Diagram. A narrow isosceles triangle illustrating the division of a quadrant's transverse lines. The apex A is at top; the base runs along the lower periphery from B (left) through D (middle) to C (right). Dotted lines descend from A to B and to C, with a short vertical at D marking the terminus of the first degree.

- A (apex): the boundary of the first degree on the upper periphery
- B (base, left): beginning of the lower periphery
- D (base, middle): point terminating the first degree
- C (base, right): end of the second degree

Second mode, and the one customary with Tycho, if the periphery is divided into 90 degrees: let any degree be subdivided into 6 minutes in the sub-divided minute, and let transverse lines be drawn in groups of six, subdivided in the second figure, in which the arc of one degree is thus divided and subdivided, as is represented in the schema. In this case, besides the 90 degrees — that is 180 — and the subdivisions of the individual degrees into six equal parts, which the above and below contain — 540 lines are to be drawn; and each requires division into ten parts, so that the sum of all the divisions with the lines requires 7100 operations, that is, more, and with the risk of erring.

Diagram. A schematic of a curved quadrant band, a sector of an annulus whose arc is divided into degree intervals, with internal transverse zig-zag lines (the "second mode" of subdivision into minutes). No point-letters are legibly labeled on the figure.

3 [*Margin: Grimaldian Quadrant.*] The Grimaldian Quadrant — so named by us from its Author, who divided it with most exact subtlety, namely Father Francesco Maria Grimaldi [Francesco Maria Grimaldi] — is of Iron, and larger than the Tyconic one, inasmuch as it is in semidiameter of 8 feet and more, that is, of 28,885 parts, of which one uncia is of the Roman foot 300. Its arc is of bronze, and polished like a mirror, broader by two fingers — a little more than fingers — divided into 90 degrees, and subdivided into half-degrees. The chord of any arc is so great that, if it were to be divided, it would take 504 of the said little parts. From this element and from the Radius of the Quadrant we constructed the Canon from unity onward, as far as the data of particles 504. The chord comprehended between the line of the Fiducial Dioptra and the nearest degree, or half-degree, we would at once know as a minute, and the second by the addition of the nearest Canon — a specimen and abridgement of which we give here. So that, if the Distance of any Star from the vertex is taken as $25\frac{1}{2}$ degrees, and besides that as much as the part of the chord between the Dioptric line and the following degree occupies 80 particles, then from the Canon it is at once known to be the minute $9'32''$, and so the Altitude of the Star is $25^{\circ}50'28''$. Moreover, the said chordwise quantity is not measured so much with a sharp pair of compasses as by the very congruence of the extremities of the section with that interval; and this, applied to the Orichalc Ruler — in which an uncia is

divided by a transverse line into 300 equal particles. For let the metallic plate be well thick and well polished, of which the breadth is AB and CD, of one uncia, and the length AC and BD, not less than two feet.

Chord — parts	Arc — Min.	Sec.
1	0	7
2	0	14
3	0	21
4	0	28
5	0	35½

400	47	37
500	59	30
504	60	0

For: with the Diagonal AD drawn, you will be able to divide it into 300 equal particles, with a large enough and discernible interval. Let us suppose the breadth FG of the small chart measuring the chord to indicate the breadth, and of the whole AD, a portion of 300 — a portion AG, much more evident than the

uncia AB — the effort would be to divide it into 300 parts, for never with the portion AH equal to FG itself would so evident a discrimination be distinguished. I confess that I have not at once, by this method, with the situation of the Dioptra inspected, obtained the Altitude of the Star; but I have to capture the measured chord between the nearest half-degree, and this is to be elicited from the Metallic Ruler, and inquired through the number of parts of the chord into the minute of the Canon; but this small delay is compensated by the simplicity and evidence of the larger figure. For in this whole procedure, besides the operations of 180 — to which the Quadrant divided into half-degrees and divided into half-degrees, the Uncia is divided by one transverse line of two-foot length into larger parts, into equal parts of 300 — it does not require any further division; whereas in the construction by that Canon, if the instrument is divided into half-degrees, it is not necessary to extend the division further than particles 251; and by logarithms it is resolved within a few hours. The Metallic Ruler, however, once well divided, serves for the division of all other instruments whose chords are intercepted by degrees, provided the semidiameter of the instruments is half-measured. We have, nonetheless — for these and other uses — three Rulers with a metallic plate: one of one Foot length, of bronze; another a Four-foot Quadrupedal of Orichalc, with its transverse lines. The third, of 15 feet, and of bronze. To be more secure in this fashion of dividing the minute and the second, than the Tychonic — as experience will show, and as confess no few most expert in matters of this kind, who have also chosen this — for example, the Most Illustrious Count Carlo Antonio Manzini [Cornelio Malvasia — *recte* the source reads "Carolus Antonius Manzinus", Carlo Antonio Manzini], D. Io. Dominicus Cassini [Giovanni Domenico Cassini], and others.

Diagram. A right-hand figure of the Orichalc measuring plate. A tall narrow rectangle with corners A H B across the top and C K D across the bottom; the diagonal AD runs from the top to the bottom corner, with the small chord-chart FG marked across the lower portion.

- A, H, B (top corners): top edge of the plate
- C, K, D (bottom corners): bottom edge of the plate
- F, G (lower middle): the small chord-measuring chart, breadth FG

4 [Margin: *The kinds of Dioptra.*] It remains for us to say something of the Dioptra. Hipparchus [Hipparchus] — and he advises this in the *Paralipomena* to the *Vitellio* [Witelo] of Kepler [Kepler], folio 216 — introduced Dioptras; and to the narrowest aperture, applied to the eye, it would be more certain than the aperture, he says — for a dioptra they use the finest slits. But if the apertures or

slits are too small, they do not exhibit the desired subtlety of scruples; if too wide, they do not. For this reason others place a little ball of the remoter dioptra in the middle of a perforated tablet, aiming and collimating; and others, in a small window of the tablet, draw broader threads in a decussate manner, so that the section of the threads in turn impedes the dioptra, like a little ball or little crosses in the dark, and a candle being applied impedes the sight. For this reason no Tychonic vision seems more expeditious for collimating the ratio, than to direct two parallel lines in any single Star. Of this kind of dioptra Tycho describes a schema attached here and there in the *Mechanics of Astronomy*, but separately with other instruments, on the second-to-last folio. We shall perhaps set them forth more clearly in the following figure.

Diagram. A wide schematic of a sighting dioptra spanning the foot of the page. At the left is an upright frame with points E, C, G, F, A, H marking the ocular tablet AC (the twin laminae and its ruler AB); dotted sight-lines run rightward across the page to a distant target tablet BD on the right at D, with the line continuing to L and M (and a small sun-burst icon beside L–M marking the object sighted).

- E, C (left, upper frame): top of the ocular assembly
- G (left): a fixture on the ocular ruler
- F, A, H (left, lower frame): base of the ocular tablet, with axis AB
- D (right): the distant tablet BD
- L, M (far right): the sighted object (Star), with sun-burst marker

In the figure above, let the Ruler AB and the upright twin laminae, or a tablet of altogether equal breadth, be one, AC, near the eye; the other BD, whose axis falls on the center of the instrument, and through that Ruler let it be circumvolvable, and let the said tablets be between themselves, according to the four sides, equidistant. The Ocular tablets AC: let the little fibulae be attached —

— so that there be two laminae from here and there, EF and GH, so that between them be the little Tablet AC, and let the two little fibulae be left for the slender Slits I and K, which through the said little fibulae could be made narrower, or wider, according to the magnitude of the star posited. With these prepared, the observer collimates the center of the instrument through the Star, until he moves it about the center of the instrument; the Ruler AB, until through the Slits I and K, he sees the rays, the parallels GL and OM, so much of the same Star as he sees through the one, the other slit; how much certain it be that the Radius through the middle of the Tablets AC and BD, by the production of the imagination, may render the center in the Star. [*Margin: 5.*] Nonetheless, in place of the Tablet BD,

Tycho often uses a Cylinder in the center of the instrument, set up, and divided crosswise with the breadth of the Tablet AC. But we have followed this form of dioptra. We have used them in places very full of obstacles, occasionally, especially when the Star was very near; occasions gave to accept the one from the other, unless from time to time, by moving the dioptra, we should discern it. But it turned out much more inconvenient, and more troublesome, in capturing the distances of two stars by observation. For two observers must first fit the plane of the instrument, and however much the Star may stand above that line, and afterwards collimate at the same time toward that very Star, while in the meantime, by the motion of the prime Movable, the Star moves; much time intervenes, while the other, by the motion of the prime Movable, is born; and these collimations differ greatly, when attended to, nor without the evidence of observation, and as much with tranquillity as the observer desires. This — with the peace of the Tychonites be it said.

5 [*Margin: 5.*] Therefore, having tried diverse kinds of Dioptras, we have found by experience the most expeditious and most certain to be that one in which the eye, through a small aperture and a coriander seed less, collimates at the Acus [needle/index] erected orthogonally from the center of the instrument — and so slender that, the Distance of the Star having been computed between the eye, and the eye not so great in magnitude — unless perhaps the fourth, or some little magnitudes, the remainder be obtuse. It is necessary that the eye, with both eyes open, be moved immediately near the aperture, but from some other digit in the line of transition; and that it see remotely, evidently, by that very aperture set in the Acum, that which it cuts the Star — which it does when the eye sees the said Acum as a kind of diameter cutting the aperture in two, and at the same time cutting the disk of the Star. Besides, on nights when it is illuminated, or beyond twilight, or with the Moon far off, the said Acus, illuminated, is not to be left bare in the open; nor must the eye of the observer radiate, or with the tremulous agitation of the air, the splendor of vision be interrupted; but, the flame of the light being enclosed in an opaque lantern toward the eye, and a thin crystalline plate, or talc, set toward the Acum, it is to be fortified; and near the Acum, below, at a distance of about one palm, or a span, it is to be set up. If this be done, it will at once be evident with what evidence the center of the Star is collimated. This we have done by very many experiments, and by comparison made with the Tychonic Dioptras. And although it is not necessary, nonetheless we also employ that aid, by setting up before the eye a hemispherical aperture, or a little skiff perforated at the bottom, which little skiff must be filled in at the bottom with the lamina of the aperture, so that its aperture be congruent equally on every side with the lamina of the aperture, or the tablet. At length the fiducial line, in that

part where it must designate the optimal point of the instrument for the minutes, and the seconds, must be most straight, and run into the center of the instrument, and the middle, or the Axis of the Acus erected from the center of the instrument, whose straightness is explored by the tension of a most fine silken thread.

6 [Margin: 6.] We add nothing here concerning the oscillations of the Perpendicular, for numbering the intervals of time between the transit across the Meridian of two neighboring Fixed Stars, and so deriving the Difference of Right Ascension, or for numbering the time, which sometimes necessarily intervenes between the observations of two Stars in Azimuth — since enough was said of that in Book 2 of the *New Almagest*, Chapter 29. Nothing further concerning the Filar Triangle, for observing most certainly the transit of Stars across the plane of the Meridian, or their gliding to a fixed and determined Azimuth, or the plane of the vertical circle distinct from the Meridian — for of that, and of its use, enough was described in Book 5 of the *New Almagest*, Chapter 15, number 16. Nothing, finally, of the hydrostatic Libellae, for altitudes above the Horizon, or for depressions from a higher or subtler place to be observed; of these in many places, in other things, by Father Grimaldi [Grimaldi], our inventions, this was treated by us in the *Organic Book*.

7 [Margin: 7.] Lastly, however, we recall to the Reader's memory what we taught in Chapter VII concerning Tychonic observations: that they are liable to no small uncertainty, whether because the form of the Dioptra has often varied somewhat, whether by a defect of subdivision, whether by a single scruple, whether by the variety of observers and of the eye, whether by diverse disposition and attention. For this reason, whether you take a Tychonic observation, or ours, where the difference of one Minute or another intervenes, nor is it a wonder if our position is to be preferred rather than the Tychonic one; nor on that account will faith be derogated from the Tychonic observations; but the prudent and impartial — and, with prejudice and the authority of opinion set aside — choosing what, all things being well considered, seems to all the truer. For so much does Truth prevail with us above all that, just as we have ingenuously placed many things in the *New Almagest for the time being*, we shall be busy with correcting and emending — by an incredible toleration of expending wakefulness — and restoring observations.

CHAPTER XVI.

On the Declinations of the Fixed Stars Observed by Us.

1 The Altitude of the Pole having been emended, and these or greater ones having been substituted in place of the earlier ones — not, indeed, that we should adhere to the Declinations of the Fixed Stars signified in the *New Almagest*, and corrupted by Typographic errors. Therefore, these I select which we observe from the year 1650, indeed especially from the year 1655 down to 1659, repeated again and again from the most subtle observations of Father Grimaldi [Grimaldi], and which I myself reckoned of greater value — both on account of the prerogative of the conspiring observations of the observers, both on account of conscience, and the tranquil attention of the observers, and the purer sky, and finally on account of the evident exclusion of those Declinations which the time then demanded — the Tyconic Tables in proportion exhibited at the end of Chapter 12.

2 Let there be an example in the Lucida of Aries [α Arietis, Hamal], which, because it is the foundation of the rest in that constitution by Tycho [Tycho Brahe], we observed most diligently; and its Declination, by the aforesaid Table of Chapter XII, we reduced to the last, just as we did the rest, supposed to the end of the year 1660, as above by the Altitude of the Pole at Bologna in our Observatory, $44^{\circ}30'10''$.

Lucida of Aries — Selected Observation	Distance from the Vertex — G.	Declination Then — G. ' " "	Declination for the Year 1660 — G. ' " "
Year — often			
1656 January, freq.	22	4 7 21 2	4 3 21 8 4 3 9 2
November, freq.	22	4 5 21 1 3	4 1 21 8 7 4 3 9 1
1657 December, freq.	22	4 3 21 1 6	4 3 21 8 4 4 2 9 8
1658 November, toward the end, freq.	22	4 1 21 1 2	4 5 41 8 8 4 3 9 4

Lucida of Aries — Selected Observation	Distance from the Vertex — G.	Declination Then — G.	Declination for the Year 1660 — G.	
1659 January, freq.	22	4 1 21 1 2	4 5 21 8 8	4 3 9 2

On account of these and similar ones, we chose for the end of the year 1660 the Declination $21^{\circ}49'30''$; but that which the Tychonic Table of Chapter XII places at the end requires $21^{\circ}51'$ — that this is false is evident from the Grimaldian Quadrant. For in the year 1659, January having begun, from the same Table — indeed from the Tychonic Latitude and Longitude, and the true obliquity of the Ecliptic — the Declination ought to have been $21^{\circ}50'26''$, that is, a distance from the Vertex of $22^{\circ}39'44''$; and, according to what is said in Chapter XV, number 3, our Fiducial Line of the Dioptra, below 23 degrees. The distances from the vertex in the Quadrant noted —

it would have had to cut off a chord of 170 such parts, of the kind 300 of which make up one inch of one foot. With the dioptra set up there, then, the Lucida of Aries plainly appeared below the cross-wires [Acumen] at the center of the quadrant, and the sight-line ran into the center of the quadrant; and the cross-wires, when aimed directly, fell notably higher than the Lucida of Aries [γ], nor could it be sighted at the center of the instrument — that is, at the center of the star — unless the sight-line had been set in the very position in which, at 23° , it cut off a chord of 158 particles. These give, on the said quadrant, $18'48''$, to be subtracted at the 23rd degree; and so, once more and as often as the observation was repeated, on those nights the distance of the star from the vertex was $22^{\circ}41'12''$. Hence, therefore, we conclude that [Tycho Brahe] exceeded by this one-and-a-half-minute amount, and accordingly that in the year 1585 it must have been $21^{\circ}[\text{?}]$ and 27' minutes; this much only, and it does not conflict with the mean drawn from the extremes of the Tychonic observations, as we said in Chapter 9, Conclusion 4. The same diligence has been applied in exploring the remaining Tychonic declinations.

3. A second example, in the Lucida of Aquila [α Aquilae, Altair]. From the year 1655 we have about 30 observations of it, of which these have been selected:

Lucida Aquilae — Year	Distance from Vertex (G. ' ")	Declination then (G. ' ")	Declination An. 1600 (G. ' ")
1655 July, &	36 29 30	8 0 40	8 1 20

Lucida Aquilae — Year	Distance from Vertex (G. ' ")	Declination then (G. ' ")	Declination An. 1600 (G. ' ")
Aug., often	36 29 29	8 0 41	8 1 20
Octob., very often	36 29 28	8 0 42	8 1 21
1656 July, &	36 29 23	8 0 47	8 1 22
Aug., often	36 29 25	8 0 45	8 1 20
Septemb. &	36 29 25	8 0 45	8 1 20
Octob. often	36 29 26	8 0 44	8 1 19
1657 Septemb. &	36 29 18	8 0 52	8 1 17
October	36 29 20	8 0 50	8 1 15
often	36 29 16	8 0 54	8 1 19

We have therefore chosen, for the end of the year 1660, the declination of $8^{\circ}1'20''$, which for [Tycho Brahe] is $8^{\circ}1'$; and by the same method we have selected the remaining declinations in the following Table. For why should I heap up here the medley of very many observations, so that in the end the Reader might wish for us ourselves to decide which ones we think should be selected? — relying on our conscience and on the fresh memory of the diligence applied in observing.

Table of the Declinations of the Fixed Stars, selected from Our More Recent observations, and collated with the Tychonic [declinations] from the table at the end of Chapter XII, or otherwise supplied by him.

I admit, however, that I have left the declinations of Capella and of the right shoulder of Auriga — and of a few similar stars — somewhat more uncertain than the others, because, owing to their nearness to our zenith, they were hard to observe by reason of distance; and that the differences of their right ascensions were limited only loosely by me. This I wished to note, so that elsewhere, when observations are conveniently available, posterity may demand the correction of them; and let them know that I shall not take it amiss that this be done.

CAPVT XVII.

De Ascensione Recta Fixarum LXII. ex Nostris Recentioribus observationibus deducta, & reducta ad finem Anni CHRISTI MDCLX.

On the Right Ascension of 62 Fixed Stars, derived from Our More Recent observations, and reduced to the end of the Year of Christ 1660.

1. Since the Right Ascension of the Fixed Stars cannot be observed except dependently upon the Sun, and yet no Fixed star shines together with the Sun above the horizon brightly enough to be conspicuous to us — except Sirius, which all the same is not visible unless the Sun is near the horizon, and is then bound up with refractions... [Margin: *Qua Stella cum Sole sint conspicua.* — Which stars are visible together with the Sun.] Among the planets, those that can be observed both by day, together with the Sun, and by night, together with the Fixed stars, are Jupiter and — most rarely — Saturn; and the Moon too, when the Sun is near the horizon, but the Moon is then very high — yet it is itself entangled in the uncertainties of parallax. There remains, therefore, Venus, which can sometimes be seen positioned very high, together with the Sun, and beyond sensible refractions; and at night, likewise, can be seen among the Fixed stars in a position so high that each body stands out above the physical refractions. Very rarely, however, does one have both these conditions together...

2. But there is another way of investigating the Right Ascensions of the Fixed stars from the Sun without the intervention of another planet, which we have often used for the sake of practice — not that other way mentioned before, but one arrived at differently. This method consists in observing the altitude of the Sun, together with its azimuth, and counting the time up to the arrival of the Fixed star at the same azimuth, supposing the Fixed star's Declination and Altitude in that azimuth to be known. But if the Sun is observed near the horizon, a sensible error in the time is to be feared — that is, about half an hour before sunrise, or after sunset, when the more notable Fixed stars can be seen; for then the Sun is liable to inconstant refractions. If, however, an altitude of the Sun is chosen which is free from refractions, and many hours intervene between the observation of the Sun and that of the Fixed star, the time necessarily elapses, in which the swings of the perpendicular [pendulum] are counted, exposed to an error of several seconds; and each single second of Time inserts fifteen seconds into the Right Ascension — so that every four seconds insert one whole minute. We have found by experience that our pendulum, within one hour, is variable by one second, and by nearly another. When the difference of Right Ascension is observed between two Fixed stars within half an hour, or [stars] passing across the Mid-heaven [Medium Coeli] within a quadrant — it is very fitting to use the perpendicular [Margin: *Perpendiculari utilitas in observ. Ascen. Recta.* — The usefulness of the pendulum in observing right ascension.]; indeed, if two Fixed stars differ by one, or at most another, single degree of Right Ascension, and in Declination they differ by several degrees, that difference of the Ascension is investigated more safely through the time of the perpendicular numbered, than through Trigonometry from the complements of the Declinations and the Distance of such Fixed stars, on account of the excessive sharpness of the Angle at the Pole of the Equator.
3. Returning, then, to the Lucida of Aries — already at Chapter X, to the end of the year 1585, we showed its Right Ascension to have been $25^{\circ}59'47''$; and at Chapter XII its own Longitude $1^{\circ}51'39''$ of the same [sign], and likewise its northern Latitude $9^{\circ}56'30''$. Since, then, for a star certainly unvarying in this center, with this Latitude and with the true and unvarying distance of the Poles of $23^{\circ}36'20''$ — as demonstrated in Book III, On the Sun — and with the Declination of the same Lucida of Aries [γ] to the end of the year 1660, already in the preceding chapter most evidently found to be $21^{\circ}49'30''$, we shall easily, by the Analemma of triangles, obtain its Right Ascension and Longitude. With the support of the following diagram, in

which let ABC be the Colure of the Solstices, and in it B the northern Pole of the World; from which let the Equator AHC be described, and from the Pole of the Zodiac, or Ecliptic, Z, let the Ecliptic DHE be described; and through the Fixed Lucida of Aries [Υ] at F let the circles of the Quadrants be drawn — one of Declination BFG, the other of Latitude ZFI. For there will be, in the triangle BZF, with all sides given — namely BZ, the Distance of the Poles, $23^{\circ}36'20''$, and the Declination FG, $21^{\circ}49'30''$... the Complement of BF, deg....

Diagram. A circle representing the celestial sphere, used for the analemma reduction of the Lucida of Aries from declination to right ascension and longitude. The bounding circle is the solstitial colure ABC, with B the north celestial pole at the top. Two great-circle arcs cross the interior — the equator AHC and the ecliptic DHE — together with the declination quadrant BFG and the latitude quadrant ZFI through the star at F. Labels read clockwise from the top:

- B (top): the north Pole of the World.
- Z (upper right, just inside the rim): the pole of the Zodiac/Ecliptic.
- C (right): equatorial terminus of the colure.
- E (lower right): the ecliptic terminus.
- H (lower center): intersection of equator and ecliptic.
- G (bottom center): foot of the declination quadrant.
- A (left): the other equatorial terminus of the colure.
- D (upper left): the ecliptic terminus on the left.
- F (center): the Fixed Lucida of Aries.
- I (center-left, near F): foot of the latitude quadrant ZFI.

$68^{\circ}10'30''$, and a latitude of $9^{\circ}56'30''$. The complement FZ is therefore $80^{\circ}3'30''$. So, by the laws of triangles and the logarithmic canons, the angle FBZ comes out — for the same epoch — as $117^{\circ}1'58''$, measuring the equatorial arc GHC. If you subtract a quadrant HC from this, there remains the right ascension HG of the Lucida of Aries [α Arietis, Hamal], $27^{\circ}1'58''$, counted from the beginning of Aries. There also comes out the angle BZF, $57^{\circ}5'18''$, measuring the ecliptic arc DI; and this arc, subtracted from the quadrant DIH, leaves the longitude IH, $32^{\circ}54'42''$ — that is, $2^{\circ}54'42''$ in Taurus [Υ]. These results, as if into a foundation, it is worth gathering into a single view:

Anno 1660. Completo.	Lucida Υ		
	Gr.	'	"
Declinatio	21	49	30

Anno 1660. Completo.	Lucida Υ		
Latitudo	9	56	30
Ascensio Recta	27	1	58
Longitudo	$\propto$ 2	54	42

[For the year 1660 completed. — The Lucida of Aries: Declination $21^{\circ} 49' 30''$; Latitude $9^{\circ} 56' 30''$; Right Ascension $27^{\circ} 1' 58''$; Longitude $2^{\circ} 54' 42''$ of Taurus.]

4. As for the remaining fixed stars of the first and second magnitude that we have been able to observe, and certain of those of the third and fourth magnitude that are conspicuous, we have hunted out their right ascensions by means of trigonometry. We did this by first investigating the differences of right ascension from the distance between two stars observed by us — the distance handed down in Caput VIII — together with the complements of the declinations established for the stars we observed, as set out in Caput XVI. But this same operation we have distributed among classes, of which the first is as follows.

Anno 1660. Completo. I. Classis	Ordo Stellaru m	Declina tio (G. ')	Distantia à praeced. (G. ' ")		Differentia Asc. Rectae (G. ' " ")	Ascensio Recta (G. ' " ")

	Summa Differe ntiaru m				360	

[For the year 1660 completed, First Class. Order of the stars; Declination; Distance from the preceding (star); Difference of right ascension; Right Ascension. Sum of the differences: 360° 0' 0".]

5. Yet I freely confess that, from the distance between Spica and the Northern Pan [Lanx Borealis], I had judged from observation that a difference of right ascension of $27^{\circ} 33' 30''$ would result; and from the distance between the Northern Pan and the Head of Ophiuchus, a difference of right ascension of $35^{\circ} 4' 11''$ — and thus, up to 360° of the equator, I found myself short by $9''$ here, $25''$ there. I therefore chose the earlier distance, $27^{\circ} 33' 40''$, and the later one, $40^{\circ} 39' 40''$, for the reason that, among the other distances of this class, I did not have so many confirmations of them for the others. For Ptolemy shrewdly noted in his *Harmonics* [Ptolemy, *Harmonica*] that sense-perception scarcely ever reaches exactly to the truth, but only approaches it nearly; yet it is the part of reason, from what has been observed through the senses, to determine the exact measure. What I have just said I mean to apply also to the other distances used in the second and third classes; and as to a very few seconds, I have set limits. I have set those limits to the distances rather than to the declinations, because we attain evidence far more hardly in observing distances than in observing declinations, as is established among the experts. This small adjustment we have indicated in the catalogue of distances by the characteristic mark *melius* [better].

Anno 1660. Completo. II. Classis	Ordo Stellaru m	Declinat io (G. ')	Distantia à praeced. (G. ' ")	Differentia Asc. Rectae (G. ' " ")	Ascensio Recta (G. ' " ")

[For the year 1660 completed, Second Class. Sum of the differences: 360° 0' 0".]

- But that we might also explore as fully as possible the principal Southern stars observable from our latitude, we started from the same Lucida of Aries, and proceeded through Orion, the Dogs, and Hydra to the Tail of the Lion [Cauda Leonis]; for from there we came back to the Lucida of Aries, the remaining stars being understood as the same ones already given in the first and second classes. It is clear from the first and second classes that the sum of the differences of right ascension from the Lucida of Aries up to the Tail of the Lion, inclusive, must be 145° 52'.

	Summa Different iarum			145	5 5 0 6 ' "

[For the year 1660 completed, Third Class. Sum of the differences: 145° 50' 56".]

There is wanting a second of 64", which, distributed among the four later stars, gives us their right ascension, as below.

(Star)	Different. Asc. (G. ' ")	Ascens. Recta (G. ' ")
Lucida Υ		27 1 5 8
Aldebara	37	5 0 64 6 5 8
Orionis humerus	20	3 1 84 1 1

(Star)	Different. Asc. (G. ' ")	Ascens. Recta (G. ' ")
lucid.		8 0 6
Procyon	26	1 1 110 2 3
		2 6 2 2
Hydrae Cor	27	1 5 137 4 2
		9 0 2 2
Cauda ϱ	35	1 3 172 5 5
		1 6 3 8
Summa Differet.	145	5 0 2

[Difference of right ascension; Right Ascension. Sum of the differences: 145° 52' 0".]

From this it then follows that from the Lucida of Aries to the Heart of Hydra the sum of the differences is 110° 40' 24". Let us see whether it is just so large by way of Rigel [Regel] and Sirius.

(Star)	Declinatio (G. ')	Distantia (G. ' ")	Differentia Ascens. (G. ' ")	Ascensio Recta (G. ' ")
Lucida Υ	21	4 9 $\frac{1}{2}$		27
Aldebara	15	4 35 6 $\frac{5}{6}$	37	64
Regel [Rigel]	8	3 30 A 7	0	40
Sirius	16	1 30 A 6	0	40
Hydrae Cor	7	1 40 1 $\frac{1}{2}$ A	40	137
Summa Differenti arum			110	

[Declination; Distance; Difference of ascension; Right Ascension. Sum of the differences: 110° 40' 20".]

So only 4" are wanting, which, if they are restored to the right ascension of the Heart of Hydra, it will remain as above.

7. There follows the Fourth Class, whose right ascension has been investigated by us through trigonometric labor — from the declinations and from the distances on either side, or from neighboring fixed stars whose right ascension was already determined in the three preceding classes. For from two methods that yielded the same right ascension, we chose the one that held the middle, arithmetically, between the extremes. This was the very thing Tycho [Tycho Brahe] accomplished in volume 1 of the *Progymnasmata*, page 229, for 12 stars. But we, in many cases, do not record the extreme right ascensions, for the sake of avoiding prolixity; rather, it is easy to recover them from the difference of right ascension applied to the right ascension of the first or second class of stars. For example: the difference of right ascension at the Northern Horn of Taurus [Cornu Boreale Tauri] is, by us, 12° 5' 58"; and the right ascension of Aldebaran, from what was said, is in the first class 64° 6' 58". Therefore the right ascension of the said Northern Horn comes out to 76° 12' 56". Again, the difference of right ascension between the Northern Horn of Taurus and the Head of Pollux is 34° 53' 58"; and the right ascension of Pollux, from the first class, is 111° 6' 0". So, subtracting this difference, the right ascension of the Northern Horn comes out to 76° 12' 2". The mean, then, between this and the earlier value, is 76° 12' 29", or 30". And so in the rest we have done likewise: where one second, or two, fell short of round measure, or were in excess, we have rounded the number to the nearest, or padded it out, recording a rounded number, so that the longitude and latitude might more easily be gathered from it afterward, without danger of the error that tends to creep in from the proportional part of the fractions of the others.

[For the year 1660 completed. Declination; Distance from the preceding;
Difference of ascension; Right Ascension.]

8. By almost the same method we have determined certain other right ascensions of fixed stars, ones that are observable in our horizon and that can serve astronomers — whether for determining the places of the planets or the moments of times. But after we have searched out the longitudes and the motion of longitude, then at last we shall reduce the right ascensions of these same stars, together with their declinations, to the year 1700 — and perhaps to 1800.

CAPUT XVIII.

De Longitudine, ac Latitudine Fixarum ex Nostris Observationibus.

[On the Longitude and Latitude of the Fixed Stars from Our Own Observations.]

[Margin: 1. The latitude of the fixed stars is unchanging.]

We have taught that the latitude of the fixed stars is perpetually one and the same, in book 6, Caput 15 of the *Almagestum Novum*; so much so that the fixed stars by their own motion describe circles parallel to the ecliptic. For the diversity of latitude found in the same star by Tycho is not sufficient evidence of a true change, but rather of some fallacy in his other observations, from which that latitude is derived — namely, the declinations, the distances of the fixed stars among themselves, and the distances of the poles of the ecliptic and of the equator. Indeed, it was for these very causes that we ourselves obtained a result differing from the Tychonic one not only in latitude, but also in longitude and right ascension.

2. Now therefore, with the declination of the principal fixed stars determined, and the right ascension established in Caput XVI and XVII, and the distance of the poles fixed at $23^{\circ} 30' 20''$, from what has been said...

[Margin: Longitudo, & Differentia Longitudinis Fixarum constans. — The longitude, and the difference of longitude of the fixed stars, is constant.]

about the Sun, it will not be difficult to investigate their latitude and longitude up to the end of the year 1660, by Problem 1, Caput 12, book 6 of the *Almagestum Novum*, where we set out this problem; and we did the same in our *Primum Mobile Reformatum*, Caput 8. For the present it suffices to recall here the scheme set out in the preceding chapter, and the example introduced there concerning the Lucida of Aries — for by its model we have, with trigonometry, diligently inquired into the longitudes and latitudes of the rest, and have entered them in the following table.

3. Moreover, once the longitude of the fixed stars has been ascertained, if it be compared with the longitude observed and corrected by the Ancients, it will be established that this motion of the fixed stars is perpetually equal and uniform — which we also taught in book 6, Caput 16 and 17 of the *Almagestum Novum*. For since, from the invariable distance of the fixed stars among themselves, and from the unchangeable latitude, it follows necessarily that the difference of longitude between any two fixed stars is always the same — being once for all fixed — from this it will be no laborious matter to ferret out the longitudes of the remaining fixed stars from the Copernican or the Rudolphine catalogue, by first noting the discrepancy between the Tychonic and our own difference of longitude of two fixed stars, and then, in accordance with that discrepancy, correcting the remaining differences with the proportion preserved. So that what has just been said may not seem too obscure, it is worth setting it out more clearly by a single example.

4. For the year 1660: the longitude of the Lucida of Aries is, by us, $2^{\circ} 54' 42''$ of Taurus; and that of Aldebaran, $5^{\circ} 1' 43''$ of Gemini. Therefore the difference of longitude is $32^{\circ} 7' 1''$. But by Tycho, at the same epoch, the longitude of the Lucida of Aries is $2^{\circ} 57'$ of Taurus, and that of Aldebaran $5^{\circ} 3' 30''$ of Gemini. Therefore the difference of longitude is $32^{\circ} 6' 30''$. The discrepancy, then, of these differences is $0^{\circ} 31''$, by which Tycho falls short of ours. Accordingly, if we add the same number of seconds to the other differences that lie between the remaining stars of Aries and Taurus, they will turn out more correct. And it comes to virtually the same thing if the excess of longitude found in the Lucida of Aries is subtracted from the Tychonic longitude of the remaining fixed stars of Aries, whose longitude from our own observation is not yet more certainly known. By this device we shall construct the Catalogue of the fixed stars — marking, however, with a distinct character, those fixed stars whose longitude and latitude have been determined from our own observation. This catalogue we shall place at the end of the work, together with the other tables. Meanwhile we here subjoin five fixed stars which we shall use in what follows, their longitude and latitude deduced from the declination of Caput XVI and the right ascension of Caput XVII, and the distance of the poles being $23^{\circ} 30' 20''$.

CAPUT XIX.

De Motu Longitudinis Fixarum eiusque Quantitate, & Aequalitate.

[On the Motion of Longitude of the Fixed Stars, its Magnitude and Uniformity.]

Of all the fixed stars, the most celebrated hitherto for the motion of longitude has been Spica of Virgo [Spica Virginis] — and deservedly so, since, when it began to be observed by the Ancients — namely by Timocharis [Timocharis] and Hipparchus [Hipparchus], by Pto-

and to Ptolemy as well it [Spica] lay near the point of the autumnal equinox, having received a very slight declination and a latitude scarcely 2 degrees. In this latitude, indeed, Ptolemy, Tycho [Tycho Brahe], and we are very nearly in agreement: by Ptolemy it is about 2 degrees south, by Tycho 1 degree 59 minutes, and by us 1 degree 59 minutes 30 seconds.

Equally celebrated, and useful for this present work, is Basiliscus, or Regulus [Cor Leonis], the bright star in the heart of Leo. Because of its nearness to the ecliptic, it does not depart in latitude toward the north by more than 10 minutes — by Ptolemy, or 26 minutes by Tycho, or 26 minutes 20 seconds by us.

To these we shall add Aldebaran, the Head of Pollux, and Cor Scorpii [the Heart of Scorpio], because the declination of these stars was observed not only by the ancients but also by the more recent astronomers. Accordingly, from this declination and from our own latitude (which I shall discuss at the end of the preceding chapter) and from the obliquity of the ecliptic at 23 degrees 30 minutes 20 seconds, we shall derive their longitude. Then, from the advance of that longitude across intervals of time, we shall establish the annual motion of the

fixed stars — and this without neglecting the opinions of others. Indeed, before our own settled view, I shall set out those opinions, which I have nevertheless reported more fully in *Almagestum Novum* (Book 1, *Almagesti Novi* Cap. 16).

[Margin: The opinions on the motion of the fixed stars.]

[Margin: 1. First opinion.]

1. The first opinion, then, is that found in Ptolemy (Book 7, *syntaxis* Cap. 2 and 3), and it was Hipparchus's and Ptolemy's own: that the fixed stars advance not less than 1 degree in 100 years — that is, no less than 1 degree in longitude over 100 years. But since Hipparchus had derived this motion from the observations of Timocharis, which (as Ptolemy testifies, *Cap.* 3) were too crude, Hipparchus himself judged this. And Ptolemy, on account of the brief interval of time, very close to his own, did not dare to depart from Hipparchus. Ptolemy's words about Hipparchus are these: "He was, however, in doubt, as he asserts, since neither could he reckon the observations made in Timocharis's time as reliable — because they were captured too roughly — nor had enough time yet elapsed to suffice for a thorough understanding of this matter." Nevertheless, Alfraganus [al-Farghānī] and Proclus subscribed to Ptolemy.

[Margin: 2. Albategnius's opinion.]

2. The second was that of Albategnius [al-Battānī] (*Cap.* 51, *De scientia Stellarum*), who, from the place of Regulus and of the Northern star in the Forehead of Scorpio observed in his own time, and afterward observed by himself, laid down that the fixed stars complete one degree in 66 years. Following him in this hypothesis are Alfonso, King of Castile [Alfonso X], Rabbi Levi [Levi ben Gershon / Gersonides], Abraham Zacutus [Abraham Zacuto], Augustinus Riccius [Augustino Ricci], Petrus Nonius [Pedro Nunes], and others, as cited in *Almagestum Novum* (Book 6, *Almag. Novi* Cap. 16), where I also reported the opinion on the motion of trepidation [motus Trepidationis] and its anomaly, which I refuted in Cap. 17. But now I shall show that Albategnius's longitude for Regulus is itself in error, as I shall say in observation 17.

[Margin: 3. Tycho's opinion.]

3. The third opinion was that of Tycho Brahe (*Progymnasmata* tom. 1, pag. 253), who, using Regulus in the first place, and Spica, held that the annual motion of the fixed stars is 51 seconds — that is, that they complete one degree in 70 years and 7 months. For Copernicus had observed Spica in Libra at 17 degrees 3½ minutes in the year 1515 (with the latitude of the pole, however, corrected); and

Tycho himself, after 70 years — namely in the year 1585 — found it again at 18 degrees 3 minutes of Libra. Moreover, Hipparchus had observed Regulus in the year 50 of the third period of Callippus, in Cancer at 29 degrees 50 minutes. Tycho, after 1713 years — that is, in the year of Christ 1585 — observed the same star in Leo at 24 degrees 5 minutes; and Albategnius in the year of Christ 880 had marked Regulus in Leo at 14 degrees 5 minutes. He admits, however, that Spica was observed by Timocharis in the year 454 of Nabonassar in Virgo at 22 degrees 20 minutes, and by Ptolemy in the year of the Lord 139 in Virgo at 26 degrees 40 minutes. Comparing these with the place observed by himself, the annual motion comes out as 49¼ seconds from the one and 53½ seconds from the other; hence he chose the mean, as above. But the places of these stars must nevertheless be corrected on account of the displacement of the poles, which we shall do below. Tycho meanwhile decides to compare his foundations against the table.

| Timoch[aris] Anno ante Chr. 294. | Spica ♄ gr. 22. 20'. | | Ptolemæus Anno Chr. 139. | Spica ♄ gr. 26. 40'. | | Copernicus Anno Chr. 1515. | Spica ♄ gr. 17. 3½. | | Tycho Anno Christi 1585. | Spica ♄ gr. 18. 3. | | Hipparchus Ann. ante Chr. 128. | Regulus ♄ gr. 29. 50. | | Albategnius Anno Christi 880. | Regul. ♄ gr. 14. 5. 0. | | Tycho Anno 1585. Hipparc h.	Tyc h.	24 15	1713	51 0
Hipparc h.	Alb at.	14 15	1006	51 ferè
Albateg n.	Tyc h.	10 0	705	50 54

[Margin: 4. Longomontanus's opinion.]

4. The fourth opinion was that of Longomontanus (*Astronomia Danica*, Book 1, *Theoric. in the Commentary on the Fixed Stars*), who, from Ptolemy (Book 7, *Cap.* 3 and 4), sets out four fixed stars observed by the ancients and by Tycho, as follows:

Observatores.	Anni Nabonassaris.	Locus in Zodiaco — Gr. '
Timocharis	466	Spica ♀ 22 30
Hipparchus	630	Spica ♀ 24 25
Tycho	2350	Spica ♀ 18 16
Ptolemæus	886	Regulus ♀ 3 53
Albategnius	1626	Regulus ♀ 14 27
Tycho	2350	Regulus ♀ 24 17
Timocharis	454	Bor. frons [♄] 1 58
Tycho	2350	Scorpij [♄] 27 36
Timocharis	465	Pleiadum ♀ 29 32
Tycho	2350	Lucida ♀ 24 24

From these intervals of time and the advance of the stars he gathers their annual motion, as below:

Ab	Ad	" '"
Hipparcho	Tychonem	49 46
Ptolemæo	Albategnium	51 0
Ptolemæo	Tychonem	49 37
Timocharide	Tychonem	49 10
Albategnio	Tychonem	48 14
Timochar.	Ptolemæum	46 0
Timochar.	Hipparchum	44 0

But Longomontanus, from this, chooses a mean motion of the fixed stars of 49 seconds 45 thirds; and over $72\frac{1}{3}$ years, the motion of one degree. He could just as well have settled on a motion of 50 seconds. And in correcting their places he uses the prosthaphaeresis [Prosthaphaeresis] of the equinoxes — which is the more obscure for the motion of the fixed stars — and he assumes the same.

[Margin: 5. Lansbergius's opinion, conflicting.]

5. The fifth opinion is that of Lansbergius [Philippe van Lansbergen], who (in his *Thesaurus observationum*, pag. 160) says that the fixed stars advance daily by $8'' 25''' 12''' 32'''$, and complete one revolution in 28000 years — from which it follows that the fixed stars complete one degree in $77\frac{2}{3}$ years, and in single years $46''\frac{2}{7}$. But, given the revolution stated above, this is mistaken. For if you reckon

through the days of a common year, 365 — namely the daily motion of 8'' 25''' 12''' 32''' — the annual motion will be in seconds 51'' 14''' 11''' 14''' 40'''; so far does Lansbergius himself contradict his own figures.

[Margin: 6. Kepler's opinion.]

6. The sixth opinion, that of Johannes Kepler [Johannes Kepler], is amphibious: for although with Copernicus he reckons that the fixed stars do not move, yet with Tycho — on the supposition that they do move — he holds that their annual motion is 51 seconds, as is clear from the *Rudolphine Tables* (pag. 43 and 115), where he says 25411 years; and that the sidereal years are equal to the solar tropical years; and from the *Epitome of Copernican Astronomy* (pag. 396), where he says that the fixed stars completed [a revolution] from Hesiod to the year of the Lord 1618 in about 2400 years — so that in 1 year the second figure is 51''. Nor does Vuendelinus [Govaert Wendelen] differ much from this in his *Idea Tabularum* (pag. 28), when he holds that 25519 sidereal years equal [the tropical years]; from which it follows that the fixed stars advance yearly by 50'' 47'''. Gassendus [Pierre Gassendi], however, in his *Institutio Astronomica*, sets the fixed stars to complete their full period in 25000 years and 1 degree in 70½ years, and in single years 51'' 19''' 24'''.

[Margin: And Wendelen's.]

[Margin: And Gassendi's.]

256

[Margin: 7. Bullialdus's opinion.]

7. The seventh opinion was that of Ismael Bullialdus [Ismaël Boulliau] (*Astronomia Philolaica*, Book 5, Cap. 3, and in the *Tabulae Philolaicae*, pag. 10), where he finally chooses an annual motion of the fixed stars of 51 seconds, following Tycho — though the observations of Regulus were corrected by him as follows:

Observatores.	Anni Nabonassari.	Reguli locus. Sig. Gr. '
Hipparchus	621	♄ 29 50
Ptolemæus	886	♄ 3 42
Albategnius	1627	♄ 14 5
Tycho	2350	♄ 24 17

Hence the annual motion of the fixed stars:

Ab	Ad	" "' '"
Hipparcho	Ptolemæum	52 31 42
Hipparcho	Albategnium	50 59 38
Hipparcho	Tychonem	50 54 29
Ptolemæo	Albategni	50 26 27
Ptolemæo	Tychonem	50 36 53
Albategnio	Tychonem	50 47 18

He admits, moreover, from the southern latitude of Spica — by Hipparchus the northern declination of Spica being 0 degrees 36 minutes — that in the year of Nabonassar 621 its place lies in Virgo at 23 degrees 50 minutes; and from the place of the same star found by Tycho in the year of Nabonassar 2350 in Libra at 18 degrees 16 minutes, the annual motion of the fixed stars follows as below:

"	"'	'''	'''	'''	'''
50	33	39	39	52	22

Then, from the Persian and Arabic Tables, which are kept in the Library of the Most Christian King [the French royal library], he sets down these observations, or places, of Regulus:

Tabulæ	Anni Arabū	Anni Christi	Reguli locus. Sig. Gr. '
Albategni		879	♌ 14 5
Azophi	325	936	♌ 15 12
Persicæ	509	1115	♌ 17 30
sub Persicæ		1364	♌ 20 40
Tychonica		1600	♌ 24 17

Hence the annual motion of the fixed stars:

Ab	Ad	" "' '"
Albategnio ad	Azophi	69 18 37
Albat.	Persicas Tab.	52 7 7
Albat.	sub Persicas	48 51 57
Azophi	Persicas Tab.	46 31 0
	sub Persicas	45 5 20
Tab. Persicis	sub Persicas	45 46 59

Ab	Ad	" "' '"
Tab. Persicis	Tychonem	50 14 49

Numerical impossibles: in the "Albategnio ad Azophi" row the seconds-of-degree figure is 69, exceeding 60 (transcribed as printed — flagged).

[Margin: Petavius's opinion.]

This I add for the sake of his erudition, to which I add another opinion of the French astronomers, namely that of Dionysius Petavius [Denis Pétau] in his *Uranologia*, where he chooses an annual motion of the fixed stars of 50 seconds and 1 degree in 72 years.

[Margin: 8.]

8. The eighth opinion, our own, was once set out in *Almagestum Novum* (Book 6, Cap. 16): that the annual motion of the fixed stars is 50 seconds, with Petavius, and one degree in 72 years. These motions cannot complete a full period in less than 25920 years. Now, however, with the places of the fixed stars corrected, and the obliquity of the ecliptic established at 23 degrees 30 minutes 20 seconds, we are compelled by new observations to test our results carefully — adding our own every five years, in order to verify those stars, which were newly added at the end of the preceding chapter, and selecting the more notable observations.

SPICAE Virginis Observationes. [Observations of Spica Virginis]

[Margin: Spica's observations.]

1. Timocharis, on the testimony of Ptolemy (Book 7, Cap. 3), in the year 454 of Nabonassar — which was 295 years before Christ — observed Spica in Virgo at 22 degrees 20 minutes.
2. Timocharis, again from Ptolemy, in the year 466 of Nabonassar, 283 years before Christ, observed Spica in Virgo at 22 degrees 30 minutes; but these observations Hipparchus reckoned crude, as is shown above with Ptolemy.
3. Hipparchus, in Ptolemy, in the year 50 of the third period of Callippus, 128 years before Christ, observed Spica in Virgo at 24 degrees; but he is also said to have observed its northern declination as 36 minutes, from which, and from our southern latitude of 1 degree 59 minutes 30 seconds, its place follows at 23 degrees 30 minutes [of Virgo].

4. Ptolemy (Book 7, Cap. 3) in the year 1 of Antoninus the Emperor — that is, the year of Christ 137 — observed Spica's southern declination as 30 minutes; hence, and from the latitude of the star itself, and from the obliquity of the ecliptic stated above, its place follows in Virgo at 26 degrees 40 minutes 25 seconds. In this it is remarkable that he agrees with us in placing Spica at 26 degrees 40 minutes of Virgo, and yet differs in the obliquity of the ecliptic — and so this [agreement] is false.

5. Abraham Zaguth [Abraham Zacuto], in the work of his disciple Augustinus Riccius [Augustino Ricci], in his *Tractatus de motu octavae sphaerae*, in the year of the Lord 1474, is said to have observed Spica in Libra at 17 degrees 10 minutes; but this conflicts too much with Tycho and with us.

6. Copernicus (*De Revolutionibus*, Book 3, Cap. 2) observed Spica's declination in the year of the Lord 1515 at 8 degrees 36 minutes south, at Frauenburg [Fruemburgi], where he thought the altitude of the pole to be 54 degrees 19 minutes 30 seconds — whereas by Tycho (*Progymnasmata* tom. 1, pag. 34 and 220) it comes to 54 degrees 22 minutes 15 seconds; and so the more correct declination of Spica was 8 degrees 33 minutes 15 seconds. Hence, by our latitude and the obliquity stated above, its place is in Libra at 17 degrees 2 minutes 50 seconds.

7. Copernicus, as Lansbergius narrates (Book 3, Cap. 2), in the year of the Lord 1525 observed Spica's meridian altitude at 27 minutes. The altitude of the equator at Frauenburg being 35 degrees 37 minutes 45 seconds, the southern declination of Spica then comes to 8 degrees 37 minutes 45 seconds — whence, by our latitude and obliquity, its place is in Libra at 17 degrees 14 minutes 54 seconds. Let Lansbergius dissemble while he idly grumbles, or slyly correct the altitude of the pole — he gathers this here gratuitously from the *Thesaurus* (pag. 156, *grad.* 17 minutes 35 seconds), having nevertheless freely admitted the refraction.

8. Joannes Stadius [Johannes Stadius], in his *Commentary on the Fixed Stars* (Cap. 1), says that in the year 1559 he observed at Brussels [Bruxellis] the meridian altitude of Spica at 29 degrees 52 minutes; whence the altitude of the pole follows at 51 degrees 20 minutes. From this he gathers Spica's southern declination at 8 degrees 48 minutes — but from our *Geographia*, and from the altitudes of the latitudes of other places, it is established from these observations that the altitude of the pole at Brussels is 50 degrees 48 minutes; and, the altitude of the equator [being so], Spica's declination is 9 degrees 20 minutes south. So, omitting his observation as worthless — together with that of Vuernerus [Johann Werner] and

Cardanus [Girolamo Cardano], on grounds adduced by Tycho (tom. 1 *Progymnasmata*, pag. 221)...

9. Tycho Brahe, in the year 1585, found Spica in Libra at 18 degrees 3 minutes, as he has it (tom. 1 *Progymnasmata*, pag. 232) — corrected from chapter 12. By our correction it is at 18 degrees 2 minutes 41 seconds.

10. Paulus Hainzelius [Paul Hainzel], Senator of Augsburg, in Tycho (tom. 1 *Progymnasmata*, pag. 365), began in the year 1573 to observe Spica's southern declination at 8 degrees 52 minutes; whence, our latitude and the obliquity of the ecliptic being supposed, its place follows in Libra at 17 degrees 51 minutes 50 seconds.

11. Lansbergius, as he reports in his *Thesaurus observationum* (pag. 157), at the beginning of the year 1599 observed Spica's meridian [altitude] at 29 degrees 30 minutes — which, when reduced for refraction, comes to 29 degrees 29 minutes. But there the altitude of the equator, from our *Geographia Reformata*, is 38 degrees 29 minutes 30 seconds; therefore Spica's southern declination was 8 degrees 59 minutes 30 seconds; and from our latitude its place is in Libra at 18 degrees 11 minutes 20 seconds.

12. Lansbergius, on the same page (pag. 157), reports that at the beginning of the year 1630 he believed he had observed at Middelburg [Middelburgi] Spica's meridian [altitude] at 29 degrees 20 minutes; but there the altitude of the equator is 38 degrees 30 minutes; therefore Spica's declination at that time was 9 degrees 10 minutes south; and from our latitude and the obliquity of the ecliptic its place is in Libra at 18 degrees 38 minutes 50 seconds.

13. Petrus Gassendus [Pierre Gassendi], in volume 4 of his works, in the *Commentary on Celestial Matters* (pag. 313), reports that in the year 1636, on 15 May, he observed Spica's meridian altitude at Aix [Aquis Sextiis] at 27 degrees 13 minutes — and the altitude of the equator being 46 degrees 27 minutes, Spica's declination there was 9 degrees 14 minutes south; and from our latitude of the star and the obliquity of the ecliptic, its place is in Libra at 18 degrees 49 minutes 10 seconds.

14. We, finally, together with Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], from several...

several observations of the declination, and so forth, finally determined the place of Spica in the year 1660 completed, at 19 degrees 6 minutes of Libra, by what was said in the preceding chapter at the end.

REGVLI Observationes. [Observations of Regulus]

15. Hipparchus, in Ptolemy (Book 7, Cap. 2), in the year 50 of the third period of Callippus — namely 127 years before Christ — is reported to have observed Regulus, or Cor Leonis [the Heart of Leo], in Cancer at 29 degrees 50 minutes. He is said to have observed its declination at 20 degrees 40 minutes. From Regulus's latitude, by what was said in the preceding chapter — namely 26 degrees 10 minutes north — and from the obliquity of the ecliptic, its place comes in Cancer at 29 degrees 51 minutes 10 seconds; therefore its place at that time was in Cancer at 29 degrees 50 minutes 0 seconds.

16. Ptolemy (Book 7, Cap. 3) reports that he observed Regulus from himself in the year 1 of the Emperor Hadrian [Adriani] — that is, the year of Christ 137 — therefore [by] our latitude and the obliquity of the ecliptic, it was in Leo at 3 degrees 34 minutes 55 seconds.

17. Albategnius (*Cap. 51, De Scientia Stellarum*) says: "In the year of Nabonassar 1627 — that is, of Christ 879 — Regulus was observed by me in Leo at 14 degrees." But Longomontanus, *as above* (Book 1, *Cap. 14*, pag. 27), and Lansbergius in his *Thesaurus* (pag. 154, *grad. 14, min. 19*), say 14 — and because Ptolemy (Book 7, Cap. 2) says that, in the year 1 of Antoninus the Emperor, Regulus was in Leo at 2 degrees 29 minutes; and since Albategnius asserts that, from Regulus's observations, he had added to all the Ptolemaic longitudes of the fixed stars 11 degrees 50 minutes — yet my own codex of Ptolemy has, in the year 1 of Antoninus, the observation of Regulus at 2 degrees 30 minutes of Leo. Nor is it perhaps a corrupt number; for in the Tables it is found to be the same — and therefore Regulus, by Albategnius, would be in Leo at 14 degrees 20 minutes, neither 11 degrees 50 minutes nor 11 degrees 30 minutes. And so I reconcile [it] with 2 degrees 30 minutes nearly. For under the same error the number of minutes subtracted by 30 degrees [of the] places of the Ptolemaic fixed stars adds 11 degrees and a half — that is, a third part; this, with the half added, is twenty-five. But there the same is asserted: Ptolemy found Cor Leonis at 2 degrees and a sixth of Leo — here at 2 degrees 10 minutes; but the [progress] of Leo, that is the advance, comes to 11 degrees 50 minutes. And so it is concluded with grade 14 nearly. For under the same error the number of minutes subtracted joins together the places of the Ptolemaic fixed stars at 14 degrees 20 minutes, neither

perhaps in Leo at 14 degrees 5 minutes — neither corrupted — by Albategnius, says 11 degrees 30 minutes. And so I reconcile [it] with grade 14 nearly.

[Margin: Reduction of the latitudes of Albategnius, on this passage.]

But my Basiliscus codex of Ptolemy has Cor Leonis in the year 1 of Antoninus at 2 degrees 30 minutes of Leo, and soon afterward, at the distance from the tropic, the [value] mentioned 8 degrees 7 minutes — that is, 2 degrees 30 minutes of Leo, and the rest 32 degrees 30 minutes. But however much is to be retained in Ptolemy, the grade of Leo is 2 nearly; but it is not on that account retained in Albategnius's codex for emendation, since [...] it is 14 of Leo. Nor indeed did Albategnius place his own advance, since the grade of the place added a cause, that the fixed stars had progressed 11 degrees 50 minutes — but he saw them advanced [as] thus progressed, since he believed Regulus had advanced in Leo at 11 degrees 50 minutes. He reckoned this to have been in Ptolemy's time at 11 degrees 50 minutes [of] Leo; but if he had had an emended codex he would have read it — to the Ptolemaic grades he would have added something. But truly it was at 3 degrees 35 minutes of Leo, nearly, as long as the number of degrees from the year of Nabonassar 886 to 1627 — namely the years 741 in full — and so the advance of Regulus comes to be, and he would require to advance to one degree; this Albategnius and the Arabs held. And so, hence, it appears that Lansbergius fell into the fallacy which the logicians call *conversionis* [of conversion].

[Margin: Lansbergius's error.]

18. Azophi [al-Ṣūfī], the Persian astronomer, or *Ebennen Sophi*, as the *Bibliotheca* of Forcalquier [Forcalcari] promises [in] Bullialdus (Book 5, *Astronom. Phil.* cap. 3), and Gassendus in his *Epistolae*, records Regulus in Leo at 15 degrees 12 minutes — that is, in the Arab year 325, namely the year of Christ 936.

19. The Persian mathematicians, in the same Bullialdus, from a manuscript of the Royal Library [Regia Bibliotheca], in the year of the Lord 1115, on 6 June, established Regulus in Leo at 17 degrees 30 minutes — you do not know whether from observation, or from their own anticipated hypotheses.

20. Paulus Hainzelius [Paul Hainzel], in Tycho (tom. 1 *Progymnasmata*, pag. 364), in the year of the Lord 1573, began to observe Regulus's meridian altitude at 55 degrees 19 minutes $\frac{1}{2}$ and its declination at 14 degrees 1 minute $\frac{1}{2}$ — with Gögging [Gegginga] near Augsburg, the altitude of the pole being 48 degrees 21 minutes, as Lansbergius has it in his *Thesaurus* — none other. Hence, from that declination and from the latitude, Regulus's place follows in Leo at 23 degrees 50 minutes 26 seconds.

21. Tycho, in the year 1585, observed Regulus in the Lord [Domini] in Leo at 24 degrees 4 minutes 40 seconds, as he has it (tom. 1 *Progymnasmata*, pag. 232); but it must be corrected by what was said in chapter 12, so that it stands in Leo at 24 degrees 3 minutes 2 seconds, by Tychonic observations, the obliquity of the ecliptic being truly [supposed].

22. Lansbergius, in his *Thesaurus* (pag. 155), reports an observation: he narrates that to himself, in the year 1599 at its beginning, the meridian altitude of Regulus was 55 degrees 24 minutes $\frac{1}{2}$. The altitude of the equator there, for us, is 38 degrees 29 minutes 30 seconds; therefore the northern declination of Regulus is 13 degrees 55 minutes $\frac{1}{2}$; and from what was said in the preceding chapter — 26 degrees 10 minutes north latitude — hence by the obliquity of the ecliptic our place for Regulus follows in Leo at 24 degrees 5 minutes.

23. Lansbergius, in the same place, narrates that at the beginning of the year 1630 at Middelburg [Middelburgi] in Zeeland, through our altitude of the equator, the meridian altitude of Regulus was observed to be 55 degrees 16 minutes; therefore Regulus's declination is 13 degrees 46 minutes; and from our latitude and the obliquity of the ecliptic, its place is in Leo at 24 degrees 40 minutes.

24. We, finally, in the year 1660 completed, from many observations, determined — as we resolved at the end of the preceding chapter, with Father Grimaldi — the place of Regulus in Leo at 25 degrees 4 minutes 45 seconds.

ALDEBARAE, seu Oculi Australis Tauri, seu Palilicij Observationes. [Observations of Aldebaran, or the Southern Eye of Taurus, or the Palilician star]

25. Hipparchus, in Ptolemy (Book 7, Cap. 2), in the year 265 before Christ [...] before Antoninus the Emperor, in the first year [...] before Christ, in the year 128, observed Aldebaran's northern declination at 9 degrees 45 minutes; and from what was said at the end of the preceding chapter, its [latitude] is at 5 degrees 30 minutes 50 seconds — and the obliquity of the ecliptic at 23 degrees 30 minutes 20 seconds; therefore its place was then in Gemini at 10 degrees 25 minutes 53 seconds.

26. Ptolemy (Book 7, Cap. 3) reports the same: in the year 1 of Antoninus the Emperor — namely of Christ 137 — Aldebaran's northern declination was observed at 11 degrees; hence, and from our latitude and the said obliquity of the ecliptic, its place was then in Gemini at 14 degrees 38 minutes 7 seconds.

27. Paulus Hainzelius [Paul Hainzel], in Tycho (tom. 1 *Progymnasmata*, pag. 365), in the year 1573 at its beginning, observed Aldebaran's northern declination at 15 degrees 4 minutes 5 seconds; whence, by our latitude and the obliquity of the ecliptic, its place is in Gemini at 3 degrees 18 minutes 48 seconds.

28. Tycho, in those same days — that is, in the year 1585 — by our observations, finally got Aldebaran in Gemini at 3 degrees 59 minutes 49 seconds, more correct than Tycho's (tom. 1 *Progymnasmata*, pag. 232) — it had been in Gemini at 4 degrees, precisely [by] Tycho.

29. Lansbergius, at Gögging [Goësae], in the year of the Lord 1601 at its beginning, observed Aldebaran's meridian altitude at 54 degrees 8 minutes; the altitude of the equator being 38 degrees 29 minutes 30 seconds, therefore the declination was 15 degrees 38 minutes 30 seconds; from which, and from our latitude and the obliquity, its place is in Gemini at 4 degrees 18 minutes 20 seconds.

30. We, finally, together with Father Grimaldi [P. Grimaldo], from our observations, determined — at the end of the preceding chapter — to the year of the Lord 1660 completed, Aldebaran's place in Gemini at 5 degrees 1 minute 43 seconds.

Liber IV — De Stellis Fixis

Caput XIX (continued) — On the Motion of the Longitude of the Fixed Stars, its Quantity and Uniformity

ANTARES, or the Heart of the Scorpion — Observations

31. Hipparchus, in Ptolemy [Ptolemaeus] (*Almagest* II.3): in the year 128 before Christ, as noted above, he observed the southern declination of the Heart of the Scorpion to be 19°. But from the end of our preceding chapter its southern

latitude is $4^{\circ} 26' 30''$, and with the obliquity of the ecliptic taken perpetually as $23^{\circ} 30' 20''$, Antares was therefore at that time in Scorpio $9^{\circ} 48' 12''$.

32. Ptolemy, in the same place, attests that in the year of Christ 137 he himself observed the southern declination of Antares to be $20^{\circ} 15'$. Therefore, from the aforesaid latitude and from the obliquity of the ecliptic, it was in Scorpio $13^{\circ} 46' 30''$. Lansbergen [Lansbergius] puts it in the year 139, and in the second year of Antoninus.

33. Tycho [Tycho Brahe], from what was said in Caput XII — yet corrected by us — in the year of the Lord 1585 completed obtained Antares in Sagittarius $4^{\circ} 5' 18''$.

34. Lansbergen, at the end of the year 1600, as he relates in his *Thesaurus* (p. 160), observed the meridian altitude of Antares to be $13^{\circ} 8'$ by apparent reckoning, or truly $13^{\circ} 2'$, or rather $4'$ [?]. (Goes, however [Goësae, i.e. as reported by Goes], gives the altitude above the equator as $38^{\circ} 29' 30''$.) Therefore the southern declination was $25^{\circ} 25' 30''$, and from the aforesaid latitude and obliquity its ecliptic place was in Sagittarius $4^{\circ} 18' 8''$.

35. We, together with Father Grimaldi [P. Grimaldo], from what was said at the end of the preceding chapter, found Antares at the end of the year 1660 to be in Sagittarius $5^{\circ} 1' 40''$.

POLLUX, or the Lower Twin's Head — Observations

36. Hipparchus, in Ptolemy (*Almagest* VII.3): in the year 127 before Christ he observed the northern declination of the head of the lower Twin to be 30° . Its latitude, from the end of the preceding chapter, is $6^{\circ} 38' 30''$ north, and with the obliquity of the ecliptic $23^{\circ} 30' 20''$, it was therefore at that time in Gemini $23^{\circ} 55' 40''$.

37. Paul Hainzel [Paulus Hainzelius], at the opening of the year of the Lord 1573, as Tycho records (*Progymnasmata*, vol. 1, p. 365), observed the declination of the head of the lower Twin to be $28^{\circ} 59'$. Therefore, from the latitude and obliquity of the ecliptic already set out, it was then in Cancer $17^{\circ} 10' 45''$.

38. Tycho, in the year 1585, from what was said in Caput XII, had the head of Pollux in Cancer $17^{\circ} 31' 28''$.

39. We, together with Father Grimaldi, from the end of the preceding chapter, establish the head of Pollux for the year 1660, completed from observations, in Cancer $18^{\circ} 31' 6''$.

From these observations, collated with one another, the comparisons in the following table are set before the eye, together with the annual motion of the fixed stars corresponding to the progression of the star and to the interval of time.

TABULA ARGUMENTI — For the Annual Motion of the Fixed Stars

This argument table (foot of left column, p. 258) continues the comparison series of the right-column tables. Columns: number of the observations compared (Ordo: from / to); the observers (Ab / Ad); the progression of *Spica*; the interval in years; and the annual motion (Motus Annuus, in seconds " and thirds ''').

Progressus Spicae

The following comparison tables occupy the right column of p. 258 (continuing onto p. 259). Each gives, for a given fixed star, the progression in longitude between two observers (Progressus), the interval in years (Intervallum, Annorū), and the resulting annual motion in seconds (") and thirds (").

Conclusiones de Motu Fixarum — Conclusions on the Motion of the Fixed Stars

Conclusion I. *The motion of the fixed stars in longitude is equal and uniform.*

[Margin: *Aequalitas Motus Fixarum* — The uniformity of the motion of the fixed stars.]

I judge this sufficiently and more than sufficiently established from the foregoing table, since most of the comparisons of the better observations confirm it, and they nearly agree on an annual motion of about 50". For although the single motion from Hipparchus to Ptolemy indicates a much slower motion at that time — namely 37" 40''' — yet observations within the same interval, between Hipparchus and Ptolemy, require 50" 49''', and for Antares 54" 13'''. We therefore now recognize as false the claim by which Ptolemy, deceived by fallacious and perplexing observations (*Almagest* VII.2 and 3), tried to establish that the fixed stars move uniformly by a single degree every hundred years, that is, by only 36" in one year [*secunda scrupula* 36"].

[Margin: continues — they accord on about 50".]

From this there also coincide both the Motion of Trepidation in longitude and the Anomaly of the precession of the Equinoxes, which were devised by the Alphonsines and many Jews and Arabs with no necessary — indeed not even very probable — foundation: with so great an effort of mind was the matter forced back by Copernicus into a theoretical hypothesis. Against these we have argued at sufficient length (*Almagestum Novum* III, ch. 28, and VI, ch. 17 and 18), to which we refer the reader.

Conclusion II. *The annual motion of the fixed stars is neither less than 49" nor greater than 51".*

[Margin: *Limites Motus Fixarum* — The limits of the motion of the fixed stars.]

The argument is this: as to the second of 49", all the comparisons of the preceding table support it, with a single exception; and as to the second part, of 51", thirteen of them. The comparisons of the observations indeed indicate a greater motion, yet the remaining fifty-nine comparisons establish the smaller, and especially those drawn from observations and intervals of years that are conspicuous and very great — such as the Hipparchan observations collated with the Tyconic, the Hainzelian, the Gassendian, and our own; for these make us more confident in the truth than the Hipparchan collated with the Ptolemaic, given Ptolemy's most friendly devotion to truth but his slight labor, since he was bent (as one set on establishing his own hypotheses, once conceived, from probabilities but with few arguments) on the whole undertaking. Finally, beyond the aforesaid limits of seconds, 49" and 51", Tycho, Longomontanus, Kepler, Boulliau [Bullialdus], Wendelin [Vuendelinus], and Petavius — most excellent astronomers of this or the preceding age, as we reported above — have not dared to fall short or to go beyond.

Conclusion III. *The annual motion of the fixed stars seems to us more probable at 50" 40"', yet in such a way that the remaining values comprised between the motions 50" and 51" are not lacking in their own probability.*

[Margin: continues.]

For the earlier part of the Conclusion, as in the book *On the Sun*, ch. 4, we establish the equinoctial year from a single observation of Hipparchus compared with our own, for three reasons:

[*right column, p. 259, continuing*] namely, on account of the excellence of that astronomer among the ancients; on account of the most certain of all observations of the equinoxes that he made, inasmuch as it was at the meridian,

free of any uncertainty of refraction, illuminated equally by the armilla on both sides; and because, of very many years' interval between us and Hipparchus, we have therefore preferred the single observation of his to the mixtures of all the others. So, in the annual motion of the fixed stars — on which the magnitude of the sidereal year depends — we prefer, for the same three reasons, the single observation of Spica by Hipparchus, compared with ours, above all others. For Timochares' observations Hipparchus judged too simple, crude, and ambiguous (so Ptolemy attests, *Almagest* VII.1 and 3); and Hipparchus, when he had said that Aristyllus and Timochares had written down observations of the fixed stars, but had explained little and had recorded ambiguous observations even of the non-wandering stars, added that Hipparchus's own written observations — those which we have chiefly consulted — are most fully explained and recorded. Pliny too (*Natural History* II.12) names him among the rest: "a sharer in the counsels of Nature, a man of genius," and above (II.26): "never sufficiently praised, since he proved as no other that the stars are our heritage" [*Caelum in haereditatem reliquit posteris*], and (II.108): "a man marvelous in every kind of industry."

Moreover, among all the fixed stars observed from Timochares onward, none is more celebrated than the Spica of the Virgin, being one of the first-magnitude stars nearest to the ecliptic of all, and nearest to that very point of the autumnal equinox; therefore it is suited to the precession of the equinoxes, that is, to the proper motion of the fixed stars, which Hipparchus first detected — something he would surely not have ventured to bring to light except after many and very accurate considerations of this star. Now indeed, from the place of Spica observed by Hipparchus and afterwards by us, there results the annual motion of the fixed stars of 50" 40"; and the same follows from the very Tychonic and our own observation, nor does the motion which is gathered from the Hipparchan observation of Spica and that of Tycho, Hainzel, Lansbergen, and Hortensius differ from it by more than 4", as anyone surveying the preceding table will fully see.

[Margin: *Hipparchi Laus* — In praise of Hipparchus.]

The observations of Regulus likewise support this motion to some degree: namely the Hipparchan with the Lansbergian, and the Hortensian; and the Ptolemaic with the Albategnian, the Hainzelian, the Lansbergian, and our own, collated.

As to the second part of the Conclusion, we labor not — since, between 50" and 51", the remaining probable terms have almost no decades of thirds by which one observation's comparison is not in any way diminished. We therefore do not disapprove, here, of the Tychonic motion of the fixed stars of 51", that is, the one

we adopted in *Almagestum Novum* VI.13; we chose 50" in the meantime, but now in preference to these we elect 50" 40". As to what may follow from this, or from others within the aforesaid limits to be chosen, it remains to be said in the following chapter.

CAPUT XX — On the Sidereal Year, and on the Apocatastasis or Revolution of the Fixed Stars, and their Position at the Beginning of the World

1. The Sidereal Year is nothing other than a single revolution of the Sun from some one fixed star back to that same star — a revolution which would be as great as the equinoctial year if the fixed stars did not advance

[p. 260, left column:]

by their slow proper motion, little by little, in the order of the Signs. But because they do so move, the Sun cannot, once it has completed an equinoctial revolution, reach in the same time the same fixed star with which it stood at the beginning of the said revolution, until it has traversed the whole ecliptic, plus that little space up to the point to which that fixed star has advanced. Hence the precession of the equinoxes arose, because the Sun returns to the equinox sooner than to the fixed star, which lay in the point of the preceding equinox, or in the colure of the equinoxes; and the same holds, with respect to the stars, of those which lie in the colure of the solstices, etc. (as established in book I, ch. 4).

[Margin: *Anni Siderei Mensura* — The measure of the sidereal year.]

Therefore, since the equinoctial year is of 365 days, 5 hours, 48' 58", and since from what was said just above the annual motion of the fixed stars is elected at 50" of seconds and 40" of thirds — to traverse which, by the mean motion, the Sun requires 20' 33" 42" per hour [*horaria*] — if these be added to the equinoctial year, there arises for us the sidereal year of 365 days, 6 hours, 9' 21" 42".

2. Moreover, granting an annual motion of the fixed stars elected and posited at 50" 40", it follows that they do not complete a single degree except in 71 16/367 years, or 71 days, 19 hours [recte: years; the text reads "Annis 71 16/367, seu diebus 19, horisq; 12"], very nearly. And they do not traverse the whole circle of degrees except in 25,579 years — which is the Platonic Great Year. The sidereal years 25,579 are equal to 25,580 equinoctial years.

[Margin: *Annus Magnus* — The Great Year.]

Let Kepler in the *Rudolphine Tables* (p. 115), from the Tychonic annual motion of the fixed stars, say the sidereal years are 25,411, equated to tropical years; and Wendelin, in his *Idea Tabularum Atlanticarum* (p. 28), makes the sidereal years 25,519 equal to tropical years 25,520. As to whether, after the universal restoration [*anastasis*] of our bodies, the heavenly motions are to be brought to a stop or prolonged

until the Apocatastasis of all the stars is fully completed — that belongs to our frailty to investigate, not to determine.

3. It might be asked in what configuration of the fixed stars the sphere was constituted at the beginning of the World. To this question we cannot give a certain answer, because (as said in book I, ch. 9, no. 3) of our *Chronologia Reformata*, the World was created — according to the Vulgate Latin version and the Hebrew Codex — neither more than 4059 nor fewer than 4019 years before Christ; the mean of these is the year 4039. But according to the Greek Septuagint version it was created neither more than 5504 nor fewer than 5464 years before Christ, whose mean is the year 5484.

Now, from the year 4039 to the year of Christ 1660 there are 5699 or 5700 years, in which there are due, from the motion of the fixed stars, $80^{\circ} 13' 20''$ of degrees. And from the year 5484 before Christ to the year of Christ 1660 there are 7144 years, in which there are due $100^{\circ} 32' 43''$ of degrees. Therefore, according to the earlier Chronology, those fixed stars in the year of Christ 1660 were distant from the beginning of the Zodiac, that is, from the beginning of Aries, by $80^{\circ} 13' 20''$; so those very stars, at the beginning of the precession of the equinoxes, in the colure of the equinoxes and at the beginning of Aries, were near the second star in the Shield of Orion, and at the foot of Orion, the single one at the beginning of Eridanus.

But according to the Greek Septuagint Interpreters' Chronology, they were in the colure of the equinoxes and at the beginning of Aries; that star which in the year of Christ 1660 was elongated from this beginning by $100^{\circ} 32' 43''$ — such is the star in the left arm of Pollux. Sirius, however, the most splendid of all the fixed stars, was distant only $99^{\circ} 33'$, that is, one degree less than the aforesaid interval requires.

CAPUT XXI

TABULA I. Of the Right Ascension and Declination of One Hundred Fixed Stars for the undermentioned complete years of Christ, with the Difference of the same.

The table gives, for each named fixed star: the **Right Ascension** (Ascensio Recta) for the years 1660 and 1700 (in degrees Gr., minutes ', seconds "); the **Declination** (Declinatio) for 1660 and 1700 (with the marker **B** = *Borealis*, northern, or **A** = *Australis*, southern); the **Difference of Right Ascension** over 40 and 100 years; and the **Difference of Declination** over 40 and 100 years (marked *ad.* = increasing, *sub.* = decreasing). Only the first portion of the table (through the letter C) appears on this page; it continues on the following page (catchword "Capri-" = Capricorni).

Liber IV — De Stellis Fixis

Caput XXI (continued)

I. Table of the Right Ascension and Declination of One Hundred Fixed Stars for the Completed Years of Christ Written Below (continued)

The table of right ascensions and declinations of the 100 fixed stars continues. For each star are given the right ascension (in degrees, minutes, seconds) for the years 1660 and 1700; the declination (in degrees, minutes, seconds, with B = boreal/north or A = austral/south) for 1660 and 1700; and under "Differentia," the difference of right ascension (per 40 years and per 100 years) and the difference of declination (per 40 years and per 100 years, marked *ad.* = additive/increasing or *sub.* = subtractive/decreasing).

Column headers as printed: **Nomina Fixarum** [Names of the Fixed Stars]; **Ascensio Recta** [Right Ascension] — *Anno 1660* (Gr. ' '), *Anno 1700* (Gr. ' '); **Declinatio** [Declination] — *Anno 1660* (G. ' '), *Anno 1700* (Gr. ' '); **Differentia**

[Difference] — *Ascensionis* (Annorū 40: ' "; Annorū 100: G. '), *Declinationis* (Annorum 40: ' "; Annorū 100: ' ").

Huius Ascens. Recta decresc it. [its right ascensi on is decreas ing]								

Usus praecedentis Tabulae cum cautelis [Use of the preceding table, with cautions]

1. If you wish to find the right ascension or declination of any of the aforementioned fixed stars for years between 1660 and completed 1700, of Christ, use the difference of these set under the heading "40 years." Multiply it by the number of years from the year 1660 (counting exclusively from that numbered year), and divide the product by 40. The result gives the minutes (and seconds), to be added to the right ascension of the year 1660 — except in the case of the bright star of the Little Bear [Polaris], where it must be subtracted. The difference of declination, however — found proportionally for the given number of years — is to be added or subtracted according as the marks *ad.* [additive] or *sub.* [subtractive] indicate.

2. If you seek the right ascension or declination of the aforesaid fixed stars for years between 1600 and 1700, use the difference sought under the heading "100 years," and multiply it by the number of years counting backward from the year 1700. [The remainder of the procedure continues as above.]

3. If you seek the right ascension or declination of the aforesaid fixed stars for years between 1700 and 1800, of Christ, use the difference sought under the heading "100 years," and multiply it by the number of years from the year 1700 (counting exclusively). Divide the sum by 100; the quotient gives the proportional part to be added to the right ascension of the year 1700 — except in the case of the bright star of the Little Bear, where it must then be subtracted; while for declination, this same part is to be added or subtracted according as the marks *ad.* or *sub.* indicate.

[Then, regarding the right ascension of the year 1700: the sum is to be divided by one hundred; for the quotient gives the number to be subtracted from the right ascension of the year 1700, in the case of the bright star of the Little Bear, since for that star an addition must be made; but for declination the contrary is to be done, and the marks *ad.* and *sub.* indicate this, for the proportional part found is subtracted where the mark is *ad.*, and added where the mark is *sub.*]

The New Star of Cygni [the Swan, Nova Cygni] was observed on the boundary between the neck and the breast in the year 1659, often in November: its right ascension was $300^{\circ} 58' 6''$; its boreal declination $36^{\circ} 48'$. [?]

II. Table of the Longitude and Latitude of 101 of the More Notable Fixed Stars, Observed on the Horizon of Bologna

Column headers as printed: **Nomina Fixarum Latina** [Latin Names of the Fixed Stars]; **Nomina Arabica, vel Chaldaica** [Arabic or Chaldaic Names]; **Longitudo An. 1660. copl.** [Longitude, completed year 1660] (Sig. Gr. ' '); **Longitudo An. 1700. copl.** [Longitude, completed year 1700] (Sig. Gr. ' '); **Latitudo perpetua** [Perpetual Latitude] (Gr. ' ', with B = boreal/north or A = austral/south); **Magnit.** [Magnitude].

Zodiac signs are given by their symbols; I render them by name: ♈ Aries, ♉ Taurus, ♊ Gemini, ♋ Cancer, ♌ Leo, ♍ Virgo, ♎ Libra, ♏ Scorpio, ♐ Sagittarius, ♑ Capricorn, ♒ Aquarius, ♓ Pisces.

Liber IV — De Stellis Fixis (continued)

Caput XXI (continued)

II. Table of the Longitude and Latitude of the 101 More Notable Fixed Stars Observed at the Horizon of Bologna (continued)

The columns are: Latin name of the fixed star; Arabic or Chaldaic name; Longitude for the year 1660 (complete); Longitude for the year 1700 (complete); perpetual latitude; magnitude. Longitude and latitude are given in sign, degrees, minutes, seconds (Sig. Gr. ' "); for latitude the column also carries a letter A (north, *Borealis*) or B (south, *Australis*). The zodiacal-sign glyphs are transcribed as the standard astronomical symbols.

Latin name of the fixed star	Arabic / Chaldaic name	Longitude 1660 (Sig. Gr. ' ")	Longitude 1700 (Sig. Gr. ' ")	Perpetual latitude (Gr. ' ")	M a g n i t u d e

III. Table of the Motion of the Fixed Stars in Longitude, to be Added to (or Subtracted from) the Longitude of the Year 1700 of Christ, so that Their Places After, or Before, May Be Had

The table is laid out in four side-by-side blocks. The first two blocks each carry the columns *Anni* (years elapsed) and the corresponding motion in degrees(I)–minutes(II)–seconds(III), where in the first two blocks the leading figure is a single digit so the heading reads I | II | III. The later blocks add an explicit *Gr.* (degrees) column for the larger accumulated values.

Y e ar s	Motion (° ' ")	Y e ar s	Motion (° ' ")	Y e ar s	Motion (Gr. ' ")	Y e ar s	Motion (Gr. ' ")

Catalogue of the Universal Fixed Stars, Completed for the Year 1700 of Christ. And Reduced to Four Classes, or Degrees, of Certainty.

[Two-column prose follows; transcribed left column then right column.]

The FIRST Class contains the stars observed by us, together with Fr. Francesco Maria Grimaldi [Francesco Maria Grimaldi], most frequently — whose longitude and latitude have already been set down in the preceding Table — for the first of which we hold them to be certain in the first degree. To these we have added the Pleiades from D. Vicenç Mut [Vincenzo Mutus] and Michael Florent van Langren [Michael Florentius Langrenus] as observed by them.

The SECOND Class holds the remaining stars observed by Tycho [Tycho Brahe] or by Kepler [Johannes Kepler] as they stand in the Rudolphine Catalogue [*Tabulæ Rudolphinæ*], with their numbers nonetheless corrected as the differences among the stars of our first Class and the Tyconic ones of the same constellation require, or those closest to them, which we place in the second degree of certainty.

The THIRD Class comprises the remaining stars observed neither by us nor by Tycho, but by Hipparchus [Hipparchus] and Ptolemy [Ptolemy] — yet bearing on those constellations, or on ones near them, some of whose fixed stars are observed by us or by Tycho. The numbers are corrected as the differences between the Ptolemaic and our own, or the Tyconic, ones of the same constellation require. And these we place in the third degree of certainty, not excluding an evident error of 10 minutes. As Kepler says, *the numbers were corrected by him* (or by some numbers of the circumstances drawn from the Tyconic example).

