratus [?], of which you may take this summary.

		Altitude of the Tail of the Lion in the east	After noon at Aix
Beginning of the eclipse		19° 55′	12^h 22^m
True beginning		23° 0′	12^h 39^m
	2	24° 20′	12^h $46½^m$
	5	27° 0′	13^h 0^m
Digits obscured	6	28° 0′	13^h $6½^m$
	8	29° 20′	13^h 14^m
	9	30° 25′	13^h 20^m
	10	31° 45′	13^h $27½^m$
	11	32° 35′	13^h 32^m
		Bright star of ♈	
Total obscuration		17° 10′	13^h 36^m
		Altitude of Arcturus	
	1	26° 50′	15^h 12^m
Digits recovered	2	28° 35′	15^h $21½^m$
	3	28° 55′	15^h 23^m
	4	29° 30′	15^h 26^m
	5	30° 35′	15^h 34^m
		Spica ♍	
	7	19° 40′	15^h 43^m

		Altitude of the Tail of the Lion in the east	After noon at Aix
	8	21° 55′	$15^h\ 59^m$
	10½	22° 40′	$15^h\ 5½^m$
End			$16^h\ 9½^m$

[Margin: 1639]

In 1639, on June 1, an eclipse of the Sun was observed at Danzig by Johannes Hevelius through a bare aperture, with an hour-striking clock corrected to an accurate sundial. Albert Linemann reports on it as follows in his fourth *Memoria Secularis*.

	Time
Beginning of the eclipse	$5^h\ 20^m\ 42^s$
6 digits obscured	$5^h\ 58^m\ 8^s$
Middle	$6^h\ 21^m\ 31^s$
6 digits again	$6^h\ 44^m\ 50^s$
End	$7^h\ 14^m\ 55^s$
Greatest quantity of digits	10 digits 48′
Duration	$1^h\ 54^m\ 13^s$

At Stettin in Pomerania, however, as the same Linemann relates, Master Lorenz Eichstaedt observed the beginning at $4^h\ 58^m$ and the end at $7^h\ 7^m$. At Leiden, moreover, Master Kechelius [Samuel Kechel], using Snel's quadrant, observed the beginning with the Sun at an altitude of 30° 30′, that is, at $4^h\ 33^m$, the end with the ☉ at an altitude of 13° 21′, or at $6^h\ 27^m$, and at the maximum 10 digits 20′. So Linemann reports.

But Father Fournier, in Book 12 of the *Hydrographie*, Ch. 17, relates that at Paris the most celebrated mathematicians, having divided the places among themselves, observed this eclipse. Thus in the monastery of the Discalced Carmelite Fathers, the western window was taken by Master Roberualius [Gilles Personne de Roberval], Master Mydorge the Treasurer and Father Denis Pétau. They found the beginning of the eclipse with the Sun at an altitude of 32° 50′ and the end with it at an altitude of 13° 43′. From this Fournier infers, for the beginning, the hour $4^h\ 19^m\ 28^s$ if Gassendi's pole altitude of 48° 52′ is assumed, but $4^h\ 19^m\ 30^s$ if 48° 45′, with parallaxes and refractions computed.

But Master Beaugrand the Secretary, President Pasqualis [Étienne Pascal] and Master Hardi [Claude Hardy] the Counsellor, near the Châtelet, in a library, with a clock set exactly to the Sun, observed the beginning at $4^h\ 25^m$, the middle at $5^h\ 23^m\ 30^s$ and the end at $6^h\ 34^m$. They also found the ratio of the Sun's apparent diameter to the Moon's apparent diameter to be as 155 to 163, and 9 digits 34′ at the height of the obscuration.

At Blois, Master Beaune [Florimond de Beaune], Royal Counsellor and a most ingenious and excellent mathematician, observed in our college the beginning at $4^h\ 17^m$, the end at $6^h\ 17^m$, and 8½ digits. At La Flèche [Flexijs],

moreover, Fathers of our Society Vatierus [?], Deriennes [?] and Fournier, each a professor of mathematics, observed in the Royal College the beginning with the Sun at an altitude of 34° 30′, or at 4^h 6^m; the middle with the Sun at an altitude of 23° 0′, at 5^h $18½^m$; and the end with the Sun at an altitude of 13°, at 6^h 20^m.

At Aix, further, Gassendi observed the beginning at 4^h 44^m, with the Sun at an altitude of 28° 30′, and the middle at 5^h 45^m, with the Sun at an altitude of 18° 53′ and 8 digits 10′ obscured. At Rome, Master Bertus [?] observed the beginning at 5^h 15^m, with the Sun at an altitude of 23°, the greatest obscuration at 6^h 16^m, with the Sun at an altitude of 12°, and 8½ digits; the Moon's diameter appeared to him smaller than the Sun's by a 34th part. But Kircher says that at Rome the beginning was observed at 5^h 33^m, or with the Sun at an altitude of 38° 24′, and that 8 digits were obscured with the Sun at an altitude of 9° 43′, or at 6^h 10^m. But the altitudes of the ☉, 23° and 38°, disagree too much; yet that is how I read it. In Canada, Father Castelanus [?], at the Residence of the Conception, observed the middle of the eclipse, of 4 digits, at 10^h 15^m in the morning. Father Agathangelus Britannus, a Capuchin, at Cairo in Egypt, says that no part of the Sun was obscured. So Fournier reports, in the place cited above.

[Margin: YEARS of Christ.]

[Margin: 1641]

In 1641, on the night following October 18, Albert Linemann, as he himself reports in his fifth *Memoria Secularis*, observed the following phases of a lunar eclipse at Königsberg in Prussia.

Phases	Altitude of Aquila in the west	After noon
Penumbra	41° 50′	☩ ☩
True beginning of the eclipse	41° 20′	7^h 17^m
3½ digits obscured	40° 20′	7^h 22^m
5 digits obscured	37° 0′	8^h 4^m
6¼ digits, the maximum	33° 36′	8^h 37^m
5 digits, decreasing	30° 0′	9^h 8^m
Exact end	23° 45′	9^h 57^m

He adds that at Danzig Hevelius observed the beginning at 7^h 1^m 15^s, the middle at 8^h 26^m 15^s, the end at 9^h 51^m 0^s, and 7 digits at the maximum; that at Paris Gassendi observed the end at 7^h 50^m; and that at Franeker Phocylides Holanda observed the end at 9^h $3½^m$, as he himself relates in the *Epitome Astronomiæ reformatæ*.

[Margin: 1642]

On the eclipse of 1642, which took place on April 14, which we observed at Bologna and then communicated with others to Govaert Wendelen in 1646, it will not be useless to indicate here what Wendelen thought, from his letter to me dated at Brussels on September 5 [Nonis Septembris] of the same year. He

writes that our observation gives the strongest support to his hypotheses. He regrets that at Paris Boulliau observed the beginning at $12^h\ 10^m$, when it should have begun there at $11^h\ 45^m$, since Herk is east of Paris by 18^m, and at Herk the beginning was observed accurately at $12^h\ 3^m$. He regrets, I say, a disagreement of 25^m in the time; but how justly I fear that he makes Herk too far east, I shall show in my *Geographical Book*.

[Margin: 1643]

The eclipse of the ☾ of September 27, 1643, was observed by Antonius Garratus [?] near Senlis, 2′ east of Paris; its end, says Boulliau in the prolegomena to the *Astronomia Philolaica*, agrees with Boulliau's to within 1′.

[Margin: 1645]

On August 21, Johannes Hevelius says in Ch. 5 of the *Selenographia*, he observed at Danzig the following phases of a solar eclipse, from corrected altitudes of the Sun.

[Margin: YEARS of Christ.]

Phases	After the preceding midnight: time
Beginning	$11^h\ 23^m\ 45^s$
Digits obscured: 2	$11^h\ 38^m\ 0^s$
5	$12^h\ 1^m\ 30^s$
6	$12^h\ 11^m\ 30^s$
7	$12^h\ 22^m\ 0^s$
Middle: 7¾	$12^h\ 41^m\ 20^s$
Digits obscured, decreasing: 7	$12^h\ 54^m\ 45^s$
6	$13^h\ 6^m\ 0^s$
5	$13^h\ 15^m\ 30^s$
4	$13^h\ 23^m\ 45^s$
3	$13^h\ 31^m\ 30^s$
End of the eclipse	$13^h\ 53^m\ 0^s$

But Father Iacobus Billy [Jacques de Billy] of the Society of Jesus, in a short but learned letter written to me, affirms that the beginning of this eclipse was accurately observed at Reims on the 21st at $1^h\ 53^m$ before noon, and the middle at $0^h\ 58^m$ before noon, but that the end could not be observed. He adds that Reims and Châlons lie under the same meridian.

[Margin: 1646]

In 1646, on January 31, Johannes Hevelius observed at Gedanum, or Danzig, in the morning before sunrise, the beginning of the lunar inumbration at $5^h\ 21^m\ 4^s$ after midnight. He says that this beginning was about degree 118 of the Moon's limb and the mountain of the Arcadians (for he is alluding to the names in his *Selenographia*); that 4 digits were obscured at $5^h\ 33^m\ 36^s$ and 11 digits at $6^h\ 12^m\ 52^s$; that the semidiameter of the shadow was estimated at 46′ 30″; and that clouds prevented the rest.

In the same year, on July 27, the eclipse of the Moon could not be observed at Herk by Wendelen. He writes to me, however, in a letter of this year that remnants of the penumbra were visible to him until 7^h 55^m.

[Margin: 1647]

To what I related of the eclipse of the year 1647 observed by Hevelius it must be added that the beginning of the eclipse was about degree 170 of the Moon's limb and the end about degree 247. For in his *Selenographia* he divides the circumference of the Moon's disc into 360 degrees, as though libration allowed those degrees always the same position. We, however, think it better to name certain small spots across which the boundary of the shadow passes.

[Margin: 1649]

In 1649, on May 25, D. Vicenç Mut observed the beginning of a lunar eclipse at Majorca at 13^h 16^m after noon, with Arcturus at an altitude of 42° 10′ towards the west. He rightly wonders that by Wendelen's *Atlantic Tables* it should have begun at Majorca at 12^h 44^m 41^s; he admits, however, that to the naked eye the umbrago began at 13^h 8^m. So he says in a letter to me. But the equation of natural days, which Wendelen neglected, not rarely produces these disagreements.

[Margin: Wendelen's disagreement with the observations.]

[Margin: 1649]

In 1649, on November 4, there was an eclipse of the Sun, which Father Theodorus Moretus [Theodoor Moretus] of the Society of Jesus observed at Kostelec in Bohemia: only the end, that is, at 5^h 15^m after noon, with the image of the Sun brought in through an optical tube; for the clouds denied him the middle and the beginning. He adds that the town lies towards the east of Prague, on the same parallel, at almost 15 great German miles, or 90 or 100 Italian. When he took the altitude of the Sun, the perpendicular was to its shadow as 57 to 546, the shadow observed being the one that indicated the altitude of the Sun's centre, in the middle of the doubtful edge of the solar shadow. Then, having found the meridian line at the same place by means of the Sun's double shadow, he found on November 7 at noon that the height of the perpendicular was to the length of the Sun's shadow as 57 to 108. The most courteous Father wrote this to me at once, on the 8th.

[Margin: D. Vicenç Mut's diligence in astronomical observations.]

Not very long after I had received this, there came to me a letter from Majorca from D. Vicenç Mut, dated the 16th, in which he set out in full his observation of this eclipse, made by him at Majorca accurately, as he usually does; and it went as follows. He received the image of the Sun on paper through the telescope described above in this appendix, at Book 3, Ch. 10. The image of the Sun not yet eclipsed was of 4150 parts, of which the image of the Sun at apogee had been found to be 4000. Now, of the parts of which the whole image was 4150, the obscured part observed in the eclipse was as below.

Parts of the ☉ obscured	Altitude of the ☉	After noon
Beginning: 1	32° 32′	1^h 22½^m
332	31° 20′	
518	30° 33′	
830	29° 56′	
955	29° 27′	
1100	28° 25′	
Middle: 1205	27° 47′	2^h 3⅛^m
830	23° 23′	
518	22° 19′	
332	21° 27′	
End: 1	20° 21′	3^h 2½^m

[Margin: YEARS of Christ.]

[Margin: The Moon's diameter.]

The greatest obscuration was 9′ 25″, of which the diameter was 32′ 28″, or 3 digits 33′. The Moon's diameter, moreover, was of 4230 parts, of which the Sun's was 4150. Looking at the Sun also through a tube, but one fitted with coloured glasses, he clearly saw the Moon somewhat larger than the Sun, and by a little more than on the paper. The Moon was at perigee, and trigonometric exactness gathers its hourly motion as 36′ 43″, but in doing so supposes the sum of the semidiameters of the luminaries to be 32′ 47″, the obscured part of the Sun at the height of the eclipse 9′ 25″, and the true latitude of the Moon 4′ 40″.

[Margin: Praises of the pendulum in the measurement of time.]

Johannes Hevelius observed the same eclipse at Danzig, using a clock that showed every single second, checked against a sundial, which gave 54^m after noon when the striking clock gave 55^m 35^s. As soon as one o'clock after noon was complete, the reciprocal vibrations of the pendulum began to be counted, of which 43¼ made up one minute and 2596 a whole hour. *For these*, says Hevelius, *if rightly counted against a sundial accurately divided into minutes, snatch the palm from all clockwork in showing the time (as experience bears witness)*. What would Hevelius say now of our pendulums, adjusted to the motion of the fixed stars? But let us go on, and set out the phases that the clouds and the towers in the way did not deny him, from his letter to Eichstaedt, written on 1650 January 5 and afterwards forwarded to me when it was made public.

Digits eclipsed	Time by the striking clock	Vibrations of the pendulum, begun from 1 o'clock after noon	Time after noon from the pendulum
Beginning	2^h 27^m 30^s	3807	2^h 28^m 0^s
5¾	3^h 15^m 0^s	5819	3^h 14^m 30^s
5½	3^h 17^m 0^s	5910	3^h 16^m 36^s
5⅜	3^h 19^m 45^s	6029	3^h 19^m 22^s
5	3^h 22^m 30^s	6151	3^h 22^m 10^s
4⅞	3^h 24^m 0^s	6216	3^h 23^m 41^s
4¾	3^h 27^m 0^s	6326	3^h 26^m 19^s
4⅝	3^h 28^m 0^s	6392	3^h 27^m 45^s

Digits eclipsed	Time by the striking clock	Vibrations of the pendulum, begun from 1 o'clock after noon	Time after noon from the pendulum
4¼	$3^h\ 32^m\ 40^s$	6598	$3^h\ 32^m\ 31^s$
3½	$3^h\ 39^m\ 0^s$	6873	$3^h\ 38^m\ 50^s$
1⅛	$3^h\ 56^m\ 0^s$	7611	$3^h\ 55^m\ 56^s$
0½	$3^h\ 59^m\ 0^s$	7741	$3^h\ 58^m\ 57^s$
End	$4^h\ 1^m\ 0^s$	7831	$4^h\ 1^m\ 0^s$

[Margin: Disagreement of the astronomical tables with the sky.]

He adds the position of the horns relative to the ecliptic. The right cusp, inclining towards Corus, stood 53½° from the zenith and 45° from the ecliptic, on the small circle of phases of the computer; the left cusp stood 68° from the zenith and 14° from the ecliptic, when the eclipse was at its height. When a quarter of the Sun's diameter was dark, the right cusp held exactly the point of the zenith. Moreover, the eclipse ended towards the Hellespontius, 55° from the point of the zenith and 27 from the ecliptic; from which he gathers that it began towards Corus at about 60° from the point of the zenith. As for the calculation from the astronomical tables straying so far from the truth, he suspects that something lies hidden in the equations of the times.

[Margin: YEARS of Christ.]

[Margin: 1649]

In the same year 1649, on the night between November 18 and 19, we observed here at Bologna the total obscuration, or immersion, of the Moon, when Procyon was 55° 35′ from the vertex, that is, at $18^h\ 45^m\ 50^s$ after noon of the 18th. We were not able to observe the rest. Father Nicolaus Mascardus [Nicolò Mascardi] of the Society of Jesus, however, wrote to me from the West Indies, namely from the port of Panama, that the beginning of this eclipse was observed by Father Franciscus Ruggius [?], a man highly skilled in mathematics, at Panama at the eleventh hour after noon, and that its duration was 4 hours. From this we are certain that the interval between Bologna and Panama is not $7^h\ 46^m$. For if the total obscuration at Bologna was at $18^h\ 46^m$, then the beginning of the eclipse was before this time, and indeed by very nearly one hour according to astronomical calculation, that is, at $17^h\ 46^m$. If you subtract 11 hours from these, $6^h\ 46^m$ remain, to which there answers a difference of meridians of 101½°. But since neither we in any way, nor perhaps Father Ruggius, observed the beginning with the greatest exactness, we may not conclude from this a difference of longitude that is exact in every respect.

[Margin: The difference of meridians of Bologna and Panama.]

[Margin: 1650]

In 1650, on May 15, the Moon rose above the horizon at Majorca already eclipsed. At the greatest obscuration the illuminated part of the Moon was 9′ or 10′. The end of the eclipse, caught with a telescope, was with Regulus at an altitude of 40° 29′ towards the west, that is, at $9^h\ 32^m\ 24^s$. So the observer himself, D. Vicenç Mut, wrote in full to me in his letter sent to Bologna on

June 24; in it he wonders, indeed, that Wendelen's calculation falls short of this observation by 32′. I judge that this arose chiefly from the fact that he disregarded the equation of natural days.

[Margin: Disagreement of Wendelen's tables with the sky.]

AD LIBRVM VI.

To Book VI.

CAP. III. No. 1. To the authors who present and explain the constellations must be added Caussinus [Nicolas Caussin] in *De domo Dei*, Book 2, Ch. 22, and Iulius Schillerus [Julius Schiller] of Augsburg, Doctor of both Laws, who, with Ioannes Bayerus [Johann Bayer] supplying a new and more accurate *Uranometria*, made the starry heaven Christian, sacred names and figures being put in the place of the ancient figures. In the preface to the work, published in the year 1627, he gives the reason for his undertaking, and he cites in his support St Justin Martyr in the *Oration to Antoninus Pius*; Lactantius in Book 5 of the *Divine Institutes*, Ch. 10; and Blessed Isidore in Book 3 of the *Origins*, the chapter on astronomy, who execrate the Gentiles because they brought into the heavens the names of beasts or of the most wicked men. He also replies to objections, especially to the one in which it was said to be absurd for anyone to say that Saints regard one another in trine or quadrate aspect, as is said of the planets and the other stars.

[Margin: Whether the names of the stars are to be taken from the Saints.]

CAP. VI. No. 2. I have already mentioned Julius Schiller, who made the starry heaven Christian. In this I certainly praise the man's piety, but I do not see that he obtained what he wanted. If anyone nevertheless wishes to know into what persons or sacred things he changed the figures and names of the stars, and does not have that book, let him run through the following catalogue, in which we have also set down the Arabic names corrected by Vuilhelmus Schikardus [Wilhelm Schickard], professor of languages at Tübingen, and the number of stars attributed to each constellation by Schiller, from the *Uranometria* enlarged and reformed by Bayer. Moreover, since he transformed the twelve signs of the zodiac into the 12 Apostles, he also took their characters and marks mostly from the instruments with which they suffered martyrdom. For he assigns to St Peter the key, to St Andrew the cross, to St James the Greater the pilgrims' staff, to St John the chalice, to St Thomas the spear, to St James the Less the fuller's club, to St Philip the small cross, to St Bartholomew the knife, to St Matthew the two-edged axe, to St Simon the saw, to St Thaddaeus the mace, and to St Matthias the axe. And in place of that distich,

Sunt Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libraq. Scorpius, Arcitenens, Caper, Amphora, Pisces.