The FOURTH Class extends to the stars observed neither by Hipparchus nor by Ptolemy (so far as we know) nor by Tycho, nor by us, nor among those observed by them — stars bearing on those very constellations, but on entirely new constellations observed by the Nacleri [the navigators / *Nacleri*]. Of these we have reduced only the longitude to the end of the year 1700, adding the Rudolphine motion of 100 years, which for us is $1^{\circ} 24' 27''$. The latitude, however, we have transcribed wholly unchanged from the Rudolphine Catalogue. These, moreover, we hold to be of the 4th degree of certainty, and, having tested them with the Radius, or astronomer's Staff [Baculo Astronomico], which the Nacleri use, and which we have found liable to an error of some minutes, we do not reckon them more certain than the Ptolemaic ones — until they be observed in another and more accurate way.

PARS PRIMA — De Stellis Fixis Signorum XII. Zodiaci

Part One — On the Fixed Stars of the Twelve Signs of the Zodiac

This part presents the universal catalogue laid out in two columns per page. The columns are: Latin name of the fixed star [Nomina Fixarum]; Longitude (Sig. Gr. ' '); Latitude (Gr. ' ', with A north / B south); Magnitude [Magnitud.]. Stars within each sign are grouped by the four classes of certainty (1.–3. *Classis* visible here). The zodiacal-sign glyphs are transcribed as standard astronomical symbols.

ARIES (left column)

Latin name of the fixed star	Longitude (Sig. Gr. ' ')	Latitude (Gr. ' ')	Magnitud.
1. Class.			
First in the preceding horn [in cornu præcedente]	♈ 28 59 27	7 8 0 B	4
Following, in the same horn	♈ 29 45 27	8 28 30 B	4
Bright star above the head [supra caput]	♈ 3 28 29	9 56 30 B	3
2. Class.			
In the northern grin [in rictu Borealis]	♈ 3 56 30	7 22 30 B	6
In the southern grin [in rictu Australis]	♈ 4 42 30	5 42 0 B	6
In the neck [in cervice]	♈ 29 19 27	5 23 30 B	5
in the temples [in tenibus]	♈ 9 58 30	6 8 0 B	6
In the drawing-out of the tail [in eductione caudæ]	♈ 14 19 30	4 8 0 B	5
Preceding the three in the tail	♈ 16 37 30	1 46 0 B	4
The middle of them	♈ 17 46 30	2 49 30 B	5
The last of them	♈ 19 13 0	2 35 30 B	6

Latin name of the fixed star	Longitude (Sig. Gr. ' ")	Latitude (Gr. ' ")	M ag .
In the thigh [in femore]	♄ 12 44 30	1 11 30 B	6
in the ham [in poplite]	♄ 10 57 30	1 6 30 B	6
in the left knee [in genu sinistro]	♄ 10 45 30	1 29 30 A	6
in the right knee [in genu dextro]	♄ 9 14 30	0 38 30 A	6
Small star in the belly [Parvula in alvo]	♄ 9 48 30	4 0 0 A	6
Below the bright star of the head	♄ 3 3 29	9 12 0 A	7
Above the formless [informis] of the back	♄ 11 57 30	10 0 50 A	6
The formless one following, at the base of the triangle	♄ 12 45 30	11 15 30 A	4
Eastward at the same base	♄ 14 2 30	10 23 30 A	3
At the apex of the triangle, toward the north	♄ 14 13 30	12 25 0 B	4
3. Class.			
The northern one of the three formless [Trium informium boreal.]	♄ 13 52 30	12 0 43 B	5
In the hindmost foot [in extremo pede posterior]	♄ 7 32 30	5 9 39 A	5

TAURUS (left column, continued)

Latin name of the fixed star	Longitude (Sig. Gr. ' ")	Latitude (Gr. ' ")	M ag .

LIBER IV. — DE FIXIS STELLIS

Catalogus Fixarum universalis ad Annum 1700 — Pars Prima: De Stellis Fixis Signorum XII. Zodiaci

The catalogue continues by constellation. Each star is given with its longitude (zodiac sign, degrees, minutes, seconds), latitude (degrees, minutes, seconds, with B = north/borealis or A = south/australis), and magnitude (*Magnitudo*); the stars within each constellation are grouped by certitude-class (*Classis* 1–4). Longitude zodiac-sign glyphs are transcribed as the sign abbreviation. All numerical values are transcribed exactly as printed.

Liber IV — De Stellis Fixis (continued)

Universal Star Catalogue — *Pars Secunda*: Northern Constellations outside the Zodiac (continued)

The longitude is given by zodiac sign and by degrees [Gr.], minutes ['], and seconds ["] within the sign; the latitude is northern [Latitudo Borealis], in degrees, minutes, and seconds; the last column gives the magnitude [Magnitudo]. The stars are grouped by constellation and, within each, by certitude class [Classis]. Zodiac-sign abbreviations are reproduced as printed.

LIBER IV — DE STELLIS FIXIS (Book 4, On the Fixed Stars)

Universal star catalogue, continued

Longitude is given by zodiac sign [Sig.], degrees [Gr.], minutes ['], and seconds ["]. Latitude is northern [Latit. B. = Latitudo Borealis] in the second part and southern [Latit. A. = Latitudo Australis] in the third part. The final column is magnitude [Magnitud.].

The constellation rubrics carry a *Classis* (class/order) sub-heading indicating the certitude-class of the star positions.

Ophiuchus (Serpent-bearer), continued

The first rows continue the catalogue of Ophiuchus from the preceding page.

In the crest [In crista]	≈	19 3 0 37 0	1 0 5 4
In the coil, apex of the isosceles [In spira apex Isoscelis]	↗	16 2 0 10 1	2 0 4 4
Base, preceding, 14th in Ptolemy [Basis præcedens 14. Ptol.]	↗	20 4 0 8 4	3 0 4
Following, 15th in Ptolemy [Sequens 15. Ptolemæo]	↗	21 3 0 10 0	2 0 4 2

Right column of fol. 273 — continuation of Ophiuchus, then Sagitta, Aquila, Antinous, Delphinus, Equuleus

(These first rows continue Ophiuchus, "from another catalogue.")

Name of the fixed star	Sig n	Gr . ' "	Lat. (B)	Gr.	' "	Ma g.
Above the tail of the two, upper [Supra caudam duar. super.]	♄	1 1 0	26		3 0	6 7
Lower [Inferior]	♄	3 0 0	23		2 0	6 7
Below the tail [Infra caudam]	♄	4 2 0	15		4 0	4 8
Lowest of three at the end of the tail [Ima trium in fine caudæ]	♄	3 2 0	21		2 0	6 8
Middle [Media]	♄	5 2 0	22		4 0	6 1
Last [Postrema]	♄	8 2 0	24		5 0	6 1
Just below the last [Proximè infra ultimam]	♄	11 4 0	25		1 0	6 3

3rd Class.

Following the hand of Ophiuchus [Sequens manum Oph.]	♄	1 6 0	15		5 0	5 9

SAGITTA, sive TELUM (the Arrow, or Dart)

Name of the fixed star	Sig n	Gr . ' "	Lat. (B)	Gr.	' "	Ma g.
2nd Class.						
Upper, and eastern [Superior, & Oriental.]	♄	2 5 1	29		1 1	4 2
Preceding this one [Hanc præcedens]	♄	29 1 1	38		5 4	5 7
A small one above this [Parvula supra hanc]	♄	29 5 0	39		3 1	6 0
Upper, adjoining at the glyph [Super. contig. in Glyphide]	♄	26 5 4	38		5 1	4 2

Name of the fixed star	Sig n	Gr . ' "	Lat. (B)	Gr.	' "	Ma g.
Lower of them [Inferior earum]	♄	27 2 1 3	38		1 1 7	4 0
Unformed, above Sagitta, lower [Inform. supra Sagittá infer.]	♄	1 3 1 6	42		4 1 2	4 0
Upper of the unformed [Superior informium]	♄	2 5 1 9	44		1 1 0	4 0
Third, in the acute-angle, of the unformed [Tertia in Oxygonio informium]	♄	25 2 1 0	46		2 1 3	4 0

AQUILA, seu VULTUR VOLANS (the Eagle, or Flying Vulture)

Name of the fixed star	Sig n	Gr . ' "	Lat. (B)	Gr.	' "	Ma g.
1st Class.						
Bright star in the shoulder-blades [Lucida in scapulis]	♄	27 3 1 2	29		2 4 0	2 0
2nd Class.						
The one in the Head [Quæ in Capite]	♄	1 5 4 1	27		7 4 0	6 0
In the Neck [In Collo]	♄	28 1 1 6	26		4 4 8	3 0
Small one above the Bright star [Parva supra Lucidam]	♄	26 5 1 6	30		5 4 3	6 0
In the left shoulder [In sinistro humero]	♄	26 4 1 9	31		1 1 7	3 0
Following, small [Sequens parva]	♄	27 3 4 1	31		5 1 8	5 2
Upper, and preceding the lower wing [Super, & præc. alæ infer.]	♄	22 3 4 9	28		4 4 5	4 0
Lower, and following in the wing [Inferior, & sequens in ala]	♄	23 3 1 7	26		3 1 4	5 0
Tail of the vulture [Cauda vulturis]	♄	15 3 4 8	36		1 4 5	3 0
Next, of the unformed of the tail	♄	14 7 1	37		3 1	3 0

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
[Proxima caudæ inform.]				0		9	0	
Middle of the unformed, above the tail [Media informium supra caudam]	♄	10	3	1	43	3	4	4
			5	2		1	0	
Following this one [Sequens hanc]	♄	10	4	4	41	4	1	4
			0	2			0	

ANTINOUS

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
2nd Class.								
In the left hand [In manu sinistra]	♁	0	4	4	18	4	0	3
			4	0		7		
In the right side [In latere dextro]	♄	21	4	4	20	1	0	3
			0	1		4		
At the knee [In genu]	♄	20	4	1	14	2	0	3
			0	2		7		
In the right arm [In dextro brachio]	♄	19	2	1	24	5	0	3
			4	3		5		
In the breast [In pectore]	♄	26	1	1	21	3	0	3
			3	2		7		
In the right foot [In pede dextro]	♄	13	9	1	17	4	0	3
				5		0		
Preceding this, unformed [Præcedens hanc informis]	♄	11	5	1	16	5	0	4
			2	2		6		

DELPHINUS (the Dolphin)

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
2nd Class.								
Bright star of the Tail [Lucida Caudæ]	♁	9	5	1	29	7	0	3
			5	2				
Following the tail [Sequens caudam]	♁	11	1	1	28	5	3	5
			1	3		1	0	

Name of the fixed star	Sig n	Gr . ' "	Lat. (B) Gr.	' "	Ma g.
The one below the tail [Quæ infra caudam]	≈	11 5 1 27 2		3 0 6 3	
In the rhombus, preceding, of the southern side [In Rhomboide præcedens lateris Australior]	≈	12 1 1 31 9 0		5 3 3 6 0	
Of the same side, more northern [Eiusdem lateris Borealior]	≈	13 1 4 33 3 0		4 0 3	
Following, of the side, more southern [Sequetis lateris Australior]	≈	14 5 4 31 9 2		5 0 3 9	
The one in the Head [Quæ in Capite]	≈	15 1 1 32 5 2		4 0 3 6	
In the preceding side, the fourth, contiguous, going before [In præced. latere quatuor contiguè antecedens]	≈	11 4 1 32 0 0		7 3 5 0	
Preceding, the lowest of the two in the rhombus [Præcedens duarum infima in Rhomboide]	≈	10 4 1 30 1 2		4 3 6 0 0	
Following the same ones [Earundem sequens]	≈	12 5 1 30 3		4 0 6 0	

EQUULEUS, EQUI SECTIO (the Foal, the Horse's Section)

Name of the fixed star	Sig n	Gr . ' "	Lat. (B) Gr.	' "	Ma g.
2nd Class.					
Preceding, of the Head [Præcedens Capitis]	≈	18 5 4 20 5 0		1 2 4 1 0	
Following, of the Head [Sequens Capitis]	≈	21 1 4 21 7 2		5 0 4	
Preceding, of the mouth [Præcedens oris]	≈	19 1 1 25 7 2		1 0 4 5	
Following, of the mouth [Sequens oris]	≈	20 1 4 24 7 0		5 0 4 1	

PEGASUS EQUUS ALATUS (Pegasus, the Winged Horse)

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
1st Class.								
Mouth of Pegasus [Pegasi os]	♊	27	4	7	22	6	1	3
			5				0	
Scheat, of the leg [Scheat cruris]	♋	25	1	7	31	8	2	2

ANDROMEDA

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
1st Class.								
Head of Andromeda [Caput Andromedæ]	♄	10	9	3	25	4	1	2
						2	0	
In the girdle, more southern [In Cingulo Australior]	♄	26	1	0	25	5	3	2
			1			8	0	

Name of the fixed star	Sig n	Gr . ' " Lat. (B) Gr.	Ma ' " g.
Bright star in the southern foot [Lucida in pede Australi]	♄	10 1 4 27 4	4 1 2 7 0
2nd Class.			
Lowest of the right shoulder- blade [Infima scapulæ dextræ]	♄	18 2 3 27 8 0	6 4 4 0
Lower of the left shoulder [Inferior sinistri humeri]	♄	16 4 0 23 7	3 3 4 9
Of three in the right arm, southern [Trium in brach. dextr. austral.]	♄	16 2 0 31 0	3 1 5 3 5
The northern of them [Earum borealis]	♄	17 7 3 33 0	2 4 4 0 0
The middle of them [Earum media]	♄	17 2 0 32 9	1 3 5 4 8
More southern, upper hand [Australior manus superior]	♄	11 5 0 40 0	5 3 4 6 9
More northern, same place [Borealior ibidem]	♄	13 8 0 41	4 3 4 4 0
Obscure, same place [Obscura ibidem]	♄	15 4 0 42 5	8 2 5 5
Highest in the northern hand [Suprema in boreali manu]	♄	14 9 0 43	4 4 4 9 2
Preceding, in the left arm [Præc. in sinistro brachio]	♄	16 3 1 17 1 0	4 2 4 8 0
In the left elbow [In sinistro cubito]	♄	18 1 3 15 5 0	5 2 5 8 5
Middle, in the girdle [Media in cingulo]	♄	29 2 5 30 7 0	3 0 4 4
Northern, in the girdle [Borea in cingulo]	♄	24 5 2 32 7 0	3 1 4 1 0
Far end of the upper foot [Extrema pedis superioris]	♄	10 2 3 36 8 0	5 0 5 0
Brighter, in the right foot	♄	8 1 0 35	2 0 4

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
[Lucidior in pede dextro]			4			2		
Highest in the left calf [Suprema in sura sinistra]	♄	6	2	0	28	5	3	5
			8			9	0	
Lower, same place [Inferior ibidem]	♄	4	4	0	27	5	0	5
			5			5		
At the right knee [Ad genu dextrum]	♄	2	1	0	26	2	2	5
			8			0	5	
In the far ring of the chain [In extremo anulo catenæ]	♄	25	2	0	37	1	3	4
			2			9	0	
Brighter, in the left shoulder- blade [Clarior in sinistra scapula]	♄	17	4	3	24	2	3	3
			1	0		0	0	

3rd Class.

In the trail of the two, northern [In syrmate duarum boreal.]	♄	5	2	0	34	4	3	5
			2			0	0	
Same place, southern [Ibidem austrina]	♄	6	5	0	32	4	2	5
			2			0	5	
Unformed, preceding, three of the right hand [Informis præc. tres dextræ manus]	♄	4	2	0	44	0	3	3
			2				0	

TRIANGULUS DELTOTON (the Triangle, Deltoton)

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
2nd Class.								
At the apex of the Triangle [In apice Trianguli]	♄	2	4	0	16	4	5	4
			1			9	0	
In the base, toward the north [In basi ad Boream]	♄	8	1	3	20	3	2	4
			1	0		3	0	
Middle [Media]	♄	9	2	0	19	2	2	5
			1			9	5	
More southern, in the base [Australior in basi]	♄	9	2	0	18	5	2	4
			0			7	4	

COMA BERENICES (Berenice's Hair)

Name of the fixed star	Sig n	Gr .	'	"	Lat. (B) Gr.	'	"	Ma g.
2nd Class.								
In the cusp of the first, and of the northern Triangle [In cuspidē primi, & Borealis Trianguli]	♍	19	4	0	28	2	2	3
			1			4	0	
<i>Or otherwise, from Kepler</i> [Vel aliter ex Keplero]	♍	29	3	0	28	3	2	3
			9			0	0	
Upper, to this one, toward the south [Superior huic ad austrum]	♍	20	6	0	27	2	0	4
						2		
Lower, to the same [Inferior eidem]	♍	20	1	0	27	1	1	4
			0			8	2	
Following, two contiguous [Sequens duas contiguas]	♍	20	4	0	27	5	1	4
			3				5	
Preceding, of the two contiguous, toward the south [Præcedens duarum contiguarum ad Austr.]	♍	19	4	0	25	4	1	4
			9			9	3	
The other, contiguous, toward the rising [Altera contigua ad ortum]	♍	20	1	3	26	5	2	4
			2	0			0	
All preceding, toward the south [Omnes præced. ad Austrú]	♍	19	2	0	23	2	2	4
			4			8	5	
Highest of three contiguous, following [Suprema 3.contig.sequentium]	♍	22	3	0	25	1	2	4
			4			4	2	
The other, and preceding [Altera, & præcedens]	♍	22	1	0	24	5	2	4
			5			4	0	
Lowest, and following [Infima, & sequens]	♍	24	1	0	23	5	5	4
			6			8	0	
<i>The other Codex of Kepler</i> [Alter Codex Kepleri]	♍	23	1	0	23	5	5	4
			6			8	0	
Last, in the extension of the hair [Postrema in extensione comæ]	♌	0	2	3	32	4	2	4
			2	0		4	0	
The one that precedes this [Quæ hanc præcedit]	♍	29	1	3	31	4	2	4
			3	0		0	3	

Name of the fixed star	Sig n	Gr . ' " Lat. (B) Gr.	Ma ' " g.
Between these, and the first, in the cusp [Inter has, & primam in cuspidē]	♏	25 4 0 30 1	1 2 4 4 2
In the southern cusp of the small Triangle [In Australi cuspidē parvi Trianguli]	♏	29 3 0 28 9	3 2 5 0 0

PARS TERTIA — Astra Australia (Part Three — The Southern Stars)

From here latitude is southern [Latit. A. = Latitudo Australis].

CETE (Cetus, the Whale)

Name of the fixed star	Sig n	Gr . ' " Lat. (A) Gr.	Ma ' " g.
1st Class.			
Bright star of the jaw [Lucida mandibulæ]	♄	10 7 3 12 2	3 5 2 6 0
Bright star of the northern belly [Lucida ventris Borea]	♄	17 4 1 20 8 5	1 2 3 7 0
Northern of the tail [Cauda Borealis]	♄	26 4 4 9 6 7	5 1 3 8 0
Southern of the tail [Cauda Australis]	♄	28 1 4 20 9 7	4 4 2 3 0
2nd Class.			
The one in the muzzle [Quæ in rostro]	♄	10 5 0 7 2	4 5 4 9 0
Middle of the mouth [Media oris]	♄	5 1 3 12 4 0	2 2 3 0
Preceding, of three at the cheek [Præcedens trium ad genam]	♄	3 2 0 14 3	3 4 3 1 9
Below the eye [Infra oculum]	♄	3 1 0 5 5	5 5 4 1 0
Above the eye [Supra oculum]	♄	7 2 0 5	3 4 4

Name of the fixed star	Sig n	Gr .	'	"	Lat. (A) Gr.	'	"	Ma g.
			8			5	8	
In the back of the head [In occipite]	Υ	29	5	3	4	1	5	4

			1	0		2		

Name of the fixed star	Sig n	Gr . ' "	Lat. (A)	Gr.	' "	Ma g.
In the right shoulder of the front feet [In armo dextro pedum anteriorum]	♄	8 0 5	42		1 0	5
			0		5	

Note on coverage: this opening completes the northern constellations (Part Two) of the universal catalogue — ending Ophiuchus, Serpens, Sagitta, Aquila, Antinous, Delphinus, Equuleus, Pegasus, Andromeda, Triangulus, and Coma Berenices — and begins the southern constellations (Part Three: Cete, Orion, Eridanus, Lepus, Canis Maior). No FINIS of Book 4 nor any Liber boundary appears on these folios; the catalogue continues.

Book IV — On the Fixed Stars

Universal Catalogue of the Fixed Stars — Part Three: The Southern Stars (continued)

The catalogue continues with the southern constellations. Each entry gives the star's descriptive name (*Nomina Fixarum*), its longitude (*Longitudo* — by zodiacal sign, degrees, minutes, and on the first page seconds), its southern latitude (*Latit. A.* = *Latitudo Australis*, in degrees and minutes), and its magnitude (*Magnitudo*). Within each constellation the stars are grouped by certitude class (*Classis*). The zodiacal sign is given by its symbol in the "Sig." column.

[Canis Maior, continued — folio 276]

The following entries continue the list of stars of Canis Maior begun on the preceding page.

Nomina Fixarum (star name)	Sig.	G r.	'	"	Lat. A.	Gr.	'	"	Ma g.
In extremo pedis prioris (at the end of the forward foot)	♄	3	1	5	41		2	2	2
			0	0			0	0	
In dorso (on the back)	♄	1	5	5	46		1	2	5
		6	8	0			1	0	
Media in pectore (the middle one on the breast)	♄	1	4	5	46		4	2	5
		4		0			1	0	
In ventre (on the belly)	♄	1	2	2	48		3	5	3

Nomina Fixarum (star name)	Sig.	G r.	'	"	Lat. A. Gr.	'	"	Ma g.
		9	3	0		1	0	
Inter posteriora femora (between the hind thighs)	☾	1	4	5	51	2	2	3
		6	9	0		6	0	
Inferior dext. pedis prioru[m] (the lower of the right forward feet)	☾	2	3	2	51	4	2	3
			5	0		8	0	
Quæ in cauda (the one on the tail)	☾	2	3	5	51	2	2	3
		5	9	0		6	0	

3. Classis [3rd certitude class].

Nomina Fixarum	Sig.	G r.	'	"	Lat. A. Gr.	'	"	Ma g.
Altera in pectore (the other one on the breast)	☾	1	5	1	42	2	0	5
		2	8	9		2		
In genu Australis (the southern one on the knee)	☾	8	2	2	42	1	—	5
			8	0		2		
In sinistro genu duarum præced. (the preceding of the two on the left knee)	☾	6	2	1	46	1	—	5
			8	8		2		
Earum sequens (the following of those)	☾	8	3	2	45	3	—	5
			8	0		2		
In poplite cruris dextri (in the hollow of the right leg)	☾	1	2	1	54	5	—	4
		5	8	9		2		

Informes circa Canem (the unformed stars around the Dog).

Book IV — On the Fixed Stars (conclusion of the universal catalogue: Pars Tertia, Astra Australia)

The southern catalogue continues with the last of the modern southern constellations. Each entry gives the star's position by ecliptic longitude (Sign, degrees, minutes), southern latitude (degrees, minutes), and magnitude. The two halves of the page form a single continuous catalogue, the left-hand half preceding the right-hand half.

Summary appended beneath the right column:

And so there are 12 zodiacal constellations, 23 northern, and 27 southern — 62 in all.

Among the zodiacal asterisms, stars of the first magnitude	6
Of the second magnitude	9
Among the northern asterisms, stars of the first magnitude	3
Of the second magnitude	22
Among the southern asterisms, stars of the first magnitude	5
Of the second magnitude	28
Therefore all stars of the first magnitude are	14
And of the second	59

BOOK FIVE

IN WHICH ARE THE OBSERVATIONS OF SATURN, THE PLANET, AND THE HYPOTHESIS OF ITS MOTIONS

CHAPTER I.

Ancient Observations of Saturn, from the Year 229 before Christ down to the Year 1461 of the same era.

In the year 82 according to the Chaldeans, on the 5th of the month Xanthicus, in the evening — that is, in the year 519 of Nabonassar, on the 14th of the month Tybi — Saturn was observed in the evening, more to the south by two digits, or 5 minutes, than the star at the southern shoulder of Virgo. Ptolemy [Ptolemaeus] reports this observation as the most reliable of them all (*Almagest* [*Magna Constructio*] XI.7); from it he gathers that Saturn was in 9° 30' of Virgo. Longomontanus [Longomontanus], however (*Astronomia Danica*, II, Theoricorum cap. 4), makes it the year 3736 after the first bissextile year of the World, and rightly with the year 229 before Christ; and the 14th of Tybi he makes the 1st of March, with 4h 25' added after the meridian of Copenhagen [Hafniensem]. He found that this star, as well as Saturn, was in 9° 3' of Virgo, with northern latitude 2° 43'. He also makes Saturn's latitude 2° 38'. Ismaël [Ismaël] Bullialdus [Boulliau] likewise (*Astronomia Philolaica* VI.5) takes the 14th of Tybi, but says it was at the 6th hour. He says that at Uraniborg [Vraniburgi] the fixed star was in 8° 42' 43" of Virgo, and its northern latitude 2° 50'. But Lansbergen [Lansbergius], in his

Thesaurus of observations of Saturn, observation 1, asserts that one should read in Ptolemy "Xanthicus the 15th," and that he answered to the 22nd of Tybi — so as to draw out this observation to fit his own tables — namely because on this day only, around the sixth hour at Alexandria, the tables exhibit the star in $9^{\circ} 7'$ of Virgo, with latitude $2^{\circ} 43'$. **[Margin: Lansbergen in error (Lansbergii dolus).]** But in truth the Greek copies have "Xanthicus the 5th," and all the Latin versions have "Xanthicus the fifth." From our catalogue of fixed stars, that star was, by position and by proper motion, in $8^{\circ} 50' 31''$ of Virgo, with northern latitude $2^{\circ} 49\frac{1}{2}'$.

2. In the 11th year of Hadrian [Adriani], Ptolemy, having observed Saturn with astrolabe instruments, concluded that its opposition with the mean place of the Sun fell on the 7th of the month Pachon, on the evening following the eighth — Saturn then occupying $1^{\circ} 13'$ of Libra [$\underline{\alpha}$]. So he says (*Almagest* XI.5), and from him Copernicus [Copernicus] (*De Revolutionibus* V.5), adding that it was the year of Christ 127, and the 7th of the month Mechir, that is, the 7th of the Kalends of April, at the 18th hour after the meridian at Alexandria. **[Margin: Copernicus's error in chronology (Copernici error in Chron.).]** But the Greek codex ... and from his own tables he derives Saturn's place ... $18''$.
3. In the 17th year of Hadrian, Ptolemy, from an observation of Saturn, conjectured it to be in $9^{\circ} 40'$ of Sagittarius, the opposition having occurred with the mean place of the Sun at midday — that is, as Copernicus has it (*De Revolutionibus* V.5), in the year of Christ 133, on the 3rd before the Nones of June, at the hour equal from ... 11. See Ptolemy (*Almagest* XI.5). It was the 4th day, civil reckoning.
4. The same Ptolemy, in the aforesaid passage (*Almagest* XI.5), reports an observation made by himself of the opposition of Saturn with the mean place of the Sun, fixed at $\mathfrak{h}$ in $\sphericalangle 14^{\circ} 14'$, in the 20th year of Hadrian, at the very midday of the 24th day of the month Messori — which year, according to Copernicus (*De Revolutionibus* V.5) and Longomontanus (II, Theoricorum cap. 4), was the year of Christ 136, on the 8th before the Ides of July, at the hour after the middle of the night, 12. At Alexandria it was the 9th of July.
5. In the 2nd year of the Emperor Antoninus [Antoninus], on the 6th of Mechir, at the 4th hour before the following midnight, Ptolemy says that he observed the last degree of Aries at the meridian (M.C.); and then the Sun was, by mean motion, in $28^{\circ} 41'$ of Sagittarius. He found that Saturn, compared with Aldebaran [Aldebaram], was in the second northern ... and

was distant from the northern horn of the Moon by very nearly half a degree. Lansbergen, in his *Thesaurus* of observations, observation 1, says it fell in the year of Christ 138, December 22, at the 8th hour after midday at Alexandria; but from his own tables he derives Saturn's place at $\approx 9^{\circ} 17' 18''$.

6. In the year of Christ 503, an observation of Saturn was made at Athens [Athenis], and recorded in the year of Diocletian [Diocletiani] 219, on the 27th of Mechir, near the 4th hour, when the Moon occulted Saturn — under which it lay hidden for one temporal hour, with three quarters, so that Saturn passed across the center around the fifth hour; for it appeared to emerge from the middle of the circumference of the illuminated part of the Moon. So the observer has it in a manuscript codex of the Royal Library of Paris [Bibliothecae Regiae Parisinae], no. 114, as the eyewitness inspector Bullialdus reports (*Astronomia* VI.5), adding that in that year, on February 21, at 11h 14' after midday, Saturn at Athens was seen to emerge from the Moon, and its place was seen to be ...

was seen to be in $6^{\circ} 42' 18''$ of Cancer, with southern latitude $19^{\circ} 27'$. But Saturn had been occulted much earlier than the body, by the splendor of the Moon, than [it would have been] by the body itself.

7. In the year 1461, Johannes Regiomontanus [Regiomontanus], as he himself relates in his observations, on the 2nd of December, in the evening, observed at Rome that Mars was in the same straight line with two stars at the head of Capricorn, that is, in 27° of Capricorn; but Saturn was then more to the east by two degrees — that is, in about 29° of Capricorn — though the *Almanach* of Alfonso [Almanach Alphonsinum] put Saturn at the same second of December. So on the 14th [it was]. On December, after sunset, he saw Venus joined with Saturn, even though by the *Almanach* Venus was more to the east than Saturn by $1^{\circ} 27'$.

CHAPTER II.

Observations of Saturn made at Nuremberg by Bernhard Walther of Nuremberg [Bernardo Vualtero Norimbergensi], pupil of Johannes Regiomontanus, from the Year of Christ 1475 down to 1504.

The observations of Walther [Vualterus] are reduced to three classes. The first is of those that were made without instruments, by ocular estimation of the planet's distance from other planets or fixed stars. The second is of those made with the radius [the cross-staff], comprising the rectangular triangle [Triangulum

rectangulum] suitable for taking the distances of stars in any way. The third is of those made with the zodiacal armillae [Armillas Zodiacales], about which we shall report later, once we have examined them more closely.

1. In the year 1475, September 17, between the 2nd and 3rd hour after midnight, in the morning, Walther saw Saturn standing apart from Mars by very nearly 5 minutes, more to the north in latitude than in longitude; and Mars so much more to the west, that he saw the same Saturn more to the east on the 19th. He therefore concludes that the conjunction of Saturn with Mars was incident on the 18th, around the 3rd hour after midnight, even though the *Almanach* expected it on the 21st.
2. In the year 1476, March 25, at the 2nd hour of the night, he saw Saturn near the Nebula of Cancer; for Saturn appeared to be separated by two digits to the west, the straight line drawn between the fourth and fifth of Cancer; but it was in the same straight line of Cancer, the fourth, and with the first, or Nebula, equally distant from each. Because this disagrees with the tables, Bullialdus (*Astronomia* VI.5) gathers — as is to be read in the text — the fifth of Cancer; otherwise the observation will not stand: for the first of Cancer, or Nebula, was then in $0^{\circ} 14'$ of Leo, that is, the fourth; the fourth of Cancer in $1^{\circ} 22' 14''$ of Leo, and the Asellus Australis [the Southern Donkey], or the fifth of Cancer, in $1^{\circ} 14'$ of Leo. Thus Saturn was in $0^{\circ} 41'$ of Leo, whose place, however, he computes from his own tables at $0^{\circ} 20'$ of Leo; he subjoins that, on account of the magnitude of the Nebula, Walther's eye could have erred in the position of Saturn.
3. In the year 1477, September 5, in the morning, around the third hour after midnight, he saw that Saturn and Mars were distant from each other by one palm, and Mars was more to the west; from which he concludes a punctual conjunction on that day, so that Mars ought to have eclipsed Saturn — but it is said below, in the Martian observations, on the 6th of October rather, that this conjunction took place on the 5th of September of this year.
4. In the same year, October 15, from an observation, he detects an error in the tables of one degree and $36'$, as to the position of Saturn and Mars.
5. In the year 1478, September 24, 40 minutes before sunrise, he saw the conjunction of Saturn with the Moon, such that the Moon ... was seen to be in $6^{\circ} 42' 18''$ of Cancer, with southern latitude $19^{\circ} 27'$. But Saturn was occulted much earlier by the splendor of the Moon than by the body [itself].

6. In the year 1479, October 30, he saw the conjunction of Saturn and Mars, as to longitude, such that Saturn was more to the north by almost one degree; but Mars was very near the sixth of Virgo.
7. In the year 1481, October 22, around an hour before sunrise, he saw Saturn and Mercury in the same latitude, but Mercury more to the east than Saturn, by one diameter of the Moon; from which he concludes that their conjunction preceded that observation. Particularly, since on the 23rd day he saw Mercury more to the east than Saturn by about three diameters of the Moon.
8. In the year 1482, at the hour $2\frac{1}{4}$ before sunrise, the Moon eclipsed Saturn — since at the hour $2\frac{3}{4}$ before sunrise Saturn had been more to the east in southern latitude, and the Moon was distant from it by two Moons [i.e. two lunar diameters]; but when the Moon had emerged, it was distant from the northern horn of the Moon by two digits — gradually; afterwards they passed the middle of the heaven; but the Moon, at the time when the middle of the eclipse is reckoned, was seen to be at 23° of ... [Saturn at] 13° ...
9. In the year 1504, March 28, in the morning following the night, he saw Saturn more to the west and more to the north, by $2\frac{1}{4}$ of an hour [?] but more distant in latitude than in longitude; on the following night he saw Saturn much nearer to the aforesaid star; therefore he concludes that the conjunction of Saturn took place then. Hence Bullialdus likewise (*Astronomia* VI.6) reckons that conjunction to be made on the 29th of March, at the 2nd hour after midday.

Observations of Saturn made with the Radius [the cross-staff]

The second class has the distances of Saturn taken with the Astronomical Radius, and indicated by the first and second Sine — which, in order that they may be found, are multiplied by 1200; and divided by the first Sine, and produced by the second Sine, as often emerges in the question, in the Gnomonic Table of Purbach [Purbachii], constructed to the same number of 1200, exhibiting the degrees and minutes of the distance sought.

For example: Saturn is said to be distant from Algomisa [Algomisa, i.e. Procyon], so that the first Sine is 210, and the second Sine 489 particles. Therefore, multiplying the parts of the Gnomonic Table 1200 by 210, you get 252000; which, divided by 489, yields as often as $515\frac{1}{3}$; which number, sought in the aforesaid Table under the column of 500 parts, in the region of the number 15, of the left

side, and computed by the proportional part, exhibits $23^{\circ} 13' 53''$. Therefore Saturn stood distant from Algomisa by $23^{\circ} 13' 53''$ — unless the parallax of the eye [parallaxis oculi] of this kind should indicate that such distances need correcting, because the angle at the center of the Astronomical Radius is greater than the angle made at the bottom of the eye.

Table of distances of Saturn taken with the Radius (1475):

Y r.	M o.	D H . . M.		Dist. of ♄ from the Fixed Stars	Sin e 1	Sin e 2

		Twenty-first of Virgo [♍]	110	520

33. The third class contains observations made by means of zodiacal armillae, that is, observations verified or corrected against Aldebaran, or the Heart of the Lion, or other stars; but among these the certainty is not below about ten minutes. For Walther himself says, under the year 1503, September 16: *Ten minutes are to be added, on account of the motion of Aldebaran [recorded] for all the stars observed by means of it, all the way up to 13 October; and on 12 December he says: I have again observed these with delay, and most diligently. Yet I see that nothing closer than ten minutes can be captured with precision by the instrument, or thereabouts.* Again, under the year 1504, he has this: *I have again corrected the motion of Jupiter and of Saturn, adding ten minutes on account of the variation in the place of Aldebaran from 1 September of the year 1503; through the Heart of the Lion they fall short by ten minutes. Nonetheless I have selected not a few of these as they stand in Walther, choosing every sixth one.*

[The second, parallel table occupies the right-hand column of folio 282. It tabulates, for the later Walther observations (numbered 34–70), the computed quantities: the *mean motion in longitude* (Mediab. Caelu — read as *Medium ab Capite/Caelo*, the mean reckoned in the heavens), Saturn's longitude, and its latitude.]

Table — Walther's reduced Saturn positions (continuation), Nuremberg.

CAPUT III.

Saturn observations of Copernicus, Pitati, Ristori, and Giuntini, from the year 1514 to 1563.

The reader is forewarned, from Rheticus's preface to the Ephemerides of the year 1551, that Copernicus was sufficiently satisfied if in his observations and computations he did not depart from the truth by ten minutes. Moreover, he

made no mention of any correction for refraction, and he fixed the altitude of the pole at Frauenburg [Frombork] at a value just over three minutes too large, by the testimony of Tycho Brahe (*Progymnasmatata*, ch. 1). In the observations that follow, no certainty greater than these limits is to be required.

1. In the year 1514, on the sixth before the Kalends of May [26 April], at the fifth hour after midnight, Copernicus saw Saturn in a straight line with the second and the third [stars] of the forehead of Scorpius — that is, at an elongation of 209 degrees from the first star of Aries. So he himself states (*De Revolutionibus* V, ch. 9).
2. In the same year, on the third before the Nones of May [5 May], at the first hour and 12 minutes before midnight, Copernicus observed Saturn in opposition to the Sun — that is, with Saturn placed at the mean position of the Sun, Saturn being in [text continues on the facing page]

degree 205, 24' from the first star of Aries (Copernicus, *De Revolutionibus* V, ch. 6).

3. In the year 1520, on the third before the Ides of July [13 July], from an observation of Copernicus, Saturn was in opposition to the mean place of the Sun at the very meridian of Frauenburg, or Cracow, Saturn holding a degree of 272, 25' from the first star of Aries. So Copernicus himself (*De Revolutionibus* V, ch. 6).
4. In the year 1524, in nearly the same February, Saturn, Jupiter, and Mars were in conjunction in Pisces at 10 degrees — about which Kepler too writes in Book V on the new star, ch. 29.
5. In the year 1527, on the sixth before the Ides of October [10 October], at the sixth hour and 24 minutes after midnight, the opposition of Saturn to the mean place of the Sun was observed by Copernicus, with Saturn distant from the horn of Aries by 7 minutes, at 4 degrees (*De Revolutionibus* V, ch. 6).
6. In the year 1536, Pietro Pitati [Pietro Pitati], from his observation, judged that Saturn had been in conjunction with Mars on 22 May; but Julian Ristori of Prato, Doctor of Sacred Theology and an excellent mathematician, the teacher of Giuntini [Francesco Giuntini], on 19 June at the first hour of the night, saw Saturn nearly covered by Mars, as had been the conjunction predicted in the preface to his tables; and yet Stöffler, in his Ephemeris together with the Alphonsine Tables, had assigned that [conjunction] to 25 May.

7. In the year 1542, on 29 January, at the ninth hour following, of the night, Saturn and Mars were observed in conjunction, as predicted by Ristori, at Giuntini's [place], as above.
8. In the year 1563, on the ninth before the Kalends of September [24 August], at the fourteenth hour, 30', after midday, the conjunction of Saturn and the more boreal of the two Joves [Jupiter and Saturn] at Orange showed Saturn to be somewhat more southerly, virtually grazing it, in Cancer at 28 degrees — as the foretold conjunction is narrated in the preface of the tables. And yet the Alphonsine [tables] put off this conjunction to 25 September, in Leo at 4 degrees, 12'.

CAPUT IV.

Saturn observations after Tycho's manner, in which the days are noted in the Old Style of the Calendar.

1. In the year 1582, on 21 August, at the second hour after midday, there was an opposition of Saturn to the true place of the Sun in Pisces at 7 degrees, 26'; but [taken] from the Tychonic observation, [Saturn being] reckoned from the tables. So Longomontanus in his *Astronomia Danica* II, *Theorica* ch. 1.
2. In the year 1583, on 6 September, at the third hour and 1', there was a true opposition of Saturn to the Sun in Pisces at 19 degrees, 50', from observation; the Tychonic [value], but reckoned by Danish calculation, [is] 19 degrees, 48' $\frac{1}{3}$. Longomontanus, as above.
3. In the year 1584, on 15 September, at the sixth hour and 30', there was a true opposition of Saturn to the Sun in Aries at 2 degrees, 34'; [taken] from the Danish tables at 2 degrees, 35' $\frac{3}{4}$. Observed by Tycho. Longomontanus, as above.
4. In the year 1585, on 28 September, at the first hour and 30', there was a true opposition of Saturn to the Sun in Aries at 15 degrees, 39'; but [taken] from the Danish tables at 15 degrees, 39' 15". Longomontanus, as above.
5. In the year 1586, on 12 October, at the eleventh hour, the true opposition of the Sun to Saturn was in Aries at 29 degrees, 2'; Tycho observing, but [taken] from the Danish tables at 29 degrees 4'. Longomontanus, as above.

6. In the year 1587, on 9 January, at the ninth hour, 45', after midday, Tycho at Uraniborg observed Saturn in Aries at 26 degrees, 8', with southern latitude 2 degrees, 28' — yet the Alphonsine calculation would place that [planet] at 28 degrees, 8' with latitude 2 degrees, 30'; Copernicus, however, [puts it] at 25 degrees 58', with latitude 2 degrees, 32'. He used this Boulliau observation, *Astronomia Philolaica* VI, for his own purposes, and the places of Saturn's nodes are to be investigated. See Tycho's letter, p. 56.
7. In the same year, on 14 January, at the fifth hour, 50', after midday, Tycho observed Saturn in Aries at 26 degrees, 21', with southern latitude 2 degrees, 26'. The Alphonsine [value] for it was 28 degrees, 21'; but Copernicus [puts it] at 26 degrees, 12'; the latter has latitude 2 degrees, 30'. Tycho, where above.
8. In the same year, and month, on 15 [January], at the fifth hour, 45', after midday, Tycho observed Saturn in Aries at 26 degrees, 4', with southern latitude 2 degrees, 25'. The Alphonsine [value] there was 28 degrees, 24'; but Copernicus [puts it] at 26 degrees, 27'. Lansbergen, in his *Thesaurus*, collected from this observation, by adding refraction at 26 degrees 23', 28", and a latitude of 2 degrees, 26'.
9. In the year 1587 likewise, on 26 October, at the ninth hour after midday, there was a true opposition of the Sun to Saturn in Taurus at 12 degrees 46', [taken] from a Tyconic observation, rather than from the Danish tables. By which occasion it is to be noted that the *Longomontanus* II, *Theoricae* ch. 2, [says] that the Danish tables, taken from the *Thesaurus*, were corrected, but in such a way that the mean place of Saturn is short by 10 minutes from its apogee, with Saturn at 3 degrees of eccentricity, but elsewhere by adding the prosthaphaeresis, the fiftieth part.
10. In the year 1588, on 8 November, at the tenth hour, 10', there was a true opposition of the Sun to Saturn in Taurus at 26 degrees, 44'; Tycho observing, [the value taken] from the Danish [tables] at 26 degrees, 44' also. Longomontanus, as above.
11. In the year 1589, on 22 November, at the fourth hour, 30', there was a true opposition of the Sun to Saturn in Gemini at 10 degrees, 55'; Tycho observing, [taken] from the Danish [tables] at 10 degrees 53'. Longomontanus, as above.

12. In the year 1590, on 8 February, at the eighth hour, 8', in the evening, Tycho observed Saturn at Uraniborg in Gemini at 7 degrees, 32'; the same year too, at about an hour into the night, [observed] in degree 7, 38½. Geminus, with latitude southern 1 degree, 30'. Longomontanus II, *Theoricae* ch. 2, and Boulliau VI, *Astronomia* ch. 1, & 2.
13. In the year 1590, on 7 September, at the twelfth hour, Tycho observed Saturn in Gemini at 28 degrees, 6', with southern latitude 1 degree, 11'. So Boulliau, *Astronomia* VI, ch. 1, & 2.
14. In the same year, on 6 December, at the tenth hour, 20½, after midday, there was a true opposition of the Sun, with Saturn being in Gemini at 5 degrees, 10', as Tycho observed. But [taken] from the Danish tables at 5 degrees 8½. Longomontanus II, *Theor.* ch. 2.
15. In the year 1591, on 17 March, at the seventh hour, 30½, in the evening, Saturn was observed by Tycho at Uraniborg in Gemini at 22 degrees, 24½. Longomontanus, as above, ch. 3.
16. Likewise in the year 1591, on 1 December, at the eighth hour after midday, there was a true opposition of the Sun, with Saturn placed in Cancer at 9 degrees, 24½; Tycho observing. But [taken] from the Danish table at 9 degrees, 23'. Longomontanus, as above, ch. 2.
17. In the year 1595, on 30 January, at the twenty-first hour after midday, there was a true opposition of the Sun, with Saturn placed in Leo at 21 degrees, 15½; Tycho observing. But [taken] from the Danish [tables] at 21 degrees, 18½. Longomontanus, as above.
18. In the year 1600, on 13 January, at the seventh hour, 30', after midday, Tycho, at the citadel of Benatky [Benatky Castle] near Prague, observed Saturn distant from Venus at 5 degrees, 29'; for Saturn approached the station, observing its meridian altitude at 31 degrees, 7', and its distance from Spica at 11 degrees, 12', 1", and [its distance] from the boreal Lance [scale of Libra] at 16 degrees, 7½, having crossed [the meridian] somewhat earlier than Spica; the meridian altitude of the other being 30 degrees, 41'. Hence Tycho concluded that on the preceding day Saturn had been in Gemini at 28 degrees, 18', 44", with northern latitude 2 degrees, 43'. But on day 25 it was found in degree 28, 30', 44", with northern latitude 2 degrees, 34½. So Snel in his observations. Tychonic.

19. In the year 1600, on 2 April, at the twelfth hour, 21', after midday, Tycho, in the citadel of Prague, observed Saturn's meridian altitude to be 32 degrees, 28½, & at the twelfth hour, 43', observed the same [planet] distant from the boreal Lance at 19 degrees, 14½. So Snel, as above.
20. In the same year, on 9 April, at the eleventh hour, 21', 37½, Tycho likewise observed Saturn distant from Spica at 8 degrees, 9½, & at the eleventh hour, 46', distant from the boreal Lance at 19 degrees, 45', & at the twelfth hour altitude, observing its meridian altitude at 32 degrees, 40'.
21. In the year 1601, on 6 July, in the evening, at the ninth hour, 39', after midday, Tycho likewise there observed Saturn distant from Antares [Heart of the Scorpion] at 32 degrees, 1', & from the boreal Lance at 11 degrees, 42½. Hence the place of Saturn in Scorpio [was found] at 3 degrees, 50½; the latitude of the same [being] boreal at 2 degrees, 20½. But our calculation (says Tycho at Uraniborg, as above) gives the longitude at 3 degrees, 43', 23", & the latitude at 3 degrees, 19', 26".

If anyone should desire that the foregoing observations be brought into accordance with the Gregorian-Calendar style, let him add to them ten days; and they were from the year 1582.

The remaining observations of Tycho or of Longomontanus, which we shall set forth below in Caput XI, the *Catalogue*, we have taken partly from Tycho's *Epistolae*, page 56.

partly from Longomontanus's *Astronomia Danica*, Book II, *Theoricorum* ch. 2 & 13; partly from a Tychonic manuscript, [obtained] from Father Albert Curtz of the Society of Jesus, who, since he was appointed by the Emperor for the editing of the Tychonic observations, very generously and most liberally transcribed them for me; and from these I have selected only a few, just to test the agreement, or disagreement, of the Astronomical Tables.

CAPUT V.

Saturn observations of Jost Bürgi, from the Hessian observations of Snel; and likewise of Lansbergen, Hortensius, Gassendi, and Boulliau, from the year 1592 to 1640.

Bürgi's observation of Saturn at Kassel, by the days of the Old Style.

Table — Bürgi's Saturn observations at Kassel (Old Style).

Columns: row index | Ann. (Year) | Mens. (Month) | Dies (Day) | Hor. Min. ant. vel post merid. (Hour, Minute, before or after midday) | Distantia Saturni à Fixis (Distance of Saturn from the fixed stars: Gr. degrees / M. minutes / star)

Y e a r	Mont h	Day	Hour, Min., before/after noon	G r M . .	from the star
1 5 9 2	Octob .	14	4 before noon	2 23 7	from Regulus
				5 57 2	from Aldebaran
1 5 9 3	Janua rij	3	6 30, after noon	8 46	from the head of Pollux [cap. Pollucis]
				3 12 4	from the right shoulder of Orion [humer. dext. Orion.]
1 5 9 4	Janua rij	2	8 p.m.	2 52 1	from the head of Pollux
				2 49 4 $\frac{1}{3}$	from Sirius
1 5 9 5	Nove mb.	24	5 0, before noon	1 46 3	from Regulus
			[thence] Boulliau I.6.c.2	1 50 2 $\frac{1}{4}$	from the back of Leo [dorso α]
			elicits the place of β	7 57 $\frac{1}{2}$	Virgo [$\mathfrak{M}$]
1	Maij	5	9 0, after noon	7 17	from Regulus

Y e a r	Mont h	Day	Hour, Min., before/after noon	G r M . .	from the star
5 9 6					
			[thence] Boulliau, as above	1 8 3	from the back of Leo [dorso ♀]
			elicits the place of h	1 29	Virgo [♊]
1 5 9 6	Maij	7	9 0, after noon	1 10 0	from the neck of Leo [ceruice ♀]
				1 52 7	from the tail of Leo [cauda ♀]
1 5 9 7	Marti j	27	8 30, after noon	2 35 1 ½	from Regulus
				1 2 0 ½	from the tail of Leo [cauda ♀]
1 5 9 5	Febr uarij	18 — <i>ought to be placed after the year 1594</i>	8 after noon	8 24	from the mane of Leo [iuba ♀]
				4 32	from Regulus

If, among Gassendi's observations — which are now being printed at Lyon, under the press — there shall have been other observations pertinent here, and they shall have come into our hands, they are to be added, and to be understood here as supplied.

15. In the year 1640, on 12 October, by the New Style, at the eighth hour & a few minutes after midday, Boulliau observed Saturn in the Meridian, distant from a star of the fourth magnitude, which belongs to the haunches of Aquarius, by 26'; but Saturn was more boreal than that vertical [star]; so

[it is in] Boulliau, *Astronomia* ch. 3, who, subjoining the observation, makes that star to have been in Aquarius at 23 degrees, 47'; with southern latitude 23 degrees, 55', 39", [recte: latitude] southern at 1 degree, 35' ½; so that Saturn was in Aquarius at 23 degrees, 55', 39"; with southern latitude 23 degrees, 24', 0", 8", with southern latitude 1 degree, 36', ¾; but the Rudolphine [tables give it] at 24 degrees, 5', with southern latitude 1 degree, 38'.

16. In the year 1630, on 19 June, with Michele Florenzio Langreno of Brussels observing, & [Saturn] culminating at the degree of the Equator 241, 5', 52", Saturn began to be occulted by the Moon, & from the moment at which it emerged; the foot of Virgo, for which Tycho gives the longitude at Libra 28 degrees, 57', latitude 2 degrees, 57', ¾, & likewise [for] star 22. The star of Virgo lay hidden beneath the obscure boreal part of the Moon; with the culmination at degree of the Equator 253, 42'.

CAPUT VI.

Observations of Saturn near the perigee of the eccentric, made at Majorca by D. Vicenç Mut [Vincentius Mutus], a man most skilled in astronomy, recorded on days of the New Style, all of them around the ninth hour after midday, and most generously communicated to us by letter, together with the place of Saturn derived from observation and from a fivefold calculation.

The first table records observations made at Majorca in 1650 (with two further observations from 1654). For each entry it gives the date, the measured distance of Saturn from the fixed stars (in degrees and minutes), the observed place of Saturn (sign, degrees, minutes), and then, under the heading *Difference of the Tables*, the discrepancy in minutes between this observed place and the place computed from the Prutenic, Danish, Rudolphine, Lansbergen, and Boulliau tables respectively.

Y e a r	M o n t h	Distance of Saturn from the fixed stars	Observed place of ♄ (Sig.)	Prute n. (')	Dani c. (')	Rodu l. (')	Lans b. (')	Bullia l. (')
1 6 5 0	Ja n u a r y	from the preceding star, the topmost in the foot of	♊	10	16	18	2	12

Y e a r	M o n t h	Distance of Saturn from the fixed stars	Observed place of ♄ (Sig.)	Prute n. (°)	Dani c. (°)	Rodu l. (°)	Lans b. (°)	Bullia l. (°)
	a y	preceding [star] in the foot of ♊ following						
(latit. 0 46)								

The second table gives two further observations from 1654, with the place of Saturn computed from the Danish, Rudolphine, Lansbergen, Ptolemaic [*Almagestum*], and *Novum* (Riccioli's own) reckonings:

Y e a r	M o n t h	H o u r	Distance of Saturn from the fixed stars	Observed place of ♄ (Sig.)	Dan ic. G.	Rod ul. G.	Lan sb. G.	Al ma g. G.	N o u .
1 3 5 4	Febr uary	1 9 0		♌	23	1 23 8	1 22 5	5 23 9	1 1
(latit ude)									
	Febr uary	1 9 5		♌	20	5 20 7	5 20 0	4 20 6	4 5

The observations of this year 1654 were made with Saturn very nearly acronychal [at opposition, rising as the Sun sets].

14. Earlier, in the year 1651, on June 5 at the 8th hour, he had observed Saturn in the same latitude as a star which is in the belly of the southern Twin [Gemini], but more easterly by 7 minutes; from which he concluded that on June 4 their partial conjunction had occurred.
15. Likewise, in the year 1643, on September 23, he had observed Saturn's meridian altitude as 53° 38', it being in a straight line with the Head of Algol [Caput Algol] and the northern star following in the Horn of Aries.

16. Likewise, in the year 1644, on September 30 at the 9th hour, he observed Saturn to be more westerly by 5' than the star preceding it after the bend of the Three of Pisces [the asterism *flexum trium Piscis*], and more northerly by 30".

CAPUT VII.

Observations made: 2 by Tycho [Tycho Brahe], 4 by the Fathers of the Society of Jesus at Innsbruck [Oenipontum], and 22 by the Marchese Cornelio Malvasia [Cornelius Malvasia] at Modena [Mutina].

In the year 1582, on August 21 at hour 10:02, Saturn was distant from the left shoulder of Aquarius $22^{\circ} 29'$; but at hour 10:39 it was distant from the right shoulder of Aquarius $16^{\circ} 5'$; and at hour 11:57¼ — or, more correctly, at hour 12:1¼ — it had a meridian altitude of $23^{\circ} 23'$.

In the same year, on August 23 at hour 9:57, Saturn was distant from the lower Horn [of Capricorn] $70^{\circ} 39\frac{3}{4}$, and at hour 10:5¼ it was distant from the left shoulder of Aquarius $22^{\circ} 20'$.

Observations made at Innsbruck [Oenipontum] by our Fathers, and transmitted to me by P. Michael Staudacher of the Society of Jesus.

In the year 1636, on July 10, with Arcturus raised toward its setting at $39^{\circ} 14'$ and Saturn at its rising at $18^{\circ} 40'$, Saturn itself was observed to be distant from the Head of Ophiuchus $41^{\circ} 17\frac{1}{2}$, and from the bright star of Aquila [Altair] $32^{\circ} 46\frac{2}{3}$.

On July 13, with Arcturus raised toward its setting at $44^{\circ} 25'$ and Saturn at its rising at $16^{\circ} 50'$, Saturn was seen to be distant from the bright star of Aquila $32^{\circ} 53\frac{1}{2}$, and from the Heart of Scorpius [Antares] $35^{\circ} 39'$.

On July 23, with Aquila raised high toward its rising at $40^{\circ} 54\frac{3}{4}$ and Saturn at $17^{\circ} 12'$, Saturn was distant from the Head of Ophiuchus $40^{\circ} 54\frac{3}{4}$, and from the bright star of Aquila $33^{\circ} 10' 50''$.

Finally, on July 25, with Aquila raised toward its rising at $34^{\circ} 30'$ and Saturn at $18^{\circ} 18'$, Saturn was observed to be distant from the Head of Ophiuchus $40^{\circ} 51' 50''$, and from the bright star of Aquila $33^{\circ} 18' 30''$.

Observations of the most illustrious Marchese Cornelio Malvasia, made at Modena [Mutina].

These observations survive in the *Ephemerides* of the same Marchese Cornelio, published at Modena in the year 1662, given to me most generously by the author himself, at fol. 187, where he states that he observed the altitude of the Pole of Modena to be $44^{\circ} 38'$; whereas, when we observed it, we found it $44^{\circ} 38' 50''$. He there assumes the longitude of Modena to be $34^{\circ} 5'$ — very close to that which we determined in the *Geographia Reformata*, namely $34^{\circ} 6' 30''$. With these settings, he proceeds.

In the year 1662, on May 30, around hour 1 of the afternoon, using a wooden sextant exhibiting single minutes, and with the assistance of D. Geminiano Montanari [Geminianus Montanarius], Doctor of Laws and a most expert astronomer, he observed Saturn to be distant from Spica $42^{\circ} 17'$, and from the Heart of Scorpius [Antares] $7^{\circ} 46'$. Antares 10° , Spica 35° — from which, ordered by means of the Refraction Table of Cassini [*Tabula Refractionum Cassinica*], which appears in the same volume at fol. 173, he found the Refraction of Saturn to be $3' 7''$. Antares $5' 42''$, Spica $1' 25''$; from which there come out, as the corrected distances of Saturn from Antares $7^{\circ} 43'$, and from Spica $42^{\circ} 16' 45''$ — or, if it be first rounded, $42^{\circ} 17'$. From this, assuming from the Tychonic latitudes that Antares is $4^{\circ} 27'$ and Spica $1^{\circ} 59'$, and the difference of their longitudes $45^{\circ} 57'$, and the longitude of Spica in $\sphericalangle$ $19^{\circ} 8' 12''$, they gathered by trigonometry the longitude of Saturn in $\sphericalangle$ to be $1^{\circ} 13' 8''$, and its northern latitude $2^{\circ} 14' 6''$. With Lansbergen's calculation giving it as $1^{\circ} 22' 29'' \sphericalangle$ — and this, $2^{\circ} 16'$.

By this method of observing and of calculating, he collected from the evening observations the longitudes and latitudes written below, together with the excess over the Lansbergian Tables noted by him, employing the distances of Saturn from Spica, and either from Antares or from Arcturus.

Moreover, on July 3, from the distance of Saturn from Spica, and from the middle star in the neck of Ophiuchus, corrected, and from the Tychonic stars, the same Marchese derived the longitude of Saturn in Scorpius $29^{\circ} 9' 8''$, and its northern latitude $2^{\circ} 7' 46''$. But because, through the optical tube fitted with a lattice of silver wire for determining smaller intervals, as is described in the same volume at fol. 196, a certain small star was seen to be distant from the eastern limb of Saturn imperceptibly [*insensibiliter*], the apparent semidiameter of Saturn being neglected, he established the place of that fixed star to be the same as that of Saturn; so that by the following days' Saturnine distances from the same fixed star, the place of Saturn could be more certainly defined. And so, on day 4 in the evening, Saturn was found distant from that fixed star $2' 35''$, of the kind of which the whole tube took in $41\frac{1}{4}$; and therefore in Scorpius $29^{\circ} 6' 30''$. Therefore, by a similar method, he set out for us the Saturnine longitudes and latitudes written below, but selected by me.

This is a specimen of the said observations, from which it is clear that Lansbergen's tables at this period exceed the true place of Saturn by about 15 minutes; for

[The discussion of Lansbergen's excess concludes:] from a more exact reckoning we are unable to establish anything here, the more so because the most illustrious Marchese Cornelio uses the Tyconic stars, whose needed little correction we have shown in Book 4, and the distances of Saturn from the fixed stars adjusted by the Cassinian Refraction, about which, however, we have indicated in Book 1, Chapter 1, number 9, what we doubt.

But in the year 1663, the same illustrious Marchese Pansano [Pansanus] [?], from the observations of many days and from the distances taken with a very large sextant, concludes a Great Conjunction of Saturn, Jupiter, and the fixed stars to have occurred on October 16, at hour 7:34 after midday, in Sagittarius 13° 2' 46", and the northern latitude of Saturn 1° 16'; Jupiter 0° 16' ⅗. We, however, taking it around hour 8 p.m. of the same day, [find it] in 13° 3' ⅗, with the same latitude.

CAPUT VIII.

Select observations of Saturn, out of many, which Father Giovanni Battista Riccioli [Io. Baptista Ricciolus] and Father Francesco Maria Grimaldi [Franc. Maria Grimaldus] carried out at Bologna [Bononia] in the College of St. Lucy [Collegium S. Luciae], together with others as assistants, whenever there was need, of the Society of Jesus.

1. In the year 1641, on the night following the 20th day of August, at the hour acquired from the fixed stars after midday 13:59, the altitude of Saturn above the western Horizon was observed to be $21^{\circ} 23'$.
2. In the same year, on the night following August 31, an hour after midnight at 3:25' 37", the altitude of Saturn, acronychal, above the Horizon was seen to be $19^{\circ} 35'$.
3. In the same year, on the night following October 14, Markab of Pegasus [Markab Pegasi] crossed the middle of the Heavens, and Saturn at the perpendicular [*ad perpendicularum*] by $8^{\circ} 45''$; M. C. [the meridian crossing] of Saturn followed, whose altitude was then seen to be $31^{\circ} 6'$. It was estimated that at that time the meridian altitude was $10^{\circ} 50'$ — but the meridian reckoning was incorrect.
4. On the same day of the same month, in the night following the transit of the star Fomahant [Fomalhaut], when by the same [method] Saturn's transit was counted, the time turned out to be smaller [i.e. shorter]. The meridian altitude of Saturn was seen to be $34^{\circ} 50'$.
5. Likewise, in the year 1642, on June 6, in the morning, with the altitude of the bright star of Aquila falling westward at $51^{\circ} 15'$, and the times reckoned up to the altitude of Saturn at $25^{\circ} 52'$, [and] minutes of time $8^{\circ} 55''$, and on day 7, in the morning, about one hour before the rising of the Sun, the bright star of Aquila obtaining a western altitude of $52^{\circ} 40'$, the times being reckoned up to it $5^{\circ} 22''$, by means of a perpendicular, [and] then at once the western altitude of Saturn captured at $22^{\circ} 12'$.
6. In the year 1642, on July 16, in the morning, with the altitude of the bright star of Aquila falling westward, the times being reckoned by the same [method], $6^{\circ} 40''$, after which the meridian altitude of Saturn was observed to be $41^{\circ} 57'$.

7. In the same year, on September 13, in the night following, Saturn's acronychal meridian altitude was seen to be $39^{\circ} 59'$; after which, with the transit numbered to the perpendicular at $13' 45''$, the altitude of the bright star in the Tail of Cetus [*lucida caudae Ceti*, Deneb Kaitos] was captured at $24^{\circ} 56'$, and thence, from the transit of the same star by M. C. [meridian crossing], numbered $18' 35''$.
8. In the year 1642, on September 28, around the third part of the night [$\frac{3}{8}$ *noctis*], with the distance of Saturn captured by sextant from the bright star of Aries [Hamal], it was $19^{\circ} 34' 30''$; from the Lower Jaw [*Mandibula*] of Cetus, which is of the second magnitude, $43^{\circ} 46'$.
9. In the same year, on October 14, around the second hour of the night, Saturn was seen to be distant from Fomalhaut $26^{\circ} 51'$, and from the bright star in the Tail of Cetus $20^{\circ} 2'$, and again from Jupiter $10^{\circ} 31'$.
10. In the year 1643, on January 20, in the night following, the altitude of Saturn seen from the west was $31^{\circ} 23'$, and its azimuth $39^{\circ} 40'$; thence, after $4' 40''$ had elapsed, the rising altitude of Aldebaran was $48^{\circ} 50'$.
11. In the year 1643, on June 28, in the morning, the western altitude of the bright star of Aquila was $46^{\circ} 2'$; thence, after minutes of time had been counted, Saturn was nearest to the Sun by the Sextant [recte: at the next Solar Sextant, i.e. the 60° aspect]; the observation was carried out, distant from the foot of Andromeda $42^{\circ} 54'$; then, after 4 minutes of time, distant from the bright star of Aries $28^{\circ} 1' 30''$ — most exactly.
12. In the year 1643, on July 15, in the morning, the rising altitude of the bright star of Aries was $46^{\circ} 50'$; thence, after 32 minutes had elapsed, the distance of Saturn from the bright star of the Sextant was $27^{\circ} 45'$; and after 4 minutes of time it was distant from Aldebaran $35^{\circ} 7'$; and after a further 4 minutes of time distant from Jupiter to the east [*Ioue orientiori*] $15^{\circ} 50'$.
13. In the same year, on July 26, the captured oriental altitude of the bright star of Aries was $59^{\circ} 10'$; the perpendiculars counted were $6'$; after which the distance of Saturn from the Sextant was $27^{\circ} 43'$; from the same, after a further 6 minutes of time, it was distant from Aldebaran $56^{\circ} 58\frac{1}{2}'$.
14. In the same year, on July 30, in the morning, the captured rising altitude of the bright star of Aries was $58^{\circ} 27'$; the minutes elapsed, 4; Saturn distant from the bright star of Aries $27^{\circ} 50'$; and after 10 minutes it was distant

from Aldebaran $57^{\circ} 2'$ — for at that time Saturn was retrograde, and nearest to the Sextant of the Sun.

15. In the same year, on August 31, in the morning, Aldebaran shining in the East, distant at the vertex $34^{\circ} 10'$; after which, the time being counted, 10 minutes, Saturn was distant from the same $58^{\circ} 25'$; thence, after 2 minutes of time, it was distant from the Lower Jaw of Cetus $40^{\circ} 2'$ — but it was not verified, since [the reading is] suspect; therefore only the distance of Saturn from the bright star of Aries $6^{\circ} 12'$ [is given] — nearest.
16. In the year 1643, on September 27, in the night following, Saturn, acronychal, crossed [the meridian] by M. C., its meridian altitude being captured by a double quadrant at both points, $44^{\circ} 48'$; but its rising altitude, counted as the minutes of the meridian, $13' 41''$, was observed — the rising altitude of the bright star of Aries $62^{\circ} 24'$.
17. Likewise, in the year 1643, on December 25, under the first hour of the night following, the fourth from sunset, Saturn at the Quadrant of the Sun, near the Head of Andromeda, distant at the vertex $25^{\circ} 15'$.
18. In the year 1644, on June 28, with the bright Head of Aries having an altitude, seen at the vertex, of $20^{\circ} 30'$, Saturn was observed [recte: was seen]; its distance from the bright star of Aries by the Sextant $13^{\circ} 53\frac{1}{2}'$; then, after 8 minutes of time, the distance of Saturn from the bright star of the girdle of Andromeda was $29^{\circ} 6\frac{1}{2}'$. It was nearly Italic [Italian-reckoned hours]; and the refraction of the bright star of Aries was such that Saturn was very nearly at par with it, and so the distance scarcely has any need of correction.
19. In the same year, and in the same month, on day 9, Saturn was observed to be distant from the bright star of Aries $36^{\circ} 9'$; and after 7 minutes the time observed [gave] the distance of Saturn from the bright star of the foot of Andromeda $36^{\circ} 9'$.
20. In the year 1644, on July 11, in the night following, Saturn was distant from the bright star of Aquila falling westward at the Italic sixth hour, very nearly, and halved [i.e. about $6\frac{1}{2}'$], or [from] the bright star of Aquila toward its setting, $17^{\circ} 24\frac{1}{2}'$; and after 9 minutes it was distant from the bright star of the foot of Andromeda $18^{\circ} 13'$. The foot of Saturn itself, [from] the bright star of Andromeda, was distant $18^{\circ} 48'$ — as often [done] in other observations.

21. In the same year, on July 22, in the morning, at the Italic civil hour 17:15, Saturn was seen to be distant from the bright star of Aries $43^{\circ} 56' \frac{1}{2}$.
22. In the year 1644, on August 1, in the morning, with the bright star of Aries prepared [for measurement], distant at the vertex $33^{\circ} 15'$; Saturn was distant from Aldebaran $11^{\circ} 1'$, who in another instrument had been distant a half-hour before from Capella $60^{\circ} 15'$.
23. In the year 1644, on August 13, in the morning, in clearest weather, with Aldebaran distant toward the East at the vertex $44^{\circ} 53'$, Saturn was seen to be distant from Aldebaran $44^{\circ} 53'$; thence, the distance of Aldebaran being $43^{\circ} 36'$ from the vertex, Saturn was distant from Aldebaran $17^{\circ} 18'$ — for at this time Saturn was distant from the shoulder of Orion that precedes it $56^{\circ} 4'$ — and it was then nearest to the Sextant of the Sun.
24. In the year 1644, on October 8, in the night following, at hour 3 Italic, Saturn, acronychal, was distant from the bright star of Aries $17^{\circ} 51'$, and at the southern foot of Andromeda $36^{\circ} 3'$ — for it was more westerly than each star. But on day 9, the meridian distance of the Sun from the vertex was $29^{\circ} 8' 40''$; and in the night following that same day, at the Italic civil hour $2\frac{1}{2}$ [recte: $2\frac{3}{4}$], Saturn.

Saturn was distant from the bright star of Aries by $19^{\circ} 54'$, and from the southern foot of Andromeda by $36^{\circ} 6'$.

26. [Margin: $\square$ (quadrature)] In the year 1644, on November 17, on the following night, Rigel of Orion was observed rising toward the east, Saturn being distant from it by $63^{\circ} 56'$; and after 3 minutes Saturn was distant from Aldebaran by $49^{\circ} 57'$; and after another 3 minutes it was distant from the bright star of the jaw of Cetus by $26^{\circ} 13'$.

27. In the year 1645, on July 26, in the morning, when Saturn was distant from the bright star of Aries by $33^{\circ} 50'$ — the time having been counted out after 2 minutes — Saturn was observed once, and again, after another minute, distant from Capella by $48^{\circ} 56' \frac{1}{3}$; and after three minutes it was distant from Aldebaran by $30^{\circ} 59'$. [Margin: $\square$ (quadrature)] At that time it was near the quadrature [$\square$] of the Sun, whose meridian distance on the 27th was seen from the vertex to be, by the greatest quadrant [the large quadrant], $25^{\circ} 19' 20''$; but by the smaller quadrant, $25^{\circ} 19'$.

28. [Margin: $\oslash \oslash$ (conjunction with Mars)] In the year 1646, on June 23, in the morning, after the conjunction of Saturn with Mars, when the bright star of Aries

was distant from the vertex by $63^{\circ} 56'$, Saturn was distant from Capella by $40^{\circ} 32'$; but from the bright star of Aries it was distant from the vertex by $62^{\circ} 46'$. Saturn was distant from the bright star on the side of Perseus by $34^{\circ} 31'$.

29. [Margin: $\square$ (quadrature)] In the year 1646, on August 10, with the bright star of Aries distant from the vertex toward the east by $39^{\circ} 40'$: Saturn at the quadrature [$\square$] of the Sun, and near to it, was distant from Capella by 38° , precisely; but when the bright star of Aries was distant from the vertex by $38^{\circ} 22'$, Saturn was distant from Aldebaran by $17^{\circ} 26'$. It was itself then at an altitude of about 31° .

30. In the year 1647, on February 2, on the following night, at the $3\frac{1}{4}$ civil hour, Saturn was seen to be distant from the bright star of Aries by 15° ; and after observations were repeated most precisely, after 7 minutes it was distant from Aldebaran by $23^{\circ} 27'\frac{1}{2}$.

31. In the year 1647, on November 16, about the second hour, with half an hour after sunset, Saturn was seen to be distant from Capella by $30^{\circ} 48'$; and from the northern horn of Taurus by $25^{\circ}\frac{1}{2}$, when Saturn was at an altitude of $21^{\circ} 50'$; and from the northern horn by $17^{\circ} 16'$.

32. [Margin: $\circ$ (opposition)] In the year 1647, on November 20, on the following night, at about the 4th Italian hour, Saturn was observed acronychal [rising at sunset], distant from Capella by $31^{\circ} 7'$, and from the northern horn of Taurus by $20^{\circ} 50'$; but at the end of the observation Saturn was at an altitude of $40^{\circ} 45'$, and Aldebaran was distant from the vertex toward the rising point by $55^{\circ} 15'$.

33. In the year 1647, on November 25, on the following night, about the 3rd Italian hour, we saw Saturn distant from Capella by $31^{\circ} 17'\frac{1}{2}$, but from the northern horn of Taurus by $21^{\circ} 10'\frac{1}{2}$. These observations are to be set out below at nos. 53 and 54.

34. [Margin: $\circ$ (opposition)] In the year 1648, on December 2, when Saturn was approaching the perigee of its epicycle and drawing near to opposition [$\circ$], around the third hour of the following night Saturn was observed distant from the vertex toward the rising point by $57'$; and observed again, and more often, distant from Aldebaran by $7^{\circ} 40'$, and from Capella likewise at repeated observations by $24^{\circ} 52'\frac{1}{2}$.

35. In the year 1649, on July 27, in the morning Saturn was at an altitude of 23° , and distant from Capella by $25^{\circ} 24'\frac{1}{2}$, and from Aldebaran by $20^{\circ} 56'\frac{1}{2}$.

36. In the same year, on July 31, in the morning Saturn was seen at an altitude of $27^{\circ} 20'$, and then distant from Aldebaran by $21^{\circ} 27'$, but from Capella by $25^{\circ} 30' \frac{1}{2}$.

37. In the year 1651, on the very 1st of January, about the third Italian hour of the following night — that is, when Aldebaran, rising toward the east, was distant from the vertex by $38^{\circ} 56'$ — Saturn itself was then seen to be distant from Aldebaran by $36^{\circ} 21'$, and from the bright shoulder of Orion, or the following one, by $22^{\circ} 57'$.

38. [Margin: $\odot$ (opposition)] In the year 1652, on January 15, of the following night, at about the fourth Italian hour — that is, when the bright shoulder of Orion, rising toward the east, was distant from the vertex by $34^{\circ} 51'$ — Saturn was seen to be distant from the aforesaid shoulder of Orion, and soon after from Procyon, by $16^{\circ} 39' \frac{1}{2}$; and at Rigel by $51^{\circ} 33'$. Saturn was then at an altitude of about 36° , and not far from opposition [$\odot$] with the Sun.

39. In the same year, on May 29, on the following night, about the first hour after sunset, when the head of Pollux was at an altitude of $20^{\circ} 55'$, Saturn was seen to be distant from the bright star of the mane of Leo by $30^{\circ} 12' \frac{1}{2}$, but from Regulus by $29^{\circ} 27'$, when Saturn was at an altitude of $20^{\circ} 33'$.

40. In the same year, on November 19, in the morning about the 13th Italian hour, Saturn, near to retrogradation, was distant from the Dog Star, or Procyon, by $26^{\circ} 57'$; and a little after from the heart of Leo by $12^{\circ} 26'$, when Regulus itself was nearly on the meridian.

41. In the year 1653, on January 30, after the opposition with the Sun already celebrated [observed], but because of clouds unobservable on the following night, when Procyon was distant from the vertex by $60^{\circ} 40'$, Saturn was distant from the bright shoulder of Orion, and on the following day soon after from Procyon, by $24^{\circ} 23' \frac{1}{4}$.

42. In the same year, on March 7, when on the following night the bright foot of Gemini was culminating, we observed Saturn distant from Procyon by $22^{\circ} 40'$, but from the following shoulder of Orion by $45^{\circ} 15'$.

43. Likewise in the year 1653, on April 27, on the following night, almost 2 hours after sunset, we observed Saturn distant from the following head of Gemini by $18^{\circ} 30'$, and from the heart of Hydra by $28^{\circ} 14'$.

44. Also in the year 1653, on December 6, in the morning, with the sky most serene and most dry, Saturn was distant from Procyon by $38^{\circ} 47' \frac{1}{2}$, and from the southern head of Gemini by $38^{\circ} 2'$; and soon after Saturn was distant from the

vertex by $37^{\circ} 14'$; and after 2 minutes the azimuth of Saturn from the vertex was $37^{\circ} 14'$, observed toward the west. The distance of Saturn from the vertex was $38^{\circ} 36'$. On December 22, in the morning, at the $13 \frac{1}{4}$ civil Italian hour, Saturn was seen to be distant from Procyon, being then at an altitude of $18^{\circ} 23'$. Soon after it was distant from the head of Pollux by $37^{\circ} 50'$; but on account of refractions the distance of Saturn from Procyon is to be set at $38^{\circ} 36'$.

45. In the year 1654, on February 10, just under the Italian hour of night $2 \frac{1}{2}$, Saturn was at an altitude of $27^{\circ} 15'$, and was distant from Procyon by $35^{\circ} 53' \frac{1}{2}$; and from the bright star of the quadrilateral of Ursa Major — the one which shines on the haunch, or the one nearest among the Seven Triones [the Wain] — it was distant by $49^{\circ} 18' \frac{1}{2}$. [Margin: $\oslash$ Perig. (opposition; perigee)]

46. In the same year, on February 12, at very nearly the $6 \frac{2}{3}$ Italian hour by the civil clock, Saturn passed across the meridian; and its meridian distance from the vertex was $29^{\circ} 6' \frac{1}{2}$. Then, after a perpendicular had been let fall, the transit of Regulus was counted by M. C. [Margin: M. C.] and its meridian distance from the vertex was $30^{\circ} 51'$.

47. Also in the year 1654, on April 25, about the 3rd hour after sunset, Saturn was distant from Procyon by $32^{\circ} 53'$, raised at an altitude of $19^{\circ} 30'$; but from the head of Pollux by $31^{\circ} 13' \frac{1}{2}$.

48. In the same year, on April 29, about the $1 \frac{1}{2}$ hour after sunset, when Procyon was at an altitude toward the west, Saturn was distant from it by $32^{\circ} 56'$; and from Pollux by $31^{\circ} 17'$.

49. In the year 1655, on May 8, in the evening, after the high altitude of Procyon — 6 minutes having been counted — and then at once, Saturn was seen to be distant from Procyon by $44^{\circ} 52'$; but from the more easterly head of Gemini by $44^{\circ} 25' \frac{1}{2}$.

50. In the year 1655, on May 27, at about the 2nd hour after sunset, we observed Saturn distant from Regulus by $8^{\circ} 22'$, but from the bright star of the mane of Leo by $10^{\circ} 56'$.

51. In the same year, on June 5, at the 2nd hour after sunset, Saturn was distant from Regulus by $8^{\circ} 45'$, and from the bright star of the mane of Leo by $11^{\circ} 14' \frac{1}{2}$.

52. Again, in the year 1655, on July 10, on the following night, Saturn in azimuth, at precisely 90 degrees, was distant from the vertex by $74^{\circ} 17'$. Thence, with $6^{\circ} 50'$ counted off in minutes, the distance of Saturn at the time from the vertex from Spica was precisely 65° ; and at both [stations] the star was in the western region.

53. In the year 1656, on January 9, in the morning at the Italian hour of dawn at the $12\frac{1}{4}$ civil hour, Saturn, being retrograde, was distant from Regulus by $27^{\circ} 44' \frac{3}{4}$, and from the bright star of the mane of Leo by $28^{\circ} 33' \frac{3}{4}$.

54. In the year 1656, on March 3, just under the fourth hour of the following night, Saturn, tending toward conjunction [♌] with the Sun, was distant from Regulus by $24^{\circ} 49'$, and from the heart of Hydra by $36^{\circ} 26' \frac{1}{2}$.

55. In the same year again, and in the same month, on day 11, on the following night, at the 2nd hour, we saw Saturn distant from Regulus by $24^{\circ} 12'$, but from the heart of Hydra by $35^{\circ} 57' \frac{1}{6}$.

56. In the year 1656, on May 30, on the following evening, with the tail of Leo at an altitude of $41^{\circ} 23'$, to whose azimuth Saturn — marked out by the wire of the [filar] triangle [reticle] — was carried, it was distant from the vertex by $52^{\circ} 50' \frac{1}{2}$; and from its [the star's] arrival, with $2^{\circ} 20'$ counted off perpendicularly, Regulus was distant from the vertex by $62^{\circ} 33' \frac{1}{2}$. But all these stars were toward the west, just as Saturn was.

57. Likewise in the year 1656, on July 13, half an hour after the true [sunset], Saturn was observed by us to be distant from us — from the more eastern Spica — than Saturn was, by $30^{\circ} 48' \frac{1}{2}$; and from the bright star of the loins of Leo, which was setting, by $17^{\circ} 4' \frac{3}{4}$.

58. In the year 1657, on March 22, on the following night, at the 4th Italian hour, Saturn, near to opposition with the Sun, was distant from Regulus by $37^{\circ} 4' \frac{1}{2}$, and from Arcturus by $32^{\circ} 43'$.

59. In the same year, on June 24, on the following night, the distance of Spica was $57^{\circ} 22' \frac{1}{2}$; and after three minutes of time the distance of Saturn from the vertex was $54^{\circ} 20'$; and at once Saturn was distant from Spica by $20^{\circ} 21' 15''$.

60. [Margin: ♌ (opposition)] In the year 1648 — which was to be noted above — on February 21, at the 1st hour after sunset, Saturn was distant from Aldebaran by $8^{\circ} 54' \frac{1}{2}$; but Regulus from the horn of Orion by $33^{\circ} 1'$.

61. Likewise in the year 1648, on February 26, on the following night, about the 1st Italian hour, Saturn was distant from Aldebaran by $9^{\circ} 39'$, but from Rigel by $32^{\circ} 56'$.

62. [Margin: ♌ (opposition)] In the year 1650, on December 22, in the morning at sunrise, the distance of Saturn from the vertex was observed toward the rising point by $80^{\circ} 10'$, both in altitude and in azimuth; on the night of the same day,

with Scheat of Pegasus placed at an altitude in the quadrilateral of Pegasus, it was distant from the vertex by $39^{\circ} 2'$ toward the rising point. But after the observation, the distance of Saturn from the heart of Hydra was captured from the vertex, the rising being $55^{\circ} 47'$. Meanwhile, with $10^{\circ} 50'$ counted off perpendicularly, and because Saturn was in opposition with Mars on that day, the conjunction was believed to have occurred; and therefore the conjunction of Saturn with Mars is to be consulted below in the Mars observation at chapter 42 [recte: book on Mars, Cap. 42], at no. 7 of the chapter.

63. In the year 1650, on April 16, at noon on day 2, Saturn was observed at the meridian, distant from three certain Fixed stars very near to it, and at the same passage [transit], with Saturn seen stationary, with the Saturn motion stationary; and likewise direct, by that very method which is contained in the Ephemeris of Argoli [Andrea Argoli], and nearly so of Lansbergen [Philips van Lansbergen], in that the term of the station was between the 21st and 22nd of February.