(They are Aries, Taurus, Gemini, Cancer, Leo, Virgo, / and Libra, Scorpius, the Archer, the Goat, the Amphora, Pisces.)

he appends this:

Clauis, Crux maior, Baculus, Scyphus, Hasta, Sudisque, Crux, Culterque, Bipennis, Serra, & Claua, Securis.

(Key, Greater Cross, Staff, Cup, Spear and Club, / Cross and Knife, Two-edged Axe, Saw and Mace, Axe.)

[Margin: The instruments and characteristic marks of the Apostles.]

Ancient constellations	Schillerian constellations	Arabic names from Schickard	Number of stars
Ursa Minor	St Michael the Archangel	*Arrucabatho*, that is, the wagon	42
Ursa Maior	The Little Ship of St Peter	*Dubol achbaro*	51
Draco	The Holy Innocents	*Attanino*, the Dragon	52
Cepheus	St Stephen	*Chiphus*	43
Bootes	St Sylvester	*Arramichus*, that is, the spear-bearer	38
Coma Berenices	The Scourge of Christ	*Huzimethon*, the Handful	14
Corona Borea	The Crown of Thorns of Christ	*Alphankacho*, the open flower	17

Toucan and	St Raphael the Archangel		8
Hydrus with the Cloud	Part of St Raphael		20
Sum of all the stars: 1692		Sum	555

[Margin: The number of the stars is incomprehensible.]

On the number of the stars being incomprehensible to us, on account of the authority of Holy Scripture, see the opinion of St Augustine, *De Civitate Dei*, Book 16, Ch. 23; St Thomas on Genesis, Ch. 15; and Alonso Tostado on Deuteronomy, Ch. 1, Question 6. Add also Aristotle, *Meteorologica*, Book 1, Ch. 8, where he speaks of the sporades; Seneca, *Naturales Quaestiones*, Book 2, Ch. 32; and finally the Coimbra commentators on *De caelo* 2, Ch. 12, Question 1.

[Margin: Some stars of the firmament are higher than others.]

CAP. VII. No. 2. That some fixed stars are higher than others was also the opinion of Geminus in the *Elements of Astronomy*, Ch. 1, where he says: *It must not be thought that all the stars are placed under the same surface, but that some are higher, others lower.* Gilbertus [William Gilbert] stated the very same thing without hesitation in *De Magnete*, Book 6, Ch. 3, saying: *Nor is there any doubt that, just as the planets are distant from the Earth by unlike intervals, so those huge and very numerous lights are separated by various and very remote altitudes from the Earth.* Johannes Hevelius supports them in his *Selenographia*, Ch. 7.

[Margin: The Copernican distance of the fixed stars.]

No. 15. To the Copernican distances of the fixed stars add the opinion of René Descartes in the *Principles of Philosophy*, Part 3, no. 20. He affirms there that if this distance is compared with distances known to us, the one commonly attributed to the fixed stars is no less incredible than any greater one; but if it is compared with the omnipotence of God the creator, none can be conceived so great that it is for that reason less credible than any smaller one. To explain the phenomena of comets conveniently, however, he thinks that a very great space must be set between the fixed stars and Saturn. But no one has so far demonstrated absolutely that comets are above Saturn, as I show in Book 8, Section 1, Ch. 23.

At the end of no. 17, in the last table, add the distance of the fixed stars of 60 000 000 terrestrial semidiameters, which Kepler later chose in the *Epitome*, as I said here in no. 11; and the distances of Aristarchus, Mästlin and Gassendi, which I report in Book 9, Section 4, Ch. 28, no. 2. Besides these, Peter Crüger, as cited by Hevelius in the *Selenographia*, p. 162, thinks that the sphere of Saturn is to the sphere of the fixed stars, as regards diameter, as a pea to 15 feet, in which 900 peas are contained; and so the diameter of Saturn is contained in the diameter of the firmament 900 times.

[Margin: The position of the Pleiades observed by D. Vicenç Mut.]

CAP. X. On the position of the Pleiades and their distance from one another, observed with the most exact instruments and with the tube, D. Vicenç Mut wrote to me from Majorca in a letter of 1650 March 5, and he says that the distances were those written below.

The middle and bright star of the Pleiades, from the following more northerly star	31′
The following more northerly star, from the lowest, the one nearest the western star	30′
The following more northerly star, from the brighter of the western stars	22′
The following more northerly star, from the more northerly western star	11′
The brighter of the western stars, from the more northerly western star	22′
The middle and bright star of the Pleiades, from the lowest western star	22′
The brighter of the western stars, from the lowest western star	24′
The middle and bright star of the Pleiades, from the upper eastern star	27′
The upper of the eastern stars, from the one at the point towards the east	4′

He adds that the brighter of the western stars crossed the meridian at exactly the same altitude as the bright star of the Pleiades, and the upper of the eastern stars 1′ higher. From these, with the Tychonic longitude and latitude of the bright star of the Pleiades set down, he gathers the following longitudes and latitudes for the end of the year 1649.

	Longitude in ♉	North latitude	Magnitude
The brighter western star of the Pleiades	24° 28′ 11″	4° 9′ 40″	5
The more northerly western star	24° 38′ 30″	4° 31′ 36″	6
The lowest, the one nearest the western star	24° 45′ 0″	3° 53′ 30″	6
The following more northerly star	24° 45′ 30″	4° 23′ 56″	6
The middle and bright star of the Pleiades	25° 6′ 0″	4° 0′ 0″	3
The one at the point towards the east	25° 31′ 30″	3° 51′ 20″	5
The upper of the eastern stars	25° 32′ 30″	3° 54′ 0″	7

From these he gathers that the position set down by Tycho and Lansbergen must be corrected, but above all Lansbergen's, which puts the distance between the middle star of the Pleiades and the western one at 1° 18′, as great as that between the first and middle stars of Orion's Belt, although it is plain even to the naked eye that it is much less. Besides these he sets down six other small stars in this asterism, smaller ones. Van Langren, however, who also observed them himself with a telescope, sets down ten in all, counting the ancient ones, while in position and figure he comes as near as possible to Mut, as I gather from van Langren's scheme sent to me from Brussels in 1647 on July 6.

[Margin: The error of Tycho and Lansbergen in the position of the Pleiades.]

CAP. XVI. I do not know from where Bartholomæus Kechermannus [Bartholomäus Keckermann], in the *Systema Astronomiae*, Book 1, Sect. 1, Ch. 6, has dared to say that according to the common opinion the period of the fixed stars requires 49000 years, unless perhaps he takes for the common opinion the fictions of the Kabbalists, undeservedly attributed to Alfonso.

[Margin: The period of the fixed stars.]

CAP. XVII. I report and refute the fiction of Ioannes Pena [Jean Pena] about the unequal motion of the fixed stars in Book 9, Sect. 4, Ch. 3, in the scholia. This inequality, moreover, Giovanni Antonio Delfino seems to presuppose in his book on the celestial globes and motions, Ch. 12, but he does not establish it on sufficiently firm reasons, since he merely reports the opinions of others. See also Caussinus, *De domo Dei*, Book 2, Ch. 24.

[Margin: The inequality of the motion of the fixed stars is false.]

CAP. XXI and XXII. See also Caussinus, *De domo Dei*, Book 2, Ch. 25.

CAP. XXIII. To the opinion of Aristotle, who thought that the Milky Way is in the highest part of the air, as a great and perpetual comet arising from a continuous supply of exhalations, St Damascene subscribes in his *Physics*, Ch. 14. Among those who have imagined a double Milky Way, one ethereal and the other aerial, is Franciscus Piccolomineus [Francesco Piccolomini], on the

Meteorologica, Ch. 9. But those of Leuven and of Paris, and some Thomists, and most recently Cæsar Raus [?], Tract 4 on the *Meteorologica*, Ch. 1, and Hieronymus Trimarchus [?], on Book 1 of the *Meteorologica*, Disputation 4, Sect. 8, say that Aristotle's text is corrupt. Trimarchus also adduces Maurolico and Father Aegidius Camart [Gilles Camart], a Frenchman, General of the Minims, men most skilled in the Greek language, who say that the Greek text of Aristotle preserved from ancient times in the treasury at Messina does not contain that opinion. Tanner, however, on that passage, says that the Philosopher was speaking only by way of disputation.

That the Milky Way consists of a heap of very small stars is taught, besides those I named in this chapter, by Albertus Magnus, Scaliger, Cardano, Goclenius, Trimarchus above, Francesco Resta in Tract 1 of the *Meteorologica*, Book 1, Ch. 9, Isaach Habrecthus [Isaac Habrecht] in the *Comet of the year 1618*, and Longomontanus in the appendix to the *Astronomia Danica*, Ch. 5. Longomontanus adds, however, that a multitude of small stars is not sufficient for that whiteness unless a denser matter of the heaven lies beneath it in that part; because in a clear and moonless sky innumerable stars set close together are seen everywhere, and yet that tract of the sky does not grow white from them, for lack of density. From this he confirms Tycho's view of new stars and of certain comets as compacted from this denser matter of the heaven. But those stars that are seen outside the Milky Way are neither near one another nor so great in number as those seen in the Milky Way with the help of the telescope, and so that greater density does not seem necessary. Much less is the opinion of Gemma Frisius to be accepted, who, in Book 1 of *De divinis Naturae Characterismis*, Ch. 6, suspected that the Galaxy is in the ethereal or fiery region beneath the lunar heaven, since it neither hides the Moon or the other planets from us nor blunts their light.

[Margin: Opinions on the Milky Way.]

AD LIBRVM VII.

To Book VII.

SECTIO I. See Caussinus, *De domo Dei*, Book 2, from Ch. 16 to Ch. 20.

CAP. II. That the companions of Saturn move along a plane parallel to the equator was observed by Galileo, as he relates in Dialogue 2 of *De Mundi systemate*. What I have indicated about the shadow and the diameter of Saturn is set out in Book 7, Sect. 6, Ch. 14.

[Margin: The companions and shadow of ♄.]

CAP. III. On a fifth satellite of Jupiter, see Scheiner's suspicion in his letters to Markus Welser, p. 38. On the digressions of the satellites from Jupiter, reckoned in the measure of terrestrial semidiameters according to the various opinions on the distance of Jupiter from the Earth, see Sect. 6, Ch. 12 of this Book. Further, Hevelius says in Ch. 4 of the *Selenographia* that the 5 small stars which Šírek took to be Urbanoctavian and Jovial were observed by him in 1642

on August 28 and September 4, and in the years 1643, 1644 and 1645, in the same place, around the 13th degree of Aquarius, and at an unchanged distance. They are therefore fixed stars.

[Margin: The number and digression of the satellites of ♃.]

CAP. IV. The order of the planets is confirmed from the occultations of the superior planets by the inferior; we review some of these in this Book, Sect. 6, Ch. 14. What I said here, however, in No. 4 about Aristotle and in No. 5 about Plato is to be understood according to the probable opinion of some, which will be discussed in Book 9, Sect. 3, Ch. 3 and 4.

[Margin: The order of the planets.]

SECT. IV. CAP. V. The argument from the latitude and inclination of the planets for the motion of the Earth is treated in Book 9, Sect. 4, Ch. 9, No. 13.

SECT. V. CAP. IX. At No. 3 add here, from Kepler's *Harmonics*, Book 5, Ch. 4, the revolutions of the planets about the Sun written below, gathered from the delays of all the degrees of the whole circuit: long, middling and short.

Reuolutiones Planetarum circa Solem

Revolutions of the planets about the Sun

	Days	Minutes of a day	Daily motion, ′	″	‴
Saturn	18769	12	2	0	27
Jupiter	4332	37	4	59	8
Mars	686	59	31	26	31
The Earth with the Moon	365	15	59	8	11
Venus	224	42	96	7	39
Mercury	87	58	245	32	25

SECT. V. CAP. IX and X. See Caussinus, *De domo Dei*, Book 3, Ch. 12.

SECT. VI. CAP. IV. Scholium 3. Beware here of the error of Julius Schiller, who, in his *Cælum stellatum Christianum*, p. 23, says that Mars sometimes becomes as near the Earth as the Moon, and indeed even nearer, namely when it is at the 27th degree of Aquarius. He drew this from the *Systema Astronomicum* of Keckermann, Book 2, Ch. 5. For it is one thing to become nearer than the Sun, another to become nearer than the Moon.

[Margin: The approach of Mars to the Earth.]

CAP. XIV. At No. 2 add that Jupiter was occulted by the Moon in 1647 on January 20, namely by about a third part of the Moon, on its north side, when Procyon was at an altitude of 33° 56′ towards the west; and that Jupiter was left behind by the Moon when Regulus was at an altitude of 53° 43′ towards the west. So D. Vicenç Mut observed at Majorca, as he himself wrote to me, and as he later reported in his *Sol Alphonsinus*, p. 27. Again, in the same year on April 12 the Moon covered Jupiter with its northern part, with Regulus at an altitude of 57° 18′ towards the west, namely at 9^{h} 56^{m}. Jupiter emerged from the Moon's eclipsing with Regulus at an altitude of 49° 12′ towards the west,

or at 10^h 48^m. So Jupiter lay hidden under the Moon for 52^m; the same man observed this in the same place and wrote it in full to me.

[Margin: Jupiter occulted by the ☾ twice in the same year.]

But this astronomer's diligence and skill will be evident to posterity from the *Sol Alphonsinus* and from many other observations which, with the greatest candour of spirit and generosity, he has communicated to me, if either he himself publishes his own or I survive. The same holds for van Langren, who at Madrid in 1632 on February 5 saw Mars covered by that part of the Moon which lies between the spot of Balthasar and the Lake of Posidonius, when 178° 38′ was culminating. Then, after 57^m ⅓, he saw it come out from the spot of the Moon called Leototi. And in 1643 on August 15 he saw Mars covered by the Moon with degree 300° 33′ culminating, and come out with 308° 54′ culminating.

[Margin: In praise of D. Vicenç Mut and of van Langren.]

[Margin: Mars twice covered by the Moon.]

[Margin: For our names for these spots, see p. 205.]

FINIS PARTIS I. TOMI I.

End of Part I of Volume I.

INDEX NOMINVM AC RERVM INSIGNIVM Quæ in Priori Parte Tomi Primi Continentur.

Index of the notable names and matters contained in the first part of Volume I.

The first number signifies the page; the second the column, unless it exceeds two; otherwise it too signifies another page. When the same matter recurs in both columns, 1 & 2 is set down.

AB

The time of Abilfedea, after the preface, p. 39.2

Opinion of Abilfedea on the circumference of the Earth 61.2.63

Aboassar, see Abū Maʿshar.

Opinion of Abomadus on the circumference of the Earth 61.2.63

Opinion of Avraham Zacuto on the motion of the fixed stars, p. 166.1 & 2.168.444.2.448.1

Abraham Auenezra [Avraham ibn Ezra]; see Auenezra.

Apsis [Absis, absidis]: what is it? 145.1

Line of the apsides: what it is 506.1; whether it passes through the centre of the Sun or of the Earth 527 & 536.2

Whether a change of the apsides changes kingdoms. 679.2

Motion of the apsides, its proportion and law. 156.2

Abulfeda, see Abilfeda.

AC

Acceleration of motion, see velocity.

An acronychal planet [Acronychius, vel Acronyctus Planeta]: what is it? 40.1

Sphere of the Sun's activity. 395.2 [?]
Declination of the magnetic needle: what it is 80.2; how great it is, and where it is nil. 81.1 & 2
AD
Logistical addition and its rules. 6.2
Adelmus observes a spot under the Sun, taking it for Mercury. 97.2.98.1
Opinion of Adriaan Metius on the circumference of the Earth 62.2. His reckoning of the distance of the fixed stars from one another 430.2
AE
The Egyptians, the most ancient cultivators of astronomy, Preface 9 & 11
The equant circle: what is it? 147.2.505.2. Reasons for introducing it 513.1. Whether it is to be admitted in the Sun. 148.2
The equator: what is it? 14.2. Its functions and properties. 15.1
Equation: what is it? 145.2. Its rules in the solar eccentric: in the same place.
Physical and optical equation: what are they? 147.148.150
Greatest equation of the solar motion 146.2.157
Geometrical investigation of the solar equations. 147.1
Greatest equation of the lunar motion. 257.2.259.1.260.2.262.2.265.2.273.274.2.280.1 & 2
Equation of the centre in the epicycle: what is it? 508.1
Equation of the argument, or epicyclic equation, or equation of the orb: what is it? 260.1.509.2
Equation of the centre, or eccentric equation: what is it? 260.1.509.1
Geometrical investigation of the lunar equations. See the Hypothesis of the Moon.
Greatest equation of the three superior planets, from p. 555 to 561; of Venus and Mercury, 583 to 586
Geometrical investigation of the equations. See the Hypothesis of each planet.
Equation of natural days, its necessity, kinds and rules. 177 to 181
Position and marking out of the equinoctial line. 15.1
Equinoctial year. See Year.
Equinoxes: when and where they occur. 15.1.131.1
The day of the vernal equinox in the time of Christ, p. 131.1
How the equinoxes are to be observed. 133 & 134
An equinox appearing twice on the same day because of refraction. 133.2
Precession of the equinoxes: what it is, and of how many kinds. 21.1 & 165.1
Civil anticipation of the equinoxes. 130.1
Astronomical precession of the equinoxes, equivalent to the motion of the fixed stars 165. Its anomaly 165 to 169. Its theory 169 to 173. Rejection of the same anomaly. 167.1 & 2
Equinoxes observed by Hipparchus and Ptolemy. 134
Weight of the air. 56.1

Altitude and regions of the air 81 & 82.729 & 730. See the index of the second part.

Whether there is air around the Moon. 187.2

Varieties of the tide of the sea 73.1. Causes 73.2.91.2.74.1. See the index of the second part. Period. 186.1

Whether the eternity of the world is sufficiently refuted from the wearing away of mountains. 68.1

Altitude of Etna. 67.2

But look for the correction of this altitude in the index of the second part.