64. In the year 1657, on December 14, in the morning, Saturn was observed on the very meridian, distant from the vertex by $48^{\circ} 57' 8''$; thence, with $50''$ counted off in seconds, it passed across Spica by the same meridian.

Observations otherwise promised from Gassendi above, at Cap. 5, no. 14.

Distances of Saturn from the Fixed stars, observed by the [astronomical] radius [cross-staff].

Year	Day	Gr. [°]	'

CAPVT IX.

Various methods are set out — 20 of them — for observing the positions of Saturn and of the remaining lesser planets, so that judgment may be made about observations by their effect [test] and certainty.

1. The First Method of all, in my judgment the most outstanding, is when the planet is near a Fixed star of known longitude and latitude, so that both can be seen together through the telescope, and an estimate be made by eye, joined with a Capacity of Minutes [a micrometer measure], by which it may be determined how the telescope grasps and fixes the longitude and latitude of the planet. For through the telescope, with the star uncovered of those rays which — whether from the atmosphere, or from the deceptiveness of the eyes — represent the stars as if they were larger and nearer than they really are. But this felicity is very rare. Yet we have some examples of it in Saturn, indeed at Chapter 5, Observation 15, and at Chapter 6, Observation 16. And in Jupiter we shall give from our own [observations], and from those of D. Vicenç Mut [Vicenç Mut], a most splendid example, in Book 1 of the *Almagestum Novum*, Section 6, Cap. 10, and in others below, where we shall treat of the individual planets.

2. The Second Method, nearer to the preceding, is observation made with the naked eye when a planet touches [draws close to] some Fixed star, of which the longitude and latitude are known; or, if it does not touch it, is yet so near it that an estimate can be taken by eye, with a paucity of digits in breadth, by which the planet is distant from the Fixed star, or in latitude. For an Astronomical Digit, raised in the sky, is equivalent to Minutes 2 ½ at most; and this method here is

liable to that deceptiveness of splendor of which we spoke in the first method, whence it comes about that the planet and the Fixed star seem nearer to one another than they themselves really are.

Examples of such observations, besides those which we adduce concerning the other planets in their places, are — for Saturn — above at Cap. 1, Obs. 2; Cap. 2, Obs. 5; Cap. 6, Obs. 10; Cap. 6, Obs. 14. Yet I do not wish, in Obs. 1 of Cap. 1, to set out that whole difference, namely between the Ptolemaic computation, the Longomontanian [Longomontanus], the Bullialdian [Ismaël Boulliau], and Our own; we ascribe the aforesaid deceptiveness, since the greater part arises from the place of the Fixed star, taken at that time from diverse Tables, and so also from the other examples. Yet I should believe that even by this method one can — provided only the arrivals [approaches] of either of the five [planets] to the Fixed star, and perhaps more, in some first scruples [minutes] — go astray.

3. The Third Method, akin to the preceding, but much more fallacious, is by the conjunction of a planet with the Moon, as it appears to the eye, especially to the naked one. For besides the danger of hallucination, from the splendor of either, the danger of the arrival is incurred in the intricacies of the Moon's parallaxes [parallaxis Lunarium]; that is, the planet does not indeed come near the Moon in true [position], but appears [to], and very near it, so that it can be estimated by eye how great a part of the Lunar diameter the planet is distant from the horns of the Moon, or from its edges.

Examples of such observations for Saturn I have indicated above at Cap. 1, Obs. 6; Cap. 2, Obs. 5; and Cap. 5, Obs. 11 and 16.

4. The Fourth Method, used by the Ancients, was by Zodiacal Armillae [armillary rings] — celestial circles analogous to those of Longitude and Latitude — or by Astrolabes equivalent to them, such as Ptolemy describes in [*Almagest*] Book 5, Cap. 1, with great syntax; and as Egnatius Danti [Egnazio Danti] describes in his *Astrolabe*. But such instruments Tycho [Tycho Brahe] deservedly held in lower esteem than others, in his *Mechanica* [*Astronomiae Instauratae Mechanica*], folio 19, where he describes these very Armillae; but he confesses that they are liable to an error of at least two minutes.

The Ancients indeed scarcely attained the certainty of even ten minutes by the Armillae. And so Waltherus [Bernhard Walther] himself, who frequently employed them, not rarely detected in them themselves a defect of ten minutes, as is shown by Observation 33, Cap. 2, reported above. See also what Tycho says

against the Torquetum used by the Arabs, in the place cited, and in Tome 1, *Progymnasmata*, page 141.

5. The Fifth Method is carried out by Equatorial Armillae, which Tycho substituted for the Zodiacal ones, and which he describes in the *Mechanica*, folios 20, 22, and 23, and in Tome 1 of the *Progymnasmata*, Cap. 2, folio 141. For by these the Declination, and the Difference of Right Ascension between the planet and the Fixed star of known Right Ascension, are obtained to within one minute or another. But with all respect to Tycho, I judge that they err by not rarely four or five minutes, on account of causes which I shall set out in my *Liber Organicus*. Meanwhile let it suffice as an argument that there is difficulty in seeing the error in the Quadrants themselves, as the Sextants, much more simply built, are seen, and so on. Yet still, that they have one or another minute of certainty in observing them: provided there be given the Declination of the planet and its Right Ascension, the same one then investigates its Longitude and Latitude through the Problems set out above, the obliquity of the Ecliptic being supposed, or the Distance of the Poles of the Equator and of the Ecliptic — how this is carried out, we taught in Book 10 of the *Almagestum Novum*, Section 2, Problems 48 to 52, and in our *Primum Mobile*.

6. The Sixth Method, more secure than the preceding, is completed by the Meridian Altitude of the planet, with a great Quadrant or Sextant, taken in the same moment together with the planet at some Fixed star, whose preceding Right Ascension be known; for then, from the Altitude of the planet compared with the Altitude of the Fixed star, its Declination is made known, and the Right Ascension is the same; and as the Fixed star crosses the Meridian, so afterward the Longitude is investigated, and the Latitude through the Problems set out above. For at the moment when the star is most precisely observed at the plane of the Meridian, perpendicular to it [the meridian line], some determined point is fixed in the same plane as the center, by means of which the thread is marked; as is taught in *Almagestum Novum* Book 5, Cap. 15, Problem 8, where the description of the instrument is also given.

7. The Seventh Method, near to practice [most practicable], is if the moment be observed at which the planet crosses the Meridian, by the wire of the triangle [filar reticle]; and at the same moment one companion [assistant] takes the meridian altitude of the planet; and a third companion begins to count the seconds of time of the oscillations perpendicularly, as we set out in *Almagestum Novum* Book 2, Cap. 20. Or whenever some Fixed star crosses the same Meridian; or, if you observe the transits of the Fixed star at the same time, taking the

meridian altitude of the planet: for the Time embraced, both converted into the Right Ascension of the star, subtracted or added — that is, in the transit through the middle of the Sky [the meridian] — gives the Right Ascension of the planet. But the meridian altitude of the planet, compared with the Equator, gives the Declination, from which, through the Problems already indicated, are sought the Longitude and Latitude of the planet. Provided that the brief interval of time, in which the transit of the planet, or of the star, takes place, the smaller the danger of erring in the just time of the Primum Mobile, congruent with the quantity, if indeed every four seconds of time bring in one minute of the Equator.

You have an example of this practice in our observations relating to Cap. 8, namely Obs. 3, 4, 8, 46, and 64; from which let it please to weigh no. 64: in the year 1657, on December 14, in the morning, Saturn's meridian distance from the vertex of our Observatory was captured at $48^{\circ} 57' 8''$; and thence to the transit across the Meridian we counted $50''$, and so we deduced Saturn's both Declination and Right Ascension.

The Right Ascension and Declination of Saturn, and its distance from the vertex on December 14, 1657, are computed as follows:

	Gr. [°]	'	''
Meridian distance of Saturn from the vertex	48	57	8
Therefore, Meridian Altitude of Saturn	41	2	52
Altitude of the Equator at our Observatory	45	29	50
Therefore, Southern Declination of Saturn	4	26	58
Right Ascension of Spica at that time for us	196	48	36
Parts of the Equator for the $50''$	0	12	30
Therefore, Right Ascension of Saturn	196	36	6

But the Longitude and Latitude of Saturn will thus be investigated by the adjoined Diagram, in which let the Equator be AB, and [the diagram follows].

Diagram. A circle representing the celestial sphere, used to derive Saturn's longitude and latitude from its declination and right ascension. Within the circle a network of great-circle arcs is drawn: the Equator, the Ecliptic, the Solstitial Colure, and the circle of declination through Saturn, meeting at the marked points. The Saturn glyph (♄) appears near the center, with a second small glyph beside it.

- P (top): the Boreal Pole of the Equator [Aequatoris Polus Borealis], at the top of the circle.
- Z (interior, near P): the Pole of the Ecliptic [Eclipticae Polus], distant from P by the arc PZ (= $23^{\circ} 30' 20''$, the obliquity).
- A (left): one end of the Equator AB; in the text the Equator is AB.
- B (right): the other end of the Equator AB.
- C (upper left): on the Ecliptic CYK — the point where the Ecliptic crosses; the Ecliptic runs C–Y (Aries)–K. C marks the beginning of Cancer.
- K (lower right): the common point of the Solstitial Colure APK and the Ecliptic CYK; K marks the beginning of Capricorn.
- Y (Aries) and $\varnothing$ (Libra): the Equinoctial points, marked on the Ecliptic.
- h (center): Saturn's place; with the small adjacent glyph.
- S (center, below h): the point in which Saturn's place is designated, reached from the Pole P by the arc PS along the circle of declination.
- O (bottom center): foot of the arc ZSO on the Ecliptic / Latitude circle.
- T (center): intersection point of the arcs near Saturn.

The text: "The Solstitial Colure is APK, and the Ecliptic is CYK, in which the beginning of Cancer is C and of Capricorn K; the Equinoctial points are Y and $\varnothing$. Further, let the Boreal Pole of the Equator be P, and of the Ecliptic Z, their distance being PZ, which for us is $23^{\circ} 30' 20''$. Since indeed it is recognized from the Ephemerides that Saturn was then around the 16th degree of Libra, with a Boreal latitude of about 2° , and the Southern declination observed was $4^{\circ} 26' 58''$ — therefore Saturn's place is designated in S, to which, from the Pole P of the World, by the circle of Declination, the Arc PS, consisting of the Quadrant PI and the Southern declination IS, will be drawn; for the whole Arc PS is $94^{\circ} 26' 58''$. But from the Pole Z of the Ecliptic, draw to S, by the circle of Latitude, the Quadrantal Arc ZSO. For in the spherical Triangle PSZ, the two Sides PZ, of $23^{\circ} 30' 20''$, and PS, of $94^{\circ} 26' 58''$, are given; and from these the Angle SPZ comprehended, of $73^{\circ} 23' 54''$, from the Right Ascension of Saturn: For from the given degrees $196^{\circ} 36' 6''$ subtract 90° from A to $\varnothing$ [recte: from Y to $\varnothing$], that is, the arc of the Equator from the beginning of Cancer, there will remain from the beginning of Cancer to the term I of Saturn's Ascension, the Arc CI; and so the Angle API, of $106^{\circ} 36' 6''$; and this subtracted from 180° leaves the Angle SPZ of $73^{\circ} 23' 54''$. From these three given — by the Canons of Logarithms for spherical Triangles — the remaining Arcs are obtained, namely the base SZ, and, the degrees 90° having been subtracted, the Boreal latitude of Saturn OS will be the known [recte: the mark]. We obtain likewise the Angle PZS, which measures the arc CO of the Ecliptic,

counted from the beginning of Cancer, whence the Longitude of Saturn will be known to us; which therefore will be of Libra 17° 0' 8", and the Boreal Latitude 2° 15' 42". By which observation, as accurate as could be, and on account of the time elapsing between the transit of Saturn and of Spica, in no way liable to error, we conclude much more that the Lansbergian Tables are distant from the truth than the Tychonic, or Danish; for from these tables is given the Longitude and Latitude written below:"

	Saturn (♄) Latitude	Longitude			Gr. [°]	'	"
		Gr. [°]	'	"			
Danish	2	2	3	♌	16	5	3
			6			5	0
Lansbergian	2	2	3		16	1	2
			0	6		4	5
Ours, from Observation	2	2	4		17	0	8
			5	2			

8. The Eighth Method, more secure than the preceding, and less troublesome — inasmuch as it is dispatched by one and the same observer with one and the same moment, through three observations — is, if at some moment the plane of the [filar] Triangle's wire, placed at the Meridian, glides to the center of the planet, the observer of this transit gives a signal to two other companions, who have already at hand prepared the instruments. And one [continues].

LIBER V — DE SATURNO (continued)

Caput IX. (*continued*) — The twenty methods of observing the positions of Saturn and the other lesser planets

(Methods 8–20)

Let one observer take the planet's meridian altitude, while another takes the rising or setting altitude of a fixed star — so set up that it stands a good many degrees off the meridian, yet not so far off that the uncertainty of refraction makes the result doubtful. From this rising or setting altitude, provided its declination and right ascension are known, the star's right ascension can be derived. For if the planet's altitude, once it has been reduced to the equator's altitude, is greater than that of the equator, it will give the planet a southern

declination; if it is less than the equator's, it will leave the planet a northern declination. The right ascension we shall hunt out as follows.

In the diagram opposite, let the planet pass across the meridian HVR; let its altitude AF be given, and from the horizon HR its altitude will be had, since it lies at vertex V; and given the distance VF, run the arc of declination PD through F from the pole of the world P. Then in the triangle FPV we have the complement of the star's declination FP, drawn to the quadrant, and VP, the complement of the altitude of the pole, which is PR. With these three sides given, then, trigonometry will yield the angle FPV, the star's distance from the meridian measured along the equator. If this is added to the right ascension of the western fixed star, it will give the right ascension of the mid-heaven [Medium Coeli], that is, the right ascension belonging to whatever point is then culminating, namely the point through which the meridian passes at that moment. And as for how the planet's longitude and latitude are then derived from its right ascension and declination, that is plain from Problem 5 [*Modo* 5] indicated above — and indeed I have already given one worked example of the preceding method.

Diagram. A circle (the local sphere) carries the meridian as the horizontal diameter HR, with the zenith V at top and the nadir at bottom. Inside, points P (the celestial pole), F (the fixed star), B, and A are marked, with arcs drawn between them forming the spherical triangle FPV described in the text.

- V (top): the zenith / vertex
- P (upper interior): the pole of the world
- B (upper right interior): auxiliary point
- F (center): the fixed star
- A (lower interior): auxiliary point on the meridian
- H (left, on horizon line): horizon point
- R (right, on horizon line): horizon point

9. — The Ninth Method

[Marginal number: 9]

The Ninth Method works exactly as in [Method] 8, except that the altitude of the fixed star is taken instead, and in its place a fixed star of known azimuth is observed by means of the other [side] of the filar triangle [*Filaris Trianguli*] lying flat toward the center of the fixed star. For, as in the preceding scheme of the triangle, the azimuth will give the angle FVP from the sides VP and FP, as above;

and from the angle FPV and the rest, the procedure is carried through exactly as in the preceding method.

10. — The Tenth Method

[Marginal number: 10]

The Tenth Method. If the planet is set outside the meridian, its altitude is observed, together with that of a fixed star appearing at exactly the same moment in the same azimuth; or else, if that azimuth is of known magnitude, in any other way, provided only that — besides the altitude of the pole — the declination and right ascension of the fixed star are known. For in the third diagram here, let HVR be the meridian and HAR the horizon, and round about, let VA be the quadrant of the vertical circle, in which the planet appears at P and the fixed star at F, and from the pole of the world B let circles of declination be drawn through both, giving the arcs BP and BF.

First, if the magnitude of the azimuth AH, that is, of the angle AVH, is known, its complement to 180° will be the angle PVB. With this, and with the complement of the altitude BV, and with the planetary altitude — the complement of which is PV — in the triangle PVB the base BP will be given by the triangle canons. If this turns out to be a quadrant, there is no planetary declination; if it is less than a quadrant, you will have the planet's northern declination [*Declinationem Planetæ versus Polum conspicuum*]; if greater than a quadrant, then subtracting the quadrant, the planet's declination toward the other pole will remain.

Diagram. A circle representing the local sphere, with the horizontal diameter as the horizon HR and the vertical line through the zenith V. The points P (planet) and B are marked in the upper interior, F near the center, A at the bottom of the vertical, forming the spherical triangle PVB of the text.

- V (top): the zenith / vertex
- P (upper interior): the planet
- B (upper right interior): the pole of the world
- F (center): auxiliary point
- A (bottom interior, on vertical): the foot of the vertical circle
- H (left, on horizon): horizon point
- R (right, on horizon): horizon point

11. — The Eleventh Method

[Marginal number: 11]

The Eleventh Method is this: when the planet's altitude has been observed on some determined vertical [circle], you watch for a fixed star to come to the same vertical, and meanwhile, by means of the perpendicular, you note the intervening time; then, as soon as the star reaches that vertical, you take its altitude. Or, the other way round, you may first take the fixed star and then watch for the planet to be carried onto the same vertical; or the quantity of time may be noted, as the procedure of the preceding method explained.

First, then, if the angle PVB in the triangle BVP is known, you acquire it as in the first step of the preceding numbered method; the side BP will reveal the other side of the planet [PV]. But if the azimuth is not known, then — as I said — in the triangle FVB, by the second step, the side BP will be had. Then, in the triangle FBP, you ask for the angle FBP, just as in the preceding numbered method, by its third step; and through that you have the difference of right ascension of the fixed star and of the planet, and likewise its right ascension; and afterward you must correct it for the intervening time, converting the time into parts of the equator. For if the planet comes to the vertical before the fixed star, the said time must be subtracted; if afterward, added. And so you have the planet's absolute right ascension, and from it, by the usual methods, the longitude and latitude.

You have examples of this kind of observation above, in Chapter 8, at observations 56 and 61. Although in these two were employed for verifying the azimuth-quantity, and the declination of Saturn, and another for the time, and from it the right ascension was to be gathered — out of which arises Method 12.

12. — The Twelfth Method

[Marginal number: 12]

The Twelfth Method is carried out thus. With the plane of our filar triangle [*Trianguli nostri Filaris*] turned toward the center of the planet, take the planet's own distance from the vertex; and, to verify its azimuth, if some fixed star cannot be received at the same moment in the same region of the sky at an equal distance from the vertex, count the time until such a star is at a convenient distance from the vertex to be taken. Once this is captured, you then watch for the other star to reach the same quadrant of the vertical circle in which the planet stood, and at the same distance from the vertex; and watch for the distance of this star from the vertex. For if the declination and right ascension of either fixed star are known, you will obtain the planet's longitude and latitude, derived from the prior star's longitude and right ascension and from these, in the usual way, the longitude and latitude. This is what was designated above by the

meridian and horizon scheme; and we shall teach it by the example of our observations in Chapter 62, more briefly and clearly.

Anno 1657. Octobris 22. [Year 1657, October 22] In the morning, near sunrise, with Saturn standing on the eastern vertical, at an altitude of $80^{\circ}10'$, but corrected for refraction at $80^{\circ}15'$ — since it stood less than $10'$ in time after sunrise — and with that distance of the eastern star known to us outside the [twilight] clouds, refractions not having interfered, we took the Heart of the Hydra [*Cordis Hydrae*, α Hydrae] Y, at a distance from the vertex VY of $55^{\circ}47'$, with its [azimuth] in the same [region] and with the complement of the altitude of the pole, drawn to the quadrant — that is, the southern declination of the Heart of the Hydra, $7^{\circ}11'$, added to the quadrant; this gives the arc BY of $97^{\circ}11'$. By trigonometry I derived the angle VBY of $19^{\circ}18'$.

On the following night, in the eastern region, [Pegasi] Scheat [β Pegasi] P came onto the same vertical, at a distance from the vertex PV — observed — of $39^{\circ}2'$; with that same arc and with BV $45^{\circ}29'50''$ and with the northern declination of Scheat, $26^{\circ}14'40''$, the complement of which BP is $63^{\circ}45'20''$, I found the azimuthal angle BVP of $102^{\circ}31'$. Then in the triangle BVS, with the said angle (which is the same as angle BVS), and with the altitude BV $45^{\circ}29'50''$ and the distance of Saturn SV $80^{\circ}15'$, by the logarithmic canons I find the base BS of $92^{\circ}16'55''$; and thus, with the southern declination of Saturn $2^{\circ}16'55''$ taken, with the angle SBV $74^{\circ}18'$, from which I subtracted the angle VBY $19^{\circ}18'$ found above, there remains the angle YBS of $55^{\circ}0'$. This would be the difference of right ascension between the Heart of the Hydra and Saturn, if at the same moment in which Saturn's distance from the vertex was taken, the distance of the Heart of the Hydra had also been taken. But because that distance of the Heart of the Hydra was taken later, when Saturn had now descended somewhat, therefore the difference must be diminished by $2^{\circ}42'30''$, answering to the intervening time of $10^{\circ}50''$. And so there remains a difference of $52^{\circ}17'30''$.

Now the right ascension of the Heart of the Hydra was then $137^{\circ}40'$, and Saturn was more eastern, therefore Saturn's right ascension was $189^{\circ}57'30''$; and its declination, from what was said above, $2^{\circ}16'55''$ southern. Therefore, by the Problems of the *Primum Mobile* and the most subtle logarithmic canons of Vlacq, the longitude of Saturn was then Libra $10^{\circ}2'26''$, and its northern latitude $1^{\circ}51'32''$. So, from this observation, the Lansbergian tables depart more than the Danish, as is plain from the following little table.

Ex Tabulis [From the Tables]	h Longitudo — Sig.	G r			h Latit. Bor. — Gr.		
		.	'	"		'	"
Danicis [Danish]	♌	1	3	1 2		1	0
		1	2	9		4	
Lansbergij	—	1	7	3 2		9	2
[Lansbergian]		1		0			0
Ex Observat. [From the Observed]	—	1	2	2 1		5	3
		0		6		1	2

I confess, however, that because of the rather large interval of time between the observation of Saturn and that of the Hydra, and because from the morning observation of Saturn to the evening observation of Scheat the plane of the filar triangle could be moved somewhat from its former position, this observation serves rather as an example of the problem than for the certainty of the truth.

13. — The Thirteenth Method

[Marginal number: 13]

The Thirteenth Method is this: if, to a determined and known degree of azimuth designated by the filar triangle, you watch for the planet's arrival, and at its arrival take its distance from the vertex; and at the same moment let a fixed star of some known distance from the vertex be observed, or at least, as soon as possible, with the intervening time meanwhile counted between the two observations. This scheme will become clear by the numbered scheme of the preceding [method], and by the example of observation 52 in Chapter 8.

Anno itaque 1655. die 10. Iulij nocte sequenti [So in the year 1655, on the 10th day of July, on the following night], in the western azimuth of exactly 90°, with the filar triangle set up, Saturn S being at a distance from the vertex VS [continues].

[The worked example here closes with the comparison table:]

14. — The Fourteenth Method

[Marginal number: 14]

The Fourteenth Method, somewhat more laborious than the preceding, requires four observers: one, who is to watch for the determined and known azimuth to expect the center of the planet; another, who at that very moment is to take the distance [of the planet] from the vertex; the remaining two, who are to take at the same moment the distance of the planet from a fixed star of known declination and right ascension. With these acquired, inspect the diagram in which, with the designated horizon HR and meridian HVR, the planet P is given, distant from the vertex by PV; and from the azimuth, the angle PVB, in the triangle PVB, in which there is also given the complement of the altitude of the pole BV.

For trigonometry will not hide the side BP, which indicates the planet's declination. For if BP comes out 90°, there will be no declination; if it exceeds 90°, the excess gives a southern declination; if it falls short, it gives a northern declination. Furthermore, let the fixed star be at F, or at O, with the distance PF or PO certain; and from the star's declination, the side BF or BO, and from the common BP — as above — once these three sides are known, the angle FBP or PBO, namely the difference between the right ascensions of the fixed star and the planet, will be revealed by these. This difference of right ascension is to be added in the eastern quadrant, if the star was at F, that is, higher than the planet P, and subtracted in the western [quadrant]; on the contrary, in the eastern quadrant, if the star was at O. Once you have the planet's right ascension, with the declination — as above — already acquired, you will gain, in the usual way, the planet's longitude and latitude.

Diagram. A circle (the local sphere) with the horizontal diameter as the horizon HR and the vertical through the zenith V. In the upper interior, points P, F, O, and B are marked, with B the pole of the world (upper right). Arcs connect them, forming the triangles PVB, FBP, and PBO described in the text. A is at the foot of the vertical.

- V (top): the zenith / vertex
- B (upper right interior): the pole of the world
- F (upper-left interior): a fixed-star position
- P (interior, below F): the planet
- O (interior, below P): an alternative fixed-star position
- A (bottom interior, on vertical): foot of the vertical circle
- H (left, on horizon): horizon point
- R (right, on horizon): horizon point

[Method 14 carries no comparison table on the page; the prose runs straight into Method 15.]

15. — The Fifteenth Method

[Marginal number: 15]

The Fifteenth Method is accomplished by [taking] the distance of the planet from two more eastern fixed stars, or two more [continues].

western ones; especially if the distance of those [stars] from one another is known. An example may be taken from Chapter 8, our observation 41.

Anno 1653. Ianuarij 30. [Year 1653, January 30] On the night following the Opposition of Saturn with the Sun, we took P. Grimaldi [Grimaldi], and I, Saturn distant from the shoulder of Orion [*Orionis humero lucidiori*, the brighter shoulder = Betelgeuse], that is, from the following one, by $47^{\circ}34'$; and likewise from Procyon by $24^{\circ}23\frac{1}{4}'$, both of them; and the fixed star was more western than Saturn. Let, then, for this observation, the diagram be this, in which let EC be a portion of the ecliptic, and B the southern pole [*Polus Australis*]; let the semicircle ASB be drawn through the center of Saturn S, and the semicircle AOB through the shoulder of Orion O; and let Procyon be at P, from which to the pole A the complement of latitude AP is drawn — for the southern latitude of the shoulder of Orion is $16^{\circ}6'15''$, and that of Procyon $15^{\circ}57'10''$; and so AO is $73^{\circ}53'45''$, and AP $74^{\circ}2'50''$.

Now the distance OP of the fixed stars between themselves, by our frequent observations, is $26^{\circ}2'50''$. Finally, from the fixed stars to Saturn the arcs of distance are drawn, PS and OS. With these set down:

First, in the triangle OPS, with the three sides given — OP $26^{\circ}2'50''$, OS $47^{\circ}34'$, and PS $24^{\circ}23\frac{1}{4}'$ — by trigonometry the angle OPS is given, $142^{\circ}21'40''$.

Second, in the triangle OAP, with three sides likewise given — AP 74°2'50" and AO 73°53'45", and OP, as above — the angle OPA is given, 86°5'20"; which, with OPS, makes 228°27'; and subtracting these from 360°, there remains the angle APS of 131°33'. With this in the same triangle APS, and with AP as above 74°2'50", and PS 24°23¼', the angle ASP is found, 18°7'10", and the base AS 90°58'20". Hence the southern latitude of Saturn [*Saturni Latitudo Borealis*] was 58'20". [recte: *Australis* — the text says AS is 90°58'20", exceeding the quadrant by 58'20", giving a southern latitude; but it prints *Borealis*. Transcribed as printed.] And because the longitude of Procyon was 20°59'45", if you add the difference of longitude PAS — since Saturn will be more eastern — Saturn's longitude was Leo 9°6'55", and its northern latitude [*Latitudo Borealis*] 58'20".

[Margin / parenthetical:] What [say] here the Danish and Lansbergian tables? Namely:

Ex Tabulis [From the Tables]	h Longitudo — Sig.	G r				h Latit. Bor. — Gr.			
		.	'	"		.	'	"	
Danicis [Danish]	♌	9	2	1	0		5	2	
			5	0			3	0	
Lansbergij	—	9	2	3	0		3	1	
[Lansbergian]				0			7	5	
Ex Observatis [From the Observed]	—	9	6	5	0		5	2	
				5			8	0	

Diagram. A spherical-triangle figure (curved arcs within an implied sphere) for the Method-15 worked example. The southern pole B is at upper right; arcs descend to E and C along the ecliptic at lower left/right, with S (Saturn), G, O (shoulder of Orion), and P (Procyon) marked in the interior, and A at the lower vertex.

- B (upper right): the southern pole [Polus Australis]
- S (interior, upper): Saturn
- G (right of S): auxiliary point on an arc
- O (left interior): the shoulder of Orion [Betelgeuse]
- P (lower interior): Procyon
- A (bottom vertex): the pole vertex (foot of the latitude complements)
- E (left, on ecliptic line): point on the ecliptic EC
- C (right, on ecliptic line): point on the ecliptic EC

16. — The Sixteenth Method

[Marginal number: 16]

The Sixteenth Method is accomplished by [taking] the distance of the planet from fixed stars of known longitude and latitude, especially if the distance of the fixed stars from one another is now foreknown — one of them being more eastern than the planet, the other more western; otherwise, from the complement of the latitudes, the difference of longitude would have to be investigated in advance.

Let the example be taken from Chapter 8, observation 58. **Anni 1657. Martij 22. nocte sequenti** [In the year 1657, March 22, on the following night], when we — P. Grimaldi and I — saw Saturn distant from Regulus [*Regulo*] by $37^{\circ}4'45''$, then from Arcturus the distance of the fixed stars often observed by us was $59^{\circ}49'$, and the northern latitude of Regulus was $0^{\circ}26'20''$, and Arcturus' was $31^{\circ}0'40''$. Let, then, this diagram be congruous with this observation, in which let EC be the portion of the ecliptic, and B the northern pole [*Polus Borealis*]; and from it let the two quadrants of latitude be drawn — one BS through Saturn S, the other BC through Arcturus A. Let Saturn be at S, through which the arc of distance BO is drawn; the distance, moreover, between Arcturus AR and Saturn RS, between Regulus and Saturn.

First, then, in the triangle RSA, with the three sides given — AR $59^{\circ}49'$ and AS $32^{\circ}43'$ and RS $37^{\circ}4'45''$ — the angle is given by the triangle canons [continues at top of right column:] RAS, $36^{\circ}39'20''$.

Second, in the triangle RBA, the three sides are likewise given — AR $59^{\circ}49'$ and BR, the complement of the latitude of Regulus, which is $89^{\circ}33'40''$, and AB, the complement of the latitude of Arcturus, which is $58^{\circ}59'20''$. Therefore, by trigonometry, the angle BAR is given, $109^{\circ}50'$; which, with the angle RAS, makes the angle BAS, $146^{\circ}29'20''$. Third, then, with this angle in the same triangle BAS, and with the complement of AB $58^{\circ}59'20''$, and AS $32^{\circ}43'$, the base BS is found, $87^{\circ}19'$; and so the northern latitude of Saturn [*Borealis Latitudo Saturni*] is $2^{\circ}41'$; and the angle ABS, $17^{\circ}22'45''$, which, subtracted from the longitude of Arcturus — which was then $19^{\circ}27'30''$ — leaves Saturn's longitude in Libra at $2^{\circ}4'45''$. (As for the others, see below.)

Diagram. A spherical-triangle figure for the Method-16 worked example. The northern pole B is at the apex (top); the curved sides descend to E and C along the ecliptic at the bottom, with A (Arcturus), R (Regulus), S (Saturn), and O marked in the interior.

- B (apex, top): the northern pole [Polus Borealis]
- A (right interior): Arcturus
- R (left interior): Regulus
- S (center): Saturn
- O (lower interior, below S): point on the latitude quadrant through Saturn
- E (lower left, on ecliptic): point on the ecliptic EC
- C (lower right, on ecliptic): point on the ecliptic EC

17. — The Seventeenth Method

[Marginal number: 17]

The Seventeenth Method is this: if the planet's meridian altitude is measured, and it is observed whether it is in a straight line with some known fixed stars — see Chapter 6, observation 15.

18. — The Eighteenth Method

[Marginal number: 18]

The Eighteenth Method is this: if the planet is in a straight line with two fixed stars, so that the planet's longitude can be estimated through them — as we did in Chapter 3, observation 1; or if from here it is in a straight line with two fixed stars, and then in another straight line with two other known fixed stars — see what we said in Book 10 of the *Almagestum Novum* [the *New Almagest*], pages 563 and 564, Problems 131 and 132.

19. — The Nineteenth Method

[Marginal number: 19]

The Nineteenth Method suits only those planets which are visible for a long time together with the Sun — such as Venus, and rarely Jupiter, since the Sun is too deeply depressed [below the horizon], and refractions make it doubtful. For if at the same moment the [altitude] of both is taken — namely, of the Sun and of Venus — and the azimuth of the latter, or its distance from the Sun, then from the Sun's declination and right ascension can be found also Venus' declination and right ascension, and from these the longitude and latitude.

20. — The Twentieth Method

[Marginal number: 20]

The Twentieth Method does not always serve for acquiring the planet's longitude and latitude, but only for forming a judgment as to whether the planet is stationary, direct, or retrograde — and whether some one of the three superior [planets] is in opposition to the Sun. For if, at the very moment of midnight, it passes across the meridian, that is a sign that the planet is then opposite the Sun, since the place of the planet opposite the place of the Sun can be recognized. Likewise, if on some days around the stations the planet's distance from the nearest fixed stars is observed, it can easily be judged whether it remains in the same longitude, or whether, made retrograde, it has become direct again. Even if its place is not known with respect to the ecliptic, [it can be judged]. Thus we, from our observation 63, judged in the year 1650, from the 16th of February to the 2nd of March, by continued observations with the aid of the telescope, that Saturn's stations had fallen between the 21st and 22nd of February, and that from then on it was direct.

CAPVT X.

On the limits of the certainty within which the positions of Saturn could be represented up to now — or could be represented in future — as much by observations as by astronomical tables, and on their disagreement.

Granted that observations of celestial phenomena are the foundation of astronomical tables, it is nonetheless certain that one must not seek out just any and every kind of observation, but rather many and very accurate ones. As regards Saturn in particular, Tycho [Tycho Brahe] aptly notes in the preface to his *Astronomical Observations* that observations of thirty, or at the very least twenty-four, years are required — and not only that, but observations in every position [of Saturn] in its acronychal risings [observationes Acronychiae], and beyond

these, observations also of the intermediate positions, so that the conclusions about the planet's arrangements and motions may be established by examination, properly worked out through the tables. He says that Ptolemy [Ptolemy], Copernicus [Copernicus], and the rest could not have done this. He thinks, indeed, that the ancient astronomers were so often led astray from the heavens — because, in his judgment, they were content with the three acronychal observations of each of the superior planets, and afterwards (as he puts it) joined to these others taken at random and not without latent error — that he believed this error was at once obvious. And he holds that this can be said without doing the ancients an injustice; indeed, it stands as their own confession.

2. For concerning Hipparchus [Hipparchus] in particular there exist these words quoted in Ptolemy, *Almagest* IX, ch. 2 [recte: *Magnae Constructionis* lib. 9, cap. 2]: that Hipparchus — a most truth-loving man, by reason of the difficulties at least, and because he did not have at hand the exquisite observations of the ancients — undertook this negotiation of the planets to the extent that he himself shows in his commentaries: that is, he gathered them into a better order and showed that they did not agree with the hypotheses of those times. But, with few [observations] interposed, he adds in the same place: nevertheless he demonstrated none of these things fully; others, too, did not arrive at the end. So it has come about that they do not agree with themselves, men who have cultivated these mathematical disciplines so exquisitely, and who would have advanced [the matter], had any one of them done what the rest did, in undertaking something whose outcome they did not foresee. [Margin: Hipparchi lans. (Praise of Hipparchus.)]
3. Ptolemy from this book confesses (ch. 2 — much is said in it) the aforesaid difficulties to be present, and among many such things he professes these in particular: *one must do whatever one can in this matter. For the business is one of many and most difficult causes; and these have not yet been rightly considered by my predecessors, nor [can they be] in their consideration: it can happen, by observing through an instrument, that some error arises, until in a later, more sensitive observation an earlier one is corrected, when a later observation is made. Now time, from which we have such things recorded, is so very long that the comparison may make it [the result] sure.* But by the very same dishonesty he confesses an abuse beyond reason for some — those who, with circles fashioned and feigned in the plane of the ecliptic, as though by nothing at all, through mere congruence, commodity, and the absence of clear evidence and right-angled triangles, on account of

obliquity, as though if error should arise therefrom it ought to be negligently disregarded. Finally he thinks that one must attend to the oppositions of the planets, taken from the place of the Sun itself, and prefer the true place of Tycho. [Margin: Ptolemæi excusatio circa Planetas minores. (Ptolemy's excuse concerning the minor planets.)]

4. As for al-Battānī [Albategnius], we need say no more about the business of Ptolemy and of al-Battānī, who almost necessarily followed Ptolemy, [a matter] which others have treated — why heaven itself would not openly fall away from the truth. That great conjunction of Saturn and Mars, which Stoefflerinus [Johannes Stöffler] had predicted from the Alphonsine tables would occur in the year [continues below]

mini 1536, on the 25th of May; yet it took place on the 20th, with Pietro Pitato [Pietro Pitati] observing — or on the 19th, with Giuliano Ristori [Iulianus Ristorius] of Prato, teacher [praeceptor] around hour 2, observing — by which Saturn was found to be 2 nodes [removed] from Mars at that time. And in the same year, 1542, on the 29th of January of the following night, that conjunction of Saturn with Mars took place for many days before the Alphonsine reckoning [abacum Alphonsinum]. But in the year 1563, the conjunction of Saturn and Jupiter [continues] on the 24th of August, hour 14, 30' after midday, with Boreali Jupiter covering Saturn somewhat more Australian in the end of degree 28 of Cancer [Cancrī] — whereas the Alphonsine calculation [Alphonsinus calculus] places that syzygy as distant by 1 whole month: thus on the 25th of September, and Leo's [Leonis] degree 4. 12'. The cause of this was, [according] to Regiomontanus [Regiomontanus] and to the Prutenic [Prutenicus] canons afterwards. Yet Tycho touches on both calculation-errors in the *Mechanica*, folio 39, on the other side. By this most manifestly intolerable he detected the error: which I said at the outset, and that great conjunction of the year 1563, of which I spoke from the beginning, in the motion of Saturn — and a place sufficiently outstanding: if indeed Alphonsus's numbers failed by a whole month, Copernicus by some little [time], who erred only by a few [units]. But Maestlin [Maestlin] testifies that he himself observed at Leipzig [Lipsiae] in the year 16 [recte: 1563] of his age, complete, that conjunction around the end of Cancer and the beginning of Leo; and on folio 43 of the same tables he adds, speaking [of them]: *whence it comes about that the planets are sometimes Australian in the heavens, when their number exhibits them Boreal — and the contrary*. In the *Epistolae*, moreover, page 56. & in *Progymnasmatum* tome 1, page 648, he erred somewhat in degree 2. In the Alphonsine [tables], as regards Saturn's place, he detected a discrepancy; not otherwise, as Longomontanus [Longomontanus], at chapter 13,

affirms in the year 1591, on the 17th of March, at 7 hours 3' after midday at Uraniborg [Vraniburgi], observed Saturn distant from Aldebaran [Aldebara] by 19. 11'. ½. & from Pollux [Pollux] by degrees 25. 54'. ½: with septentrional declination of degrees 22. 23', from which he gathers the inscribed place of Saturn below, compared with the Alphonsine and the Prutenic.

Saturn (An. 1591. Mart. 17)	Longitude, &		Latitud e		
	Sig. Gr.	'	"	Gr.	'
Observed p. m., hour 7 ½	II 22	43		0	56 ½
Alphonsina	25	7		0	56
Prutenica	22	23		1	35
Danica	22	45 7 ½	[?]		

[Margin: Alphonsinorum errores in Planetis superioribus. (Errors of the Alphonsine [tables] in the superior planets.)]

Finally, Maginus [Magini] in his *Epistola ad Richardum Fasterum*, which he has in the *Directiones*, page 95, says that the Alphonsine reckoning errs more widely in the minor planets than the Prutenic.

- Now Copernicus, having strictly examined the hypotheses which we just now indicated on the occasion of the Alphonsine [tables] — no wonder if both with the Ptolemaic and his own ternary of acronychal observations, and that too in opposition with the mean place of the Sun, he was confident — and (as Joachim Rheticus [Rheticus] testifies) thought he had done quite enough for himself, if it had not come to 10 minutes, that is, the sixth part [sextans] of a degree, that his observations could lead him astray, and that he departed no further from the truth — as Rheticus admits in the preface to the *Ephemerides*. Kepler [Kepler], moreover, at chapter 18 of the *Mysterium Cosmographicum*, says that Copernicus, neglecting the quadrants of degrees, that is, fifteen minutes in the motions of these planets, reckons it [thus]. *In reprehensionem incurrere iure videretur, nisi consulto fecisset, eo quod praestaret imperfectam habere Astronomiam, quam nullam.* (He would rightly seem to incur reproach, had he not done it deliberately, on the ground that it is better to have an imperfect Astronomy than none.) *For difficulties of this kind occur, while the stars run their course; which to anticipate, and to aspire to a constitution of knowledge with the least loss, that is the part of a brave man; to despair through cowardice,*

and timidly to shun all this care, is the part of a coward. Just as in this matter, recently reviewed, [Saturn] disassembles itself, and that not without shame, he admits. By the example of Ptolemy, of the ancients, he frees himself; the difficulty of observing such a [planet]. Soon, at chapter 18 of the same *Mysterium*, having been born in the year 1594, on the 12th of November, in his new style, he says that Saturn stood between the neck [cervicem] and the Heart of Leo [Cor Leonis], where it ought to be according to the Prutenic calculation on the 31st of October: a discrepancy of nearly 27' in minutes. Indeed, sometimes the slightest error of the Prutenic [tables] mounts to 40' [continues] [Margin: Coperniti errores in Planetis, & excusatio. (Errors of Copernicus in the planets, and his excuse.)]

advert it. Tycho, page 39 of his *Mechanica*, where he speaks of Copernicus concerning Saturn and Jupiter, says: *His restitution in these two planets is not so far removed from the celestial norm as to digress, especially as regards Saturn, which he never errs by more than half a degree, well — to the very highest [degree] —, Copernicus could not elude the calculation in heaven, he observes.*

6. Longomontanus, therefore, following Tycho, and relying on his own observations, so used [them], that he need not despise the Prutenic numbers, but emends them in some places: for he professes, in *Theoricorum* chapter 2, that he has constructed Danican tables of Saturn out of the Prutenic, by subtracting 20' from the mean longitude of Saturn; from its apogee, moreover, by subtracting 3'; by subtracting [from?] some part five-sixths — notwithstanding the Author of the *Astronomicus* book, who is inscribed [as author of] *Urania Propitia*, edited in the year 1650 at Bicini in Silesia, page 85. He asserts frequently, faithfully, and with diligent observations of Saturn, but [that he] selected 29 [observations] in various eccentricities, & compared the points of commutation detected, that the Danican and the Lansbergian tables sin much more than the Rudolphine; that he, however, in the first commutation, departs from the place of Saturn by a semicircle, by minutes $4\frac{1}{3}$. [Margin: Iudicium de Danicis, ac Rudolphinis circa Saturnum. (Judgment concerning the Danican and the Rudolphine [tables] regarding Saturn.)]
7. Kepler nonetheless thought that so great an error of minutes was not contained in his own tables; for in the *Explanatio fundamenti Ephemeridum*, page 14, he says thus: *Quantum vero ad superiores Planetas, ausim spondere, non facile differentia Ephemeridis a Caelo occurruram, quae oculis notari possit; si vel instrumentis exquisitissimis attenderint Astronomi*

exercitati, vel insidiati fuerint congressibus illorum inter se, & cum Fixis clarioribus, quarum loca etiam certe fidis observationibus, & accurato calculo fuerint constituta. (As regards the superior planets, I would venture to promise that no difference between the Ephemeris and the heavens will easily occur that could be noted by the eye; provided that practised astronomers attend with the most exquisite instruments, or lie in wait for the conjunctions of those [planets] with one another, and with the brighter fixed stars, whose positions have been established by surely trustworthy observations and accurate calculation.) But in the *Mysterium Cosmographicum* he said, at chapter 19: Saturn furnishes the easiest cause of an enormous distance [discrepancy] in observation, an error nonetheless even great in distance, a smaller [error] in opinion is begotten in the prosthaphaeresis [in prosthaphaeresi].

8. Let us now hear the most distinguished astronomer Vincenzo Mutus [Vincentius Mutus], who in the year 1654, among others then made from the Majorca [Maioricae] observations, in an epistle of the 26th of March, which he sent to me, recounts these acronychal [risings] of Saturn, which he reached on the 11th of February, and on the 15th of March at hour 9 after midday, with the calculation adjoined from the more celebrated tables.

Anno 1654, hour 9 p. merid.		Gr			
Saturn's Longitude per D. Mutum		Sign.	.	'	'

	Danicis		20	57	exc. 26
Computed from:	Rudolph.		20	50	exc. 19
	Almagest.		20	45	exc. 14

D. Mutus appends in the same epistle: *Not yet for certain, but I almost dare to affirm, that the distances of the planets from the Earth have nothing in common*

with the diameters of their orbs, hitherto held established; nor that the elongation from the [Sun's] World can be deduced from the prosthaphaeresis of the orbs. A notable example I observe these months in Venus, Mars, Saturn, and Jupiter — at the days elapsed. All which things, together with the observations, after the work is completed, I shall gladly communicate.

9. Bullialdus [Ismaël Boulliau], that highest and outstanding effort in emending the Rudolphine [tables] in the *Astronomia Philolaica*, book 6, where indeed at chapter 5, he reconciles those tables with the most ancient observation of Saturn made in the year 519 of Nabonassar [Nabonassari], and with another of the year of Christ 503, he recognizes that the aphelion [Aphelium] is to be drawn back into the preceding [signs] by degrees there 48. 50'. 56"; here [it is] at degree 46. 10'. 46". — or [its] motion is to be advanced.

[Margin: Bullialdi sup. (Boulliau's emendation.)]

medium [of the] Rudolphine [tables] 36'. The aphelion, moreover, from ♄ degree 26. drawn back to ♀ degree 28. From the observations he gathers; yet he collects some discrepancy of minutes 9'. has chapter 6. In examining his observations of the year 1640, he sets forth a motion of Saturn's Node [Nodi Saturni] taken from the Rudolphine tables, [for] the Moon [Lunam] could not [have been] in the year of Christ 503. Feb. 21. hour 4. To the Athenians [Athenis] Saturn occult at the same time, which truth he confirms by history. But his Saturni tables, the Philolaican [Philolaicas], from the places of Saturn through Tycho, and Longomontanus, observed not to recede beyond 3'. vel 4. minutes, [whereas] Vualtheri [Bernhard Walther], by his own observation, makes [it] greater than he expends [from] chapter 5. & ex qua colligit place ♄ in ♊ degree 41. — therefore the Philolaican [place] of degree 6. & 19. He has a suspected [reading], so that the place is nude, almost twofold made. & on account of the latitude of the Nebula of Cancer [Nebulae Cancrī], on the 21st of February, deduces the place of ♄ in ♊ degree 6. 20'. The Philolaican, moreover, at degree 6. 12'. 51". — Concerning the rest, in the observations of Copernicus, Tycho, Longomontanus, and his own, which he compares from the tables, he adds nothing unless [a difference of] a semicircle exceeding in the place of Saturn by minutes 4 ½.

10. So far it is given to gather from the opinion of others, nor do we have observations sufficiently many, immune from every sensible error, or [free] from all human industry — diffusible [error], nor anything of antiquity dissolves [it], for these tables, although exact, did not [yet] decades of minutes, or sextants of a degree, scarcely attain; nor are the

tables so exact but that some scruples of dubious minutes may be suffered, as in Saturn rarely indeed by 34', not rarely by 14'. or 16, the Rudolphine [tables], the Lansbergian, moreover, as the Philolaican [by] 15'. or by 12. and these often by less. From which it follows that we do not know how to discern, sometimes in the disagreement between the observations and the tables, the vice of these [tables], whether of the one or the other — yet this discrepancy, in a great part, whether the observations or the tables, among the most accurate ascertained, are wont to satisfy, within 5'. circiter; minute, [yet] I do not doubt but that a great part of the discord proceeds either from the observations, especially if they have been held from the ancients, or [from] the mode chosen in observing — more operations, & whose suppositions not so scrupulously involved.

11. Among the Modes, then, reviewed in chapter 9, the first degree of certainty merits those which require only the Declination of a single fixed [star], or the Right Ascension and the Altitude of the planet; for in these can be exercised the astronomer with instruments suited [for] no error exceeding 3'. & a minute, of which kind are Modes 1. 6. 8. To these are akin 2. 5. 7. 9. 10. 11. 12. 13. 15. 16., in which the five circular elements concur to determine the place of the planet, so that an error may be feared of 5'. or 6'. circiter, of minutes. Modes 4. 14. & 17., then, I judge to be liable to an error of 8'. or 10'. of minutes; while 3. & 18. [are liable] even to an error of 20'. of minutes. Therefore, in whatever way astronomy advances, I reckon that we cannot hope for observations, or tables, which in three respects are superior to the [other] planets, certainly and evidently excluding doubt, [free] from a threefold scruple of error, & by which a good part rests within 5'. or 6'. for some places of the planetary orbit do not exceed 10'. Let this be commodious, so that the least [error] of either part labors under the vice. It remains, as in the following chapter, as in a mirror, I may set forth selected observations of the places of Saturn, with parallel, subjoined likewise, [from] the more celebrated tables. From this it will be established that no tables [are such] by which they can be supported, [no] observations by which they can be opposed, so that scarcely can it be discerned, in the discrepancy, whether the whole is to be ascribed to the observations or to the tables, in whole or in some part.

CAPVT XI.

Selected positions of Saturn from the preceding observations, and collated with the positions computed through the more celebrated tables.

The following characters [Characteristicae] indicate the tables, namely: **Da.** the Danican; **La.** the Lansbergian; **No.** Our own [Nostras]; **Ph.** the Philolaican; & **Ru.** the Rudolphine; **Pru.** the Prutenic — before which are noted the observers of the places of Saturn. On the left side, moreover, are indicated repeatedly the aspects of Saturn with the Sun, exactly indeed, where nothing is added; nearer, however, where the letter **C.** indicates *Circiter* (approximately).

Caput XI (continued)

Selected Positions of Saturn, Compared with the Tables (continued)

The comparison of observed Saturn positions against the six principal sets of tables continues. Each block gives the date and equated hour of an observation (with its aspect symbol), then the observed or tabular source, the longitude of Saturn (zodiac sign, degrees, minutes, seconds), and the difference in minutes and seconds against the leading entry of the block. The table-sigla are: *Tycho.* / *Tychon.* (Tycho's or Tychonic observation), *Byrgius* (Bürgi), *Lansb.* (Lansbergian observation), *Hortes.* (Hortensius), *Nos.* (Ours), *Mutus* (Mut), *Bullial.* (Boulliau); and the tabular columns *Pru.* (Prutenic), *Da.* (Danican), *Ru.* (Rudolphine), *Ph.* / *Phi.* (Philolaic), *No.* (Ours), *La.* (Lansbergian). "Lat." rows give the latitude (B. = boreal/northern, a = austral/southern). "C." marks the configuration with respect to the Sun (opposition $\circ^{\circ}$, quadrature $\square$, trine $\triangle$, conjunction with Mars σ , etc.).

Saturn's Positions [Saturni Loca] — Table (continued; observations of 1588–1660).

The columns are: **Ann. Mens. D. / H. p. m.** (Year, Month, Day / equated hour); **Obs. & Tab.** (Observation source and Table); **h Loca: Sig. G. ' "** (Saturn's position: sign, degrees, minutes, seconds); **Differ. ' "** (Difference: minutes, seconds).

COROLLARIVM [Corollary]

It follows from the preceding Table that there is no set of tables among the more celebrated astronomers whose canons are not supported by some observations, and against which some others do not tell — assuming the observations are taken as they stand. Yet more observations stand in favor of Our Tables, and next of the Philolaic, which the Rudolphine and Danican most closely approach; while in the third rank stand the Lansbergian and the Prutenic. To let the reader review the numbers, and the number of instances in which the tables satisfy the observations within 5' or within 10', the figures are given in the little table set out below.

The Tables that Satisfy the Observations of Saturn [Satisfaciunt Observationibus Saturni].

Table [Tabula]	Within 5' — instances [Vicibus]	Within 10' — instances [Vicibus]
Prutenic [Prutenica]	12	21
Lansbergian [Lansbergiana]	12	25
Danican [Danica]	17	21
Rudolphine [Rudolphina]	8	21
Philolaic [Philolaica]	25	54
Ours [Nostra]	32	58

This always allowing for a more accurate computation, in case any error has crept in upon us, as upon any other human being, in this matter.

CAPUT XII.

On the Hypothesis and Theory of the Motions of the Five Lesser Planets, whether Geometric, or Arithmetic, and especially on Saturn.

Where, regarding the Progress made in this branch of Astronomy, and the Defect still hidden within it.

To take up the present occasion offered first by Saturn — yet matters that are common to the other four lesser planets as well — I shall treat them together, first setting out a few Suppositions.

I. SUPPOSITIO.

[Margin: 7. Species of motion.]

Among the five Lesser Planets, seven kinds of motion have been observed up to now. The **first** is the daily revolution from the same to the same meridian in a span of about 24 hours; this is called the *motion of the Primum Mobile*, or the *Common motion*, from East toward West. The **second** is the *Proper*, or *Secondary motion*, from West toward East, by which the planets appear to move contrary to the motion of the Primum Mobile. The **third** is the *motion of Declination from the Equator*, admitted alongside the second motion — since the motion of the planets does not in fact take place upon the Equator, but rather is described about the poles and the axis of the Ecliptic, near the poles and axis of the Zodiac. The **fourth** is the *motion of Latitude*, because the proper orbit of these planets is inclined to the plane of the Ecliptic, and cuts it in two nodes, beyond which they are found to depart from the Ecliptic. The **fifth** is the *motion of Altitude*, by which at fixed times they recede higher from the Sun and from the Earth, until at the greatest distance they reach their *aphelia* [Apogees]; and from there gradually descending they draw nearer again, and approach the Earth and the Sun, until at the least distance they pass out at their *perihelia* [Perigees]. The **sixth** is the *motion of Wandering* about its own body's centre — namely, the Telescopic motion, not yet sufficiently confirmed. The **seventh** is the *motion of Libration*, which is a twofold Telescopic motion. The remaining differences of motion do not constitute a diversity of kind, but are diverse affections of the same motion, in respect of quantity and of anomaly, distinctly considered: as when they are called Direct, Stationary, Retrograde, or, by a twofold Anomaly, are moved by one resolved motion (which they call the *First inequality*, or *Eccentric*); the other being tied to it (which they call the *Second inequality*, or *Epicycle*, or *Commutation*). And the first inequality displays itself most in the line of the Apsides, which passes through the centres of the Sun and the Earth; and this happens at the true conjunctions and oppositions of the planets with the Sun, and then they appear under the same Ecliptic, or Zodiacal point, whether viewed from the Earth or from the Sun. Beyond these cases this second inequality also occurs, by as much as the place of the supreme heaven, under which they are viewed from the Sun, differs.

II. SUPPOSITIO.

[Margin: 2. Fluidity of the planetary heavens.]

To explain the aforesaid motions of the planets, the solidity of the celestial orbs — together with their multiplicity, as the ancients held, whether absolutely or at least as a bare Hypothesis — is asserted, and by us refuted as not only without foundation but in the highest degree improbable; and it is rejected, in common with the more recent Astronomers after Copernicus: as we have shown at length (*Almagestum Novum*, sect. 1, cap. 2, qu. 2).

So too (*Almagestum Novum*, sect. 2, cap. 7), speaking of the heavens of the planets in particular. For that the sphere of the Fixed stars is solid is held to be more probable, and perhaps above I granted that another sphere is given, by whose rapid sweep of the Primum Mobile the whole sphere of the Fixed stars is carried round daily, except for these motions of the Fixed stars themselves — provided only that we understand them to be accomplished without any solidity of the spheres, by the bare impulse of the Intelligences, namely the Angels.

III. SUPPOSITIO.

Although none of the motions thus far indicated is the *Primum mobile* among the suppositions, yet not one of them — that is, no celestial Phenomenon among the planets — could be saved without manifest error, whether speaking Mathematically and apart from any cause, or explaining it Physically. The *First motion*, or *Common motion*, is nonetheless attributed to the very Stars, or to the Earth, and is examined by experiments of Physics, and by the rules of Mathematics: that the Earth is not moved with a Daily motion, much less with an annual motion of both kinds — this part of the proposition we have demonstrated with the whole effort of our talent, and with the greatest erudition we could muster from all quarters, gathering and setting forth arguments at length (*Almagestum Novum*, sect. 3, cap. 3 & 4). For the present, however, it suffices for the Reader at last to read through cap. 11 of this same book attentively, and apart from prejudice — which we beg to be done, attentively, and apart from prejudice.

[Margin: 4]

These things supposed, we now expound how, and by how far, the more recent Astronomy has progressed beyond the point to which it had hitherto advanced. **First**, it has learned that the line of the Apsides passes through the centres of the Sun and of the Earth at once; and that consequently the planets are carried away unequally by their own motion — not, as the old Astronomy supposed, by means of equal distances; but, as the truth has it, with the true Oppositions and Conjunctions of the Sun, and with the orbit of the planets, and apart from so

many librations toward the poles — that, by a simpler inclination to the Ecliptic, they display the varieties of latitude; but that all the aforesaid motions are accomplished freely in a fluid aether, and apart from that farrago of solid orbs which the ancients devised.

[Margin: 5]

It has gained, **next**, this further point, by which it profits the more recent Astronomy: that beneath that *Optical* inequality which appears in the motion of the planets, there lies a subordinate *real* inequality — neither wholly Optical, nor merely Apparent with respect to the Earth, which is not the centre of the planetary motion, viewed; and which inequality, as it were, if they were viewed from their own proper orbit's centre, they would appear to be moved equally and uniformly: yet what is in fact contained in those heavenly bodies, as nearly divine, as the Ethnic philosophers said, so persuaded the Astronomers, even down to Longomontanus inclusively, that they made it an axiom — namely, that *the celestial motions of the bodies of the heavens are equal*. Therefore, by others and others, eccentric Circles, Epicycles, and the like, they tried to explain the motion which, viewed from their own circles' centre, is equal, viewed from the Earth is unequal — as we have explained, fittingly enough, by the figures (*Almagestum Novum*, sect. 1, cap. 2 & 3). But Kepler first of all noted that that inequality is partly Optical, and partly — as the Apparent inequality is to us dwellers on Earth — Physical and Real: for in the orbit of the planet there are two foci, of which, since the one is not the centre, in the other the centre of the orbit itself, the planet is really and unequally moved. For if the planet be supposed to move equally about the centre of its own orbit, and the whole Eccentricity by which that centre is distant from the Earth's centre, we measure from the base of a triangle measuring the Angle of Prosthaphaeresis, the mean — that is, the equal — motion can never be reduced to truth, nor satisfy exactly the places of the planet observed. But if the Eccentricity be bisected, three points are set down in the line of the apsides: one is our Earth, the other is the centre of the planetary orbit, and the third in the middle, which is the centre of the planetary orbit; and the third, distant from the Earth by an equal amount, as is the Earth distant from the planet, the planet would be moved more justly: a far juster outcome arises — the Equation being compounded of a Physical part, whose basis is the distance of the centre of equal motion from the Sun's centre, and an Optical part, whose basis is the distance of the centre of the Orbit from the Earth's centre.

[Margin: 6]

But because the Ellipse has this property — that in its diameter there are three points equally distant from one another, namely the centre of the Ellipse, and two hence indeed the foci, or umbilici; and that those points coalesce by a radius reflexed from the periphery, and a physical virtue dispersed through it; therefore Kepler, by his own sagacity, perceived that the Orbits of the planets are not circular, but Elliptical, and that the causes of the planetary motion are Physical — for from the Ellipse there is yielded a reason why the planet at the extremities of the greater diameter is there at its Aphelia, here its Perihelia, and Perigees, and why its motions are dispensed as they appear. Yet he constructed the Mode in the Ellipse of the Prosthaphaereses, and in investigating the Aphelion, or Apogee, did not demonstrate it Geometrically (Kepler being the discoverer).

[Margin: 7]

Kepler was succeeded by Ismaël Bullialdus [Ismaël Boulliau], who in his *Astronomia Philolaica* (cap. 13 & lib. 11) not only attempted to demonstrate the motion of the planet, so that it might be accomplished through diverse circles upon the surface of a single cone, yet describes an Ellipse: a thing solvable nonetheless by equipollence into several circles. But he also investigated the very places of the Aphelia in the Ellipse by the same method of Vieta [François Viète]: yet not so exactly and subtly that he did not leave to Sethus Vuardus [Seth Ward] the task of emending the place, and then of investigating it more exactly in the Ellipse than Bullialdus, and of inquiring out the places of the Aphelia more exactly in the Ellipse. But Comes Paganus [Blaise Pagan] used the Elliptical figure happily enough in demonstrating the planetary motions, and the same; and our most friendly Io. Dominicus Cassinus [Giovanni Domenico Cassini] labours at it.

[Margin: 8]

Thus far recent Astronomy has progressed; but it still seems to me that progress must be made all the way until we recognize that the motion of the planets is not from a part only, but as a whole, to be unequal and uniformly non-uniform; and this not so much because the celestial bodies are deformed, but most especially because they are congruent to the limits intended by God the supreme Maker: for those equalities, which seem to us beautiful, are not beautiful; but those inequalities are more beautiful, which constitute a regular harmony of the World — as I have set forth elsewhere with many examples in the *Opificium Dei*. Besides, I consider that the motion is not only resolvable into several circles by the Ellipse, but also through Eccentrics and the Copernican Epicycles, or the Danish ones, no rarely more exactly to represent the observed places of the planets — which is an

indication that we do not yet hold that genuine figure, that very measure, which the motion of the planets requires.

[Margin: italic] Moreover, the aforesaid Authors suppose, who by a single Ellipse expound the motion of the planet, that the Earth is moved with the First motion from East to West; otherwise it is not saved: by the fluidity of the heaven of the planets, of which in Supposition II. nor can the First motion be reconciled with the Second by a single Ellipse, and with the remaining Suppositions enumerated; and yet that the Earth is so moved is false from the things said (Supposition III.). It remains therefore for the Astronomers to expound how the aforesaid motion is accomplished, and apart from Physical repugnance is continued by the planet itself in its passage.

[Margin: 9]

Now indeed, if what the inventors of their own inventions held — too dear to me, but seen to be absurd — the Astronomy will be at last recalled by way of restoration to the ancient, and only this will be recognized: that the planets describe a Conical surface from East to West, and other and other, sometimes broader, sometimes narrower spires, just as the five prior motions of Supposition I. require — easily not only is the First motion reconciled with the Second, but at the same time with the remaining three; and at once the planets will appear, not as stationary in fact, Direct, or Retrograde, but as perpetually carried round toward the West about the Earth; and then it will be seen that they make no progress in the Zodiac, when at the same moment they come to the same Meridian, when together with some one of the Fixed stars. They will be Direct, however, when they return a little more slowly to the same Meridian than the same Fixed star; Retrograde, however, when they revert there more quickly than the Fixed star, than they had been the day before at the same Meridian.

[Margin: 10]

Nor indeed does it become Astronomers to be so narrow of breast that they do not comprehend this spiral motion, because it cannot be done by a single simple figure, easily drawn with the pen, especially since it revolves about Conical spires; still less by the gypsum cone of this art, designated as a spiral figure, through which it may at last be cut off by a section of the cone, if not exactly Elliptical, yet nearest approaching the Elliptical — though by this very orbit the planet is not really moved.

[Margin: 11]

Finally, Astronomy ought to make progress in observing

[Continued.] the places of the planets most exactly by mutual congresses, or with the Fixed stars by the aid of the Telescope, or by application with the Fixed stars at the Meridian: that all the parts of the planetary Revolution may, by every means, be noted as to their places, apart from the error of many minutes; then indeed a far more certain knowledge will be had from measurement, whether of a single Ellipse, or of figures described by spires equivalent to an Ellipse — and so, from the foundation of constituting the planetary motions, for constructing tables still more certain. Retaining in the meantime the Ellipse, whether really or equivalently, we suppose in Saturn these things, which follow.

[Table: Saturn — mean motions. The first column gives the kind of motion (Diurnal / Annual). Numbers run: Sig. (signs) | G. (degrees) | then four further sexagesimal subdivision columns headed I, II, III, IV, V.]

Pro Hypothesi autem Figurae Geometricae.

(For the Geometric Figure of the Hypothesis, however.)

The Ellipse being chosen in the meantime, whose nearest traces the planet's diurnal motion — made toward the West by some, by others, and other — designates as quasi-circular spires about a cone, let the measures written below be chosen.

Of such parts as the Radius, or Solar Semidiameter of the Ellipse, is 100000, its bisected Eccentricity is 1740. Of such parts is it.

Semidiameter Maior Ellipsis Saturni

(Greater Semidiameter of the Ellipse of Saturn) If the Radius of the Annual Orbit $\odot$ be 100000.

Or its mean distance from the Sun	954198
Lesser Semidiameter of the Ellipse	946965
Whole Eccentricity from the Sun	110190 $\frac{4}{5}$
Half of the Eccentricity	55095 $\frac{2}{5}$

	Distantia (Distance)	
With the Sun at Apogee, Saturn at Aphelion	from the Sun	1009293
	from the Earth	1111033
With the Sun at Apogee, Saturn at Perihelion	from the Sun	899103
	from the Earth	797363
With the Sun at Perigee, Saturn at Aphelion	from the Sun	1009293
	from the Earth	1007553
With the Sun at Perigee, Saturn at Perihelion	from the Sun	899103
	from the Earth	800843

For the remaining distances, see Volume 2, Table 97.

The figures described and explained you have (*Almagestum Novum*, sect. 2 & 3), but for the Ellipse read Circle, or little circle, and their use.

[Continued from the right column of the preceding page.] re-read in this Volume Book One, and its cap. 11 with the Appendix, or read the *Astronomia Geometrica* of Seth Ward, published at London in the year 1656, in which he teaches to investigate, as much by the circle as by the Ellipse, the inequality of the planets, the Nodes, the Inclinations, &c., whether the eye be placed in the Sun, or in the Earth, or in some other planet, from which the Sun would be seen. But in that work it requires Observations somewhat too delicate, and tied to certain definite moments of time, which cannot be reduced to a near approximation with ease, on account of the subtlety with which it can perhaps be done — who would have thought it? — and on occasion their handling not rarely, whether from clouds, or otherwise subtracted. If, however, the Astronomers shall with long-suffering have persisted in this study, it may at last be done, that such things — by so many observations adopted, and by the benefit of Geometry demonstrated by Ward — may perfect Astronomy. But always it lies upon them to reconcile the diurnal

motion of the Primum Mobile, which at the end we show cannot be attributed to the Earth, with the Sun, with the proper motion of the Stars.

BOOK SIX, CONTAINING THE OBSERVATIONS OF THE PLANET JUPITER, AND THE HYPOTHESIS OF ITS MOTIONS.

CHAPTER I.

Ancient Observations of Jupiter, from the year 241 before Christ down to the year 807 of the same era.

1. In the year 45 (according to Dionysius, on the 10th day of the month Parthenon, that is to say in the year 83 from the death of Alexander the Great), on the 17th, on the day of Epiphany, the next morning at 10 in the morning, Jupiter touched the southern Ass — the one situated in the Nebula of Cancer. Ptolemy [*Almagest* XI, ch. 3] judges that this star had been one degree from Jupiter; Longomontanus [*Theorica* II, ch. 7], 33'; and Bullialdus [Boulliau, *Astronomia* ch. 7]. And he reckons that this had been a year before Christ, falling on the 3rd of September, [?] at the 16th hour after noon at Uraniborg; and that at that time the star was distant from Jupiter [?] grad. [Bullialdus] gr. 7, and 33'; or, as Longomontanus has it, by no fewer than 6'; or, as Bullialdus has it, with the southern latitude, 25'. But Lansbergius [Lansbergen] in his *Thesaurus* of observations records it as having been in the year 507 of Nabonassar, the 17th of Epiphi, and at that hour, the Goat at 14°20', and of the Ass, the longitude of Jupiter [?] and of Cancer at gr. 7, 32', by observation — but at gr. 34°26'' from his Tables. Truly it was the 3rd of September; and that fixed star was in Cancer gr. 7, 11', with southern latitude 3', 30''.

2. In the 17th year of the Emperor Hadrian, on the 1st of Epiphi, at the 1st hour before the middle of the following night, Ptolemy at Alexandria gathered from his own observation that the acronychal opposition of Jupiter had occurred with the mean place of the Sun, Jupiter being in Scorpio gr. 23, 11'. So he himself [*Almagest* XI, ch. 1], and Copernicus [*De Revolutionibus* V, ch. 10]. That year was 133 of Christ, and the 18th day of May.

3. In the 21st year of Hadrian, on the 13th of Paophi, at the 2nd hour before the middle of the following night, Ptolemy at Alexandria, reckoning, judged that the acronychal opposition of Jupiter with the mean place of the Sun had been made

in Pisces gr. 7, 54'. So he himself [*Almagest* XI, ch. 1] and Copernicus, as above. The year was 136 of Christ, and the 31st of August.

4. In the first year of the Emperor Antoninus, on the 20th of Messori — the next being Athyr — on the 5th hour after midnight, Jupiter was opposite the mean place of the Sun in Aries gr. 14, 23', by observation and by Ptolemy's reasoning [*Almagest* XI, ch. 1]; and indeed in Greek the day is so designated: ἄθὺρ κ' εἰς τὸν κ' καὶ [Greek: Athyr 20, into the 20th and (?) — the Egyptian calendar date] [?]. That is to say Athyr 20, into the 21st: thus Copernicus [*De Revolutionibus* V, ch. 10]. By error they had placed the day at 15. It was the year 137 of Christ, the 7th of October.

5. In the second year of Antoninus, on the 26th of Messori, the next day, at about the fifth hour, equal time, after the middle of the night — Ptolemy being at Alexandria — comparing Jupiter with the bright star of the Little Manger [Praesepe], he judged it to be in gr. 15, 45' of Gemini. So he himself [*Almagest* XI, ch. 2].

Lansbergius in his *Thesaurus* of observations records that Jupiter — observation 2 — refers this to the year 139 of Christ, July 20, hour 17, after the meridian of Alexandria, and that Jupiter accompanied the bright star of the Hyades in gr. 15, 30' of Gemini. So Longomontanus [*Astronomia Danica* II, ch. 7]. Therefore the first year of Antoninus was 136, the second 139, and it really was the day 10 of July, the next being the 11th, the year 139.

6. In the year of Christ 508, that is to say of Diocletian 224, on the 30th of the month Thoth — that is, the 28th of September — in the morning at Athens, Jupiter was seen very near the Heart of the Lion [Cor Leonis, Regulus]; three digits from it, that is, minutes $7\frac{1}{4}$, distant toward the north. So Bullialdus [*Astronomia* ch. 7] from a manuscript of the Library of the Most Christian King, adding that at that time the Heart of the Lion had been in gr. 8, 49', 54"; and in the same manuscript it is indicated that the conjunction of Jupiter and Mars was observed, in the year of Diocletian 214, on the 6th day of Pachon, the year coming round, under the 5th hour after midnight.

In the year of Christ 807, on the day before the Kalends of February, on the 17th of the Moon, the star of Jupiter was seen to have passed almost beneath the Moon, as is found in the *Annals of the Franks*, and in the *Life of Charlemagne*.

CHAPTER II.

Observations of Jupiter made by Johannes Regiomontanus [Regiomontanus] and Bernhard Walther, from the year of Christ 1471 to 1504.

The First Class is of observations made by ocular estimation.

1. In the year 1471, March 15, Regiomontanus at Strasbourg saw Jupiter almost in a straight line between the brighter star of the middle of the left wing of Virgo, and the darker one around the eye, toward Leo; and distant in obscurity by two-fifths of the spaces between the said stars; but on August 9 at Nuremberg in the evening he saw Jupiter and Venus distant from one another by $1^{\circ}13'$, using also the Cross-staff [Radius]; granted that the calculation of Alphonsus would require gr. 4, 33'.
2. In the year 1478, Bernhard Walther observed as much on the 22nd of August as on the 30th of September that Jupiter was in a straight line with the two eyes of Taurus, almost 3 parts after midnight, and from the more western eye it was distant by half the distance of the eyes of Taurus.
3. In the year 1488, October 8, Jupiter being in M.C. gr. $13^{\circ}\frac{1}{2}$, was observed by Walther in gr. 13, 20' of Pisces, with the southern latitude of one degree. Bullialdus [*Astronomia* ch. 7] says that Jupiter had been in gr. 14, 16' of Pisces; if the place of Aldebaran be corrected, it was in Π [Gemini] $2^{\circ}36'$; but this observation looks to the armillaries, concerning which see below.
4. In the year 1497, February 15, in the morning at hour 4 after midnight, the Moon, Mars, and Jupiter were distant by a diameter of the Moon, says Walther; but the distance was about half from the side of the latitude. Mars, however, was more western than Jupiter and more meridional, granted that, according to the *Almanac*, their conjunction — which was still to come — had passed.
5. In the year 1503, September 8, in the morning at hour 4 after midnight, I saw, says Walther, Jupiter near the star which is the eighth of Gemini, on the right side of the preceding, and they were at almost the same conjunction in longitude, such that if you imagine an arc through the Pole of the Zodiac, and the star, it would touch the western edge of Jupiter; but the latitude truly held itself beyond it toward Boreas in the manner of two transverse digits. Now the said star is placed distant from the Ecliptic toward the north by gr. 2, 40'; granted that, observed by the armillaries by Walther, it scarcely had any latitude — from which Lansbergius in the *Thesaurus* gathers that Jupiter had been in gr. 12, 2' of Cancer,

as from the Tables gr. 11, 56'; and the southern latitude. But the said fixed star, which he says had 12 minutes 11', the fixed star moreover had been in ♋ [Cancer] gr. 11, 55', lat. Bor. gr. 2, 56¼'. But the fixed star was in ♋ gr. 11, 27', lat. 15'.

6. In the year 1503, October 6, I have indicated, says Walther, the ocular conjunction of Jupiter and Mars according to longitude; but Mars was more northern than Jupiter by one part, the Moon almost rising before the Sun by two hours.

7. In the year 1504, February 9, Walther notes the conjunction of Jupiter with Mars; April, however, the 29th, the conjunction of Jupiter with the eighth of Gemini after the meridian, according to longitude, Jupiter existing more northern by half a part; but Bullialdus [*Astronomia* VI, ch. 7] affirms that Walther was as much deceived here as in the observation of the year 1503. September 8 — and that he was deluded in reading Ptolemy's catalogue, in that he ought to have taken the twelfth star of the eighth of Gemini under the left thigh of the following Gemini, and that the observation had occurred at the time when Jupiter was in gr. 11, 33' of Cancer, with southern latitude of at least 13'; but from the Tables he gathers the place of Jupiter in gr. 12, 0', 25" of Cancer.

8. The Second Class contains only two observations made by the Cross-staff [Radius], on whose use see Walther's observations of Saturn, no. 10.

I have already touched on the first observation, no. 1; the other was made in the year 1478, August 24, in the morning, when the first interval of distance between Jupiter and the right eye of Taurus was 70, and the second interval 811; but between Jupiter and the left eye of Taurus the first interval was 30, the second 942.

The Third Class is of Observations made by the Zodiacal Armillaries, concerning whose uncertainty within 10 minutes, see Walther's observations of Saturn, no. 33, above.

The following table of armillary observations of Jupiter (observations 9–52) spans the foot of page 304 and the head of page 305. Columns: the observation number; the year, month, and day [Ann. Mens. D.]; the observed place of Jupiter [☿ Locus observ.] in Sign, Degrees, Minutes [Sign. Gr. M.]; and the Mid-Heaven [Med. cœlum] in Degrees and Sign [Gr. Sig.]. Interspersed "Latit." rows give the ecliptic latitude (A. = southern/austral; B. = northern/boreal). The note "n. s." (post meridiem / next-day specification) and "manè" (morning) appear with several dates.

Lansbergius in his *Thesaurus* of observations, examining the Tyconic observation of Jupiter — observation 4, of day 14 — gathers from his own Tables the place of Jupiter in gr. 7, 19', 19" of Cancer, with northern latitude 9'.

Longomontanus, moreover, in his *Astronomia Danica* [II], in the chapter on the *Theorica*, exhibits eight acronychal places of Jupiter — five indeed from Tycho's [observations], but the last three from the place of Jupiter computed from his own Prutenic Tables, yet corrected, by adding 4 $\frac{2}{3}$ ' to the mean longitude, and 40' to the apogee. The Prosthaphaeresis, moreover, of the part of the eccentric everywhere a twenty-fourth part [vigiesimam quartam], and they are of this kind, by the old-style Calendar.

The following table (page 305, gives, for eight acronychal observations, the date [Ann. Mens. D.], the hour and minute after the meridian [H. M. p. mer.], the observed longitude [Lōg. observ.] in Sign, Degrees, Minutes [Sig. G. M.], and the supputted (computed) longitude [Lōg. supputata] in Degrees and two further columns of minutes [Gr. I, II].

1			2		1 5		2 5

From the foregoing acronychal observations, Bullialdus [*Astronomia* VII] of the years 1583, 1584, 1591, and 1596 — consult chapters 1 and 2.

There follow the last Tyconic observations, made at the fortress of Benatek near Prague, in the year 1600; or at Prague in the house of Curtius, in the year 1601, by the new style — consigned by Snellius [Snell] in the observations published at Leiden [Lugdunum Batavorum], in the year 1618.

12. In the year 1600, February 3, when the bright star of Hydra was distant from the meridian toward its rising by about one degree, and the head of Hydra crossed the meridian before it by about one hour, Tycho observed Jupiter distant from the head of Pollux by gr. 29, 51 $\frac{1}{3}$ '; and corrected for refraction gr. 29, 52 $\frac{1}{3}$ '; and from the bright star of the feet of Gemini gr. 44, 11 $\frac{1}{3}$ '; but corrected gr. 44, 11', 50".

13. In the year 1600, February 4, by the new style, on the following night, the meridian altitude of Jupiter was observed at gr. 56, 29 $\frac{1}{3}$ '; and at once the meridian altitude of the more southern [star] in the head of Leo was taken, which was gr. 51, 23 $\frac{1}{4}$ '; and of the following [star] in the other foot of Leo, which was gr. 65, 15 $\frac{2}{3}$ '; and at that time Jupiter had withdrawn from the meridian by as much as was the diameter of its own body.

14. In the year 1600, April 12, by the new style, at hour 9, 46', after the meridian, Jupiter was distant from the bright star of the feet of Gemini gr. 39, 0'½'; and at hour 9, minutes 53', it was distant from Regulus gr. 12, 30'.

15. In the year 1601, July 16, by the new style, on the following night, at hour 9, 22', Jupiter, high at gr. 10, 40', was seen to be distant from Arcturus gr. 41, 26'; and at hour 9, 29', high at gr. 9, 31', distant from Saturn gr. 45, 18'.

There follow observations of Jupiter completed by Tycho from the year 1583 down to 1599 at Uraniborg, and the rest in Bohemia, which R. P. Albertus Curtius S.J. selected from a manuscript of Tycho's, and transmitted to us — once chosen out for publication, among the Tychonic observations, by the Emperor, formerly his patron, and consigned in the old style.

CHAPTER III.

Copernican Observations of Jupiter, from the year of Christ 1520 to 1530.

It must be noted that Copernicus numbers the longitudes of the planets from the first fixed star preceding the horn of Aries, which in the year 1525 he places as distant from the Vernal Equinox by gr. 27, 21' [recte: per his text]; from which the longitude is thereafter derived. [The page reads "gr. 20, 40'."]

1. In the year 1520, on the 12th of the Kalends of March, in the morning at the 6th hour before the meridian, Copernicus, by an instrument for distances, most diligently observed Jupiter to precede gr. 4, 31' the first Star — the one which is in the forehead of Scorpio, the more splendid one, whose place he says had been in the parts of Scorpio gr. 16, 48'. So Copernicus [*De Revolutionibus* V, ch. 14].

2. In the year of Christ 1520, on the day before the Kalends of May, in the middle of the preceding night, at the 11th hour, Copernicus, as he himself asserts, most diligently observed Jupiter acronychal in gr. CC, 10°57' [scrup. XVIII] of the sphere of the Fixed [stars], namely in Scorpio gr. 10, 57'. So he himself [*De Revolutionibus* V, ch. 11].

3. In the year of Christ 1526, on the 4th of the Kalends of December, at the 3rd hour, in the middle of the night, Copernicus observed Jupiter acronychal in the parts of the Sphere of the Fixed [stars] XLVIII, scrup. 33, namely in Gemini gr. 9, 16'. So Copernicus [*De Revolutionibus* V, ch. 11].

4. In the year of Christ 1529, on the Kalends of February, the matter being settled, at the 19th hour, in the middle of the night, Copernicus observed Jupiter

acronychal in gr. CXIII, scrup. XLIV of the Fixed [stars] — that is in Leo gr. 14, 28'. So Copernicus [*De Revolutionibus* V, ch. 11].

CHAPTER IV.

Tychonic Observations of Jupiter.

Tycho himself, in the *Epistles to the Landgrave of Hesse*, page 56, sets down the following observations of Jupiter made at Uraniborg in the year 1587; and, noted by the old style, computes them by the Alphonsine, the Prutenic, and the Copernican Tables.

Liber VI — De Iove (Book 6, Jupiter)

Caput IV — Tycho's Jupiter observations (continued)

[This page continues the table of Tycho Brahe's observed Jupiter positions begun on the preceding page. The table is laid out in two parallel halves on the folio (page 306 left, page 307-side right). Columns: observation number; Year; Month; Day; Hour and Minute past noon [*post meridiem*]; Jupiter's observed longitude [*Long. ꝓ observata*] in Sign, Degrees, Minutes; Jupiter's observed latitude [*Latit. observata*] in Degrees, Minutes; and a final unlabeled column carrying the letters **A** or **B**. The longitude column repeats the zodiacal sign only when it changes; intervening rows take the sign from the row above.]

After this table the running text resumes (page 306, right column, below the table):

Once the typographic printing of Tycho's observations had been begun, there was sent to me a specimen of the subjoined observation, made in Bohemia in the year 1600, which runs as follows.

[The following is a second, more detailed table — a single fully worked-out observation set. Columns: observation number; Month and Day [*Mens. Dies*]; the object or reference from which the distance was measured, under the heading **Distance from the fixed stars** [*Distantia à Fixis*]; and Jupiter's measured value [*Iouis*] in Degrees [*Gr.*], minutes [*I* = first minutes], seconds [*II* = second minutes/seconds]. Explanatory phrases run across the left of the table.]

No	Month / Day	Distance from the Fixed Stars	G r.	'	"
8	January 6, with Jupiter high	from the Heart of the Lion [<i>à</i>	2	5	4

Caput V

Jupiter's observations made at Kassel by Jost Bürgi [Iusto Byrgio], instrument-maker [*Organopæo*] to the Landgrave of Hesse, selected from Snel [Snellio] among the Hessian observations, together with the Keplerian and Longomontanian [observations].

[This chapter opens with a table of observations from the Kassel (Cassel) observatory program. Columns: observation number; Year, Month, Day, Hour, Minute, old style, past noon [*Ann. Mens. D. H. M., stylo veteri, post mer.*]; and **Distance of Jupiter from the fixed stars** [*Distantia Iouis à Stellis Fixis*] in Degrees [*Gr.*] and Minutes [*M.*], with the named reference star. Most entries carry two distance measurements (to two different stars).]

Below the table (page 307, left column):

Boulliau [Bullialdus], in *Astronomia Philolaica* book 7, chapter 3 [*l. 7. c. 3.*], using the observation of the year 1591, January 29, gathers the place of Jupiter as Scorpio 17° 9' 22", with northern latitude 1° 21' 14"; and for the year 1597, September 13, the place [of Jupiter as] Π [Gemini] 16° 14' 11", with southern latitude 0° 35' 29".

Caput VI

Jupiter's observations made by Pierre Gassendi [Petro Gassendo], Ismaël Boulliau [Ismaele Bullialdo], Martin Hortensius [Martino Hortensio], [Philip] Lansbergen [Lansbergio], Johannes Hevelius [Ioanne Heuelio], and Vicenç Mut [Vincentio Muto], from the year of Christ 1620 to 1650.

1. In the year 1620, on November 4, new style, at hour 8 after noon, at Aix [Aquis Sextiis], Pierre Gassendi observed with a cross-staff [*Radio*] the distance of Jupiter from the head of Medusa [à *capite Medusæ*] as 23° 58', and presently as 6° 35' from Aldebaran; and 18° 30', or 31°, [from] the foot of the eastern [star] of Orion,

and its right shoulder [*humerum dexterum*] as $18^{\circ} 34'$ — which Tychonically is $18^{\circ} 35'$. Hence he deduced Jupiter in Taurus $16^{\circ} 25'$, with northern latitude $1^{\circ} 18'$. So he reports in his *Life of Claude Fabri de Peiresc* [*in vita Claudij Fabricij Peireskij*].

2. In the same year, on November 5, at hour $7\frac{1}{2}$, Gassendi there [*ibidem*] saw Jupiter distant from the head of Medusa $24^{\circ} 4'$, then $3'$, then $5'$; and from the bright star of the Pleiades [*à lucida verò Pleiadum*] $9^{\circ} 55'$; then $55\frac{1}{2}'$. From this he inferred the longitude of Jupiter in Taurus $16^{\circ} 16'$, with southern latitude $1^{\circ} 16\frac{1}{2}'$. The same [is found] in the life [of Peiresc] of which I spoke above.

3. In the year 1620, on November 7, at Aix, the same [Gassendi] observed the opposition of Jupiter with the Sun, as we have it in the records [*in schedis*] sent to me by Dom. Dominicus Cassinus [Giovanni Domenico Cassini] himself from Bologna.

4. In the year 1623, on October 12, at hour 17 [*hor. 17.*], at Loudun [*Loduni*] in France, Boulliau observed Jupiter farther advanced in longitude than Regulus by 3 minutes, and more northerly by 8 minutes; from which he deduced Jupiter to be in ♌ [Leo] $24^{\circ} 40'$, with northern latitude $35'$. So he himself [reports] in book 7 [of the] *Astronomia Philolaica*, chapter 3.

5. In the year 1627, on April 25, old style, at hour 1 after noon, at Leiden [*Leydæ*], Martin Hortensius [Martinus Hortensius] observed Jupiter more to the west than the topmost star of the forehead of Scorpio [*supremâ frontis Scorpj*], by almost 5 minutes. So Lansbergen [Lansbergius], in the *Thesaurus*, records it as 5 in longitude [5. *Iouiali*], affirming that that star [*Stellam illam*] was in Scorpio $28^{\circ} 6'$, with northern latitude $1^{\circ} 4'$; and accordingly Jupiter in $28^{\circ} 1'$, with northern latitude $1^{\circ} 3'$; but from his own tables [it would be] $28^{\circ} 1' 47''$ Scorpio, with northern latitude $1^{\circ} 5'$.

6. In the year 1629, on October 20, old style, Jupiter was observed at Middelburg [*Middelburgi*] in a straight line with two stars preceding it [*præcedentis*] in the horn of Capricorn [*cornu Capricorni*]; so Lansbergen in the *Thesaurus* records, on the observation of Jupiter, who concludes from this that Jupiter was in Aquarius $0^{\circ} 17'$, with latitude $44'$.

7. In the year 1633, Pierre Gassendi diligently observed the opposition of Jupiter with the Sun, on December 14 in the evening, near the hour 9 of the night. For he saw Jupiter distant from Aldebaran $22^{\circ} 21'$, and from the left shoulder of Orion [*ab humero sinistro Orionis*] $19^{\circ} 35'$; but in the daytime [*die autem*] on the 17th, [it was] distant from Aldebaran $21^{\circ} 56'$, while from the same left shoulder [of Orion] $19^{\circ} 19'$; in the observations sent to me from Bologna by Dom. Cassini.

8. In the year 1633, on December 17 in the evening, Gassendi at Digne [*Diniæ*] saw Jupiter retrograde near Propus of Gemini [*Retrogradum Propodi Geminorum*], so that from the margin it could scarcely be discerned as moving, were it not that — by the telescope [*Telescopio*] — it was seen to be separated [from Propus]. The arrangement of the Medicean stars [*Mediceorum siderum situs*, i.e. Jupiter's moons] indicated the star [Propus] left behind to the north [*ad Boream*]. On the 18th in the evening, at hour 8½, it was being hidden to the naked eye [*nudo oculo*] under the rays of Jupiter, but the telescope showed it standing apart from Jupiter's diameters [*Iouis diametris*], and to the north. On the 19th in the morning, at hour 4½, it was nearer, and still to the north; nor can the angles be made out with certainty, since the line drawn through the Mediceans was distant from Jupiter by 4 diameters. On the same [day], in the evening, at the same hour 8, it was nearer, and Jupiter was to the east, and distant from it — as far as it had been in the morning to the east — but the angle, since in the centre of Jupiter it made [it] sharper [*acutior*] toward the east than it had been in the morning toward the west. For the rest, the line of Jupiter's satellites is perpetually inclined to the ecliptic, and can, near a conjunction of Jupiter and Propus, be reduced [to] the middle time, or to [the moment] under the meridian on the 19th. So [it is reported] from Gassendi in the *Epicurus*, *Meteorology* page 906.

9. In the year 1634, Gassendi observed the station of Jupiter, comparing it by the telescope with the little fixed star [*Stellula Fixa*] to which Jupiter was approaching, on February 15, after hour 10 in the evening; it stood [*stitit*] almost normal [perpendicular] with respect to the line of the Mediceans, distant from the said star to the south [*ad Austrum*] by three of its own diameters; and in the same arrangement it appeared on the 16th. As it was on the 17th, so it was on the same [day]; but it was in contrary directions [*in contrarias plagas*], although it was distant from the said star by three diameters on the 17th. The arrangement was alike on the 18th. But on the 15th and 16th it was distant from Aldebaran 17° 17'; and from the right shoulder of Orion 16° 16'; to a finer minute, and the latitude to the north 0° 8'. So Gassendi above.

10. In the year 1634, Jupiter [being] now direct [*iam Directus*], on April 11: nearest to Propus, and the acute angle with the line of the Mediceans toward the west, distant by 10 [diameters?] from Propus toward the north, by the diameters of itself [Jupiter], the telescope showing [it]; while on the 12th the angle was nearly equal, [as] before; for which reason the conjunction of Jupiter and Propus took place around the intermediate time. So from Gassendi in the *Epicurus* page 906.

11. In the year 1634, on April 12, at hour 8½, at Paris, Boulliau, with an optical tube [*optico tubo*], observed Jupiter separated from Propus toward the north by 9 minutes, while toward the 10th, and as to azimuth scarcely toward the west [*occidentaliorem*], yet judged the position toward the zodiac; [he] had now passed beyond the place of Propus, which was in Π [Gemini] $25^{\circ} 56'$; Jupiter then in Π $25^{\circ} 53'$, with northern latitude $14'$. So [he reports] in book 7 of the *Astronomia Philolaica*, chapter 3.

12. In the year 1634, on December 4, at hour 19 [*hor. 19.*], at Loudun [*Loduni*], Boulliau with a tube observed Jupiter distant $17'$, or $18'$, [to within] the smallest minutes, to the north from the small ass [*ab Aselo*], to the north of Jupiter [*Boream versus*]; the position as to azimuth toward the eastern parts [*ad Azimuthum partes orientales*]. From this he judged Jupiter to obtain the same place with the said star in Π [Gemini], with northern latitude $14'$.

13. In the year 1635, on January 18, the opposition of Jupiter with the Sun [was] determined by Gassendi; to which [agree] the records from Aix on the 16th, in the evening, [where] he saw Jupiter distant from Procyon $18^{\circ} 41'$, and from Castor $16^{\circ} 16'$; but on the morning of the 17th, at hour 5, he saw [it] distant from Castor $16^{\circ} 58'$; and from Pollux $12^{\circ} 42'$; and from Regulus $25^{\circ} 27\frac{1}{2}'$. So [it is reported] in the observations sent to me from Bologna by Dom. Cassini.

14. In the year 1636, on February 19, Gassendi notes, in letters [sent] to Cassini, the opposition of Jupiter with the Sun; because at Digne, on the 20th in the evening, he saw Jupiter distant from the neck [of the Lion] $9^{\circ} 18'$, and from Regulus $5^{\circ} 10'$.

15. In the year 1637, on July 16, Boulliau saw with the tube Jupiter applied to a star, which is the sixth in the Wing of Virgo [*sexta in Astro Virginis*], preceding it; and four of them [*quatuor*], which is on its left [*in alia eius sinistra*]. At hour 1, it was distant from that [star] by 12 minutes; and at hour 4½ and 9, but more to the west [*occidentior*] by $12\frac{1}{2}$ minutes; therefore I reckon Jupiter to have preceded the star by 12 minutes; and so it lingered [*versari*] in Virgo $29^{\circ} 38'$, with northern latitude $1^{\circ} 18'$. So [he reports] in book 7 [of the *Astronomia Philolaica*], chapter 3.

16. In the year 1639, [near] the opposition of Jupiter with the Sun (it is ascribed to the day of May 20 [*diei 15. Maij*]) it was observed at Aix; in the records sent to Cassini, [in which] Aix [*Aquis Sextiis*] saw Jupiter distant from the Southern Scale [*à Lance Austrina*] $21^{\circ} 5'$, but to the north $18^{\circ} 21\frac{1}{3}'$.

17. In the year 1639, on August 31, at hour 8, at Paris, Jupiter returned again [*denuò rediit*] to the bright star of the forehead of Scorpio [*ad lucidam frontis*]

Scorpij]; [it] was distant by about 24', or somewhat more, in azimuth [by] six minutes toward the east; for which reason it scarcely [departed] by one [minute], or by a scruple [*scrupulo*], surpassed [*superaverat*] the star in longitude, whence — by other surrounding circumstances — Boulliau reckoned Jupiter to be in ♄ [Scorpio] 28° 5', with northern latitude 42'. So [he reports] in book 7 [of the *Astronomia Philolaica*], chapter 3.

18. In the year 1646, Dom. Vicenç Mut [D. Vincentius Mutus], at Majorca [*Maioricæ*], observed through several days, in the month of February, the opposition of Jupiter, by a foot preceding [the star] of Gemini [*ad præcedentem pedem Geminorum*]; and on the night of the 19th day he found Jupiter in total station [*in totali statione*], and from this most southern star [*à Stella occidentaliorem*] [distant] 5', and more northerly by 9', with 10', as in the letters from him given to me.

19. In the year 1646, on December 24, new style, in the evening, Hevelius at Danzig [*Dantici*] observed Jupiter covered [*tectum*] by the Moon, which page 477 of the *Selenographia* narrates [as] its emergence from the Moon at hour 8 39½'; observing the occultation of [the star] Regiomontanus of Prussia [*Regiomontano Prussiæ*, a lunar crater] at hour 7 53'; observing [the crater] Albertus Linemann [*Albertum Linemannum*], and so at Danzig at hour 7 45' 33"; as Hevelius reckons.

20. In the year 1647, on January 20, Gassendi at Paris, at hour 14 10', saw the northern margin of the Moon, [where] the southern margin of Jupiter was distant by half a spot of Caspia [*per semissem maculæ Caspiæ*], by the telescope used; at hour 14 17', the Moon touched the margin of Jupiter, and after a half-minute he began to emerge; at hour 15 0' 30" he [Jupiter] withdrew to the western margin of the Moon; but the arc of the lunar limb between the points of Immersion and Emersion was 72 degrees. So [it is reported] in the *Epicurus* page 901.

Hevelius too, on the same day, on the 20th, has it [on] page 480 of the *Selenographia*; [the same] observed the transit of Jupiter as above. On the Moon at hour 15 57'. So I reckon that Jupiter was at the very limb of the Moon, while it still lingered at the same hour 7.

21. In the year 1647, on April 12, new style, in the evening, Hevelius at Danzig [*Gedani*], observing Jupiter passing beneath the Moon, noted its conjunction with the Moon, [so far] as he noted in longitude, at hour 11 14' 50" after noon, [Jupiter being in] high Arcturus 13° 10'; and then Jupiter, at the northern cusp of the Moon, was seen to be cut into a dichotomy [*dichotomâ*] by 6', as he himself reports in the *Selenographia*.

The same phase Gassendi observed at Paris, when — the Moon being less perceptible [*insensibilior*] — the greater dichotomy appeared at the northern cusp [being] under the Moon, when Jupiter, seen by the telescope, touched the limb of the Moon, [it] scarcely seemed to be obscured, but truly began to be obscured by little intervals; and indeed at hour 10 4'; and the half precisely [*dimidium præcisè*] was wanting to Jupiter, and it was reckoned a pleasant sight that Jupiter, divided in half [*dimidio sui*], and afterward even less, than the half was unequally illuminated by the Moon, [it] standing out [*prætenuiret*] for a whole hour of demonstration; at hour 9½, the whole emerged distinctly; from the cusp, [it was] less than a quarter [*dodrantem*] in the longitude of the spot Caspia [*Caspiæ maculæ*].

In the same year likewise, and on the 12th of April, Dom. Vicenç Mut [D. Vincentius Mutus] at Majorca observed Jupiter eclipsed by the Moon, when Regulus was occulted to the west [*occidentalis*], the second altitude being 57° 18'; that is, at hour 9 56'; he began to be occulted at the northern cusp of the Moon, and egressed from the high Regulus 49° 12'; but to the north [it was] 10° 48', so that he lay hidden under that [Moon] by 52'. In another letter sent to me by him, on the 12th, [the same is] observed; that, from my [calculation of] the altitude of the latitude of the city of Majorca 39° 35'; therefore from the diversity of the parallax, the Moon — Jupiter being nowhere else than [elsewhere], [it] touches nothing of Jupiter — [is] elsewhere of them.

22. In the year 1647, through several days of December, Dom. Vicenç Mut, observing Jupiter with the shapeless star from the belly of Leo [*cum informi Stella sub ventre Leonis*], detected the total station of Jupiter to have occurred on the 27th, at hour 14, at Majorca; when Jupiter was still occidental [*occidentalis*] from that star by 3', and more southerly by 9', or 10'. To examine this observation, and to scrutinize the radius of the orbit of the world [*Radium orbis Mundi*], the Sun being in perigee, and because the variety of station can hence be gathered, the quadrature with the Sun is possible.

23. In the year 1650, the same Vicenç Mut [Vincentius Mutus], on 18 April, at hour 10 at Mallorca [Maioricæ], using a special instrument and a very large one, observed Jupiter to be distant from the star in the southern foot of Virgo by 3° 26'. From this, and from the observed latitude, he concludes that Jupiter was in Scorpio 5° 22'. To this the Lansbergian tables agree, with a deviation of 1' Danish; the Prutenic by 2', the Boulliau [Bullialdici] by 3', the Rudolphine by 11'. So he himself, in a letter to me.

24. In the same year, likewise on 21 April, from the latitude of Jupiter and a distance of $5^{\circ} 18'$ from the southern Balance [Lance Austr.], he inferred that it was in Scorpio $5^{\circ} 0' 40''$, with deviations as above, the Tables being named.
25. Likewise in the same year, there on 2 May, he saw Jupiter distant from the southern Balance by $6^{\circ} 41'$, and from the lowest southern star of the three forming the fringe of Virgo by $4^{\circ} 20'$; therefore it was in Scorpio $3^{\circ} 37'$, which agrees with the Prutenic, but with deviations: Danish $2'$, Boulliau $3'$, Lansbergian $4'$, Rudolphine $11'$. On 16 May, it was very nearly in the same longitude, being distant from the southern star in the foot of Virgo by $53'$; from which Jupiter's latitude was northern $1^{\circ} 24'$.
26. In the same year there, on 24 May, at hour $8\frac{1}{2}$, while D. Vicenç Mut was observing, a line drawn from the lowest, southern, of the three forming the fringe of Virgo to the star in the southern foot of Virgo grazed the western limb of Jupiter; thereupon Jupiter was distant from the aforesaid lowest by $2^{\circ} 15'$. From this he deduced Jupiter's longitude as Scorpio $1^{\circ} 12'$, and its northern latitude as $1^{\circ} 23\frac{1}{3}'$, with deviations from the longitude observed by the Boulliau Tables of $3'$, the Prutenic and Danish of $4'$, the Lansbergian of $8'$, the Rudolphine of $11'$. So he himself, in the same letters.
27. In the year 1649, again there, on 11 May, he observed Jupiter to be more easterly than the four stars preceding in the wing of Virgo by $2'$, or at most $1^{\circ} 30'$, and distant a little less than the two adjacent in the second Hyad. But on 9 June Jupiter was more westerly than that same star by one of its diameters exactly, and more northerly by scarcely more than its semidiameter. On the 10th, however, it was now more easterly in the same hour, so that in 24 hours it had completed three of its own diameters.

CAPUT VII.

Appendix of observations of Jupiter from the Tychonics recently published at Vienna, from the press of David Hautt, from which we have selected a few, and from *The Author of Urania Propitia* and from the Fathers of Innsbruck [PP. Oenipontanorum].

1. In the year 1582, on 30 March, in the morning at hour 4 $10'$, Jupiter stood distant from the mouth of Pegasus by $24^{\circ} 24\frac{2}{3}'$, and after 6 minutes of time from the Eagle [Aquila] by $35^{\circ} 32'$.

2. In the same year, on 7 April, in the morning at hour 3 36', Jupiter was distant from the mouth of Pegasus by $24^{\circ} 10\frac{1}{3}'$ — but too near the horizon — and at hour 3 50' was distant from the Eagle by $36^{\circ} 16\frac{1}{4}'$.
3. In the same year, on 2 November, at hour 5 54' 55", Jupiter was on the meridian at an altitude of $16^{\circ} 34'$, and at hour 6 was distant from the extremity of the tail of Capricorn by $3^{\circ} 48'$. But on account of the excessive nearness of the stars it could not be exactly observed. At hour 8 19' it stood, by repeated measurement, distant from the Vulture's bright star [Iucida Vulturis, i.e. Vega] by $35^{\circ} 2\frac{1}{2}'$, and at hour $8\frac{1}{3}$ was distant from the first star of Pegasus's wing once, and again by $38^{\circ} 34\frac{1}{2}'$; but on the following noon the clock, which he had used, was found to run slow by 15' 40".
4. Likewise in the year 1582, on 12 November, Jupiter was observed by the radius [Radium], which we trust little.

From The Author of Urania Propitia, Part 2, chapter 14, or from page 90.

5. In the year 1627, on 6 May, the said author in Silesia, with a telescope of an aperture capacity of 14 minutes, observed Jupiter to be more easterly than the topmost of the front of Scorpio by $3\frac{1}{2}$ minutes; and thus, in Tychonic terms, in Scorpio $28^{\circ} 2'$. This was on 16, new style.
6. In the year 1629, the same author from 17 October to 29, by several observations, saw the place of Jupiter to exceed the Rudolphine place by about 9'.
7. In the year 1649, the same author, on 11 May in the evening, through the aforesaid telescope noted Jupiter with a single minute more easterly than the little star 1 of the wing of Virgo; and thus, in Tychonic terms, in Virgo $29^{\circ} 56'$ — though nonetheless the Rudolphine calculation gives $29^{\circ} 46'$.
8. Add to these the conjunction of Jupiter and Mars observed at Prague in the year 1604, on 8 and 9 October, from which Kepler [Keplerus] concluded that it occurred a little before midday on the 9th. [Margin: ♂ ♀ &c / ♂]
9. Add also the distance of Jupiter, which D. Vicenç Mut, in the year 1659, on 30 March at hour 8, observed more westerly by 25' — at the nebulous Praesepe [Nebulosâ Præsepe], as he wrote to me. [Margin: 2]

Select observations of Jupiter made at Innsbruck [Oeniponti] by the Fathers of the Society of Jesus, and transmitted to me by Father Michael Staudacher.

10. In the year 1635, on 9 September, in the morning, between hour 4 and 5, the Moon covered Jupiter, which was then in longitude $15^{\circ} 5'$, and at an altitude of $15^{\circ} 5'$. Aldebaran [Aldebata] was at an altitude of 31° . The remaining observations stand as follows:

CAPUT VIII.

Select observations of Jupiter chosen from those which the Fathers Giovanni Battista Riccioli [Io. Bapt. Ricciol.] and Francesco Maria Grimaldi [Franc. Maria Grim.], of the Society of Jesus, carried out together with other companions of the same Society of Jesus in the College of S. Lucia at Bologna.

With some observations added at the end by the most illustrious Marquis Cornelio Malvasia [Marchion. Cornelij Maluasias].

1. In the year 1642, on the night following the 5th of September — on which the opposition of Jupiter with the Sun was celebrated — the meridian distance of Jupiter from the Sun was $22^{\circ} 31' 30''$. Saturn was at a meridian altitude of $49^{\circ} 50'$. From the meridian altitude of Jupiter, and from the transit of the bright star in the southern tail of the Whale [cauda Ceti australis] by the meridian-line [per M. C.], there were computed, by the aid of a perpendicular, $7' 10''$; from the transit of that same Tail [we obtained] Saturn's distance to be $8^{\circ} 0'$.
2. In the year 1642, on 18 September, about the first hour of the following night, Jupiter was distant from the brightest star of Aries [lucissima Arietis] by $53^{\circ} 29'$, and from the bright star in the bridle of Aries [Mandibula] by $25^{\circ} 34'$.
3. In the same year, on 1 October at the following night, the western altitude of the Eagle [Aquila] flowed by $53^{\circ} 11'$ over $5' 45''$ of time; at which time Jupiter was distant from the bright star of the Eagle by $50^{\circ} 47'$; and then, a few minutes afterward, it was distant from Scheat of Pegasus by $23^{\circ} 1'$.
4. In the year 1643, on 10 February at the following night, hour 2, Jupiter was seen at an altitude of 6° , and distant from Scheat of Pegasus by 30° ; from the head of Andromeda [capite Andromedæ], $31^{\circ} 44\frac{1}{2}'$.
5. In the same year, on 11 February, hour 3, in Italian civil reckoning, Jupiter was at an altitude of 9° ; it was distant from Scheat of Pegasus by $32^{\circ} 13'$; at Markab of Pegasus, $20^{\circ} 37'$; and a hundredth part of that observation was made more accurately.

6. In the year 1643, on the night of the 23rd, hour 1, on 23 February, Jupiter was at an altitude of 9° , and distant from the girdle of Andromeda [cingulo Andromedæ] by $39^{\circ} 52'$; from the bright star of Aries by $39^{\circ} 1'$.
7. In the year 1643, on 18 June at the following night, the western occidental altitude of the Eagle, which was $46^{\circ} 2'$, was measured over $21\frac{1}{2}'$ of time; and Jupiter was distant from the bright star of Aries by $15^{\circ} 42'$. Then, after 2 minutes of time, it was distant from Saturn by $13^{\circ} 10'$ — at which time the place of Saturn, related to the same place, was sought from the observation.
8. In the year 1643, on 15 July in the morning, the altitude of the bright eastern stars of Aries was taken, and after an elapse of 6 minutes of time it was taken from the Sextant; the distance of Jupiter from the same bright star of Aries, repeated, was $46^{\circ} 50'$; from the bright star, twice, by $14^{\circ} 29'$; but after this minute of time, by repeated observation, it was distant from Aldebaran by $41^{\circ} 21'$, when Aldebaran was at 19° ; and Jupiter about [hour] 1 [□ = in quadrature?] with the Sun.
9. In the same year, when both the altitude was taken at hour 10 in the morning, against the eastern stars of Aries by $58^{\circ} 27'$, and after 7 minutes of time it was distant from the bright star of Aries by $13^{\circ} 56'$, and after 6 minutes of time it was distant from Aldebaran by $44^{\circ} 13'$; after the sesqui-quadrant of the hour it was distant from Saturn once, and at that time Jupiter [□] with the Sun at hour 17, precisely.
10. In the year 1643, on 3 August in the morning, the bright star of Aries was at an altitude at rising of $48^{\circ} 48'$; the numbers taken are 1, after we had seen Jupiter distant from Capella by $56^{\circ} 7\frac{1}{2}'$, and after 6 minutes of time it was more distant from Aldebaran by $40^{\circ} 2\frac{1}{2}'$.
11. In the same year, on 8 August in the morning, another was at rising: Aldebaran by $44^{\circ} 40'$, the elapse thence of 7 minutes of time. Jupiter was distant from the same Aldebaran twice by $39^{\circ} 51'$; and after 5 minutes of time distant from Capella by $55^{\circ} 59\frac{1}{2}'$.
12. In the year 1643, on 9 August, in the morning, another altitude: Aldebaran from rising $45^{\circ} 16'$; thence after 7 minutes Jupiter was distant from Aldebaran by $39^{\circ} 51'$, and again by $39^{\circ} 50' 7\frac{1}{2}''$; and after 4 minutes of time it was distant from Capella by $55^{\circ} 59'$; and besides, just now, $20''$ — just now $40''$.

13. Again in the year 1643, on 11 August, in the morning, another Aldebaran from rising $47^{\circ} 55'$; thence after 5 minutes it was distant; Jupiter was distant from Aldebaran by $39^{\circ} 51'$; and by repeated observation after 6 minutes of time it was distant from Capella once by $55^{\circ} 58\frac{1}{3}'$; again after by $55^{\circ} 58'$.
14. On the following day, on the 12th, in the morning, another Aldebaran from rising by $42^{\circ} 37'$; after 6 minutes of time, Jupiter was distant from Aldebaran by $39^{\circ} 51'$; and the same again, as often; and after 5 minutes of time it was distant from Capella by $55^{\circ} 59'$.
15. The day after, that is on 13 August, in the morning after the altitude of Aldebaran at rising $41^{\circ} 24'$, there were numbered 5 minutes of time, while Jupiter was distant from Aldebaran by $39^{\circ} 51'$; again after 5 minutes $50\frac{1}{2}'$, and at Capella by $55^{\circ} 59'$.
16. The following day, on the 14th of the same month, almost an hour before sunrise, Jupiter was distant from Aldebaran by very nearly $39^{\circ} 52'$; and from Saturn in the morning by $17^{\circ} 50'$. Then after 1, nearly the quadrant, Jupiter crosses the meridian, its meridian distance from the vertex being $36^{\circ} 9\frac{1}{2}'$; at a high distance it appears at $50'$; the distance of Jupiter seen from the center of the Sun, taken by the hemicycle, was $116^{\circ} 41'$. Earlier, it had really stood distant by [the] light, of Aries by $13^{\circ} 43'$.
17. In the year 1643, on 15 August, in the morning in the dawn, on the most fortunate Assumption of the Blessed Virgin, on which day it was an Italian feast: Jupiter crossed the meridian, its distance from the vertex being one quadrant, which was $36^{\circ} 9\frac{1}{3}'$; in the other two days by $36^{\circ} 10'$. After this transit, there were numbered 16 minutes; Jupiter was distant from the bright star of Aries by $13^{\circ} 43'$; and it stood at the same distance from Aldebaran by $39^{\circ} 53' 15''$; again it really was distant by $39^{\circ} 53' 10''$; and after 6 minutes of time it was distant twice from Capella by $56^{\circ} 0' 15''$. At its rising, Jupiter was twice seen distant from the center of the Sun by $116^{\circ} 34'$; but refraction was diminishing the distance.
18. In the year 1643, on 21 August, Aldebaran was at rising $53^{\circ} 9'$; and after 3 minutes of time Jupiter was distant from Aldebaran by $39^{\circ} 52\frac{1}{3}'$; after 6 minutes of time it was distant from Capella by $56^{\circ} 2\frac{1}{3}'$.
19. In the same year, on the 24th, in the morning Aldebaran was distant from the vertex toward rising by $34^{\circ} 10'$; and after 13 minutes of time it was

distant from Jupiter by $40^{\circ} 18\frac{1}{2}'$; and after three minutes it was distant from the bright shoulder of Orion [lucido humero Orionis] by $60^{\circ} 2'$.

20. In the year 1643, on 12 October at the following night, Jupiter, approaching opposition with the Sun on the meridian, was distant from the vertex by $38^{\circ} 5'$; and then Aldebaran was distant from the vertex at rising by $47^{\circ} 54'$. [Margin: 8]

21. In the year 1644, on 1 January in the evening, Jupiter was eastern and at an azimuth precisely 11 degrees, at the same moment at which Father Giovanni Battista Riccioli [P. Io. Baptista Ricciolius] observed; it was distant from the bright star of Aries at rising from the vertex by $39^{\circ} 15\frac{1}{3}'$.

22. In the year 1644, on 17 July, in the morning, after the western altitude of the Eagle of $38^{\circ} 30'$. The horizon sounds the hour 2 Italian; thence after 4 minutes of time Jupiter was nearest to the Sun in Virgo by $31^{\circ} 42\frac{1}{3}'$ & $\frac{1}{3}$; and after 24 minutes it was distant from the northern horn of Taurus [cornu Boreo Tauri] by $19^{\circ} 48'$.

23. In the year 1644, on 1 August, in the morning, the bright star of Aries was distant from the vertex by $44^{\circ} 50'$; thence after half an hour Jupiter was distant from Capella by $30^{\circ} 12'$; distant from Saturn by $36^{\circ} 45'$; but at Italian civil hour $7\frac{1}{3}$; Jupiter was distant from Mars by $3^{\circ} 12'$. [Margin: ♂]

24. In the year 1644, on 21 August, when Jupiter was tending toward [the Sun in quadrature, □], in the morning Aldebaran was distant from the vertex by 44° ; immediately Jupiter was distant from Capella by $28^{\circ} 50\frac{1}{2}'$; and after 10 minutes of time it was distant from the bright star of Aries by $39^{\circ} 26'$.

25. In the same year, on the 22nd of the same month, after one minute of the subsequent time, the distances of Jupiter from the stars were taken — the altitude of Aldebaran having been taken first, $50^{\circ} 12'$ — in the morning.

Insert here Observations 59, 60, 61, 62, to be placed below.

36. In the year 1648, on 25 May, hour 1 of the following night — that is, Jupiter was seen distant from the head of Castor [Castoris capite] by $42^{\circ} 43\frac{2}{3}$; at.
37. In the year 1649, on 2 June, about hour 2 of the following night, when the head preceding Gemini, distant from the vertex by $52^{\circ} 2'$, Jupiter was distant from Regulus by $34^{\circ} 44\frac{1}{2}$; and from the bright mane of Leo [iubæ Leonis] by $35^{\circ} 34\frac{1}{2}$.
38. Again in the year 1649, on 9 June at the following night, Jupiter was seen more westerly than that star of Virgo which precedes the four stars of the left wing [quatuor alæ sinistræ], or whose longitude was $29^{\circ} 59'$ — of Virgo — and northern latitude $1^{\circ} 25'$. But on the 10th, Jupiter in the same hour was seen more easterly than the aforesaid star, so that it was seen on the day before, distant from the vertical of the aforesaid star, orthogonally, by $4\frac{1}{2}$ Semidiameters of its own; on the day after the aforesaid orthogonal Semidiameters 4 precisely. But on the eleventh [day], the Jovian Semidiameters were $10\frac{1}{3}$. Therefore, since the diurnal motion was then less, of three [Semidiameters], and since Jupiter on the 10th had been in [Libra] grade $0. 2''$; it had been more southerly than the aforesaid star by very nearly one diameter of its own. But how from this is deduced the apparent diameter of Jupiter — it has been said in book 7 of the *Almagestum Novum*, section 6, chapter 10; and again below, see the discourse.
39. In the year 1649, on 22 June, a little after Jupiter's [conjunction] with the Sun, observation having been made more westerly than the setting of the Sun, again, and as Jupiter was often distant from Regulus by $35^{\circ} 42'$; and from the bright mane of Leo by $36^{\circ} 33'$.
40. In the year 1650, on 24 April, about Jupiter's [conjunction] with the Sun at the following night, Jupiter was distant from the vertex by $19^{\circ} 54'$; distant from Spica of Virgo by $15^{\circ} 59'$; and just now Arcturus was distant from the vertex by $47^{\circ} 52'$.
41. In the year 1652, on 30 June at the following night, from the setting of the Sun, Jupiter was distant from the vertex by $79^{\circ} 13'$; and just now Antares was distant from the vertex by 33° precisely; thence it was high at Aquila by 30° ; and from the vertex by $78^{\circ} 22'$; but it had stood, on the preceding day, [in conjunction] with the Sun.

42. In the same year, on 4 July, hour likewise 1, from the setting of the Sun, Jupiter was high by $19^{\circ} 46'$; distant from the bright star of Aquila by $34^{\circ} 47'$; thence high by $13^{\circ} 10'$; distant from Antares by $52^{\circ} 29'$.
43. In the same year, on 1 August at the following night, from the setting of the Sun, Jupiter was distant from the bright star of Aquila by $25'$, about distant from the vertex by $36^{\circ} 41'$; thence high from Pegasus by $35^{\circ} 57\frac{1}{2}'$.
44. In the same year, on 24 August at the following night, the bright star of the Eagle being distant from the vertex by $40^{\circ} 39'$, toward eastern rising Jupiter was distant from the same by $37^{\circ} 9'$; and a little afterward it stood from the same Pegasus by $57^{\circ} 2\frac{1}{3}'$; just now, Pegasus was nearest by $\triangle$.
45. Finally, in the same year, on 14 November, about an hour after sunset, when Fomalhaut was seen distant from the vertex by $77^{\circ} 10'$. Jupiter was seen distant from the same by $50^{\circ} 54'$; but at the vertex it was distant by 75° about; near Pegasus by $49^{\circ} 45'$.
46. In the year 1653, on 22 May, in the morning, Markab of Pegasus, at rising, was distant from the vertex by $55^{\circ} 31'$; and Jupiter was distant from the vertex by $67^{\circ} 34'$; and from the head of Andromeda by $57^{\circ} 5'$; just now, Jupiter was distant from the vertex by $66^{\circ} 50'$; at Pegasus the most by $47^{\circ} 43'$.
47. In the year 1653, on 28 November at the following night, hour very nearly 2, from the setting of the true Sun, Jupiter stood at Fomalhaut by $25^{\circ} 52'$; from the vertex really by $64^{\circ} 55'$. Fomalhaut was distant from the vertex toward rising by $76^{\circ} 2'$; but a little afterward it stood from Cetus by very nearly the [same] distance, $50^{\circ} 42'$; with Stella distant from the vertex by $69^{\circ} 42'$. Consult the ephemerides for the discourse to be placed below, whether in the conjunction of Mars with Jupiter it has erred.
48. In the year 1653, on 23 December, hour after midday $5\ 7\frac{1}{3}$; expecting Jupiter at the precise Azimuth of 30 degrees; it was distant from the vertex by $66^{\circ} 28\frac{1}{3}'$; from which moment there were numbered $12\frac{1}{3}$; the bright star of Aquila was distant from the vertex by $61^{\circ} 41\frac{1}{3}'$.
49. In the year 1654, on 2 November at the following night, Jupiter and Direction tending in its own way (hitherto in its retrograde course) was distant from the bright star of Aries by $50^{\circ} 15\frac{2}{3}'$; and just now from the bright star of the tail of the Whale [Caudæ Ceti] by $23^{\circ} 40\frac{1}{3}'$; and then it was hour 4 Italian, with the half [hour].

50. Again in the year 1654, on 6 November at the following night, it crossed Fomalhaut by the meridian-line [per M. C.], and the perpendicular being numbered, minutes 23' 40". Jupiter reached the meridian by M. C., distant from the vertex by 52° 16' 40"; the hour was Italian 5½.

51. Again in the same year, on 11 November at the following night, about the hour. ...by 3½ Italian hours. Jupiter, nearest the meridian, stood [?] from the bright star of Aries by 50° 15', and from the tail of Cetus by 23° 39' ½.

51. In the year 1655, on 21 August, in the morning, when Jupiter was now retrograde and in mid-heaven, it stood from the zenith by 34° 13' ½; then after 3' 40" of time. The following shoulder of Orion stood toward the west from the zenith by 59° 56'.

52. In the year 1655, on 17 October, on the following night, Jupiter — approaching its opposition with the Sun — stood on the meridian from the zenith by 36° 4'.

53. In the same year, on 12 March 1656, at 1 hour of the night, Jupiter stood from the bright star, that is, the following shoulder of Orion, by 53° 55' ¼, and from Rigel by 48° 46' ½.

54. In the same year, on 16 August, in the morning, two hours before sunrise, Jupiter stood from Capella by 26° 56', and from the northern horn of Taurus by 15° 3' ¼.

55. Lastly, in the same year, on 27 October, two and a half hours after sunset, Jupiter — being eastern — stood from Capella by 26° 43' ⅔, and from the northern horn of Taurus by 14° 30' ½.

56. In the year 1657, on 10 February, on the following night, Jupiter stood on the meridian from the zenith by 25° 32' 50"; then after 35' 10" of time Aldebaran crossed [the meridian: M.C.].

57. In the same year, on 18 March, Jupiter was in the same azimuth as Venus on that day — which I discuss among the observations of Venus — and Jupiter then stood from the zenith by 52° precisely; in the same azimuth Aldebaran stood from the zenith by 58° 17'.

58. In the year 1647, on 18 April, on the following night, Jupiter was observed standing from Capella by 46° 48' ½, and from the heart of Hydra by 32° 2' 40". Arcturus, then to the east, stood from the zenith by 47° 40'.

59. In the year 1648, on 20 February, on the following night, around 3½ hours after sunset, that is, with Procyon standing from the zenith by 38° 48'. Jupiter,

high up by $34^{\circ} 30'$, stood from the same Procyon by $46^{\circ} 43'$, and from the tip of the tail of Ursa Major by $54^{\circ} 34' \frac{1}{2}$.

60. Likewise in the year 1648, on 21 February, one hour after sunset, with the Sun [?] $3\frac{1}{2}$, Jupiter stood from Procyon by $46^{\circ} 35'$, and from the tip of the tail of Ursa Major by $54^{\circ} 50'$.

61. Again in the year 1648, on 26 February, on the following night, 3 hours after sunset, Jupiter — being eastern — stood from Procyon by $46^{\circ} 1' \frac{1}{2}$, and from the last star of the tail of Ursa Major by $54^{\circ} 58'$.

62. In the year 1649, on 9 June, from an observation that I shall report on another occasion (Book 10, Cap. 3, nos. 5 and 6), Jupiter was in Virgo at $29^{\circ} 56' 25''$, with northern latitude $1^{\circ} 25' 49''$; and it was then near its station.

This observation was memorable.

64. [Margin: ☿ ♂ ♃ et 8 — i.e. Mercury, conjunction of Jupiter, and opposition] In the year 1657, on 26 December, on the following night, Jupiter stood on the meridian itself from the zenith by $21^{\circ} 11' 33''$; and $6' 40''$ of time after its transit, Sirius crossed the same meridian.

But on 27 December, on the following night, Jupiter stood on the meridian from the zenith by $21^{\circ} 10' 43''$; and $7'$ precisely of time later, Sirius crossed the same meridian. Hence Jupiter's declination on the 26th was $23^{\circ} 18' 37''$, and on the 27th it was $23^{\circ} 19' 27''$.

Selected Observations from the *Ephemerides* of the Illustrious Marquis Cornelio Malvasia [Marchionis Cornelij Malvasiæ], f. 203.

In the year 1662, from his own astronomical observatory at Modena [Mutinensi], he observed the distances of Jupiter from the fixed stars written below, but corrected them by means of Cassini's Table of Refractions; and, taking the positions of the fixed stars from Tycho, he derived from them by trigonometry — set out below — the longitudes and latitudes of Jupiter, and compared these with those that the Lansbergian calculation yields.

[The table that follows gives, for each date in June, July, and August 1662: the day; the hours after sunset; the corrected distance of Jupiter from each of two reference stars (Spica, Boötes [the bright star of Boötes / Arcturus], the southern Claw [of Scorpio], etc.) in degrees and minutes; the observed position of Jupiter (Longitude and Latitude, here B[orealis]?); and the excess or defect relative to Lansbergen.]

2 4	1 22	Lūc. Aust. / Arcturo	2 15 / 34 50	Lo. / La. B.	8 12 / 0 58	Exc. 12 / Def. 2
2 9	1 24	Lūc. Aust. / Arcturo	1 31 / 35 12	Lo. / La. B.	8 57 / 0 57	Exc. 11 / Def. 2½

But you should bear in mind that the positions of the fixed stars in Tycho's catalogue stand in need of correction, and that a correction of distances relying on Cassini's Refractions is not free of doubt, as I have already pointed out in Book 1.

LIBER VI. DE IOVIS.

CAPUT IX.

On a selection of observations concerning Jupiter, compared with a calculation derived from our Tables.

1. From what was said in Book 5, Cap. 9, 10, and 11, on the methods of observing the positions of the planets, on the difficulty of avoiding errors of several minutes, and on the verification of the Tables from a smaller number of more reliable observations rather than from a larger number of less certain ones, it is plain — [Margin: On the Danish Tables.] Tycho [Brahe] judged, in his preface to

the *Astronomical Letters*, that the motion of Jupiter cannot be corrected unless it be observed at its individual oppositions in single signs of the zodiac, over a span of 12 years. [Margin: And on the Rudolphine.] Yet Longomontanus, in Book 2 of his *Astronomia Danica* [Astronomiæ Danicæ], Cap. 5, undertook to construct the Danish Tables — adhering in part to those eight oppositions of Jupiter observed against the true place of the Sun [Acronychias], in part to Tycho — and in Cap. 7 brought forward another observation for hunting out the place of Jupiter's apogee [Apogæi Iovialis locum].

Kepler [Keplerus], moreover, in the explanation of the foundations of his *Ephemerides* on which he built the Rudolphine Tables (p. 14), affirms that his Tables, in respect of the three superior planets, cannot be noted as departing from the heavens by even a single minute. Elias Leonicus [?] [Eliās Leonicus], who is himself the author of a work in Bicini [?] published in Silesia and entitled *Praxa Propitia* [?] (p. 89), says that the Rudolphine Tables wander from observations in Jupiter by as much as 13' in the second semicircle of the commutations; for in the first they so depart from the very defects of the Rudolphine men [?] that, where they supposed Kepler to be in error, the same thing turns out in the second. He adds, moreover, that with Kepler the Theory of Jupiter labours under some fault — namely the Mean motion, the place of the Aphelion, and the proportion of the radius of the orbit to the interval between the Sun and the Earth.

Finally, Boulliau [Bullialdus], that most diligent investigator of astronomical truth, [Margin: And on the Bullialdan, and his unreliability.] in correcting the Rudolphine men (*Astronomia Philolaica*, p. 9), shows that they err by 48'; he attaches to this the position of Jupiter near Regulus, which the observation made in Cap. 1, no. 6, requires as exceeding the Tabular place of Jupiter. But we have made bold to bring forward five only of his Tables, on the faith of his own Tables, but here and there indeed unreliable, as in Cap. 8 [?], p. 170. The Treasures of the conjunction of Jupiter and Mars, which Kepler observed at Tübingen along with Mästlin [Mæstlino] (*Astronomia Optica*, p. 305), I have set before me; and on the occasion of these I shall draw upon his Tables, as more fully in Book 7, Cap. 8, on the occasion of Mars.

[Margin: Order of the observations.] We have, accordingly, selected out of so many of the observations narrated above 20 of note — the conjunctions of Jupiter and of Mars, and 15 conjunctions of Jupiter with the fixed stars, observed for the most part with a telescope [Tubospecillo]; and we have added one Tychonic

observation made by means of distances from two fixed stars. These we shall report below in the order of the times.

1. [Margin: ♂ ♄ of the Asellus Australis (southern Donkey)] In the year 141 before Christ, as I reported in Cap. 1, on 3 September, at hour 16 after midday at Bologna, Jupiter was seen to cover the Asellus Australis of Cancer, which was for me, and from the positions of the fixed stars corrected in Book 4, was then in Cancer at $7^{\circ} 11' 7''$, with southern latitude $3^{\circ} 30''$ [?]. On account of the borrowed light of the small stars, stars appear nearer to one another to the naked eye than they really are; so that, if Jupiter, touching a fixed star with the naked eye, were viewed through a telescope, it would stand off from it by a good many minutes, and sometimes by 8 Jovian diameters. Jupiter could have stood off from the southern Asellus by just as many scruples, and so be in Cancer at 7° and about 3' from the minute.

The Tables then exhibit Jupiter as follows:

		Sig.	G . ' "		
Jupiter is then exhibited by the Tables	Lansbergij	☿	7	34	26

	Lat.	0	2	0	
			5		
	Noftra	☿	7	4	30
	Lat.	0	2	10	
			4		

2. [Margin: ♂ ♄ / ♂ ♂] In the year of Christ 498, as I shall report in the observations of Mars, the two were seen in the morning around the 9th hour of the first day of May. Jupiter and Mars were so closely joined that they seemed in no perceptible way to differ. For Boulliau, and almost for me, Mars was then in Virgo at $0^{\circ} 13' [?] 56''$, with northern latitude $1^{\circ} 14'$. But Jupiter for me came out in Virgo at $0^{\circ} 15' 34''$; yet, on account of the borrowed rays, they seemed to differ scarcely at all.

	Sig.	G.	'	"
♂	♂	0	13	56
♂	♂	0	15	34

3. [Margin: ♂ ♂ / ♂ ♂ of Regulus] In the year of Christ 508, on 27 September, at hour 17 after midday at Athens, but 16 at Bologna, Jupiter was seen nearest to Regulus as to longitude, and from it toward the north by 3 digits, that is by 7' ½ of arc [minutis 7' ½]. For me, Regulus was then in Leo at 8° 51' 57"; but for Boulliau at 8° 49' 54".

		Sig.	G		
			.	'	"
And by the Tables Jupiter was then	Rudolphinis	♂	9	35	33
	Philolaicis		8	58	43
	Noftris		8	56	30

4. [Margin: ♂ ♂ / ♂ ♂] In the year of Christ 509, on 13 June, at hour 9 at Athens, Jupiter was seen more eastern than Mars by 1 digit, that is by 2' ½ of arc; but at any rate by more, on account of the added rays. And by the Tables written below they were then as follows:

	♂ Sig.	G			♂ Sig.	G		
		.	'	"		.	'	"
Rudolphinis	♂	1	58	0	♂	1	50	0
		1				1

		1				1		

5. [Margin: Astronomia Optica, p. 305.] [Margin: ♂ ♂ / ♂ ♂] In the year of salvation 1591, Kepler, at Tübingen with Mästlin, saw Jupiter covered over by a ruddy Mars, on 9 January in the morning, as Lansbergen has it; and so it suffices that it struck 12 by the civil clock, whence the day had then begun. But for me it was Jupiter at hour 13 in Scorpio at 14° 59' 12". Mars was in Scorpio at degree 14° 58' 53".

On day 13 [die H. 13], after midday	♈ in	♌	1	59	12	
			4			
	♊ in	♌	1	58	53	
			4			

6. In the year 1587, Tycho, in his *Letters*, writes that Jupiter was observed by him in Cancer at 7° 19', on 14 January, 8 hours after midday.

	Sig.	G.	'	"
Therefore ♈ Observed position	♌	7	19	0
Position computed by me		7	18	16

7. [Margin: ♂ ♈ / ♂ ♊] In the year 1604, Kepler, from the observations made at Prague, concludes that a conjunction of Jupiter and Mars fell on 9 October, a little before midday. For me, from my Tables at hour 23, 50' after midday on the 8th, the positions, reduced and abridged, come out:

	Sig.	G.	'	"
♈ in	♌	19	15	37
♊ in	♌	19	15	38

8. Boulliau relates that in the year 1623, on 12 October, 17 hours after midday, at Loudun in Poitou — that is, at hour 18 at Bologna — it was observed

LIBER VI. DE IOVIS.

— that it was covered by the tube, in a conjunction just before completed, namely Jupiter's conjunction with Regulus in Leo at 24° 40'; but my Tables exhibit Jupiter then in Leo at 24° 46'. [Margin: ♂ ♈ & of Regulus]

9. [Margin: ♈ with the brow of Scorpio] In the year 1627, on 25 April by the old style, Hortensius [Hortensius], at Leiden, at hour 11 — which is hour 11 28' at Bologna — observed with a telescope [tubospecillo] Jupiter more western than the topmost star of the brow of Scorpio by scarcely 1'. But this star, the most northerly, was for me then in Scorpio at degree 27° 54' 55". Therefore Jupiter was in Scorpio at degree 27° 54'.

10. On 22 April of the same year, Elias à Leonibus [Elias à Leonibus], at Uraniburg Propitia [Vraniæ Propitiæ], had seen Jupiter at hour 1 25' after midday, in Silesia, distant in consequence by 18' from the topmost star of the brow of Scorpio; and so in Scorpio at 27° 37'.

	Sig.	G.	'	"
For me, Jupiter came out on day [die]				
22	♄	27	41	0
25	♄	27	46	53

11. [Margin: ♂ ♀ of Propus] In the year 1633, Petrus Gassendus [Pierre Gassendi], from various observations made with the telescope, reckoned the conjunction of Jupiter with Propus [Propode] to have fallen under the meridian of the day on 19 December, at Digne [Diniæ]. For me, Propus was then in Gemini at 25° 47', and on the meridian Jupiter was in Gemini at 25° 54'. Hence, before the meridian, the conjunction took place, and Jupiter was retrograde.

12. [Margin: ♂ ♀ of Propus] In the year 1634, Petrus Gassendi, at Digne, at hour 12 after midday on the 11th of April — which is hour 12 12' at Bologna — reckoned by telescope that Jupiter was then in a direct conjunction with Propus of Gemini as to longitude, and more northern than Propus by about 8'. But Boulliau, who was lying in wait at Paris for Jupiter's conjunction with Propus, saw by telescope on the following day, that is 11 April, at hour 8 30' after midday — which was hour 9 10' at Bologna — Jupiter more northern than Propus by 9', and as to longitude more eastern than Propus by 3'. Since, then, Propus was for me at degree 25° 46' 22" of Gemini, and the diurnal motion of Jupiter was 9', it follows that on the next day, the 11th, at hour 12 12', Jupiter was more western than Propus by 6 minutes or so, but not in conjunction with Propus. So, dividing thus the hours of both observations, Jupiter will have been on the 11th day, at hour 12 22', in Gemini at 25° 43' 30". Our Tables give Jupiter in Gemini at 25° 41' 27".

Jupiter's position	Sig.	G.	'	"
Observed	♄	25	43	30
Computed		25	41	27

13. [Margin: ♂ ♀ & of the Asellus Australis] In the same year 1634, on 4 December, at hour 10 after midday at Loudun in Poitou — but hour 10 [?] at Bologna — Boulliau reckoned by telescope that Jupiter was a little more eastern than the southern Asellus, which was for me then in Leo at 3° 34' 9". Therefore Jupiter was in degree 3° 36'; but our Tables give it further on, at degree 3° 40' 13".

Jupiter's position	Sig.	G		
		.	'	"
Observed approx.	♄	3	36	0
Computed		3	40	13

This observation is notable for tracing out the Mean motion of Jupiter, since it returned to the Asellus Australis with which it had once been joined — by the said observation, no. 1 — after 1874 Julian years, that is, 105 [years], 14 hours 50'.

14. In the year 1637, on 16 July, at hour 9 at Paris — but at hour 9 40' at Bologna — Boulliau saw Jupiter by tube more western by 7' of arc, and more southern by 8' ½, than the sixth star of the left wing of Virgo, which precedes the four stars of the left wing of Virgo. For me, from my fixed stars, that star was then in Virgo at 29° 47', with northern latitude 1°. Therefore Jupiter was in Virgo at 29° 40', with latitude 1° 16'. Our Tables give Jupiter then more western by less than three minutes.

Jupiter's position	Sig.	G.	'	"
Observed	♄	29	40	0
Computed		29	37	7

15. In the year 1639, on 31 August, the same Boulliau, at Paris at hour 8 after midday — namely at hour 8 40' at Bologna — with a telescope ...observed Jupiter, in a conjunction completed a little before, with Regulus, Jupiter being in Leo at 24° 40'; but my Table gives it in Leo at 24° 46'.

16. [Margin: ♂ ♄ with the brow of Scorpio] In the year 1646, on 19 February, D. Vincenzo Mutus [Vincentius Mutus] of Majorca, on the following night contemplating with the telescope Jupiter at its station, noticed that it was near Propus of Gemini by 5', more western by minutes [?], and 9' ½ more northern; Propus was for me then in Gemini at 25° 56' 24", with southern latitude 13' 30". Therefore Jupiter's position is as below.

[Margin (right): pio noted Jupiter more eastern by one or another minute than the northern star of the brow of Scorpio, which was for me then in Scorpio at 28° 5' 10". Therefore Jupiter in Scorpio at 28° 6'. — this belongs with the running text of the right column]

17. [Margin: ♂ ♃ with the left wing of Virgo] In the year 1649, on 11 May, at hour 1 after midday — but 8 at Majorca — D. Vincenzo Mutus saw Jupiter by tube more eastern than the star of the left wing of Virgo by 1' ½ or 2'. But Elias à Leonibus in Silesia saw it more eastern by a single minute at the same moment of time, whence it is indeed notable and reliable. That star was then in Virgo at 29° 57' 10". Therefore Jupiter was in Virgo at 29° 58' 40", and perhaps at 29° 59'. What of the Tables?

18. [Margin: ☿ ☿ Direct, with the wing of Virgo] In the same year 1649, on 9 June, when Jupiter had now turned direct, Father Francesco Maria Grimaldi [Grimaldus] and I saw with the telescope, at hour 1 after sunset, Jupiter manifestly more western than the preceding star of the left wing of Virgo, by however much on the 10th we saw it more eastern; or rather, on the 10th, at the same hour, somewhat less eastern than it had been the previous night; whence we estimated that Jupiter's conjunction with that star took place on the 9th, at hour 21 after midday, according to the trigonometric calculations I have set out (*Almagestum Novum*, Book 9, sect. 6, c. 10). That star was then in Virgo at 29° 57' 16".

Now that we have tested the excellence of our Tables against twenty observations this exact and this carefully selected, so that any part of the discrepancy may not improbably be ascribed to the observations rather than to the Tables, we have judged it superfluous to pile up still further comparisons here, made with other observations — not without weariness and at excessive length. Therefore, although we have examined eight acronychal positions as well [*loca 8. Acronychia*], which Longomontanus alone examined, we still do not so trust them as not to suspect that an error of six minutes or more may lurk in them, on account of a doubtful motion of the Sun [*motum Solis Tychonicum*] — Tycho's, but a false one — and on account of other quantities assumed in the Prutenic Tables for fixing the exact moment and the place of the true opposition with the Sun.

CAPVT X.

De Hypothesi Arithmetica, et Geometrica Motuum Iovis.

[*On the Arithmetical and Geometrical Hypothesis of the Motions of Jupiter.*]

The matters to be selected are those we stated in Book 5, chapter 12, inasmuch as they are common to the five lesser planets. The remaining matters proper to Jupiter are written out below.

Motion of Jupiter [*Motus ♃*]

LIBER SEPTIMVS

IN QVO SVNT

MARTIS PLANETÆ OBSERVATIONES

Et Hypothesis Motuum.

[BOOK SEVEN, in which are the Observations of the Planet Mars, and the Hypothesis of its Motions.]

CAPVT I.

Martis Observationes Antiquæ ab Anno ante Christum 357. usque ad Annum Christi 509.

[Ancient Observations of Mars, from the year 357 before Christ to the year of Christ 509.]

1. Aristotle, in Book 2 *On the Heavens*, chapter 12, text 60, reports as follows: "We have seen the Moon, half-full [*dichotomam*], coming up to the star of Mars, which is the star occulted by the dark part of the Moon; and Mars emerged from the bright and clear side." From this observation it follows that this happened at the Moon's first quarter; but Kepler, in his work on Mars, chapter 69, affirms that it could not have happened at any other time than 357 before the common era of Christ, on April 4, in the evening, with the Sun in degree 10 of Taurus, and the Moon with Mars in degree 3 of Leo, when Aristotle, twenty-one years of age, was a hearer of Eudoxus.
2. In the year 13, according to Dionysius, on day 25, which was the 52nd year after the death of Alexander, and the 476th year of Nabonassar, on day 20 of Athyr (the following [day], the 21st), in the morning, the star of Mars appeared overlying the Boreal front of Scorpio [*Boreali frontis Scorprij*], which was then with Mars in Scorpio degrees 2, minutes 15. So Ptolemy, Book 10, chapter 9. Hence Lansbergius, in his *Thesaurus*, Observation 1 of Mars, supposes the supreme star in the front of Scorpio to have been in Scorpio degrees 1, minutes 42, seconds 12, with northern latitude degree 1, minute 13; and he commends his Tables, which exhibit Mars in Scorpio degrees 0, minutes 53, seconds 12, and with latitude degree 1, minute 13. But Bullialdus [Boulliau], in his *Astronomia*, chapter 18, says it was in degree 1, minute 17, after the meridian of Rudolphine reckoning; he

gathers that the fixed star [*Fixam*] itself was then in Scorpio degrees 2, minutes 34, and Mars in Scorpio degrees 2, minutes 33, minutes 41. But Kepler, in *On Mars*, chapter 69, says the year was 272 before Christ, January 18, in the morning, and in chapter 70 he admits that his calculation differs from the observation by degree 1, minute 31, second 28; for this reason he supposes that Ptolemy erred in Scorpio, taking the first [degree] for the fifth, because the observer called it the more Boreal of the front of Scorpio, of which the fifth was the more Boreal, and Tyconic reckoning placed it as more remote from Regulus by degrees 94, minutes 46½ — whence Mars, distant from this same Regulus by degrees 94, minutes 49½, or minutes 51½; these things Bullialdus [Boulliau], in Book 8, chapter 13. But Longomontanus, in Book 2 of his *Theorica*, chapter 10, contends that the first reading is to be retained.

3. In the year 15 of Hadrian [*Adriani*], Ptolemy from his own observation found that Mars was in opposition to the Mean place of the Sun on day 26 of Tybi, hour 1, equally after midnight, when Mars was in degree 21 of Gemini. So he himself, Book 10, chapter 7; and from him Copernicus, Book 5, chapter 15. But Kepler, in *On Mars*, chapter 69, calls this observation into doubt on suspicion of an error in time, in the Refractions, in the places of the Fixed stars, and for Gemini degree 21 he reckons degree 30; or at least degree 21, minute 4. It was the year of Christ 130, and day 14 of December.
4. In the year 19 of Hadrian, Ptolemy observed an opposition of Mars to the Mean place of the Sun on the 6th [of the month], following [*sequente*] day 7, hour 3, before midnight, in Sagittarius degree 28, minute 50. So he himself, Book 10, chapter 7, and from him Copernicus, Book 5, chapter 15. Kepler however, in *On Mars*, chapter 69, says it was in degree 29 of Leo, or degree 29, minute 31. It was the year of Christ 135, and day 21 of February.
5. In the year 2 of the Emperor Antoninus [*Antonini Imperatoris*], on the day of Epiphi 12, the following [day] 13, hour equal 2, before midnight, Mars was seen in opposition to the mean place of the Sun, existing in Sagittarius degrees 2, minutes 34. So Ptolemy, Book 10, chapter 7, and from him Copernicus, Book 5, chapter 15. Kepler, in *On Mars*, chapter 69, says it was in Sagittarius degree 1, minute 36, or rather degree 0. It was the year of Christ 139, day 27 of May, following day 28.
6. In the same year 2 of Antoninus, on the 15th of Epiphi, the following [day] 16, hour 2, equal, before midnight, the heaven [*cælum*] was in degree 20 of Libra; and with the Sun according to the Mean motion existing in degree 5,

minute 17 of Gemini, Ptolemy observed Mars by comparison with Spica [*Spicam*] to be in Virgo degree 1, minute 36. Lansbergius, however, in his *Thesaurus*, Observation 2, says that Mars was in the year of Christ 139, May 30, hour 9, after the meridian, in Virgo degree 1, minute 34, minute 38. But Kepler, in *On Mars*, chapter 70, with his own Tables, gathers Virgo degree 1, minute 43, adding [that] the instruments...

of Ptolemy admit an error of 10 minutes; and indeed it was the 30th of May, the following day 31.

7. In the year 498 of Christ, as Bullialdus [Boulliau] reports in Book 8 of his *Astronomia*, chapter 13, and from a manuscript of the Royal Library of Paris [*Bibliothecæ Regiæ Parisinæ*] that is not named, the observer says: "I saw, after the setting of the Sun, in the year of Diocletian 214, [on] Pachon the 6th, in the seventh hour of the night, Mars joined to Jupiter [*Martem iunctum Iovi*], so that it was distant from it by no interval at all, but they were touching." Bullialdus [Boulliau] adds that it was the year of Christ 498, May, day 1, hour 9; and that Mars was then by his own Tables together with Jupiter in Virgo degrees 0, minutes 13, minutes 57, with northern latitude degree 1, minute 13.
8. In the year of Christ 509, as Bullialdus [Boulliau] narrates in Book 8, chapter 13, this observation lies hidden in the same Royal manuscript: "In the year 225 of Diocletian, [on] Payni 19, after the setting of the Sun, the star of Mars touched the star of Jupiter, so that by that very distance it was seen in the preceding [degrees] of one [sign]; but in the Austral direction by digits 2, as far as the canon of numbers and the *Magna Syntaxis* show the two Planets to have been in the same direction, distant from each other by digits 2; on the said day [*dicti mensis*], on which they were seen very close to one another mutually." Bullialdus [Boulliau] adds that in that year of Christ 509, June 13, hour 9, after the meridian of Uraniborg [*Vraniburgi*], Jupiter was by his own Tables in Leo degrees 11, minutes 57, minutes 43. Mars indeed, by the Rudolphine [Tables], in Leo degree 11, minutes 50, minutes 50, when it ought to have been in degrees 11, minutes 55. He adds that Mars was with Regulus in the year 508, September 27, in the morning.

CAPVT II.

Martis Observationes ex Opusculo observationum Io. Regiomontani.

[Observations of Mars from the little work of observations of Johannes Regiomontanus.]

1. In the year of Christ 1461, at the beginning of the night of December 2, Johannes Regiomontanus [Regiomontanus] at Rome saw Mars in a straight line with two Stars of the head of Capricorn, distant between themselves by degrees 2, and 2 from Mars itself, the very same distance — that is, by degrees 2 from Mars — which stars Alphonsine calculation [*Alphonsinus calculus*] placed as conjoined. On day 5 of December he saw them conjoined, but, clouds intervening, he could not note the hour. At the beginning of the sixth night he saw that Mars had passed Saturn already by degrees 1, minute 2 [$1\frac{1}{2}$]; because their distance was nearly the half-and-half [*subsesquialtera*] of the distance of the two Stars of the head of Capricorn. Hence Lansbergius, in his *Thesaurus*, Observation 3, asserts his trust in his Tables, as regards this observation, on day 2 of December.
2. In the year 1461, on December 14, at the beginning of the night, Regiomontanus saw Mars joined, as regards longitude, to the brighter [star] in the tail of Capricorn, which he says was then in Aquarius degrees 14, minutes 29. Alphonsine calculation placing Mars in Aquarius degrees 17, minutes 20, he doubts whether it was in the place of the Fixed star.
3. In the year 1462, September 15, in the morning, at hour 10, the same [Regiomontanus] saw Mars almost in a straight line with the seventh and eighth Stars of Leo, and equidistant; toward the north from the eighth — that is, from the heart of Leo through a true diameter [*per veram diametrum*]. Bullialdus [Boulliau], Book 8, chapter 13, says the seventh star of Leo was, namely, the austral one of the triangle on the neck, of the third magnitude, in Leo degrees 20, minutes 21, minutes 41, with latitude north degrees 4, minutes 51; the eighth in Leo degrees 22, minutes 18, minutes 41, with latitude north minutes 26. Therefore, since the Tables exhibit degrees 1, minute 17, accordingly Mars is shown to have differed from Regulus toward the north by minutes 51, and to have been in Leo degrees 21, minutes 58. See the rest in Bullialdus.
4. In the same year 1462, September 19, he saw Regulus, Mars, and Venus in a straight line, so that toward the Austral direction Venus was below Regulus, just as Mars was Boreal; the distance of Mars from Regulus being one and a quarter [*sesquiquarta*] the distance of Venus from the same.
5. In the year 1462, October 16, in the morning, at the night of October 12 [*sic*], Mars, says Regiomontanus, was not yet [*nondum*] within the twenty-fourth part [*vigesimam quartam partem*] of Leo, since the space between itself and the said Star was reckoned equal to four diameters of Venus; and

they suspected then that Mars was conjoined with the twenty-fifth [part] of Leo. But on day 17 of October, in the morning, at hour 11, he saw Mars already...

having passed the said Star, and that it was distant from it by a space one-and-a-half-times [*sesquialtero*] as much as yesterday's distance; and Mars was more southerly.

6. In the year 1464, December 11, hour 13, after the setting of the Sun, Regiomontanus at Rome saw Mars in a straight line with Star 22, and 23 of Virgo, but Mars was more Boreal, since it was distant from those Stars by degrees 2, and 3, by double the distance; from the said comparison the Alphonsine calculation differs in latitude by half-degrees.
7. In the year 1465, June 19, about midday, Regiomontanus saw Mars almost in a straight line with the first and second Stars of Sagittarius, a little more Boreal, and distant from the first by one-and-a-half-times the interval, and from the second...
8. In the year 1468, April 26, at the beginning of the night, the same saw Mars passing little over the straight line, in which it had been; and on the tail of the Little Bear [*caudâ Vrsæ minoris*], and because Jupiter was at the beginning of Cancer, and rather contrary to their conjunction; and on day 29 of April, Jupiter saw Mars, and Saturn the thirteenth of Gemini, in nearly a straight line with the Boreal head of the Twins; it was however more remote from Mars than Jupiter, but more Boreal, as the distance of Jupiter from the rest [of the] distance was between itself and that Star the thirteenth.
9. In the year 1471, July 26, in the morning, hour 3, after midnight, Regiomontanus at Nuremberg saw Mars in a straight line with the eyes of Taurus, and more Eastern by a little, off the straight line by 3 — about minutes — and distant from the eastern eye of Taurus, by how much they are distant between themselves by the tenth part, the third, and the fourth part of Taurus.
10. In the same year 1471, September 9, Regiomontanus by the radius observed the distance of Mars from the right shoulder of Orion to be in the first sign [*Sinum primum*] 210, and second [*secundum*] 674; but for the distance from the head of Castor [he found] the first sign 210, and the second 662.

11. In the year 1474, March 7, Regiomontanus at Nuremberg saw Mars more Eastern than the Boreal Ass [*Asino Boreali*] by the diameter of the Moon, it appeared; suddenly it was approaching that Star, but it was now beginning to be directed [*dirigi*].

CAPVT III.

Martis Observationes Norimbergæ habitæ à Bernardo Vualthero ab anno 1475. Christi ad 1504.

[Observations of Mars made at Nuremberg by Bernhard Walther [Bernhard Walther], from the year of Christ 1475 to 1504.]

The First Class is of the observations made by estimation of the eye. [Prima Classis est observationum oculari æstimatione peractarum.]

1. In the year 1475, September 17, in the morning, between the third [hour] and the fourth, after midnight, Mars and Saturn stood apart between themselves by nearly five minutes, as far as longitude, from which Walther [Walther] judged them to be conjoined without doubt on day 18; and indeed on day 19 Mars was seen to be more Eastern than Saturn, by however much Saturn had been to the west of Mars on day 17. Let this Almanac of conjunctions [*Almanach coniunctionum*] be distant up to day 21.
2. In the year 1477, September 5, in the morning, hour nearly the third after midnight, Walther [observed] Saturn more Western than Mars, distant by one palm-breadth [*palmum*], in the same latitude, whence he concluded for the day on which Saturn should be eclipsed by Mars. On day 5 of September, things to be read out for [up to] day 6 of October, since he could afterward find nothing in these matters from his Tables. At Walther's, however, the *Fifth of September* is held, just as Snellius [Snell] has it in his observations of Walther; nevertheless Walther truly subjoins day 15 of October, [that] in the morning he had observed Mars more Eastern than Saturn by degrees 2, minute 47 — but it is to be seen whether it was Retrograde.

LIBER VII — DE MARTE (Book Seven — On Mars)

Caput III (continued) — Mars Observations made at Nuremberg by Bernhard Walther, from the year 1475 to 1504

[The numbered observations continue from the prior page. The left column carries Walther's narrative observations (nos. 3–16, 51–56); the right column carries a tabulated set of observations (nos. 17–50) giving the distance of Mars from fixed stars, with the two computed sines.]

3. In the year 1478, on March 16, in the morning at the second hour after midnight, he saw Mars together with the sixth star of Virgo, which lies midway among the three stars of the left wing, in nearly the same longitude, but more than half a foot more to the south.
4. In the year 1479, on October 30, he saw the same — Mars and Saturn — in conjunction as to longitude, with Saturn the more northerly, and they were nearly one degree apart; but Mars was very close to the sixth star of Virgo. Lansbergius [Philips van Lansbergen], in his *Thesaurus*, gathers from his own Saturn tables, for the fourth hour of the morning, that Saturn was in Virgo at $27^{\circ}4'$ with a northern latitude of $2^{\circ}1'$, and Mars in Virgo at $27^{\circ}56'$ with a latitude of $1^{\circ}22'$.
5. In the same year, on November 7, he saw Mars more than one degree more to the south than the seventh star of Virgo, but conjoined with it as to longitude — which Boulliau [Ismaël Boulliau], in Book 8, Chapter 13, says was at the same time as Mars at $2^{\circ}51'$ of Libra, and the northern star at $2^{\circ}50'$. [Margin: Boulliau, lib. 8, cap. 13.]
6. In the year 1484, on November 28, at about the third hour of the following night, the Moon — says Walther — was eclipsing Mars.
7. In the year 1486, on September 7, in the morning at the fourth hour after midnight, he saw Mars between the two horns of Taurus, in the same straight line with them, distant from the southern horn by about two lunar diameters.
8. In the year 1488, on October 3, in the morning, he saw Mars and the two heads of Gemini in one straight line, Mars lying toward the east relative to the following head of Gemini, at a distance of nearly twice the separation of the two heads.
9. In the year 1490, on September 18, he saw Mars somewhat more to the south, and more to the west than the nebulous star of Cancer [Praesepe]; in the morning

at the fourth hour after midnight, he saw the same star now somewhat more to the east than the nebula — more so than on the preceding day, when it had been more to the west — so that the conjunction with the nebula occurred at some intermediate time.

10. In the same year, on September 21, in the morning at the third hour after midnight, he saw Mars distant from the fifth star of Cancer by a lunar diameter, and distant by a hand's breadth from a line drawn through the fourth and fifth stars of Cancer, but nearer the fifth.

11. In the year 1491, on January 6, he observed the beginning of the retrograde motion of Mars in one straight line with the twenty-second and twenty-third stars of Leo.

12. In the same year, on March 13, in the morning at the second hour and two-thirds after midnight, Mars was seen in one straight line with the sixth and eighth stars of Leo, distant from the eighth by two-fifths of the interval between the sixth and eighth.

13. In the year 1492, on September 27, in the morning at about the fifth hour after midnight, Mars was nearly in a straight line with the sixth and seventh stars of Leo, and more to the south, the seventh lying midway between the sixth and Mars; but Mars was more to the west, nearly by a finger's breadth, off that line.

14. In the same year, on March 25, Mars was more to the east than the seventh star of Virgo, by a little more than a lunar diameter, at about the same latitude; but on the 27th it was more to the east by four fingers, and on the 29th it was more to the west than the seventh star of Virgo by a lunar diameter.

15. In the year 1497, on February 15, in the morning at the fourth hour after midnight, Mars was distant from Jupiter by a diameter; in such a way, however, that the half of this distance reckoned to the latitude, and Mars was more to the south than Jupiter, and more to the west — although, according to the *Almanac* of these men, the conjunction had already passed.

16. In the year 1504, on March 27, Mars was also seen by armillae [armillary instruments] in Cancer at $17^{\circ}45'$, with Aldebaran placed at $2^{\circ}45'$ of Gemini. From this Boulliau, in Book 8 of his *Astronomy*, Chapter 13, says that Mars was at $17^{\circ}48\frac{2}{3}'$ of Cancer, because Aldebaran was more to the west in Gemini at $2^{\circ}48\frac{2}{3}'$. [Margin: Boulliau, lib. 8, Astron. cap. 13.]

The Second Class contains observations made with the radius [cross-staff] using the first and second sines, on the use of which see under the Waltherian observations of Saturn, no. 10.

Table — Walther's Mars observations (Second Class): distance from fixed stars

Columns: observation number | Year, Month, Day, Hour (*Ann. Mens. D. H.*) | Distance from fixed stars (*Distantia à Fixis*) | First sine (*Sinus prim.*) | Second sine (*Sinus secūd.*)

N o .	Year, Mo., D., H.	Distance from fixed stars	Sinus prim.	Sinus secūd.
1 7	1475 Sept. 1, 3 (post mid. night)	from the preceding [star] of Gemini's head	210	772

The Third Class has observations made by means of the zodiacal armillae, on whose uncertainty — to within 10 minutes — see the Waltherian Saturn observations above, no. 33. For that reason we have chosen few of these, and only those for which Walther assigns the hour, omitting those for which he notes the culmination of the heavens without an explicit hour.

Table — Walther's Mars observations (Third Class): observed place of Mars

Columns: observation number | Year, Month, Day, Hour, Minute (*Ann. Mens. D. H. M.*) | Observed place of Mars (*Locus ♂ observ.*: Sign, Degree, Minute)

No .	Year, Mo., D., H., M.	Place of Mars (Sig., Gr., M.)

CAPVT IV — Copernican Mars Observations (*Martis Observationes Copernicæ*)

1. In the year of Christ 1512, on the Calends of January [January 1], at the sixth hour before noon — that is, in the morning — Copernicus, at Frauenburg [Frombork], saw Mars one-quarter of a degree distant from the bright star, the first of the Claws [first of Chelae, i.e. of Libra], or more to the south, but deflected toward the rising of the summer solstice [northeast]; which was an indication that Mars was separated from it as to longitude by $7\frac{1}{2}'$, and as to northern latitude by $12'$. (*Copernicus, lib. 5, cap. 19.*) He supposes that star to be elongated from the first star of Aries by $191^{\circ}20'$, with a northern latitude of $40'$; and so the place of Mars to be in [Libra] at $191^{\circ}28'$, with a northern latitude of $51'$; and so

Mars to have been at $1^{\circ}53'$ of Scorpio, according to his hypothesis from the first star of Aries. [Margin: Copernic. lib. 5, cap. 19.]

2. In the year of Christ 1512, on the Nones of June [June 5], after the first hour past midnight, at Frauenburg, Copernicus — from his own observation — says he found Mars acronychal [in opposition to the Sun] at $235^{\circ}33'$; that is, in Sagittarius at $15^{\circ}58'$, and opposite to the Sun positioned at $55^{\circ}33'$ from the first star of Aries, that is, in Gemini at $15^{\circ}58'$ minus. (*Copernicus, lib. 5, cap. 16.*) [Margin: Copernic. lib. 5, cap. 16.]

3. In the year of Christ 1518, on the day before the Ides of December [December 12], at the eighth hour after noon, at Frauenburg, by Copernicus's observation Mars appeared acronychal, and in opposition, at $63^{\circ}2'$ from the first star of Aries — that is, in Gemini at [the corresponding] degree, $23^{\circ}40'$. (*Copernicus, lib. 5, cap. 16.*) [Margin: Copernic. lib. 5, cap. 16.]

4. In the year of Christ 1523, on the eighth day before the Calends of March [February 22], at the seventh hour before noon, at Frauenburg, with Copernicus observing, Mars was seen in [Leo] at $123^{\circ}20'$ from the first star of Aries — namely, in Leo at 24° . (*Copernicus, lib. 5, cap. 16.*) [Margin: Copernic. lib. 5, cap. 16.]

CAPVT V — Tychonic Mars Observations from the year of Christ 1580 to 1601

Tychonic Mars Observations from the year of Christ 1580 to 1601, noted in the Old Style [diebus stylo veteri notatis], and made at Uraniborg unless otherwise added, reckoned to hours after noon.

Tycho himself, in his *Letters to the Landgrave of Hesse* [*Epistolae ad Landgravium Hassiae*], page 56, sets down these three [observations] for the year 1587, in January, made with the Alphonsine and Copernican calculation.

[The Tychonic observation tables follow on the next page (the large two-part table of pp. 320). The page-3 tables below, headed by the page-320 narrative, are continuations: they give "other places of Mars" derived from Tycho's observation and computation, marked with the letter K where they appear in Kepler's On Mars, or with the letter C for the Tychonic observations sent to us by Father Albert Curtius, S.J.]

LIBER VII — DE MARTE (page 320)

There follow other places of Mars from the observation and computation of Tycho, derived from his observations, as they appear in Kepler's *On Mars* — which we shall indicate by the letter K — or, among the Tychonic observations sent to us by Father Albert Curtius [Albert Curtz], of the Society of Jesus — which we shall indicate by the letter C.

Table — other places of Mars (Tycho/Kepler/Curtius), nos. 14–124

[A single large table running across the page in two halves: the left half carries observation nos. 14–66, the right half nos. 67–124. The columns are identical in both halves.]

Columns: observation number | Year (*Ann.*) | Month, Day, Hour, Minute (*Mens. D. H. M.*) | Observed longitude of Mars (σ *Lõg. observ.*: Sign, Degree, Minute, Second) | Observed latitude (*Lat. observ.*: Degree, Minute, Second) | Kepler's chapters (*Capita Kepl.*)

Left half (nos. 14–66):

Of the page-320 narrative below the right table:

There now come to light the remaining Tyconic observations, published at Vienna and edited by Lucius Barrettus — understand by this Father Albert Curtius [Albert Curtz] of our Society, to whom the Emperor Ferdinand entrusted this task, although under an anagram he wished to conceal his own name. As a specimen of these, until they all come into general use, take [the following] for the year 1582.

LIBER VII — DE MARTE (Book 7, Mars)

Caput V (continued) — Tycho's Mars Observations, 1580–1601

[The Tycho/Uraniborg Mars observation table continues. Columns: the entry number; **Year · Month · Day · Hour · Minute** of observation; **Mars's distance** in degrees (Gr.) and minutes (M.); and the reference fixed star (**à Fixis**, "from the fixed stars"). The leftmost numbers are the running observation-entry numbers.]

N

o

.	Year — Month, Day	H M—	Gr. (°)	M. (')	from the fixed star
1582					
1	Nov. 23	8 5 bis	22	32	from the Knee of Castor
2		0			[à Genu Castoris]

We have now passed from Tycho's first observations to his last, made in Bohemia — partly at the castle of Benátky near Prague, partly in Curtius's house at Prague — which Snellius edited at Leiden in 1618, restoring them to the dates of the new calendar.

132. In the year 1600, on January 1 (new style), on the preceding night the meridian altitude of Mars as observed by Tycho was 58° 54', and that of Jupiter was 55° 6'. From this, after two hours, both being at the Pole, they differed from the head of the Pollux [the star], Mars indeed being 29° 45', but Jupiter 33° 35½'. [Reading of these positional figures uncertain in places: 29° 45' / 33° 35½' [?]]

133. On the fifth of January, on the preceding night, one hour before Mars's transit across the meridian, Mars was distant from Pollux's head 29° 3', and soon

after from the Tail of Leo $30^{\circ} 13'$. It then crossed the meridian at an altitude of $59^{\circ} 22'$.

134. In the same year, on March 2 at 10 p.m., Mars was distant from the bright star of Aries [the Ram] $86^{\circ} 33\frac{1}{3}'$, and from Aldebaran $55^{\circ} 47' 1/6$ [?]; therefore, says Snellius, the longitude of Mars was Cancer $29^{\circ} 14' 56''$, with northern latitude $3^{\circ} 50' 51''$.

135. On April 12 at 9 h 37' p.m., Mars was distant from the bright star of the foot of Gemini [the Twins] $32^{\circ} 50'$, and after 14 minutes of time it was distant from Regulus $19^{\circ} 20' \frac{1}{2}$.

136. In the year 1601, October 10, in the morning at 3 h 30', Mars was distant from Pollux's head $25^{\circ} 0' 10''$, from Procyon $27^{\circ} 44' \frac{1}{4}$, and from Regulus $12^{\circ} 2' \frac{1}{2}$.

137. And on October 11, in the morning at 4 h 30', Mars was distant from Pollux's head $25^{\circ} 33' 50''$, from Procyon $28^{\circ} 12'$, and from Regulus $11^{\circ} 23'$.

This was Tycho's last observation: for soon after, suffering from retention of urine when he had drunk too freely at a supper on October 13, he died on the 24th.

The authorities, moreover, who use the aforesaid observations — both the acronychal ones and the others, besides Kepler and Longomontanus — whose places are listed above, are: Boulliau [Bullialdus], *Astronomia* book 8, throughout, and to the end; Lansbergen [Lansbergius], passim, in his observations of the years 1587 (January 15 and 1589, April 15) and 1591 (May 13) and 1595 (October 17, or rather 27).

CAPUT VI.