AF

The part of Africa known to the ancients 64

The wind Africus. 76.1.78.1

AG

Agathocles made good use of an eclipse of the Sun. 291.2

Verses of Agesianax on the spots of the Moon, p. 211.1

Opinion of d'Aguilon on the light of the Moon 197.2.200.1; on the spots of the Moon 206; on the light of the minor planets. 495.1

AL

Opinion of Alammon [?] on the circumference of the Earth. 61.2

Doubtful opinion of al-Battānī on the place and motion of the apogee and on the eccentricity of the Sun 157.1.158.1. Inconsistency in his hypothesis of the solar distance, the diameter and the shadow of the Earth 124.2. His opinion on the light of the planets 495.1. On the motion of the fixed stars 165.2.168.1.444.1. On the greatest declination of the Sun 160.1. On the circumference of the Earth 61.2.63.1. On the magnitude of the planets. 708.709

Observation by al-Battānī of the greatest declination of the Sun 160.1; of eclipses of the Sun and Moon 250.370.2. On the place of Regulus and of the northern star of the forehead of Scorpius. 449.1

The time of al-Battānī, after the preface 29.1

Lunar hypothesis of Albert Curtz of the Society of Jesus. 270.1

Observations of eclipses by Albert Linemann. 743.744

Opinion of Albertus Magnus on the distance of sight 64.2; on the altitude of the air. 82.1 & 2

Opinion of Albuassim on the motion of the fixed stars. 444.2.448.1

Opinion of Abū Maʿshar on the great conjunctions 671.2.672.1.677.1. The time in which he flourished, after the preface 29.1

Opinion of Alcabitius on the great conjunctions 677.1; on the division of the houses. 43.2

The geographical line of Alexander VI. 726.1

The victory of Alexander the Great over Darius, highly notable for an eclipse. 292.1.364.2

The runners of Alexander the Great. 63.1

Opinion of Alessandro Achillini on the motions of the heavens. 129.2

Opinion of al-Farghānī on the size of the Earth 57.2 and its circumference 61.2.63.1; on the motion of the auges 158.1. The time in which he flourished, after the preface, p. 29.2

Opinion of Ibn al-Haytham on the altitude of the vapours 39.1. The time in which he flourished, after the preface. 29.2

Alidade: what is it? 160.1

Effects of floods. 68.1

Almiçatarath [almucantar]. 12.1.27.1.28.2

Opinion of Almaeon on the circumference of the Earth 61.2. The time in which he flourished, after the preface. 29.2

Opinion of al-Biṭrūjī on the motion of the first and second movable 129.2.453.2, and on the place of Venus 101.2.494.2, and on the light of the planets 495.2

Altitude of the Alps. 67.2

The time, praises etc. of King Alfonso, after the preface. 29.2

With what helpers King Alfonso composed the Tables. 166.1

Opinion of Alfonso on the motion of the fixed stars 166.1.168.448.452.1. His hypothesis of the motion of the three superior planets in longitude 505 to 513, and in latitude 608; of the motion of Venus and Mercury in longitude 561 to 566, in latitude 609.

The Alphonsine measures of the orbs 511.512.665.666.681.682.

Opinion of the Alphonsines on the motion of the auges, p. 158.1.588.1

Errors of the Alphonsine Tables 375.1.440.444.2.498.2.499.

Fictions of the Alphonsine Jews on the period of the fixed stars and of the auges. 444.1 & 2

Altitude of the pole and of the equator: what it is, and how it is investigated. 15.1.16.1

True and apparent altitude: what is it? 324.1

The circle of altitude: what is it? 27.1

Altitude of a star 28.1; how it is found, p. 327.328

Whether the altitude of the planets varies 680

AM

Circumference of a sphere: what is it? 8.2

The Amphiscians: who are they? 26.1

Ortive amplitude: what it is 12.1.28.2; how it is investigated. 461.2

AN

Anacamptics: what are they? 2.2

Anaclastics: what are they? 2.2

Anaxagoras, skilled in eclipses 288.291.2

Anaximander, discoverer of the ecliptic. 20.1

Observations of eclipses by Andreas Arzet [?] of the Society of Jesus. 251.379.1 & 2.382.2

Andreas Scottus [Andreas Schott] of the Society of Jesus, corrector of the Antonine Itinerary. 58.2

The constellation Andromeda, and its description. 407.2
Angels cannot move the Earth 51.1. They move the heavens and the planets: see the index of the later volume.
From what the measure of an angle comes. 5.1
The spherical angle: what is it? 28.2
Angles of great circles. 28.2
The angle of commutation. 533.1
The angle at the Sun: what is it? 533.1
The angle at the Earth. 533.1 & 2
The angle at the planet, or parallax of the annual orb. 533
The angle of the ecliptic and the meridian. 28.2
The angle of the ecliptic and the horizon. 28.2
The angle of the ecliptic and the vertical. 327.328.329
The angle of the ecliptic and the circle of latitudes, p. 327 to 329
The angle at the pole of the ecliptic made by the colure of the solstices. 439.2
The angle at the pole of the equator. 439.2
The angle of longitude and latitude: what is it? p. 324.2
Kinds of solar years. 128.129.
The vertent, tropical and equinoctial year, p. 128 & 130.2
The civil and the astronomical year 128.2
The Egyptian year: what is it? 128.2
The great canicular year. 128.2
The Great Year of Plato 130.1 & 680; of Firmicus, of Aristarchus, of Aretes, of Dion, of Heraclitus, of Orpheus, of Cicero, of the Jews. 130.2
The Great Lunisolar Year. 130.1 & 241 to 244
The Julian and Gregorian year. 129.1
Reform of the year under Julius Caesar and Gregory XIII. 129.1
Various forms of years among different nations. 130.1
The four cardinal points of the year, and their intervals among the ancients 135 and the moderns. 141.142
By what method the length of the tropical or equinoctial year is investigated 135.2: from the sidereal year, in the same place; from the lunisolar cycles 136.2; from the revolution of the Sun to the solstitial points 137.1, or to the equinoctial points 137.1.138. See also 736.2
The length of the equinoctial year according to various authors. 139.1 & 176.1
Inequality of the equinoctial year: by whom and why it is asserted 173.2.174.1. Its equality asserted 174 & 175. Some insensible inequality nevertheless admitted. 175.2
The beginning of the astronomical year differs among different peoples. 182
Method of investigating the lunar year 253.1; of how many kinds it is 241.1. Its length varies among different authors. 256
Anomaly: what is it? 145.1

Mean and true anomaly of the eccentric, and of the epicycle or orb 259.266.508.509.510.531.532

The anomaly of the Moon is manifold, namely the free, the temporary monthly and the perpetual monthly. 259.260.265 to 267

Coequated anomaly. 266.2.532

Anomaly of commutation. 528.533

Anomaly of the precession of the equinoxes. 165

Anomaly of the obliquity of the ecliptic. 162

The constellation Anser Americanus. 410.1

The constellation Antinous. 407.2

The Antichthones: who are they? 187.2

The antipodes: who they are 25.2; whether there are any, and by whom they have been denied 26.2. The antipodes of Italy: who they are. 26.2

The Antiscians: who are they? 26.1

The Antoeci. 25.2

The fiction of Antonín Maria Šírek on the distance of the Sun 111.2. His theory of the Moon 275. His opinion on the companions of Saturn, corrected 273.724. His fictions on the rotation of the planets 99.1, and on the distance of the fixed stars 418.1. His observation of the number of the satellites of Jupiter, singular but suspect. 489

AP

Aphelion: what it is 145.1. Its investigation in the Sun 153 to 156; in the Moon 267; in the superior planets 547.548; in the inferior 586 to 597; its place 552.553.592

The constellation Apis Indica. 410.1

Apocatastasis: what it is 145.1. Of how many kinds, p. 670.671

The apogean winds: what are they? 80.1

Apogee: what is it? 145.1

Place of the Sun's apogee at various times 156.157. Its motion 157.158; its anomaly or equality. 157.2.158.159

The monthly apogee of the Moon, and its motion and period. 239.2.241.1.254.2

The true and mean apogee of the Moon, of the epicycle or of the eccentric. 259.2.262.1.263.1

The monthly apogee of the Moon. 265.2.267.2

Motion of the apogees of the minor planets. 501.506.1.508. Their geometrical investigation 544 to 550 & 586 to 597.

Opinion of Apollonius of Perga on the stations of the minor planets. 648.2. The time in which he flourished, after the preface. 30.2

Prophecy of Apollonius from an eclipse, on the killing of Domitian. 367.2

Opinion of Apuleius on the place of Venus. 493.1

The constellation Apus. 410.1

AQ

Water and air have some weight, p. 55.1

Comparison of water with earth in bulk. 72.1 [?]
Weight of water. 56.1.59.1
The variable measure of waters to be drawn off 69.1, and their levelling. 64.2
The levelling of waters. 54.2.64.2.69.2
The velocity of waters. 70
The constellation Aquarius, and its description 401.2. Its rising. 470.1
The constellation Aquila 407. Its rising. 470.1
AR
The time of Aratus, after the preface. 30.2
Theses of Archimedes on the measurement of the circle 5.2, and of the sphere 9.1, and on bodies floating in a liquid 55.1.56.2; on the diameter of the Earth 61.2; on the order of the planets. 101.1
The time and praises of Archimedes; after the preface, p. 30.2
The time and praise of Archytas; after the preface. 31.1
Arcturus and its description 405.2. Its rising 470.1. What it is in Holy Scripture. 406
Measure of a circular arc. 5.1
Similar arcs: which are they? 5.1
The arc of shining of the stars, or of emergence 42.1.659.660. Its intervals and times. 661
The arc between the centres of the luminaries, for eclipses. 315.336.2.340
The area of the circle, its measurement, and its ratio to the square. 5.2.6.1
The knowable number of the sand. 64.1
Weight of silver and of quicksilver. 56.1
Argoli's error in the *Cosmographia* 50.2. His system of the world. 101
Description of the constellation Argo Navis. 409.1
Mean and true argument: what they are in the theories of the planets. 259.2.509.2
Description of the constellation Aries 398.2. Why its first star is the beginning of the zodiac, and when 19.2.398.2.402.1
Aristarchus's problem on the distance of the Sun, explained 109.110. His good judgement in this kind of matter 237.1. His opinion on the motion of the Earth 104.1. The time in which he flourished, after the preface. 31.1
Opinion of Aristotle on the order of the planets 101. His time, after the preface. 31.1
Use of equinoctial armillae. 133
Arithmetic: what it is 2.2. Its elements. 6.2
Velocity and times of the human artery 88.2.730.2
Observation by al-Zarqālī of the Sun's apogee and eccentricity 157.1. His opinion on the motion of the fixed stars 166.172.2. His time, after the preface, p. 31.1
AS
The ascendant, or horoscope: what it is 29.1. Its finding. 326.2

Right and oblique ascension: what it is, and of how many kinds 28.2.29.1. True and apparent: what they are. 324.2

Rules and axioms of right and oblique ascensions. 30

To investigate the right ascension of a star from observations 431 to 435, and the oblique, p. 461

Increments and decrements of right ascensions, and rules. 439

The right ascension of some fixed stars decreases as the longitude increases, and which stars, and for how long. 459 & 460

The ascensional difference: what it is 29.1. Its finding. 460.2

To find the ascending point of the ecliptic, p. 326.5[76]

How many aspects of the stars there are, the causes of their number, and their characters 43.1.243.1.663 to 665, and the harmonic configurations. 667.668

The number of the aspects according to the moderns, p. 664.665 & 726.2

Aspects to the Sun in which the stations of the planets occur. 646.2.658.1

Equation and reduction of the aspects to the ecliptic 665.666 and to the equator. 667

Parts of the as. 8.1

In what astrum and sidus differ. 393.1

Names of the stars: Greek, Egyptian, Ara- bic, Chaldean, from p. 398

Whether it is expedient to change the names of the constellations. 411.1

The order of the constellations set out in verse. 413.2

Why the figures of the constellations are irregular. 393.1

Who devised the images of the constellations. 394.1

Sympathy of the constellations with the planets. 398

Description of the constellations of the zodiac, tales about them, etc. 397 to 403

Description of the northern constellations. 403 to 407

Description of the southern constellations. 407 to 410

Description of the new constellations. 410

Difference of astrology from astronomy. 2.1

Emptiness or uncertainty of judicial astrology. 2.1.159.1.165.1.215.2.292.678.679.737.1, and in the Preface, p. 3.

Praise of sound astrology, Preface. 3 & 7

Praise of astronomy for its excellence, evidence, usefulness, etc., Preface, from p. 1 to 6; and for the predictions of eclipses 288.1 & 290.1, and in the Preface, p. 3.

Ignorance of astronomy, harmful to some 288.1, even to philosophers, Preface. 18

Definition and parts of astronomy, and the sciences that serve it. 1 & 2

Origin, progress and ages of astronomy: Preface, from p. 8 to 13

Astronomy cultivated by kings and emperors. Preface, p. 5

What the right use of astronomy is. Preface. 6

[76]so printed; by the index's own key a number above 2 in this place signifies a further page

The abuse of astronomy censured by the holy Fathers. Preface. 6.7.8
Comparison of the old and the new astronomy 332.1 & 557.2, and in the Preface. 13 to 18
Astronomy always teems with new difficulties. Preface, from p. 16
Astronomers are superior to others in talent and mind, and better fitted for the other sciences. Preface. 2 & 3
Whether the method of astronomy uses a vicious circle. 216.1 & 699.2
The chief errors of certain astronomers. Preface. 13
AT
Athanasius Kircher of the Society of Jesus: his liberality 361.2.402.2; his erudition 402.2; his opinion on the obliquity of the ecliptic 163.1; on the substance of the Sun. 92.2
Shadow and height of Mount Athos. 67.2. But see the index of the second part. 730.1
The time of Atlas, after the preface. 31.1
Height of Mount Atlas. 730.1
AV, & AX
Which planets are increased in light? 658.2
Opinion of Avraham ibn Ezra on the motion of the fixed stars 166.1; on the division of the houses. 43.2
Altitude of the pole at Avignon. 382.1
Why St Augustine denied the antipodes. 26.2
Weight of gold. 56.1
The constellation Auriga: its description. 407.1
Astronomical automata. 504.2.505
The aux [Aux, augis]: what is it? 144.2
Axis of the sphere: what is it? 8.2
AZ
Azimuth: what is it? 12.1.27.1.29.2
The observation of azimuths is unreliable, and how it may be carried out with more certainty 355.2.499; see the index of the later volume.
al-Ṣūfī, mathematician of the Persians 398; his time, after the preface. 31.2
BA
Height of Monte Baldo. 67.2
The constellation Balæna: its description. 407.2
Error of Baranzanus on the Tychonic measures. 523.1
Rising of the star Basiliscus. 473.2
Bateometria: what is it? 2.2
BE
Bede's opinion on the order of the planets 494.1; his time, after the preface. 31.2
Error of Benedetto Castelli on the measure and velocity of waters. 70.1 & 2
Coma Berenices. 407.2

Error of Berossus the Chaldean on the Moon's own light, refuted 195.196.214.2; his time, after the preface. 31.2

Bettini's opinion on the distance of vision 65.1; on the Moon's distance 226.1; on annular eclipses of the Sun 387.1; on the penumbra of the Earth eclipsing the Moon 305.2; on the spots of the Moon 206; and on the distance of the fixed stars. 416.1

Bettini's age, praise, etc., after the preface. 40.1

BL

Error of Giuseppe Biancani on the height of mountains, p. 54.1

BO

Altitude of the pole at Bologna. 132.2.405.1

Bonaventura Cavalieri's Planetary Wheel [Rota Planetaria] 503.2; his attempt at equations in the elliptical form 535; his skill in astronomical matters 459; his demonstration on the parallelism of the Sun's rays. 100.1

Praise of Boulliau, after the preface. 39.2

Boulliau's observations of eclipses. 251.280.381.382.384

Boulliau's solar hypothesis 149 to 151 & 737.1; his lunar hypothesis 270.271; his hypothesis of the three superior planets in longitude 526 to 535, in latitude 627.630; and of the two inferior planets in longitude 576 to 579, in latitude. 627.630

Boulliau's ingenuity in investigating the lunar motion. 245.2

Boulliau's peculiar method of equating natural days. 180.2.181

Boulliau's ingenuity in substituting eclipses of the Earth for the calculation of solar eclipses. 338

Boulliau's uncertain opinion on the Moon's diameter, p. 230.1

Boulliau's criticism of Kepler's analogies. 278.1

Boulliau's observations in favour of lunar libration. 210.211

Boulliau's argument against the cause of lunar libration. 215.2

Altitude of the pole at Byzantium. 164.1

CA

Age, death, etc. of Cabeo, after the preface. 41.1

How large a portion of the heavens is hidden from us. 13.1.50.1

That the heavens are spherical 3 & 4; hemispherical, as some have thought. 4.1 & 725.2

Height of the heavens, see distance of the fixed stars.

Thickness of the heavens, and the semidiameter of their convexity and concavity. 692.693

Girth and circumference of the heavens. 694

Differences among the heavens according to more recent observations. 695

In how much time a moving body, in its descent, would pass through the height of the heavens. 697

Form of the geometric calculation for the longitude of the Sun 143 or 150; of the Moon: Ptolemaic and Alphonsine 258, Copernican 260, Tychonic 262,

Magini's 265, Keplerian 265, Boulliau's 271, Lansbergen's 273, Wendelen's 272, Šírek's [Reithensis] 275, our own 280. But for latitude, 283 to 285.

Form of the geometric calculation for the longitude of the three superior planets: Ptolemaic and Alphonsine 510, Copernican 516, Tychonic and Danish 519 to 521, Lansbergen's 524, Keplerian and Boulliau's 532.533, our own 538. And for latitude: Ptolemaic and Alphonsine 609.610, Copernican 612, Lansbergen's 616, Danish 619, Keplerian 623 to 626, Boulliau's. 627.630

Form of the geometric calculation of the two inferior planets, in longitude: Copernican 613, Lansbergen's 617, Longomontanus's 620.621, Keplerian 623 to 626, Boulliau's, p. 627 to 630

The time of Callippus, after the Preface. 32.1

Callippic period of the Moon. 243.2

Cause of summer and midday heat. 99.2

Opinion of Campanus on the division of the houses. 44.1

Levelling of canals to be led off, p. 66.2.69.2

Description of the constellation Cancer. 400.2

The constellation Canis. 409

What the Dog Star [Canicula] is, what the dog days are, and their effects. 409

Rising of the Dog Star and duration of the dog days. 472.2

The canicular year 128.2.462.463.464.671

Rising of Capella. 472.2

The constellation Capricorn. 401.2

The monstrous birth of Cardano 725.1. Error on the approach of the Sun. 737.1

Error of Charles Malapert in attacking the nearness of Mars to the Earth. 695.2

Altitude of the pole at Kassel. 160.2

The constellation Cassiopeia. 406.2

Catoptrics: what is it? 2.2

Height of the Caucasus. 67.2; but see the index of Part 2.