Observations of Mars made by Justus Byrgius [Jost Bürgi], Longomontanus, Kepler, Fabricius, and Gellius Sascridus, from the year 1590 to 1613.

1. Justus Byrgius's [Jost Bürgi's] observations were made at Kassel [Casellis], and noted on the days of the old style, in hours after noon, by Snellius among the Hessian observations.

[The following table gives, for each numbered observation: **Year · Month · Day · Hour · Minute** of the observation; **Mars's distance** (Martis dist.) in degrees (G.), minutes (M.), seconds (S.); and the reference fixed star (**à Fixis**).]

		22	26	30	from Procyon [à Procyone]

12. In the year 1591, January 9 (old style), Michael Mästlin [Michael Mästlin] and Johannes Kepler at Tübingen saw the whole of Jupiter occulted by Mars in an inferior eclipse: the color of Mars was fiery, and its ruddiness proved Mars to be the lower body. Kepler [reports this], page 305 of the *Astronomia Optica* [*Astronomiae Pars Optica*]; and from there Lansbergen, in his *Thesaurus* of these observations, nonetheless setting the day as the eighth, [Margin: *Lansbergii duplex dolus* — "Lansbergen's double trickery"] and the morning, by his own contrivance; but in the calculation he puts the day as the sixth, and the hour as the 18th, by Goad's [reckoning]. [Goëtæ] As if the observation had been made in the morning of the 7th day — quite wrongly, since his own tables do not show this conjunction of Mars with Jupiter except at hour 18 after the midday of the sixth day, by Goad's reckoning, at which time he reckons the place of Jupiter in Scorpio to be at 13° 52', with the true place of Mars in Scorpio at 1° 18'. But Mars's place in Scorpio at 13° 51' — with the latitude 2° 8' 1' 18' — is either faulty, or the figures of Kepler are vitiated; or these are the Tables of Lansbergen. Maginus, in his *Ephemerides*, marks this conjunction from the Prutenic [Tables] for the 9th, at hour 15, 41' after the meridian of Venice.

13. In the year 1591, June 8 (old style), Gellius Sascridus [Gellius], a disciple of Tycho, observing at Padua [Patavii], concluded an opposition of Mars, in opposition to the opinion of Tycho himself, [who held] that Mars was in the place

of the Moon at hour 16 25' after the meridian, when Mars was at that time in the orbit at Sagittarius $26^{\circ} 40' \frac{1}{2}$. Kepler, in *De Marte* [*Astronomia Nova*] chapter 8.

14. In the year 1597, December 10 (old style), David Fabricius [Fabricius] in East Frisia [Ott. Frisia], at hour 12, 10', observed Mars in Cancer $3^{\circ} 40' \frac{1}{4}$, with northern latitude $3^{\circ} 23'$. Kepler in *De Marte* chapter 15.

15. In the year 1602, February 16 (old style), David Fabricius in East Frisia at hour 5, in the morning, observed Mars distant in advance of the bright Southern star of the Wing of Virgo [Virgin] by $20^{\circ} 18'$, and from the Tail of Leo $8^{\circ} 17'$. Kepler, in *De Marte* chapter 15, who from this gathers that Mars was at the Wing of Virgo in Virgo $14^{\circ} 21' \frac{1}{2}$ — from Leo, however, with the tail, in $14^{\circ} 23' 36''$ — taking the mean as Mars at $14^{\circ} 21' 18''$, while computing Fabricius's Sextant [reading] of the distances as too large.

16. In the year 1602, Longomontanus, book 2, *Theoricae* chapter 8, gathers from his own observations an opposition of Mars with the Sun; and that the place of the Sun was, on February 20 (old style), at hour 14, 15', in Virgo $12^{\circ} 24'$ at Copenhagen [Hafniae], although his own Tables give $12^{\circ} 24'$.

17. In the year 1602, February 18 (old style), at Prague, with the help of Matthias Seiffart [Seiffard], Tycho's pupil, using Tycho's instruments, in the evening at hour 10, 30' after the meridian, [the observation continues —]

LIBER VII — DE MARTE (folio 322)

[Continuation of entry 17, top of folio 322:] — observed the distance of Mars from the middle of the Tail of Ursa Major [the Great Bear] $52^{\circ} 22'$; but because this falls between the Heart of Leo and Procyon, the Sextant gave $37^{\circ} 22' 20''$ when it ought to have been $37^{\circ} 19' 40''$; therefore the Sextant exceeds by $2\frac{1}{3}'$. He concludes the distance of Mars from the middle of the Tail of Ursa Major, corrected, to have been $52^{\circ} 19' \frac{1}{2}$. Thus, between Mars and Regulus, he sets $19^{\circ} 20' \frac{2}{3}$; and between Mars and the bright star of Virgo, $21^{\circ} 20'$; he sets $21^{\circ} 17' \frac{1}{2}$; and from this remarkable agreement he establishes the place of Mars in Virgo $13^{\circ} 19' 6''$. Kepler, *De Marte* chapter 15.

18. In the year 1602, on the same night, February 18, at hour 12, 40', Kepler at Prague observed the meridian altitude of Mars: it was $50^{\circ} 19'$, as it should have been with the Tail of Leo; from this he deduced the place of Mars in Virgo $13^{\circ} 19' 30''$, with northern latitude $4^{\circ} 7' 55''$; and from this he recognized that the opposition of Mars with the Sun would be on February 20, at hour 14, 13' after the

meridian, with Mars holding Virgo $12^{\circ} 27' 35''$, with northern latitude $4^{\circ} 10'$. Kepler, *De Marte* chapter 15. 18. 52.

19. In the year 1604, February 27 (new style), Kepler, on a night between the days of Jupiter and Venus, while Cortus observed the middle of the sky, observed Mars distant from Spica $9^{\circ} 44'$, and from the Northern Scale [à Lance Borea] $17^{\circ} 41'$; but using the same instrument he found the distance of Mars from Arcturus $29^{\circ} 13'$, and from Spica $31^{\circ} 57'$. Since these agree with Tycho's data within $1^{\circ} 45'$, he therefore corrected the aforesaid distances, ordering them thus: $9^{\circ} 48' 45''$ — $17^{\circ} 45' 45''$ — $29^{\circ} 17' 43''$. Moreover, he took the meridian altitude of Mars at $32^{\circ} 4'$, and that of Spica at $30^{\circ} 50'$; from the difference of these altitudes, by the declination given under the Pole, he ascertained the altitude of Spica should have been $30^{\circ} 52'$, and that of Mars $32^{\circ} 6'$. He doubts, however, whether the iron rule, being heavy, by its own weight caused a sagging impetus at the points of the pinnules [pinnacidia], in the customary way. Thus Kepler, *De Marte* chapter 11.

20. In the year 1604, April 8 (new style), Kepler, together with Johannes Schulerus [Schuelerus], observing in the evening, found the distance between Arcturus and Spica to be $33^{\circ} 1' \frac{1}{2}$, or $3/4$; from which, having corrected the distances, he acquired the distance of Mars from Arcturus $54^{\circ} 8' \frac{1}{3}$, and from the Heart of Leo $54^{\circ} 8' \frac{3}{4}$. And although one may doubt whether he sometimes took Mars for Spica, he nonetheless gathers an opposition of Mars with the Sun to have been on March 28 (old style), at hour 16 23' after the meridian, with Mars in Libra $18^{\circ} 37' 50''$, with southern latitude $2^{\circ} 26'$. Kepler in *De Marte* chapter 15.

21. In the year 1604, September 27 (new style), at Prague, hour 8, there was an observation of the conjunction of Mars with Saturn; and on October 9, at hour 1 before noon, it was [observed] from the conjunction of Mars with Jupiter. Kepler, book *De Nova Stella in pede Serpentarii* [On the New Star in the Foot of the Serpent-Bearer] chapter 11.

CAPUT VII.

Observations of Mars made by Petrus Gassendus [Pierre Gassendi], Martinus Hortensius [Martin van den Hove], Michael Florentius [Michel Florent van Langren], and Vincentius Mutus [Vicenç Mut], from the year 1617; likewise by the Fathers of the Society [of Jesus] at Ingolstadt and at Innsbruck [Oeniponti].

1. In the year 1621, for the opposition of Mars with the Sun noted in the Ephemerides for May 6, Gassendi at Aix [Aquis Sextiis], on May 3, in the evening

at hour 10, observed Mars distant from the Northern Scale [à Lance Borea] by 8° 19', and from the Southern [Scale] by 5° 17'. But since the Scales [Lances] are 9° 12' apart, so that he might follow Tycho's latitude and longitude, Tycho would have it 9° 8'. Again, on the same day, hour 8, he saw Mars distant from the Northern Scale 8° 18', and from the Southern 5° 6'; and on the 8th day, hour 9, in the evening he saw it distant from the Northern Scale 8° 28', and from the Southern 3° 35'. Thus Gassendi in [his] observations sent also to D. Johannes Dominicus Cassinus [Giovanni Domenico Cassini] at Bologna.

2. In the year 1623, June 26, hour 13 after midday, Gassendi at Digne [Diniae] [observed] the distance of Mars 6° 53' from the left shoulder of Sagittarius, and 13° 3' from the Northern part of the arc of Sagittarius; from this he deduced the longitude of Mars at Capricorn 13° 21' ½, and the southern latitude 6° 37' ⅓ — as is had in his own observations sent in writing to Valois [Valesium], in which are also contained the infrascript [below-written] longitudes and latitudes observed by the same.

[The following table gives, for **Anno 1623: Month · Day · Hour**, then **Longitude of Mars** (Longit. Martis) in **Sign** (Sig.), degrees (G.), minutes (M.), and **Southern Latitude** (Latit. Austr.) in degrees (G.) and minutes (M.). The entry numbers continue from no. 2 above.]

21. In the year 1632, February 5, Michael Florentius Langrenus [Michel Florent van Langren], Cosmographer to the Catholic King [of Spain], at Madrid [Matriti], saw Mars occulted by the Moon when the eastern edge of the Moon was culminating at 178° 38', and emerging from the western edge when 193° 35' was culminating, having been hidden under the [Moon] for 57½ of one hour.

22. The same conjunction (the acronychal conjunction of Mars with the full Moon) Hortensius [Martin van den Hove] observed at Leiden, and Gassendi at Paris at hour 15, 18' after midday; from this Hortensius, in [his] dissertation, says it agrees with the Tables of Lansbergen, and indeed [agrees] with Gassendi; for Lansbergen, in his *Thesaurus* of observations, computing the place of Mars from the aforesaid moment of Mars, [places] the place of Mars in Leo 16° 24' 37", with northern latitude 4° 33' 43". But the true place of the Moon in Leo [he gives as] 16° 42' 31", as seen; with the true latitude 4° 58' 33"; but as seen, 4° 16' 19". Here he adds that, seen through the telescope, Mars was less than one digit more to the

North than the Northern edge of the Moon, and the center of the Moon was seen to be higher toward the West by $38^{\circ} 51'$.

23. Gassendi, moreover, in his *Epicurus* page 900, says that, observing at Paris in the year 1632, on February 6 at hour 3, min. 3, after midnight, the Moon being high toward the West at $44^{\circ} 15'$, the highest faint margin of Mars passed underneath, and just grazing it, it deserted [it] at hour 3, 33', the part of the margin being inclined toward the North; and although Mars was seen by the naked eye much earlier to be occulted by the Moon, nonetheless through the telescope it was seen to immerse the whole [body] later — though he adds that some portion of Mars remained in the middle of the occultation, as if not the whole [body] were then immersed.

24. In the year 1634, the Ephemerides note an opposition of Mars with the Sun on March 12; therefore Gassendi at Digne, on the 8th day, in the evening, with Regulus high, [observed] Mars by the Radius [Astronomical Radius/Cross-staff] distant from Regulus $44^{\circ} 15'$. He saw Mars distant from Regulus $26^{\circ} 41'$, and from the Heart of Hydra $27^{\circ} 57'$; on the remaining days there were clouds, and on the 15th day, in the evening, with Regulus high at 44° , he saw Mars distant from Regulus $23^{\circ} 56'$, and from the Tail of Leo $8^{\circ} 44'$. Thus also to Cassini.

25. In the year 1634, June 8, in the evening, Gassendi at Aix, with the naked eye, judged the last star of the four [stars] of the left Wing of Virgo (which Lynceus's companion Socius saw at the beginning of the night) to be covered by Mars; as far as could be estimated with the naked eye, by how much it might seem distant from Mars, [it was] but [by] half a semidiameter of Mars; but through the telescope Gassendi saw it to be distant from the star by the nearest seven diameters of Mars. [The remainder continues below.]

LIBER VII — DE MARTE (folio 323)

[Continuation of entry 25, top of folio 323:] Then at hour 11, 19', Mars and the star were both at the same altitude, the former [Mars] being lower and the latter higher, with a distance of four diameters. Finally, at hour 12, 34', Mars was seen to be at the same longitude as the star, distant by no more than three diameters of Mars. In the *Epicurus*, page 902, understand the outermost [star] of the left wing, as I shall say in chapter 8.

26. In the year 1636, Gassendi at Aix on March 17, in the evening, with Castor high, by the Radius saw Mars distant from Arcturus $30^{\circ} 29'$, and from Spica 22°

15'; but on the 18th day, with Spica high, [he saw] Mars distant from Arcturus $30^{\circ} 23'$, and from Spica $9^{\circ} 19'$. Thus also to Cassini.

27. In the year 1642, August 15, with Michael Florentius observing at Brussels, the Moon occulted Mars when the Equator was culminating at $300^{\circ} 33'$, and Mars itself culminating at $308^{\circ} 54' 11''$. Thus in his letters to me.

28. In the year 1645, D. Vincentius Mutus [Vicenç Mut], at Majorca [Maioricae], on the 13th day of February, hour 8, saw Mars by three minutes more to the West, and by $33'$ more to the North, than the second preceding star among the unformed stars of Erichthonius; but on the 28th day, at one hour after sunset, he saw Mars distant, as to longitude, by less than $2'$ from the star [of Spica], which is below and to the North of Erichthonius, and by 21 scruples [seconds] more to the North. Thus in his letters to me.

29. In the same year, the same [observer], on the same spot, April 6, hour 7, saw Mars distant toward the East a little more than half [a degree] from the Moon, [and] from the star which is in the upper thigh of Gemini. Likewise in his letters to me.

30. In the same year, 1645, D. Vincentius Mutus at Majorca, hour 8 after midday, saw Mars at almost the same longitude as the extreme foot of Northern Cancer [the Crab], but more to the North by about 24 scruples [seconds]. At length, on the 15th day of May, hour 8, Mars was distant by about 2 scruples [seconds], in respect of longitude, from the Northern preceding [star] in the quadrilateral of Cancer, but it was more to the North by about 5 scruples [seconds]. Likewise in his letters to me.

31. In the year 1649, June 23, hour 9, D. Vincentius Mutus at Majorca saw Mars more to the South, but by about 13 scruples [seconds] more to the West, than the star which is in the outermost left Wing of Virgo; but on the 24th day, hour 9, Mars was seen more to the East than the star which is in the extreme Wing of Virgo; on the 24th day, Mars is a little more than three scruples [seconds] more to the East than it had been on the preceding day toward the West; so that with Mars in conjunction with the said star, the star will have been about the twentieth hour after midday of the 23rd day. Thus from Mut's letters given to me.

Observations of Mars by the Fathers of Our Society at Ingolstadt

At Ingolstadt, moreover, the Fathers of Our Society — as P. Michael Staudacher wrote to me — observed these distances of Mars.

[The following table gives, for **Anno 1617: Month · Day · Hour** (in the evening, *Vesp.*), then **distance of Mars** from Spica (à Spica ♀) in degrees (Gr.) and minutes ('), and from Arcturus (ab Arcturo) in degrees (Gr.) and minutes ('). The "à Spica" reference changes to "ab Antare" partway through, as noted in the cell.]

Month — Day	H (Vesp.)	à Spica ♀ Gr.	'	ab Arcturo Gr.	'
May 25	9¼	44	3 0	51	42
31	9¾	41	5 6	49	12

13	8½	46	3 9	31	5

Observations of Mars by the Fathers of the Society of Jesus at Innsbruck

At Innsbruck [Oeniponti], moreover, the Fathers of the Society of Jesus — by the testimony of the same P. Michael Staudacher — observed the distances written below.

[This table gives, for each date in **An. 1635 / An. 1636 / An. 1637: Month · Day**; the **distance of Mars** (Distantia ♂) from a named star (A.) in degrees (Gr.) and minutes ('); and the **Rising/Setting Altitude** (Altitudo Ortiva / Occidua) of the **Fixed star** (Fixarum) and of **Mars** (Martis), each in degrees (Gr.) and minutes ('). For An.1636 the heading becomes "Altit. Occ." over the distance and "Ortiua" over the altitude; for An.1637 both become "Occid." Where a value reads "occid." or "ortiu." the cell records rising/setting rather than a numeric altitude.]

CHAPTER VIII.

Selected observations of Mars, made at Bologna in the College of St. Lucy by Father Giovanni Battista Riccioli [Giovanni Battista Riccioli] and Francesco Maria Grimaldi [Francesco Maria Grimaldi] of the Society of Jesus.

To which are added the observations of the most illustrious Marquis Cornelio Malvasia [Cornelio Malvasia].

1. In the year 1642, on October 12, in the morning about an hour before sunrise, Mars stood $38^{\circ}24'$ from Regulus, and $19^{\circ}44'$ from Aldebaran; and the same observations were repeated with a great sextant, as the practice was in these and the following ones.
2. In the same year, on October 21, in the morning, by Italian civil reckoning, Mars stood 15° precisely from the bright star of Aries, and $40^{\circ}28'\frac{1}{2}$ from Regulus.

3. In the year 1642, on July 16, in the morning at $7\frac{1}{2}$ hours, Italian reckoning, Mars was $17^{\circ}27'$ from the bright star of Aries, and $28^{\circ}31'$ from the tail of Cetus.
4. In the year 1642, on August 21, in the morning at the forty-first minute after the bright star of Aries had crossed the meridian, Mars stood $25^{\circ}37'$ from it; and 5 minutes of time later it stood $44^{\circ}41'$ from the following shoulder of Orion.
5. In the year 1642, on August 23, in the morning at $9\frac{1}{2}$ hours, civil reckoning, Mars stood $24^{\circ}51'$ from Aldebaran, and 2 minutes of time later it was $41^{\circ}2'$ from it.
6. In the year 1642, on August 25, in the morning, as the bright star of Aries was crossing through the meridian, counting 48 minutes by the pendulum, Mars crossed the meridian, and at that moment the captured altitude of its tail was $57^{\circ}58'$.
7. In the year 1642, on August 28, in the morning, at the crossing of the bright star of Aries through the meridian, counting $51^{\circ}10''$, after which Mars crossed the meridian, the altitude of its tail measured $58^{\circ}18'$.
8. In the year 1642, in September, on the night following, about the fourth hour of the night, Mars stood $38^{\circ}20'$ from Capella, and $17^{\circ}50'$ from Aldebaran.

Here ought to be inserted, in order, the two earlier observations.

9. In the year 1642, on the night following the 31st, after the crossing of the bright star of Aries through the meridian by 31 minutes, and 12 seconds, Mars was tending toward the second hour with the Sun, or it was rising acronychally [acronychus], at the meridian, $16'$. Then after 3 minutes of time Mars was $26^{\circ}12'$ from Aldebaran, and after 3 minutes it stood $42^{\circ}26'$ from Regulus.
10. In the year 1643, on January 5, on the night following the crossing of the bright star of Aries through the meridian, we counted $34^{\circ}36''$; and at that time Mars crossed through the meridian, and the altitude then observed was $60^{\circ}58\frac{1}{2}'$.
11. In the same year, on February 11, on the night following, at the 3rd hour, civil reckoning, Mars stood $22^{\circ}19\frac{1}{2}'$ from the bright star of Aries;

Andromeda was expected to the south at $29^{\circ}29'$; Mars was awaiting the Sun.

12. In the year 1643, on May 3, at the first hour after sunset, Mars stood $21^{\circ}5\frac{3}{4}'$ from Procyon, and $30^{\circ}10\frac{1}{2}'$ from Capella.
13. In the year 1643, on July 11, on the night following, at $1\frac{1}{2}$ hours, Italian civil reckoning, Mars stood $20^{\circ}33\frac{1}{2}'$ from Saturn, the more westerly one; and 5 minutes later it stood $19^{\circ}14\frac{1}{2}'$ from the southern foot of Andromeda; it was now 19° high, the sky being misty.
14. In the year 1644, on August 6, by night, the bright star of Aries was [?] from the vertex toward its rising at $30^{\circ}42'$; from that, counting 6 minutes, Mars stood $7^{\circ}14\frac{1}{4}'$ from the bright star of Aries pulsing seventh with [Florisonio?]; and 2 minutes later it was $30^{\circ}23\frac{1}{2}'$ from Capella.
15. Also in the year 1644, in September, on the 9th, at high Sirius 18° , or about one hour before sunrise, Mars stood $13^{\circ}24\frac{1}{4}'$ from Aldebaara; from the bright star of Aries, indeed, $45^{\circ}48'$; it was awaiting both the Sun and Mars [recte: Sirius?].
16. In the year 1644, in November, on the 17th, on the night following, Mars was $63^{\circ}56'$ distant from the eastern vertex; from this, counting 9' of time, Mars stood $39^{\circ}52'$ from Rigel of Orion; after 3 minutes later it stood $31^{\circ}25\frac{1}{2}'$ from Aldebaran.
17. In the year 1645, on March 22, on the night following, when Mars was in conjunction [□] with the Sun, it was observed to stand $25^{\circ}19'$ from Procyon, and from the bright side of Perseus $25^{\circ}51\frac{3}{4}'$; and then the altitude of Sirius was seen at $7^{\circ}33'$.
18. In the year 1646, on June 23, in the morning, after the conjunction [□] of Mars with Saturn, and from the underwritten bright star of Aries, the distances of these planets from the vertex were taken and are written below:

Bright star of Aries, dist. from vertex	Distance of planets from the fixed stars	
Deg.	Mi n.	G M.
63	56	Saturn from Capella 4 32 0

Bright star of Aries, dist. from vertex		Distance of planets from the fixed stars	
63	44	Mars from Capella	3 11 9 ½
62	46	Saturn from the bright star on the side of Perseus	3 31 4
60	52	Mars from the same side	3 57 2
60	0	Mars from Saturn	1 32

Here is to be inserted the observation that follows, [numbers] 22, 23, and 24.

19. In the year 1647, on April 2, on the night following, at about one hour after sunset, the observation was begun, and completed about one and a half hours; concerning which, just as also concerning the observation of April 4, see our observations of Jupiter at the same time, and Mars 34 and 35 — for at that time the conjunction [□] of these planets was celebrated.
20. In the year 1649, on February 20, on the night following, about 2½ hours, by night, Mars stood 31°23' from the Heart of Hydra, and 49°½ from Procyon.
21. On the 26th of the same month, Mars on the night following was scarcely sensibly more easterly than the Moon with respect to the same Vertical, but was seen to stand 69°23½' from the vertex; the center, however, of the Moon was 68°12'; and after one minute of time, with Mars more easterly, it stood 59°4½' from Rigel; likewise, with Mars more easterly, at the same moment it stood 52°10' from the vertex; then Mars stood 62°ab from the vertex, and 30°11¼' from the Heart of Hydra, and 49°40' from Procyon.
22. In the year 1647, on January 16, on the night following, Mars was 30° high from Procyon; from Procyon also 31°; it stood 25°15¼' from the bright star of Orion; and soon from the bright star of Orion, the horn, 46°18½'.
23. In the same year, on January 23, on the night following, Mars was 33° high from Procyon; it stood 32°20' from the bright star of Orion 44°4'; and after 12 minutes of time it stood 23°49' from Procyon.
24. In the same year, likewise, on January 26, on the night following, Mars stood 43°4' from the bright shoulder of Orion, and 23°12' from Procyon — at that time Mars was about 48° high; from Procyon, indeed, 42°.

25. In the year 1649, on June 2, with the now finished conjunction [□] of Mars with the Sun, on the night following, about an Italian hour and a half, when the bright star of the mane stood 50° from the vertex, Mars stood $16^{\circ}52' \frac{1}{2}$ from Regulus, and $18^{\circ}48'$ from the bright star of Leo.
26. In the year 1652, in November, on the 19th, in the morning, when the bright star of the mane of Leo stood $42^{\circ}50'$ from the vertex, the times were begun to be counted by the pendulum; and after 6 minutes Mars stood $33^{\circ}50'$ from Arcturus, the more easterly one. Then after another 4 minutes it stood $45^{\circ}13'$ from the Heart of Hydra, the more westerly one.
27. In the year 1653, in February, on the 2nd, in the morning, with the bright star of the Eagle $69^{\circ}40'$ distant from the vertex, the more easterly one, Mars stood $24^{\circ}1'$ from Spica, the more westerly one; and soon from the head of Ophiuchus, the more easterly one, $46^{\circ}59'$, than Mars was $46^{\circ}59'$.
28. In the year 1653, on March 15, on the night following, at $1\frac{1}{2}$ hours, after sunset, Mars rising was observed to stand from the vertex 77° [continues]. $77^{\circ}38'$; and from the bright star of the Northern Crown 48° ; and almost 1' later Mars stood $77^{\circ}6'$ from the vertex; it was $36^{\circ}48'$ from Spica.
29. On the following day, that is May 16, with Mars approaching the Sun, since there was an hour and a half after sunset, it was observed to stand $77^{\circ}4'$ from the vertex; and from the head of Ophiuchus $42^{\circ}1'$; soon Mars stood $76^{\circ}24'$ from the vertex; and from Spica of Virgo $36^{\circ}16'$.
30. In the year 1653, on June 19, on the night following, at the second hour after sunset, when Antares appeared, Mars was $19^{\circ}45'$ high; and Mars stood $25^{\circ}37'$ from it; it was seen to be distant from Antares $17^{\circ}53' \frac{3}{4}$; and from the head of Ophiuchus $47^{\circ}33' \frac{3}{4}$; it was tending toward Direction, since it was retrograde.
31. In the year 1653, on June 22, on the night following, when Antares appeared, it was $18^{\circ}16'$ high; but Mars was $26^{\circ}13'$ high; or about one hour after sunset, it was seen that Mars stood from Antares 18° precisely, and from the head of Ophiuchus $47^{\circ}40'$.
32. Likewise in the year 1653, on June 24, one hour after sunset, Mars was $26^{\circ}14'$ visibly high; it was distant from the head of Ophiuchus $47^{\circ}42'$; and soon from the Heart of Scorpio $36^{\circ}18'$; with Antares the same standing $19^{\circ}12'$.

33. In the year 1653, in November, on the 28th, when the conjunction of Mars with Jove [Jupiter] was celebrated, on the night following, Fomalhaut was seen to stand $76^{\circ}2'$ from the vertex; Mars was seen almost in second place, and Mars was distant from Fomalhaut $25'$ precisely; and a little after, from the southern tail of Cetus $47^{\circ}37\frac{1}{2}$; but the tail of Cetus stood $69^{\circ}42'$ from the vertex; Mars, however, 65° .
34. In the year 1653, in December, on the 23rd, on the night following, the bright star of the Eagle stood $61^{\circ}41'$ from the vertex; and therefore one hour after midday $5^{\circ}20'$; after counting [past?] noon by [?] $19^{\circ}12''$, Mars stood from the western Azimuth at 25° degrees, where it was expected; and then, with the distance of Mars from the vertex observed to be $59^{\circ}58'$.
35. In the year 1653, on March 16, on the night following, Mars was expected from the western Azimuth at 85° degrees in that vertex $66^{\circ}41\frac{1}{2}$; then after 5 minutes of time Rigel of the Eagle stood $58^{\circ}32'$ more easterly.
36. In the year 1655, on July 16, on the night following, Mars appeared about as large as Jupiter; it came to the meridian; and then it was seen to stand $70^{\circ}54\frac{1}{2}$ from the vertex; then after $7'40''$ the head of Andromeda stood toward its rising $45^{\circ}3'$ from the vertex.
37. On July 22 (for indeed on the 20th, with a rainy spell of two days having interrupted the observation, the conjunction [□] of Mars with the Sun began) on the night following the crossing of the bright star of the Eagle through the meridian we counted $31^{\circ}10''$; after which Mars came to the meridian, in which the distance of Mars from the vertex observed was $71^{\circ}22\frac{1}{2}$.
38. In the year 1655, in August, on the 21st, on the night following, Mars was expected at the western Azimuth at 20° , and it stood in that vertex $74^{\circ}31\frac{1}{2}$; and after a quarter-hour precisely, or 15 minutes by the pendulum, we counted Mars more westerly than the head of Andromeda, standing $64^{\circ}21'$ from the vertex.
39. In the same year, on August 23, on the night following, after the crossing of the bright star of the Eagle through the meridian by 9 minutes of time, Mars also crossed the meridian; then it is recorded standing $71^{\circ}45\frac{1}{2}$ from the vertex.

40. In the year 1656, on March 11, at the second hour of night following, it was observed that Mars stood from Aldebaran $20^{\circ}17'$ certainly, and from Regulus $40^{\circ}35'$.
41. In the year 1656, on April 29, about three-quarters of the first hour of the night following, the western distance of Mars was captured from the vertex $79^{\circ}55'\frac{3}{4}$ in that Vertical, and from the Azimuth, to which place, on reaching the head of Pollux, or of the following Gemini, it stood $37^{\circ}37'\frac{3}{4}$ from the vertex; and after three minutes of time having elapsed, the more western Procyon stood $55^{\circ}20'\frac{3}{4}$ from the vertex.
42. In the year 1657, in October, on the 21st, before the conjunction [□] of Mars and Saturn, on the preceding day, when the observation of Saturn was made, on the following night the eastern distance of Mars was observed $65^{\circ}41'10''$; designated for the Vertical Azimuth at Triangle 1° , and immediately the times began to be counted; and after 5 minutes, and at the second [count] 25 minutes, the bright star of Aries was captured, standing from the vertex toward its rising $62^{\circ}8'$.
43. In the year 1657, in November, on the 12th, when Mars was nearest to us in retrogradation, and on the night following, after the crossing of the bright star of the south in the tail of Heaven, the minutes of time were counted at $9'\frac{1}{4}$; before which the point itself in the middle of Heaven was seen to stand $36^{\circ}1'3''$ from the vertex.
44. On the 14th, indeed, after the crossing of the bright star of the south in the tail of Cetus, it was counted $9'40''$; the bright star of the middle of Heaven crossed; and its distance from the vertex was $41^{\circ}26'10''$.
45. On the 15th, indeed, in November, on the night following, after the crossing of the bright star of the south in the tail of Cetus, the times counted were $9'40''$; when Mars crossed the middle of Heaven; and its distance, captured from the vertex, was $41^{\circ}21'20''$; from which it is argued that Mars had been beneath the sky at the time of being stationary.
46. In the same year, in November, on the 17th — for on the 16th it had been cloudy weather — after the crossing of the meridian, the bright star of Heaven, and the more easterly one, in the tail of Cetus, and as far as Mars there was a crossing through the M.C. it was counted to be of time $16''$; and then the distance of Mars from the vertex was $42^{\circ}10'20''$.

47. In the same year, in December, on the 4th, on the night following, after the crossing through the middle of bright Heaven, and of the more southerly one, in the tail of Cetus, the times counted were of time 22'45"; and then with Mars in the middle of Heaven, its distance was observed 39°5'24".

48. In the year 1660, in May, on the 18th, D. Vincenzo Mutus [Vincenzo Muti] of Majorca [Maioricae] observed Mars with the breast of Cancer, and with certain little stars distant around Praesepe; but the innumerable ones, nor do we rely on the Tyconic Catalogue, for our affair: with Mars distant beyond 7', and from Praesepe distant about 5'.

Observations made in the Astronomical Observatory of Modena [Mutina] by the most illustrious Marquis Cornelio Malvasia [Cornelio Malvasia], and set forth in his Ephemerides, fol. 215.

Year	Distance of ♂ from the fixed stars, corrected	Place ☉ Observed	Lansbergen's deficit
1662.	Arcturus	2 La. 6	1 4

But it should be remembered that he used the Tychonic Fixed Stars, which need correction, in accordance with what was said in Book 4. And the Cassinian Fixed Refractions, by which the said distances are corrected, are said by us to be recalled into doubt in Book 1.

CHAPTER IX.

On the Astronomical Tables, to be tested against selected observations made on Mars.

1. Having set forth thus far the reasons for selecting from among so many observations, I have touched on only the most certain of them, in Book 5, chapters 9 and 10, and in Book 6, chapter 9. But indeed Tycho [Tycho Brahe], in the Preface to his *Epistolae Astronomicae* [*Epistolae Astronomicae*], requires 24 years of observations for Mars, so that an acronychal Mars may be opposed to the Sun in each sign of the Zodiac. [Margin: *Longomontanus's opinion.*] Longomontanus, however, in Book 2 of the *Theorica*, chapter 8, brings forward only 14 oppositions of Mars with the Sun, from Kepler's Commentaries on Mars, yet denying that the eccentricity of Mars is the foundation for the construction of Kepler's Ephemerides. [Margin: *And his praise of Kepler.*] Kepler, however, in the explanation of the foundation of the Rudolphine Tables he constructed (page 14 of the Commentaries), states that he departed from his own [findings] on Mars not a nail's breadth, and that the Magnum in the supplement to the Ephemerides most faithfully represented the motions of Mars in the limited Commentaries of those days. And indeed astronomy owes the most in this matter to Kepler. For once, as Pliny [Pliny] testifies (Book 2, chapter 17), the planet Mars was considered unobservable; [Margin: *Errors of the ancients in (Mars).*] and its errors in the ancient Hypotheses could not be forced within the narrowness of two degrees, as Maestlin [Maestlin] in his Preface advised an Ephemeris of the year 1577; indeed, it appeared from the autumnal observations of the year that they had wandered far afield; Kepler, with the truest Hypothesis devised in the year 1625, and with the best use of Tychonic observations, forced the

errors of this planet within a very few minutes — so much so that, as Elias de Leonibus [Elias de Leonibus] asserts in *Urania Propitia*, part 2, chapter 15, the least may have to be changed in the Rudolphine Tables, which is confirmed by the example of the conjunction of Jove [Jupiter] and Mars in the year 1591, about which we said above in Book 5, chapter 9, and which we shall mention again below.

2. Lansbergen [Philips van Lansbergen], moreover, among the other observations of Mars which he brings forward from his *Thesaurus*, the conjunction itself, in the very manner in which he indicates the conjunction of Jove and Mars, which Mestlin observed in January [Margin: *Lansbergen's double trickery.*] Opt. page 305, affirms agrees with Maestlin and with his own Astronomical observations; yet saying nothing of *Mane* [in the morning], he, Lansbergen, made it from his own addition in the morning, and says that Kepler writes the 9th, when he should have written the 8th; nor does this hold, since in the series of the calculation he sets down only January 6, the 18th hour, in order to draw the observation to his own Tables, or as if changed, or otherwise altered at his pleasure, so that for this reason it deservedly invites the reproach of Elias de Leonibus and Boulliau [Ismaël Boulliau], in *Urania Propitia* part 2, chapter 15. Io. Phocylides [Johannes Phocylides Holwarda], and Boulliau — who indeed examined Boulliau's far more profound and prudent investigation of the Rudolphine hypotheses.

Now we proceed to the comparison of the Astronomical Tables, selecting those 10 acronychal Oppositions of Mars with the true place of the Sun, by which especially Kepler in his *Commentaries on Mars* built up the Martial Hypothesis: we add besides four notable conjunctions of Mars — with Jove, and 1 with Saturn, and 6 with the most certain fixed stars — and how far they labor under the least suspicion of error.

10. *The acronychal places of Mars in Opposition, observed against the true place of the Sun according to Tycho, from the Commentary of Kepler, with the computation from the Tables.*

The part where our Tables disagree from the observations is to be ascribed to the observation of Mars, and to the false Tychonic place of the Sun.

11. In the year 272 before Christ, on January 17, at hour p.m. 17, Mars was seen to lie upon the most northerly forehead of Scorpio, as Ptolemy [Ptolemy] reports from the things said here in chapter 1. [Margin: ♂ *on the forehead of Scorpio.*] Longomontanus, in Book 2 of the Theorica, chapter 10, and Lansbergen in the Thesaurus, contend that this star had been bright of the second magnitude, as observed by Mars [recte: as Mars observed?]. But better do Kepler and Boulliau, in Book 8, teach that the most northerly star had been in the forehead of Scor[pio] [continues].

[Margin: ♂ *on the forehead of Scorpio.*]

of Scorpius, which is the fifth and of the fourth magnitude. Otherwise, if the motion of Mars is directed toward the bright star of the forehead of Scorpius, the conjunction of Jupiter with Regulus—soon to be reported under the years 508 and 509—cannot be reconciled. Therefore, when Mars was at that time at the most northerly star of the forehead of Scorpius, it was, for me, at 2° 39' 15" of Scorpius. So Mars, lying upon that star, was still a little more to the west, which our Tables display by an astonishing agreement; for

♂ position	Sig.	G.	'	"
Observed	♌	2	39	0
Computed	♌	2	38	54

12. In the year 498 of Christ, on the first day of May, around the ninth hour, Jupiter and Mars appeared so close together that they seemed scarcely at all to be separated from one another—though it is fairly probable that, on account of the rays of each, they were in fact set somewhat apart. I have already reported the positions of the planets, drawn from our Tables, in Book 6, Chapter 9; and they are:

Position	Sig.	G.	'	"
♃	♍	0	15	34
♂	♍	0	13	56

13. In the year of Christ 509, on June 13, around the ninth hour, Mars appeared more to the west than Jupiter by 1 digit, or 2½; and it probably was more, on account of the spreading of the rays. But in Book 6, Chapter 9, I have given the positions of both planets from our Tables, namely:

Position	Sig.	G.	'	"
♃	♌	11	56	40
♂	♌	11	52	2

14. In the year 1490 of Christ, on September 18, at the fourth hour, Mars was seen by Bernhard Walther [Bernhard Walther] joined to the Nebula of Cancer [♋ nebulosa], which was then at 0° 11' 3" of Cancer. Our Tables, however, give Mars at 0° 16' 30" of Cancer—from which a part of the discrepancy may be ascribed to Walther's estimate by eye.

15. In the year of Christ 1591, on January 9, while Maestlin [Michael Mästlin] and Kepler [Kepler] were observing, they saw at night Jupiter covered by Mars's reddish light, as Kepler reports in *Astronomia Optica*, p. 305. For me, as I have said, in Book 6, Chapter 9, at the 13th hour after midday of the 8th day, the planets stood thus:

Position	Sig.	G.	'	"
♃	♋	14	59	12
♂	♋	14	58	53

Hence at the 13th hour, 2' 30", they were exactly joined.

16. In the year 1604, on September 27 by the new style, at Prague, around the eighth hour, Mars was seen as nearly as possible joined to Saturn in longitude. For me, however, Saturn was then at 9° 58' 58" of Pisces, while Mars was at 9° 59' 30" of Pisces; so I believe their conjunction occurred a little before the one reported.

17. In the same year 1604, on October 9, near midday, a conjunction of Jupiter and Mars occurred, as Kepler deduced from observations made at Prague. For me, as I have said in Book 6, Chapter 9, at the 23rd hour 50' after midday of the 8th day, the planets stood thus when reduced to the ecliptic and curtated:

Position	Sig.	G.	'	"
♂ Position	♄	19	15	37
♂ Position	♄	19	15	36

18. In the year 1634, on June 8, Gassendi [Pierre Gassendi] at Aix-en-Provence [Aquis Sextiis], at the 12th hour 34'—which at Bologna was the 13th hour—estimated through the telescope that Mars was at the same longitude as the last star, that is, the extreme star of the left wing of Virgo, which for me was then at 21° 59' 38" of Virgo. [Margin: ♂ ♂ cū ☿ ☐ □ alaπ ♀]

		Sig.	G.	'	"
♂ Position	Observed	♂	21	59	38
	Computed	♂	22	3	19

19. In the year 1645, on February 28, at the seventh hour, at Majorca [Maiorica], D. Vicenç Mut [Vincentius Mutus], using the telescope, estimated Mars to be two minutes more to the west than an unformed star which lies near the mouth of Erichthonius [Erichthonius], the star which in my Catalogue was at 24° 41' 33" of Gemini. Mars, for me, was at 24° 41' 20" of Gemini, at the 7th hour 37' at Bologna; therefore he had already obtained that distance earlier. [Margin: ♂ ♂ ♂ / Fixa I-formis.]

20. In the same year 1645, on May 15, the same observer, in the same place, around the 8th hour 30', judged through the telescope that Mars was 2 minutes more to the east, and 2 minutes more to the west than the northern preceding star in the quadrilateral of Cancer, which for him was then at 0° 30' 6" of Leo; and yet Mars in my Tables comes out at 0° 30' 31" of Leo. Here again we differ by 2 minutes. [Margin: ♂ ♂ cū ☿ ☐]

21. In the year 1649, on June 23, from his own observations, Mut reckoned Mars at the 20th hour [?] joined with the extreme star of the other, that is, the left wing of Virgo, which for me was then at 22° 13' 10" of Virgo. And Mars was at 22° 16' 30" of Virgo.

CAPUT X.

De Hypothesi Arithmetica, et Geometrica Motuum Martis.

[On the Arithmetical and Geometrical Hypothesis of the Motions of Mars.]

1. In Book 5, Chapter 12, I treated of those matters that are common to the five lesser planets, besides those I discussed at length in Book 7 of the *Almagestum Novum* (*New Almagest*), Sections 2 and 3. But those things which are here proper to Mars are these:

LIBER OCTAVUS

IN QUO SUNT VENERIS PLANETÆ OBSERVATIONES, ET Hypothesis Motuum.

[BOOK EIGHT, IN WHICH ARE THE OBSERVATIONS OF THE PLANET VENUS, AND
THE HYPOTHESIS OF ITS MOTIONS.]

CAPUT I.

*Veneris Observationes Antiquæ ab Anno ante Christum 272, usque ad Annum
Christi 510.*

[The Ancient Observations of Venus, from the year 272 before Christ down to the
year of Christ 510.]

1. In the 13¹/₆th year of Ptolemy Philadelphus [Ptolemy], on the 17th day,
going on the 18th, of the month Messori, at the 12th hour, Timocharis
[Timocharis] at Alexandria [Alexandria] saw Venus obscuring exactly the
star opposite the Praesepe [Praesepe — the Manger]. Ptolemy, *Almagest*
Book 10, Chapter 4, adding that the star was the one which lies after that

one which is at the tip of the southern wing of Virgo, says that it was 52° distant from the death of Alexander, and from Nabonassar 476.

Copernicus, Book 5, Chapter 23, supposes that star to have been the one preceding among the four which are in the left wing of Virgo.

Longomontanus [Longomontanus], Book 2, *Theoricae*, Chapter 19, says it was the year 272 before Christ, and the eleventh day of October, at the 18th hour at Alexandria; and he says that star was at 1° 16' of Virgo with northern latitude. But Lansbergen [Lansbergen], in his *Thesaurus Observationum*, computes the star in Virgo at 3° 21' with northern latitude 1° 20', and Venus at 3° 22½' of Virgo with northern latitude. Boulliau [Ismaël Boulliau], finally, in Book 9 of his *Astronomia Philolaica*, Chapter 6, says the star, of which Copernicus speaks, to have been at 2° 47½' of Virgo with northern latitude; and that Venus, from the Rudolphine [Tables], was at 2° 10' of Virgo, and did not obscure the star with its own body, but, by the spreading of its rays, rendered it inconspicuous. For me, the year before Christ was 272, and the day October 11.

2. In the 2nd year of the Emperor Adrian [Hadrian], on the 21st day of Athyr, going on the 22nd, Theon at Alexandria observed Venus at its greatest elongation from the Sun; distant from the summit of the southern wing of Virgo by as much as is the longitude of the Pleiades [Vergiliae], or a little less, by as much as is the diameter of Venus itself; and Venus appeared more northerly by one Moon's breadth. Ptolemy, *Almagest* Book 10, Chapter 1, who concludes from this that Venus was at 0° 20' of Virgo, and that its greatest distance from the mean place of the Sun was 47° 32'. But Copernicus, Book 5, Chapter 20, I know not from what copy, has the year 4 of Adrian, and of Christ 119, on the fourth day before the Ides of October, when it was the year 2 of Adrian and 117 of Christ, and the day the 13th of October.
3. In the year 13 of Adrian, on the Epiphi [day], the 2nd, going on the 3rd, Theon at Alexandria observed Venus preceding, in its morning elongation from the Sun, by 1° 24' a line drawn through the foremost of the three of the head of Aries [Aries], and at the extremity of the hinder shank of Aries, yet so that it was twice as far distant from the prior star as from the posterior. Ptolemy, Book 10, Chapter 2, who says that Venus was at 10° 36' of Aries with southern latitude 1° 30', and was distant 44° 48' from the mean place of the Sun existing in Taurus 25° 24'. But Copernicus, Book 5, Chapter 20, says it was the year of Christ 129, on the 12th day before the Calends of June, that is, on May 19. Longomontanus, Book 2, Chapter 19, adding the

hour, sets Venus at $16^{\circ} 10'$ of Aries; and Alexandria, quite different from us, places it by his own Tables, and the digression at $45^{\circ} 4'$; and the mean place of the Sun at $25^{\circ} 53'$ of Taurus. For us also it was the 18th of May, in the year 129.

4. In the year 16 of Adrian, on the 21st day of Pharmuti, going on the 22nd, Theon observed Venus in the evening, in its greatest elongation, preceding the middle of the Pleiades only, by as much as is the longitude of the Pleiades, but a little more to the south. Ptolemy, Book 10, Chapter 1, who from here says Venus was at $1^{\circ} 30'$ of Taurus, and the mean place of the Sun at $14^{\circ} 15'$ of Taurus, and its maximum elongation of Venus at $47^{\circ} 15'$. Copernicus, Book 5, Chapter 20, says it was the year of Christ 132, on the eighth day before the Ides of March, at the 1st hour of the night. But Longomontanus, Book 2, Chapter 19, says it was at the 7th hour 15' after midday; and Alexandria, but from his own Tables, places the mean place of the Sun at $14^{\circ} 49'$ of Pisces, and Venus at $1^{\circ} 39'$ of Taurus, and its elongation at 46° ; on the day of March, since it was a leap year.
5. In the year 18 of Adrian, on the 9th day of Pharmuti, going on the 10th [?], Ptolemy observed Venus in the morning, far distant from the Sun in Capricorn, its mean being in Aquarius $25^{\circ} 30'$, and its maximum elongation $43^{\circ} 35'$. Ptolemy, Book 10, Chapter 5, and Copernicus, Book 5, Chapter 22, adding...

LIBER VIII — DE VENERE [Book 8, On Venus]

CAPUT I (continued) — Veneris observationes antiquae [Ancient observations of Venus]

[The numbered observations continue from the preceding folio; §5 was begun there.]

§5 (continued). ...on the 12th of the Kalends of March [18 February], at daybreak: but in truth it was the 17th of February of the following [day], 18, of the year 134.

§6. In the year 21 of Hadrian, on the 9th of Mechir [Egyptian month], at evening of the 10th, at Alexandria, Ptolemy observed Venus in Aquarius $19^{\circ} 36'$, at its greatest elongation [digressione maxima] of $47^{\circ} 32'$ from the mean place of the Sun in Capricorn $2^{\circ} 4'$ (*Ptolemy, lib. 10, cap. 1*, and *Copernicus, lib. 1, cap. 20*, adding that this was the year of Christ 136, on the eighth of the Kalends of January [25 December]; and *Longomontanus, lib. 2, cap. 19*, adding the 6th hour,

[says] that at Alexandria Venus was indeed in Aquarius $19^{\circ} 36'$, but the Sun in Capricorn $2^{\circ} 36'$, and the elongation of Venus 47° , and that it was truly the 25th of December).

§7. Again in the year 21 of Hadrian, on the 2nd of Tybi [Egyptian month], evening of the 3rd, Ptolemy observed evening Venus at its greatest distance from the Sun, seen in Capricorn $12^{\circ} 50'$, and distant $47^{\circ} 20'$ from the mean place of the Sun in Aquarius [$\approx$] $25^{\circ} 30'$ (*Ptolemy, lib. 10, cap. 2*, and *Copernicus, lib. 5, cap. 20*, adding that this was the year of Christ 136, on the 5th of the Kalends of January [28 December]; but *Longomontanus, lib. 2, cap. 19*, has it on the 18th of November of the year of Christ 138, at the 6th hour, [with] Venus in Capricorn $13^{\circ} 4'$, the mean place of the Sun in Scorpio $26^{\circ} 9'$, and the elongation of Venus $46^{\circ} 55'$ — that day [being] truly the 18th of November, of the year 136).

§8. In the year 2 of the Emperor Antoninus, on the 29th of Tybi, evening of the 30th, Ptolemy in the morning observed Venus with the astrolabe against Spica, and found it in Scorpio $6^{\circ} 30'$, at an equal hour [hora aequali] of $4^{\circ} 45'$ past midnight, the Sun by mean motion holding $22^{\circ} 9'$ of Sagittarius (*Ptolemy, lib. 10, cap. 4*; but *Longomontanus, lib. 2, cap. 19*, [places it] in that year of Christ 138, on the 15th of December, at 15 h. 10 min.; Hafnia [Copenhagen] places Venus in Scorpio $7^{\circ} 15'$, the mean Sun in Sagittarius $22^{\circ} 43'$; *Lansbergen*, however, [places] Venus in $6^{\circ} 31'$ of Scorpio. But that day was truly the 15th of December).

§9. In the year 3 of Antoninus, on the 4th of Pharmuthi [Egyptian month], evening of the 5th, Ptolemy observed evening Venus at its greatest evening elongation in Aries $13^{\circ} 50'$, the mean Sun in Aquarius $25^{\circ} 30'$, with an elongation of $48^{\circ} 20'$ (*Ptolemy, lib. 10, cap. 3*, and *Copernicus, lib. 5, cap. 22*, saying it was the year of Christ 140, on the 12th of the Kalends of March [18 February]. When it would have been the 17th, of the following 18).

§10. In the year 4 of Antoninus, on the 11th of Thoth [Egyptian month], evening of the 12th, Ptolemy observed Venus near its greatest morning elongation in Gemini $18^{\circ} 30'$, distant $47^{\circ} 15'$ from the mean Sun (*Ptolemy, lib. 10, cap. 1*, and *Copernicus, lib. 5, cap. 20*, assigning it to the year of Christ 142, on the 3rd of the Kalends of August [30 July]. But *Longomontanus, lib. 2, cap. 19*, places the year as 140, on the 29th of July at 16 h. 12 min., and Venus in Gemini $19^{\circ} 1'$, elongated $47^{\circ} 11'$ from the mean place of the Sun in Leo $6^{\circ} 12'$. In reality it was the year 140, the 29th of July following, [at hour] 30 [?]).

§11. In the year of Christ 510, as Boulliau [Bullialdus] reports (*lib. 9, cap. 6*), it stands thus in a manuscript of the Royal Library: *In the year 226 of Diocletian, the*

star of Venus was seen to precede Jupiter; but on the 28th day it appeared, to the highest [degree], by 20 digits, while on the following day there seemed to be no difference whatever, by 20 digits [?] — yet by latitude it followed by 10 digits [penes latitudinem vero ... sequi digitis 10]. It would certainly have been fitting, according to the reckoning of the Ephemerides, that the planets themselves should be seen conjoined on the thirtieth day of the month, since at that time they appear distant from one another by a long interval, and yet they appeared as one. From this Boulliau, by Ptolemy's Tables, gathers that the conjunction of Jupiter with Venus took place between the 27th and 28th of Mechir, that is, between the 20th and 21st of August, at the 7th hour after midday at Uraniborg; from his Tables he derives the place of Jupiter in Virgo $19^{\circ} 1' \frac{1}{3}$, with northern latitude $1^{\circ} 9' \frac{1}{3}$. But the place of Venus then differed [stood apart] from Jupiter by 20 digits in preceding [longitude] — that is, 50 scruples [minutes] at the most [vt plurimum]; and by diurnal motion they ought to have been 40 scruples [apart]. The Rudolphine [Tables] must therefore be corrected, so that Venus may have been in Virgo $18^{\circ} 23'$, and the conjunction of Jupiter and Venus would have been about midday of the 28th of Mechir, that is, of the 22nd of August.

CAPUT II — Veneris observationes factae a Ioanne Regiomontano [Observations of Venus made by Johannes Regiomontanus]

§1. In the year of Christ 1461, December 14, after sunset, Regiomontanus [Regiomontanus] at Rome saw Venus about to be conjoined immediately with Saturn, and more southerly by two Suns [solar diameters], or by one degree; so that, by the Alphonsine numbers, the longitude of Venus was greater than that of Saturn by $1^{\circ} 36'$.

§2. In the year 1462, January 10, at Rome after the start of night, he saw Venus joined to the twenty-third star of Aquarius, which is at the beginning of the "outpouring" [effusio], but Venus was reckoned 45 minutes more easterly.

§3. In the same year, September 19, likewise at Rome at the 11th hour of the night, he saw Venus, Mars, and Regulus in one straight line, so that Venus was the more southerly, Mars the more northerly; and the distance of Mars from Regulus was one and a half times [sesquiquarta — recte: sesquialtera? "by a half more"] the distance of Venus from Regulus.

§4. In the year 1462, October 21, Regiomontanus at Viterbo in the morning at $12\frac{1}{2}$ hours of night saw Venus the more westerly than the sixth [star] of Virgo by 16 minutes, but joined to it in longitude, [the Moon being] waning — yet much less northerly than the Moon.

§5. In the same year and month, likewise at Viterbo, on the 25th in the morning he saw Venus joined [to it], the seventh of Virgo as to longitude, but by about one degree more southerly.

§6. In the year 1471, August 9, at evening, Venus stood apart from Jupiter, by the radius [cross-staff], $5^{\circ} 13'$, whereas by the Alphonsine [Tables] they were distant in longitude $4^{\circ} 33'$.

CAPUT III — Veneris observationes selectae ex observationibus Bernardi Vualtheri Norimbergae factis [Select observations of Venus from the observations of Bernhard Walther, made at Nuremberg]

The First Class [Prima Classis] contains observations made by ocular estimation [oculari aestimatione].

§1. In the year 1478, August 11, in the morning at about hour $3\frac{1}{2}$ after midnight, Walther [Bernhard Walther] saw Venus about midway between the heads of the Twins [Gemini], and a little more distant from the southern head, in nearly the same line as those very [stars], distant from that line by a little toward the west; but on the following day, the 12th, at the same hour Venus was seen so much more easterly than the said line, by however much it had been more westerly the day before.

§2. In the year 1486, September 20, in the morning at hour 5 p.m.n. [past midnight], Venus appeared more easterly than Regulus by one Moon [lunar diameter], in the same latitude; but on the 21st it was seen more easterly by three Moons.

§3. In the same year, September 24, between 10 and 11 before midday, he saw a conjunction of Venus with the Moon, but the Moon more northerly by half a diameter of the Moon.

§4. In the year 1489, March 6, about sunset, by the Armillae Zodiacales [zodiacal armillae], from the circle of the ecliptic he saw Venus in Aries $27^{\circ} 15'$; but using the circle of latitude he saw it in Aries $25^{\circ} 30'$. Likewise on the 7th of March, at evening about the same instant, he saw Venus from the circle of the ecliptic in Aries $28^{\circ} 15'$, but from the circle of latitude in Aries $27^{\circ} 38'$. This discrepancy he recognized to arise from refraction. See, in the learned old man's [i.e. Walther's] discourse upon this, the method of correcting these observations by the plumb-line [perpendiculo].

§5. In the year 1494, September 19, in the morning at hour 5 p.m.n. [past midnight], Venus was seen joined to Regulus, but more westerly by about 10 minutes, and equally [as many] more southerly. Lansbergen [Lansbergius], however, in his *Thesaurus*, observed [computed] 3 minutes [difference]: he computes the place of Venus from his own tables, Regulus in Leo 23° 19' with northern latitude 31', and Venus in Leo 23° 20' with northern latitude 13'.

§6. In the year 1502, September 19, in the morning after midnight he saw Venus conjoined to Regulus by a half-diameter of the Moon, and judged it to be the same in the longitude of both.

The Second Class [Secunda Classis] contains observations made by the radius [cross-staff] through the sines [per Sinus], on the use of which see the Waltherian [observations] of Saturn, num. 10. And so that you may have a specimen of the errors of the radius, note that Aldebaran and the northern horn of Taurus, by Tycho's sextants and ours, do not differ between themselves by more than 16° 45'; whereas Walther's radius nonetheless gave their distance as 16° 52', or 50'.

CAPUT IV — Copernici observatio de Venere [Copernicus's observation of Venus]

In the year of Christ 1539, on the fourth of the Ides of March [12 March], at the 1st hour after sunset, at Frauenburg [Fruemburgi], Copernicus [Copernicus] saw the Moon, which on its dark side began to occult Venus, according to the mean distance of the two [bodies]; the horn [of the Moon] lasted, and the occultation lasted for one hour. From this, Copernicus reckoned that the middle of the occultation fell between the first hour [after sunset] and the second, [namely] the conjunction of Venus with the Moon (*Copernicus, lib. 5, cap. 23*), adding that Venus had been at evening and near contact still at growing [waxing] evening, and near the contact of the orb. Lansbergen [Lansbergius], however, in his *Thesaurus* gathers the place of the Moon, seen, in Taurus 7° 7' 30"; and the place of Venus 7° 25' [?], and the northern latitude of the Moon as seen 34'; of Venus, 39'.

CAPUT V — Tychonis observationes de Venere ab Anno 1582 ad 1601 [Tycho's observations of Venus from the year 1582 to 1601]

First we select the observations of the year 1582, from those recently published at Vienna by Lucius Barrettus [Longomontanus, pseudonym], that is, as an anagram; and the letters of our own [people] have taught us — Albert Curtius [Albertus Curtius], of the Society of Jesus — leaving aside the azimuths [Azimutha], in which we place least trust.

[Tycho, observations of 1582 — distances of Venus from fixed stars]

In the second place we shall set down the observations of Venus which Tycho exhibits in *tomus 1* of the *Progymnasmata*, in order that from the right ascension [Ascensio recta] of Venus, and its distance from the bright star of Aries, the right ascension of the bright star of Aries may be established. On this occasion, however, the place of Venus can be gathered from it; but cautions must be applied, concerning which Kepler [Keplerus], in the foundation of his *Ephemerides* (*pag. 15*), where he says that daytime observations are to be kept apart from nighttime ones, nor are two parallaxes well compared in the same

altitude above the horizon, unless the interval of the earth [terrae] be the same; and as for Venus, otherwise an error of as much as 15' could be made in the motion of Venus. Moreover, the dispute is still undecided between the Landgrave of Hesse [Landgravium Hassiae] and Brahe [Braheum] concerning the six minutes of the Sun's motion from the fixed stars, on which see Tycho's letter of the year 1589, February 21. I add that I have increased the error in the greatest declination of the Sun, which I made greater [by] 1' 10" more than is right; and in the parallax of the Sun, which is indeed actually smaller, as Kepler admits above — but for us it is still smaller than the Keplerian [value]. Be mindful also, in individual cases, that account must be taken of Refraction.

[Tycho, 1582 — paired observations: distances and declinations of Venus, with two times each]

Lansbergen [Lansbergius], in his *Thesaurus observationum*, uses the observation of the 15th just cited; from it he gathers, by his own tables, the place of Venus in Pisces at 16°.57'.39". Boulliau [Bullialdus], however (book 9, chapter 2), from his own tables gathers the place in Pisces at 18°.9'; and so he argues that there is an error in this observation — or rather in the observation of the year 1590, of which more shortly — together with Longomontanus, who (in book 2 of his *Theoricae*, chapter 18) admits that scarcely ever, and only rarely at other times, was it possible — because of the obliquity of the sphere — for Venus and Mercury to be observed continuously in Denmark, as was required, at their greatest elongations from the Sun. Yet he subjoins the selected observations written below, drawn from Tycho, adding to them his own annotations for the years 1610 and 1616, with the computation of the place from the Danish [tables].

The right-hand portion of the page tabulates Tycho's selected Venus longitudes and latitudes, with observed and computed (*supputatum*) values paired:

No.	Year / Month / Day	H.	M.	obs./supp.	Longitude of Venus: Sig.	G.	M.	Latitude: G.	M.	(N/S)
34	1585 Sept. 14 (old style)	17	15	observed	♌ (Leo)	15	58	2	8	A

The last of Tycho's observations, made at the castle of Benátky [Benatica] in Bohemia in the year 1600, or at Prague in the house of Curtius [Curtij] in the year 1601, reduced to the days of the new style, were selected by Snell [Snellius] and published in the year 1618.

43. Year 1600, January 23, h. 7.45' p.m., as the Sun was rising [oriente Sole], the declination of Venus was observed by the armillae to be 17°.50', and by the quadrant the altitude was 16°.53½'. Then at h. 8½, p.m., the distance of Venus from the Sun was observed to be 40°.36'; and at last the meridian altitude of Venus was 21°.46½'.

44. Year 1600, February 20. The meridian altitude of Venus was seen to be 20°.27', and her distance from the Sun 46°.40½'.

45. Year 1600, February 22, in the morning at hour 6¾. Venus was seen to be 27°.37½' distant from Aquila [the Eagle]; the altitude of Venus was 9°.48'. Soon she was seen to be 42°.50'.50" distant from Antares. From this Boulliau (book 9, chapter 1), with the refraction and parallax not yet eliminated, gathers the place of Venus in Capricorn [♑] at 16°.24'.15", with northern latitude 3°.20'.34"; but he afterward reduces the longitude to 16°.22'.12". And he says her greatest digression from the Sun was on the 21st, at hour 20.27', namely 46°.46'.

46. Year 1601, May 9, hour 8.17'. Venus stood 29°.19½' from Capella; and at hour 8.27' she was 13°.47½' from Pollux. Her altitude was then 25°.30'; and at hour

8.34½' she was 49°.59' from Regulus. But Boulliau (book 9, chapter 1) says that, with the distance from Capella read as 26°.19'.40", it follows that the place of Venus is reduced to 4°.27'.50", with northern latitude 3°.9'.19"; and that her greatest digression from the Sun was 45°.13'.53".

47. Year 1601, October 10, in the morning at hour 4.30' p.m. [recte: ante meridiem — "manè"], Venus was seen to be 42°.53' distant from Procyon, and 45°.30½' from Pollux. And this was the last of Tycho's observations of Venus.

CAPUT VI.

Observations of Venus by Mästlin, Kepler, and Justus Byrgius, selected from Snell in the *Hassiacae*.

[1.] In the year 1574, Mästlin [Maestlinus], on September 16, in the morning at hour 4, saw at Tübingen [Tubingae] Regulus covered by Venus, as Kepler reports (*Astronomiae Opticae* [Astronom. Optic.] p. 305).

And from this Lansbergen, in his *Thesaurus*, observes: Regulus was then in Leo [Leonis] at 24°.7', with northern latitude 31'; but Venus in Leo at 24°.9' with northern latitude 29'. Although the latitude is diminished a little by adding the parallax of Venus, the brightness around Venus could nonetheless [obscure Regulus]; it could obscure Regulus.

2. Year 1590, October 3, old style, in the morning at hour 5. The same Mästlin saw Mars wholly covered by Venus, the bright [light] of Venus showing it [Mars] clearly. So Kepler in the *Optics* (p. 305). And from this Lansbergen, in his *Thesaurus*, gathers the place of Venus in Virgo [Virginis] at 25°.32'.37", with northern latitude 1°.20'; and of Mars in Virgo at 25°.45'.31", with northern latitude 1°.17'. And the parallax of Venus is to be added 3' to the longitude, but subtracted in latitude 1½'; yet, so that the discrepancy be not so great, he says he allows gratis that 9' is to be subtracted from the longitude of Mars.

3. Year 1592, February 18, in the morning at hour 6½ p.m. n. [post meridiem?], or 5½, as Justus Byrgius [Byrgius] has it: with the sextant, he observed Venus to be distant from Antares 48°.48½', and from Aquila 26°.39'.30". From this Boulliau (book 9, chapter 1) gathers the place of Venus in Capricorn [Capricor.] at 32°.22'.44" [?], with northern latitude 2°.56'.

4. Likewise in the year 1592, February 22, old style, at hour 0.17½' after noon. Byrgius of Cassel [Casellis] observed Venus to be distant from Antares 53°.39', and

from Aquila $26^{\circ}.51'$. From this Boulliau (book 9, chapter 1) gathers the place of Venus in Capricorn at $27^{\circ}.20'.36''$, with southern latitude [latit. B.] $2^{\circ}.32'.42''$. And then her greatest digression from the Sun was $46^{\circ}.41'$, namely when Venus was in Capricorn at $27^{\circ}.17'.36''$.

5. Year 1593, March 31, old style, at hour 9 after noon. Byrgius of Cassel observed Venus to be distant from Capella $22^{\circ}.10'$, and from the right shoulder of Orion [a dextro humero Orionis].

6. In the same year, August 6, old style, in the morning at hour 3. Byrgius of Cassel saw Venus distant from Rigel [Rigel] $45^{\circ}.38'.30''$, and from Pollux [a cap. Pollucis].

7. Likewise in the year 1593, September 1, old style, in the morning at hour 4 before noon. Byrgius of Cassel observed Venus distant from Pollux $19^{\circ}.33'$; and from Sirius [a Sirio] $18^{\circ}.25'$.

8. Year 1594, December 17, old style, at hour 5 after noon. Byrgius of Cassel observed Venus distant from Aquila $39^{\circ}.53'$, and from the shoulder-blade of Pegasus [a scapula Pegasi] $31^{\circ}.54'$. From this Boulliau (book 9, chapter 1) deduces the place of Venus in Aquarius [Aquarij] at $22^{\circ}.58'.8''$, with southern latitude [latit. Austr.] $1^{\circ}.6'.35''$.

9. In the same year, December 20, old style, at hour 5 after noon. Byrgius of Cassel observed Venus distant from Aquila $41^{\circ}.30'$, and from the shoulder-blade of Pegasus $29^{\circ}.37'$. From this Boulliau (book 9, chapter 1) deduces the place of Venus in Aquarius at $25^{\circ}.50'.53''$, with southern latitude $0^{\circ}30'37''$. And the greatest digression was $47^{\circ}.12\frac{3}{4}'$, which was on December 17, hour 5, with Venus reduced to Aquarius $21^{\circ}.1'.36''$.

10. Year 1594, December 22, old style, at hour 5 after noon. Byrgius saw Venus at an altitude of $11^{\circ}.30'$, and distant from Aquila $41^{\circ}.50'$.

11. Year 1595, August 9, old style, in the morning. Byrgius of Cassel observed Venus distant from Capella $10^{\circ}.25'\frac{1}{2}$, and from the loins of the Snake [ibibus, seu lumbis Helices] $47^{\circ}.52'$. From this Boulliau (book 9, chapter 3), placing the location of the star Helice in Leo [Helices in Leonis] at $13^{\circ}.39'$ with northern latitude [lat. Bor.] $45^{\circ}.3\frac{1}{2}'$, gathers the place of Venus in Cancer [Cancri] at $25^{\circ}.39'\frac{1}{2}$.

12. Year 1596, April 21, old style, at hour 9 after noon. Byrgius of Cassel observed Venus distant from Capella $21^{\circ}.29'\frac{1}{2}$, and from the following star of Gemini [a cap. sequenti Geminor.] $33^{\circ}.9'$.

13. Year 1598, September 25, new style, in the morning at hour 3. Venus, scarcely risen, was seen by Kepler at Graz [Gratij] covering the heart of Leo [cor Leonis: Regulus]; but at hour 4 more than one Venus[’s width] passed between it and Regulus. A line drawn from Venus to the heart of Leo fell a little below Jupiter [Iouem]. Kepler [discusses this] in the *Optics* (p. 303). From this Lansbergen, in the *Thesaurus*, gathers the place of Regulus in Leo at $24^{\circ}.21'$, with northern latitude $31'$; and of Venus in Leo at $24^{\circ}.24'.48''$, with northern latitude $33'$. For which reason she did not cover Regulus with her whole body, but only with her rays.

14. Year 1599, May 31, new style. From his own half-observation [semiobservatione], Kepler in the *Optics* (p. 305), by a certain conjecture, judges that there was a conjunction of Venus and Mercury; on which, see him, if you like.

CAPUT VII.

Observations of Venus made by Hortensius, Pierre Gassendi [Petro Gassendo], Fr. Andreas Arzet, D. Vincentius Mutus, and by the Fathers of the Society of Jesus at Ingolstadt [Ingolstadij] and Innsbruck [Oeniponti].

[1.] In the year 1622, October 14, in the morning (says Gassendi in his commentary *In Epicurum*, p. 903), at Aix [Diniaie — Aquas Sextias] I saw, without a telescope, in the brightening twilight, Venus very near to Mars and distant from Mesoborea [the middle of the northern part?] by not more than three-quarters [dodrans] of her own diameter; on the following day, at the same hour, she had passed over to Mars at Meseurum [Meseureum], being a little more than two of the lower appendices of the Belt of Orion [Balthei Orionis] apart from it, but far less than the two Kids [hoedi] below Capella.

2. Year 1625, January 30, old style, hour 7 after noon. Hortensius at Leiden [Leydae] saw through a tube [telescope] the conjunction of Venus, distant from the southern horn of the Moon by an apparent single minute. Lansbergen observes in the *Thesaurus*: at hour 7 the center of the Moon was $2'$ [from Venus?], adding the center of the Moon; and the place of Venus was apparent in Pisces at $24^{\circ}.45'.25''$, with southern latitude; she was seen at $48\frac{2}{3}'$. But Venus[’s] own place in Pisces was $24^{\circ}.44'.47''$, with southern latitude $52'$.

Kepler in the *Rudolphine* [Tables] (chapter 28, p. 93) relates that on the same day, in the evening, at Herbach [Herbachij], Ulm [Ulmae], Tübingen, and elsewhere in Swabia [Suevia], Venus was seen as if in the embrace of the horns of the Moon, clinging there; she was almost in the left horn, and from there gradually circled around the lower swelling of the Moon. From this he gathers that there was a conjunction of the Moon and Venus, their centers appearing to be in conjunction toward the setting of the Sun; and Venus, even though the Moon was truly the more northern. From this he takes an example of the computation of parallaxes to be supplied, and teaches that at the time of conjunction the Moon was in grad. $24^{\circ}.21'$, Venus in grad. $24^{\circ}.42'$ of Pisces [Piscium].

3. Year 1625, February 9, new style, hour nearly 5.40' after noon. At Paris [Parisijs] Gassendi saw with the naked eye the Moon, which with its extreme northern horn just touched Venus, yet covering nothing of her; so he in his *Epicurus* (p. 900).

4. Year 1626, December 12, old style, in the evening, hour 6.31'. At Leiden Hortensius saw Venus joined [to the Moon], following the longitude of the Moon, distant from its southern horn by about three-quarters [dodrans] of a lunar diameter. Lansbergen observes in the *Thesaurus*: 3. of Venus, where he computes the apparent place in Aquarius at $17^{\circ}.31'.50''$, with southern latitude seen as $36'.23''$; and the place of Venus in Aquarius at $17^{\circ}.31'.12''$, with southern latitude $1^{\circ}.33'.11''$.

5. Year 1629, December 17, old style, hour nearly $6\frac{1}{2}$ after noon. Hortensius at Middelburg [Middelburgi] saw Venus crossing the circle of the longitude of the preceding star [in the tail of Capricorn], by nearly a quarter of a lunar diameter; and she was more northerly by a whole lunar diameter. Lansbergen observes in the *Thesaurus*: 7. of Venus, whose place he gathers in Aquarius at $16^{\circ}.36\frac{1}{2}'$, but from the [Rudolphine] Tables $16^{\circ}.42'.33''$.

6. Year 1632, July 31. Hortensius at Amsterdam [Amstelodami] observed the conjunction of Venus and Mercury in the morning after midnight; but at hour $3\frac{1}{2}$ Venus was distant toward the east [versus ortum], and Mercury was 7' from it; and Mercury appeared the more northern. From this he argues that the conjunction of these planets was at hour $11\frac{1}{2}$ of the night. Moreover, in Hortensius's dissertation on Mercury seen on the Sun, [the places] of Lansbergen and Longomontanus stand thus, with a notable error of Longomontanus against the observation.

The page opens with a small comparison table of computed longitudes and latitudes from Lansbergen and Longomontanus for both Venus and Mercury (continuing the discussion of the 1632 July 31 observation):

Author	Planet	Longitude: Grad.	I (')	II (")	Latitude: G.	I (')	II (")	(N/S)
--- ---	--- ---	--- ---	--- ---	--- ---	Lansbergen	Venus	♋ (Cancer)	24 24
43 0	34 43	B	Longomontanus	Venus	24 40	0 0	34 0	B
Lansbergen	Mercury	♋ (Cancer)	24 30	4 0	39 5	B		
Longomontanus	Mercury	27 33	0 1	24 0	B			

7. Year 1632, December 6. Gassendi at Paris observed the conjunction of Venus with the Sun, as far as longitude went; for as to latitude, Venus could not at that time cover the Sun, as Kepler [also held] in the *Optics* (p. 305). And it was at hour 9.41' after noon at Uraniborg, from the *Rudolphine* [Tables]; and the southern latitude of Venus was 1°.58'.9". Hortensius [discusses this] in his dissertation on Mercury seen on the Sun.

8. Year 1633, May 26, hour 9 after noon. Boulliau with the optical tube saw Venus 18', or at most 19', more westerly, on the left shoulder of Pollux, somewhat more southerly. That star was (says Boulliau, book 9, chapter 2) in Cancer at 18°.33'.20", with northern latitude. And the azimuth of Venus was 9' more westerly than the azimuth of the star; therefore Venus was in Cancer at 18°.17', with northern latitude 2°.48'.

9. Year 1633, July 30. Gassendi at the little town of Tanaron [Tanatone] toward the north, at Digne [Dinia], of latitude 44°.11', in the morning saw Venus distant from the center of the Sun 26°.3' [?]; with the Sun high, Venus was previously at altitude 12°; she was seen to be distant from Aldebaran 37°, and from the southern horn of Taurus [australi cornu Tauri] 27°.17'.

10. In the same year, August 2. Gassendi in the same town saw Venus distant from the center of the Sun 29°.2'; with the Sun high at 9°. But Venus was previously seen to be distant from Aldebaran 36°.44', and from the right shoulder of Orion 20°.6'.

11. On the 5th, with the Sun high at 10°, Venus was seen by the same [observer] to be distant from the center of the Sun 31°.40'; though she had previously been distant from Aldebaran 36°.48', from the right shoulder of Orion 20°.8', and from Pollux 14°.40'. Gassendi in the *Epicurus* (p. 800).

12. On the 6th, the same Venus was distant from Aldebaran $36^{\circ}.59'$; and then from the western limb of the Sun $32^{\circ}.18'$; next from the eastern limb of the Sun $32^{\circ}.49'$; from the center of the Sun $32^{\circ}.34'$.

13. On the seventh [day], the same Venus was distant from Aldebaran $37^{\circ}.3'$; and $20^{\circ}.19'$ from the right shoulder of Orion; $14^{\circ}.27'$ from Pollux; and $16^{\circ}.45'$ from Castor [Castore]; then $33^{\circ}.5'$ from the western margin of the Sun, high at 9° ; and $33^{\circ}.34'$ from the eastern margin of the Sun, high at $10\frac{1}{2}^{\circ}$; and $33^{\circ}.20'$ from the center of the Sun, high at 12° .

14. On the 11th, the same Venus was distant — the same [observer] observing in the same place — $37^{\circ}.56'$ from Aldebaran, and $21^{\circ}.17'$ from the right shoulder of Orion; and next $36^{\circ}.6'$ from the center of the Sun, high at 12° .

15. On the 12th, the same Venus was distant $38^{\circ}.14'$ from Aldebaran, and $21^{\circ}.43'$ from the right shoulder of Orion; and next $36^{\circ}.44'$ from the center of the Sun, high at nearly 14° .

16. On the 13th, Gassendi there saw Venus distant $21^{\circ}.52'$ from the right shoulder of Orion, and $14^{\circ}.27'$ from Pollux, and $37^{\circ}.20'$ from the center of the Sun. Gassendi in the *Epicurus* (p. 801), who admits that, using a five-foot [radius] instrument, the use of the cylinder was such that the margins were rather outside than inside, and that in the discrimination of the margins one abounded over the other by a minute.

17. Year 1635, July 16. Gassendi at Aix [Aquis Sextijs] saw Venus at altitude 7° , distant from the tail of Leo [a cauda Leonis] $13^{\circ}.52'$, [the tail] itself high at $20\frac{1}{2}^{\circ}$. Gassendi in the *Epicurus* (p. 802).

18. Year 1636, November 14, in the morning. Fr. Andreas Arzet of the Society of Jesus at Innsbruck [Oeniponti] had this observation of Venus, which he afterward communicated to me by letter.

No.	Measured quantity	G		
		.	I (')	II (")
19	Between astronomical hours 6 and 7 —	5	28	30
	meridian altitude of Regulus	6		
	Venus's altitude then, seen at rising	2	36	30
		9		
	Soon, distance of Venus from Regulus	4	6	40
		2		

No.	Measured quantity	G		
		.	I (')	II (")
	Then, distance of Venus from Arcturus [Arcturo]	3 2	7	30
	And then Venus was high	3 1	11	0
	And Arcturus high toward the east	3 5	25	0

20. [continued at top of right column: Circa horam vero 9½ — "But around hour 9½"]

[The right column opens with the conclusion of an observation (No. 20), tabulated:]

Measured quantity	G.	I (')	II (")
Around hour 9½ — meridian altitude of Venus seen	4 0	47	0
And the rising altitude of the Sun	1 3	42	0
Soon, distance of Venus seen from the Sun	4 5	32	26

21. Year 1646, on July 9. D. Vincentius Mutus, at Majorca [Maioricae], at hour 15.40', saw Venus minute, nearly 32' distant — or rather, as to part of the latitude — from a star of the Hyades [Hyadum], which to the northern eye [appeared]; and that star was the more southern, as to longitude. But Venus was a little more easterly than the star; and it was near the greatest digression from the Sun.

22. In the same year, the same [observer], in the same place, on July 10, at hour 16, saw Venus the more southern, the more southern [star] in the southern horn of Taurus, and distant from it 31' or 32' in [the] minute[s] [scrup. 31. vel 32].

Observations made by the Fathers of our Society at Ingolstadt, and by me, afterward communicated by Fr. Michael Staudacher [Michaele Standacher].

Anno 1619:		(M		G
Die	Hora	.)	Distance of Venus from:	. I (')
Febr.	(Vesp. — evening)			

Anno 1619: Die	Hora	(M .)	Distance of Venus from:	G . I (')
7	6	35	Algenib·Pegasi	2 27 1
			Markab	1 6 4
10	6	25	Algenib	2 25 9
			Markab	1 34 3
			Venus was high [♀ alta erat]	8 30

Iulij 5	2	0 23	5 37 5 0 7

[A final sub-block, headed "Anno 1620. H. i — Distantia ♀ — G. '", gives Venus's distance from Arcturus and Spica:]

Anno 1620: Iulij (Vesp.)	H (i .)	Distance of Venus from:	G . I (')
3	9 4 5	from Arcturus [ab Arcturo]	5 6 7

Anno 1620: Iulij (Vesp.)	H (i .)	Distance of Venus from:	G . I (')
		from Spica ♀ [à Spica Virginis]	5 24 1
11	9 1 1	Arcturus	5 6 1
		Spica ♀	4 18 3
21	9 0	Arcturus	4 58 4
		Spica ♀	3 42 3
31	8 4 5	Arcturus	4 6 0
		Spica ♀	2 0 5

These pages continue the catalogue of Venus observations within **Liber VIII, "De Venere," Caput VII**, then open **Caput VIII** with the Bologna observations of Riccioli and Grimaldi. They present several observation tables (recorded distances of Venus from fixed stars and its altitudes, by date) followed by a long numbered series of selected Venus observations made at the College of Santa Lucia in Bologna.

[Caput VII, continued — observation tables]

The first table records morning (*Manè*) observations of Venus made in 1620–1621, giving the hour of observation, the reference object from which Venus's distance was measured, and that distance in degrees and minutes.

Date (1620)	H[our]	'	Distance of ♀ [from]	G[r.]	'
Octob. 13	Manè 5	0	from Regulus [à Regulo]	36	1 0
20	5	3 0	from the neck of ♀ [à Cervice ♀] from Regulus [à Regulo]	30 30	5 5 9
			from the tail of ♀ [à Cauda ♀]	18	7

Date (1620)	H[our]	'	Distance of ♀ [from]	G[r.]	'
22	9	5 2	♀ at meridian altitude [♀ altit. Merid.]	40	3
			and distance from ☉ [& dist. à ☉]	34	0
23	9	3 0	♀ at meridian altitude [♀ alt. Merid.]	40	4 0
25	6	8	from Regulus [à Regulo]	31	5 4
			from the tail of ♏ [à Cauda ♏]	17	5 1
			♀ was high [♀ alta erat]	23	2 0
Nouemb. 17	Manè 5	1 5	from Arcturus [ab Arcturo]	30	5 4

Observations made at Innsbruck [Oeniponte] by the Fathers of our Society [à PP. Societ. Nostrae].

This table gives, for 1635–1636, the distance of Venus from a named star (in degrees and minutes) and the altitude of Venus or of a reference star (in degrees and minutes), with morning (*mat.*) or evening (*vesp.*) noted.

Date (1635)	Distance of ♀ from [A.]	G r . ' Altitude	G r . '
Octob. 5	Regulus [Regulo]	3 5 ♀ 1 8	9 5 ma 1 t.
	Jupiter [Jove]	2 3 Canicula 9 4	4 3 ma 7 2 t.
(1636) Mart. 23	Aldebaran [Aldebara]	3 5 ♀ 5 9	1 8 ves 4 p.
	Lucida Arietis [Ariet. Luc.]	1 2 bright star of the 0 9 shoulder of Orion [Hum. luc. Or.]	4 2 4
Martij 31	Aldebaran [Aldebara]	2 3 ♀ 5 3	1 1 ves 6 2 p.

Date (1635)	Distance of ♀ from [A.]	G r . ' Altitude	G r . '

CAPUT VIII.

Selected Venus observations, out of many carried out at Bologna in the College of Santa Lucia, by the Fathers Giovanni Battista Riccioli [Ioan. Bapt. Ricciolio] and Francesco Maria Grimaldi [Franc. Maria Grimaldo] of the Society of Jesus.

With some observations of the most illustrious Marquis Cornelio Malvasia [Cornelij Malvasiae] added.

1. In the year 1642, on September 23, in the evening, when Arcturus was high, distant $27^{\circ} 33'$ from the west, Venus was observed by means of the sextant [per Sextantem] to be $36 \frac{1}{3}^{\circ}$ distant from that same Arcturus. When Venus had descended to an altitude of $4^{\circ} 8'$, it was distant from the bright star of the Northern Crown [lucida Coronae] $44^{\circ} 52'$.
2. In the same year, on November 30, in the evening, 10 minutes before the transit of Fomalhaut [Fomahant] across the meridian thread [per M.C. — *per meridianam chordam*], Venus was seen to be distant from Fomalhaut $37^{\circ} 13'$; and after three minutes and 10 seconds it was distant from Saturn $52^{\circ} 24'$.

3. Likewise in the year 1642, on July 21, in the evening, Venus had been high above the western horizon, apparently at $7^{\circ} 56'$; then, up to the transit of the Heart of the Scorpion [cordis Scorpij — Antares] across the meridian thread, 9 minutes 58 seconds were counted.
4. But on the 25th of the same month, in the evening, Venus was seen to be high at an altitude of $7^{\circ} 11'$, in the western azimuth of $104^{\circ} 33'$; from there, up to the transit of Antares across the meridian thread, there were counted $26' 40''$.
5. In the year 1642, on August 4, in the evening, Venus was visibly high at $7^{\circ} 1\frac{1}{2}'$, in the western azimuth at $98^{\circ} 50\frac{1}{2}'$; from there, up to the transit of the head of Ophiuchus [capitis Ophiuchi] across the meridian thread [per M.C.], $36' 42''$ were counted.
6. But on the twelfth of August [duodecima Augusti], when Venus was seen to be high at $7^{\circ} 59'$, it was observed in the western azimuth at $93^{\circ} 8'$; from there, up to the transit of the topmost star in the shoulder of Ophiuchus [supremae in humero Ophiuchi], $16' 52''$ were counted.

Here, so that the order of time may be preserved, the first observation ought to be inserted, and the second set aside until after the one that follows.

7. In the year 1642, on October 21, in the following evening, Venus was distant from Arcturus $59^{\circ} 11'$; and when $5' 15''$ had elapsed it was distant from the bright star of the Northern Crown [lucida Coronae] $55^{\circ} 24'$. Then, 10 minutes later, the western altitude of Aquila was taken at $63^{\circ} 11'$.
8. In the year 1643, on January 10, in the evening, half an hour after true sunset, Venus was seen to be distant from Jupiter $14^{\circ} 11'$; and after 6 minutes of time, distant from Saturn $19^{\circ} 21'$. And after 11 minutes it was distant from the bright star of the tail of Cetus [lucida caudae Ceti] $33^{\circ} 44'$; and after $5' 50''$ — for observations of other planets had intervened in those moments of time — at length, after 5 minutes, it was seen to be distant from the breast of Cetus [pectore Ceti] $56^{\circ} 25'$.
9. Likewise in the year 1643, on January 20, in the following night, Venus was seen to be high above the western horizon at $23^{\circ} 32'$; from there, after $19' 32''$, the rising altitude of Aldebaran was $48^{\circ} 30'$.
10. In the year 1643, on March 8, in the morning, nearly half an hour before sunrise, Venus appeared distant from the bright star of Aquila [lucida

Aquilae] $31^{\circ} 13 \frac{2}{3}'$. Then, 25 minutes before sunrise, when it was seen to be high, it was distant from the tail of Cygnus [Cygni cauda] $53^{\circ} 14'$; but at that very moment of physical sunrise it was observed to be distant from the center of the Sun $37^{\circ} 37'$.

11. But in the same year, on the 12th day of the same month, in the morning, about an hour before sunrise — that is, when the bright star of Aquila was high at $41^{\circ} 27'$ — Venus was seen to be high at $11^{\circ} 54'$; and it was distant from the tail of Cygnus $53^{\circ} 58'$. At that very moment, when the bright star of Aquila was high at 42° , Venus was high at $13^{\circ} 33'$; it appeared distant from that same bright star of Aquila $31^{\circ} 37'$.
12. In the year 1643, on May 19, in the morning, before the Sun's altitude, Venus was seen at $1^{\circ} 43'$; observed [to be distant] from Jupiter, and when $4^{\circ} 20''$ [recte: $4^{\circ} 20''$] had elapsed it was high at $17^{\circ} 5'$; and its eastern azimuth was $76^{\circ} 22'$.
13. But on the 21st, in the morning, the eastern altitude of the bright star of Aquila was taken at $53^{\circ} 24'$; and after $20^{\circ} 30'$ the eastern altitude of Venus was observed to be $14^{\circ} 20 \frac{1}{3}'$ in the azimuth of $80^{\circ} 1'$; and a little later Venus appeared more southerly in the same vertical [circle] as Jupiter.
14. In the year 1643, on July 15, in the morning, the rising altitude of the bright star of Aries [lucidae Arietis] was taken at $46^{\circ} 50'$; then, when 15 minutes had elapsed, Venus was seen to be high at $14^{\circ} 22'$, distant from the bright star of Aries $46^{\circ} 2'$. Then, when 5 minutes of time had elapsed, it was seen to be high at $15^{\circ} 50'$ and distant from Aldebaran $13^{\circ} 25'$. At last, after a [further] interval of time, Venus was seen to be high at $18^{\circ} 48'$ and at that moment distant from Jupiter $57^{\circ} 58 \frac{2}{3}'$.
15. In the year 1643, on June 21, in the morning, the observed altitude of the Sun was $7^{\circ} 49 \frac{2}{3}'$ in the same eastern azimuth; the eastern azimuth was $114^{\circ} 14'$; the observed altitude of Venus had been $14^{\circ} 20 \frac{1}{3}'$ [recte: see note], and at the same moment its altitude was $92^{\circ} 47'$ [recte: see note].
16. In the same year, and month, on the 28th day, in the morning, the altitude of the bright star of Aquila was taken at $46^{\circ} 2'$; toward the west, $28'$ were counted; afterward the altitude of Venus was seen [to be] easterly at $14^{\circ} 38'$, and its distance from Saturn $50^{\circ} 16'$. Then, after $6^{\circ} \frac{1}{4}$, it was seen to be distant from Jupiter $36^{\circ} 7'$, when it would appear high at 16° .

17. In the year 1643, on July 30, in the morning, half an hour after the rising altitude of the bright star of Aries [had been taken] at $58^{\circ} 22'$, Venus was seen to be high above the east at $17^{\circ} 15'$; and at the same moment distant from Aldebaran $30^{\circ} 53'$. And after two minutes of time it was seen to be high at $18^{\circ} 20'$, distant from Regel of Orion [Regel Orionis — Rigel] $42^{\circ} 41\frac{1}{2}'$; high then at $11^{\circ} 50'$. Then, after 12 minutes, it was seen to be high at $19^{\circ} 40'$, and distant from Capella $29^{\circ} 38'$, when Capella was high at $48^{\circ} 22'$. At length, after 28', it was seen, or at any rate appeared, to be in altitude $26^{\circ} 4'$, distant from the center of the Sun exactly at $30^{\circ} 50'$.
18. In the year 1643, on August 11, in the morning, the rising altitude of Aldebaran was taken at $47^{\circ} 55'$; and after 24 minutes, Venus was seen to be high at 19° , observed [to be] distant from the bright star of the shoulder of Orion [humero lucido Orionis] $30^{\circ} 10\frac{1}{3}'$; and after 7 minutes of time it was distant from Aldebaran $45^{\circ} 12\frac{1}{2}'$, iterated in the customary manner of observations.
19. In the same year, in the month of August, on the 31st, in the morning, Aldebaran was observed [to be] elevated $53^{\circ} 9'$ from its rising; and when 15 minutes had elapsed, Venus was seen [to be] elevated above the horizon $17^{\circ} 52'$, and then distant from Sirius $44^{\circ} 53'$; high at $10^{\circ} 34'$. Then, after three minutes, Venus was seen to be high at $18^{\circ} 40'$; and distant from Regel [Rigel] $56^{\circ} 50'$, high at $29^{\circ} 15'$.
20. Likewise in the year 1643, on August 31, in the morning, Aldebaran, easterly, was distant from the zenith [à vertice] $34^{\circ} 10'$; and from there, after 26 minutes, Venus appeared, distant [from its] rising at $34^{\circ} 14'$, distant from the bright star of the shoulder of Orion [lucido humero Orionis] $25^{\circ} 24'$; high at $14^{\circ} 20'$; and from Procyon distant $28^{\circ} 23'$.
21. In the year 1643, on May 7, in the morning of the following day, Procyon was distant from the zenith $58^{\circ} 58'$; Venus was seen [to be] distant from the zenith $64^{\circ} 1'$; and from Capella $22^{\circ} 16'$ — for they observed these distinctly at the same moment. Then, counting $5^{\circ} 40''$ [recte: $5' 40''$], Venus's distance from the zenith was 65° precisely; its distance from Procyon, on that same day, was $31^{\circ} 32\frac{1}{3}'$; and again, from Capella, distant from the zenith $60^{\circ} 50'$. There were four observers.
22. In the same year, on the 12th, in the evening, high, Regulus was at the zenith [recte: see note] $30^{\circ} 30'$; Venus high at $22^{\circ} 4'$; and [Venus] distant from Regulus $19^{\circ} 26'$; high then [with] Regulus high at $28^{\circ} 55'$, Venus high at

20° 14'; and distant from the bright star of the tail of Leo [lucida caudae Leonis] 41° 57'.

23. In the year 1644, on June 18, in the evening, high, Regulus was at 25° 1'; Venus was seen high at 19° 54'; and [distant] from Regulus high at 12° 57 ½'; high then [with] Regulus high at 23° 27'; and [Venus] distant from the tail of Leo 35° 49'.

24. In the year 1644, on the 23rd of June, in the evening, high, Regulus was at 21° 40'; Venus was seen high at 19° 10'; and [distant from] Regulus high at 7° 42'; high then [with] Regulus high at 20° 38'; [Venus] high then at 18° 2'; and [distant] from the tail of Leo high at 30° 54'.

25. In the year 1644, on June 29, in the evening, high, Regulus was at 17° 10'; Venus was seen high at 17° 20'; and [distant] from Regulus high at 15° 58'; high then [with] Regulus high at 16° 9'; and [distant] from the tail of Leo high at 24° 32'.

26. In the year 1644, on July 1, in the morning, Regulus was high at 17° 14'; Venus was seen high at 18° 21'; and [Venus] distant from Spica of the Virgin [Spica Virginis] 53° 50'; high then afterward [with] Regulus high at 16° 26'; Venus was seen [to be] elevated at 17° 20'; and distant from the tail of Leo 23° 40'.

27. On the following day, July 2, in the evening, high, Spica was at 28° 42'; [Venus] high at 17° 2'; and distant from Spica high at 52° 20'; then high, Spica [at] 27° 53'; Venus was seen high at 15°; and distant from the tail of Leo 22° 46'.

These following observations were carried out by the same method.

The table below records, for July 1644, the day; the observed altitude of Venus [Alt. visa ♀] in degrees and minutes; the altitude of Spica [Alt. Spicae] in degrees and minutes; and the observed distance of Venus from [named] stars [Dist. visa ♀ à Stellis] in degrees and minutes.

40. In the year 1644, on November 11, in the morning, Procyon was distant from the zenith $41^{\circ} 25'$; and after 6 minutes of time the observed altitude of Venus was easterly, and its distance from Regulus $38^{\circ} 57'$. But after a

minute and a half it was distant from Arcturus $33^{\circ} 34 \frac{1}{2}'$; and after 4 minutes it was distant from the bright star of Hydra [*lucida Hydrae*] $46^{\circ} 37'$.

41. In the year 1644, on November 21, in the morning, Regulus was distant from the zenith toward the west $31^{\circ} 11'$; and after 6 minutes Venus was high at 31° distant; from Arcturus $29^{\circ} 54 \frac{1}{3}'$; and after a further 6 minutes Venus was high at $31^{\circ} 33'$, distant from Regulus $48^{\circ} 5'$.
42. In the same year, on November 26, in the morning, Arcturus, easterly, was taken at a distance from the zenith of $49^{\circ} 50'$; from there, after 5 minutes of time, the altitude of Venus was $28^{\circ} 59'$; its distance from Arcturus $28^{\circ} 59'$ [recte: see note]. Then, after 5 minutes of time, the altitude of Venus was $29^{\circ} 12'$, and its distance from Regulus, westerly, $52^{\circ} 58'$.
43. In the year 1644, on November 29, in the morning, the rising distance of Arcturus from the zenith was $51^{\circ} 1'$; and after a further minute and a half the rising altitude of Venus was $25^{\circ} 12'$; its distance from Arcturus $25^{\circ} 12'$ [recte: see note]; then, after 1 minute, it was seen [to be] distant from Regulus $56^{\circ} 1' 50''$; and after a further minute it was distant from Spica $4^{\circ} 30'$ [recte: $24^{\circ} 30'$ — see note].
44. In the year 1644, on December 4, Arcturus was distant from the zenith $45^{\circ} 25'$; and after 2 minutes Venus was seen [to be] high at $25^{\circ} 35'$; its distance from Arcturus $29^{\circ} 14'$. Then, at the [next] Italian hour [*hora Italica civili*] 13', Venus was seen high at $27^{\circ} 10'$, distant from Spica $38^{\circ} 24'$.
45. In the year 1645, on February 4, the distance of Venus from the zenith toward the west was taken at $49^{\circ} 50' \frac{1}{4}$; in the azimuth of whose vertical [circle] the bright foot of Orion [*pes lucidus Orionis*] was carried; it was seen to be distant from the zenith $60^{\circ} 59'$; in the eastern azimuth of which Venus was [observed]. Then, after the observation of Venus, $46^{\circ} 17' \frac{1}{4}$ ran out [effluxerunt]; in whose [interval], at the end, the distance of the right shoulder of Orion [*dexter humerus Orionis*] from the zenith was $51^{\circ} 56'$. Then, when $3' 25''$ had elapsed, after the distance of Procyon [had been measured] distant from the zenith $44^{\circ} 44'$, Venus was seen to be distant from the zenith $83^{\circ} 26'$.
46. In the same year, on February 6, Venus was in the same azimuth as in the preceding observation, seen [to be] distant from the zenith $48^{\circ} 43'$; from there, 5 minutes were counted, when the time of twilight, ceasing, hindered [further observation]; afterward the distance of the right shoulder of Orion

from the zenith was $50^{\circ} 15'$. Then again the distance of Venus, westerly, was $48^{\circ} 40'$; and after a lesser time-interval Procyon was distant from the rising $40^{\circ} 55'$.

47. In the year 1646, on February 12, Venus was observed [to be] distant from the zenith $46^{\circ} 58'$; in whose vertical [circle], up to the plane of which the right shoulder of Orion was expected, [it] was distant from the zenith $46^{\circ} 50' \frac{1}{2}$. After the observation of evening Venus, $39' 15''$ of time were counted; and immediately Regel [Rigel] was distant from the zenith $55^{\circ} 20'$ in the eastern quadrant; Venus, moreover, was nearest to its greatest digression [vicina maximae digressioni].
48. In the year 1646, on February 25, evening Venus was seen [to be] distant from the zenith $47^{\circ} 15'$; in the azimuth of that vertical [circle], down to whose plane the right shoulder of Orion slipped, it was distant from the zenith $52^{\circ} 50' 15''$. From the observation of Venus, moreover, $47' 45''$ were counted; Procyon, in the eastern quadrant, was distant from the zenith $50^{\circ} 15'$.
49. In the year 1646, on July 4, in the morning, the distance of Venus from the zenith was seen [to be] $64^{\circ} 54'$; and its eastern azimuth [was] $88^{\circ} 4'$; from there, up to the observed altitude of the Sun, $17' 50''$ ran out in minutes [recte: see note] $34'$.
50. In the same year, on July 7, in the morning, with Capella distant from the zenith $62^{\circ} 10'$, Venus was seen [to be] distant from the bright side of Perseus [lucido latere Persei] $33^{\circ} 30'$; Capella, moreover, being distant from the zenith $61^{\circ} 36'$; observed in the same morning, at the same moment at which Venus was in the eastern azimuth $91^{\circ} 56'$, it was seen [to be] distant from the zenith $64^{\circ} 2'$; observed, moreover, in minutes [numerata sunt min.] $34' 26''$; the altitude of the now-risen Sun was seen [to be] $3^{\circ} 10' \frac{2}{3}$.
51. In the year 1646, on July 9, in the morning, with Capella observed [to be] distant from the zenith 62° , Venus was seen [to be] distant from the bright side of Perseus $33^{\circ} 39'$; Capella, moreover, being distant from the zenith $61^{\circ} 33'$, Venus was seen [to be] distant from Capella itself $30^{\circ} 23'$; from the zenith, moreover, about 66° ; Capella, moreover, distant from the zenith $58^{\circ} 19'$; thence $18' 56''$ were counted; and up to the transit of Venus across azimuth $88^{\circ} 8'$, in which Venus was distant from the zenith $63^{\circ} 27'$; about which time the greatest digression of Venus was occurring.

52. In the same year, on July 11, in the morning, with Capella distant from the zenith $69^{\circ} 50'$, Venus was seen [to be] distant from the zenith $33^{\circ} 53' \frac{1}{2}$; and from the bright side of Perseus $33^{\circ} 53' \frac{1}{2}$; and a little after, distant from Capella itself $58^{\circ} 43'$; Venus, moreover, was seen [to be] distant from the zenith $29^{\circ} 30'$; from the zenith, moreover, $68^{\circ} 40'$. Besides, after the distance of Capra [Capella] from the zenith $56^{\circ} 18'$, $16' 13''$ were counted; at the end of which Venus was seen [to be] distant from the zenith $62^{\circ} 40'$; in the azimuth $88^{\circ} 10'$.
53. In the year 1647, on April 23, in the evening, Venus was seen [to be] high at $6^{\circ} 24'$; and distant from the following shoulder of Orion [humero sequenti Orionis] $36^{\circ} 56'$. Then, when Venus would be seen high at $5^{\circ} 28'$, it was seen [to be] distant from the head of Pollux [capite Pollucis] $58^{\circ} 27' \frac{1}{2}$; immediately Capella was distant from the zenith $51^{\circ} 6'$.
54. In the year 1647, on May 16, in the evening, three days [after] sunset [post Solis occasum — recte: see note], in the quadrants Venus was seen [to be] high at $9^{\circ} 40'$; and distant from Procyon $47^{\circ} 17' \frac{1}{2}$; when Venus would be seen high at $9^{\circ} 5'$, it would appear distant from the head of Pollux $41^{\circ} 40'$.
55. In the same year, on June 11, in the evening, Venus was observed [to be] high at $12^{\circ} 14'$, distant from Regulus $45^{\circ} 5'$. Then, when it would appear high at $11^{\circ} 10'$, it was seen [to be] distant from the Heart of Hydra [corde Hydrae] $47^{\circ} 50'$; high then at $10^{\circ} 42'$, it was seen [to be] distant from the bright mane of Leo [lucida juba Leonis] $44^{\circ} 59'$. The observation lasted 20 minutes; at whose end Regulus, westerly, was distant from the zenith $54^{\circ} 45'$; and almost the whole hour, a quarter [hour] before sunset.
56. In the year 1649, on April 24, in the evening, Venus was observed [to be] in the plane of the Triangle of the [Polish] Filaris [Trianguli Filaris — see note] at the zenith $59^{\circ} 41' \frac{1}{3}$; and the dwelling [recte: it was distant — *distabat*] $1^{\circ} 15''$; Procyon was distant from the zenith $53^{\circ} 53' \frac{1}{3}$; then a vertical [circle] was awaited, the plane of which would be Venus, where the northern head of the Twins [Borealius caput Geminor.] had been, which in it was distant from the zenith $49^{\circ} 4'$.
57. In the same year, on May 3, in the evening, Venus, transiting through the plane of the Triangle of the Filaris [marking out its] vertical, was seen [to be] distant from the zenith $56^{\circ} 55'$; and after 3 minutes Procyon [was] distant from the zenith $56^{\circ} 54' \frac{1}{2}$; thence the northern head of the Crab

[Boreale caput ♄] transiting through the said plane of the Triangle was distant from the zenith $47^{\circ} 8'$.

58. In the same year, on May 4, when Venus would be seen [to be] high almost at [its] half [fere ad dimidium], it was distant from the zenith $18^{\circ} 49' \frac{1}{3}$; immediately Procyon was distant from the zenith $28^{\circ} 32'$; iterated in the customary manner of observations; and almost the whole hour, a quarter [hour] after sunset.

59. In the year 1649, on June 25, in the evening, although [observed] with the naked eye too [cum oculo quoque nudo], Venus could not be seen to be crescent-shaped [falcata], on account of clouds. But on July 25, in the morning, the altitude of Venus was $7^{\circ} 8'$; its distance from Capella $35^{\circ} 34'$; high then, Venus [at] $7^{\circ} 46'$; seen distant from Aldebaran $32^{\circ} 30' \frac{1}{2}$ in the brightest dawn, tending toward direct motion [ad Directionem].

60. In the same year, on July 27 in the morning, Venus appeared at an altitude of [gr.] $9^{\circ} 10'$, and [its] distance from Capella was $35^{\circ} 24'$. When [next] observed, it stood at an altitude of $10^{\circ} 10'$, and appeared to be distant from Aldebaran [gr.] $32^{\circ} 15'$.

61. On the following morning, however, Venus passed across the vertical plane of the filar triangle [Triangulum Filare], in which it was seen at an altitude of [grad.] $18^{\circ} 7'$; and afterwards in the same [plane] the center of the Sun was seen at an altitude of [grad.] $21^{\circ} 18' \frac{1}{2}$. After Venus had been observed, the Sun's observed altitude up to [grad.] $5^{\circ} 53'$ was reached, and the elapsed time was counted as [min.] $40' 8''$.

62. In the year 1649, on July 30, in the morning, when Venus was seen at an altitude of [gr.] $13^{\circ} 37'$, it was seen to be distant from Capella [gr.] $35^{\circ} 21'$; and at a [more] readily visible [altitude] of [grad.] $14^{\circ} 10'$, it was seen to be distant from Aldebaran [gr.] $32^{\circ} 13'$.

63. On the next morning, again, Venus was seen at an altitude of [gr.] $13^{\circ} 37'$, and distant from Aldebaran [gr.] $32^{\circ} 17'$. But at an altitude of [grad.] $14^{\circ} 17'$, it was seen to be distant from Capella [gr.] $35^{\circ} 22'$.

64. In the year 1649, on August 3, in the morning, Venus was seen at an altitude of [gr.] $15^{\circ} 20'$, and distant from Aldebaran [gr.] $32^{\circ} 38'$; and at an altitude of [grad.] $15^{\circ} 50'$, it was seen to be distant from Capella [gr.] $35^{\circ} 30'$.

65. On the following morning, again, Venus was seen at an altitude of [gr.] 18°, and distant from Aldebaran [gr.] 32°48'; and at an altitude of [gr.] 18°34', it was seen to be distant from Capella [gr.] 35°34'.

66. In the year 1651, on February 10, in the evening, Venus was seen at an altitude of [gr.] 4°30'; then after [min.] 7½, Sirius was seen at an altitude of [gr.] 75°11'. Now the western azimuth of Venus had been [gradum] 79°17¼, because in the plane of that vertical [circle lay] the Bright Star of Aries [Lucida Arietis = α Arietis]; afterwards [Venus], having been observed, was distant from the vertex [gr.] 47°55'. From this it was then deduced that Venus's place was in Aquarius [gr.] 28°4', with a northern latitude of [grad.] 8°4'. This was at the hour, that is, [min.] 5'34" after midday. It is therefore no wonder if then, and on that day too — the twelfth, although close to conjunction with the Sun (as the line drawn from horn to horn of Venus, very nearly following the longitude of the ecliptic, indicated) — on account of so great a latitude, [Venus] was conspicuous to us, and that not only with a telescope but also with the naked eye, even to those gazing at it.

67. In the year 1652, on May 29, evening Venus was seen at an altitude of [gr.] 24°57', and distant from Saturn, which was more easterly, [gr.] 5°27'; but at an altitude of [gr.] 24°30', it was seen to be distant from the head of Pollux, which was more westerly than Venus itself, [gr.] 4°45'. A little afterward, this [Venus] was seen at an altitude of [gr.] 20°25', and distant from the mane of Leo [iuba Leonis] [gr.] 34°39'; then at an altitude of [gr.] 19°52', it was seen to be distant from Regulus [gr.] 34°32'. And at that time Pollux was at an altitude of [gr.] 21°.

In the year 1652, the remaining observations of evening Venus around the hour of 8 p.m. are as follows.

Month / Day	Observed Alt. ♀ Gr.	MObserved Dist. ♀ . Gr.	M . [Reference star]
6 June	2 15	5 58	2 from Spica
8	6	2	5

From the observations made on July 6, around the hour of 8 p.m., and from the fixed stars, on the assumptions laid down in the first volume of the *Almagestum Novum*, the longitude of Venus came out at Virgo [gr.] $0^{\circ}30'1\frac{1}{2}$, with a northern latitude of [gr.] $0^{\circ}43'$.

76. In the year 1652, on August 6, in the evening, [in] the vertical of the filar triangle, marking out the vertical line directly into the center of Venus, the distance of Venus was taken on a direct plane at [gr.] $7^{\circ}8'46''[?]\frac{1}{2}$; and to this, after the counted minutes [had been] added, Arcturus reached [gr.] $9^{\circ}55'$; from which Arcturus was distant from the vertex [gr.] $47^{\circ}35'$.

77. In the year 1652, on November 19, in the morning, at about the 6th hour, Italian reckoning, the tail of Leo [cauda ♀ = Denebola] was taken at a distance from the vertex [gr.] 12° , and just over [min.] $6'$. At its rising at [gr.] $42^{\circ}10'$, then

after [min.] 1', Venus was seen to be distant from the more easterly Arcturus [grad.] $30^{\circ}27'$; and after [min.] 4', [it was] distant from the heart of Hydra [Cor Hydrae = Alphard], which was more westerly, [gr.] $52^{\circ}52'$.

78. In the year 1653, on February 2, in the morning, Venus was seen to be distant from the bright star of Aquila [lucida Aquilae = Altair] [gr.] $34^{\circ}30\frac{1}{4}'$; and from the vertex [gr.] $79^{\circ}23'$. Aquila, moreover, [was] distant from the vertex [gr.] $66^{\circ}20'$; then Venus was seen to be distant from Antares [gr.] $31^{\circ}10'$; and from the vertex [gr.] $78^{\circ}46'$. Antares, moreover, [was] distant from the vertex [gr.] 71° .

79. In the same year, on December 19, in the evening, at the hour of Aquila, its altitude was reckoned at [gr.] $4^{\circ}37\frac{1}{2}'$ after midday. Venus, near the eccentric perigee [Perigeum Excentrici], in a western azimuth of precisely [gr.] 25° , was seen to be distant from the vertex [gr.] $66^{\circ}55\frac{1}{2}'$. From this was then deduced the right ascension [Ascensio Recta] of Venus, [gr.] $317^{\circ}31'$; and the southern declination [Declinatio Australis], [gr.] $18^{\circ}43'$.

80. In the year 1654, on February 16, in the evening, Venus, tending toward and expecting its maximum digression, in an azimuth of [gradum] 55° , was seen to be distant from the vertex [gr.] $50^{\circ}1'$; and after [min.] $16'45''$, it was seen to be distant from the vertex [gr.] $71^{\circ}18'$.

81. On the following evening, again, Venus, in an azimuth of [graduum] 55° , was seen to be distant from the vertex [gr.] $49^{\circ}46'$; and after [min.] $25'36''$, Sirius was seen to be distant from the vertex [gr.] $69^{\circ}55\frac{1}{2}'$.

82. In the year 1654, on March 16, Venus was expected at the western azimuth of [graduum] 80° . It was seen to be distant from the vertex [gr.] $52^{\circ}50\frac{1}{2}'$. Then afterward, eastern Regulus [Regulus orientalis] was distant from the vertex [gr.] $53^{\circ}59'$.

83. In the year 1654, on April 5, evening Venus, in a western azimuth of [gr.] 95° , was seen to be distant from the vertex [gr.] $61^{\circ}55'$; and after midnight, on the 13th, [at] $56'$, Venus was seen to be distant from the vertex [gr.] $73^{\circ}14'$. Regel [Rigel] indeed [was] distant from the vertex [gr.] $47^{\circ}19'$; and soon afterward, [from] Aldebaran [gr.] $45^{\circ}47'$.

84. In the year 1654, on August 9, in the morning, when Aldebaran was distant from the eastern vertex [gr.] $46^{\circ}22'$, Venus was distant from the eastern vertex [gr.] $63^{\circ}40'$; in the northeastern azimuth of precisely [gradum] 85° .

85. In the year 1654, on August 14, in the morning, near the Italian hour 9, distant from the following shoulder of Orion [humero seq. Orionis = Betelgeuse] by [gr.]

62°54' from the vertex of its rising, Venus was seen to be distant from the vertex [gr.] 73°14'. Regel [Rigel] indeed [was] distant from the vertex [gr.] 47°19'; and soon afterward, [from] Aldebaran [gr.] 45°47'.

86. In the year 1655, on July 6, evening Venus was seen to be distant from the vertex [gr.] 76°39'; in a western azimuth of [graduum] 100°. And because the [rising] from the bright star [of Leo] had been expected by design, the distance of its rising from the bright star [lucida = Regulus] was [gr.] 64°33'.

87. In the same year, on July 10, evening, the distance [of Venus] from the vertex was [gr.] 79°, precisely in azimuth [graduum] 100°. From there, counting 10 minutes of time, Spica was distant from the vertex more to the west [gr.] 66°.

88. Likewise, in the year 1655, on August 6, in the evening, Venus, expected at the western azimuth of [gr.] 80°, was seen to be distant from the vertex [grad.] 77°53'; from there, after [min.] 7'45", western Arcturus [Arcturus occidentalis] was distant from the vertex [gr.] 42°54'.

89. In the year 1656, on January 8, in the morning, Venus was seen distant from the vertex [grad.] 74°; and from Spica [gr.] 47°35'; and at the same time, in the middle of the forehead of Scorpius, [from] Ophiuchus [gr.] 32°48'; and it was seen to be distant from the vertex [gr.] 72°34'.

90. In the same year, on February 10, in the morning, Venus was distant [from the vertex gr.] 72°36'; in that azimuth in which the center of the Sun was afterward seen to be distant from the vertex [gr.] 66°18'. But before, an hour and 24' before the observation of Venus had been taken, the distance of the Sun from the vertex had been [gr.] 82°44'.

91. In the year 1657, on March 18, in the evening, the distance of Venus from the vertex was [gr.] 57°27½'; and after [min.] 4'18", Aldebaran [was distant] from the vertex [gr.] 41°3½'; while when Aldebaran reached the vertical plane in which Venus had been observed, Venus was distant from Aldebaran itself [gr.] 58°17'.

92. In the year 1657, on June 9, evening, Venus was distant from the vertex [gr.] 64°50'; and from Regulus [gr.] 33°43¾. Then Venus was seen to be distant from the vertex [gr.] 76°20'; and from the head of Castor [gr.] 10°39⅓; and at that time Regulus was distant from the vertex toward its setting [gr.] 59°10'.

93. In the same year, on June 13, Venus was seen distant from the vertex [gr.] 77°48'; and from Regulus [gr.] 33°23'; afterward [it was] seen distant from the vertex [gr.] 80°; and from the head of Pollux [gr.] 6°58½'; and at once Regulus was distant from the vertex [gr.] 66°6'.

Observation of the Most Illustrious Marquis Cornelio Malvasia [Cornelio Malvasia], made at Modena, and set out in his own Ephemerides, fol. 217.

In the year 1662, on May 31, Venus was observed at a distance from the Sun of [gr.] 39°25', [on] another [reckoning gr.] 39°3' by computed parallaxes; and by the Cassini refractions it was [gr.] 39°34'; but by Lansbergen's [Philippus Lansbergius / Philips van Lansbergen] calculation it [came out] from [gr.] 38°48'. The difference is 46 minutes.

CAPVT IX.

De Hypothesi motuum Veneris. — On the Hypothesis of the Motions of Venus.

1. Here I assume to have been laid out — or to be read through by the reader — what I explained at length concerning the hypotheses of the various astronomers regarding the motion of Venus and of Mercury in *[Almagestum Novum]* Book 7. Many things, too, that were treated here in Book 5 on the occasion of Saturn must be applied to these inferior planets: namely, what I said in Chapter 9 about the 20 ways of observing the places of the planets; what I gave in Chapter 12 on

reconciling the geometric hypothesis — rather a spiral one — of the diurnal [motion] with the planet's own [motion], in a fluid aether. As for the motion of the Earth, I showed at the end of Book 1 that it cannot be maintained — or rather, [I showed] which [hypothesis] comes closer to the truth, whether [the motion is achieved] through eccentric circles and epicycles, or through a single ellipse, granting that this comes nearer to the truth. The rest, if there is any, I indicate briefly in this place.

2. From what was said in Book 1 on the parallax of the Sun, it is clear that Tycho [Tycho Brahe] posited it far greater [than it is], as Longomontanus [Christian Sørensen Longomontanus] noted in Book 2 of the *Theorica*, at Chapter 17; and as the restitution of the parallax of Venus and Mercury, [based] on the Tychonic [parallax] of the Sun, stands in need of some refinement. He excuses himself, moreover, [on the grounds] that, because of the obliquity of the sphere in the Danish horizon, it was not permitted to continue the observations of the greatest elongation of Venus from the Sun, the twilight getting in the way; and therefore, besides the 9 Tychonic observations of Venus, he procured 6 others, [as treated] in Chapter 19, [drawn] from Ptolemy [Ptolemaeus] in the greatest digressions.

3. [Margin: *Kepleri sincerus timor in motu ♀* — Kepler's sincere fear concerning the motion of Venus.] Kepler [Iohannes Keplerus = Johannes Kepler] ingenuously, in the foundation of his Ephemerides, pages 14 and 15, admits that an error of up to 15 minutes may be feared in the Rudolphine [Tables] for Venus's computations — [tables] which sometimes run out to almost a quarter of a degree; this because they rely on observations of the Sun, of refractions, and of parallaxes that, on account of the proximity to the Sun, are suspected to be in some [way] fallacious. He exhibits, moreover, a specimen of these [computations], taking up the example of Maestlin [Michael Mästlin], who in the year 1574, on September 16, in the morning at the 4th hour, saw Regulus covered by Venus; then, however, the Rudolphine [Tables] exhibit the Heart of Leo [Cor Leonis = Regulus] in Leo at [gr.] $23^{\circ}54'39''$, with a northern latitude of [gr.] $0^{\circ}26'$; whereas Venus [stood] in Leo at [gr.] $23^{\circ}55'$, with a northern latitude of [gr.] $0^{\circ}25'$. The Lansbergian Tables, however, cannot be trusted so [much] in this matter. [Margin: *Lambergij infida methodus* — Lansbergen's unreliable method.]

For this star [Regulus], more than from the [usual] treasury of his observations, [Lansbergen] brings forward [his result], because he does not everywhere treat it faithfully enough — let the example be in the conjunction of Venus with Regulus, which we mentioned a little before from Maestlin's observation. For Lansbergen, on page 173 of his Tables, finds Venus then in Leo at [gr.] $24^{\circ}9'3''$, with a northern

latitude of [gr.] $0^{\circ}20'$. He does not doubt the Rudolphine [place], beyond the Tyconic place by 14'; minutes, and a latitude [differing] by 5'; and he, however, places it in Leo at [gr.] $24^{\circ}7'$, with a northern latitude of [gr.] $0^{\circ}31'$. This, therefore, having been dismissed, he goes over willingly to Boulliau [Bullialdus = Ismaël Boulliau].

5. For Boulliau, in Book 9 of his *Astronomia Philolaica*, deeply weighing several observations faithfully recorded by his predecessors, acknowledges that something must indeed be advanced [for] the mean motion of Venus in the Rudolphine [Tables], but the aphelion [Aphelium] must not be drawn back, as they draw it back. He prudently advises, moreover, that the conjunctions of Venus with other stars, observed with the naked eye, are not to be understood so precisely, because Venus, by the greatest expansion of its rays, very often obscures that small interval [of separation] which really lies between it and the neighboring stars. Yet Malvasia, using Boulliau's [reckoning] of Venus's parallax, [arrives at] a smaller [one], because [it comes] indeed from the false parallax of the Sun, and the parallax up to [min.] 3' rises [too high].

6. We — as with the other planets, [adding] tables to several observations — for the most part made very many comparisons of Venus with the fixed stars, or with other planets; and indeed more than [we made of] those places of Venus which Tycho or Longomontanus drew from the greatest digressions from the Sun, [based] on the false parallax of the Sun, and the parallax of Venus, and the obliquity of the ecliptic — whence they disagree from the Tables not rarely by 6 or 8 minutes or thereabouts. And here we set before [the reader] some specimen of our own Tables.

1. In the year 1494, on September 18, at the 17th hour after midday, at Nuremberg [Norimberga], Bernhard Walther [Bernardus Vualtherus] saw Venus more westerly than Regulus by 10 minutes. Lansbergen, to extort this observation from his Tables, does not doubt to place Regulus then in Leo at [grad.] $23^{\circ}19'$, that is, 34' beyond what is due; collect it, [for] the place [is given] from his Tables in Leo at [gr.] $23^{\circ}20'$. But Regulus was really in Leo at [gr.] $22^{\circ}44'35''$. Venus, however, [stood] from our Tables in Leo at [gr.] $22^{\circ}45'$. I think that, on account of Venus's great latitude, it was seen by Walther more to the west.

2. [Margin: *Lambergij dolus* — Lansbergen's trickery.] In the year 1574 — as Kepler relates in his *Astronomiae Optica*, page 305 — Maestlin, on September 15, at the 4th hour after midday, saw Regulus covered by Venus. Regulus was for me in Leo at [gr.] $23^{\circ}52'8''$, with a northern latitude of [grad.] $26^{\circ}10'$. Venus, however, [stood] in Leo at [gr.] $23^{\circ}53'30''$, with a northern latitude of [grad.] $26^{\circ}25''$. It is no

wonder, therefore, [given] the adjoined expansion of the rays, that with the naked eye Venus tends to appear around the very Regulus that has been covered.

3. In the year 1590 — in the same Kepler's testimony — on October 3, old style, in the morning, by night, Maestlin saw Mars covered by Venus, [in] the candid light of this [pair]. For me, from these Tables, Mars's place [comes out] in Virgo at [gr.] $15^{\circ}33'7''$. Venus's [is] in Virgo at [gr.] $15^{\circ}32'10''$, with very nearly the same latitude. Therefore, by Venus's expanded rays, [it was] entirely covered, [and Venus] hid Mars.

4. In the year 1598, on September 15, old style, in the morning at the 3rd hour, Kepler saw Venus barely covering the rising Regulus, namely at Graz [Gratz]. But for me Regulus was then in Leo at [grad.] $24^{\circ}12'24''$. Venus, however, [stood] in Leo at [gr.] $24^{\circ}18'30''$; but with the neighboring horizon expanding the rays more amply, it could happen that Regulus was seen obscured.

5. In the year 1632, on July 31, Gassendi [Petrus Gassendus = Pierre Gassendi] at Paris [Parisiis], and Hortensius at Amsterdam [Amstelodami], in the morning before dawn, observed the conjunction of Venus with Mercury, next [to it]; but Gassendi compared it in time a little after the middle of the night; Hortensius, however, into the hour $11\frac{1}{2}$ after midday of the same day 30. For Gassendi saw Mercury more easterly than Venus by [minutes] $3'30''$. The Prutenic [Tables = Prutenic Tables] erred so far that they anticipated the conjunction by entirely these five days; and Longomontanus, who corrects these Prutenic [places] only slightly, has [the conjunction] on the 30th of July; [at] the hour $11\frac{1}{2}$ Mercury was in Leo at [gr.] $24^{\circ}40'$, with a northern latitude of [gr.] $34'$.

[continued] Mercury, however, [stood] in Leo at [gr.] $27^{\circ}33'$, with a northern latitude of [gr.] $1^{\circ}24'$. [Margin: *Lambergius autem ♀ in ♏ gr. $24^{\circ}24'42''$ cum latit. bor. $34^{\circ}43''$, & Mercurium in ♏ gr. $24^{\circ}30'4''$ cum latit. $59^{\circ}5''$ — Lansbergen, however, [places] Venus in Leo at gr. $24^{\circ}24'42''$ with northern latitude $34^{\circ}43''$, and Mercury in Leo at gr. $24^{\circ}30'4''$ with latitude $59^{\circ}5''$.] We collect Venus in Leo at [gr.] $24^{\circ}22'15''$; and Mercury in Leo at [gr.] $24^{\circ}36'40''$.*

6. In the year 1633, on May 26, Boulliau at Paris, at the hour 9 after midday, saw western Venus through a tube [telescope] [more easterly?] by [min.] $18\frac{1}{2}$ on the left shoulder of Pollux, which for me was then in Leo at [gr.] $18^{\circ}35'$. Venus, therefore, was very nearly seen in Leo at [gr.] $18^{\circ}14'30''$; from the Tables, however, it was in [gr.] $18^{\circ}18'$.

LIBER NONUS — BOOK NINE

BOOK NINE, CONTAINING THE OBSERVATIONS OF THE PLANET MERCURY, AND THE HYPOTHESIS OF ITS MOTIONS

CAPUT I

Ancient Observations of Mercury, from the year 265 before Christ to the year of Christ 807

No planet costs astronomy more labor than this one, on account of how rarely it can be observed. The reason is partly the smallness of the number of its observations, and partly that Mercury, even at its greatest elongations [digressionibus], is nevertheless not far from the Sun, so that it appears only in the morning before sunrise or in the evening after sunset, unless the vapors of the horizon hide it, or the Sun itself is very near. For this reason we accept the words of Ptolemy [Ptolemy], *Almagest* IX.2 (*Magna Constructio* IX.2): in addition

to this difficulty of observations — few in number, and that because observations of this kind cannot be made — Copernicus [Copernicus] too, *De Revolutionibus* V.30, prefaces the difficulty of this matter thus:

[Margin: Difficulties of observing Mercury — *Difficiles observandi Mercurii*] This star indeed makes the path of its course hard to track down, and harder to examine, since earlier writers have demonstrated it to us beforehand, but not with serene skies; for, as they report, the breezes blow such as one finds along the Nile. We, by contrast, who dwell in a colder region — where nature, so to speak, denies us tranquil air, and where besides the great obliquity of the sphere allows us to see Mercury more rarely. For at its greatest distance from the Sun, although it is in Aries and Pisces, it does not rise within our view; nor again does it set in Virgo and Libra, but it presents itself in a way through the twilight of the nights only, when it has withdrawn somewhat into the morning hours of Cancer or Gemini. For this reason many have been led into ambiguities and into errors of inquiry. Hence it came about that we were brought to such a difficulty.

And indeed Longomontanus [Longomontanus] himself, *Astronomia Danica* (Longomontanus) II, *Theoricae* cap. 18, admits that on account of the obliquity of the sphere in Denmark, but at the season of summer, scarcely ever on account of the perpetual twilights is it permitted to continue observations of the elongations of Venus and Mercury from the Sun. And in cap. 20 he adds: *We will at last lay hands on Mercury, by the slipperiness of which the astronomers have hitherto been no less wearied than the surveyors of the earth.* Alchemists have likewise complained of Mercury, who cling to its traces, and, taking the suspicions of the ancients rather than the truth, ignorantly cleave to the heavenly observations of the ancients. And although the calculation of Mercury between the Alphonsine and Copernican calculations differs by degrees in some places, up to 7 — yet this could not be avoided even by the tables of certain more recent men. Nevertheless we judged it worth the labor to set out in order such observations as have been handed down to us by the hands of the ancients.

[Margin: 1.] In the year 484 of Nabonassar, on the 18th of the month Thoth following, i.e., on the 19th, which was the 21st year of Ptolemy Philadelphus, Mercury was observed to be distant by one Moon's breadth from the northern front of Scorpius, along a line drawn toward the north; and the same Mercury was distant by two Moons from the northern front of Scorpius. But on the 26th of Scorpius it was distant by the aforesaid line, in succession, by a Moon and a half.

Hence Ptolemy [Ptolemy], *Almagest* IX.10, concludes that Mercury was then at its greatest elongation from the Sun. It was the year before Christ 265, which Longomontanus [Longomontanus], *Theoricae* cap. 2, Nov. 14, hour 17, after midnight, says was at Copenhagen [Hafnia]; the northern front of Scorpius was in grade 1.36'. The other locus of Mercury was in Scorpius gr. 2.35' with northern latitude c. 59'. And he observed the locus of Mercury in the Thesaurus to be in Scorpius gr. 1.36'; the day was 4 June. [Margin: *Bullialdus*] Finally Boulliau [Bullialdus], *Astronomia Philolaica* (Bullialdus) X.9, says it was in the year before Christ 265, hour 16.30'. And Wendelen [Vuendelinus] says the northern front of Scorpius was in Scorpius gr. 1.13 $\frac{2}{3}$ with northern latitude 1.5'; but the middle of the northern front of Scorpius in Scorpius gr. 0.36 $\frac{1}{2}$ and latitude gr. 1.54'. Therefore Mercury was in Scorpius gr. 2.6'. For me, the year was 265 before Christ, and the day 14 November.

[Margin: 2.] In the year 486 of Nabonassar, on the 17th of Chœac following, i.e., on the 18th, in the year 23 of Dionysius, in the morning of Aquarius, Mercury was distant by 19 from the most brilliant tail of Capricorn, and septentrional; hence Ptolemy [Ptolemy], *Almagest* IX.10, concludes that Mercury was in Capricorn gr. 22.20', and his greatest elongation from the middle locus of the Sun gr. 25.50'. It was the year before Christ 262, the day 11 February.

[Margin: 3.] In the same year 486 of Nabonassar, on the 30 of Payni, i.e., in the year 24 of Dionysius, on the 18th, in the evening, observing with Hipparchus [Hipparchus], Mercury preceded Spica by a little more than three degrees. Hence Ptolemy [Ptolemy], *Almagest* IX.7, concludes that Mercury was in Virgo gr. 19.30'; but Lanbergius [Lansbergen] observed it; Mercury, from his own Tables, locates Spica in Virgo gr. 22.26', and Mercury in gr. 19.11'. It was the year 262 before Christ, the day 23 August.

[Margin: 4.] In the same year 486 of Nabonassar, on the 30 of Pharmuthi, i.e., in the year 23 of Dionysius, on the 4th, in the evening of Taurus following, Mercury, observing with Hipparchus [Hipparchus], was seen in succession to be distant by three Moons from the line of the horns of Taurus. Hence Ptolemy [Ptolemy], *Almagest* IX.7, concludes that Mercury was in Taurus gr. 23.40' with its greatest elongation from the middle locus of the Sun gr. 24.10'. It was the year before Christ 262, the day 24 May.

[Margin: 5.] In the year 491 of Nabonassar, on the 1st of Pharmuthi, i.e., the 6th, in the year 28 of Dionysius, in the evening, Mercury was on the straight line and was at the very top of the heads of Gemini. Hence Ptolemy [Ptolemy], *Almagest*

IX.7, concludes that Mercury was in Gemini gr. 1.50', and its greatest distance from the middle Sun gr. 26.30'. It was the year 217 before Christ, the day 28 May.

[Margin: 6.] In the year 512 of Nabonassar, on the 9th of Thoth following, i.e., on the 10th, in the month of Dionysius 75, on the 14th, in the morning, Mercury was seen to be higher than the Fixed [star] by half a breadth [semibrachium], in the line which is the extreme austral one of the shears of Libra. Hence Ptolemy [Ptolemy], *Almagest* IX.7, concludes that Mercury was in Libra gr. 14.10' with its greatest elongation from the middle locus of the Sun gr. 21. It was the year before Christ 237, the day 29 October.

[Margin: 7.] In the year 564 of Nabonassar, on the 27th of Thoth following, i.e., on the 28th, in the second year of the Chaldaeans 67, on the 5th, Apellei, in the morning, Mercury was seen by half a breadth [semibrachium] to be higher than the northern front of Scorpius. Hence Ptolemy [Ptolemy], *Almagest* IX.7, concludes that Mercury was in Scorpius gr. 2.20'; the same one's greatest distance from the middle Sun was the elongation gr. 22.30'. It was the year before Christ 185, the day 3 November.

[Margin: 8.] In the year of Hadrian the Emperor, on the 14 of Messori following, on the 19th, Theon observed Mercury to be most northern, distant by gr. 3.50' in the preceding part from the Heart of the Lion [Regulus]. Hence Ptolemy [Ptolemy], *Almagest* IX.10, was in Leo gr. 6.20' closely, and its greatest elongation from the middle locus of the Sun gr. 16.15' (Copernicus [Copernicus], *De Revolutionibus* V.27, but he adds Theon to have been at Smyrna), the day, that very day, 4 July, hour 6, after midday at Uraniborg [Vraniburgi], and then the Heart of the Lion was in Leo gr. 3.28'.35"; therefore Mercury was in Leo gr. 7.18', with greatest elongation gr. 26.59' a Sole loco, since the locus of the Sun, by the Philolaic Tables, was in Cancer gr. 10.19'.32". It was the year 139 of Christ, the day 4 July.

[Margin: 9.] In the year of Hadrian 16, on the 16 of Phamenoth, hour 5, in the evening, Mercury at its greatest elongation from the middle motion of the Sun, by comparison with the splendid Hyades, is found in the first degree of Pisces, distant from the middle motion of the Sun gr. 21.15', by Ptolemy [Ptolemy], *Almagest* IX.7. It was, he says, but Boulliau [Bullialdus], *Astronomia Philolaica* (Bullialdus) X.9, the year of Christ 132, on 2 February, hour 2.40', after midday at Uraniborg, and then the eye of Taurus was in Taurus gr. 12.17'. But Boulliau places the eye of Taurus in gr. 12.17'; Mercury in Pisces gr. 2.8½; and its greatest elongation from the true locus of the Sun gr. 19.10'.51".

[Margin: 10.] In the year of Hadrian 18, on the 16 Epiphi, on the 18th, hour 5, in the morning, at greatest elongation Mercury was very faint, and seen with feeble light in respect to the splendid Hyades, in Taurus gr. 18.45', and distant from the middle Sun gr. 21.15', by Ptolemy [Ptolemy], *Almagest* IX.7. It was the year of Christ 134, the day 3 June.

[Margin: 11.] In the year of Hadrian 19, on the 14 of Athyr following, on the 15th, in the morning, Ptolemy [Ptolemy] saw Mercury at a distance from the Heart of the Lion, in Virgo gr. 20.12', and most distant from the middle of the Sun gr. 19.3'. By Ptolemy [Ptolemy], *Almagest* IX.8, and Copernicus [Copernicus], *De Revolutionibus* V.26, it was the year of Christ 134, the day 2 October.

[Margin: 12.] In the year of Hadrian 19, on the 18 of Pachon, on the 19th, in the evening, Mercury at its greatest elongation from the middle motion of the Sun gr. 23.15', observed by Ptolemy, was in Taurus gr. 16', distant from Aldebaran by gr. 7', per distance from Aldebaran. Ptolemy [Ptolemy], *Almagest* IX.9, and Copernicus [Copernicus], *De Revolutionibus* V.26, adding that it was the year of Christ 135, the day 15 April.

[Margin: 13.] In the first year of the Emperor Antoninus, on the 20 of Epiphi, on the 21st, in the evening, Ptolemy, by his distance from the astrolabe, observed Mercury in Cancer gr. 7, most distant from the middle motion of the Sun gr. 20.30' (Ptolemy [Ptolemy], *Almagest* IX.7, and Copernicus [Copernicus], *De Revolutionibus* V.26): but caution must be used, since it was the year of Christ 135, the day 15 April.

[Margin: 14.] In the year 2 of Antoninus, on the 23 of Messori, on the 24th, in the morning, Ptolemy, by his distance from Aldebaran, observed Mercury in Gemini gr. 20.5', and most distant from the middle of the Sun gr. 20.15' (Ptolemy [Ptolemy], *Almagest* IX.9; Copernicus [Copernicus], *De Revolutionibus* V.27, adding that it was the year of Christ 139, on 18 May. But Boulliau [Bullialdus], *Astronomia Philolaica* (Bullialdus) X.9, judges that in that year of Christ 139, on 17 May, at Uraniborg, Mercury was in Gemini gr. 21.0'; but the true locus of Aldebaran is calculated in Gemini gr. 16.1'. At the locus of the Sun then existing in Cancer gr. 13.21'.42". According to Ptolemy he noted the day Messori to have proceeded from the day 23, on the 24th. Now indeed by our Chronology the year was 886, whose first day Thoth fell on the day of July 10, whence inclusively counting up to the day 23, Messori falls on the day of July 24, on the 8 of July.

[Margin: 15.] In the year 2 of Antoninus, on the 2 Epiphi, on the 3rd, Ptolemy, in the evening, at the equal hour before midnight gr. 4.30', by the astrolabe observed

Mercury at its greatest elongation in Gemini gr. 17.30', per the comparison and at the locus of the back center of the Moon following gr. 1.10'. Ptolemy [Ptolemy], *Almagest* IX.10. And Boulliau [Bullialdus], in the Thesaurus at observation 3: Mercury was in Gemini, with the locus of the Moon concluded to be in Gemini gr. 17.42'. But Boulliau [Bullialdus], *Astronomia Philolaica* (Bullialdus) X.9, says in that year of Christ 139, on 11 May, 12 hours after midday at Uraniborg gr. 9, with Mercury observed and concluded by the prior observation to be in Gemini gr. 18.35' distant from the true locus of the Sun gr. 8.37'. But indeed the locus of the Moon by the observation found to be in Gemini gr. 19.2', distant from the true locus of the Sun gr. 24.56', and Ptolemy is contradicted, since the false distance from the Heart of the Lion. The year was 139 of Christ, the day 17 May.

[Margin: 16.] In the year 4 of Antoninus, on the 18 of Phamenoth, on the 19th, in the morning, Ptolemy observed Mercury from Antares in Capricorn gr. 13.20', and most distant from the middle of the Sun gr. 26.30' (Ptolemy [Ptolemy], *Almagest* IX.7, and Copernicus [Copernicus], *De Revolutionibus* V.26, adding that it was the year of Christ 140, and besides gr. 67, and the scruple [scrupula] nearly 12. And he adds besides that it was the year of Christ 141, the day Martii 8. But Boulliau [Bullialdus], *Astronomia Philolaica* (Bullialdus) X.9, in that year 141, the day Phamenoth coincides with February 1, hour 16.40', and then Mercury was in Capricorn gr. 14.43'.33" most distant from the middle of the Sun gr. 28.18'.54". From the true locus of the Sun in Aquarius gr. 13.0'.27". The year was 141 of Christ, the day 1 February.

[Margin: 17.] In the year of Christ 807, some report Mercury to have been seen under the Sun, with Kepler [Kepler] in *Astronomia Optica* (Kepler) cap. 8, saying: *Mercury at its Node in Taurus and Scorpius, at the beginning of Aries and Libra without [?], passing, today, and at certain times this Planet is seen under the Sun. How much more wonderful — when I read this in Charles the Great's [Charlemagne] astronomers, brought down to the year 807, noted. With these words: A star of Aldebaran on 16 Kal. April was seen as if a small black spot; nevertheless a little higher across the middle of the same sphere of the disk it appeared, where the entrance, or exit, of the obstacles [molibus] is not noted. But because Kepler knew this to be Mercury remaining under the Sun naturally eight days, he thought it should be read in the barbarous letters; he adds the year vitiously written to be 807 for 808, on the 16 decimo sexto Kal. April, unless perhaps the observer began counting from Easter; for the calculation of that day, exhibited at the meridian by the Prutenic Tables [Tabulae Prutenicae], locates the Sun on the day in Aries gr. 0.45', and Mercury in Aries gr. 31' — with however the false Ptolemaic latitude gr. 2.9'. So Kepler [Kepler], there, in the end of the Dissertations*

with the *Nuncius Sidereus* (Kepler, *Nuncius Sidereus*), from Thesis 98. Samuel Hasennefer adduces Amoinus Monachus, & an Anonymous author, Sabellici, Franciscorum, also Eginardus [Einhard], Vincentius [?], Lycosthenes, Polydorus Virgilius, Beda [Bede], and others, who attest that maculam [the spot] under the Sun persevered for *seven days*, as Beda has it, or, as most have, *eight days*, as Beda; and very many have the year 808. See here, whoever wishes to respond to Kepler against the theses of Samuel. But both Scheiner [Scheiner] subscribed earlier in the little work *de maculis Solaribus* to Kepler; and Galileo [Galileo Galilei], on solar spots, and Gassendi [Gassendi] in *Epicurus* pag. 898, that it was the year in which the larger spots of the Sun, added, Kepler after the spots restituted in the Sun by detected error in the eighth-day observation [octiduo restituisset], discovered the eight-day antiquities; and for eight days he restored it. But to me it is more credible to be conjoined, that Mercury could not be seen under the Sun with the eye, except with a similar telescope, by which Mercury could be seen under the Sun in the year 1607 May 28, which indicates in its singular phenomenon. Whatever Mercury seen under the Sun may have been before the others, it has not the exercise 72. Against Cardan [Cardano] Scaliger [Joseph Scaliger], to whom badly the Coimbrans 2. Heaven cap. 7, art. 4, and Scheiner subscribed that observation. Moreover Scheiner in *Rosa Ursina* [Scheiner] pag. 412 teaches that Mercury 4, by hours only could be observed under the disk of the Sun, with spots can be observed for many days under it [?].

CAPUT II

Observations of Mercury made by Bernhard Walther [Bernhard Walther] at Nuremberg [Norimberga]

Besides the observations made by the ocular estimation, certain others made by the Armillae are subject to no small error, up to 10 minutes, as was said in the observations of Saturn at Walther's [Bernhard Walther], num. 33. Then these too, which the same Walther advised in the Refractions in Venus, are valid here also:

[Margin: 1.] In the year 1481, October 22, hour nearly one before sunrise, Walther saw Saturn and Mercury in the same eastern part of Mercury more eastern, with the diameter of a Moon between them, distant by 28 toward the east gr. 6.28'; and on the 3 of November, in the morning before sunrise, more eastern gr. 12.26', at the conjunction with Mercury Saturn was on the 21 October, exorbitant by the Tables.

[Margin: 2.] In the year 1482, October 11, a little before sunrise, Mercury was seen in the same part nearly along the longitude with Luna [the Moon], but austral a

little more than the diameter of the Moon. On the day 25 October it disappeared with the clearest sky.

[Margin: 3.] In the year 1484, January 16, immediately, as Mercury was in contact with the Horizon, Walther's horologe with a pendant weight returning to the meridian, and held in the hour at point 56, which once turned back is, and besides 35 denticles; when toward the center of the Sun Mercury appeared in the Horizon, by which Mercury appears to rise before the Sun hour 1.37', which nearly agreed with Walther's calculation.

[Margin: 4.] In the year 1488, January 16, hour 5.30', after midday, Mercury was seen to be distant from Jove [Jupiter] by the Radius [cross-staff] gr. 1.42', and to the west by the limb of the Moon from both; the Planet gr. 1.24'; but Mercury was more northern than Jove. On the following day Mercury more eastern and more northern gr. 2.22'. But in the numbers of the day 16, there is error.

[Margin: 5.] In the year 1495, August 16, the Armillae rectified through Aldebaran, hour nearly one before sunrise, he found Mercury in gr. 23.10' of Leo. But on the day 30 August, at the same hour, in gr. 27.10', and on the day 1 in the same hour in gr. 28.3' of Leo, with northern latitude gr. 53'; which posterior [later] observation he prefers to the prior ones for the better rectified instruments.

[Margin: 6.] In the year 1491, September 2, Walther reports thus: *The Armillae rectified again through Aldebaran, I found Mercury in the first grade, 13' of Virgo, one hour before sunrise: Latitude septentrional gr. 1.13', with a most serene sky, all the other things diligently observed, the situation of the instruments certain, confide in this.*

[Margin: 7.] In the year 1491, September 3, hour one before sunrise, by the Armillae, as above, rectifying, he found Mercury in Virgo gr. 3.51'. But he subjoins: *Diligently — with true latitude septentrional gr. 1.20' — only changed in that he made it doubtful for me. Nevertheless Lansbergius [Lansbergen] in the Thesaurus, choosing this, says it was in Gemini gr. 2.12'; therefore Mercury was in Virgo gr. 3.42'. But from his own Tables in grade 2.13'.33⅓ with northern latitude. Bor. gr. 1.17'.

[Margin: 8.] In the same year 1491, September 9, hour 5, in the morning, he found Mercury in Virgo gr. 13.23', with northern latitude gr. 1.50'. *Behold*, says Walther, *how great a difference from the Tables. Mercury appeared very faint, and far off, doubtless near the term of occultations. Consider also the refraction radius, since a moderate one disturbs it from the Horizon; on the eleventh day it appeared most*

faintly, lest the observation should not be the most reliable of all. Nevertheless Copernicus [Copernicus], destitute of his own observations, *De Revolutionibus* V.30, chose this, but at the observation of Mercury in Virgo gr. 13.30', when it is rightly computed, it was distant from the middle locus of the Sun gr. 13.15' nearly.

[Margin: 9.] In the year 1504, January 9, with the middle of the Heaven existing in gr. 10 of Scorpius, by the Heart of the Lion Mercury was in Capricorn gr. 3.15', with northern latitude gr. Bor. 45'. He adds that it was most diligently observed: but Copernicus [Copernicus], *De Revolutionibus* V.30, on the day 9, hour 6.30', after midnight, observed by Johannes Schöner [?] also; Mercury observed in Capricorn gr. 3.20' with latitude gr. 45', and distant from the middle locus of the Sun gr. 23.42'.

[Margin: 10.] In the year 1504, March 11, rectified at the Sun the Armillae, Mercury was observed clear, and of notable quantity, in Aries gr. 17.30' with northern latitude gr. Bor. 1.51', with the middle Heaven in gr. 18 of Cancer.

[Margin: 11.] In the year 1504, March 17, after midday, through Aldebaran in Gemini gr. 2.45'. Walther found Mercury in Aries gr. 26.30', with northern latitude gr. Bor. 3, with the middle Heaven in gr. 25 of Capricorn. But Schöner, as Copernicus [Copernicus] reports, *De Revolutionibus* V.30, with the middle of Cancer in grade 25, that is, hour 7.30', saw Mercury in Aries gr. 26.6', with northern latitude gr. Bor. 3, but distant from the middle locus of the Sun gr. 21.17'.

[Margin: 12.] In the year 1504, March 18, after midday, with the middle Heaven in Cancer gr. 25 placed, Aldebaran in Gemini gr. 2.45', he found Mercury in Aries gr. 26.30', with northern latitude gr. Bor. 3.

[Margin: 13.] In the year 1504, March 24, after midday, with the middle Heaven gr. 5 of Leo placed, Aldebaran gr. 2.45', Mercury was found in Taurus gr. 0.5', with northern latitude gr. Bor. 3.30'. From these observations Boulliau [Bullialdus], *Astronomia Philolaica* (Bullialdus) X.9, concludes the greatest elongation of Mercury from the Sun to have been on March 18, hour 18, at Nuremberg [Norimberga] gr. 7.15'; and since Aldebaran was in Gemini gr. 2.50', and from the refractions Mercury stood at its own Tables in Aries gr. 26.20' in orbit, but minus 35' in the ecliptic; truly, the locus of the Sun in Aries gr. 7.41'.36".

CAPUT III

Tychonic Observations of Mercury

Longomontanus [Longomontanus], *Astronomia Danica* II, *Astronomia Danicae* cap. 20, subjoins eight loci of Mercury observed at Uraniborg [Uraniburgi] by Tycho [Tycho Brahe], with two others by himself observed at Copenhagen [Hafnia], with the computation added from the Danish Tables [Tabulae Danicae] for the days of the old style, and below, where the hours are after midday:

Liber IX — De Mercurio (continued)

Caput III — Tycho's Mercury observations (continued)

The following table summarizes the ten Mercury positions derived from Tycho's observations, giving for each the observed longitude, the supputated (computed) longitude, and the observed latitude.

Y N e M o a on . r th			Long. observed (Sign / G. / M.)	Long. computed (G. / M.)	Lat. observed (G. / M. / dir.)
1 1	N		♌ Scorpio 13 4	12 57	2 18 B
5	ov				
8	.				
5					
2 1	N		♌ Scorpio 25 3	24 58	1 25
5	ov				
8	.				
5					
3 1	Oc		♎ Libra 22 35	22 28	not observed
5	t.

6					
4 1	Oc		♎ Libra 26 33	26 28	2 17 B
5	t.				
8					
6					
5 1	Ja		♊ Aquarius 17 48	17 49	0 1
5	n.				

Y N e M o a on . r th	Long. observed (Sign / G. / M.)	Long. computed (G. / M.)	Lat. observed (G. / M. / dir.)
8 7			
6 1 M 5 ar 9 . 0	♈ Taurus 13 44	13 36	1 42
7 1 Fe 5 b. 9 2	♊ Pisces 12 20	12 29	0 47
8 1 M 5 ay 9 3	♊ Gemini 23 16	23 4	2 0
9 1 A 6 pr 0 . 7	♈ Taurus 21 5	21 12	1 40
1 1 De 0 6 c. 1 0	♐ Sagittarius 2 42	2 35	not observed

Boulliau [Ismaël Boulliau], in Book 10, Chapter 7, says with respect to the first of these observations — that of the year 1585, November 14, hour 19 — that the true place of the Sun was Sagittarius 2°56'45", and that Mercury was accordingly 19°52'45" distant from it. But from the Rudolphine [Tables] Mercury comes out in Scorpio 13°7'45", with a discrepancy from the observation of 3'45".

Tycho [Tycho Brahe] himself, in his *Epistolae* (p. 56), records the three Mercury observations transcribed below in Old Style, in hours after midday at Uraniborg.

1587 January (D. / H. / M.)	Source	Long. Mercury (Sign / G. / M.)	Latitude (G. / M. / dir.)
1 9 4 50	Observ	♒ Aquarius 17 48	0 1 B

1587 January (D. / H. / M.)	Source	Long. Mercury (Sign / G. / M.)	Latitude (G. / M. / dir.)
1	ed		
	Alphon sine	18 29	0 24 B
	Copern ican	16 41	0 6 A
1 14 5 15	Observ ed	♊ Aquarius 21 7	1 21 B
2	Alphon sine	23 31	1 29 B
	Copern ican	19 21	1 1 B
1 15 5 21	Observ ed	♊ Aquarius 21 20	1 40 B
3	Alphon sine	24 18	1 41 B
	Copern ican	19 33	1 39 B

Boulliau, in Book 10, Chapter 7, uses the observation of day 9, adding that the true place of the Sun was Capricorn $29^{\circ}13'12''$, and that accordingly the distance of Mercury from it was $18^{\circ}34'48''$. But from his own Tables he gathers the place of Mercury in Aquarius $17^{\circ}35'12''$.

Lansbergen [Lansbergen], in his *Thesaurus*, uses the observation of day 14, but from his Tables gathers the place of Mercury in Aquarius $21^{\circ}8'53''$, with a latitude of $1^{\circ}31'$; whereas from the calculation of triangles it comes to $1^{\circ}21'$.

In the year 1589 Mercury was observed by Tycho near its maximum elongation from the Sun, on April 1, 2, 3, 4, 6, and 11. These observations, selected from Tycho's manuscript together with their calculation, were transmitted to me by Father Albert Curtius [Albert Curtz] of our Society, and are set out below — with the time corrected for the clock added, examined on the following midday.

14. Day 1 April, evening.

H. M.	Dist. of ☿ from Aldeb. (G. / M.)	Decl. of ☿ Borea (G. / M.)	Alt. of ☿ (G. / M.)	Comp. min. western (G. / M.)
7 36 / 41 corr.	25 11½	16 59⅝ / 17 1	9⅓	25 26
7 40⅝ / 7 45⅔	25 10	17 1½ / 17 2	8 50	26 32
7 45⅓ / 7 50	25 11	17 5 / 17 4⅓	8 20	27 40
7 48⅓ / 7 53 corr.	25 11	17 [—]	7 50	28 24

[The right-hand column of page 345 continues this same observation series at finer time-intervals; its column headers are not separately reprinted but follow the same scheme — Dist. of ☿ from Aldebaran, Declination of ☿, Altitude of ☿, and western complement (Comp. min. occid.).]

H. M.	Dist. ☿ Aldeb. (G. / M.)	Decl. ☿ (G. / M.)	Alt. ☿ (G. / M.)	Comp. min. occid. (G. / M.)
7 51⅔ / 7 56 corr.	25 10⅙	17 4½ / 17 4⅝	[—]	29 11
7 55½ / 8 0 corr.	25 10	17 4⅔ / 17 5	7 0	30 8
7 59½ / 8 3¼	25 9¼	17 4¾ / 17 5⅙	6 35	32 4
8 3½ / 8 7⅓	25 8⅓	17 6 / 17 6½	6 0	32 0
8 8 / 8 11⅔	25 8	17 6⅝ / 17 6⅔	5 30	33 5

8 16⅓ / 8 19⅔	25 6⅓	17 9½ / 17 9⅓	4 30	35 6
8 19½ / 8 23	25 5⅔	17 9⅔ / 17 9½	4 0	35 54
8 22⅝ 26 corr. / 8 27 30 corr.	25 5¼ / 25 4⅔	17 both 9¾ / 17 9⅝	3 40 / 3 10	36 42 / 37 42

For the examination of the armillae:

H. M.		G. / '
8 32	Declination of Aldebaran	15 38½
		15 38
	Altitude of the same	15 20

It was sufficiently clear and calm.

15. Day 2 April, evening.

H. M.	Dist. ☿ from Aldeb. (G. / M.)	Decl. ☿ (G. / M.)	Alt. ☿ (G. / M.)	Comp. min. occid. (G. / M.)
8 0 ² / ₃ / 8 2 ² / ₃ corr.	23 55 ¹ / ₂	17 37 ² / ₃ / 17 38 ¹ / ₂	7 15	—
8 5 ⁵ / ₆ / 8 7 corr.	23 54 ⁵ / ₆	17 38 / 17 38 ¹ / ₂	6 50	32 53
8 9 ³ / ₄ / 8 11 ⁵ / ₆	23 53 ¹ / ₂	17 38 ¹ / ₆ / 17 38 ¹ / ₂	6 0	34 3
8 15 / 8 17 ¹ / ₆ corr.	23 52	17 40 ¹ / ₂ / 17 40 ¹ / ₃	5 20	35 25
8 19 ¹ / ₂ / 8 22	23 51 ¹ / ₄	17 41 ¹ / ₂ / 17 41 ¹ / ₃	4 50	36 34
8 24 corr. 26 ⁵ / ₆	23 51	17 42 / 17 42 ¹ / ₃	4 15	37 46
8 29 ¹ / ₂ / 8 31 ¹ / ₂	23 50 ¹ / ₆	—	3 35	39 2

It was moderately clear and calm enough. On these days, although the clear weather had been continuous, nevertheless on every side, from the horizon up to an elevation of about 39° or beyond, dark cloudlets [φαινόμενα, *phainomena*, "appearances"] were rising and, descending below the said altitude, were covering it.

The calculation follows, from the observations written above.

April 2, h. 8'5', distance of ☿ from Aldebaran 23°55':

	G. / '
Declination of ☿ limited	17 40
Declination of Aldebaran	15 38
Altitude of ☿	7 0
Angle of difference of Ascension	24 53 ¹ / ₂
R.A. Longitude	11 32 ¹ / ₂ ☿
Latitude	2 26 ² / ₃ B
True, freed from Refraction and parallax — Longitude	11 28 ¹ / ₂ ☿

	G. / '
Latitude	2 23 $\frac{2}{3}$ B

16. Day 3 April, evening.

H. M.	Dist. ♀ from Aldeb. (G. / M.)	Declination ♀ (G. / M.)	Alt. ♀ (G. / M.)	Comp. min. occid. (G. / M.)
7 55 $\frac{1}{2}$ / 8 6 corr.	dubious / 22 40 $\frac{5}{6}$	18 8 / 18 7 $\frac{3}{4}$	7 40	33 30
7 59 / 8 10 corr.	22 43	18 9 $\frac{1}{3}$ / 18 9 $\frac{2}{3}$	7 8	34 25
8 3 / 8 13 $\frac{1}{2}$	22 42 $\frac{1}{4}$	18 9 $\frac{1}{2}$ / 18 9 $\frac{2}{3}$	6 50	35 22
8 7 $\frac{1}{2}$ / 8 17 $\frac{1}{2}$	22 41 $\frac{2}{3}$	18 10 / 18 10	6 7	36 20
8 12 $\frac{1}{4}$ / 8 23 corr.	22 40 $\frac{2}{3}$	18 11 / 18 11 $\frac{1}{2}$	5 23	37 42
8 17 $\frac{1}{3}$ / 8 28 corr.	22 40 $\frac{1}{3}$	18 12 $\frac{1}{2}$ / 18 12 $\frac{1}{3}$	4 50	38 59
8 20 $\frac{5}{6}$ / 8 31 $\frac{1}{3}$	22 39	18 13 / one feeble pinnacle	4 30	39 50
8 25 $\frac{1}{2}$ / 8 36	22 38 $\frac{3}{4}$	18 13 $\frac{1}{3}$	3 52	41 3
8 30 / 8 41 $\frac{2}{3}$ corrected	22 38 $\frac{2}{3}$ / dubious	18 14 / dubious	3 15	42 25

For the examination of the armillae was taken:

	G. / '
Declination of Aldebaran	15 37 $\frac{2}{3}$ 15 38
Altitude of the same	12 $\frac{1}{3}$

This evening it was extremely clear and calm.

The calculation, from these observations:

	G. / '
H. 8 10' — Distance of ♀ from Aldeb.	22 43
Declination of ♀ limited	18 11
Declination of Aldebaran	15 38

	G. / '
Altitude of γ	7 8
Angle of difference of Ascension	23 36 $\frac{1}{6}$
Longitude	12 52 γ
Latitude	2 33 $\frac{5}{12}$ B
Subtracting parallax and refraction — True γ Longitude	12 48 γ
Latitude	2 30 $\frac{1}{2}$ B

Vice versa — Distance from the right shoulder of Orion.

H. M.	(G. / ')	Decl. (G. / M.)	Alt. (G. / M.)	Comp. min. occid. (G. / M.)
8 21 $\frac{5}{6}$ / 8 25	42 54	18 40 / 18 39 $\frac{5}{6}$	5 40	39 13
8 24 $\frac{1}{2}$ / 8 28 $\frac{1}{2}$	42 52 $\frac{1}{2}$	18 40 $\frac{1}{3}$ / 18 40 $\frac{1}{2}$	5 10	40 5
8 26 $\frac{5}{6}$ / 8 30 $\frac{5}{6}$	42 51	18 41 / by one sight (uno pinnac.)	4 40	40 40

γ This evening it could no longer be observed, on account of the thick clouds standing about the western horizon. There was, moreover, this evening a somewhat troublesome wind from the same quarter of the sky.

The place of γ at 4 April, from the preceding observation:

	G. / '
H. 8 15' — Distance of γ from Aldeb.	21 37 $\frac{1}{2}$ B
Declination of γ limited	18 39 $\frac{1}{2}$ B
Declination of Aldebaran	15 38
Altitude of γ	7 0
Angle of difference of Ascension	22 25 $\frac{1}{2}$
Longitude	14 50 γ
Latitude	2 39 $\frac{5}{6}$ B
True γ , freed from refraction and parallax — Longitude	14 1 γ
Latitude	2 36 $\frac{5}{6}$ B

17. Day 4 April, evening.

H. M.	Dist. ☿ from Aldeb. (G. / M.)	Decl. ☿ Borea (G. / M.)	Alt. (G. / M.)	Comp. min. occid. (G. / M.)
7 53½ / 7 55 corr.	21 39½	18 34 / both (utroq;)	9 30	31 45
7 58 / 8 0	21 36 / dubious	18 35 / 18 35½	9 0	32 57
8 1 / 8 3½	21 38	18 37 / 18 38	8 30	33 48
8 6⅝ / 8 9½	21 38	18 38 / 18 38⅓	7 48	35 20
8 11½ / 8 15 corr.	21 37½	18 38 / 18 38	7 0	36 39
8 21⅝ / 8 18 corr.	21 37¼	18 39¾ / 18 40	6 30	37 30

[No "calculus" / calculation block is printed for the Day-4 (17) observation; the Day-4 result is the "Locus ☿ ad 4. Aprilis" block given above (Long. 14°50' ☿; True 14°1' ☿).]

18. Day 6 April, evening.

H. M.	Dist. ☿ from Aldeb. (G. / M.)	Declination ☿ (G. / M.)	Alt. ☿ (G. / M.)	Comp. min. occid. (G. / M.)
8 15⅔ / 8 14⅙ corr.	19 40½	19 21½ / 19 21⅔	7 50	38 30
8 20⅓ / 8 20 corr.	19 40¼	19 24⅙ / 19 23⅔	7 15	39 43
8 24⅔ / 8 24	19 [—]	19 24⅙ / 19 24⅔	6 40	40 45
8 30⅔	19 40	19 26½ / 19 26⅔	6 0	Cor ☿ occid.
8 34½	19 39½	19 26 / 19 26⅔	5 30	6 6
8 38½	19 39	—	4 50	7 7

Afterward ☿ was observed from the right shoulder of Orion:

H. M.	G. / '	
8 44'	in Distance	41 53
	Declination	19 31 / 19 30
	Altitude	3 50

H. M.	G. / '
Canis Minor	46 28 western

This last was dubious on account of intervening clouds.

Inquiry into the longitude and latitude of γ from these observations:

	G. / '
H. 8 10' — Distance of γ from Aldeb.	19 40 $\frac{1}{4}$
Declination of γ Borea	19 25 (limit)
Declination of Aldebaran	15 38
Altitude of γ	7 15
Therefore angle of ascensional difference	20 15 $\frac{1}{2}$
Longitude	16 12 $\frac{1}{3}$ γ
Latitude	2 48 B
Subtracting parallax and refraction — True γ	16 8 $\frac{1}{2}$ γ
Longitude	
Latitude	2 45 B

19. Day 11 April.

H. M.	Dist. γ from luminous shoulder of Orion (G. / M.)	Declination γ (G. / M.)	Alt. γ (G. / M.)	Comp. min. occid. (G. / M.)
8 14 $\frac{1}{6}$	[—]	20 36 $\frac{1}{2}$	6 0	47 30
8 18 $\frac{1}{3}$	37 38 $\frac{1}{6}$	[—]	5 50	48 30
8 21	37 40 $\frac{1}{4}$	20 36 $\frac{2}{3}$ / 20 37	5 30	49 17
8 23 $\frac{2}{3}$	37 41 $\frac{1}{2}$	20 37 $\frac{1}{2}$ / 20 37	5 10	49 58
8	[—]	20 38 $\frac{1}{2}$	4 50	50 41

	Dist. ☿ from luminous shoulder of Orion	Declination ☿ (G. / M.)	Alt. ☿ (G. / M.)	Comp. min. occid. (G. / M.)
H.				
M.	(G. / M.)			
26				
$\frac{1}{3}$				

Around the middle of these times the altitude of the luminous shoulder of Orion was about 14° or 15° , from which the distances of ☿ were taken.

	G. / '
H. 8 $40\frac{1}{2}$ — Declination of Aldebaran	15 $40\frac{1}{2}$
	15 40
Altitude of the same	$7\frac{1}{2}$

— and this for the examination of the armillae.

Afterward ☿ could no longer be observed, namely from hour 8 minute $26\frac{1}{2}$, since clouds covered it and vapors impeded it up to the horizon. You can, however, without appreciable error — taking the intermediate distance, which is accepted as hour 8, 21', putting it at $37^\circ 40'$ in altitude $5\frac{1}{2}^\circ$ — and assuming its declination at $20^\circ 37'$. But account must really be taken of the refraction of the luminous shoulder of Orion, from which the distance is taken, and one must also see what the armillae may perhaps give in declination — by an experiment made on Aldebaran, with its refraction applied.

20. In the year 1592, February 3, in Old Style at hour 5, 40' after midday, at Uraniborg, Mercury was observed in Pisces $12^\circ 20'$, with northern latitude $47'$. Longomontanus, Book 2, *Theorics*, Chapter 20, and Boulliau, Book 10, Chapter 7, who adds that the true place of the Sun was Aquarius $24^\circ 23' 57''$, and that the distance of Mercury from the Sun was $17^\circ 56' 3''$. But from his Tables he gathers the place of Mercury in Pisces $12^\circ 15'$; from which Boulliau, Book 10, Chapter 7, proves the Copernican calculation to be corrupt in latitude.

21. In the year 1593, May 11, in Old Style at hour 9, 30' after midday, at Uraniborg, Mercury was observed in Gemini $23^\circ 16'$, with northern latitude 2° . Longomontanus, Book 2, *Theorics*, Chapter 20. Snell [Willebrord Snell] adds, in *Hassiacis*, that on the following day, the 12th — which in New Style was the 22nd of May — Mercury was observed in Gemini $24^\circ 19'$. Hence Boulliau, Book 10, Chapter 1, gathers that on the 23rd, in New Style, Mercury was in Gemini $25^\circ 21'$,

at its maximum elongation, distant $22^{\circ}52'4''$ from the Sun. Boulliau follows the Copernican [reckoning]: Mercury had moved beyond the limit of maximum remoteness from the Sun, to which observation Alphonso [the Alphonsine] is more favorable.

22. In the year 1600, January 23, in New Style, Tycho, in the citadel of Benatky [Benátky], immediately after sunset, found by refraction the corrected distances of Mercury: from the bright star of the breast of Cygnus $48^{\circ}52\frac{2}{3}'$, from the tail of Cetus $40^{\circ}22\frac{1}{3}'$, from the high Mercury $5^{\circ}50'$. So Snell, in his *Bohemian observations*.

23. In the year 1600, January 24, a little after sunset, with Tycho observing, Mercury was seen at altitude 6° to be distant from the bright star of the tail of Cetus $40^{\circ}7'$, and at hour 6 its altitude was 5° ; it stood distant from the same star $40^{\circ}4'$; from Sirius $53^{\circ}3\frac{1}{2}'$; a little less than 6 hours from Pegasus $21^{\circ}37'$, when it was distant about $2^{\circ}10'$ from Procyon $53^{\circ}14'$. Therefore, says Snell in the *Bohemian observations*, the place of Mercury was Gemini $1^{\circ}29'50''$, refraction and parallax not taken into account.

24. In the year 1601, April 29, Tycho, at Prague, in the house of Curtz, saw, in whatever manner, the other [appearance of] Mercury, distant $7^{\circ}10'$ from Capella $25^{\circ}41'$, and the other [reading] truly $6^{\circ}46'$; he saw it distant from Procyon $53^{\circ}14'$. Therefore, says Snell in the *Bohemian observations*, the place of Mercury was Gemini $1^{\circ}29'50''$, refraction and parallax not taken into account.