CE

Description of the constellation Centaurus 409.2; its rising. 472.2

Various effects of the centre of gravity, and corollaries drawn from them. 53 & 54

Centre of gravity and of magnitude: what is it? 52.2

The centre of the Earth is the centre both of gravity and of magnitude 52.2, and of all heavy bodies. 53

Whether the centre of heavy bodies is the centre of the universe. 727.1

The centre in the theories of the planets: what is it? 259

Weight of wax. 56.1

Description of the constellation Cetus. 407.2

CH

Chaldean period of the Moon. 243.1

Chaldean system. 494.1
The constellation Chamaeleon. 410.1
Marine chart. 80.2
Chorography: what is it? 2.1
Christoph Clavius of the Society of Jesus, see Clavius.
Christoph Grienberger of the Society of Jesus examines the ratio of the diameter to the circumference 5.2; observes an eclipse 251; arranges a catalogue of the fixed stars with right ascensions and declinations. 398
Christoph Scheiner of the Society of Jesus observes the elliptical Sun, and is the first to lay open the causes of this phenomenon 94.2; observes the spots and faculae of the Sun with the greatest diligence, and before Galileo did 95.2; also the diameter of Venus 714.2 and the eclipses of the Moon 377.1; his problem on the distance of Jupiter and on the eclipses of the satellites 492.1; his error on the Sun's diameter. 119.2
The shrewdness of Cristoforo Colombo in using an eclipse against the barbarians. 291.2
Opinion of Christoph Rothmann on the height of vapours 39.1, and on the depth of the Sun at the limits of twilight, in the same place.
Chronology: what is it? And the knowledge of it, necessary for astronomers. 3.1
Chronologisms [Chronologismi] to be resolved through eclipses. 362.1.365.1, etc.
CI
Cicero's system 493.1, and his opinion on the harmonic sounds of the heavens. 481
Nobility of the circle 3.1.4.1; its definition and properties. 4 & 5
Centre, circumference, and radius or semidiameter of the circle: what are they? 4.2
Measurement of the circle, and its rules. 5 & 6
Division of the circle into 360 degrees, and of these into their fine parts. 6.1
Division of the circle into the parts of the as. 8.1
Ratio of the circle to the sphere. 9.1
Great circles and non-great circles on the sphere: which are they, and how many? 10.2.11.1 & 2
Notable properties of the circles of the sphere. 11
What the Arctic and Antarctic circles are. 10.1
Circles of the always appearing [semper Apparentium]: which are they? 10.2 & 22.2. Their size. 23.2
Ratio of the smaller circles to the great circles. 22.1
The vicious circle to be avoided in astronomy, p. 216.1
Ratio of the circumference to the diameter of the circle 5.2. Measurement of the circumference, given the diameter. 6.1
CL

The Emperor Claudius orders the causes of a solar eclipse to be explained. 291.2

Praises of Clavius, after the Preface. 32.2

Clavius's slip in cosmography 50.2; on the height of mountains 64.1; and on the distance of vision. 65.1

Age and praise of Claramontius, after the Preface. 45.1

Cleombrotus, terrified by an eclipse through ignorance. 291.1

The time of Cleomedes, after the Preface. 32.1

Cleomedes's opinion on the apparent size of the Earth 58.1, and on the size of the Sun against Epicurus 126.1; on the light of the Moon against Berossus 196.1.197.1.199.1; on annular eclipses. 307.2 & 387.1

The lunar cycle of Cleostratus. 241.2

Use and unreliability of ancient clepsydras, p. 88.2.117.2

Distinction of climates and anticlimates. 24

CO

Columella's opinion on the annual cardinal points, p. 135.1

The colure: what it is, and of how many kinds. 20

Functions of the colures of the solstices and the equinoxes. 20

Coma Berenices. 407.2

Rule of combinations. 413.2

Which planets are combust, and when. 658.2

The concentrepicycle: what is it? 143

Great and Greatest conjunctions: what are they? 671

Whether true or mean conjunctions are to be considered 672. In which places of the zodiac they occur, p. 672

Number and order of the Great conjunctions since the beginning of the world 673. Their intervals, p. 674 & 675

History of the Great conjunctions, with general changes in affairs. 675

Notable conjunctions of Saturn, Jupiter and Mars 675.676, and likewise of Jupiter and Saturn, in the same place.

The disputed force of the Great conjunctions, p. 677 to 679

Conjunctions compatible with the stations and retrogressions of the planets. 658

The time of Conon, after the Preface. 33.1

Complement of an arc: what is it? 29.2

The point of contact in the theories of the planets: what it is, and what its use is. 507.2

The time, praise and death of Copernicus, after the Preface, p. 41.1

Copernicus's system and his opinion on the threefold motion of the Earth 102. But read the index of the later volume.

Copernicus's error on the diameter of the Sun and of the shadow 124.2.228.1; on the altitude of the pole at Frombork 160.1 & 223.2; on the parallaxes of the Moon 223.2; in the hypothesis of the Moon. 261.262

Copernicus's lunar hypothesis. 260 to 262

Copernicus's hypothesis of the three superior planets in longitude, with objections, 514 to 519; and in latitude. 612 to 615
Copernicus's hypothesis of the two inferior planets in longitude 567.570; in latitude. 613.615
Copernican measures of the orbs. 517.570.682.683
Copernican observations of eclipses. 247.1.250.372.1
Cornelius Gemma's observation of eclipses. 372.2.373.1
Corona Australis 410.1; Corona Borealis 406.2; its rising. 472.2
Ratio of the bodies of the world and of the regular bodies to the intervals. 492.689.703.704
The five Platonic bodies. 703.704
Description of the constellation Corvus 410.1; its rising. 472.2
Cosmography: what is it? 2.1
CR
The constellation Crater. 410.1
Twilight: what it is, and how its beginning and end are observed. 37.1
Duration of twilight. 38
How great the Sun's depth is when twilight begins or ends. 38.1
The duration of evening twilight is greater than that of morning twilight. 40.1
Error of Crescenzio on the distance of vision. 727.2
CV
The Roman cubit, the Alexandrian, etc. 61.2
Ratio of the cube to the sphere, and its reduction to the sphere. 9.1 & 2
To culminate, and culmination: what is it? 29.2
Which are the currents of water in the ocean? 72.2
The runners of Alexander the Great. 63.1
Curtation of the interval: what it is, and what its use is, p. 641.642
CY
Various lunisolar cycles. 241 to 244
The constellation Cygnus and its description. 406.2
Ratio of the cylinder to the sphere, and its reduction to the sphere. 9.1 & 2
Height of Mount Cyllene. 67.2
Cynosura, see Pole Star.
The city of Cyrene has no solstitial shadow. 61.2
DA
David Fabricius's lunar theory. 270.1
DE
Declination: what it is 29.2; true and apparent declination: what they are, p. 324.1
Circle of declination. 27.2.29.2
To investigate the declination of the stars. 431.432
Increases and decreases of declinations, and their rules. 439
Description of the constellation Delphinus. 407.2

Democritus's opinion on the equal distance of the fixed stars 493.1. His lunar period. 243.2

Ratio of density among the bodies of the planets, with their intervals and with the metals. 705

Deviation of the planets 501.502; its investigation. 640

GOD alone knows the size of the luminaries 237.1 and the distance of the fixed stars. 393

The Providence of GOD in eclipses 289; in the irregular figure of the constellations 393.2; in the new phenomena of the heavens: Preface. 18

Which is the right and which the left part of the world? 22.2

DI

Diameter of the circle: what is it? 4.2; its ratio to the circumference 5.2; its measurement, given the circumference. 5.2

Diversity of the diameter in the theories: what is it? 260.1

Diameter of the apsides, and of the mean longitudes: what is it? 506.2

Apparent diameter of the Sun 116 to 120; true, p. 120.121

Apparent diameter of the Moon 227 to 233; true, p. 233.234

Apparent diameters of the luminaries from eclipses. 375.2.379.1

How the apparent diameter of the fixed stars and the minor planets is investigated. 423.2.707.716

How great the apparent diameter of the planets is, p. 708.713; and the true. 709.713

How great the apparent diameter of the fixed stars is. 423.424.716.717

Apparent diameter of the Earth viewed from the stars, and of the stars viewed from elsewhere than the Earth. 58.2.719.2.720.721

Dicaearchus's opinion on the height of mountains. 66.2

Dichotomy of the Moon: what it is, and what its use is, p. 108.193.2.731.2

The day: what it is, and of how many kinds. 31.1

The natural, artificial and civil day. 31.1

Day of the Sun, and day of the primum mobile. 15.31.2 & 725.2

The days on which the Sun now enters the signs of the zodiac 33.2, and formerly, in the time of Augustus. 468

Inequality of the artificial day, and its causes, p. 32.1 & 726.2

Varying length of the artificial day and its causes 32.1, and rules. 32.2.33.1

Different beginnings of the natural day among different nations. 34.2 & 118.2

Different numbering of natural days for those sailing eastward, etc. 35.2

Inequality of natural days, and causes of the inequality 176 to 181. The equation according to the ancients 178; according to more recent writers 179; by whom it was neglected 179; the threefold form of this equation. 180

Dionysiodorus's opinion on the circuit and diameter of the Earth. 62.2

Which planets are direct 645, and in the hypothesis of the moved Earth. 646

Arcs and times of directions. 500.2

What the arc of directions is, and its size, p. 646.647

Theory and causes of directions according to Vitruvius and Pliny the Elder 503.648; from Apollonius of Perga and Ptolemy 648 to 654; from the hypothesis of the moved Earth. 654 to 658

Distance of vision, or to which vision extends. 13.1.727.2

Distance of the tropics. 29.2

By what methods the distance of the Sun from the Earth is investigated 105 to 109.734; how great it is according to various authors 110 & 111; how erroneous it is among certain ancients. 111

By what reasoning the distance of the Moon from the Earth is investigated 221 to 225. How great it is according to various authors. 226

By what methods the distance of the fixed stars from the Earth is investigated, and how great it is. 414 to 420

Distance of the stars according to Xenocrates. 493.1

Rules for the greatest and least distances by which the planets stand from the Earth, from one another and from the Sun. 681 to 690

Greatest and least distances of the planets from the centre of the Earth 686.687; from the Sun 687.688; from one another and from the fixed stars. 689 to 691

Harmonic ratios of the distances of the planets and of the fixed stars 416.1; and their analogy with the regular bodies and with the periodic times 689.1; with the bodies of the planets 704.705; and with the distances of the Sun. 688.2

True and apparent distance from the zenith: what is it? 324.1

Precepts of logistical division. 7.2

Diurnal motion of the Sun 126.140; of the Moon 239.255; and of the other planets. 645

DE

Dodecatemoria. 29.2.393.1

Circles of the celestial houses. 27.2

Number, order, names and significations of the celestial houses. 20.43.2.44

Difference between celestial houses and signs, p. 393.1

The constellation of the fish Dorado. 410.1

EC

ECLIPSES LVNÆ.

Eclipses of the Moon.

Definition, causes and kinds of lunar eclipses 293 to 295. Possible and necessary limits 309. Magnitude 310. Duration 311 to 313. Duration of total eclipses and stay in darkness 313.314. Type and inclinations, p. 315.316

History of total eclipses of the Moon. 362.2.364.1 & 2.365.1 & 2.367.1.368.1.369.2.370.1.371.1 & 2.372.1.373.1 & 2.374.2.375.1.376.2.377.1 & 2.378.1 & 2.379.1 & 2.380.1 & 2.381.1.383.1

Eclipses of the Moon in which the Moon was extinguished. 382.1 & 740.1

Eclipse of the Moon smaller in the middle than at the extremes. 307.1

Whether an eclipse of the Moon is caused by the shadow, or by the penumbra of the Earth or of the atmosphere. 305 & 306

Colours of an eclipse of the Moon. 203.1.308.309.323.1
Eclipse of the Moon with both luminaries above the horizon. 307.2.367.1
What spring and autumn eclipses of the Moon have that is peculiar to them. 180.2
Eclipse of the Moon of 6 digits, and its use. 218.2
Eclipses of the Moon selected for establishing the lunar motions. 250
Eclipse of the Moon favourable to Alexander the Great. 364.2
The portent of a lunar eclipse destroys Nicias, p. 291.2.364.1
Eclipse of the Moon predicted by Gallus Sulpicius. 365.2
Eclipse of the Moon used by Colombo to terrify the barbarians. 291.2
Eclipse of the Moon predicted by our men to the Cantian prince [Principi Cantiani]. 291.2
A most celebrated eclipse of the Moon, on account of the multitude of observers. 381.382, etc.

ECLIPSES SOLIS.

Eclipses of the Sun.
Definition, kinds and causes of eclipses of the Sun 316.317. Limits 333.334. Magnitude 334. Duration 335.336. Inclinations. 337.2
Paradoxes of solar eclipses. 325.1
Causes of annular eclipses, or eclipses of the Sun with a bright ring around the Moon 198.2.199.1.323.1. History. 231.203.1.367.2.368.2.372.2.375.1 & 2.379.1.387
Total eclipses of the Sun, and their history. 231.360.362.1.363.1.364.1.365.1.366.1.367.1 & 2.368.1.369.2.370.1 & 2.371.1 & 2.372.1.376.2.385 & 386
Eclipses of the Sun in which stars were seen. 370.1 & 2.371.1.372.1 & 2.365.1.369.2
Eclipse of the Sun predicted by Thales. 291.1.363.1
An eclipse of the Sun terrifies Cleombrotus 291.1, but not Pericles 364.1, nor Agathocles 291.1.365.1, nor Xerxes [Xersem] 363.2, nor Claudius. 291.2 & 367.2
Eclipse of the Sun ominous for Pelopidas 364.2, and for Julius Caesar 366, and for Augustus 367.1, and for Domitian 367.2, and for Nerva 367.1, and for Gordian 368.1, and for King Louis. 370.1
Eclipses of the Sun at the conception and death of Romulus, and on the birthday of the City. 362.1
Notable theorems of eclipses of the Sun. 388.1
Morning and evening eclipses of the Sun are deceptive. 387.2

ECLIPSES TERRAE.

Eclipses of the Earth.
Eclipse of the Earth: what it is, and its causes 338. Limits 346. Magnitude and duration 341. Various problems 342.343. Type 344.345
Mutual eclipses of the minor planets 288.2.289.1.721.722.723. Of the satellites of Jupiter. 493.1

ECLIPSIVM COMMVNIA.

Matters common to eclipses.

Spurious eclipses. 289.1

False or fabulous causes of eclipses. 286.287.288

The superstition of appeasing eclipses. 287

Excellence of foreseeing eclipses. 288

Use of eclipses for the distance between meridians 17.2, and for the distance of the Sun and the diameters of the luminaries, but not so certain 107.2.233.1, and for history and geography. 289.293

Small eclipses test the reliability of astronomical tables better than large ones. 378.2

Contrast and comparison of eclipses of the Sun and the Moon. 356

Intervals, revolutions and number of eclipses. 345 to 350

The way of observing eclipses, and its deceptiveness, p. 350 to 356 & 740.2

Difficulty of observing eclipses, disagreements, etc., in the Preface. 16

Disagreement of observed eclipses with astronomical calculation, or among observers. 372.1.373.1.374.2.376.1.380.2.383.1

Chronology of eclipses observed before Christ. 361 to 367

The many miracles of the eclipse at the death of CHRIST, p. 357

Chronology of eclipses observed after Christ. 367 to 384

Catalogue of portentous eclipses. 292 & 293

Order and number of eclipses from the ephemerides of two centuries. 389.390

The ecliptic: what it is, and its functions. 18 & 19

Sign by which the ecliptic is to be recognised in the heavens, p. 20.1 & 189.1

To find the ascending point of the ecliptic. 326.2.461.2.462.2

What the ecliptic would be like if no planets existed, but only fixed stars. 456.2

How great the obliquity of the ecliptic is, and whether it varies 19.2.159.162.737.2; how it is investigated 160.161; its immutability is established. 163.164

Anomaly of the obliquity of the ecliptic, supposing that it changes, and its theory 162.164.2.169 to 173.

EG

Egnazio Danti's great gnomon set up at Bologna for observing the Sun's course 132; his observation for the Sun's greatest declination 160.1, and of eclipses. 372.2.373.1

EL

Semidiameter of the elementary sphere. 695.1

Description of the ellipse. 152.1

Elliptical path of the planets according to some more recent writers. 150.151.529

Use of the ellipse in the motion of the planets. 275.1

The ellipse resolved into two circles for the use of equations. 151.2.152.1.533

EM, EN

Embadometry: what is it? 2.2
Arcs and times of emersion and occultation of the stars. 659 to 661
Error of Empedocles on the distance of the Sun and the Moon, p. 111.1
The time of Endymion, after the preface. 33.2
EP
Epacts: what are they? 241.1
Writers of ephemerides, and places. 388.2
The dullness of Epicurus on the distance and size of the Sun, refuted. 105.2.125.2.126.1.736
The epicycle: explanation, use, properties, rules. 142 to 145 & 508 to 510
The epicycle of the five minor planets is of variable size. 502.2.537.1
Alphonsine size of the epicycle and deferent in Italian miles. 695.1
Symmetry of the epicycle with the deferent, see Hypotheses and Measures.
Whether the epicycle of the Moon requires a rotation of the Moon. 208.2
Epoch: what is it? 182.1
How epochs of the motions of the Sun, etc., are to be established 182.183; and of the Moon 357; and of the fixed stars 477; and of the other planets: Ptolemaic 512.2.566, Copernican 518.2 & 571, Tychonic 522 & 576, Lansbergen's 525 & 574, Keplerian and Boulliau's 535 & 579, our own. 540 & 582
Epochs of the nodes and limits: Ptolemaic 611, Copernican 615, Lansbergen's 618, Longomontanus's 622, Keplerian 626, Boulliau's 630, our own. 631
EQ
The constellation Equuleus. 407.2
The constellation Equus, see Pegasus.
ER
Erasmus Reinhold, see Reinhold.
Eratosthenes's opinion on the size of the Earth 61.1. Error on the distance of vision 64.2, and on the distance of the Sun 111.1, and on the distance of the Moon 226.2, and on the obliquity of the ecliptic and the measure of the Earth. 163
The constellation Eridanus. 408.1
The ingenious piety of Erik van der Putte toward the Most Blessed Virgin. 413
ET, & EV.
The Etesian winds: which they are, and when they blow. 80.1
The time of Euclid, after the preface. 34.1
The time of Euctemon, after the preface. 34.1
Lunar cycles of Euctemon and Philip. 242.1
The solstices of Euctemon, crudely observed. 242.1
Eudoxus's cycle of the Moon 242.1, and his opinion on the lunar year and month. 256
Eudoxus's opinion on the Pole Star 167.404.1, and his observation concerning Canopus 167.1; his time, after the preface. 34.1
Eudoxus's system 101; but see the index of the later volume.

EX

The eccentric: explanation, use, properties, rules. 143 to 146 & 506 to 510

The eccentric orb, absolutely, and in a certain respect. 147.1

Investigation of the Sun's eccentricity 153 to 156; its size, varying among different authors 156.157; its change, disputed 158.2.159.1; theory of this change 169 to 173; whether it changes kingdoms. 159.1

Whether the eccentricity of the Sun and of the other planets is to be bisected. 148.530.532.2

Variation of the eccentricity of the minor planets. 502.2 & 506.1

Investigation of the eccentricity of the three superior planets 544 to 550; of Venus and Mercury. 597 to 604

Eccentricity of the Moon: Ptolemaic 257.2, Magini's 262.1, Tychonic 262.2, Lansbergen's 273, Keplerian 267, Boulliau's 271.1, that of Antonín Maria Šírek, or of Rheita [seu Reithensis], 274, our own. 279

Height of exhalations. 39

FE

Ferdinandus Magellanus [Fernão de Magalhães]. 642

Weight of iron. 56.1

FI

Isoperimetric figures: which they are, and their capacity. 3.2

Equilateral figures: which they are. 3.2

Excellence of the spherical figure. 3.1 & 2

Fixed stars: why so called 393.1; their praises and uses 393.2; substance 394.2; qualities 398; figure 395.1; configuration into constellations. 393.2

The light of the fixed stars: where it comes from, and how much 395.396. Their scintillation 396.397; colours and density, p. 397

Asterisms of the fixed stars with the number of stars: in the zodiac 398 to 402; northern 403 to 407; southern. 407 to 413

Number of the fixed stars seen without a telescope 411.2 & 412; absolutely, innumerable and known to God alone 412 & 413; greater toward the north than toward the south. 413.1

Magnitude of the fixed stars: into how many classes, and how many in each class. 413

The apparent magnitude and diameter of the fixed stars: by what methods it is observed 422.423; how great it is 422.423. The true magnitude, however: how great it is. 424.425.716.717

Distance of the fixed stars from the Earth: whether it is finite or infinite 414.2.415.1; by what methods it can be determined, and how great it is. 415 to 420

Distance of the fixed stars from the planets. 690.691

Parallax of the fixed stars. 414.420

Refraction of the fixed stars. 420.421

Speed of the fixed stars in the daily motion. 419.2

Proper motion of the fixed stars: by whom it was detected, and how. 165.2

Proper motion of the fixed stars and its period according to various authors 166.168.444 to 448 & 479 & 737.1

Motion of the fixed stars: whether uniform or non-uniform, and whether direct or retrograde. 165 to 168.448 to 451.