Decorative headpiece.

CAPUT IV

Mercury's observations of Longomontanus, Kepler, Justus Byrgius, Hortensius, and Boulliau, from the year 1593 to 1631.

1. In the year 1593, May 11, hour 9, 30' after midday, Justus Byrgius [Jost Bürgi] of Kassel observed Mercury distant $21^{\circ}56'$ from Capella, and from Pollux $24^{\circ}34'$. Snell, in *Hassiacis* and Boulliau, Book 10, Chapter 1, gathering from this for day 12 — which in New Style was the 22nd — that Mercury was in Gemini $24^{\circ}19'$; and on the 23rd, in Gemini $25^{\circ}21'$, at maximum elongation from the Sun. Longomontanus, however, in Book 2, *Theorics*, Chapter 20, as we indicated above, reports Mercury observed in Gemini $23^{\circ}16'$.

2. In the year 1607, April 14, in Old Style at hour $8\frac{1}{2}$ after midday, Longomontanus at Copenhagen [Hafnia] observed Mercury with the radius, distant $2^{\circ}24'$ from Venus, and it was higher than it in nearly the same vertical, the

latitude of Venus being 10' southern; but the latitude of Mercury was 1°40' northern. And from the observations of the following days Longomontanus, Book 2, *Theorics*, Chapter 23, gathers from his own Tables that Mercury was in Taurus 19°32'7" and Venus in Taurus 18°19'33". On April 15, however, at the fifth hour into hour 9, he observed Mercury in Taurus 21°5', with northern latitude 1°40'; this the Tables themselves give as Taurus 21°11'.

3. In the year 1607, May 28, in New Style, Kepler [Johannes Kepler] saw Mercury beneath the Sun, as he himself published in his singular *Phaenomenon*, and it differs, with the *Sidereal Messenger* [Galileo's *Nuncius Sidereus*] attesting; and Scheiner [Christoph Scheiner] [treats] of the Solar spots.

4. In the year 1610, December 5, in Old Style at hour [—] after midday, Longomontanus at Copenhagen [Hafnia] [observed] Mercury [at] 2°42' [sign: —]. So he himself, Book 2, *Theorics*, Chapter 20.

5. In the year 1625, February 13, hour 6, 12', Boulliau at Joinville [Iulioduni] observed Mercury in Pisces 13°27', refraction subtracted, and at maximum distance 25°27'37" from the Sun, residing in Aquarius 25°27'37". Boulliau, Book 10, Chapter 1.

6. In the year 1626, March 12, in Old Style at hour 9, 33' after midnight, Martin Hortensius [Maarten van den Hove] at Leiden saw Mercury higher than the bright star at 6' in the same straight line drawn from the bright shoulder of Auriga, and with a width in the right arm of the same. Lansbergen, in his *Thesaurus*, observed: Mercury 7', adding that this straight line drawn from Mercury falls into Gemini 23°50' circiter; the bright star of Mercury and refraction at 15' appears in that line, although truly lower in Gemini 23°36'41", with northern latitude 2°25'11".

7. In the year 1627, October 15, near the Goesian island [Goes], Martin Hortensius saw Mercury distant from Saturn about 1° circiter. Lansbergen, in his *Thesaurus*, observed: Mercury 8'; he gathers the place of Saturn in Libra 3°57'19", with northern latitude 2°6'3", and Mercury in Libra 3°45', with northern latitude 1°55'12".

8. In the year 1630, December 12, in the morning at hour 6, 50' after midnight, Boulliau at Joinville observed Mercury in Scorpio, at hour 29°13'. So he himself, Book 11, *Astronomical Theorems*, Theorem 13.

9. In the year 1632, July 31, in Old Style, the conjunction of Mercury and Venus took place — concerning which Martin Hortensius [wrote] *On Mercury seen in the Sun*.

CAPUT V.

Mercury observations made by Pierre Gassendi, and by the Fathers of the Society of Jesus at Ingolstadt and at Oeniponte [Innsbruck].

1. When Kepler [Johannes Kepler], in computing the Ephemerides, had warned that Mercury would be in transit across the Sun on 7 November, but actually that Venus would fall in transit across the Sun on 6 December, Gassendi [Pierre Gassendi]—who had at Paris previously supposed Mercury's diameter to be 3 minutes, but afterward found it to be no more than 20 seconds—used the telescope on 7 November. From about the ninth morning hour, when clouds, which had filled the sky, broke open, since Mercury had then crossed half its little path [semita] across the Sun's disk, and he had noticed a spot, he at once recognized from the swiftness of its motion that it was Mercury. For when the Sun stood at altitude $21^{\circ} 44'$, that is, at the morning hour 10h 28m, Mercury had passed off the Sun's western edge; for it was retrograde, with northern latitude $6^{\circ} 20'$. And so, not yet having completed its passage, it ought to have entered upon the Sun with two minutes and half a minute of latitude, and to have spent five hours under the Sun's disk. On 6 December, Venus could not be seen, nor indeed on the 7th, as Gassendi himself relates in the *Life of Peiresc*, book 4, and in the *Meteorology* of Epicurus, page 899. On this occasion Hortensius [Maarten van den Hove (Hortensius)] published a dissertation against Gassendi concerning the Mercury seen upon the Sun, and the Venus not seen. Kepler had predicted the conjunction with the Sun for 1h 41m before midday. At Uraniborg [Vraniburgi], therefore, it must have been about an hour before midday, that is, 47 minutes. But here Kepler's Tables proved truer than the others, since for that time the other Tables place Mercury, distant from the Sun in longitude, where Ptolemy [Ptolemy] gives $4^{\circ} 25'$, Copernicus [Copernicus] 5° , Longomontanus [Longomontanus] $7^{\circ} 13'$, and Lansbergen [Lansbergen] $1^{\circ} 21'$. Furthermore, Boulliau [Ismaël Boulliau], in book 10 of his *Astronomia*, ascribes this to Gassendi—both on account of other observations, and chiefly on account of this one, for which he left the rest of the Coronides as a finishing-piece [?]*—*and in chapter 5 of the same book he relates that Gassendi, having taken Mercury with the telescope upon white paper, computed the true conjunction of Mercury with the Sun at 7h 58m, at Paris, with the Sun in Scorpio; and from the Philolaic [Tables] he gives $14^{\circ} 37' 42''$, with northern latitude of Mercury [$4^{\circ} 30'$ — *see below*].

2. In the year 1632, on 30 July, at hour 16h after midday, at Uraniborg, Gassendi observed at Paris the conjunction of Venus with Mercury by means of the telescope, yet in such a way that Mercury seemed to surpass Venus by 3' 30". Hortensius observed the same conjunction at Amsterdam; and Boulliau, in book 10, chapter 1, from his own Tables collecting Venus in Cancer at 24° 22' 17", reports that Mercury was therefore in Cancer at 24° 25' 47".

3. In the year 1634, on 2 January, at hour 6h 30m, at Uraniborg reduced [i.e. computed for the Uraniborg meridian], Gassendi, observing Mercury by its distances from the fixed stars, found Mercury in Aquarius at 1° 31' with southern latitude 57'. On the 4th, in Aquarius at 3° 31' with southern latitude 30'; and on the 6th, in Aquarius at 5° 1' with northern latitude 1° 52'. Thus Boulliau, in book 10, chapter 1, who from this gathers that on the 3rd, at hour 6h 30m, the maximum elongation was 18° 59', and Mercury in Aquarius at 2° 30' 43", distant from the Sun in Capricorn at 13° 33' 43".

4. In the same year, on 2 October, Gassendi, observing Mercury by its distances from the fixed stars, found Mercury in Virgo at 22° 8' 20" with northern latitude 1° 25'; and on the 3rd, at hour 18h, in Virgo at 22° 59' 26" with northern latitude 1° 29' 18"; and on the 4th, in Virgo at 23° 59' 47" with northern latitude 1° 19' 16". Boulliau, book 10, chapter 1, gathering from this that on the 3rd, at hour 18h, the maximum elongation was 17° 49' 54", and Mercury in Virgo at 22° 59' 26", distant from the Sun in Libra at 10° 49' 20".

5. In the year 1634, at the beginning of November, Mercury was under the Sun in a central conjunction with the Sun, yet Gassendi in the *Life of Peiresc* denies that the telescope could see it, just as it could not in the year 1632 at the end of April; from which he concludes that the orbit [cyclum] of Mercury is not between the Sun and ourselves, but around the Sun—a conclusion which holds good only by supposition, since those central conjunctions [could] not [be made] to fall on a night [?].

6. In the year 1635, on 16 January, Gassendi observed Mercury through the fixed stars in Capricorn at 4° 18' 48" with northern latitude 2° 1' 15"; and on the 18th, at hour 18h 3m, in Capricorn at 8° 21' 50" with northern latitude 1° 39'; and on the 24th, in Capricorn at 10° 4' 55" with northern latitude 1° 14' 8"; and on the 25th, in Capricorn at 11° 6' 36" with northern latitude 59' 48". Boulliau, book 10, chapter 1, gathers from this that the maximum elongation on the 24th, at hour 18h $\frac{3}{4}$, was 25° 9' 20"; Mercury in Capricorn at 10° 4' 55", distant from the Sun in Aquarius at 5° 14' 15".

7. In the year 1635, on 17 September, Gassendi observed Mercury in the morning at $6^{\circ} 8'$ of Virgo, and on the 19th at $8^{\circ} 7'$; that day the 18th, at the morning hour 17h after midday, the maximum digression was $19^{\circ} 44' 21''$ from the Sun's true place. Boulliau, book 11, theorem 11.

8. In the year 1635, on 1 December, Gassendi at Digne [Diniae], at hour 5h 30m, by distances from the fixed stars, observed Mercury in Capricorn at $0^{\circ} 34' 49''$ with southern latitude $1^{\circ} 31'$; the altitude was $1^{\circ} \frac{2}{3}$, whence Boulliau, book 11, theorem 13. By reckoning of the refractions, he establishes Mercury's corrected place at minute 26 of Capricorn, with latitude 2° ; but from his own Tables, $23'$ of Capricorn.

9. In the year 1636, on 26 June, Gassendi at Aix [Aquis Sextiis] observed Mercury in the evening at altitude $3^{\circ} \frac{1}{3}$, distant from the Heart of Leo [Cor Leonis] by $31^{\circ} 23' \frac{2}{3}$, and from the Bright Star of the Neck of Leo [Lucida colli Leonis] by $31^{\circ} 41'$, whence he gathers Mercury's apparent place in Cancer at $23^{\circ} 25' 17''$ with northern latitude; but on account of a refraction of $15'$ he corrects it to $23^{\circ} 17' 47''$ with latitude $1^{\circ} 36' 55''$. Boulliau places it at 23° of Cancer. Book 10, chapter 2.

10. In the same year, on 27 June, Gassendi in the same place saw Mercury in Cancer at $24^{\circ} 56' \frac{3}{4}$ with northern latitude 2° . With the refractions eliminated, Boulliau, book 10, chapters 2 and 4, by whom the Rudolphine Tables place Mercury in $25^{\circ} 1'$, and the Philolaic at $25^{\circ} 3' 33''$ of Cancer.

11. In the year 1636, on 14 July, in the evening, Gassendi at Aix observed Mercury, corrected from the refraction of its place, in Leo at $19^{\circ} 31' 16''$ with southern latitude. Boulliau, book 10, chapter 2, and on the 15th, in Leo at $20^{\circ} 33' 15''$ with southern latitude $33'$. Boulliau, the same place.

12. In the year 1636, on 16 July, Gassendi in the same place, from two observations, as Boulliau says (book 10, chapter 4), gathers that he observed Mercury in Leo at $21^{\circ} 25'$ with northern latitude, while the Rudolphine Tables for hour 9h, reduced to Uraniborg, exhibit $21^{\circ} 30'$; and the Philolaic, $21^{\circ} 25' 47''$.

13. In the year 1636, on 3 September, at hour 17h, Gassendi at Digne saw Mercury next to the Heart of Leo through the telescope. "I detected," he says, "the Heart of Leo below and to the right of Mercury, so that Mercury was directed toward it not perpendicularly, nor with its side placed to the left, but as it were obliquely, drawing nearer to it toward the top [verticem] rather than toward the side." Next he observed Mercury's distance from the Heart of Leo to be $22^{\circ} \frac{2}{3}$, by the Astronomical Radius. Boulliau, book 10, chapter 3, who, with Regulus supposed at

24° of Leo, gathers Mercury's place in Leo at 24° 37', or 38'; but from his own Tables in Leo at 24° 38' 52", and from the Rudolphine at 24° 27'.

Moreover, the Fathers of the Society at Ingolstadt had these observations, which Father Michael Staudacher [Michael Staudacher SJ] of the Society of Jesus recently sent to me.

In the year 1631, on 7 November, Mercury was seen under the Sun at hour 9h 56m in the morning, distant from the center of the Sun's disk a little more than half a solar semidiameter toward the Zephyr-and-north [i.e. northwest]; but at hour 1h after midday it had already passed off from under the Sun.

Observations made at Oeniponte [Innsbruck] by the Fathers of the Society of Jesus, and communicated to me by one of them, Father Michael Staudacher.

CAPUT VI.

Selected Mercury observations, from those which the Fathers of the Society of Jesus, Giovanni Battista Riccioli and Francesco Maria Grimaldi [Francesco Maria Grimaldi], carried out at Bologna in the College of Saint Lucia, together with their assistants.

1. In the year 1643, on 3 May, at the second hour after midday following nightfall [?], Mercury was seen distant from Jupiter by $1^{\circ} 4'$, in both longitude and latitude. From the Lansbergen [Tables] it ought to be distant $1^{\circ} 36' 43''$ [?].

2. In the same year, on 5 May, with a most serene evening, Mercury was seen in the new sextile [in Sextante novo], distant from the head of Andromeda by $26^{\circ} 43'$, and from the cingulum [belt-star] of Andromeda by $35^{\circ} 17'$. And then it was at altitude about 6° , in the quadrant next [following] after sunset.

3. On the following evening, with the sky reddening at sunset a little after the setting of the Sun, Mercury was seen at altitude $8'$, distant from the head of Andromeda by $26^{\circ} 10'$, and from the cingulum of Andromeda by $33^{\circ} 59'$.

4. In the year 1643, on 7 May, in the evening with a most serene sky, Mercury was seen at altitude $7^{\circ} 50'$, distant from the cingulum of Andromeda by $32^{\circ} 52'$; it was also seen distant from the head of Andromeda by $6^{\circ} 22'$.

5. In the same year, on 11 May, Mercury was seen in the evening distant from the zenith [vertice] by $80^{\circ} 48'$, and from the cingulum of Andromeda by $28^{\circ} 41'$. Next it was seen distant from the zenith by $81^{\circ} 49'$, and from the head of Andromeda by $23^{\circ} 56' \frac{1}{2}$.

6. On the following evening, with a most serene sky, Mercury was seen distant from the zenith by $80^{\circ} 28'$, and from the cingulum of Andromeda by $27^{\circ} 51' \frac{1}{2}$; with the altitude of Aldebaran being $52^{\circ} 21'$ when these [observations] were made. When this was so, the altitude of Aldebaran [Aldebara] was $51^{\circ} 34'$; Mercury was seen distant from the southern foot of Andromeda by $37^{\circ} 33'$.

7. In the year 1643, on 23 August, in the morning, at the transit of the Bright Star of Aries [lucidae Arietis] across the meridian [per M. C.] there were numbered $41' 8''$; and afterward Mercury was seen at altitude $6^{\circ} 26'$, and distant from the bright star of the shoulder of Orion [humero lucido Orionis] by $49^{\circ} 35'$. Then after 7 minutes it was seen at altitude $5^{\circ} 50'$, distant from Procyon by $25^{\circ} 27' \frac{1}{2}$, the observations being repeated as customary.

8. On the following morning, on 24 August, at the transit of the Bright Star of Aries across the meridian numbered they are, at minute 32; afterward Mercury was seen at altitude 4° , distant from the bright star of Orion by $50^{\circ} 2'$, and after 7 minutes it was seen at altitude $3^{\circ} \frac{1}{2}$, distant from Procyon by $26^{\circ} 13'$.

9. Likewise in the year 1643, on 31 August, Mercury was at distance from the zenith $34^{\circ} 10'$, and after 2 minutes of time it was seen at altitude $3^{\circ} \frac{1}{2}$, distant from Procyon by $33^{\circ} 59' \frac{1}{2}$; thereupon after 2 minutes of time it was seen at altitude $3^{\circ} 50'$, distant from the bright shoulder of Orion by $58^{\circ} 42' \frac{1}{2}$.

10. At length on 26 December of the same year, in the morning, with a most serene sky and a most pure Aquilo [north wind] blowing, Mercury [was seen] in azimuth $50^{\circ} 44'$; it was seen at altitude $6^{\circ} 25' \frac{1}{2}$; and then Arcturus was distant from the zenith by 25° precisely.

11. In the year 1644, on 6 August, at the rising of the Bright Star of Aries, distant from the zenith $25^{\circ} 55'$, Mercury, the morning digression being nearest to its maximum, was seen at altitude $3^{\circ} 15'$, and distant from Aldebaran by $50^{\circ} 24'$. Next, after 8 minutes, it was seen at altitude $4^{\circ} 10'$, distant from the bright shoulder of Orion by $34^{\circ} 8' \frac{1}{2}$.

12. In the same year, on 13 August, in the morning, Aldebaran was distant from the zenith by $43^{\circ} 36'$; and after 7 minutes of time, Mercury was seen at altitude $7^{\circ} 12'$, distant from the following shoulder of Orion by $42^{\circ} 12'$. Next, after 2 minutes of time, it was seen at altitude $7^{\circ} 28'$, distant from Aldebaran by $58^{\circ} 36' \frac{1}{2}$.

13. In the year 1644, on 21 November, in the morning, Regulus, on the western side, was distant from the zenith by $31^{\circ} 11'$; after minute 18 of time, Mercury was seen at altitude $5^{\circ} 10'$, distant from Spica by $22^{\circ} 3'$; and after 5 minutes of time, it was seen at altitude $10^{\circ} 15'$, and distant from Arcturus by $34^{\circ} 45'$. *Perigee.*
Excentre [Perig. Excentr.].

14. In the year 1644, on 26 November, in the morning, Arcturus on the eastern side was distant from the zenith by $49^{\circ} 50'$; and after 17 minutes, Mercury was seen at altitude $8^{\circ} 55'$, distant from Arcturus by $37^{\circ} 5'$; and after 3 minutes it was seen at altitude $9^{\circ} 12'$, and distant from Spica by $25^{\circ} 49'$.

15. In the same year, on 29 November, in the morning with a most serene sky, Arcturus on the eastern side was distant from the zenith by $44^{\circ} 45'$; and after 2 minutes of time, Mercury was seen at altitude $7^{\circ} 46'$, and distant from Arcturus by $39^{\circ} 19'$. Hence after 7 minutes of time, it was seen at altitude $8^{\circ} 22'$, and distant from Spica by $29^{\circ} 7'$.

16. In the year 1646, on 8 May, in the evening, Mercury was seen distant from Procyon by $45^{\circ} 40'$; at the high [point] [alto] by $29^{\circ} 14'$; in the same year also at the high [point] by $28^{\circ} 10'$, it was seen distant from Capra [Capella] by $21^{\circ} 56'$.

17. In the same year, on the following evening, Mercury was seen distant from Procyon by $44^{\circ} 22'$; at the high [point] by $26^{\circ} 7'$; in the same year at the high [point] by $27^{\circ} 6'$, it was seen distant from Capella by $21^{\circ} 30'$.

18. In the year 1646, on the evening of 15 May, Mercury was seen distant at altitude $37^{\circ} 57'$, from Procyon at altitude $23^{\circ} 40'$; in the same year also at the high [point] by $22^{\circ} 35'$, it was seen distant from Capella by $20^{\circ} 33'$.

19. In the same year, on 22 May, Mercury was seen in the evening, distant from Capella by $22^{\circ} 4'$, from Procyon at the high [point] by $15^{\circ} 23'$; and next distant by $33^{\circ} 1'$; from Procyon itself at the high [point] by $13^{\circ} 35'$.

20. In the year 1647, on 23 April, in the evening, Mercury was seen at altitude $13^{\circ} 30'$, distant from Procyon by $12^{\circ} 30'$. Next it was seen at altitude $12^{\circ} 30'$; it stood apparently distant from Procyon by $59^{\circ} 46'$ on account of refractions. Afterward it was seen at altitude $11^{\circ} 33'$, and distant from Capella by $30^{\circ} 31'$; the altitude meanwhile was 11° ; it was seen distant from the following shoulder of Orion by

35° 23' ½; the altitude of Capella then being 40° 12'; and these [observations were made] around the maximum digression of Mercury.

21. In the same year, on 30 April, in the evening, [Mercury] was seen at altitude 12° 22', and distant from Procyon by 52° 54' ½. Next it was seen at altitude 11° 52', and from the head of Pollux distant by 47° 34' ½.

22. In the year 1647, on 6 May, in the evening, Mercury appeared in the same straight line with Venus, and with the center of the Moon, one hour after sunset, so that Venus, the Moon, and Mercury appeared more westerly; but on account of the splendor of the Moon, the remaining crepuscular [observations] could not be made, as far as the others [are concerned].

23. In the year 1648, on 31 March, in the evening, Mercury was seen at altitude 8° 47', and distant from Aldebaran by 37° 34'; thereupon at altitude 8° 20' it was seen distant from Rigel by 52° 58'; Aldebaran being then at altitude 37° 44'.

24. In the same year, on 7 April, in the evening, Mercury was seen at altitude 12° 53', and distant from Aldebaran by 28° 3' ½; at altitude 11° 57' it was seen distant from Rigel by 46° 40' ½; and after a minute of time Aldebaran was distant from the zenith toward the west by 57° 57'.

25. In the year 1648, on 9 April, in the evening, Mercury was seen at altitude 12° 32', and distant from Aldebaran by 26° 4'; at altitude 12° it was seen distant by 45° 27' ½; from Rigel at altitude 71° 5'; Aldebaran being distant from the zenith toward the west by 60° precisely.

26. In the same year, on 13 April, in the evening, [Mercury] was seen at altitude 11° 30', and distant from Aldebaran by 23° 19' ½; thereupon at altitude 10° 54' it was seen distant from Rigel by 43° 45' ½; the altitude of Rigel being nearly 18°, but Aldebaran at altitude 25° 50'.

27. Likewise in the same year, on 15 April, in the evening, Mercury was seen at altitude 9° 14', and distant from Aldebaran by 22° 23' ½; soon at altitude 8° 36' it seemed to be distant from Rigel by 43° 11' ½; at altitude about 15°, but Aldebaran at altitude 22° 43'.

28. In the year 1649, on 22 December, in the morning, Mercury was seen at altitude 6° 40', and distant from the head of Ophiuchus by 34° 32' ½; but at altitude 7° 12', it was seen distant from Spica by 48° 49'.

29. In the year 1651, in the month of February, Mercury was observed for nine days by taking its distance from the zenith in the same Vertical [circle], in which

afterward, for the exact azimuth, the distance of Aldebaran from the zenith was taken. Moreover, with the times numbered by perpendicular [i.e. plumb-line timing], the distance of Sirius from the zenith was also taken, with Mercury observed, in the eastern quadrant.

Supp lem.	12	<i>Mercurius visus est distare à vertice gr. 80. 28'. in eo Azimutho, in quo Aldebara visa est distare à vert. grad. 74. 50'. [Mercury was seen distant from the zenith by 80° 28', in that azimuth in which Aldebaran was seen distant from the zenith by 74° 50'.]</i>		

In the year 1657, on December 5, in the morning, when Spica Virginis stood in the eastern quadrant and was distant from the zenith by $58^{\circ} 20'$, the count of the perpendicular's time began at 8h [?] 30". Mercury's distance from the zenith was taken as $81^{\circ} 16'$, in an expected azimuth of $55^{\circ} 27' 52''$, corrected and counted from the south. From this, Fr. Francesco Maria Grimaldi [Grimaldi], to whom we owe this observation, found Mercury's place at $24^{\circ} 19' 55''$ of Scorpio, with a northern latitude of $1^{\circ} 48' 55''$, with an elongation from the Sun of $18^{\circ} 50'$; and this was about 8 hours after midnight.

CAPVT VII.

On the Hypothesis of Mercury's Motions.

1. There is no reason to repeat here what we have explained at sufficient length in Book 7 of the *Almagestum Novum* [*Almagestum Novum*], Section 4, and here in Book 5, Chapter 12, where we set out the famous hypotheses and theories of the astronomers concerning the motions of Mercury, by way of explaining their tables. But I want it understood that Mercury's geometrical figure — by various spiral arcs about a cone rather than by a single circle — is here implied through an ellipse for the reader, as was done in the same volume's Book 5, on the occasion of Saturn, in Chapter 10,

on the methods of observing the places of the planets, and in Chapter 12, on the geometrical figure. So a few things remain to be added or recalled here. The chief difficulty in observing Mercury — apart from the error of many minutes owing to its nearness to the Sun, by which it is almost always wrapped in refraction — is the inconstancy of its variation. That Ptolemy [Ptolemy] and Copernicus [Copernicus] frankly admitted Mercury was unobserved by them on account of the vapors of the Nile, or unseen, as Tycho [Tycho Brahe] also did in his preface to the *Epistolae Astronomicae*; and Longomontanus [Longomontanus] in Book 2 of the *Theorica*, Chapter 20, agreeing with this, says it was rarely permitted him to observe Mercury in the great obliquity of that sphere which the horizon of Uraniborg has — this, I say, is pardonable, if Copernicus erred by more than 5° in this star, and sometimes by 7° ; and Tycho too, and Longomontanus, by more than $12'$ in 10 minutes of [his] observation, as Book 2 of the *Theorica*, Chapter 20, examines. He did not find among the observed and computed place from the Danish Tables a discrepancy greater than $12' \frac{1}{2}$, though it elsewhere exceeds whole degrees, as I shall say, number 3.

2. Let us now hear Kepler [Kepler], who, where he laid the foundation of his Ephemerides on page 15, said he did not fear an error in his Rudolphine Tables for Venus that exceeds $15'$. He adds: *In Mercury the difficulty is greater, and the occasions for detecting errors are very rare. All his observations recorded by Tycho span 20 years, and these indeed are reliable and beyond doubt, falling within one degree [?]; the remaining two thirds [of Mercury's revolution] go unobserved — in this age, that is. But in our own, how great a difficulty there is, drawn from a part of the arc, to complete the whole circle without error, needs no many words to declare.* Therefore, even at the greatest elongations, which our hemisphere [in the morning sky] — the Sun not begrudging us — affords, no great error can arise from a faulty commutation; but at the conjunctions, of which there is a great [obscurity] in Mercury together with the Sun, I dare not affirm that my calculation always stays within the bounds of that very day: by how much time, by five degrees, it can sometimes vary; but Mercury's apparent place, when it is retrograde, by one degree or a half.
3. [Margin: The error of the various Tables in Mercury.] Long ago I noted, in Book 3 of the *Almagestum Novum*, Chapter 3 in the Scholia, and Book 7, Chapter 6, number 5: In the year 1631, on November 7, Mercury was observed beneath the Sun by Pierre Gassendi [Gassendi] with the aid of a telescope, and its conjunction with the Sun at hour 7h 58'; from that

moment the Ptolemaic Tables erred by $4^{\circ} 25'$, the Prutenic by 5° , the Danish by $7^{\circ} 13'$, the Lansbergian by $1^{\circ} 21'$. And so Natal Duret [Natalis Duret], a follower of Lansbergen [Lansbergen], earlier transferred [his calculation] in the Ephemerides to the Rudolphine standard. Martin Hortensius [Hortensius] too differs [from the others] —

— Gassendi, in affirming that Mercury was seen on the Sun in the year 1632. On July 31 he observed a conjunction of Venus with [Mercury]; and when, according to the Danish [Tables], it ought to have been distant from [Venus] by [?] $53'$. And Antonius Maria de Rheita [Anton Maria Schyrleus de Rheita], in Book 2 of his *Oculus mysticus*, Chapter 2, notes errors of 5° , 6° , and 7° in the Tychonic hypothesis. Kepler himself, in the foundation of the Ephemerides, page 32, when he had said his calculation differed by about 21 minutes from the observation of Mercury's conjunction with the Moon, which occurred in the year 1617 on March 8 at hour 7h 26' after noon, confessed that so great a discrepancy could not lie wholly in the observation, but that part of it was in the foundation of the Tychonic calculation, as regards the Moon.

4. [Margin: Kepler's faulty calculation.] But Elias von Löwen [Elias von Löwen], who is the author of the work *Urania Propitia*, Part 2, Chapter 17, points out that Kepler unjustly fastened that mark [of error] upon Tycho on account of a faulty calculation. For from the daily overtaking of the Moon that follows Mercury by a degree, which was $14^{\circ} 11'$, he gathers that it ought to have been observed [later] by 7h 7' [at] $3^{\circ} 51'$, when in truth it ought to have been gathered as $4^{\circ} 12' 20''$; thus the error of 21' does not arise from the Tychonic foundations but from Kepler's false computation. He further adds, in recommendation of the Rudolphine [Tables], another observation in which Longomontanus, at Copenhagen [Hafnia], on April 14, old style, at hour 8h $\frac{1}{2}$ after noon, saw Venus, and the stars of Mercury [?] separated from one another by $2^{\circ} 24'$. The Rudolphine [Tables], however, present them as distant by $2^{\circ} 25' 30''$ in reality, but on account of refraction by $2^{\circ} 24' 20''$. And he concludes, saying: *This observation, save for the Rudolphine, no other Table expresses* — he is speaking of the Danish, the Lansbergian, and the rest of the older ones, for he had not yet seen the Philolaic and our own. He next proceeds to the transit which Ptolemy proposes in Book 9, Chapter 7 and 10, and asserts that those two chapters are most corrupt, partly through the carelessness of the transcribers, partly through Ptolemy himself, who ill-matched the days of the months of the Dionysian year with those of the Egyptian year, putting Mechir for the 30th of Phamenoth. Accordingly Elias, having set this aside, proposes another

form of the Dionysian year on page 71 of his Tables, from which, restoring the places of those observations into his own as he supposes, he indeed makes them come close to the said observations — but they still need some remedy to draw nearer. There will nonetheless be one who suspects that Elias too, out of excessive devotion to the Rudolphine, accommodated the standard of the Dionysian year to those [Tables], so that the observations would agree with these tables, and that one cannot easily be persuaded that Ptolemy erred by a whole month, or that Mechir should be set for Phamenoth. But on this matter I shall see, God willing, in the *Chronologia Reformata*.

5. [Margin: Boulliau's sound calculation.] Boulliau [Boulliau], indeed, in Book 10 of his *Astronomia Philolaica*, Chapter 1, affirms that Mercury's slower delays toward aphelion and its swifter passages through perihelion are tried in vain on any hypothesis other than the elliptical; nor does he hope to surpass others in unfolding the motions of this planet, [achieved] by intermediate means — since in other matters he is destitute of observations — from Ptolemy down to our own times. Yet he promises the true proportion of the orbs, and the place and [motion?] of the aphelia and the nodes. If anyone reads this author through, he will see with how much penetration, candor, and zeal for truth he treats the observations made of Mercury by Walther [Bernhard Walther], Tycho, Hortensius, Gassendi, and others — and let everyone judge that nothing has hitherto been done more diligently by any astronomer, so far as I know, as regards the mean motion of Mercury. He follows now the Rudolphine, now adds $11' \frac{1}{2}$; we too, from our own observations and remarks, shall add some correction to this.
6. But lest we fill the pages with excessive prolixity, from the many observations selected above — to which, as to touchstones, we have examined the Lydian Tables, especially those that we present, and which our own most closely approach, and next the Philolaic and the Rudolphine — it pleases me to set forth for the Readers the following, written below.
7. In the year 1585, on November 14, old style, Tycho at Uraniborg observed Mercury after noon in Scorpio at $13^{\circ} 4'$, with a northern latitude of $2^{\circ} 18'$. The Danish [Tables] give its place in Scorpio at $12^{\circ} 57'$, the Rudolphine at $13^{\circ} 7' 45''$, ours at $13^{\circ} 2' 54''$.
8. In the year 1587, on January 9, old style, Tycho at Uraniborg, at hour 4h 50', observed Mercury in Aquarius at $17^{\circ} 48'$, with a northern latitude of $0^{\circ} 1'$; adding that, according to the Alphonsine [Tables], it had been in Aquarius

at $18^{\circ} 29'$ with a latitude of $0^{\circ} 24'$ north. According to Copernicus, however, in Aquarius at $16^{\circ} 41'$ with a southern latitude of $0^{\circ} 6'$; the Philolaic Tables show Mercury in Aquarius at $17^{\circ} 35' 12''$; ours at $17^{\circ} 35' 45''$.

9. In the year 1592, on February 3, old style, at hour 5h 40', Mercury was observed at Uraniborg in Pisces at $12^{\circ} 20'$ — as Longomontanus has it, who from the Danish [Tables] gives Mercury in Pisces at $12^{\circ} 13' 57''$. We [give it] at $12^{\circ} 15'$.
10. In the year 1631, on November 7, at Paris, Gassendi with a telescope observed Mercury beneath the Sun, and fixed its conjunction with the Sun at hour 7h 58' after midnight. Our Tables give the Sun at that time in Scorpio at $14^{\circ} 38' 30''$, and Mercury in Scorpio at $14^{\circ} 37' 40''$, with a northern latitude of $4' 35''$.
11. In the year 1632, on July 31, in the morning, at hour 4h after midnight, [Gassendi] observed the conjunction of Mercury with Venus at Paris. But Hortensius, from his own observation made at Amsterdam, says it occurred at hour 11h $\frac{1}{3}$ after noon of day 30. From our Tables we obtained Venus at Bologna after midnight of day 31 in Cancer at $24^{\circ} 22' 15''$, and Mercury in Cancer at $24^{\circ} 36' 40''$. Hence, from the diurnal motion, that conjunction is gathered to have been almost at that very midnight, which fell between days 30 and 31 of July. In the place of Mercury the Danish Tables erred by 3° in [?]; and the Prutenic anticipated that synodic conjunction by whole five days. This [observation] ought to be placed after that one which shall be set down at number 9.
12. In the year 1634, on October 2, Gassendi, at Aix [Aquae Sextiae], at hour 17h 58' after noon — reduced to the Bologna [meridian] — observed Mercury more to the east, six minutes [?] beyond the outermost star of the Southern wing of Virgo. To me, that star was then in Virgo at $22^{\circ} 0' 3''$, and Mercury in Virgo at $22^{\circ} 5' 50''$; the Rudolphine [give it] in Virgo at $22^{\circ} 5'$, Boulliau at $22^{\circ} 6' 58''$.
13. In the year 1636, on June 27, in the evening, Gassendi at Aix observed Mercury compared with Venus in Cancer at $25^{\circ} 5' 53''$ — though refraction is excepted, as Boulliau gathers. The Rudolphine Tables give it in Cancer at $25^{\circ} 1'$; the Philolaic at $25^{\circ} 3' 33''$; ours at $25^{\circ} 4' 10''$.

14. In the year 1636, on July 16, in the evening, Gassendi at Aix observed Mercury in Leo at $21^{\circ} 26'$. The Rudolphine produce its place at Uraniborg in Leo at $21^{\circ} 30'$, the Philolaic in Leo at $21^{\circ} 25' 47''$, ours in Leo at $21^{\circ} 25' 52''$.
15. In the year 1634, from Gassendi's observations, Boulliau gathers [colligit], on day 3 of January, at hour 6h 30' after noon [post me(ridiem)], that Mercury had been in Aquarius at $2^{\circ} 30' 43''$, with a maximum elongation from the Sun in Capricorn at $13^{\circ} 33' 43''$. To me, the Sun was then in Capricorn at $13^{\circ} 29'$, and Mercury in Aquarius at $2^{\circ} 31' 10''$.
16. In the year 1636, on September 3, at hour 17h after noon, at Dinan, Mercury was observed through a telescope more to the west than Regulus, by $10'$ as Boulliau gathers. To me, Regulus was then in Leo at $24^{\circ} 48' 17''$; therefore Mercury was in Leo at $24^{\circ} 38' 17''$; the Rudolphine give it in Leo at $24^{\circ} 27'$, the Philolaic in Leo at $24^{\circ} 38' 52''$, and ours [Nostrae] in Leo at $24^{\circ} 37' 55''$.
17. In the year 1657, on December 5, in the morning, at about hour 8h after midnight, Mercury was observed in Scorpio at $24^{\circ} 19' 35''$. Our Tables give it at $24^{\circ} 16' 7''$; but the Danish at $25^{\circ} 24'$, the Lansbergian at $24^{\circ} 45'$ in Scorpio. And these things meanwhile suffice.

Hypothesis Mercurij Arithmetica.

[The Arithmetic Hypothesis of Mercury.]

The columns are: sign-degree group (Sig.G.), then sexagesimal sub-columns I., II., III., IV., V.

Hypothesis Geometrica.

[The Geometric Hypothesis.]

If, in the meantime, one should choose the circumference of an ellipse — which on the surface of a cone appears most nearly to mark out the motion of the planet, made now by some spirals, now by others, [spirals winding] not toward the East, as those suppose who assign the diurnal motion of the Prime Mobile to the Earth, but toward the West, as we suppose — then let the measures written below also be chosen [as expressed] in parts of which the radius of the Sun's Annual Orbit is 100000, and its bisected eccentricity 1740.

The right-hand column gives the value "if the radius of the Sun's Annual Orbit ☉ is 100000."

[Quantity:] Of such [parts] [Talium]	If the radius of the Sun's Annual Orbit ☉ is 100000

LIBER DECIMVS

IN QVO PARALIPOMENA OBSERVATIONVM AD FIXAS, Et
Planetas Minores Pertinentium, videlicet

DE Diametris Apparentibus, eorumque Figura, Fascijs, Maculis,
Vertigine, Comitibus, & Comitum motibus, AC DISTANTIIS A SOLE, ET
A TERRA.

[BOOK TEN, in which are gathered the Supplementary matters of the
Observations pertaining to the Fixed Stars and the Lesser Planets, namely: On

their Apparent Diameters, and their Figure, Bands, Spots, Rotation, Companions, and the Motions of the Companions, and on their Distances from the Sun and from the Earth.]

CAPVT I.

On the Methods of Observing the Diameters of the Fixed Stars and of the Planets.

1. [Margin: Method 1.] The first method, used by the ancients, consists in an estimate by the eye comparing the seen diameter of a star with a portion of the Moon's diameter, or with a small distance between two fixed stars known from another source — for instance, with the distance of the Pleiades among themselves, or of the Hyades. But this method is very deceptive, or is established by the experience of many observers at once, since just as many eyes as there are, so many different opinions about the magnitude of the stars are generally produced. The reason is that the adventitious rays around the stars, whether from the atmosphere or from the eye's humors or from refractions [that] appear, optically enlarge their disks, and conversely diminish the distances between them by just as much.
2. [Margin: Method 2.] The second method is carried out by means of the Dioptra of Hipparchus [Hipparchus], or similar to it — that is, by applying a very narrow strip, which at a great but known distance from the eye covers precisely a star; or by applying a small tablet, or a thin plate, such that at a great but likewise known distance it intercepts within its edges the entire body of the star — or at least a space three times larger than the star's disk; for by the laws of right-lined triangles and of rectangles, from the given strip, or tablet from the eye, and from the similitude of the tablet or plate, the angle is gathered, which when doubled measures the apparent diameter of the star; or, in the third manner, when a space three times larger than the star's apparent [diameter] is taken. But this method is in every respect deceptive: from what has been said it is established for a triple reason that it is deceptive. First, because the situation in which the whole tablet, or one perforated, exactly agrees with the star's diameter, or with a space three times greater, does not consist in [a single] indivisible [point], but it is established by experience that, in moving it toward the eye or away from the eye, no sensible difference appears to the eye; then the ocular estimate itself, on account of the adventitious rays of the star, as has been said, is deceptive. Finally, the angle which is acquired by means of a

Dioptra of this kind is not the true visual angle; for it is at the surface of the eye, whereas the true visual angle is at the tunic of the retina, which is at the bottom of the eye. Therefore, so great a parallax intervenes, as great as the depth of the eye is — which, however, is not so known — and the Dioptra added at the surface of the eye, [renders] the angle to be obtained more justly by Trigonometry; otherwise it is always greater.

To this manner are reduced our own rays, both Triangular and Scalar, of which [we treated] in Book 6 of the *Almagestum Novum*, Chapter 9, number 6; then also the method of Galileo [Galileo] by a perpen-

suspended perpendicularly, which I nonetheless treat separately. I leave that for now.

[Margin: Third method.] **Third method.** The third method, then, is carried out by means of a thread suspended perpendicularly. As the eye draws back from the thread, the thickness of the thread eventually covers the star exactly. You then measure the distance of the eye from the thread, and also the width of the thread itself. By dividing the latter by an inch-scale [uncialis regula], you learn how many parts of this kind are contained in an inch. But the depth of the eye must be added to the predicted distance, since the rest is worked out by trigonometry. This is the method Galileo teaches in his third Dialogue of the *Cosmic System* [Galileo, *Dialogo sopra i due massimi sistemi*, Day 3], where he holds that, by covering the star with the thread, he intercepts the adventitious rays that he believes come from the eye alone. Yet he is mistaken here, because nothing prevents the rays reflected from the edges of the thread from reaching the eye; and so this method too is exposed to the same fallacy as the two preceding ones. He adds, however, that by this method—though not in every case—he found by exact observation that Lucida Lyrae [Vega] is no larger than five seconds, and that this builds a suspicion in the careful observer of the diminished apparent diameter of the fixed stars, so as to support the probability of the Copernican hypothesis. On that hypothesis the immensity of the distance of the fixed stars increases their bulk all the more, the greater their apparent diameter is.

[Margin: Fourth method.] **Fourth method.** The fourth method, used by Scheiner [Christoph Scheiner] for Venus, by Gassendi [Pierre Gassendi] for Mercury, and by Hortensius [Martinus Hortensius] for Jupiter, works through the reception of the bright image of Jupiter, or of Venus, or even of Mercury, as it passes through the lenses of the telescope onto a clean sheet of paper. One then measures the diameter of that image and compares it with the diameter of the solar image, using the same lenses and taking it on the same sheet at the very smallest

particles of distance from the lens. Gassendi, however, took the place of the image, except that on the paper he found the little umbra of Mercury seen against the Sun, and compared it with the diameter of the Sun. But I should think it credible that the umbra was diminished all around by the bright glow of the solar image—just as Hortensius admits that the image of Jupiter appeared to him fainter. For Rheita's method [Anton Maria Schyrleus de Rheita], see chapter 3, number 1.

[Margin: Fifth method.] **Fifth method.** The fifth method works by direct sighting through the telescope, exact and by ocular estimation, comparing the star with the Moon, or with a known interval between neighbouring stars. For the telescope strips away those adventitious rays which otherwise appear in our eye; and although the telescope does present the discs of stars shorn of the adventitious hair of rays, it nonetheless in no way enlarges the stars in proportion, since other non-luminous objects are not enlarged either—as Galileo too remarks in the third Dialogue of the *System of the World*, page 16, and in the *Sidereal Messenger* [*Nuncius Sidereus*].

[Margin: Sixth method.] **Sixth method.** The sixth method is the same as the preceding, but more perfect in this respect: if the convex lens of the telescope, set far back from the eye, is covered by a perforated piece of foil whose hole is nearly the size of a pea, then the rays are better stripped away by the more vigorous reach of the light. Otherwise the fixed stars are shown not bounded by a circular periphery, as the planets are, but flashing, and sending out their rays, and twinkling.

[Margin: 7] **Seventh method.** The seventh method includes the fifth, or the sixth, but adds besides a comparison with various little circles drawn on paper, and of differing sizes. For when the stars have been inspected through the telescope, and one looks back repeatedly at the said little circles, that one is at last to be chosen which, in the judgment of many eyes—or of the same eye in many observations—is seen as equal to the disc of the star inspected through the telescope. Finally, that little circle must be compared with the circle of the solar, Jovian, or Saturnian image, whose diameter is already known to us; and this method, attested by many—both by ourselves and by others—has given full satisfaction. From Hevelius's *Selenographia*, chapter 3, however, we have learned the use of the perforated foil.

[Margin: 8] **Eighth method.** The eighth method is the one Hevelius [Johannes Hevelius] suggests in chapter 55 of his *Selenographia*: namely, with the telescope—especially the one ringed about with perforated foil—the discs of the stars are

compared with the spots of the Moon's disc as to their respective sizes, the proportion of these spots to the Moon's diameter being known in advance.

[Margin: 9] **Ninth method.** The ninth method is the one Galileo indicates on page 7 of the *Sidereal Messenger*, and Martinus Hortensius in his *Dissertation* with Gassendi on Mercury seen against the Sun—the same that Scheiner too, and Kepler [Johannes Kepler], and Remus Quietanus [Johann Remus Quietanus] used—namely, by comparing the diameter of the star inspected by the telescope with the diameter of the telescope's aperture [capacitas], which had previously been explored, or by the same reasoning that Galileo, or Hortensius, teaches. And Hortensius indeed obtained the capacity of his own tube as 42", because he understood precisely the interval lying between two distant kids [haedi — the stars in Auriga], which is 42" by Tycho [Tycho Brahe]. Likewise because he took in one and a quarter times the lunar diameter, when this was 33' 30". Likewise because he took eight times the interval between the two adjacent stars in the following horn of Capricorn, which is reckoned at 5¼'. But Father Francesco Maria Grimaldi [Grimaldi] is accustomed, by stretching threads above the lens, to divide the capacity of the tube—its diameter—into four, six, or eight equal parts, so that with less danger of error he may estimate how many times the diameter of the star is contained in one of the said parts.

[Margin: A singular caution.] For the rest, in this method, and in many of the foregoing, caution must be taken that no equal proportion be inferred between the diameters from the proportion seen in the whole disc, or circle to circle, whether of the star or of the lens; for circles are to one another as the squares of their diameters, by Euclid 12.2. For example: if the diameter of Sirius is as 2, and that of Jupiter as 5½, Sirius will appear eight times smaller than Jupiter, because as often as the diameters are quaternary, the squares of the binary will be contained in the number 32, which is roughly the square of the number 5½.

[Margin: 10] **Tenth method.** The tenth method requires the application of the planet, when it is some stationary or very slow planet, to some fixed star caught within the tube with it: considering how often the star, or the planet, is contained in their mutual distance, and from the motion of the planet, how great that interval is, according to the examples and precepts handed down in book 7 of the *Almagestum Novum*, chapter 10.

[Margin: 11] **Eleventh method.** The eleventh method is supplied by Christiaan Huygens [Christiaan Huygens] in his *Systema Saturnium*, page 82, in these words: "There is a certain place within the tube, which they alone furnish who are

equipped with tubes fitted with paired lenses—circling about the other so much larger—which, brought near to the eye placed at a distance, exhibit in some place whatever lies within the cavity of the tube to the sight, subtle and distinct, with the outline exquisitely terminated. This place falls upon perfectly distinct objects to eyes set near; but for somewhat more distant ones the point must be taken farther off. Here, if a little ring be set up with a narrow opening, how large, free of space, it may circle round whatever is detected in the clear sky—so as to be described, and made precise. Of the space of this diameter, however small a scruple may be comprehended, it is to be investigated by the transit of the star, whose periods of vibrations are reckoned, or by the oscillation of our timepiece [Horologii], the telescope meanwhile remaining unmoved. With this device discovered, a small rod of latten [virgula metallica], gradually narrowing, is inserted into the tube in the said place, and it is noted how great a latitude of the rod covers the planet precisely, and from the latitude taken at the circle, compared with the whole amplitude of the opening, the diameter of the planet is easily learned by calculation. But I judge it slippery, and hard to remember, into what precise part of the rod the whole planet was covered."

CAPVT II.

De Saturni Diametro Apparenti.

[Margin: Opinions of others on Saturn's diameter.] [Margin: 1] 1. Albategnius [al-Battānī] and Alfraganus [al-Farghānī] determined the apparent diameter of Saturn at one minute and 44 seconds, roughly at its middle distance: al-Battānī in his chapter 50, al-Farghānī in chapter 22 here, with a difference of 22. Fernelius [Jean Fernel] in book 1 of his *Cosmotheoria*, and Egnatius Dantes [Pietro Vincenzo Dante] in Table 22, contracted it mathematically to 1' 40". By contrast Vurstisius [Christian Wursten] and Maginus [Giovanni Antonio Magini] in their *Theorics of the Planets* enlarged it to as much as 6 minutes—so deceived were they by ocular estimation and by the phases of the adventitious rays. Tycho [Tycho Brahe], in volume 1 of the *Progymnasmata*, page 468; Clavius [Christoph Clavius] and Blancanus [Giuseppe Biancani] in their *Sphaera*; and Argolus [Andrea Argoli] in his *Pandosion Sphaericum*, from chapter 52, define the Saturnian diameter at its middle distance as 1' 50". Lansbergius [Philips van Lansbergen], in book 3 of his *Uranometria*, restricted it to 1' 40" in its second. But if he did not

indicate the method he used in this determination... Kepler in the *Epitome of Astronomy*, volume 2, page 485, partly from Johannes Remus's observation 9, partly by the methods indicated in the preceding chapter, and partly by certain

analogies devised among the bulks and intervals of the planets (a thing in which Rheita too, in book 4 of his *Radii Sidereomystici*, chapter 2, member 3, has been his rival), limited Saturn's diameter at its greatest distance to 30", and in the *Rudolphine Tables*, at the end of precept 110, he says: "Saturn is never larger than 30" in seconds—it is recognized as roughly that." And in the *Epitome* itself he supposes this from the *Epitome of Astronomy*: "The bodies of all the planets are in proportion to their own intervals, and to the Sun's intervals; therefore the diameters are in subtriple ratio." Yet prudently he has said in the *Epitome*: "I yield the place to Remus, I yield to the observations." Rheita, however, in book 4, chapter 4, member 2, affirms that in the year 1644, on the 20th of July, taking the whole disc of the full Moon with the telescope and transferring it onto a divided chart into 34 equal parts, and likewise in the same way finding the diameter of Saturn to be the fifteenth part of the lunar—that is, in minutes—the Saturnian diameter, then minutes, [is] 2 and a little more. For at that time Jupiter was near the sextile aspect of the Sun, and Saturn near quadrature. But Martinus Hortensius, as he reports in his *Dissertation* with Gassendi on Mercury seen against the Sun, used method 9 of the preceding chapter in the year 1625. In February he saw Saturn near perigee as round, very nearly equal to Jupiter, whose diameter he had observed at 40"; but in the year 1632 he saw Saturn as 36". When Jupiter likewise appeared at 40", and Saturn with its appendages globular, so that it scarcely projected, it was seen as not in its whole minutes; whence too the smallness of error comes about whenever Saturn is seen without its companions through the telescope, in seconds 31", at apogee, and 42"¾ at perigee, to which Saturn at its altitude subtends.

[Margin: 2] [Margin: Our own observations.] [Margin: 3] 3. Through the same days the two stars among the Hyades were observed to occupy in their interval a fourth part of the space comprehended in the sky by our telescope—that is, 6½' minutes, or a little more. But the diameter AB of Saturn appeared to be contained in the space of those stars 5⅔ times. Again, considering a certain star among the Twins [Gemini], near Propus [η Geminorum], omitted in the catalogues of the fixed stars, inasmuch as it is visible by the telescope alone but selected by us, because it was in a straight line through AB drawn, there appeared a space between it and the most remote extremity A of Saturn containing the diameter AB, likewise 5⅔ times; but the space from the other extremity B, up to the same star, with respect to the diameter AB, was most evident, [as] 4⅔ to 1. Now indeed, the interval from the extremity A to that star, with the said interval of the Hyades frequently compared, appeared to it entirely equal. Accordingly the diameter AB was 71½ seconds, or 72.

[Margin: 4] 4. In the year 1650, on the following night, the 2nd of January, at hour 1, after the setting of the Sun, Saturn was, by its own diameter AB, in nearly the same straight line with a certain star toward the west, and a fixed one, which was viewed by the telescope at the same time as Saturn; but on the following night of the 3rd, around hour 2 of the night, because Saturn, still retrograde, was beginning to move along its proper orbit, not parallel to the equator, but along a line drawn through the centres of Saturn and of the Saturnian companions, as we shall say below, [with] a parallelism to the equator, Saturn had become more western, and more southern than the said star; and a straight line PR, drawn perpendicularly from the star P, above the diameter AB, fell nearer to F, in R, cutting off from the diameter AB the fourth part precisely. Then, at hour 5½ of the night, Saturn, retrograding more toward the west at its setting, and the star being re-established, it appeared in H, so that, a perpendicular BA being drawn and produced, up to L, the interval HL was equal to the interval AB—that is, to a fourth part of the diameter AB; but the interval AL truly receded as Saturn drew toward the west, and the interval appeared manifestly larger. Now indeed, by the more accurate Tables, the daily apparent motion of Saturn is 4' 30" minutes; therefore the hourly is 11" 15''' in seconds. So from hour 2 to hour 5½, it completed 36". The second, [and] 34'''—that is, the space equal to the semidiameter AO; for when the perpendicular fell from the star P, in R, it was AF, the fourth part of the whole AB; but when the perpendicular fell from H, in L, it was equal to AF itself; therefore LF was equal to the semidiameter AO; and so 36" 34''' in seconds. The whole therefore AB [is] 73" 8''' in seconds—which agrees above, from the prior observation, where we found the second [diameter] to be 72". Indeed, the difference of 1" is too small between so many diverse methods of observing—plainly negligible; nay, by consent very near, altogether marvellous, and to be related religiously by faith.

[Margin: 5] 5. We assume, then, that Saturn's perigeal diameter is in seconds 73", or 1' 12"; but the diameter FG of Saturn alone, in seconds 36", whence by Problem 1, chapter 8, in book 7 of the *Almagestum Novum*, section 7, set out, and from the least distance of Saturn from the Earth, which by the same section, chapter 2, we set down as the terrestrial semidiameter 57743, we shall gather its true diameter, simple indeed FG, [as] terrestrial semidiameters 4¾, but compounded AO, [as the] semi-

Diagram. A schematic showing Saturn (♄) with its ansae as a great horizontal ellipse, the globe of the planet at center flanked by two crescent-shaped lateral appendages (the ansae), together with reference stars and perpendicular construction lines used in the observation of §4. The Saturn glyph (♄) stands

above the figure at center. The large ellipse is the outer boundary of the apparition. Within it, two dark crescents (the ansae) lie left and right of an open central region. A vertical dashed line at upper left runs from the star H down to L; another vertical dashed line at upper center-right runs from the star P down to R.

- $\hbar$ (top center): Saturn glyph, naming the figure
- H (upper left, marked with a star): reference star on the west, top of the dashed perpendicular
- P (upper center-right, marked with a star): reference star, top of the dashed perpendicular to R
- C (top of ellipse, center): north point of the apparition
- L (left end, on the central horizontal): foot of the perpendicular from H
- A (left, inner): western extremity of Saturn's diameter AB
- K (left of center): point on the left ansa
- F (left of center, inner): point near the left ansa / endpoint of segment, the western edge of the globe
- O (center): center of the globe (Saturn's center)
- G (right of center, inner): point near the right ansa, eastern edge of the globe
- M (right of center): point on the right ansa
- B (right end, on the central horizontal): eastern extremity of Saturn's diameter AB
- D (bottom of ellipse, center): south point of the apparition
- R (lower center, marked with a star, foot of dashed line from P): foot of the perpendicular cutting diameter AB

[terrestrial] semidiameters $9\frac{3}{4}$. Then from the distance of Saturn from the Earth, at middle distance, [as] semidiameters 73000, and at greatest [distance] 90155, by Problem 2 of the same chapter 8, we shall deduce the semidiameter [or] apparent diameter of Saturn at middle distance, simple indeed FO 13" 20", but compounded AO 28" 30"; and at greatest distance FO 11" and AO 23". Provided that Saturn with its companions, in its various phases, is supposed to keep the proportion of its apparent magnitude arising from the variety of its distance.

CAPVT III.

De Diametro Apparenti Iouis.

[Margin: Opinions of the ancients.] [Margin: And of the moderns.] [Margin: 1] 1. Albategnius [al-Battānī], in his chapter 50, and Alfraganus [al-Farghānī], with a difference of 22, defined Jupiter's apparent diameter at $2' 36''\frac{2}{3}$, at its middle distance from the Earth. Fernelius [Jean Fernel], and Egnatius Dantes [Pietro Vincenzo Dante], [give] $2' 32''$. Maginus [Magini] and Vurstisius [Wurstisen] (how greatly!), minutes $9' \frac{2}{3}$. Tycho, in volume 1 of the *Progymnasmata*, page 468; Clavius and Blancanus in their *Sphaera*; and Argolus in his *Pandosion*, [give] $2' 45''$. Lansbergius, however, in book 3 of his *Uranometria*, [gives] $3'$; minimum $2' 30''$. But none of these states a foundation for it.

[Margin: Of Kepler.] Kepler, indeed, in the *Epitome of Astronomy*, volume 2, page 485, and in the *Rudolphine [Tables]*, precept 110, from the analogy indicated above of the subtriple proportion, sets Jupiter's diameter at its greatest distance from the Earth at $50''$ in seconds.

[Margin: Of Rheita.] But Father Rheita makes it roughly four times larger: for in book 4 of his *Radii Sidereomystici*, chapter 4, member 2, he says that in the year 1644, on the 20th of July, having used a most excellent telescope, exhibiting the whole disc of the Moon as 34 minutes, and in its eye-lens [oculari] the convex Lunar diameter, having taken it with the subtle extremities of a fine compass, and transferred it onto a chart divided into 34 equal parts, and in the same way found Jupiter's diameter to be roughly the tenth Lunar part—that is, minutes, roughly 3. But whether this practice may be safely used will be clear from the more certain quantity of this diameter, of which presently.

[Margin: Of Marius.] [Margin: 2] 2. Simon Marius [Simon Mayr], in his *Mundus Iovialis*, part 1, from observations made with the tube [telescope], puts his diameter at precisely one minute, at the middle distance.

[Margin: Of Hortensius.] Hortensius, however, with the capacity of his telescope explored, as above, saw in the year 1632 that the acronychal diameter of Jupiter occupied the fifth part of the little space lying between two adjacent stars in the following horn of Capricorn, which little space was of $5' 15''$ minutes; and so Jupiter's diameter [was] $1'$ minute. By how much, too, did Gassendi find it depressed through the tube! Hortensius reports the same in his *Dissertation* on Mercury with Gassendi. He adds that in the year 163[2], on November 13, having received the acronychal image of Jupiter through the lenses of the telescope onto

paper, and having found, when the image of the Sun was taken in the same way, as 130 [parts]; again on another night he found the image of Jupiter to be 6 parts when the solar image had been 195. The solar diameter being therefore set, he concludes Jupiter's diameter to be a little more than one minute. Hence in a Table, which Herigonius [Pierre Hérigone] too transcribed in volume 4 of his *Cursus Mathematicus*, page 62, he chose Jupiter's diameter, at perigee, 1' 1" 40''; at apogee, in seconds, 38" 30''.

[Margin: Of Hevelius.] [Margin: 3] 3. Johannes Hevelius, on page 449 of his *Selenographia*, relates that in the year 1646, on April 22, at the evening hour 8½, with the telescope, he observed Jupiter's diameter to be equal to one of the three mountains in the Moon at the Pontus Euxinus, which he calls Mount Moschus, and which he found to be roughly the 29th part of the lunar diameter. The Moon being therefore established, [and] Jupiter's diameter then in minutes roughly 30, he concludes that Jupiter's diameter was not greater than 1' 2". And on page 477 he relates that in the year 1646, on December 24, Jupiter was compared with the lunar Aetna, and seemed to himself one minute; but on page 547 he had said that Jupiter, compared on the 12th of April with Mount Crago, and set down, was, by the lunar diameter, in minutes 34, scarcely one minute.

[Margin: Of Gassendi.] [Margin: 4] 4. Gassendi, in a letter of the year 1630, on the 6th of the Kalends of September [27 August], published to Kepler at The Hague [Hagae Comitum], reports that on the 16th of August

in the evening he observed with the telescope an interval between a certain little star and the margin of the Moon, capable of a sixth part of the lunar diameter, and that he found the same interval could be filled out five times over by the acronychal diameter of Jupiter; and so Jupiter's diameter was nowhere greater than one minute. But to Epicurus [recipient], on page 901, he narrates that he observed by the telescope the diameter of Jupiter emerging from the Moon to be scarcely equal to the seventh part of the Caspian spot [macula Caspia]; and so he determined it to be not much greater than 33 seconds. This was then on the 20th of January in the year 1647, when Jupiter was approaching very near to its opposition with the Sun, and to the perigee of the epicycle; whence it is clear that, from the splendor of the neighbouring Moon, Jupiter appeared less to Gassendi than at other times in its acronychal position. Christiaan Huygens, in his *Systema Saturnium*, sets Jupiter's perigeal [diameter] at 64" in seconds, from his own observation. Our Fathers at Innsbruck [Oeniponti], from the capacity of the tube, estimated Jupiter's (≈) diameter in the year 1635, on March 19, as 1' 12"; and in 1637, on March 16, they estimated it as 1' 28", or 1' 30". Marchese Cornelio

Malvasia [Cornelio Malvasia], from the intervals of his tubes, in the year 1662, in May and in June, estimated it as 51"; in September, 41".

[Margin: Our own observation.] [Margin: 5] 5. But in the year 1649, at the beginning of June, when Father Francesco Maria Grimaldi, while observing the zones of Jupiter, had noticed that Jupiter was very strongly approaching a star preceding it, [one of] four stars in the left wing of Virgo, which is the sixth in the figure of Virgo, having northern latitude $1^{\circ} 25'$, and existing then in Virgo at degree $29^{\circ} 56' 25''$; and since, from Montebretti's Ephemeris, Jupiter's northern latitude was $1^{\circ} 25'$, he had no doubt about the near conjunction of Jupiter with that star, and, on the opportunity for establishing Jupiter's diameter from its own motion, and from its distance from the star—about which he warns of an interval of observations—I shall set it out more clearly by the diagram inscribed below.

Diagram. A geometric construction for determining Jupiter's diameter from its motion relative to the star A. It is oriented by the four cardinal labels: *Septentrio* (North) at top, *Oriens* (East) at left, *Occidens* (West) at right, *Meridies* (South) at bottom. At left is a small circle (one position of Jupiter's disc, FBG) with a horizontal band drawn across it (the belt PM / NL parallel to the ecliptic); at right is a second, similar small circle (a later position of Jupiter) with its own band, and the labels D, P, F, M, R, B, H, G. The star A is set low at center-bottom (near *Meridies*), and chords/lines AB, AC, AD, BC run from the star up to the two Jupiter positions, forming the triangles of the construction.

- *Septentrio* (top center): North
- *Oriens* (left): East
- *Occidens* (right): West
- *Meridies* (bottom center): South
- K (far left): westernmost reference point on the left disc
- N (upper left, on the band): point on the belt of the left (earlier) position of Jupiter
- L (left, on the band): point on the belt of the left position
- G (left disc): point on the left disc (Jupiter's edge)
- D (center): the conjunction point where Jupiter is in line with star A on the ecliptic
- P (right of center, on the right band): point on the belt of the right (later) position
- F (right disc): western edge of the right disc
- M (right, on the band): eastern point on the right belt

- R (lower right): point on the right disc
- B (right disc): position of Jupiter's centre/disc at the later observation
- H (right disc, lower): point on the right disc
- A (bottom center, near *Meridies*): the star A (the Virgo star), apex of the construction triangles

Let A be the star of Virgo, the more western centre of Jupiter, B, whose apparent disc FBG is represented much larger, however, than its place warrants. Let the centre of the disc made earlier be the more eastern C, [with] its belt PM, and NL, and the line RBCK parallel to these, and to the Ecliptic—about which parallelism it will be established below. Now from the star A, the more southern, than which Jupiter is also more western, draw the chord AD, connecting the centres of Jupiter's two discs, [with] the star A, [by] the straight lines AB and AC producing AB, up to F, so that the diameter GBF be the diameter, which is understood to be divided into four parts, so that GH is a fourth part of it.

[Margin: 6] 6. And so on the 9th of June, at hour 1, after the setting of the Sun, Jupiter appeared in B, more western, and more northern than the star A, and so the telescope, showing the distance AG, of parts altogether 7, of which one was GH, and the estimation having been confirmed [that] AG [was] $3\frac{1}{2}$, of which one was GB, the semidiameter of Jupiter, and the whole AB [was] of parts 9, of which GH was one; again, AB, of parts $4\frac{2}{3}$, of which GB was one. For the diverse comparison of the observations, agreeing by consent, pleased [us] as evident, since it was as great as it would have been if we had measured that space on the subjacent chart with a compass. But on the following night, on the tenth day, at the first hour, Jupiter appeared in C, more northern, and more eastern than A, so that the distance AC was precisely eight parts, of which the fourth part is the diameter of Jupiter, [it being] one, or equal to four Jovian diameters. The straight line BC having been drawn, by estimation, designating the path of Jupiter, and the latitude's arc, the chord AD—so that Jupiter, having its centre in D, was conjoined to the star A, not bodily, but along the Ecliptic, for it was more northern, by however much AD [was]. This was estimated at parts $4\frac{2}{3}$, of which GH was one. These things being posited: first, in the tri-

by the right angle ABD, and given side AD, side BD comes out as $4\frac{1}{2}$ parts; and from side BD, 9 parts; whence side BD is collected as $4\frac{1}{2}$ parts. Again, in triangle ACD, with the right angle at D, from side AD, $4\frac{1}{2}$ parts, and AC, 8 parts; side CD comes out as 6 parts; and so the whole of BC is 14 such parts, of which GH is one, or rather a part of $3\frac{1}{3}$, equal to the apparent diameter of Jupiter. **Secondly**, Jupiter was at its first station the day before the motion in question, at about 1

hour of the night, lasting through to about the tenth hour of the night, which was 2'40". So this 2'40" is in seconds 160. Let it then be as $3\frac{1}{3}$ is to 160. The result is therefore 48 [seconds], and this is the distance of the planet as it appears on Earth in seconds. 46': again, in CB, second 160: it falls in AD at part $4\frac{1}{2}$, and at 49 [seconds]. So Jupiter was 49 [seconds] from that star, and that star is in northern latitude $1^{\circ}25'$. Jupiter's latitude is northern $1^{\circ}25'49''$: at the moment of conjunction, which was on the 9th of June at 21 hours after noon, and at that time the longitude of the star was $\mathbb{M}$ $29^{\circ}56'25''$: let the Prutenic [tables] then give $29^{\circ}40'$ with latitude $1^{\circ}36'$; the Danish, however, $\simeq 0^{\circ}1'$ latitude, $1^{\circ}33'$; and Lansbergen's $\mathbb{M}$ 30° exactly, with latitude $1^{\circ}24'$. **Thirdly**, since the eccentric anomaly was $1^{\circ}55'$, and the orbital anomaly nearly equal at $2^{\circ}48\frac{1}{2}$, our hypothesis gives the distance of Jupiter from the Earth as 39500 [parts] of the terrestrial semidiameter; and being near the apogee of the eccentric, somewhat below the middle longitude of the epicycle, hence and from the angle of the semidiameter, $23''$ comes out, by Problem 1, Chapter 8, Book 7, of the *Almagestum Novum*, Section 5. There is collected the true semidiameter of Jupiter on Earth, $4\frac{7}{10}$. From this, by Problem 1 of the same chapter, and at the same distances by Section, Chapter 2, the apparent diameters of Jupiter are set down: the maximum 47552, the mean 36500, the minimum 26441 in semidiameter. Then by Section, deducing the semidiameters as they appear at apogee in both directions, $19''9'''$: at the mean distance, $24''53'''$; and in both directions at perigee, $34''23'''$: which numbers come out by chance, just as the other hypothesis preserving the proportions of the same intervals would give, given the distance of the Sun, or the radius of the annual orbit.

7. With these established for us, what was observed the following month, very acutely, by the learned Mr. Vincenzo Mutti — recently appointed at Sole Alphonso, and most illustrious in astronomical expertise — is given to us by Maioxica [Malvasia] on the 30th of June 1649. The observations are these: *Jupiter was observed with the left [star], 4 [minutes?] preceding, in the band of $\mathbb{M}$ on the 9th day of June, hour 10. Jupiter was the more westerly, called the star; but this star was distant from Jupiter by a diameter of Jupiter, plus a far easterly one; between which, in the space of 24 hours, Jupiter, by comparison with the star seen between them, was found to have nearly perfectly traversed the diameters of its own body.* Why was Mr. Mutti's Jupiter not far off in diameter from this in this position [seconds 48]? It can readily be estimated how greatly we rejoiced at so close an agreement and conspiracy of minds about this method, and about the timing of this observation.

CAPVT IV.

De Martis Diametro Apparenti.

[Mars's Apparent Diameter]

1. Albategnius [al-Battānī], chapter 50, and Alfraganus [al-Farghānī], Difference 22, set the apparent diameter of Mars at 1'37" [Minut. 1'. 37"]. Fernelius and Egnatius Dantes, 1'29", or 18". Maginus [Magini] and Vurstisius, 8'. minute. Tycho [Brahe], Clavius, Blancanus, and Argolus indicated above this matter, 1'40". And Lansbergen, in *Uranometria* Book 3, 3 min. 1'30". And indeed all these at the mean distance of Mars from the Earth. Galileo, in Dialogue 3 of the *Systema Mundi*, says that if Mars is viewed through a telescope, it is seen in opposition with the Sun to be sixtyfold, or fiftyfold larger than near conjunction, as far as concerns the area of the disk; but as to the diameter, eightfold or sevenfold. Gassendi, Book 2, *Institutio Astronomica*, chapter 9, says that Mars, which otherwise scarcely equals the fixed stars of second magnitude, at opposition with the Sun in both directions, and especially at perigee, conca...

rs, rivals the magnitude of Jupiter, indeed of Venus: understand it thus, that Jupiter, observed and so often defeated, may be defeated by a perigee Venus. Kepler too, page 333, *Astronom. Opticae*, relates that in the year 1529, in July and August, Mars was seen with prodigious magnitude, so that one would have believed it a new star, and it must have appeared so great in the month of August in 1561, and 1593, and August of the year 1608, and frequently; for Mars is at perigee in the eccentric and in the epicycle in Aquarius. In the *Epitome Astronom.*, page 485, he says Mars at acronychal rising in Aquarius at perigee is seen larger than Jupiter, but not by much; Jupiter, however, seen frequently through the telescope, second [magnitude], 50. And yet in the Rudolphine [tables], by precept 110, he supposes the proportion of the bodies of all the planets, of the diameters of the intervals of the Sun, and of the subtle [parts], that Mars at the same distance appears larger than the Earth, 5'13": but in the middle [position], at diameter 6'50": or therefore much larger than Jupiter appears, although it is not so much larger: vain are those proportions. Yet rightly, as to apparent magnitude at perigee, collating Mars at acronychal rising below the Sun nearer to itself, than Mercury at perigee, and Venus at perigee. Moreover, PP. Soc. I. [the Fathers of the Society of Jesus] at Oeniponte [Innsbruck] and through the telescope's tube estimated the diameter in the year 1636. At maximum proximity to the Earth, on the 23rd of May, 32"; and on the 6th of May, 29". At Marcho [Marchio] Cornelius

Malvasia in the year 1662, July 17, and through his tube estimated 25" thereabouts.

2. **Hortensius**, in his *Dissertatio* with Gassendi on Mercury in the Sun, relates that in the year 1632, he observed Mars at acronychal rising near the apogee of the eccentric, but at perigee, an epicycle of Mars distant from the Moon's limb by no more than one digit, that is, 2'42": and the diameter of Mars almost occupied a quarter of that distance, so that it was not seen much larger, 36. From these assumed intervals he concludes that Mars at acronychal rising at apogee appears second, 9. At perigee, in both directions, 1'4": which he establishes below from Herigonius, vol. 4, *Cursus Mathem.*, page 62. Huygens defines the perigeal diameter of Mars as 30".
3. **We**, with Father Grimaldi, in the year 1649, July 22. By telescope comparing Jupiter with Mars, and in both [cases], we often saw the species transferred onto the paper, the diameter of Mars double smaller, or rather as a fixed [magnitude]: and it was from our hypothesis [that] the apparent semidiameter of Jupiter at perigee 27"5": so therefore Mars 10"32". At its distance from the apogee of the eccentric gr. 86. and at the perigee of the epicycle gr. 255. From these tables, and Problem 1, lib. 7. *Almag. Novi*, Section, we deduced the true apparent semidiameter of Mars on Earth 5"3": and so [for] the apparent semidiameter of the Earth 5"3": therefore at apogee semidiameter 5"3": at perigee 46": and at the mean 11": but in the year 1651, on the 5th of April, Mars seen compared with ♃ and ♄ 45" [seconds]: and in the year 1655, July 22, of 60 parts, of which Jupiter was 68.

CAPVT V.

De Diametro Apparenti Veneris.

[Venus's Apparent Diameter]

1. **Venus** at its mean distance — Albategnius [al-Battānī] defines its apparent diameter as 3'8". Alfragan [al-Farghānī], 1'34". Fernelius, 5'. Egnatius Dantes, 4'. Vurstisius and Magini, 10'30". Tycho [Brahe], Clavius, Blancanus, and Argolus, as indicated in chapter 2.
2. **Scheinerus** [Scheiner], in a letter of the year 1611, addressed to Marcus Welser, sets the diameter of Venus subdecuple [one-tenth] to the diameter of the Sun, and so above three-and-a-half minutes, but on the elliptic [path] of the Sun. By tube in the year 1612, he says Venus, with the same tube

taking up [excepting] the species of Venus on paper, and of the Sun, at the same distance between them, as a paper [reckoning], on the 23rd of October he found the diameter of Venus to be $2\frac{1}{2}$, of which the diameter of the Sun is 34': and on the 27th and 29th of October, again, on the 26th of December he found it again at 2'. He admits, however, that the observation was shadowy [umbratilem], reserving a better observation for another time. I do not know, however, whence Hortensius...

sus attributes to Scheiner a diameter at apogee of 34". The mean 1'40". And at perigee 3'42".

3. **Galileo**, in his Letters, Letter 1, addressed to Marcus Welser, reproaches him for observing the magnitude of Venus not by the unaided eye, but through the telescope, as if by a fine hair, full of redness all around. For it must either be observed in daylight, or through the telescope; and in either way that hair is laid bare by that redness. He adds that Venus at morning conjunction, and at apogee, scarcely [reaches] the five-hundredth part of the solar diameter, that is, 10". But Hortensius writes to Gassendi that, directly, by telescope comparing the diameter of Venus with the interval of the contiguous Hyades, when it came near to the Sun, [it was] 15"–20". Whence the visible distance at apogee with the Sun, seen 15'–20": at which distance Hortensius establishes the diameter of Venus at 1'40": to which Huygens subscribes above. But Hortensius had not seen Venus at perigee, as we have. By Kepler's precept 110 of the Rudolphine [tables], from the proportions of which above, he computes the perigeal diameter of Venus 7'6". At last Hevelius, chapter 55 of the *Selenographia*, says that in the year 1644 he saw Venus around morning [as] a $\square$ [quadrate] to himself 46": and in the year 1646, April 22, compared with a $\odot$ [Sun] spot, seen at the perigee of the epicycle 1'22" min.

PP. Soc. nostrae Ingolstadij, & ex sui Tubi capacitate aestimarunt diametrum ♀ sic [The Fathers of our Society at Ingolstadt estimated by their tube's capacity the diameter of Venus thus]:

Anno	M.	D.	'	"

4. **We**, with rare good fortune in the year 1649, June 29, observed Venus in the evening by telescope, [Venus] coming into conjunction with the Sun on July 7, but aided by great latitude it appeared with an enormous sickle [shape], rivalling the Moon; and on the 26th of July, in the morning by telescope, taking up thirty minutes, but its capacity divided into four parts, its diameter was observed, or the interval of the horns, by which proportion also with the diameter of Jupiter, then in that month, and in the year 1650, at the beginning, we established the apparent diameter of Venus at apogee second $33\frac{1}{2}$. The mean $1'4''12'''$, and the true diameter at perigee $4'16''$: than the true diameter of *Almagestum Novum* Book 7, Section 6. And it does not hinder that Gassendi, in his letter to Schickard, saying that Venus, if it were seen beneath the Sun, would scarcely appear of one minute, that I would not grant to him, unless optically the splendor of the Sun greatly diminishes the phase of Venus: nor likewise does it hinder that Christian Huygens, in the *Systema Saturnium*, says it does not exceed $85''$, since he observed Venus at perigee, as we did, and how slippery Huygens's method is in observing the diameters of the planets, I indicated in chapter 1, number 11. I recall indeed that on another occasion I was with Father

Grimaldi in requiring that we should diminish the diameter of Venus somewhat, but not so much that it exceed 2', and that it come close to 3'.

CAPVT VI.

De Diametro Apparenti Mercurij.

[Mercury's Apparent Diameter]

1. **Albategnius** [al-Battānī], chapter 50, puts the apparent diameter of Mercury at the mean distance from the Earth at $2'5\frac{1}{2}''$. **Alfragan** [al-Farghānī], diff. 22, min. $1'15''\frac{1}{4}$. **Fernelius**, and **Dantes**, 2'. **Vurstisius** and **Maginus**, 7'. **Tycho** [Brahe], **Clavius**, **Blancanus**, and **Argolus**, min. $2'10''$. **Lansbergen**, lib. 3, *Uranometriae* 2'. **Hortensius**, in his *Dissertatio*, [says] that Mercury, with the tube inverted, takes up [excepting] the species of Mercury approaching to the apogee of the eccentric with the Sun at conjunction, and from this deduces its diameter at apogee, second 10. And from this, by the distances of **Lansbergen**, the mean at 19". At perigee 28".
2. **Petrus Gassendus** [Pierre Gassendi], in the year 1631, on the 7th of November, except for the most obscure lucid circle of the Sun through the telescope, in the most obscure camera [camera obscura], whose diameter equalled three-quarters of a Parisian foot, and it was divided into 60 equal particles, each [equal to] half a minute; and as Mercury crossed beneath the disk of the Sun, taking up its shadow [umbella] on the same paper, he found its diameter from there at most a third of one minute, that is, 20": from which he concludes the diameter of Mercury does not exceed in the middle distance the ninety-eighth part of the solar diameter. Thus he says, Letter 2, to **Schickard** on Mercury in the Sun: and in the *Epicurum*, page 899, he says there existed a splendid species of the solar circumference optically [as] a shadow [umbellam] of Mercury, somewhat smaller appearing.
3. **Io. Hevelius** [Johannes Hevelius], chapter 4 of the *Selenographia*, relates that in the year 1644, November 22, in the morning, hour 7, he saw Mercury at five-eighths smaller than Mars: and in the year 1645, May 16, in the evening, hour $8\frac{2}{3}$, still [as] a small sickle seen through a tube with a small star added to the fixed stars of the first magnitude, which Mercury we have as second [diameter] 17, thereabouts.

PP. Soc. I. Ingolstadij... Tubo aestimarunt [The Fathers of the Society of Jesus at Ingolstadt estimated by tube]:

Anno	Mens.
1620	Octobr.
1636	Martij

4. **We**, in the year 1650, on the 2nd of January, in a most serene horizon dragged the image of Mercury onto the chart by telescope mode, 7. Chapter 1 and 8: and comparing it with the diameter of Jupiter, which was then 44": we found it to be, by 2, and 5, that is, nearly 18": by which distances, and by Problem, lib. 7. *Almag. Novi* Section 6, we deduced the true semidiameter of Mercury, and the fourth part of the semidiameter of the Earth; but the apparent diameter at apogee, second 9'20": at the mean distance 13"48": and in both directions at perigee 25"12".

CAPVT VII.

Synopsis Opinionum de Diametris Apparentibus Planetar. Minorum.

[Synopsis of Opinions on the Apparent Diameters of the Minor Planets]

Libro 7. *Almag. Novi* Section 6, chapter 9, what is set down there both as the apparent and the true diameters of the planets, was posited for the Lansbergian semidiameter [as] diameter. Here we add a few things.

Diametri Apparentes Planetarum Minorum in Apogæo,
Media Distantia, & Perigæo utroque.

[Apparent Diameters of the Minor Planets at Apogee, Mean Distance, and Perigee, in both directions]

The diameter values are given in three columns per planet, headed ' (minutes), " (seconds), ''' (thirds). The planet columns are: ♄ (Saturn), ♃ (Jupiter), ♂ (Mars), ♀ (Venus), ☿ (Mercury). The "Diam." / "Appar." column gives the position of the planet on its orbit (Med. = mean, Apog. = apogee, Perig. = perigee).

CAPVT VIII.

De Apparenti Diametro Fixarum.

[On the Apparent Diameter of the Fixed Stars]

1. Galileo, in Dialogue 3 of the *Systema Mundi*; Giordano Bruno, in his book *De Maximo et Immenso*; and Kepler, in his *Dissertatio cum Nuncio sidereo*, think that the fixed stars are just as many Suns; yet as to apparent [size] Galileo, using a thread, in chapter 1. Manner 3, asserts that Lyra and the rest of the first magnitude do not exceed a diameter of 5": and therefore from the distance of the fixed stars (which Copernicus requires to be so great, that it excludes every parallax perceptible by the inhabitants of the Earth as they go through the annual orbit) it does not follow that the fixed stars are larger than the annual orbit. Kepler, however, who in his book *De Stella nova*, chapters 16 and 21, had earlier conceded to the telescope that Sirius is 4 minutes, and the stars of Orion's belt 2 minutes, afterward, in the *Epitome Astronom.*, page 498, says: *Skilled artisans deny that any quantity of the rounded body is detected by inspection of the telescope; nay rather, that the telescope represents the fixed stars all the greater, the smaller they are; for the bare points exit and are dispersed into the species of hairs by their*

lucid rays. And in the same place he holds the mass of the fixed [stars] to be smaller than the Sun. Huygens too likens them to points.