Retrograde motion of some fixed stars with respect to right ascension. 460

Distances of the fixed stars from one another: invariable. 425.2

Distances of the fixed stars observed by Tycho and by others, but more of them by us, and their table. 426 to 430

Declination and right ascension of the fixed stars: by what methods it is observed or investigated 431 to 435. Increases and decreases of both, and rules. 419

Longitude and latitude of the fixed stars: how it is derived from observations. 435 to 438

Erroneous places of the fixed stars in the ancient tables. p. 440

Longitude and latitude of some notable fixed stars from the various tables of the astronomers. p. 440

Table of the more notable fixed stars, with longitude, latitude, declination and right ascension, from our own observations. 476.477

Whether the latitude of the fixed stars changes. 441 to 444

Right ascension of the fixed stars: of which it decreases, and for how long, although the longitude increases. p. 459.460

To investigate the risings and settings of the fixed stars 460. Times of rising and setting under Augustus 468.469; selected from the poets and explained. 472.473.

Culmination of the fixed stars and mediation of the sky. 458.459

Which fixed stars are on the equator or in the tropics, and when. 457.1

Which fixed stars reach the zenith, and when 457, or the poles of the world. 458.1

Which fixed stars are always visible, and for how long. 458

FL

Origin and perenniality of rivers: from where 68 & 69. Channels along different lines around the Earth 54.2. The level [Libramentum] and height of the spring, and levelling [libellatio]. 54.2.66.2.69.2

Level of navigable rivers 70.1.71.1. Speed of several degrees, and how great 70.1. Swelling and overflow. 71.1

FO

Origin and perenniality of springs: from where. 68.2.69.1

Height of springs needed for streams to be able to run down. 66.2

Fortunio Liceti's opinion on the light of the Moon in eclipses 201.2. On the spots of the Moon. 207.1

FR

Fracastoro's opinion on the motion of the fixed stars 451. Error about the distances of the Moon and of the other planets from the Earth as invariable. 226.680.1. Fiction about the obliquity of the ecliptic. 165.1

Franciscus Aguilonius [François d'Aguilon], see Aguilonius.

Francis Drake, a distinguished ship's master. 64.2

Francesco Fontana's opinion on the rotation of the Moon [vertigine Lunæ] 208.2; observations of the lunar spots 203, and of Jupiter, Saturn and Venus. p. 485.486.487

Observations of Father Francesco Maria Grimaldi S.J. and our own on the quantity of twilight 39; on the measurement of the circumference of the Earth 59 & 60.63.1; on the height and breadth of the rainbow 83; on the height of clouds 82.2. On the vibrations of the pendulum 85.1. On measuring time by the motion of the pendulum 86.2.87.1. On the speed of falling heavy bodies and its increase 89. On the distance of the Sun by the dichotomy of the Moon 108.2.734. On the apparent diameter of the Sun 118.1 & 2. On the great gnomon of Bologna 131.2. On the equinox 134. On the obliquity of the ecliptic, or the greatest declination of the Sun 161.2. On the height of the lunar mountains 208.1. On the parallaxes of the Moon 225. On the apparent diameter of the Moon 230.2. On eclipses 383. On the distances of the fixed stars from one another 425.2. On the right ascension and declination of the fixed stars 434.2. On sickle-shaped Venus 485.1. On the belts of Jupiter and their parallelism with the ecliptic 486.2.487.1. On the companions of Saturn and their parallelism with the equator 488.1. On the apparent diameters of the minor planets and of the fixed stars. 710 to 713

Father Francesco Maria Grimaldi's critique of Scheiner on perpetual motion around the Earth 54.2. A problem rivalling that of Aristarchus for the distance of the Sun 112.1. Opinion on the spots of the Moon 207.2. Observation of a lunar eclipse 381.1. A peculiar method of observing parallaxes. 106.2

Father Francesco Maria Grimaldi's *Selenographia* and the encomium of it [eiusque Encomium] 204. Diligence in observing the motions of the lunar spots, and the observations selected for them 209 to 212. Hevelius's double error in the lunar libration, detected by him. 211.212.213

Franciscus Maurolycus [Francesco Maurolico], see Maurolycus.

KA
Reform of the calendar carried out by Julius Caesar and Gregory XIII 129.1. Miracles in support of this reform, Preface 5 & p. 725.1
KE
Praise of Kepler, after the preface. 38.1
Kepler's threefold form of equating natural days. 180
Kepler's hypothesis of the Sun 149, and of the Moon 265 to 270, and of the superior planets in longitude 526 to 535, in latitude 623 to 626, and of the two inferior planets in longitude 576 to 579, in latitude p. 623 to 626
Kepler's measures of the orbs. 533.534.578.684.685
Kepler's hypothesis of the precession of the equinoxes and of the obliquity of the ecliptic. 169.170
Kepler's lunar period. 244
Praises of Kepler 332.2.345.2.658.1; observation of eclipses. 250.251.376.377.378
Kepler's opinion on the new aspects 664, and on the cause of new stars 676.2; on the circumference of the Earth. 62.2
Kepler's very ingenious analogies and harmonic proportions of the orbs with the intervals, the regular bodies, the periodic motions and the bulk of the planets 277.278.1.689.1.705.706; but a critique of them 278.1.707, and their falsity in some places. 714.1
Kepler's opinion on the view from mountains. p. 728.1
The perplexities of Kepler's hypothesis 277.1, and its inconsistency. 277.2.278.1
Kepler's inconstancy about the distance of the Sun from the Earth 111.2, and on the diameter of the Moon 228.2, and on the size and proportions of the Sun and the Moon. 237.2
Kepler's inconsistency with himself 369.1.533.2, and slip in the parallaxes 332.2, and in the parallaxes of the annual orb. 417.2
Kepler's fiction about a crust around the globe of the Moon 215.1, and his bold wit in sacred matters 359.2.676.2; excessive criticism of Walther. 371.2
LA
Lactantius denies the antipodes. 26.1
What the Milky Circle [Lacteus circulus] is. 474.475.748.1
Van Langren's notable *Selenographia* and encomium, after the preface 40.2 & 203 & 204.748; opinion on the libration of the Moon 208.2, and on the circumlunar air 187.2, and observations of eclipses. 251.378.1.380.1 & 2
Praise of Lansbergen, after the preface. 42.1

Lansbergen's hypothesis of the Moon 271, and of the three superior planets in longitude 523.525, in latitude 616 to 618; of Venus and Mercury, however, in longitude 571 to 574, in latitude. 617 to 618

Lansbergen's measures of the orbs. 525.573.683.684

Lansbergen's hypothesis of the obliquity of the ecliptic and of the precession of the equinoxes. 169

Lansbergen's observations of eclipses. 250.251.374.2.375.2.376

Lansbergen's carelessness in observing 161.2, in the parallaxes of the Moon 224.2, in the apparent diameter of the Moon. 229.2

Lansbergen's double fabrication in the measurement of solar eclipses 323.1, and his doubtful credit against history in astronomical matters. p. 164.2.323.1.363.2.368.1.372.2.

Lansbergen's error in the parallax of the annual orb 417.2, and in the diameters of the planets 715.2; in the table and use of the parallaxes. 332.2

Observation by the Landgrave of Hesse on the Sun's greatest declination. 160.2

What geographical latitude is. 16.2

Latitude of the world known of old. 17.2 & 65

Latitude of a star, and what the circle of latitude is 28.29.2. What true and apparent latitude are. 324.1

Latitude of the planets, from the greatest latitude. p. 219.1

Investigation of the latitude of the Moon 252; its theory. 282.2.283.284

Whether the greatest latitude of the Moon is variable. 220.1

Whether the latitude of the fixed stars changes. 441

Greatest latitude of the five minor planets. 632 to 640

Motion in latitude of the same. 501.2.502.1 & 2

To construct tables of latitudes. 643

Various hypotheses of latitudes according to different astronomers: see under the name of the astronomers.

The House of the Virgin of Loreto, and its notable orientation to the quarters of the world. 13.2

LE

Leander Bandtius [?]'s lunar theory. 252

The constellation Leo 400.2; its rising. 473

Leon Battista Alberti's error in measuring the depth of the sea. 56.2

The constellation Lepus. 408.2

The land league and the sea league 62.1. The Spanish league 62.1. Variety of leagues, see Mile [Milliare].

LI

Errors of levelling. 54.2

The constellation Libra. 401.1

Level of rivers and canals. 66.2

Libration of the Moon around its own centre 208 up to 215 & 239

The libration by which the Sun moves the planets. 275.2

Height of Lilybaeum. 672
Limits of planetary latitude, see Latitudes of the planets.
Limits of the lunar libration. 209 to 212
Line of mean and of true place or motion. 145.1
Line of mean longitude 506.2, and of the true place of the planets, and of the mean and true centre of the epicycle. 506.2
Line of the mean and true apogee. 506.1
Line of apsides. 259 & 506.1
Through which regions the line called *Interim* was drawn by order of Alexander VI. 726.1
Changes of coastlines over the course of time. 67.2
LO
Mean and true place. 145.1.259.1.506
What logarithmics is, and its notable use in solving triangles. 2.2
What logistic is 2.2; its rules. 6.2
Geographical longitude and its difference: what they are 16.2; how it is investigated 17.1; whether better by eclipses of the Sun or of the Moon 17.2; whether by eclipses of the Jovian satellites. 493.1
From which meridian the start of geographical longitude is to be taken, according to various authors. 725.2
Geographical longitude counted westward: by whom. 17.2
Disagreements over geographical longitude among geographers: from what source. 17.2
Geographical longitude of certain places 249, and difference of meridians, from eclipses. 373.1.374.1.375.2.376.2.377.2.378.1 & 2.383.2.385.1
Longitude of a star, and what the circle of longitude is. 30.1
Mean and true longitude of the planets 145.259.2.509.1; what true and apparent longitude are. 324.1
What the nearer and the longer longitude [Longitudo propior, & longior] are. 145.1.146.1
Mean and true longitude of the centre. 509.1
Longomontanus's hypothesis of the Moon 263 & 739, and of the anomaly of the equinoxes and of the obliquity of the ecliptic 170, and of the three superior planets in longitude 519 to 523, in latitude 618 to 620, and of Venus and Mercury in longitude 574 to 576, in latitude 619 to 622
Longomontanus's measures of the orbs. 521.522.575.576.683.684
Longomontanus's observations of eclipses 254.255.375.376. Error in eclipses of the Sun. p. 323.1.387.1
Longomontanus's opinion on the apparent diameter of the Moon. 229
Longomontanus's opinion on the height of vapours and the duration of twilight. 39.1
LV
Lucan's lines on the high solstice and on the leftward shadows of the groves, explained. 26.1

Lucretius denies the antipodes. 26.2
Ludolph van Ceulen's most subtle inquiry into the proportion of the diameter to the circumference. 5.2
Light of the planets and the fixed stars: from where. 102.197.395.495.496
Magnitude of the luminaries uncertain 237; but see Sun and Moon.
Names and encomia of the Moon 184.185; its influence on lower things 185.2 and on the sea. 186.1
Substance of the Moon, and whether it is another Earth with its own inhabitants 186.1.187.188. If it were inhabited, what the Earth would look like from there, and with what alternation. 215
Whether the Moon has an atmosphere of air around it 187.2. Its elliptical figure. 227
Phases of the Moon: how many there are and how they are named 188.189. What the silent and the waning Moon are 188.1. With what scheme its phases are to be drawn. p. 195.1
How celebrated the first phase of the Moon is, how long after the new Moon it appears, and why now sooner, now later. 189.2 to 190 & 194
Superstitious observance of the lunar phases. p. 737.2
New Moon seen near the Sun on the same day. 190.1
To conjecture the day on which the Moon will first appear. p. 194.2
Variety of the quadrate Moon 190.1; see Dichotomy.
The Moon less illuminated at full Moon, and more at new Moon. 191.2
Portion of the Moon lit by the Sun. 191.2 & 235
How the age of the Moon is recognised, and what its regular days are. 192
For how many hours the Moon shines at night. 193.1
Through which spots the line of the dichotomous Moon passes. 210
Time of the dichotomous or bifid Moon before or after the quadratures 193.2.194.1.
Its use for the distance of the Sun. 108.731 to 734
Inclination of the lunar horns to the vertical 733; their varied situation on the lunar disc. 215.1
To find when the Moon is in the nonagesimal. p. 194.1
Proportion of the diameter of the Moon to the diameter of the Sun, derived from the horn of the Moon. 194.2
Whether the light of the Moon is from the Sun, and how the Moon reflects it to us 195 to 197.2; its secondary light near new Moons and in eclipses of the Sun. 198 to 202
From where the Moon's bright ring in an eclipse of the Sun comes. p. 198.199.203.1.323.1
From where the Moon's secondary light in total lunar eclipses comes 201.2.202.203.307.308.2, and the colours in those eclipses 203.1.379.1, or in an eclipse of the Sun. 203.1
The Moon extinguished in the middle of an eclipse. 303.306.737 & 740

Description of the lunar face and spots 203 to 206. Authors of this observation and description. 203 & 204

Names, number, figure, situation, magnitude, colour, shadows and elevation of the lunar spots 204 to 206. Roughness and unevenness of the Moon. 208 to 210 & 212 & 213

What the spots of the Moon are. 206 to 208

Measurement and quantity of the lunar mountains. p. 208.1

Various figures of the full and of the not-full Moon. 204

Place of the Moon among the planets. 216.1

How the parallaxes of the Moon are investigated 216.217; selected observations of them 219 to 226, and their quantity according to various astronomers. 223 to 226

Distance of the Moon from the Earth, and the certainty of its variation, and the manifest errors of some about it. 226

How great the greatest latitude of the Moon is, how it is investigated, and opinions on it. 217 to 220

How many nodes the lunar orbit has, and what their names are. 217.2

How the apparent magnitude of the Moon is investigated, and how great it is according to various authors 227 to 233; how it was determined by us 230 to 232, or by others. 738.1

True magnitude of the Moon compared with the Earth and the Sun. 233 to 235

The Moon viewed from the planets: how great. 738.2

Measurement of the lunar shadow and penumbra 318 to 322 & 339

Portion of the Moon seen by us 234.2; but still greater by force of libration. 209.1

Symmetry of the lunar orbs. 738.2

LVNÆ MOTVS.

Motions of the Moon.

How many and how inextricable the motions of the Moon are 185.1.237.238; their inequality 240.2; speed in the daily motion. 238

Why the Moon is always direct, or why it is incapable of stations and retrogradations. 649.2.650.1

The double rotation of the Moon. 208.2

Libration of the Moon around its own centre, its quantity, the quarters towards which it goes, times, periods, variation of the limits and nodes, causes and theory, and observations selected for these, from p. 208 to 215

Method of observing the lunar libration without deception. 210 & 211

Lunar months, years and cycles. 240 to 246

Revolutions of the Moon investigated from eclipses. p. 244 to 253

Mean motions of the Moon according to various authors, and rules for deriving them. 253.254.255

Quantity of the lunar month and year. 256

Hourly motion of the Moon from the Sun, and its proportion to the diameter. 230.312.313
Second inequality of the Moon, and its hypothesis. p. 247 & 257 to 270 & 285
Geometric form of the lunar calculation. 260 to 273
Synopsis of the lunar hypotheses 247.278.1, and new hypotheses 279 to 282 & 739 and 740
Variation of the Moon. 263.2
Monthly anomaly of the Moon resolved, etc. 267.1.276
Magnetic fibres of the lunar body. 275.276
Theory of the lunar latitude. 282.2
Reduction of the Moon to the ecliptic. 285
The constellation Lupus. 409.2
Juan López de Velasco, observer of eclipses. 373.1
LY
The constellation Lyra 406.2; its rising. 473.1
Lycosthenes's error in chronology. p. 370.1
MA
Astronomical machines. 505
Macrobius's opinion on the order of the planets 494, and on their light 495.1; the time when he flourished, after the preface. 40.1
Sunspots: their reality, motion, duration, quantity, figure, production, etc. 95 to 97.2; but more in the index of part 2.
A sunspot believed to be Mercury. 97.98
Motion of the lunar spots, see Libration of the Moon.
Names and number of the lunar spots 204.205. Figure, magnitude, situation and colour 205. Their shadow and elevation. 206
What the old and new spots of the Moon are 206 to 208. Their magnitude. 208.2
Roughness and hollowness of the lunar spots 206 & 207 & 208; not accounted for by density and rarity alone. 207
Praise of Magini, his death, etc., after the preface. 37.1
Magini's error in the height of mountains 54.1, and about the pole star 403.2. Lunar hypothesis 262.1. On the mean apogee of the planets. 513.1
How the declination of the magnetic needle is observed 14.1.80.2. How great it is in different places, and where there is none. 80 & 81
Tables of this declination: where? 728.2
Magnetism of the Moon, from Kepler. 275.276
Apparent magnitude of the stars, see Apparent diameter.
Apparent magnitude of the Earth and of the planets seen from elsewhere than from the Earth. 718 to 720
True magnitude of the Earth 61 to 63; of the Sun 121 of the Moon 234; of the fixed stars 424.716.717; of the minor planets. 709.713.716.717
Time of Manilius, after the preface. 40.1

Manilius's verses in support of the immobility of the Earth. 59.1
The singular Conception of the Virgin MARY. p. 729.2
Marianus Scotus's error in his *Chronicles*. 368.2
Marin Getaldić's experiments on the weight of liquids and metals. 56.1
Marin Mersenne's opinion on divers and on the art of sailing under water. 75.2
Time of Marinus of Tyre, after the preface. 40.1
How the depth of the sea is measured 56.1; how great it is. 71.2 & 728.1
Breadth of the sea compared with the breadth of the uncovered land. 71.2.72.1
Equilibrium of the sea, and whether one sea is higher than another 72.1.728.1; whether it is higher than the land. p. 728.1
Why the surface of the sea looks flat. 727.2.728.1
Threefold motion of the sea. 72.2.73.1 & 2
Tide of the sea and its variety 73.1.186.1, and causes 73.2.74.1.737.1. Period of the same tide 186.1; but more in the index of the second part of this tome, & 728.1
Mario Bettini of the Society of Jesus, see Bettini.
Martinus Hortensius's observations of eclipses 251.378.1, and of the apparent diameter of the planets and fixed stars. 707.708.709.714.715
Martianus Capella's opinion on the order of the planets 495.2, and on the cause of the stations. 503
Names of Mars 480.500.1. Figure, with a spot or boss. 986.1
The star of Mars unobservable 497.2; its spirals 504.2, and in the preface. 14
Mars occulted by the Moon, for Aristotle. 493.2
Threefold dimension of Mars 713; apparent diameter. 708
Magnitude of Mars at perigee 713; seen there as a new star or a comet. 658.2
Diameter of Mars observed by us. 711.713
Mars at perigee nearer to the Earth than the Sun. p. 695.1 & 2
Parallax of Mars greater than the Sun's 523.1 & 2.700.1. Motion in altitude. 500
Station of Mars scarcely perceptible. 654.1
With which planets Mars, direct or retrograde, can be conjoined. 658.1
Twin emersion and occultation of Mars at the same time, and the changeable order of its appearances. 663.2
Conjunctions of Mars with Jupiter and Saturn. p. 675-676
Motion of Mars in longitude 500.501, in latitude. 501.2
Hypothesis or theory of Mars in latitude: Ptolemaic and Alphonsine 607.608; Copernican 612 to 615; Lansbergen's 616 to 618; Longomontanian or Danish 618 to 620; Keplerian 623 to 626; Boulliau's. 627 to 630
Theory of Mars in longitude: Ptolemaic 505 to 515; Copernican 514 to 519; Lansbergen's 523 to 525; Hérigone's 526; Tychonic and Longomontanian 519 to 523; Keplerian and Boulliau's 526 to 535; ours. 535 to 540
Kinds of mathematics. 2

Those skilled in mathematics are sharper and better suited to the other sciences, preface. 2

Which planets are morning planets. 658

ME

Mediatio cæli: what the mediation of the heaven is 30.1; its equivocal meaning. 726.2

Weight of honey. 56.1

What the synodic and periodic months are 240.2.241.1; their quantity. 251

Full and hollow months. 267.2

What the month of illumination is. 190.2

Measures of intervals. 58.2

Measures of the celestial orbs, see Orbs.

Mercator's error about the pole star. 403.2

Names of Mercury 480; figure. 483.2.484.1

Place of Mercury in the order of the planets. 493.494.495

Mercury hard to observe and mostly invisible 497.2.498.1.661; and its deceptive motion 98,2 & in the preface. 14

Notable observations of Mercury. 593 to 595

Mercury seen under the Sun 97.98.483.2.494.2, and looking like a spot. 98.1

Diameter of Mercury observed by us 711.2.712.1; its quantity, in the same place.

Apparent diameter of Mercury 708.714, and true, p. 709.713

Threefold dimension of Mercury. 713

Revolution of Mercury around the Sun 607, and digressions from the Sun. 583.586.717

Station of Mercury, differing from the others. 653.2

Emersion of Mercury from the Sun's rays in Taurus and Scorpio 662. Order of emersion 663.2

Investigation of Mercury's apogee 586 to 597, and of its eccentricity. 597 to 604

Motion of Mercury in longitude 500.504, in latitude. 501.502

Hypothesis or theory of Mercury in longitude: Ptolemaic and Alphonsine 561 to 566; Copernican 567 to 570; Lansbergen's 571 to 574; Tychonic and Danish 574 to 576; Keplerian and Boulliau's 576 to 579; ours. 579 to 583

Hypothesis of Mercury in latitude: Ptolemaic and Alphonsine 609 to 612; Copernican 613 to 615; Lansbergen's 617.618; Longomontanian 619 to 621; Kepler's 623 to 626; Boulliau's. 627 to 630

Measures of Mercury's orbs, see Measures of the orbs.

What the meridian circle is, and its functions. 13

Number of meridians. 13.2

Finding and testing the meridian line. 14 & 725.2

Transfer of the meridian line. 14.2

From where the beginning of the meridians is to be taken. 725.2

Some differences of meridians derived from eclipses of the luminaries 249.2.375.2.376.2.377.2.378.1 & 2.379.1 & 2.380.1 & 2.381.1.383.2.385.1

Whether differences of meridians are certain by means of eclipses of Jupiter's satellites? 493.1

Proportion of metals in weight. 56.1

Meton's cycle and its beginning 242. His solstices crudely investigated 242.1; opinion on the lunar year and month. 256

MI

Michael Florent van Langren, see van Langren.

Difference between the miles of the ancients and of the moderns. 60

The Bolognese and Roman mile 60; Arabic 61.2; German. 62.2

Which planets are diminished in light? 658.2

MO

Descent of a moving body from the heavens to the Earth, and the time required for it 697; see the index of the later volume.

Mästlin's observations of eclipses. 373.1.374.1.376.2. Measures of the orbs of the Corrected Copernican, see Hypotheses of Copernicus. Praises and reproaches of him, after the preface. 41.1

Mountains of Chile and of Ethiopia. 730.1

How the height of mountains is exactly measured 54.1; the height of some. 67.729

But add here what is said in the second part of this first tome. p. 660 & 661

Decrease of mountains and change in the roundness of the Earth 67.2; what the argument from it against the eternity of the world is worth. 68.1

The height of mountains does not harm the physical roundness of the Earth. 48.2 & 727.1

Measurement and height of the lunar mountains. p. 208.1

How the motions of the primum mobile and the secundum mobile can be reconciled without contradiction. 129.2 & 455

Whether perpetual motion around the Earth is possible. p. 54.2

Proportion of the celestial motions to the intervals 689.1, and their incommensurability with one another. p. 680

Twofold inequality of the motion of the planets. 501.544.560

Investigation of the mean motion for the three superior planets 551 & 552, for Venus and Mercury. 604 to 607

Threefold motion of the planets, in longitude, in latitude and in altitude. 500.501

Periodic motions of the planets. 502.503

Mean motion of the Sun or of the Moon; see under the word Sun or Moon.

Mean motion in longitude of the minor planets: Ptolemaic and Alphonsine 512.566; Copernican 518.571; Lansbergen's 525.574; Tychonic or Longomontanian 522.576; Keplerian and Philolaic, or Boulliau's 534.535.579; ours 540.582

Motion in latitude, or of the nodes etc.: Ptolemaic and Alphonsine 610.2; Copernican 615; Lansbergen's 616.617; Tychonic or Longomontanian 621.2; Keplerian 626; Boulliau's and almost ours. p. 627 to 630

Roots of the motions, see Epochs.

Harmony of the motions of the five planets in the epicycle with the motion of the Sun. 509.1

Whether the mean or the true motion of the planets is attuned to the Sun. 528.536.2

Fastest and slowest daily motion of the planets. 645

Motion of the apogees. 502.2

Motion of rotation of the luminaries, see Rotation [Vertigo] of the Sun or of the Moon. For the remaining planets see p. 502.2

MV

Rules of logistic multiplication. 7.1

What the shape of the world is. 3 & 4

Whether the eternity of the world is shown to be false from change in the roundness of the Earth and from alluvial deposits. 68.1

General changes of the world falsely deduced from change in the obliquity of the ecliptic, or in the eccentricities and apogees 159.1.165.1.679, or from great conjunctions. 677 & 678

The end of the world sought in vain from the revolutions of the planets, or from changes of the eccentricities etc. 68.2.159.1.165.1.680

The world, the instrument of God. 415.2

Musical intervals, see Harmonic etc.

Altitude of the pole at Modena. 60.2

NA

What nadir and zenith are? 12.2

Distinguished shipmasters who circumnavigated the globe. 64.2

The ship *Victoria*: when, and in how long a time, it circumnavigated the globe. 64.2

Shipmasters' opinion on the circumference of the Earth. 62.1

The art of sailing under water. 75.2

Difference in the count of days for those sailing towards the west. 35.2

Measure of navigation or of a sea voyage, and speed of ships. 75

Parts, kinds and size of ships, and their oarage. 74.2

Nautical chart and compass [pyxis]. 80.1

NI

Nicias terrified by an eclipse of the Moon. 291.2

Niccolò Cabeo's attention to the measuring of mountains 54.1 and to the technique of levelling 54.2; and his true opinion on the distance of sight 65.1, and on the eternity of the world 68.2, and on the measure and speed of waters 70.2, and on the equilibrium of the seas. 72.1

His death and encomium, after the preface. 41.1

Nicolaus Copernicus; see Copernicus.

Nicolaus Mulerius's notable table of the syzygies of the Moon 245. Error in denying total eclipses of the Sun.

The constellation Nile, see Eridanus.

NO, & NV

Division of the night into four watches. 36.2

What the nodes of the Moon are, and what their names are. 217.2

Motion of the nodes, see Motion of latitude.

How the places of the nodes are investigated. 631 to 637

Places and roots of the nodes, see Epochs of the nodes.

Nodes of the lunar libration, and their change. p. 209.212

What the nonagesimal degree of the ecliptic is. 29.1

Sign that the nonagesimal degree is occupied by the Moon. 194.1

To find the altitude of the nonagesimal. 327.2

Threefold new Moon of a Moon having latitude. 192.1

To measure the height of clouds, and how great it is. p. 82

OB

How the obliquity of the ecliptic is investigated 160.161; how great it is 19.2.161.162; whether it varies 19.1.159.164. Its anomaly 162 to 164; its theory 169 to 173; Fracastoro's opinion on it. 165.1

Time for completing astronomical observations 498.1, and their difficulty or deceptiveness in all the planets 498.1 & 2; in Mars 497.2; in Venus and Mercury 497.498; in eclipses 372.1.373.374.2.376.1.380.2.382.1

OC

Of how many kinds the setting of the stars is 41.462 to 464. Order of settings in the planets 500.1.662.2.663.1

Arc of occultation of the planets. 659.660 & 661

Semidiameter and circumference of the eighth sphere 695.1. Theory 168 to 173 & 451 to 456

Height of the eye required for it to see remote places on land. 66.2

The visual sphere of an eye raised above the horizon, or its range in seeing 64 to 66.1

OE, OL, OP

Oenopides's lunar cycle 243.1, and opinion on the lunar year and month. 256

Weight of oil. 56.1

Height of Mount Olympus 67.2; called into doubt, and why. 729.2

Ophiuchus, see Serpentarius.

What optics is, and its kinds. 2.2

OR

Parallax of the annual orb. 408.1

Solid orbs and their schemes 146.2.507; but see the index of the later volume.

Measures of the orbs: Ptolemaic and Alphonsine 511.512.565.566.681.682; Copernican 517.570.682.683; Lansbergen's 525.573.683.684; Tychonic

or Longomontanian 521.522.575.576.683.684; Keplerian and Boulliau's 533.534.578.684.685; ours 538.539.582.685.686
Proportion of the orbs with their motions. 670.2
What organics is. 2.2
Astronomical implements [Organa], see Instruments.
Which planets are oriental, and when? 658
Who Orion is in the sacred scriptures. 408.1
The constellation Orion 408.1; its stars seen with the telescope 413; its rising. 473.1
The Ornithian winds. 80.1
Oronce Finé's error in the height of mountains 54.1; opinion on the circumference of the Earth 61.2.63.1
Of how many kinds the rising and setting of the stars are 40.462 to 464 & 726.2. Examples of this explained in the ancient poets 469 to 474. Arcs and times of heliacal risings 661; order of risings and settings in the planets. 661 to 663
PA
Time of Pappus of Alexandria, after the preface. 42.1
Deceptiveness of parallactic rulers. p. 220.1
What parallax is, and of how many kinds. 44.45.324
But more on these in the second volume.
General rules and theorems of parallaxes. 45.1.325
From where the measure of parallax is taken. 48.2
The crude knowledge of parallaxes among the ancients. p. 332.1
The complete doctrine of parallaxes. 727.1
Whether the Sun's parallax varies the days. 32.1
Measurement and varying quantity of solar parallaxes 113. Uncertainty 114.1; a new way of investigating them 123.1. See more in the index of part 2.
Investigation of the parallaxes of the Moon 216.222; selected observations of them. 220 to 226
Quantity of the horizontal parallaxes of the Moon according to various astronomers 223 to 226, and how a table of them is constructed. 226.2
Variation of parallaxes in the luminaries, their finding and use in eclipses of the Sun 323 up to 332.2
Horizontal parallaxes of the minor planets. 699.700
Parallax of the annual orb. 416.2
What parallel circles are. 10.2
Parallels of the climates 24; their ratio to the equator. 726.2
Parallelism of the rays of the Sun and Moon etc. 100
Altitude of the pole at Paris. 382.1
Francesco Patrizi's error in denying the roundness of the Earth. 48.2.49.1
The constellation Pavo. 410.1
PE
The constellation Pegasus. 407.2

Height of Mount Pelion. 67.2
The killing of Pelopidas after an eclipse. 291.1
Schemes of the cause and effect of the Earth's penumbra 301.302 & 308.2; its measurement 301 to 305 & 339
What the perihelion is. 145.1
Who the perioeci are. 26.1
Who the periscii are. 26.1
Cause of a pendulum's coming to rest. 731.1
The vibrations of a pendulum are of equal duration 85; its use in the measurement of time. 84 to 90 & 117.2
Height of a pendulum, and its proportion to the number of vibrations. 85.86
Height of the pendulum required for finely measuring the time of the primum mobile. 87
The swaying of the pendulum from the motion of the Earth is false. p. 91.1
Observation and opinion of the Persian mathematicians on the equinoctial year 139.1, and on the places and motion of the fixed stars. 447.448
The constellation Perseus. 407.1
How great the Roman and Bolognese foot, the Leiden, the Rhineland and the Alexandrian foot are. 58.2.61.2
Peter Apian's ingenious schemes and astronomical machines 505.2; opinion on the circumference of the Earth. 61.63
Pierre Gassendi: see Gassendi.
Pierre Hérigone's invention on the use of Jupiter's satellites in geographical longitude. 493.1
Pedro Nunes's opinion on the height of vapours and the time of twilight 39.1. Table of twilight 38; observation of the obliquity of the ecliptic 160.162.1. Problems on rowing. 75.1
PH
Philolaus's opinion on the motion of the Earth. 102
Philolaic period of the lunar cycles. 243.1
The constellation Phoenix. 410.1
PI
Height of Mount Pico. 67.2
The constellation Piscis 401, and its rising. 473.1
Piscis Notius. 410.1
The constellation Flying Fish. 410.1
Pytheas of Massalia's observation for the obliquity of the ecliptic. 164.1
PL
Various names of the planets 480.481; their signs 36.2 & 480. Analogy with various sets of seven 481, and with the Muses, or with musical strings or tones. 481 & 483
Houses, exaltation, joy, detriment of the planets. 483
Shape of the planets as it appears in the sky with the telescope. 483 to 488

Number of, and distinction between, primary and secondary planets. 492.1 & 2

Order of the planets in the heavens 493.494; see also the index of the later volume.

From where the light of the planets comes. 495.496

Shadows and mutual eclipses of the planets. 721.722

Which planets are oriental, increased and diminished in light, hypaugi and combust. 658

Whether the distance of the planets from the Earth varies 680.681, and how great it is 686.687, and distance from the Sun 687.688, and distance from one another and from the fixed stars 689 to 691. Rules for extracting these distances from the hypotheses of the astronomers 681 to 686

How the apparent diameter of the minor planets is investigated. 701 to 712

Apparent diameter of the planets 708.713, and true diameter and magnitude. 701.703.706.709.710. Apparent magnitude if they are viewed from elsewhere than from the Earth. 718

Proportion in bulk. 707.1

Slippery observations of the minor planets. 497.498

Motion of the 5 minor planets. 499 to 503

Daily motion of the minor planets. 644.2

Connection of the minor planets with the Sun in motion. 509.1

Rising and setting of the planets, kinds of risings, and their order. 662.663

Planets slow, swift, diminished in number. 644

Retrogradation and station of the planets: see Retrogradations and Stations.

Automata of the planets. 505

Revolutions of the planets; see Revolutions.

Plato's age and death, after the preface. 42.2

Plato's system. 493.1

The Platonic year. 130.1.180

What the Pleiades are in the sacred scriptures. 399.1 & 2

The constellation of the Pleiades and its story 399; rising. 473.1 & 2

Number of the Pleiades observable with the telescope. p. 412.2

How much latitude an apparent full Moon has 192.1. If the Moon has latitude, it is threefold; in the same place.

Certain paradoxes of full Moons. 191.2

Pliny the Elder's view on the height of clouds 82.1, and on the distance of the Sun 111.1, and on the magnitude of the Sun 126.1, and on the annual cardinal points 135, and on the system of the planets 101, and on the cause of the stations. 503 & 648.1

An obscure passage of Pliny the Elder explained, on the increase or age of the Moon 192.2, and on the period of eclipses. 345.1

Pliny the Elder's slip in the history of eclipses 365.2, and in asserting a universal eclipse of the Sun. 290.1

Weight of lead. 56.1

PO

What the polar circles are, and what their functions are. p. 21.22

What the poles of a circle in the sphere are? 10.2

What the poles of the sphere are? 8.2.10.1

What and how many the poles of the equator or of the world are. 14.2 & 15 & 15, and of the ecliptic 20.1, and of the horizon. p. 12.1

Description of the pole star 403.404; whether it is the same now as formerly 403.2. Its approach to the pole of the world, and its distance from it. 404.405

Why the altitude of the pole is often erroneous among the ancients 16.1. How it is exactly investigated. 15.16 & 725.2

A perpetual bridge around the Earth. 55.1

Circles and angles of position. 28.1

Posidonius's opinion on the height of clouds 82.1, and on the distance of the Sun 111.1 & 227.2, and on the light of the Moon 197.1, and on the interval between Alexandria and Rhodes. 61.2

PR

In what the civil and astronomical precession of the equinoxes differ. 21.1

What the anomaly of the precession of the equinoxes is, and how great 165 to 168; its theory. 169

The constellation Praesepe. 412.2

Time of Proclus, after the preface. 42.2

Proclus's error in the distance of sight. 64.2

Harmonic proportions. 669.670

Proportion of the bodies of the planets with their distances 704.707, and of the distances with the periodic motions. 689

Proportion of the bodies of the planets to one another in bulk. 707

Proportion of the increase in speed of heavy and light bodies. 89 & 90

Proportion of the distances of the other planets with the distance of the Sun from the Earth. 688.2

What prosthaphaeresis is 145.2; see Equation.

PT

Ptolemy's time, praise and death; after the preface. p. 43

Ptolemy's hypothesis of the Sun 143 to 147, and of the Moon 257 to 260, and of the three superior planets 505 to 515 & 608, and of the two inferior. 561 to 565 & 609 to 612

Ptolemaic measures of the orbs. 511.512.565.566.681.682

Ptolemy's system 101.1.493.1; its imperfection. 695.1

Ptolemy's opinion on the magnitude of the Earth. 61.2

Ptolemy's observations of eclipses 247.1.250.367.2.368.1, and of the equinoxes 134, and of the digressions of Venus and Mercury. 590

Ptolemy's error in the use of armillaries 133.2, and in the annular eclipse of the Sun 387.1, and in the latitude of the Moon 220.2, and in the use of the equant 513, and in the distance of the Moon at the quadratures, and its diameter. 223.1

PV

Peuerbach's death, praise, etc., after the preface. 35.1

Peuerbach's error in the mean apogee of the planets. 513.1

Erik van der Putte's ingenious devotion towards the Most Blessed Virgin, from the number of the stars. 413.2

PY

Pytheas of Massalia's notable observation for the obliquity of the ecliptic 164.1; time, after the preface. 44.2

Pythagoras's system is not the same as that of some Pythagoreans. 101.1.102.2

Pythagoras's opinion on the distances of the Sun and Moon 111.1.226.2; harmonic system. 452

Time, death, etc., of Pythagoras, after the preface. 44.2

Use and inventor of the nautical compass. 80.2

Q

Power of the number forty in human conception and birth. 185.2

RA

Rabbi Adda's opinion on the quantity of the year 137.139, and on the lunar year and month. 256

Rabbi Yitzchak, constructor of the Alphonsine Tables 166.1; his opinion on the motion of the fixed stars. 452

Rabbi Levi's opinion on the motion of the fixed stars. 452

What the radiation and aspect of the planets are, and what its use is. 42.2.43.2.665

Roots of the celestial motions, see Epochs of the motions.

Square root of a logistic number. 8.1

RE

Reduction of the Moon to the ecliptic. 285.2

Reduction of the five minor planets to the ecliptic. 641

Reduction of aspects to the ecliptic or to the equator. 665

What the reflexion of Mercury and Venus is, of how many kinds, and how great. 502.640

A fuller doctrine of refractions. 727.1

What refraction is, and of how many kinds 45.1.46; its general rules 46, and difference from reflexion; in the same place.

The differing use of refraction and parallax. p. 46.2

How the measurement of refraction is set up 114.2 & 421.2. But see more in the index of the second part.

Various causes of refractions. 115.2

Remarkable effects of refractions 32.1.115.2.116, and in eclipses. 322.2

Refractions of the Moon 227.1; of the Sun 114; of the fixed stars. 421.2

Proportion of refractions: whether it agrees with the annual motion of the Earth. 420

What the regular days of the Moon are? 192.2

Deceptiveness of parallactic rulers. 220.1

The star Regulus and its rising. 473.2
Reinhold's praise, time, death; after the preface. p. 33.2
Reinhold's error in the mean apogee of the planets 513.1, and in the parallactic table 332.2, and on the light of the Moon. 197.1
Oarage of ancient ships. 74.2
Problems of the oar and of rowing, from Aristotle and Nonius. 75.1
Number of breaths necessary within an hour. 75.2
Revising one's works, a proof of sincerity. 725
Which planets are retrograde, and when 500.2.645.2; but otherwise in the hypothesis of a moved Earth. p. 646.2
Why the Sun and Moon are incapable of retrogradation 649.1.650.1; but if they were capable, where it would take place. 650.1
What the arc of retrogradation is? 646.1 & 655; the quantity of this arc from Ptolemy 646; from the Prutenics, Magini and Lansbergen. 647
Universal rules of retrogradations. 647
Causes and theory of retrogradations 648 to 654; but in the hypothesis of a moved Earth, from 654 to 658
Revolutions of the planets with respect to the Sun and to the fixed stars 500.1 & 2.512.518.535.553.607; around the Sun 671. Of the Moon with respect to the Sun, see Cycles of the Moon.
RO
Rodrigo Zamorano's observations of eclipses. 373.1
The birthday of Rome marked by an eclipse. 362.1
The birth and death of Romulus marked by an eclipse. 362.1 & 2
SA
Time of Sacrobosco: after the preface. 39.1
The constellation Sagitta. 407.1
The constellation Sagittarius. 401.2
Height of Mount Satabyrium. 67.2
Names of Saturn 480 & 500.1. Figure and companions 487.488.712.723.724, and shadow. p. 723
Line of Saturn's companions parallel to the equator. p. 488.1
Diameter of Saturn observed by us. 712
Apparent and true diameter of Saturn, with its true magnitude. 701.708.710.713
Parallax of Saturn scarcely perceptible. 700.1
Notable conjunction of Saturn with Jupiter and Mars. 675.676
Which planets can be conjoined with Saturn when direct or retrograde. 658.1
Hypothesis or theory of Saturn in longitude: Ptolemaic 505 to 513; Copernican 514 to 519; Longomontanian and Tychonic 519 to 523; Lansbergen's 523 to 525; Hérigone's 526; Keplerian and Boulliau's 526 to 535; ours 535 to 540

Theory of Saturn in latitude: Ptolemaic 607.608; Copernican 612 to 615; Lansbergen's 616 to 618; Longomontanian 618 to 620; Keplerian 623 to 626; Boulliau's. 623 to 630

SC

Ancient use of scaphia. 163

Scheiner, see Christoph Scheiner.

To which stars twinkling belongs, and why. p. 396.397

The constellation Scorpius 401.1; its rising. 473.2

What proportional minutes are, and their use 556.557; their theory. 738.2

SE

Selenography and its authors 203; see Face and spots of the Moon.

Rules of the semidiurnal arc and quantity 33.2.34.1. A problem on this. 461.2

Seneca's prophecy and opinion on new phenomena 488.2; on the smallness of the Earth. 57.2

The constellation Serpens. 407.1

The constellation Serpentarius. 407.1

Usefulness of the number sixty. 6.1

Greek names of the sexagesimal fractions. 8.1

SI

In what *sidus* and *astrum* differ. 393.1

Signs of the zodiac, see Zodiac.

What ascending and descending signs are. 21.1

Signs of right and oblique ascension and descension. 30.2

Which signs rule which limbs. 185.2

Simon Marius's opinion on the motion of Jupiter's satellites and their digression from Jupiter. 491.1

Simon Stevin's opinion on the height of vapours 39.1; problem on the height of clouds, in the same place.

What siphons at sea are? 728.2

Sirius 409; see Canicula.

Height of the Rock of Sisimitres. 67.2

SO

Names, encomia and substance of the Sun 92.93; whether it is animate. 92.2.731.1

Round and elliptical figure of the Sun. 94.1 & 2. Cause and measure of this ellipse. 95.1

Magnetic force of the Sun 93 & 94; rejected. p. 731.1

What the Sun's light is like and how great 93, and its opacity 93.2. Extraordinary darkening and colours. 97.1

Substance of sunspots. 731.1

Spots and faculae of the Sun 95.96; one of these believed to be Mercury. 97.98

The Sun sometimes without spots. 731.1

Solar illumination and heating, and its causes. 99.2

Roundness and parallelism of solar rays. 100
Place of the Sun among the planets. 101 to 104
Distance of the Sun investigated by parallaxes 105, and by eclipses 107, and by the dichotomy of the Moon 107.108.731 to 734. Greatest and least possible limit of this distance 109. Quantity of this distance according to various authors 110.2.111; whether it varies 120.1 magnitude of the distance confirmed. 703.2.707.1
Parallaxes of the Sun 112.113.114.1; and refraction, see Refraction.
Apparent diameter of the Sun: whether it varies 233.2; how it is observed and how great it is. 95.1.116 to 119 & 735
Apparent diameter of the Sun viewed from the planets. p. 120.2 & 736.1
Apparent magnitude of the Sun on the horizon. 736.1
True magnitude of the Sun. 120.2
Portion of the Sun seen by us. 121.1
That the Sun is not a foot across. 125.2.736.2

SOLIS MOTVS.

The Sun's motion.

Inequality of the Sun's motion 142; its hypothesis. 142 to 156
Velocity of the Sun's motion. 126.127
Annual, daily and hourly motion of the Sun. 127 & 140
The Sun's stay longer in the northern signs than in the southern. 33.1
Investigation of the solar equinoxes. 147 to 156
How the Sun's depth below the horizon at the beginning of twilight is ascertained, and how great it is. 38 & 39
Greatest declination of the Sun, see Obliquity of the Ecliptic.
How the Sun's apogee is investigated, and its motion. 152 to 157
How great the Sun's eccentricity is, and whether it varies 153 to 157; when was it least, for Tycho? 737.1
Rotation of the Sun about its own centre 99, and tremor. 99.1
Which days are the solstitial days. 21.2.131.1
What the high solstice in Lucan is. 26.1
Method of observing the solstice, and its fallacy. 131.2.132.1 & 2
System of Sosigenes 101; his age and praise, after the preface. 45.1
Sothic period. 129.1

SP

What the natural, artificial and armillary spheres are? 9.2. Inventors of the armillary sphere, after the preface. 10
Right, oblique and parallel sphere, and their properties. 24 & 25
Schemes and description of the celestial sphere. 9 & 10
Circles of the sphere, and their properties. 10.2.11
Definition and properties of the sphere. 8.2.9.1
Semidiameter and circumference of the elementary sphere. 695.1

Semidiameter and circumference of the eighth sphere 695.1; its motion and theory, see Fixed stars.

Proportion of the sphere to the cylinder, cone and cube; its measurement, and its conversion into a cone or cylinder. 9.1 & 2

Writers on the sphere. 1

Proportion of spheres to their diameters. 8.2

Nobility of the spherical figure. 3.1

ST

What the station of the planets is, and the first and the second, and where the points of each lie. 645.646.650.653

Station of Mars scarcely perceptible. 654.1

At which aspects to the Sun stations occur. p. 646.2.658.1.503.1

Periodic times of stations. 500.2

Arcs of stations, and various problems. 646.647.653.656

Rules and axioms of stations. 647

Theory and causes of stations 503.1.648 to 654; but in the hypothesis of a moving Earth 654.658

Why the Sun and Moon are incapable of stations, and what if they were capable? 650.1

Points of station compared with points of contact. 651.2

Stars seen during a solar eclipse, and when. 365.1.369.2.370.1 & 2.371.1.372.1 & 2

Description of the pole star 403.404; whether it is the same now as in former times 403.2; its approach to the pole of the world 404.405; whether and when it has been or will be at the pole itself? 458

Nebulous stars. 412

Fixed stars: see Fixed stars.

Rising and setting of the stars 40.41; species of risings, with rules and examples from ancient authors, in the same place & 462 to 469

Whether the motion of the stars is circular. 3 & 4

To distinguish always-visible stars from hidden ones 23.2, and their times. 450.2

Strabo's opinion on the circumference of the Earth. 62.2

SV & SY

Rules of logistic subtraction. 7.1

Sulpicius Gallus, the first predictor of eclipses among the Romans. 288

Syene has no shadow at the solstice. 61.2

Exposition of the systems of the world 101; more in the index of the second part.

System of Pythagoras, Archimedes, Pliny the Elder, Ptolemy and Clavius. 101.1

System of Plato, and perhaps of Eudoxus, Callippus, Aristotle, Jābir ibn Aflaḥ and Theon. 101.2

Egyptian system, of Vitruvius, Capella, Macrobius and Bede. 102.1.493.2

System of Philolaus, Aristarchus and Copernicus. 102.1.103.1
The author's system, not asserted absolutely. 731.1
Tychonic system 102.2, and ours 103.1.695.2; but on these see more in the index of the later volume.
Harmonic system 415.416; more in the index of the second part.
What a syzygy is? 42.2
TA
Various starting points of astronomical tables in their epochs or roots 182; their disagreements with one another and with observations. 248.2.375.1.440.498.499
Error of the Alphonsine and Prutenic Tables. 337.2.375.440.1.498.499.644.2
Comparison of the Danish and Rudolphine Tables in the motion of Mercury. 98.2

Tabellarum, & Tabularum Libri I. Index.

Index of the small tables and tables of Book I.

Small table of the parts of the as and of the circle. 8.1
Small table of sexagesimal fractions of one hour or of a degree. 8.2
Small table of the signs of the zodiac, with their names and properties. 18
Small table of the planets, with their characters and astrological properties. 20
Small table of the Sun's ingress into the signs. 33.2 & 130
Small table of planetary hours. 37.1
Table of twilight and its duration. 38
Table of the Sun's depth at the beginning and end of twilight, with the height of vapours. p. 39
Small table of the species of rising and setting appropriate to stars. 41
Small table of aspects. 42.2
Table of the celestial houses. 44

TABVLÆ LIBRI II.

Tables of Book II.

Small table of the weight of liquids and metals. 56.1
Table of the miles contained in the size of the Earth. 61.62,63
Table of the latitude and longitude of the known world. 64
Tables of the distance to which sight extends 66.1, and serving for the levelling of rivers and canals, in the same place.
Small table of the velocity of rivers for the levelling of springs. 70.1.71.1
Tables of the winds according to the ancients and more recent authors. 76.77.78.79
Table of the declination of the magnetic needle. 81
Small table of the height of clouds. 82.2
Small table of the height and amplitude of the rainbow. 83

Table of the heights and times of pendulum vibrations. 87.88
Small table of the velocity of heavy bodies. 89.2.90

TABVLÆ LIBRI III.

Tables of Book III.

Small table of the rotation of the planets, from Šírek. 99
Table of the Sun's distance from the Earth according to various authors. 110.2
Table of the Sun's parallaxes, according to various authors. 113.2
Table of the Sun's apparent diameter from various authors 119.2, and if it is viewed from the other planets. 120.2
Table of the Sun's true magnitude from various authors. 121
Table of the portion of the Earth illuminated by the Sun, and of the angle of the Earth's shadow. 122.123
Table of the axis of the Earth's shadow, according to various authors. 125
Table of the Sun's velocity in its daily motion. 127
Small table of the equinoxes of Hipparchus and Ptolemy. 134
Table of the quantity of the equinoctial year according to various authors 139.1, and of the sidereal year. 140
Table of the Sun's mean motion. 140
Table of the Sun's stay in the northern and southern signs, or in the ascending and descending semicircle 141, or in the quadrants of the zodiac. 142
Table of the apogee, greatest equation and eccentricity of the Sun, according to various authors. 156.157 & 159
Small table of the motion of the Sun's apogee, from various authors. 158
Table of the obliquity of the ecliptic 161 & 162, and of its anomaly, in the same place.
Table of the precession of the equinoxes and of its anomaly, or the motion of the fixed stars 168, and of its equation. 173
Small table of the equation of time in eclipses. p. 180.2
Table of the starting point of astronomical tables. 182.2
Table of the roots of the solar motions. 183

TABVLÆ LIBRI IV.

Tables of Book IV.

Small table of the phases of the Moon. 189.1
Small table of the regular days of the Moon. 192.2
Table of the Moon's age, and of the hours for which it shines at night. 193
Small table of the days of the first or last lunar phase. 194.2
Selenographic table, or of the nomenclature and position of the lunar spots. 205
Small table of the Moon's greatest latitude. 219.2.220.1

Table of the Moon's distances from the centre of the Earth, and of its horizontal parallaxes according to various astronomers. 226

Small table of the Moon's apparent diameter when it appears elliptical. 227.1

Small table of the optical equation of the lunar semidiameter according to Longomontanus. 229

Small table of total and annular solar eclipses. 231

Table of the apparent diameter of the Moon at apogee and perigee, in the syzygies and in the quadratures, according to various authors. 232.1

Table of the Moon's true magnitude compared with the Earth and Sun, according to various authors. 234

Small table of the portion of the Moon seen by us at new moons and full moons, according to various authors. 235.1

Small table of the arc beyond the quadrant of the lunar hemisphere illuminated by the Sun's rays, according to various authors. 235

Small table of the axis, or length, of the Moon's shadow according to various authors. 236

Small table of the apparent diameter and portion of the Earth seen from the Moon. 236.2

Small table of the portion of the Earth illuminated by the Moon at full moons. 237.1

Small table of the Moon's velocity in its daily motion westward. 240

Table of Metonic cycles tested against true ecliptic full moons. 242

Small table of Tycho's lunar eclipses, with their disagreement from Wendelen's calculation. 248.2

Small table of the difference of longitude between Uraniborg or Bologna and certain other places on Earth. 249.2

Table of selected lunar eclipses, for deriving the lunar motions. 250.251

Table of the Moon's mean motion in longitude and latitude, annual, daily and hourly, according to ten of the more celebrated astronomers. 255 & 256

Table of the mean lunar year and month, according to the same astronomers. 256

Small table containing a synopsis of the lunar hypothesis: Ptolemaic 257; Copernican 260; Tychonic 262; Keplerian 265; Boulliau's 271; Lansbergen's 273; Wendelen's 273; Šírek's 274; ours, devised for the interim. 279.280

TABVLÆ LIBRI V.

Tables of Book V.

Chronological table of eclipses, with the notable events accompanying or following them. 292.293

Table of the axis of the Earth's shadow, and of the semidiameter of the same shadow at the place of the Moon's passage. p. 298.299 & 300

Table of the colours of eclipses. 309

Table of the bounds within which lunar eclipses are possible or necessary. 310
Table of the true hourly motion of the luminaries in the syzygies. 313
Small table of the greatest duration of a lunar eclipse. p. 313.1 & 2
Table of the inclination of eclipses to the ecliptic. 316.1
Small table of the axis of the Moon's shadow, according to various authors. 319.1 & 2
Table of the bounds within which solar eclipses are possible or necessary 333 & 334, according to various authors.
Small table of the greatest duration of a solar eclipse. p. 337.1
Small table of the apparent semidiameter of the Earth's disc viewed from the Moon. 340.1
Table for the bounds of eclipses of the Earth and of the Sun. 340
Small table of the magnitude of eclipses of the Earth. 342.1
Table serving for the intervals of eclipses. 346.1.347.1
Table of the antithesis of lunar and solar eclipses. 356
Chronological table of solar and lunar eclipses observed from the year 782 before Christ up to the year of Christ 1647. 361 to 388
Table of solar and lunar eclipses from the ephemerides, from the year 1485 up to the year 1700. p. 389

TABVLÆ LIBRI VI.

Tables of Book VI.

Double table of the asterisms of the zodiac, with their Arabic, Chaldean, Egyptian and Hebrew names, and the space of the zodiac they occupy, and the time at which their first star was at the beginning of the sign. 402
Small table of the pole star's distance from the pole. 404.2
Table of the number of the fixed stars. 412
Small table of possible combinations. 413.2
Small table of the harmonic intervals among the planets, and between them and the fixed stars: Pythagorean, Platonic and Bettini's. 415 & 416
Table of the distance of the fixed stars from the Earth according to various astronomers, in the hypothesis of a stationary and of a moving Earth. 419.1 & 2
Small table of the velocity of the fixed stars in the motion of the primum mobile. 419.2
Tables of the apparent and true diameter of the fixed stars, with their true magnitude. 424
Small table of the magnitude of the fixed stars compared with the great orb of the Earth, from Lansbergen and Hortensius. 425.1
Table of the distance of the fixed stars from one another, from Tychonic observations and our own. 426 to 430

Small table of the right ascension and declination of eight notable fixed stars for the year 1644, from our own observation 434; but of others, from Tycho. 435

Table of the longitude and latitude of 10 fixed stars observed by Tycho and the Landgrave of Hesse, with their places from the tables of Ptolemy, al-Battānī, Alfonso and Copernicus. 440

Table of the Tychonic calculation for the change in latitude of the fixed stars. 441.2.442

Small table of the annual motion of the fixed stars, from ancient and recent observations according to various astronomers 445.446 & 447, but especially. 448

Tables for establishing an unequal or equal motion of the fixed stars. 449.450

Table of Fracastoro's anomaly in the motion of the fixed stars. 451

Small table of the arc of shining for planets and fixed stars. 464.1

Small table of the risings and settings of Sirius and Procyon for the year 1644. 464

Small table of the Sun's ingress into the signs in Julian year 1. 468.2

Table of the risings and settings of 36 fixed stars at Rome in Julian year 1, or the 45th year before Christ. 469.470

Small tables of the rising and setting of Sirius and Procyon, or Canicula, for the years before Christ 400 & 45, and for the years of Christ 1600 & 1644. p. 471

Table of the declination, right ascension, longitude and latitude of 70 fixed stars, verified from our observations for the end of the year 1644. 476.477.478

Table of the equation of places for the fixed stars from the year 1644 to the year 1800. 478

Table of the motion of the fixed stars for expanded and collected years. 479

TABVLA LIBRI VII.

Table of Book VII.

Harmonic small table of the Muses, strings and tones appropriate to the planets and fixed stars. 481.2 & 482.1

Small table of the analogy of the seven planets with metals, gems, colours and humours. p. 483

Small table of the houses, sexes, etc. appropriate to the planets. 483

Small table of the digression and revolution of the satellites of Jupiter. 491.1 & 717

Small table of the disagreement between the places of Saturn, Jupiter and Mars observed by Tycho and those derived from the Alphonsine and Prutenic Tables. 499

Table containing the measures of the orbs and the distances from the Earth, as well as the mean motions, revolutions and roots of the motions of the three superior planets, relating to the hypothesis of Ptolemy and Alfonso 511.512.682; of

Copernicus and Mästlin 517.518.683; of Tycho and Longomontanus 522.523.684; of Lansbergen 525.683; of Kepler and Boulliau 534.535.684; and our interim hypothesis. 539.541.685

Table of the transformation or equipollence of the hypotheses and measures for the three superior planets. 542

Table of the oppositions of Mars, Jupiter and Saturn with the Sun observed by Tycho and Longomontanus. 551.1 & 2

Table of the revolutions of the three superior planets corresponding to collected years, from Ptolemy and Copernicus. 553

Table of the apogee and aphelion of the three superior planets for the times of the more notable astronomers. 552.2.553.1

Table of the greatest equation of the motion in longitude of the three superior planets according to ten astronomers. 561

Table containing the measures of the orbs of Venus and Mercury and their distances from the Earth, as well as the mean motions and their roots in longitude, according to the hypothesis of Ptolemy and Alfonso 565.566.682; of Copernicus and Mästlin 570.2.571.1.683; of Lansbergen 573.574.683; of Tycho and Longomontanus 576.684; of Kepler and Boulliau 578.579.684; our interim one. 582.2.685

Tables of the greatest digressions of Venus and Mercury from the Sun, according to various authors. p. 585

Table of the greatest equations of Mercury and Venus according to various authors. 586

Table of the greatest digressions of Mercury and Venus observed by Ptolemy 588, and by Tycho and Longomontanus 590.591, by us. 718.2

Table of selected observations of Venus and Mercury. 593.594.595

Small tables of the apogee of Venus and Mercury. 596.597

Small table of the eccentricity from the Sun, and of the distances from it, for the minor planets, from Kepler. 602.1

Small table of the revolutions of Mercury and Venus. p. 607

Table of the greatest latitude of the five planets, with the place and root of the nodes and limits, from Ptolemy 611; from Copernicus 615; from Lansbergen 618; from Tycho and Longomontanus 621 & 622; from Kepler 626; from Boulliau. 630.631

Small table of the greatest reduction and of curtation. 643.1

Table of the fastest and slowest true daily motion of the five minor planets. 645

Table of the arc of stations, from Ptolemy 646; from the Prutenics, Magini and Lansbergen. 647

Small table of the time of retrogradations. 647.1

Small table of the proportion of lines and velocities for stations and retrogradations. 650.2

Small table of the angle of commutation for the arcs of stations, from the Rudolphine Tables. 657.2

Small table of the distance from the Sun for emergences and for the arc of shining. 659.2.660.2

Small table of the order of risings and settings in the minor planets. 663.1 & 2

Small table of aspects and of the light of the orbs. 664.2

Small table of the equation of aspects and radiations. 665.2

Small table of the new aspects according to Kepler. 668.669

Small table of harmonic proportions. 669.2.670.1

Small table of the revolutions of the planets about the Sun. 671.1

Table of the Great and Greatest conjunctions of Saturn and Jupiter. 673

Table of the interval between lesser, middle and greatest conjunctions, in the opinion of various authors. 674.2.675.1

Table of eight greatest conjunctions. p. 677.2

Table of the greatest, mean and least distance of Saturn, Jupiter and Mars from the Earth, according to various astronomers 686, and of Venus and Mercury. 687

Table of the greatest and least distance of Saturn, Jupiter and Mars from the Sun, according to various astronomers 687, and of Venus and Mercury. p. 688

Table of the proportion of the distances of Saturn, Jupiter and Mars to the distance of the Sun from the Earth, according to various authors. 688.2

Table of the greatest and least distance of the planets from one another and from the fixed stars, according to various authors. 690 & 691

Table of the semidiameter of the convexity and concavity, and of the thickness, of the heavens according to various authors. 692.693

Table of the circumference of the heavens. 694

Small table of the Italian miles corresponding to the Ptolemaic semidiameters of the deferent and epicycle. 695.1

Table of the time in which a moving body would reach the Earth from the heavens. 696.2.697

Table of the velocity of the planets according to various astronomers. 698 & 699

Table of horizontal parallaxes for the five minor planets according to various authors. 700

Small table of the proportion of density between terrestrial and celestial bodies. 705.1

Table of the proportion of the magnitude of the other planets to the Sun, the Earth and the Moon. 706.708.709

Table of the proportion of the planets in bulk. p. 707.1

Table of the apparent diameter of the planets according to various authors. 708

Table of the magnitude of the bodies of the world. 710

Table of the apparent magnitude of the five minor planets, from our own observation. 713

Table of the observed apparent diameter. 716

Table of the true magnitude of the fixed stars. 716.717

Table of the apparent diameter of the Earth viewed from the fixed stars or from the planets. 720

Table of the Sun's apparent diameter viewed from the fixed stars or from the planets. 720

Small table of the apparent magnitude of Jupiter, Saturn, Sirius and Alcor viewed from a position other than the Earth. 720

Small table of the magnitude of the annual orb and of the orbit of Saturn viewed from the fixed stars. 720.2

Table of the height of the shadow of the planets according to various authors. 722

The constellation Taurus 398.399; its rising. 473.2

TE

Thābit's opinion on the motion of trepidation, see Motion of trepidation.

Age of Thābit, after the preface. 45.2

Notable use of the telescope on the spots of the Moon and the Sun 96.203; on the number of the fixed stars 412; on the Milky Way 412.475; on the diameters of the fixed stars and minor planets 710; on the satellites of Saturn and Jupiter 486.487.488.490; on the figure of Venus and Mercury 483.484.485; in eclipses. 740.2

To deduce a moment of time from astronomical observation. 354.355

Time in which a moving body would descend from the heavens to the Earth. 696.697

Variety of weather from the aspects of the planets. 663.2

Bounds of eclipses: of the Moon 309; of the Sun. 332.2.333.334

Figure of the Earth. 47

Why the surface of the Earth appears flat. 482

What Pliny the Elder and Patrizi objected to the roundness of the Earth 48.2.49.1, and others. 727.1

Whether the Earth is at the centre of the world. 49

Motions attributed to the Earth by some 51.104.105; but see the index of the later volume.

Immobility of the Earth asserted 51, and more fully in Book 9, section 4.

The Earth, centre of heavy bodies. 52

By what force the Earth hangs balanced in the middle of the world. 53.1

The Earth is a point with respect to the heavens. 57

Apparent magnitude of the Earth viewed from the planets or from the fixed stars. 57.2.58.1.236.1.720 & 738.2

By what methods the magnitude of the Earth can be measured. 59 & 60 & 727.1

Magnitude of the Earth according to various authors. p. 61 to 63

In how much time the Earth's circumference can be travelled. 63.1

How great the Earth's semidiameter is. 62.63

Extent of the Earth known formerly and now. 17.2.64

Magnitude of the Earth compared with water. 72.1
Portion of the Earth illuminated by the Sun's unrefracted rays 122, and by the Moon's unrefracted rays 236.2; but by the refracted rays of the Sun 303.2 to 305 & 740.2, and of the Moon 237.1; but see in part 2 of this tome, p. 662
Portion of the Earth seen from the Moon 262.237.338, and from the other planets. 719.720
Velocity of the Earth if it moved. 126.2.699
TH
Age and praise of Thales, after the preface. 45.2
Thales's opinion on the bulk of the Moon. 237.1
Thales, first foreteller of eclipses among the Greeks 288, and the eclipse he predicted. 291.363.1
Age of Thābit, after the preface. 45.2
Erection of a celestial theme. 44.2
Observation of eclipses by Theodoor Moretus of the Society of Jesus. 382.2.383.2.384.1
Opinion of Theon of Alexandria on the place of Venus and Mercury. 494.1
Age of Theon, after the preface. 45.2
Theory of the eighth sphere, see Fixed stars and Precession of the equinoxes.
Theory of the planets, see Hypotheses.
Thomas Digges's excessive confidence in the parallaxes of the superior planets. 700.2
The constellation Thuribulum. 410.1
Age of Timocharis, after the preface 45.2; observations concerning the fixed stars. 441 to 445
TO, TR, TV
What topography is. 2.1
Motion of trepidation. 166.1 & 2.444.445.1.452
The constellation Triangulum. 407.2
How necessary to an astronomer the doctrine of triangles, or trigonometry, is. 2.2
Order, intervals and zodiacal places of the trigons or triplicities. 672 to 677
Tropic of Cancer and of Capricorn. 10.1.21.2
How the height of towers is measured. 54.1
The technique of leaning towers that do not fall. 53.2
TY
Tycho's age, astronomical life, sect and death, after the preface. 46
Tycho's system. 102.2.495.1.695
Tychonic hypothesis of the Moon. 262.263
Tycho's hypothesis of the three superior planets in longitude 519 to 523, and of Venus and Mercury. 574 to 576
Tychonic measures of the orbs. 521.522.575.576.683.684
Tycho's observations of eclipses. 250.373.374.375
Disagreement of Tycho's eclipses from Wendelen's calculation. 248.2

Tycho's inconsistency in the hypothesis of the Moon. 737

Tycho's uncertain reckoning of the parallax of the Moon 222.2, and his errors in the parallax of the Sun. 731.1

Tycho's error or inconsistency in the apparent diameter of the Sun, the Moon and the Earth's shadow 124.2.228, and in the eccentricity and distances of the Sun. 737.1

Tycho's error in denying total solar eclipses. 228.231.372.385.1

Tycho's empty boast about the magnitude of the luminaries asserted by him. 237.2

Tycho's excess in the parallaxes of Venus, and consequently in the places of the fixed stars, and his error in denying that Venus at perigee is observable. p. 700 & 701

Tycho's perplexity or timidity on the motion of the fixed stars 450.2, and his opinion on the change of latitude. 441

Tycho's reliability suspect in a few observations 314.2.373.1.374.1; but see more on these in the index of the later volume.

Tycho's opinion on the height of vapours and on twilights. 39.1

Tycho's opinion on the Moon's greatest and variable latitude, and on the unequal motion of the nodes. 217.263

Violence of typhoons. 728.2

VA

Unfortunate death of Valentinus Naiboda. p. 725.1

Difference between vapours and exhalations, and how the height of each is investigated and how great it is. 39 & 82 & 726.2, and in part 2 of this first tome. 58

VE

Velocity of waters, rivers and navigation. 70.1 & 75

Velocity of heavy and light bodies in natural motion, with how great the proportion of the increment of velocity is. 89 & 90

Velocity of a moving body falling from the heavens to the Earth. 697

Velocity of the Earth's motion if it moved in the great orb. 126.699

Velocity of the Sun in its daily motion 126.127; of the Moon 238 to 240; of the fixed stars 419.2; and of the other planets. 240.1

Velocity of the planets in their proper motion. 698.699

Proportion of the velocity of the planets in their proper motion to the measures and intervals of the orbs. 650.2.670.2

When planets are said to be swift or slow. 644.1

Praise of Wendelen, after the preface. 35.2

Wendelen's lunar hypothesis. 272

Wendelen denies the inequality of natural days. 179.2

Wendelen's subtlety on a lunar eclipse, corrected. p. 300.2.301.1

Wendelen's notable observations of eclipses. p. 251.375.376.377.378.380

Wendelen's criticism of Tycho 373.2, and of Lansbergen. 376.2

Wendelen's opinion, and notable observation, for the distance and parallax of the Sun. 109

Wendelen's opinion on the air around the Moon. 187

Wendelen's ingenious observation on the proportion of the motions of Jupiter's satellites to their digressions from Jupiter. 492.2

Wendelen's opinion on the beginning of the Sothic period, or Canicular year. 129

Wendelen's tables, sometimes disagreeing with observations of eclipses. 745.1.746.1

Names of Venus. 480

Sickle-shaped and gibbous figure of Venus 484.2.485; hence unusual changes unknown to the ancients, in the same place.

Notable observation of the last evening phase of Venus. 485.1

Whether Venus has been seen under the Sun, or is visible there. 483.2.495.1

Place of Venus in the system of the world. 493 to 495

Venus appearing as an evening and a morning star on the same natural day. 661.2

Brightness of Venus producing a shadow. 662.1

Diameter of Venus observed by us and by others. p. 711.2.713 to 717

Notable magnitude of Venus around perigee, so much so that it was believed to be a comet or an unusual star. 714

Greatest digressions of Venus from the Sun. 583 to 586.717

Notable observations of Venus. 593 to 595

Tycho's excessive parallax of Venus. 700.1 & 2

Revolutions of Venus about the Sun. 607

Investigation and quantity of the mean motion of Venus. 500 to 502 & 604 to 607

Investigation of the apogee and eccentricity of Venus. 586 to 597 & 597 to 604

Stations of Venus. 654.1

Varying order of the emergences and occultations of Venus. 663.2

Hypothesis of Venus in longitude: Ptolemaic and Alphonsine 561.566; Copernican 567 to 570; Lansbergen's 571 to 574; Tychonic or Longomontanian 574 to 576; Keplerian and Boulliau's 577 to 579; ours, for the interim. 579 to 583

Hypothesis of Venus in latitude: Ptolemaic and Alphonsine 609; Copernican 613 to 615; Lansbergen's 616.617; Longomontanian 619 to 621; Keplerian 623 to 626; Boulliau's. 627 to 630

Measures of the orbs of Venus, see Measures of the orbs.

Number of the winds and their various nomenclature, old and new, from p. 75 to 80

General winds 80.1.728.1, and provincial winds in the same place.

Ornithiae winds. 80.1

Fixed, free, stormy winds etc. 728.2

Sphere of the winds, height etc. 80.1

Vergiliae, see Pleiades.
Protean verse. 414.1
Rotation of the planets about their own centre. 99.1.274.1; but for the Sun and Moon, see Rotation of the Sun and Moon.
Evening planets: which they are and when. 658
VI
Viète's lunar period 244.1; his opinion on the ratio of the diameter to the circumference. p. 9.1
How many watches of the night. 36.2
Villalpando's experiments on the weights of liquids and metals 56.1, and of water in particular, and on the measure of the Roman foot. 17.1
Willebrord Snel's opinion on the size of the Earth 62.1, and observation on the measures of intervals 59.1; his age and praise: after the preface. 46.2
Vincenzo Renieri's notable observation of an eclipse 381.1; but his slip in the history. 368.1
Vicenç Mut's excellent observations for the diameter of Jupiter 711.1, and of eclipses 383.2.384.2; and his problem for the parallaxes of the Moon 328 & 738.1; and for the diameter of the luminaries 735; and for the quantity of the year 736.1, and the eccentricity of the Sun. 737.1
Rising of the star Vindemitor. 473.2
Weight of wine. 56.1
Virgiliae, see Pleiades.
Suspension of Bishop Virgilius from sacred functions for asserting the Antipodes. 26.2
Virgo, the constellation. 400.2
Distance of vision. 13.1.64 to 66 & 727.2
Arc of vision of the planets. 42.1.654.660
Witelo's age: after the preface. 47.1
Vitruvius's opinion on the order of the planets in the world 101.493.2, and on the cause of stations and retrogradations 503.648.1; his age, after the preface. 47
VM
Shadows of gnomons are uncertain. 16.1.133.1
Solstitial shadows of gnomons: where are there none? 61.2
Observation of the equinoctial shadow. 133.1
What lines gnomonic shadows describe on a horizontal plane. 26.2
How the angle of the Earth's shadow is investigated, and how great it is 122.2.123.1; but if the rays are refracted, 303.2; see 736.1
Measuring the axis and apparent diameter of the Earth's shadow at the place of the Moon's transit, if the rays of the Sun are taken as unrefracted 123.124.2.125.296 to 299; but if the rays are refracted, p. 303 to 305 & 740.2
Quantity of the Earth's shadow, according to various authors. 300 & 740.2
Threefold figure of shadows. 293.294

A cylindrical shadow does not necessarily produce an eclipse of the Moon. 301.1
Whether a contraction of the Earth's shadow is to be admitted. p. 379.1
Various dimensions of the lunar shadow, and problems about it. 318 to 322 & 339
Length of the shadows of the minor planets. p. 721.722
Shadows of the lunar spots. 206
VR
How many times divers breathe under water in one hour. 75.2
For whom the constellation of the Bear does not set. 24.1
Names, description etc. of Ursa Major and Ursa Minor. 403.1
X
Xenocrates' opinion on the distances of the stars. 493
Xerxes' crossing into Greece, notable for an eclipse of the Sun. 363.1
Y
What hypsometry is. 2.2
Z
Why Pope Zachary suspended Bishop Virgilius for asserting the Antipodes. 26.2
What the zodiac is, and its occasion. 18.2
The signs of the zodiac: which they are, how many, and why so many. p. 18 & 19
Various names of the zodiac and of the signs. 402
Twofold zodiac: one sensible and star-bearing, the other rational. 20.1.393.402.1.726.1
Latitude of the zodiac. 19.2 & 726.1
Why the zodiac begins from Aries. 19.2
Constellations of the zodiac: which they are, and how many. 398 to 402
When the constellations and the signs of the zodiac coincided at the beginning. 402
Zones: which they are, and how many? 21 & 22
The torrid zone is habitable. 22
Breadth of the zones. 22.1 & 2

LAVS DEO.

Praise be to God.

Diagram. The printer's device, a woodcut, centred on the page between *Laus Deo* and the imprint. At the head, a child's face rests on a scrolled cartouche bearing the motto in capitals on three lines; leafy sprays and large shell-like volutes flank it, and a small grotesque mask hangs beneath it. Below is a large shield held by two winged, half-draped putti, one at each side, each standing on a scrolled bracket. The shield shows a storm: banked clouds across the top, rain falling in shafts, and a boat with a broken mast heeling among heavy waves,

with a low shore and small plants in the foreground. At the foot, within foliate scrollwork, is a small escutcheon patterned in black and white triangles. The motto is the only text on the block.

- Cartouche (top centre): FLVCTIBVS ET FREMITV ASSVRGENS BENACE MARINO — "rising, Benacus, with waves and a roar like the sea's"

BONONIÆ,