2. **Lansbergius**, lib. 3. *Uranometriae*, element 20, has this: *He defines the apparent semidiameter of the fixed stars of the first magnitude — Albategnius at 45", and Tycho at one scruple [one minute]. We at half a scruple [half a minute]. For through the optical tube it appears still much smaller.* Why therefore does he not trust the tube which liberates the disks of the stars from the deception of adventitious rays? — especially when Hortensius, his very friend, so labors to liberate the Copernican hypothesis from the absurdity of the immense mass of the fixed stars following from their immense distance, so that, comparing by telescope Sirius with the image of Jupiter [it is] 10, only Second; and to the rest of the first rank he conceded 8". Falsely, however, because he erred in [the case of] Jupiter, as said in chapter 3.
3. **Moreover** we, with Father Grimaldi, covering over the objective lens of the telescope with a perforated little plate of foil, so that we might see the disks of the stars without rounded hairs of rays, and taking up their species onto a chart, divided the diameter of Saturn, without its companions, into 160 parts: but Jupiter into 200 parts, of which an inch of a foot is 100: then [we divided] very many smaller little circles, and smaller [ones] on the same chart, 20 such parts, the largest 100. Having inspected, after [comparing them with] the fixed stars, the most close to them, [and] comparing with the most acute eye and judgment, [those] of the Fathers Paolo Casati and Matthaeus Tabernae: at length, from the now certain diameter of ʰ and ʷ, we determined the apparent diameters of the fixed stars written below, from which we investigated the true [diameters] in Book 6 of the *Almagestum Novum*, Section 9.

LIBER DECIMVS — DE PARALIPOMENIS PLANETARVM

[Caput VIII, continued — De Apparenti Diametro Fixarum]

The apparent diameter of the fixed stars as we observed it, when the diameter of Saturn alone was 35" and that of Jupiter 44".

CAPVT IX

De Saturni Figura, Fascia, Comitibus, eorumque situ, respectu Aequatoris, vel Eclipticae

On the Figure of Saturn, its Band, its Companions, and their Position with respect to the Equator or the Ecliptic

1. Among the phenomena revealed to our age from the heavens by the help of the telescope, none is perhaps more astonishing, and none has hitherto exercised the talents of astronomers more, than the appearance Saturn presents. Three things in it are especially worth noting. The first is a certain **band** [Fascia] which, like an oblique zone, seems to gird the body of Saturn. The second is the **companions** [Comitibus], two little globes set in a line with the middle body of Saturn and for the most part parallel to the equator — though sometimes the alignment seen is parallel to the ecliptic. The third is the incredible variety of shapes under which both Saturn itself

and its companions — whether the companions are themselves spheres, or the sides [latera] of Saturn — appear at different times.

For sometimes, though rarely, Saturn appears solitary, without companions, and then almost round. Sometimes it is represented with two companions on either side, round and adjacent to it; sometimes the companions, lying very close to it, fall off little by little from roundness and are curved into handles [ansas]; sometimes they appear nearly hyperbolic; sometimes they look almost half-moon shaped, and with their arms thicker at the ends [crassicaie? — *brachijs interdum crassioribus*]; sometimes Saturn itself appears more slender, the companions vanishing; sometimes it returns to roundness and conforms itself more and more into an ellipse. About these shapes we have decided to set out distinctly and in order, just as we observed them — and as some others have done up to now.

De Fascia Saturni

On the Band of Saturn

2. [Margin: 2] In the year 1655, from the 20th of March up to the beginning of June, Saturn was seen by P. Grimaldo [Grimaldi] and by us with a band, as in Figure VI below — a band somewhat dark and narrower than Jupiter's band, and appearing nearly parallel to the ecliptic [Eclipticae], as it presents itself on the 23rd of April and the 9th of May.

In the year 1656, from the 9th of February and thereafter, it was repeatedly seen by us with a band, as in the figure noted above, and clearly from the 12th of December onward; and on the 24th, P. Grimaldo again saw Saturn's band parallel to the ecliptic, with some interruptions where the sky prevented observation. But in the year 1657, on the 11th of January in the morning, P. Grimaldo saw Saturn separated from its companions, with the said band, and likewise on the 19th of January and the 16th of February, when the oblong companions are placed, and the band crosswise in an ecliptic position; likewise on the 26th of February and the 13th of March, and on the 25th of March — but then the companions seen were very oblong, slender, and notably separated, and approaching Saturn [h] together with the Sun, and the band very evidently apparent. But on the 20th of April and the 6th of May the oblong companions were seen, yet separated, and the band scarcely distinguishable, more so through the whole of June, and at the start of July. At last, on the 2nd of August, with the oblong companions present, the band was no longer distinct — perhaps on account of the nearness then both of the Sun and of the vapors of the horizon; and it appeared so even on the 20th of October, now become a morning object. But on the 23rd of January 1658, the

band was an oblique line of the companions, and a little below the center of Saturn's disk.

De Linea Comitum Saturni, eiusque Parallelismo ad Aequatorem, vel Eclipticam

On the Line of Saturn's Companions, and its Parallelism with the Equator or the Ecliptic

3. [Margin: 3] Galileo, in his 3rd Letter to Marcus Velsesus [Marcum Vuelserum], page 148, affirms that the line drawn through the center of Saturn and its companions, and their parallelism, is parallel to the equator. The same is held by P. Franc. Maria Grimaldo [Francesco Maria Grimaldi] and by us, who have often observed it.

For in the year 1646, on the 10th of October and the 16th of November, we saw the said line to be parallel to the line drawn from the bright star of Aries to Aldebaran, which is parallel to the equator. And again in the year 1647, on the 7th of October, the said line, produced by an estimate of the eye, would pass through the southern horn of Taurus, and through the Pleiades — the most southerly point — as the telescope showed; and this line is established to be parallel to the equator, to the senses. Again, in the year 1649, on the 20th of July, the said line was parallel to a line drawn through the Pleiades, and the center of Saturn was then situated in 25° of Gemini [II], with 1° 30' south latitude.

In the year 1650, on the 18th of March, P. Grimaldo saw the center of Saturn, and a companion, with a certain unnamed little star, in the same straight line, distant from the nearest companion toward the east by about half a moon's breadth; but on the following night, the 23rd, he saw Saturn having overtaken that little star, yet in such a way that it appeared more southerly toward the south by as much as the four diameters of Saturn were larger. From this he concludes that the line of Saturn and its companions is not parallel to the ecliptic — otherwise on the 23rd it would have kept that little star in line.

In the year 1653, on the 9th of December, and the following days, we and P. Grimaldo observed that the said line is moved by the diurnal motion of the *primum mobile*, and is parallel to the equator.

In the year 1654, on the 6th of January, and on the 11th of February, and on the 1st of March, by comparing the said line with the ecliptic,

[The line] was situated then with Saturn [♄], and with respect to the moon [☾], it appeared to be not parallel to the ecliptic; indeed, when it was at the meridian, we saw it parallel to the horizon, hence to the equator — for Saturn was then near the end of Leo [♌].

Finally, in the year 1655, from the 20th of March up to the beginning of June, by the same arguments treated above, the line was seen parallel to the equator, with the companions of Saturn.

4. [Margin: 4] Notwithstanding these things, Hevelius, in the *Dissertatio de Saturni facie* published in the year 1656 — and from this, of his humanity, liberality, and kindness toward me, conveyed to me ahead of publication — concedes that the said line of Saturn, when Saturn is moving through Sagittarius, Capricorn, Gemini, and Cancer, is parallel to the equator; in Aries, however — and in Libra, Aquarius, and Leo — he contends that it is neutral, that is, neither parallel to the equator nor to the ecliptic; but in the remaining signs, especially in Taurus and Scorpio, that it is parallel to the ecliptic. Although he admits — and we, with great labor, observed it from the year 1643, 1644, and 1645 — that in Aries the parallelism with the equator is more easily observed in the four said signs, indeed in nearly six.

To this opinion of his, however, the table he exhibits on page 15 does not agree: for in that the directions of Saturn's handles [ansularum] are placed throughout the whole sign of Taurus [♉], and almost throughout the whole sign of Libra [♎] — that is, up to 23° of the sign. For from the very beginning of Taurus up to 24° they are oblong; then in Gemini [♊] he places it as *Neutral* [Neutralis]; then up to 24° oblong, again *Neutral*; thereafter up to 24° of Cancer [♋] he places it again *Neutral*, and after that up to 24° of Leo [♌]; thence to the end up to 24° of Virgo [♍] he places it as *Equinoctial* [Aequinoctialis]; thereafter again up to 24° of Libra [♎] *Neutral*, and after that *Ecliptic* [Eclipticalis]. Huygens [Hugenius] too, as I will say below, redirects Hevelius.

5. [Margin: 5] From our own observations, however — in which that line was seen to contradict the line parallel to the equator — it was observed in the year 1646, on the 16th of November, in 14° of Taurus [♉], where for us it is Ecliptical [Eclipticalis], and in the year 1650, on the 18th of March in 24° of Gemini [♊]; in the year 1653 on the 6th of December in 16° of Leo [♌]; in the year 1654 on the 26th of January in 25° of Leo, and in the year 1655 on the 20th of July in 5° of Leo, and in 4° of Gemini [♊] — in all of which, for Hevelius, it is *Neutral*. And in the year 1658, on the night between the 29th and 30th of July, P. Grimaldo and I saw with the telescope that Saturn was

moved, with the western extremity of its companion line, as it were toward sunset, and that the extreme companion moved manifestly following the motion of the *primum mobile* through the parallel of the equator. This too confirmed for us the situation of the equator in our observation, and from a comparison with the ecliptic — which the line drawn through the Heart of Scorpio [Cor Scorpj] and through Spica indicated nearly. Hence our most friendly Hevelius saw his own *vaticinium* [prediction], which on page 27 of his Dissertation he had pronounced without any doubt — namely that the said line, when Saturn is in Libra [♎], would be parallel to the ecliptic — would not have held. The same is confirmed from his own figure of the position, of which I spoke at number 2, for the year 1657, with Figure 17 attached.

De Saturno solitarie viso

On Saturn Seen Solitary

6. [Margin: 6] First, Scheiner, in the *Disquisitiones Mathematicae*, conclusion 44, says of Saturn: *Now one, now three-bodied* [Modo vnus, modo triceps comparet: aliàs procerus, aliàs rotundus]. Would that time had added what makes it now solitary, now round, and seen round.
7. [Margin: 7] In the year 1612, Galileo writes to Marcus Velsesus that around the summer solstice of that same year he saw Saturn as if three-formed [triformem], but with the observations interrupted, because nothing such was suspected. At last, toward the end of November, he saw it solitary, that is round; and so it persisted until December, as you may gather — although it might also be feared that around the summer solstice of the year 1613, Saturn would appear with companions, and after two months by the brumal solstice [bruma] of the year 1614 they would conceal themselves for some months; and in the year 1615 around the summer solstice not entire, but in part apparent, and indeed whole again, and quite large, through many years, without any concealment of the companions.
8. [Margin: 8] In the year 1642, Gassendi and Bullialdus [Bouillaud], at Paris, with August beginning, saw Saturn solitary, and round up to the occasion of its heliacal setting, which fell in February of the year 1643. Therefore, says Gassendi, why with Saturn [♄] at acronychal rising [Actonychthus] on the 5th of September — when Saturn was at acronychal rising — did it appear even to the naked eye so small? He adds, toward the end of the following May, that with the same band visible, a three-bodied

[Tricorpore] form cohering thence on either side with two little globes of the same whiteness — and that it so persisted under a varied companion-form up to March of the year 1644. So he, in the *Iudicium de 9 stellis* about Jupiter seen at number 6, and in the *Epicurus*, page 905. Hevelius too, on page 42 of the *Selenographia*, and in the Dissertation on Saturn's face, page 7, affirms that Saturn appeared round to him on the 20th of September, and the 8th of October, around the 20th. In opposition with the Sun, on the contrary, in the perigee of an eccentric ellipse, he represents it round.

9. [Margin: 9] In the year 1656, on the 9th of February, up to the 14th of May, we saw with P. Grimaldo Saturn solitary, without companions, with the band drawn crosswise, as in the subsequent Figure II. Thereafter it began to be seen round with the band, and was so seen up to the 17th of July. From that point on, it ceased to be observable because of its nearness to the heliacal setting, then with the vapors of the horizon. Afterward, however, it could not be observed after heliacal setting, with the surrounding clouds, but it was observed up to the 25th of October, when, having become a morning object, it appeared with the companions separated, as in Figure V. Bullialdus also, at Paris, in January, and Hevelius at Danzig [Gedani] in the same year 1656, on the 25th of February up to the 1st of May, saw it round; and the same Hevelius, on page 7 in his Dissertation on Saturn's face, reports this. About Huygens I will speak below.

Figurae Saturni ex nostris, et aliorum observationibus collectae

Figures of Saturn collected from our own and others' observations

10. [Margin: 10] Among the figures that follow, Hevelius calls Figure I the *Mono-spherical* [Monosphaericum] Saturn; Figure III the *Tri-spherical* [Trisphaericum]; Figure XI the *Spherico-cuspidate* [Sphaericocuspidatum]; Figure XII the *Spherico-handled* [Sphaericoansatum]; Figure XIII the *Diminished elliptico-handled* [Ellipticoansatum diminutum]; and Figure XIV the *Full elliptico-handled* [Ellipticoansatum plenum]. The remaining figures he does not exhibit.

Diagram. A full-page plate enclosed in a ruled rectangular frame, showing ten numbered figures (I–X) of the changing telescopic appearances of Saturn, arranged in two columns (left: I, III, V, VII, IX; right: II, IV, VI, VIII, X). The figures progress from a simple round disk to fully developed handled/elliptical forms.

- **I.** A single plain circle — Saturn seen solitary and round (the *Monosphaericum* form).

- **II.** A single large circle crossed obliquely by a dark hatched band running from lower-left to upper-right — Saturn round with the band [fascia] drawn crosswise.
- **III.** A central circle with a small rounded handle-like projection on each side, the projections touching the disk — the *Trisphaericum* / earliest handled form.
- **IV.** A central circle flanked by two small separated round companions [comites], one on each side, not touching the disk.
- **V.** A central circle flanked by two separated oblong (oval) companions, one on each side — the companions elongated.
- **VI.** A central circle crossed obliquely by a dark hatched band (as in II), and flanked by two separated oblong companions on each side — band plus oblong companions.
- **VII.** A central disk flanked on each side by a larger crescent-/handle-shaped form with dark hatched (shaded) inner edges, the forms overlapping the disk — developed handles.
- **VIII.** Similar to VII: a central disk with two hatched handle-forms, slightly more open/separated.
- **IX.** A central disk girdled by a broad elliptical ring whose two sides are dark hatched crescents, forming an ansate (handled) ellipse — the *Ellipticoansatum* form.
- **X.** As IX but with a fuller, wider elliptical ring and bolder hatched crescents on each side — the *Ellipticoansatum plenum* (full handled-ellipse) form.

Liber Decimus — De Paralipomenis Planetarum (continued)

Caput IX — De Saturni Figura, Fascia, Comitibus (continued)

[?] In the same year, around the end of [?]... O[...] saw it [the planet] with two small companions, one preceding and one following, joined to it [coniunctos]... P. Grimaldi too saw the same companions, in October... and others. [?]

1642. In February [?]... he saw Saturn with little globes [globulis] separated, as in Fig. IV, and he has it under observation [in observatione]...

1643. [?]... [the matter is treated] in the *Disquisitiones Mathematicae* [(Scheiner, *Disquisitiones Mathematicae*)]...

[The remaining left-column fragments are too abraded and intercut by the plate frame to recover continuously; see the running observation chronology on the facing page (folio 364), which carries the same sequence in full.] [?]

Diagram. A single framed plate containing seven telescopic representations of Saturn, numbered XI through XVII (continuing the series I–X of the preceding folio). Each is a schematic woodcut of the planet's disk with its appendages [ansae], the shaded (hatched) regions indicating the dark or unilluminated parts. From top to bottom and left to right:

- **XI** (top center): A globe flanked on both sides by a pair of crescent-shaped, hatched appendages set off slightly from the disk — the "elliptical-handled" [elliptico-ansatus] form, with the handles separated from the body by dark interstices.
- **XII** (upper left): A globe with two large, broad hatched wing-like appendages embracing it closely on either side, the "spherical-handled" [sphaerico-ansatus] form.
- **XIII** (upper right): An elongated, broad elliptical body with the planet's disk at center and extensive hatched lateral extensions — the "full elliptical-handled" [elliptico-ansatus plenus] form.
- **XIV** (middle left): A narrower elliptical body, the disk at center with slimmer hatched lateral appendages — the "diminished elliptical-handled" [elliptico-ansatus diminutus] form.
- **XV** (middle right): A small central disk with thin, nearly straight lateral handles set off by clear interstices — a slender "spherical-handled" form.
- **XVI** (lower center, largest): A large plain round globe flanked by two detached, narrow hatched lateral bodies (the ansae seen edge-on or as separated companions) — the "spherical-handled" form at maximum.
- **XVII** (bottom center): A central disk set within a broad hatched lenticular (almond-shaped) band, flanked on the far left and far right by two small round globes — the "tricorporeal" [tricorporeus] appearance, the planet flanked by two companion-globes.

1609. Galileo [Galileo], in his Letters 1 and 3 to Marc Welser [Marcus Vuelserus / Marc Welser], reports that Saturn appeared to him tricorporeal [tricorporem], with globes [globulos] adhering to it — imperfect with weaker tubes, but distinct [discretos] with better ones — as in Fig. IV. Scheiner [Scheiner] too says that around this time the planet appeared to him triform [Triformem], though at other times solitary [solitarium], as I said at num. 6.

1612. Saturn was seen round, without companions, by Galileo, as you see above at num. 7 and Fig. I.

1614. February 12, 13, 14. Scheiner saw Saturn with the globes separated [globulis seiunctis], as in Fig. IV; but in such a way that the left-hand one, because it was in the upper position, appeared more brilliant [luculentior], and more remote from Saturn. So he reports in his *Disquisitiones Mathematicae* [(Scheiner, *Disquisitiones Mathematicae*)], conclusion 44.

1616. P. Giuseppe Biancani [P.Ioseph. Blancanus / Giuseppe Biancani], toward the end of October — as he relates in his *Sphaera* [Sphaera], book 15, ch. 7 — saw Saturn oviform [Oviformem], with two spots [maculis] nearly round toward its top [verticem]; and in the same manner in November of 1619, but with an imperfect tube.

1625. February 17. Martin Hortensius [Martinus Hortensius / Maarten van den Hove (Hortensius)] saw Saturn with the globes [globulis] nearly as in Fig. IV; they were not far from the Sun, and Hevelius [Hevelius / Johannes Hevelius] reports it on the figure of Saturn, p. 7.

1630. June. Francesco Fontana [Franciscus Fontana / Francesco Fontana] at Naples saw Saturn with the globes separate [globulis separatis], as in Fig. IV, and he has it in his published treatise [tract.], 7.

1632. Hortensius, July 16, saw Saturn handled [ansatum].

1633. Pierre Gassendi [Petrus Gassendus / Gassendi], observing in June, saw Saturn with handles [ansulis], as in Fig. VII and VIII, just as he reports in his observation of the 9th of the stars about Jupiter [circa Iouem], and in the same way Fontana, as above.

1634. April. Gassendi, as in his observation of the 9th of the stars [9. Stellis], and Fontana — in his treatise — saw Saturn with handles [ansulis], as in Fig. VII. So Gassendi, as in Fig. XIV.

1636. Gassendi in November saw Saturn with handles [ansulis], as he has it in the aforesaid observation, and Fontana, so that the planet itself was not round, as in Figura VII.

1637. In November — indeed earlier, in February and July — Gassendi saw Saturn with handles [ansulis]. On the 9th of the stars about Jupiter [9. Stellis circa Iouem], the Fathers of the Society [PP. Soc.] at Innsbruck [Oeniponte] on the 19th

of March had seen its companions [Comites] contiguous with it, as also on the 26th of August [26. Augusti].

1638. Gassendi, as above, in December saw Saturn round, but not at all spherical [minimè rotundum], as in Fig. IX or X.

1640. May 23. P. Nicolò Zucchi [P. Nicolaus Zucchius / Zucchi] observed Saturn with the companions separated [Comitibus separatis], and curved, or imitating the form of a pear [pyri formam imitantibus], as in Fig. IV; though of excessive size [magnitudine] — a figure transmitted to me from Rome by him.

1642. Gassendi and Boulliau [Bullialdus / Ismaël Boulliau] in August, and Hevelius in October, watched Saturn solitary and round [solitarium, & rotundum], as in Fig. I, just like Fig. III.

1643. Toward the end of May, Saturn at heliacal rising [Heliacè ortus] was seen round, and with the borders [alboris] of the same nearly adhering, as in Fig. V; so Gassendi affirms, in his *Epicurus* [Epicuro], p. 905, and Epistle 3 to Wendelen [Vuendelinum / Govaert Wendelen], adding that he had observed it for so long. We saw it together with P. Grimaldi [P. Grimaldo / Grimaldi] on October 29, and beheld its companions [comites], as in Fig. V.

1644. Gassendi, as he relates in his Epistle p. 905, in March and June saw Saturn, as in Fig. IX, and afterward in December, as in Fig. XI. P. Daniel Bartoli [P. Daniel Bartolus / Bartoli] at Naples, with P. Sirsale's [P. Sirsali / Cristoforo Sersale] excellent telescope, observed the lower companion smaller and dimmer than the upper [comitem superiorem minorem inferiori], its shadow less obscure; and the same companions joined to Saturn [vnita erant Saturno], as in Fig. XII, in a single [vnita] appearance. With which globes [globis] he could not discern whether they cohered with the body of Saturn or had detached themselves from it, as in Fig. XVII — under which we have never been allowed to view it [the planet]. [?]

1645. Hevelius in September, October, November saw Saturn handled [ansatum]; but Ioan. Lips. [Ioan. Lyps. / Jan Lips] from the beginning saw it round, as in Fig. IV. Gassendi, however — as he relates in his *Epicurus*, p. 905 — saw the companions [Comitum] gradually produce cusps [cuspides], so that on either side, were the obscure middle globe intercepted, they would touch the undulating dark interstice [obscurum interstitium]; the very same globes in lunulate [lunulate] form would, as it were, exhibit hyperbolic shapes from this cohesion, and so on account of this coherence appearing, they would be taken for handles [pro ansulis], because that obscure interstice would appear like apertures [foramina]

— yet Fontana too [held this], see Fig. 10. Fontana on the 3rd and 13th of December saw it nearly [round], as in Fig. XVII.

1646. Eustachio de Divini [Eustachius de Diuinis / Eustachio Divini] right up to 1647 and 1648 affirms that Saturn appeared to him oviform [Oviformem], as in Fig. X. Or:

1647. Hevelius on September 7 saw Saturn elliptical-handled [Ellipticoanfatum], as in Fig. XII. Gassendi, however — where above — reports that it preserved [perseverasse] the same form, which it had had the preceding year; but it was seen more confused, and its interstices [interstitia] more blunted, its cusps [cuspidibus] become rounder, and projecting more toward the borders of its dark traces [versus vestigia ferè], as in Fig. XV. This appearance lasted right up to Saturn's heliacal setting [occasum Heliacum] in the year 1648. In the month of April; but Ioan. Lips. exhibits, for the year 1647, Fig. XIV.

1646. [carried over from the previous column] XIV. And Giovanni Battista Odierna [D. Io. Bapt. Hodierna / Giovanni Battista Odierna]. Odierna [Hodierna] of the present day [Hodierna] says it appeared to him similar in form to an olive [oleae similem], with a most constant face [vultu constantissimo], from April 10 of the year 1646, right up to 1653. But Gassendi, as above, reports under the year 1646 that that dark interstice [interstitia obscura illa] began to be obliterated toward the cusps, and that the bright borders [alborem] of its handles seemed as it were to merge with the brightness of the middle globe, being less perceptibly distinguished from it. And P. Grimaldi on October 10 saw the eastern companion smaller than the other [comitem orientalem minorem altero], and nearer to Saturn; but on the 16th of November the companions [were] equal to each other and equally distant from Saturn [aequè distantes].

1647. Hevelius on September 7 saw Saturn elliptical-handled [Ellipticoanfatum], as in Fig. XII. Gassendi, however — where above — reports that it preserved the same form which it had had the previous year; though it was seen more confused, the interstices more blunted, the cusps become rounder and projecting more toward the dark traces [versus vestigia ferè], as in Fig. XV. He says this appearance lasted right up to Saturn's heliacal setting in the year 1648, in the month of April; but Ioan. Lips. exhibits, for the year 1647, Fig. XIV.

1648. February 26 and April 16, we [vidimus] together with P. Grimaldi saw the companions equal to each other, and equally distant from Saturn — so that, on account of the brightness [longitudo lucida] of the single parts [singularum partium], there was such [tanta] [splendor] — by however much the

semidiameter of Saturn's disk [Semidiameter disci Saturni]; the obscurer part, however, a little shorter [paulo breuior]; the companions longer [longiores], yet narrower [breuiiores] and larger [magis]. But in the month of May, right up to the 24th of June. But on the 10th of July the companions appeared [faciebant] together with him an oval figure [ouatam Figuram], as in Fig. X.

1649. At the very end of March, and from the beginning of April right up to the beginning of May, and on the 20th of July, when Saturn rose [ortus est] heliacally [Heliacè], and likewise on the 27th: it was seen as in July, as in Fig. XIV — indeed in August on the 23rd and in September on the 29th. P. Grimaldi and ourselves [Nobis]. Hevelius, however, in December on the 23rd saw it elliptical-handled, as in Fig. XIII; or as in Fig. XIV, just as P. Grimaldi on the days of the 12th, 13th, and 21st of December, as in Fig. XIV.

1650. January 2 and March 18 and October 12. Saturn appeared to P. Grimaldi, as in Fig. XIV; nor does Hevelius dissent: he saw it in October elliptical-handled.

1651. April 23. Saturn was seen by P. Grimaldi of a middle figure between Fig. X and Fig. XIV. Hevelius, however, in November saw it nearly spherical-handled [Sphaericoanfatus], as in Fig. IX.

1652. May 29. P. Grimaldi saw Saturn, as in Fig. XIV. Hevelius, however, in October [saw it] elliptical-handled, as in Fig. XII.

1653. At the very beginning of February, P. de Rheita [de Rheita / Anton Maria Schyrleus of Rheita] saw the companions of Saturn drawn out like torches [faces] in pyramidal flames [in flammis pyramidales], that is, as in Fig. V; nor [did] Giovanni Battista Odierna [Io. Bapt. Hodierna]. Odierna [Hodierna] of the present day [held otherwise]: about the Kalends of April he saw it of such a form, as in Fig. P. Grimaldi, however, in December saw the companions of Saturn separated from it, and pear-shaped [pyriformes], as in Fig. V. Or in either way [vtriuslibet] it was of an elongated length [longitudo] just as 13 to 18, as 13 to its longitude. But Gassendi on April 6 saw it as in Figura XIV.

1654. Through almost all of January we saw, together with P. Grimaldi, the companions of Saturn slenderer and more sharply produced [graciliores & acutè productos], as in Fig. XV. But Giovanni Battista Odierna [P. Io. Bapt.]. Zuppi [Zuppus / Zupi] at Naples on the 16th of January saw it [illum], as in Fig. XVI. So that it would not differ from ours, except in magnitude on account of the prolixity of the telescope [Telescopij insignem prolixitatem].

1655. From the 10th of March to the end of June, but chiefly on the 23rd; on April 8 and 9; but it was seen handled before May [Saturnus prius], as in Fig. VI; then on the 6th [vI.] [or "in Fig. VI"]; though Hevelius on May 30 saw it triform [Trisphaericum], as in Fig. IV; but Gassendi in June and July.

1656. From the 9th of February to the 17th of July it was seen by us round, without companions; but on the 14th of May with a band [fascia], as in Fig. II. Boulliau [Bullaldus] too, in January, and Hevelius from the 25th. From February 2 to May it was seen monospherical [Monosphaericum].

That same year a certain Canon Leoninus [Canonicus Leoninus] wrote to D. Antonio Rocca [D. Antonium Roccam / Antonio Rocca] — as I take from his letters — that D. Christiaan Huygens [D. Christianum Hugenum / Christiaan Huygens], a noble Hollander, by multiplying the diameter of Saturn fifty-fold with his telescope, observed about Saturn two companions; that a third planet [tertium planetarium], which they call Saturn's Moon [Saturni Lunam], distant from it by about three of these smaller [diameters], completes its revolution [reuolutionem] in 16 days, as he asserts [addebatq]; and that he had had another tube multiplying [the diameter] a hundred times [centies]; from which D. Rocca suspected that this was a fixed star [Stellam fixam esse]; but more of this in a later observation.

1657. P. Grimaldi saw the companions of Saturn at times, as in Fig. V; he aligned [aliquando] them in Fig. VI, near the said num. 2, under this same year. And at the end of December the companions in part [were] Satur-

1658. January 1. It was seen by us [Nobis] [as] Saturn, as in Fig. XI; and at the end of January, nearly, as in Fig. XV; though with the band still below the center of Saturn [fascia infra centrum Saturni], and an oblique line of the companions [obliqua linea Comitum]. And on February 21, similar to Figura XV. As observed by P. Grimaldi. The longitude of the bright part [Longitudo partis candidae] of either companion was equal to the semidiameter of Saturn's disk; but the obscure part a little shorter [paulo breuior]; in March, however, almost the whole [penè toto], the companions longer but narrower, and chiefly in the month of May, right up to the 24th of June. But on the 10th of July it was seen, [with] Saturn falling away [deficere] from Fig. XV, and the arms of the companions [brachia Comitum] near Saturn growing slender [gracilesce].

1661. May 13. On the following night Saturn was observed handled [ansatus], and with the companions disposed just as it itself [is], as in Figura XIV — among the foregoing [examples].

Appendix observationum Cristiani Hugeni quas post superius scripta accepi

[Appendix of the observations of Christiaan Huygens which I received after the above was written]

1656. January 16. He saw Saturn monospherical [monosphaericum], as in Fig. I, and so right up to June — indeed up to December of that year, 1655. But in October, on the 13th of that year 1656, it had already manifestly recovered its handles [ansas recuperarat], sooner than he had predicted.

1657. December. On the 17th after the heliacal rising [post ortum Heliacum], the arms of Saturn [brachia Saturni] [were] caught in [its] handles [in ansis maturè capta], as in Figura X.

1658. November. On the 10th, Saturn, much after its heliacal rising [post ortum heliacè], appeared with the arms drawn apart into broader handles [in latiores ansas adducta], as in Fig. XVI.

1659. From the 12th of February, Saturn's handles appeared very broad [latissimè], as in Figura I; he expected the tube of 23 feet [tubo pedum 23.]; for with a tube of 6 feet [tubo pedum 6.] Saturn appeared triform [trisphaericus], as in Fig. IV; or as in Fig. V — at which times it appeared now round, now solitary, the zone [Zona] cutting across its disk [discum] in various ways [bifariam]; and at other times the middle part itself appeared higher [supra medium].

Indicatur Theoria aliorum circa praedicta Phaenomena

[The theory of others concerning the aforesaid phenomena is set out]

[Margin: 11]

What P. Anton Maria de Rheita [Antonius Maria de Rheita], in book 4 of his *Radius Sideromysticus* [(de Rheita, *Oculus Enoch et Eliae / Radius Sideromysticus* 4.4)], ch. 4, thought up [excogitauerit] regarding the cause of the aforesaid phenomenon, I have related and in part discussed in book 7 of the *Almagestum Novum* [Almag. Noui], sect. 6, ch. 14, Scholion 3. Among the other things [I add this]: I think it probable, and I judge that Saturn turns about [vertigine] some center of its own which it has rolled up [conuoluit], a fact I confirm from this — that the planet itself sometimes appears now round, now oviform [ouiformis], and sometimes with a band [fascia], sometimes round; and now its sides appear, now above, now below, with the band varying its position [vario motu] about it

[as] above, and below, as I shall be able to indicate below, but below I add another Theory.

[Margin: 12 — Hevelius's hypothesis concerning Saturn / Heuelij Hypothesis de Saturno]

Hevelius, however, by the swiftness and keenness of his remarkable genius — in a little work [opusculo] recently published on the face of Saturn [de facie Saturni] — has undertaken [conatus est] to render reasonable [rationi reddere] so admirable a variety of changes [vicissitudinum]. He reckons that Saturn exhibits so diverse phases on account of its diverse aspect [aspectu], because we look at it now more directly [rectiùs], now more obliquely [obliquiùs]. Since, by optical principles, a Cylinder and an Ellipse consist of [a body which], by the oblique situation of the eye, appears circular [circulares apparere]. Hence, asserting this, Saturn appears both at apogee [in Apogaeo] — when it appears elliptical-handled [Elliptico-anfatus] — than at the perigee of the eccentric [in Perigeo Excentrici], and at the mean distance from the Earth [media distantia à Terra], as in Fig. XIV; or from the Sun [à Sole], it appears monospherical [Monosphaericus], that is, solitary and round; but in yet other situations [sitibus] spherical-handled [Sphaerico-anfatus], by latitude [latitudine] and the diverse situation in the epicycle [in Epicyclo]. And because at this time [hoc tempore] the apogee of Saturn is in 27° Sagittarius [♐], and the perigee in 27° Gemini [♊], and the mean distance in 27° Virgo [♍] and Pisces [♓], for that reason he has distributed Saturn's phases throughout the entire eccentric by a most elegant figure [figurâ elegantissimâ], and likewise by a Table, the epitome of which it pleases me to insert here.

[Margin: 13]

Phases ♄ ex opinione Heuelij

[Phases of Saturn per Hevelius's opinion]

[Margin: 14 — Indicated argument against Hevelius / Indicata argumenta contra Heuelium]

Where the Figures are wanting here, they are wanting also in Hevelius, p. 4. But neither can our Figures — the Fourth, Fifth, Sixth, Seventh, Eighth, Tenth, Fourteenth, Fifteenth, and Sixteenth, that is, the Decimaquarta and Decimasexta — represent the Hevelian hypotyposis [Heuelianam Hypotyposim] without doing violence [sine violentia]. Moreover, from our observation of the year 1656 — concerning which above, on May 14 — Saturn was in 16° Virgo [♍] [and] was solitary and round, although it was distant 11° from the place [à loco] of perfect roundness according to Hevelius; therefore on the 27th of October, in 1° Libra [♎], when it was not distant by whole degrees [non distabat integris gradibus] from the said place of perfect roundness, it ought still to have appeared round

and solitary; yet it was seen manifestly with the companions separated [cum comitibus separatis], as in Fig. V. Of Huygens's hypothesis, of which more below in several places, the Hevelian hypothesis is thereby chiefly to be disproved [improbrari], since by it Saturn ought to have been seen round throughout September of the year 1657; and yet on the 13th [of October — supplied], in the year 1656, it had already recovered its handles [iam ansas recuperarat]. In the year 1656, moreover, with Hevelius's positions, Saturn [was] placed in 18° Pisces [♊]; it ought to have appeared round, and on December 1 [it ought to have appeared] trispherical [trisphaericus]; yet in that year it appeared solitary to Galileo, and on December 1 solitary, and round.

[Margin: 15 — Roberval's hypothesis of Saturn / Roberualli Hypothesis de Saturno]

Roberval [Roberuallius / Gilles Personne de Roberval] thought the causes of the Saturn phenomenon could be explained, if it should be said that vapors [vapores] go out from its Torrid Zone [Zona Torrida], and these are elevated [eleuati], which reflect the Sun's rays back to us, when they go out from those distant places — but [they] are not elevated toward the poles [versus polos]. But these [explanations are] too liable [obnoxia] to uncertainty of physical causes, nor probably bound to certain places of the Zodiac; since nevertheless it is established [constet] that Saturn is set opposite [oppositus] in two places of the Zodiac — and in each of these it is seen round in its revolution [sui reuolutione videri rotundum], and twice in two other opposite places, where, at a quadrant's distance [quadrante] from the said distances, it appears most amply handled [amplissimè ansatum], as Huygens noted [aduertit] against him.

[Margin: 16]

Giovanni Battista Odierna [Io. Baptista Hodierna] — as Christiaan Huygens reports — at p. 43 of his *System of Saturn* [Saturnij Systematis], judged Saturn to be spheroidal in the manner of an egg [ouum] or a plum [prunum], and longer than the Hevelian [spheroid]; and that in it there are two spots devoid of light [binas esse maculas lucis expertes], as in Figura X or XIV. He held, moreover, that Saturn turns about its axis [Conuerti autem Saturnum circa sui axem] in the same period as Hevelius established, and that it is then seen round, when the longer axis of the spheroid [longior sphaeroidis axis] is directed toward us. "But," says Huygens, "since it appears altogether round as often as it is stripped of its arms [brachijs nudatus est], how are the gaps [lacunae] to be filled, which the two black spots [duabus maculis nigris] are to over-

shapes does Odierna admit? Finally, if anyone turns the aforesaid spots about the planet's axis, he will see that many phases appear far different from these — phases that do not appear on Saturn.

Christiaan Huygens's System of Saturn

17. First, Christiaan Huygens [Christiaan Huygens] reports that he used a telescope of 12 Rhineland feet down to 19 February of the year 1656; and that he then used a telescope of 23 feet. Its object-glass, the more distant lens [*remotum lamellum* / object lens], had an aperture of 4 fingers but a focal length [aperture] of 2; while the eyepiece consisted of two lenses joined together, with a single convex face of equal curvature, each lens being $1\frac{1}{2}$ fingers and a little less, with the rays converging. From this one can gauge the excellence of his object-lens, which can tolerate so short a convexity. [Margin: *The excellence of Huygens's telescope.*]

Now since he has demonstrated in his *Dioptrics* [*Dioptrica*] that the appearance seen through an optical tube has, relative to the appearance seen with the naked eye, the same ratio that the focal length of the object-glass has to the focal length of the eyepiece: and since the focal length of the aforesaid object-glass was 23 feet, or 276 fingers, while the focal length of the eyepiece was a little under 3 fingers — therefore he follows that the telescope magnifies the object some hundredfold, whereas Galileo's tube magnified only some thirtyfold. With such a telescope, then, he always saw the *ansae* [the handles] of Saturn joined together [as a ring]; whenever he saw Saturn with the handles joined, he twice saw it solitary and round; but when he saw it with the handles joined to the disk of Saturn, he twice saw it as solitary and round — that is, when the handle appeared joined to the body of Saturn through the telescope. He saw it round when he viewed it through a telescope of six feet (this was in the year 1658, on 10 November); from which he concludes that the tricorporeal [three-bodied] appearance arises from the imperfection of the tube, so that it appears tricorporeal.

Whenever, moreover, he saw Saturn round, he saw a belt [*Zona*] cutting its disk in two; at other times — namely in the year 1655 — a belt in the upper part, at other times in the lower; and he observed on Jupiter two belts [*Zonas*], no darker, as others have it, but brighter than the rest of Jupiter's body. By contrast, on Mars he observed a dark belt, and the part of the disk in the middle obscured and broad — the two parts amounting to about $\frac{1}{5}$ of the disk's diameter. As for the diameters of the fixed stars, with the lens first lightly smeared with soot he saw them as if they were bright points; and the middle star in the sword of Orion he

found not to be a single star but to consist of 12 stars, very distinctly persisting [as separate]. Finally, with such a tube he first observed for himself the little planet [*Planetulum*] wandering about Saturn, which he calls the Moon of Saturn [Titan].

18. From the year 1655, on 25 March in the Gregorian style, to the year 1659, on 26 March, in the space of 10 hours, he brings forward nearly 70 observations of this little Moon; from which it is established that this companion encircles Saturn in the same number of days [16], and returns to the same position in the same number of days, and is now nearer, now farther, and twice joined to it; and from it he obtains a distance now this way, now that, which does not exceed the first minute 3' 16", reckoned from the center of Saturn. From these things, then, having observed the positions of the Moon of Saturn, he constructs his Theory, with a circle described from the center of Saturn's globe, divided into 16 parts, whose diameter AP runs into our eyes; in which...

Diagram. A ring (annulus) seen in perspective, surrounding the globe of Saturn. The globe sits at the center, labeled A at its top. The encircling ring is labeled with letters at the four cardinal points of its ellipse.

- A (top of central globe): Saturn's globe
- B (left end of the ring): western end of the ring
- C (bottom of the ring): nearer/lower edge of the ring
- D (right end of the ring): eastern end of the ring

The ring BD passes in front of and behind the globe AC, depicting Saturn's ring system in oblique projection.

The ring here, BD, although it is separated from the globe of Saturn AC, nevertheless revolves in the Zodiac at the same pace as it [the globe], and with equal force; for it is constituted around the center of Saturn just as the Earth is, resting on no supports, yet always moving, since the whole thing is moved at once, and is equidistant from the center of Saturn, which is the center of gravity. Now when Saturn appears perfectly and most amply handled [fully open], as in Figure XIV indicated above, the diameter BD appears greater than the diameter of the apparent ellipse, of which the lesser is as 5 to 2. He proceeds then, from his own observations, on the authority of Galileo, Gassendi, Boulliau, and Riccioli, to take the line of Saturn's handles BD, that is the line of the handles, to be parallel to the Equator: in which, however, he says Riccioli is inconsistent with himself, because on one hand he shows the line of the handles to be parallel to the Ecliptic, and on the other to be parallel to the Equator. [Margin: *Riccioli vindicated against Huygens's censure.*]

[He says that] in the year 1650, on account of the observation made on 18 March by P. Grimaldi [Francesco Maria Grimaldi], he [Riccioli] denies that this line was parallel to the Ecliptic, since at that very moment Saturn was near the beginning of Cancer (for it was in fact at degree 24 of Gemini), nor could that line be parallel to the Equator, because it was parallel to the Ecliptic — and so he was therefore deceived, supposing P. Grimaldi to have erred in observing the approach to the Fixed Star, and to have thought it the same star, whereas it was a different one, as he says in *Almagestum Novum* p. 723. Now Huygens supposes, on I-know-not-what observation, which he does not cite — Saturn being at degree 20 of Gemini and ♄ — that the line of the handles passes out parallel to the Ecliptic. But here Riccioli does not suppose with him, but only that the line of the handles is at once parallel both to the Equator and to the Ecliptic, when Saturn is at the very beginning of Cancer or Capricorn, in that the parallel of the Equator does not then cut the Ecliptic, but touches it; whereas outside this position, by the very fact that the line of the handles is parallel...

Diagram. A circle representing the orbital circuit of Saturn's companion (the little Moon), divided into 16 equal parts numbered around its circumference. The center is marked **C**, with a small cross (the orthogonal axes) drawn through it. The vertical diameter runs from **A** at top (with the figures **1** and **16** flanking it) down to **P** at the bottom (flanked by **8** and **9**). The numbered positions run clockwise.

- A (top): apogee, flanked by 1 (left) and 16 (right)
- positions descending the right side: 15, 14, 13, 12, 11, 10
- P (bottom): perigee, flanked by 8 (left) and 9 (right)
- positions ascending the left side: 7, 6, 5, 4, 3, 2
- C (center): center of Saturn / center of the circuit

This companion is carried round according to the order of the Signs, from apogee **A**, through **C**, to perigee **P**. In the first observation, of the year 1655, on 25 March, it was found to have been at position 12, distant from perigee **P** by $3\frac{1}{2}$ parts; the whole circumference ACPD being 16; and on 26 March it was found to be at number 13; and on 27 March at number 14; and on 3 April...

\newpage

is parallel to the Equator, and parallels of the Equator cut the Ecliptic, that line must necessarily be inclined to the Ecliptic; which is evident from the same degree 24 of Gemini. He labors over this point most studiously, that Riccioli was not deceived; for although Huygens accedes elsewhere to Riccioli's opinion, he

affirms it neither here, since this observation overturns his own opinion concerning the parallelism of the Line of the handles, beginning at degree 20 of Gemini and ♊. Therefore, not yet content with what has been said, Riccioli shows that Grimaldi is contrary not to himself but to Riccioli — and that Grimaldi was deceived — but let me say these things in passing. Let us proceed to the remainder of Huygens's Theory.

20. The orbit of Saturn, of about 30 years, having been at length absolved [computed], he places in the same plane with the Ecliptic, with the inclination neglected, of $2\frac{1}{2}$ degrees. The axis of Saturn, about which it revolves, he posits always parallel to itself, and the plane of the surrounding ring [annulus] erected at right angles, so that around this center the parts in turn are turned [rotate], and the globe of Saturn, so that all its parts in turn are illuminated by the Sun; and the ring itself, and in the plane of the ring, a companion [Comes], or Moon of Saturn [Titan]. He posits the axis of Saturn to be roughly equidistant from the Earth's axis, at an angle of $23\frac{1}{2}$ degrees, and inclined to the plane of the Ecliptic. With the plane of the ring placed parallel to the plane of the Equator, the diameter of the apparent ellipse is greater, to which the ring is assimilated, and the diameter of the ellipse is reckoned parallel to the Equator. From this it comes about that, with Saturn existing at the beginning of Cancer ♋ and ♊, the ring ought to appear to us at its widest of all, since then our eye is raised above the plane of the ring by $23\frac{1}{2}^\circ$; and on the contrary it ought to appear most narrow at the beginning of Aries ♈ and Libra ♎ — at which positions Saturn, on our eyes incurring [falling on the plane of the ring], the ring appears [edge-on]. But by observation it is established that it is widest at degree $20\frac{1}{2}$ of Cancer ♋, and narrowest at degree $20\frac{1}{2}$ of Virgo ♍, and ♊ — from which one may conclude that the line of the handles is not exactly parallel to the plane of the Equator, but is inclined to the Equator by about 8° ; for Saturn was at degrees 25, 15' of Gemini ♊ and ♋ when it appeared widest, and this indeed in our age. The two places in Saturn's orbit are therefore opposite, in which the ellipse appears widest, and the two in which it appears narrowest; in other places, narrower or wider it appears, the more or less Saturn recedes from the said places, that is, as our eye is more or less raised above the plane of the ring.

21. Furthermore, if we were to view Saturn from the Sun, the same places of the Zodiac would be perpetually the [same], in which the plane of the ring would be led to our eyes; but as we view Saturn from the Earth, certain inequalities arise. The ring, then, by its latitude infected [affected], referring nothing of its surface to a straight line, appears as neither of the surfaces of the ring of Saturn, which on that account [appears] round and without arms [armless]. The phases — which

indeed are seen on Saturn's orbit twice in a half-year, and more — happen for another reason, namely that Saturn, existing at the beginning of Aries ♈ and Libra ♎, the plane of the ring, produced (by imagination), should pass between us and the Sun; in that case we cannot see that illuminated surface of the ring, which faces the Sun, but the other only, which suffers the alternations of shadow, because the exterior edge of the ring, although endowed with some thickness, is of such a nature that it reflects almost nothing of the Sun's rays, and so exhibits the globe of Saturn girded with a dark belt [*Zona obscura*]. Just as on the surface of the Moon certain parts appear darker, because they are unsuited to reflecting the Sun's light. And this happens the more to all the parts of the ring, the more obliquely they are illuminated by the Sun — as happens when the eccentric position of Saturn is not absent from degree 20½ of Aries ♈ and Libra ♎, beyond degree 6. With all these causes concurring, then, the round phase of Saturn lasts longer. Granted that the plane surface of the ring be even, and not rough with mountains. And so Huygens concludes: whoever sees Saturn from the Earth, whenever the eccentric position of it, or as seen from the Sun, is no more than 6 degrees distant from degree 20 of Gemini ♊ and Pisces ♉, the arms can never be seen with ordinary tubes; but with perfect tubes they can, at a distance of 6 degrees from the said limits (which limits he calls Saturn's Equinoxes), some beginning of the arms can be seen.

22. Therefore Saturn, according to Huygens's Hypothesis, either appears round about degree 20 of Virgo ♍ and Pisces ♉, or handled, but always with the handles connected to it, if the telescope is perfect...

and the feet [supports] are 12. And let it be reckoned the minimum. For if it is observed with smaller tubes, the handles are seen separated, because, as the same author teaches on p. 35, the extremities of the handles reflect a greater light to us than the parts near Saturn: whereas, when some shadow intervenes, then the extreme part of the handles appears round to some by a fallacy of vision, since all things observed from afar — as a flame and the like — appear round. But Huygens does not explain the said cause; for it cannot come from the body of Saturn, since then the shadow would have to be Calathoid [basket-shaped], and Saturn's globe would illuminate it with the greater globe of the Sun — though, on Huygens's own testimony, it [the shadow] is smaller; both because the shadow does not fall except onto that part which is behind the ring; and because that shadow which is between Saturn and the Sun, would have to be there. But still this enigma remains to be solved: why, with the perfection of the tubes equal at the same time, Saturn would appear, with the handles joined to it, with more imperfect tubes; whereas with separated handles it appears now round, now

pear-shaped [*pyriformis*], or of different figure; and why round when they [the handles] are slender, but when ample, then not round.

23. It remains, as it has appeared to Huygens himself in the times of this present age, and as those entering the future shall determine for us, that Saturn shall appear round, and without visible handles; to which, on the contrary, it shall be shown or about to be shown with the handles most amply drawn apart, and by which the thinnest [handles] are exhibited, when the telescopes are perfect, when the arm emits a brighter appearance after the heliacal setting [rising], or recovers [it] after the heliacal rising. Interval — for the intervals of these phases cannot be tied down even to the fifteenth year; or every tenth year, indeed they recur twice within one period of Saturn; both on account of the Anomaly of Saturn, and on account of the Retrogradations of it intervening between one phase and another. To this is added that the limits, which Huygens established at degree 20 of Gemini ♊ and ♎ for the most ample handles, and Virgo ♍ and Pisces ♉ for the round phase, are not certain, both on account of the inclination neglected by himself from the Ecliptic, and perhaps on account of some libration of Saturn, and the ring toward the Poles of the World. Meanwhile, however, by observation his opinion stands, that these are the times of the phases.

24. The First Phase of Saturn Solitary and Round, indeed perfect telescopes being had, ought to have been seen in the years 1613, 1626, 1642, 1655, about April; and it ought to appear in the year 1671, on 12 January, and 1685 on 2 September; and about the middle of the year 1701, Saturn existing at its eccentric position at degree 20 of Gemini ♊, or Virgo ♍, or Pisces ♉. Now about six months before the first predicted phase, when the telescopes are perfect, Saturn ought to appear with very slender arms, which it lost a little after, on account of its approach to the heliacal setting. By contrast, about six months after the first predicted phase, Saturn ought to, or shall, recover the arms, after the heliacal rising, with perfect telescopes; for indeed, on account of their thinness, it can still appear round, or be solitary. The predicted intervals can, however, be varied — produced on account of the Retrogradations of Saturn. *The Second of the extreme Phases* — namely when, with the telescopes perfect, Saturn appears most amply handled, with Saturn existing at its eccentric position at degree ♊, or ♎ 20½ — ought to occur in the year 1619 and 1634, and between 1648 and 1649; and it shall occur between 1663 and 1664, and between 1678 and 1679, and between 1693 and 1694, and between 1708 and 1709, and so on.

The Third Variety of the Phases, namely of the growing handles, occurs from the time of the recovered arms, down to the time of the second phase. *The Fourth*,

finally, occurs from the time of the second phase, down to the time at which Saturn loses, or is about to lose, the arms. Which intervals the Astronomers will then more certainly define, when, by more numerous observations through telescopes, more perfect handles of Saturn, as it were, they will have seized by hand.

Judgment concerning Huygens's Theory, and Indication of Our Own

25. Although we owe very much to Huygens, on account of his Theory of Saturn's figure, so ingeniously and learnedly invented by him; nevertheless there are certain things which still hold me in suspense. For first, as I indicated at number 21, Huygens does not adduce...

the cause whence that shadow proceeds, by which the parts of the handles near Saturn do not appear, with imperfect telescopes. But neither does he assert the reason why, with the same telescopes — for example, with our own — the whole of Saturn appears now tribodied [tri-spherical], now with the companions pear-shaped, now handled; for if those distant extremities appear round, the same things ought to appear to the same telescope. It is therefore to be added, as it seems, that those extremities appear round, when Saturn is not far distant from its Apogee, [appearing] pear-shaped when it is more distant; and at its approach to Perigee the handles are seen more and more coherent with Saturn — because then more, and more direct rays of the Sun, are reflected to us.

26. *Secondly*, from the Huygenian Hypothesis it follows that Saturn's globe always projects out beyond the plane of the ring, even when most amply handled; yet, as is established from Figure cap. 2, and from Figure 10, cap. 9, it is established that the whole appeared to us within the handles, nor can this be ascribed to an imperfection of the Tube — if [the tube] represented to us the parts of the handles nearest to Saturn, which nevertheless Huygens admits are more difficultly seen than the extremities; it would much more brightly have represented the whole globe of Saturn with the eminence projecting beyond the handles, if indeed it had thus projected.

27. *Thirdly*, there is no necessity of positing the plane of the ring parallel to the plane of the Equator, granted that the line of the handles, observed parallel to the Equator; nor likewise is it necessary that the ellipse appear, with which Saturn handled exhibits that ellipse, [or] that the ring be separated from it on every side equally. But it can be said that Saturn is girded with an elliptical ring [*Armilla Elliptica*] coherent at the extremes of the minor diameter of the ellipse; and this is the more probable, the more probable it is that the ring be joined to Saturn, and

that it traverse the Ecliptic together with it, than that the body be separated from the orbit of Saturn. Furthermore, it can be said that Saturn, about its major diameter, the elliptical ring, as if about an axis parallel to the Equator, [is] either turned [revolved] in a perfect revolution, or librated, in such a way that the ring — the part which optically bisects its own middle to us — when indeed it appears round, is sometimes in the highest part, sometimes in the lowest, so that it represents the whole of Saturn within itself, as in Figure X, cap. 9, and most amply handled. From observations both past and future, the times of these librations will be better established. But whether the plane of this ring is posited parallel to the Equator, or librating — both can be saved equally well, if I am not mistaken — all the phenomena of Saturn's figure, even if a ring coherent with Saturn be posited in place of the Huygenian ring, and be called...

A ring is girded, thin, plane, Elliptical, coherent in two places; or parallel to the Equator; or revolving in itself, or librating toward the Poles of the World.

28. It is also more probable that the plane surface of the aforesaid ring is not of equal width, but at the extreme parts wider, and at the parts coherent with Saturn's globe narrowest. For thus it is more easily understood by what cause, with imperfect tubes, the parts near Saturn more often do not appear, the extreme parts being seen rounder, nor are the angles of the ring discerned; but with tubes always imperfect, the parts of the ring coherent with Saturn are not seen — though sometimes the extreme and more remote parts appear in the form of a pear, or of a half-burnt [*semipruni*] oblong; with all tubes, however, when Saturn appears most amply handled, the handles appear broader [*latiores*] in the more remote parts.

29. But neither is it improbable that the chief cause why Saturn in this age appears most amply handled at about degree $20\frac{1}{3}$ of Gemini ♊ and Pisces ♉, is not because our eye is raised above the plane of the ring by $23\frac{1}{2}$ degrees, but because the declination of the Ecliptic from the Equator — for it [Saturn] ought to be at the very beginning of Cancer ♋ and ♎ [if it were due to that] — is not from the varied parallelism to the Equator, which is more probable, [but] is always...

continued, until the axis of the ring, by libration of the ring, or revolution, which can be so great that our line of vision falls at a right angle on the plane of the ring. But the limits of this libration, or the revolutions, can — contrary to the order of the signs — migrate from Cancer ♋ into Gemini ♊, and from Capricorn ♐ into Sagittarius ♏; or on the contrary, according to the order of the Signs,

change — say, from the beginning of the world at the beginning of Aries ♈ and Libra ♎ — also migrate at degree $20\frac{1}{3}$ of Gemini ♊ and Pisces ♉, the parallelism not always being saved of the plane, but the axis of the ring [being placed] toward the Equator. But whether either of these happens, or comes about, being destitute of the observations of past and future ages, we cannot determine.

Concerning the Figure of Saturn most recently observed by Don Giuseppe Campani

30. Don Giuseppe Campani [Giuseppe Campani], skilled in the most excellent telescopes and provided with them by his own peculiar industry through the wheel-machine he himself constructed, observed Saturn in the month of April of the year 1663 and 1664, girded with an apparent Elliptical circle, of which the Figure came to me by gift of the Author, with a little treatise expounding it, transmitted by P. Daniele Bartoli [Daniel Bartoli] — very similar to Figure XIV rather than X from the premises at number 10. But he adds the upper part, that is, toward the Arctic pole, the part of Saturn's body situated to be hidden by the ring [*Armilla*]; whereas on the contrary the lower part, toward the Antarctic pole, that is, the southern part to be covered by the part of the ring nearest to the body itself, or the globe of Saturn. He narrates besides that, inserting in the globe a white little circle, as if girded with an iron thread in the manner of a diameter through the globe, and the ring so depressed, and the equal part; and so placed in a suitable light, and observed through a small telescope, it represented to him all the diverse phases for diverse elevation, or depression of the ring, which now in this present age are discerned, and which in future years are discerned. The tube, moreover, with which he used was 28 Roman palms; observation of the year 1664, on 21 April, at the hour of the year 55; with which architects use.

31. I indeed, having inserted the globe in an elliptical ring [*Armilla*], in fact observed no less the said diverse Phases representing the diverse libration of the ring. With these things established hitherto, although Saturn never appears perfectly round, it cannot stand for an ellipse — so long as it shall not be demonstrated to be impossible that it be a ring in fact, and not appearing only elliptical — it represents all those phases that appear on Saturn.

CAPVT X.

Concerning the Figure of Jupiter, its Belts and theirs; its Parallelism to the Ecliptic, and its Satellites.

1. Whatever the vaporous Sphere may be, which P. Anton Maria de Rheita [Anton Maria Schyrleus of Rheita] asserts to be seen about Jupiter, with an ample perspicillum [eyeglass], in *Radius Sideromysticus* [*Oculus Enoch et Eliae / Radius Sideromysticus*] book 4, cap. 1, member 2 [Margin: *Jupiter's atmosphere.*]; and concerning the roughness [*asperitas*] of Jupiter, which the excellent telescope of D. Leander Bandtius, Abbot of Dispergen [Leander Bandtius], observed for himself in the year 1643, on 2 November — that is, 21 [days] after the opposition $\odot$ with the Sun — with two smaller spots, and two larger, or hollows [*cavernae*], one round, the other oval, equaling the seventh part of the Jovial diameter in length [Margin: *Jupiter's roughness and spots.*]; as I have from a Schematic from Flanders transmitted to me — since these things are rarely [seen], nor except through rare longest-sighted [most powerful] telescopes can they be discerned; these things, I say, being omitted, and similar ones — both as to the roughness, both as to the spots, which sometimes are observed in Jupiter — Hevelius bears witness on pp. 42, 44 of his *Selenographia*. Concerning the Belts [*Fasciae*] and the Satellites, as being ordinary Jovial $\sphericalangle$ phenomena, which by observing have been found out, we shall expound.

Diagram. A single rectangular ruled frame at the head of the page encloses nine small disks of Jupiter arranged in three rows of three, each disk numbered with a Roman numeral above it (I–IX, reading left to right, top to bottom). Each disk depicts a different observed configuration of Jupiter's belts [*fasciae*] — shown as shaded transverse bands across the disk. The figures illustrate the variety of belt appearances catalogued in the chronological observation list that follows.

- I (top left): two belts, both curving (concave toward the lower limb), set in the upper half of the disk, plus a fainter third band lower down.
- II (top centre): two strong, nearly straight transverse belts, one in the upper portion and one across the middle.
- III (top right): a single narrow belt a little above the centre of the disk.
- IV (middle left): two close-set belts in the upper portion, lightly curved, with a faint third band below.
- V (middle centre): a single broad belt across the middle, drawn between two boundary lines (a wide band bounded above and below).

- VI (middle right): two oblique (slanted) belts crossing the disk diagonally from upper left to lower right.
- VII (bottom left): a broad region of dense banding filling much of the disk — several belts close together, the middle one the widest and darkest.
- VIII (bottom centre): two belts, one above and one below the centre, with the lower portion of the disk appearing contracted/narrowed relative to the upper.
- IX (bottom right): two belts in the lower half of the disk, the upper one straight and the lower one curving toward the limb.

[Cross-reference: the figure numbers I–IX are cited individually throughout the dated observation list below.]

2. The belts [fasciae] that gird Jupiter's whole disk crosswise — or rather, the more prominent or deeper parts of it — were first noted, so far as I know, at Naples by Fathers Io. Baptista Zuppus [Niccolò Zucchi — *recte*; see note] and Daniel Bartolus of our Society, although Franciscus Fontana had observed the same there beforehand. Afterwards we ourselves, together with Father Franc. Maria Grimaldi [Francesco Maria Grimaldi], distinguished those same belts clearly and repeatedly with a more accurate telescope. They appear sometimes threefold, sometimes twofold, and occasionally single — bounded at each end, and now and then closed off, and at times single. Moreover, the belts are sometimes seen toward the middle of Jupiter's disk, sometimes lower down, sometimes higher up; nor are they always straight, but are sometimes bent with their convexity turned downward, and at other times turned upward. These facts are indeed a fairly clear sign of Jupiter's rotation [vertigo] about its own centre. For concerning the parallelism of these belts to the ecliptic and to the path of the satellites, I must speak separately below, after the history of the number of the belts. As for the fact that the belts sometimes do not appear at all — as is plain from the first figure of Io. Lipius of Munich [Johannes Lippius] — it is no wonder, since Gassendus [Pierre Gassendi] in his *Institutio Astronomica*, Book 3, denies that he himself ever saw them.

Fasciarum Iovis Observationes.

[Observations of Jupiter's Belts.]

In the year

1630 — On May 17, Father Nicolaus Zucchi [Niccolò Zucchi] at Rome saw two belts of Jupiter, as in Fig. II.

1633 — Franc. Fontana [Francesco Fontana] at Naples, as is recorded in the sixth treatise of his observations, observed three belts, as in Fig. I; likewise at the beginning of the year 1643.

1634 — Jupiter, which had long appeared with three belts, from the beginning of October up to the 13th — that is, up until conjunction [$\odot$, *recte*: opposition] with the Sun [?] — was seen by Father Grimaldi with two belts, one dark, the other brighter, than [the other; sentence continues below].

[The right-hand column continues the year 1634 and following:]

[1634, continued —] ... the other disks of Jupiter, as in Fig. III. But after conjunction with the Sun, up to October 20, they were seen the same, with the same three belts, one dark, the rest bright and somewhat curved, as in Fig. IV. From the beginning of November up to the 22nd of December, they frequently appeared now straight, especially at the meridian, as in Fig. V.

1644 — Father Io. Bapt. Zuppus at Naples observed two belts of Jupiter, as in Fig. II, but much larger, on account of the excellence of his telescope, which represented the Jovian diameter as nearly half a foot across.

1645 — On January 1 and 22, Fontana saw two belts of Jupiter, as in Fig. II; but on the 28th of January a third appeared to him near the margin, as in Fig. I.

1647 — On January 23, Father Grimaldi and I saw Jupiter girt with two zones at conjunction [$\odot$, *recte*: opposition] with the Sun, as in Fig. II.

1648 — Father Grimaldi, from February 24 to March 16, observed two belts on Jupiter, now straight, as in Fig. VI, which represents the observation of February 11, at 2½ hours after sunset, when Jupiter was at quadrature, moderately distant from the meridian. The upper belt appeared narrower and darker, the lower one broader and less dark; and the part of Jupiter's disk intercepted between them was much brighter than the rest of the disk. Jupiter's conjunction [$\odot$, *recte*: opposition] with the Sun had been on the 22nd of February.

1649 — On March 28, at 2 hours of the night, the belts appeared in nearly the same line with the 4 satellites of Jupiter; but on August 14 Father Grimaldi noted a single belt above the middle, in the line of the satellites, the rest not being clearly visible.

1650 — In the month of July, two belts were observed by Father Gri-[maldi]

[Margin, left of §2: Situs,]

[1650, continued —] ...maldi, in the upper part [of the disk], turned toward the south [Austrum], as in Fig. IX.

1651 — On May 29, Father Grimaldi saw Jupiter with two dark belts, enclosing a large bright space between them, as in Fig. II; but on July 11 he saw three dark belts, of which the middle one was broader and darker, and somewhat higher up near the limb than [the lower one]; the southernmost was lower down, as in Fig. VII.

1652 — On December 1, Father Io. Bapt. Hodierna [Giovanni Battista Odierna] wrote to me that Jupiter had appeared to him single-belted [Iovem Monozonium], in January and July.

1653 — On July 21, Father Grimaldi saw Jupiter three-belted [Trizonium].

1654 — Father Io. Bapt. Zuppus observed Jupiter as in Fig. VIII, in which the lower half-disk appeared contracted relative to the upper.

1656 — Father Grimaldi, on August 2, beheld Jupiter with two dark belts comprising a bright zone between them, as in Fig. VI, of which the lower belt was a little broader, and in the line of the satellites, as in October on the 1st. And on December 2, as in Fig. VII.

1657 — From October 17 up to November 6, Father Grimaldi observed three belts on Jupiter, as in Fig. III; but on the 12th up to the 19th of November, the two darker belts were failing in the manner of Fig. VII — for the two darker belts included three similar bright belts of the figure, and the third obscure one was nearest to the southern limb, as in Fig. IX; and the obscuration [reached] up to the third nearest the southern limb, as in Fig. VII. But at the end of December he saw three dark belts together with two bright ones enclosed nearly in the middle, as in Fig. VII; but in the margin a certain shading appeared toward the south, as a fourth belt [veluti quarta fascia]. [Note: this is among the earliest records of a discrete, persistent dark feature low on Jupiter's disk — a Great-Red-Spot-type observation.]

1664 — On July 1, Lord Iosephus Campanus [Giuseppe Campani], with an excellent telescope made by himself, observed three dark belts on Jupiter, fairly bright, as the most excellent Doctor Lord Io. Dominicus Cassinus [Giovanni Domenico Cassini] attests. But since I have not yet obtained the figure of these, I cannot exhibit a synopsis of them to the reader.

De Parallelismo Fasciarum, Viæ Satellitum, & Ecliptica.

[On the Parallelism of the Belts, the Path of the Satellites, and the Ecliptic.]

3. That the belts of Jupiter are parallel both to one another, and to the path of the satellites of Jupiter, and to the ecliptic — at least in respect of the satellites — was noted by Galileo in the *Nuncius Sidereus* [*Sidereus Nuncius*] and by Simon Marius [Simon Mayr] in Part 2 of his *Mundus Iovialis*, Phenomenon 6; and as to the belts, by Hevelius [Johannes Hevelius] in his *Selenographia*; likewise by us, together with Father Grimaldi, who often noticed it; and as we noted above, [drawn] through the lines from Jupiter's disk to the pair of stars [the satellites], according to the guidance of the belts and the path of the companions [satellites]. There is no need to fill so many pages with a multitude of these observations.

De Numero Satellitum Iovis.

[On the Number of Jupiter's Satellites.]

4. Although Jupiter's satellites are reckoned equal in apparent magnitude [v.] to fixed stars of the sixth magnitude — for such stars are, as it were, just so many — they nevertheless do not appear with the unaided eye, on account of the brilliance of Jupiter overshadowing them, just as the satellites of Jupiter cannot be seen without a telescope, on account of the brilliance and smallness of Jupiter, which is so near. Nor has anyone of them ever been seen at a distance of more than 12 minutes from Jupiter's disk — doubtless because of the weakness of mortal eyes, and (at the beginning, and even more in our age) on account of the lack of a telescope, until, the telescope having been granted to the world, Simon Marius in Germany — as he relates in his *Mundus Iovialis* of the year 1609, around the month of November on the occasion of conjunction [$\odot$, *recte*: opposition] of Jupiter with the Sun — began to notice three little stars around Jupiter, confirmed in the following years by varied distances [or: by observation of varied distance], on the 29th [December]; he saw three [stars] in a straight line on the 8th, and again toward the west. In the year 1610, on January 12, and from the beginning of January, he recognized [these to be] wandering planets, but Marius noticed nothing concerning Mars [the Martian observation — *recte*: ☿? see note]. Galileo, however, conscious of nothing of Marius's observation, first of all in Italy in the year 1610 on January 7, at the first hour of the night, observed around Jupiter first three little stars, and then four; nor ever more than four little wandering stars around

Jupiter, and [distinguished them] from the fixed stars by the sign that their distance from one another changed swiftly, as is [explained more fully].

[The matter is] more fully related in the *Nuncius Sidereus*. And although Scheinerus [Christoph Scheiner], in his first letter to Wellserus [Marcus Welser], suspects that there are more satellites than four — in his *Disquisitiones* he nonetheless acknowledges, both from his own observations and from those made at Rome, four only; and likewise the number, in his observations, Blancanus [Giuseppe Biancani] asserts in his *Sphaera*, page 14. Keplerus [Johannes Kepler], in his *Dissertatio cum Nuncio Sidereo*, and in the *Epitome Astronomiae*. Herigonius [Pierre Hérigone], in volume 5 of his *Cursus Mathematicus*. Carolus Malapertius [Charles Malapert] of the Society of Jesus, who calls them *Sidera Austriaca*, as Galileo [calls them] *Sidera Medicea*. D. Vincentius Reinerus [Vincenzo Renieri], who has observed them whole, for ten years. Likewise Peireskius [Nicolas-Claude Fabri de Peiresc], and Galtenus [Pierre Gassendi — *recte?*] in the life of Peireskius; and in the *Iudicium de 9 Stellis* [Judgement on the 9 Stars], these were observed by Massilia [the Marseille observers], naming them: the first, that is, the innermost, *Cosmus Minor* [the Lesser Cosimo]; the next innermost *Cosmus Maior* [the Greater Cosimo]; the next to outermost *Maria Medicea* [Maria de' Medici]; and the outermost *Catherina Medicea* [Catherine de' Medici]. Although Marius would have called the innermost *Iovialem Mercurium* [the Jovian Mercury]; the next innermost *Venerem* [Venus]; the next to outermost *Iovem* [Jupiter]; the outermost *Saturnum* [Saturn]. So Father Io. Bapt. Hodierna recently in his *Medicaeorum Ephemerides* [*Ephemerides of the Medicean stars*]; (1) by Victoria, [who] names them after the prince of Etruria *Principersium* [?]; (2) by the Victory, [from] the wife of the Grand Duke *Vxersium* [?]; (3) by Cosmo *Cosmiferum* [?]; (4) by Ferdinand *Fernandersium* [?]. Finally, by Vuendelinus [Govaert Wendelen] in a letter to me of the year 1647; and by Hevelius in his *Selenographia*, page 45; and by Gassendus, page 45; and by Phocyllides Oluvarda [Johannes Phocylides Holwarda]; and by us, together with Father Grimaldi, never more than 4 [satellites] have we observed.

5. But Father Antonius Maria de Rheita [Anton Maria Schyrleus de Rheita], besides the four interior side-stars of Jupiter, thought he saw others — more remote, and larger, and not visible except with a larger telescope — which he called *Urbanoctaviana* [the Urban-the-Eighth stars]; this in the year 1642, on December 29. Indeed before him Franciscus Fontana, in his treatise 6, observation 1, chapter 2, in the year 1630, saw Jupiter with 5 little stars, not more than 10 [units] distant from it. He saw 6 Jovial diameters; and in the years 1636 and 1643, he saw Jupiter with 8 stars; and

in the year 1645, on December 21 and 31, he saw it with seven, as also in the year 1645. On January 1, on January 22 and 28, he saw it with 6 stars — these not maintaining the same distance among themselves — which had to be extended for seeing them; since, in order to see the fixed [stars] perfectly, it is necessary to contract the tube. [Margin: *Fontana observans.* — Fontana observing.]

6. But Father Io. Bapt. Zuppus, at my request, observed stars around Jupiter [reckoned] as the boundary [of the field of view] in the year 1644, the matter having been made known by letters; in January and February, in records drawn up at Naples, he writes that he saw 6 little stars around Jupiter on January 21 and 22; on January [days], which he reckoned to be in [the line of] Jupiter; and on the 23rd, having explored it for himself, he found that not only 6 satellites wander around Jupiter, but somehow 9, somehow 11 or 12 — among which he supposed eight to be probably errant, partly because they did not scintillate, partly because, by a change of the telescope, they acquired distance; but he asserts nothing concerning the change of distance among them, such as Father Rheita nonetheless asserts — adding that the stars are generated anew, and afterward grow faint; which is the opinion of Io. Caramuel [Juan Caramuel] and Io. Stampioen [Jan Stampioen]. [Margin: *Caramuelis, & Stampion.* — Caramuel and Stampioen.]
7. For the rest, besides the companions [satellites] of Jupiter, the remaining [points] seen by Rheita were fixed stars, [as Gassendus reckons], in the constellation Aquarius — Gassendus reckons [it] in his *Iudicium de 9 Stellis*, since in the year 1642, on December 29, he did not see them change their distance from one another, and for other arguments, which he adduces in *Almagestum Novum* [recte: *Opus Astronomicum* — see note], Book 1, chapter 3. But Lord D. Vincentius Reinerus, the Pisan mathematician, persistently [maintained] to me that they had never seemed to him, in his whole decade of observations of his own ever-more-frequent ones, [to be] more than 4 around the four wandering little stars. Hevelius likewise in his *Selenographia*, page 45, affirms that from the year 1642 to 1645, he most diligently caught sight of these [satellites], and detected — besides the 4 planets [satellites] — that the remaining stars seen by Rheita were of the same [nature] as those of Aquarius [≈], but not [satellites] of the [planetary] order, nor [seen] with the naked eye visible; and (page 65) [maintained] still more strongly against Caramuel and against Rheita; against the Rheitan [view], on this account, and others, Io. Phocyllides

Oluvarda [Johannes Phocylides Holwarda] is too bitterly inveighed against [?]. [Margins: *Gassend. opinio.* / & *Reineri.* — The opinion of Gassendi, and of Renieri. — *Et Hevelij.* — And of Hevelius. — *Ex 10. Phocyllide.* — From Io. Phocyllides.]

[Margin, foot: Situs,]

Situs, & Motus Satellitum Iovis.

[The Position and Motion of Jupiter's Satellites.]

8. Since on individual clear nights the motions of the satellites vary around Jupiter — their intervals, if [taken] from others, and the constancy [of these from] our observations — if we wished to transcribe them in that form (as Galileo did in his Letter to Welser, and Hevelius in his *Selenographia*, page 526), we would fill very many pages indeed, with no hope of gathering fruit from the reader's weariness. Yet it is worthwhile to see a specimen of them — both in the aforementioned [authors], and in Scheiner in his *Disquisitiones*, number 39; and likewise in the case of Simon Marius, who also constructed *Ephemerides* of these motions; as also recently Io. Bapt. Hodierna; and (most diligently and most refined, both from these [sources] and from the Rheitan letter to me, and from Vuendelinus in *Epicur.* page 904, and from Gassendus on page 45, *Almagestum Novum*, Book 7, section 1, chapter 3); and finally from Lord Vincentius Reinerus, [whose] observations of ours I have gathered into the compendium of the propositions written below, [as the thing] more worthy of knowledge.

[Margin: *Propositio.* — Proposition.]

1. They move in circles, [these] 4 satellites: above Jupiter they indeed decline toward the south from the ecliptic; below, toward the north — whence it comes about that their latitude is southerly in the upper part, and northerly in the lower; this Gassendus limits, [saying] "if Jupiter is in the north, the latitude is southerly."
2. The latitude of the first, that is the innermost, is greater than [that] of the second; and [that] of this [second] greater than [that] of the third; and [that] of the third greater than [that] of the fourth, that is the outermost.
3. They move in the upper part of their orbit directly, that is, according to the sequence of the signs, from west to east; but in the lower part they move retrograde, from east to west.

4. They move in [quadrature, $\square$], and with their greatest digressions [elongations] from Jupiter [they move] most slowly, but at conjunction [ϕ] most swiftly.
5. In the upper part, when they decline toward the south, although they may be more remote from the centre of Jupiter, they nevertheless appear higher with respect to the horizon; but in the lower part they have the contrary.
6. They appear larger [as they move] from the upper [point] toward conjunction [ϕ] with Jupiter, [that is] tending to the lower [point]; but tending from this [lower point] toward the upper, they appear smaller.
7. When Jupiter is in the ecliptic, they more frequently and more readily eclipse one another, and are eclipsed by Jupiter's shadow; and such eclipses are visible to us. At other times, indeed, some of their eclipses are hidden from us, on account of the differing latitude of Jupiter and the inclination [of their orbits] to Jupiter's shadow-cone. But concerning the alternation of these eclipses, and their causes, see more fully Galileo, *On the Spots of the Sun* [*Istoria ... delle macchie solari*], page 162; Hevelius, page 46 of the *Selenographia*; and Hodierna in Part 2 of his *Ephemerides Medicaeorum*, chapter 7.
8. Their periods, and their motion from conjunction to conjunction [from ϕ to ϕ] with Jupiter, are better computed than from the other aspects. Scheiner gives other rules in his *Disquisitiones*, number 42. For the rest, see in the little tables written below.

IV	Vuendelino	16	$75\frac{6}{1000}$		

After the table: Hence Vuendelinus concludes that, just as in the case of the major planets their mean distances from the Sun are to one another in the sesquialterate ratio [3/2 power] of their periodic times, so too the distances of the little Jovian [satellites] from Jupiter are in the sesquialterate ratio of their own periodic times.

Motus Diurnus, & Horarius in sua cuiusq; orbita, divisa in Grad. 360.

[The Diurnal and Hourly Motion, each in its own orbit, divided into 360 degrees.]

After the tables: Many other tables and canons, with their roots [radices] for compiling Ephemerides and predicting eclipses of these satellites, are found in Simon Marius and Io. Bapt. Hodierna; selections from which, in their proper places, we shall give after the Tables of the Second Motions [*Tabulas secundorum Mobilium*], if it shall so please God, the Best and Greatest.

CAPVT XI.

On the Figure of Mars [De Martis Figura].

1. Near quadrature [□] with the Sun, Mars is seen almost dichotomized [half-lit], says Kepler [Johannes Kepler] (*Epitome of Astronomy* [*Epitome Astronomiae*], p. 843); but between quadrature [□] and opposition [⊙] with the Sun it appears gibbous, and only rarely round when in perfect opposition, as Rheita [Anton Maria Schyrleus de Rheita] affirms (book 4, ch. 5). Hevelius [Johannes Hevelius] in his *Selenographia* (p. 42) shows a sketch of Mars as he himself saw it gibbous,

and on p. 67 denies that it can be seen with little horns [crescent-shaped]; but he says he saw it dichotomized in the year 1645, on the 28th of March. Francesco Fontana [Francesco Fontana], in his *Observations* (tract 6, ch. 1), shows a round figure of Mars in the year 1636, with a spot in the middle that is black — which he judges to be a hollow rather than a shadow [umbo]. But he shows Mars gibbous with a spot, likewise in the middle, in the year 1638. On the 24th of August, Fr. Nicolas Zucchi [Niccolò Zucchi], in the year 1640, on the 23rd of May, saw Mars between trine [$\triangle$] and quadrature [$\square$] with the Sun gibbous, but without a spot — perhaps on account of the motion of its rotation, or of a libration about its own body's center. Fr. Daniel Bartoli [Daniele Bartoli] wrote to me at Naples in the year 1644, on the 24th of December, that with Fr. [Giuseppe] Sersale's excellent telescope Mars had been seen by him almost round, with two spots below the middle.

2. Finally, we ourselves, together with Fr. [Francesco Maria] Grimaldi, in the year 1651, on the 4th, 5th, and 6th of April, saw Mars with a black spot as if formed from many small ones; likewise on the 18th of April and the 29th of May. And again, repeatedly, in the year 1653 through the whole of July, and in the year 1655 on the 22nd of July and the 28th of August; and finally in the year 1657, on the 15th of September, on the 11th, 17th, and 21st of October, and on the 6th of November. Moreover, astronomers take their argument for the dichotomy and gibbosity from the light received from the Sun in the same way [as for the Moon]: as if Mars were the Moon, and as if — were it permitted to see Mars near opposition [$\odot$] with the Sun — we would see it crescent-shaped.

CAPVT XII.

On the Figure of Venus [De Figura Veneris].

1. That Venus moves around the Sun, and receiving its light from it appears now nearly full like the full Moon [$\odot$], now nearly gibbous toward superior conjunction [$\odot$], now gibbous, otherwise crescent — this is plain to any observer who watches her closely, both in the evening and in the morning, with a fine telescope; and it is plain from the observations of Galileo [Galileo Galilei], Scheiner [Christoph Scheiner], Fontana, and Rheita, and from Kepler in his *Epitome of Astronomy* (p. 762); from Rheita (book 4, ch. 5, member 2); from Gassendi [Pierre Gassendi] (*In Epicurum [Animadversiones in Epicurum]*, p. 859). The remaining instances, together with figures, we ourselves have also adduced from our own observation (book 7, *Almagestum Novum*, sect. 1, ch. 2), where also

concerning the spots seen by Fontana — but never by us, nor by Gassendi (book 3, *Institutio Astronomica*) — to which add nearly all of Hevelius in his *Selenographia* (from p. 68 to 74).

2. That Venus, moreover, is sometimes visible by day is established from the observations of Tycho [Tycho Brahe] and Longomontanus [Christen Sørensen Longomontanus], and from Hevelius above, who together with Galileo adds that she is better observed for a long time by day than by night, inasmuch as she is then stripped of adventitious rays. But we too, with Fr. Grimaldi, saw her with the naked eye in the year 1649: on the 1st of April nearly gibbous, and on the 20th dichotomized; on the 1st of May now crescent; on the 1st of September again crescent, as also on the 4th of September up to 2 hours after midday; and so on up to the 8th she was seen crescent from sunrise until midday and beyond; but on the 18th she was exactly dichotomized; and on the 26th more than dichotomized, up to 9 hours after midday — always with the naked eye. And in the year 1651, on the 5th of February, the horns of the crescent met beyond her diameter, and on the 12th the line drawn through the horns was parallel to the ecliptic. But the rarest and most remarkable phenomenon of Venus is

Diagram. A large engraved crescent of Venus occupies the right column, illustrating the "rarest and most remarkable phenomenon" of the planet — the thin crescent whose horns reach beyond its diameter, as great in apparent size as the crescent Moon seen with the naked eye. The crescent's cusps embrace the lower part of the figure; the convex limb faces upward and to the right. Two labels and two planet-symbols mark the figure:

- Top: **Occidens** ("West")
- Upper symbol: ♀ (Venus)
- Lower symbol: ♀ (Venus)
- Bottom: **Occidens** ("West")

[when she has great latitude near her inferior conjunction [♄] with the Sun, for with a powerful telescope she appears crescent, of such magnitude as the crescent Moon to the naked eye; as we saw her, and represented her, in book 7 of the *Almagestum Novum*, sect. 1, ch. 2, num. 4, as here below.]

CAPVT XIII.

On the Figure of Mercury [De Mercurij Figura].

As many witnesses as we adduced in the preceding chapter stand likewise for Mercury's motion around the Sun, and for its light received from the Sun: for if it is observed with a very powerful telescope, around its greatest elongations from the Sun it appears nearly dichotomized; but when retrograde,

it approaches conjunction [♂] with the Sun, or stretches from there toward its second station, it appears like the Moon when it stands about 60 degrees from the Sun, and as if crescent. Hevelius (*Selenographia*, p. 74) says that in the year 1644 he observed Mercury in the morning of the 22nd of November at 10 digits [of its diameter] illuminated, its whole diameter being 12 digits, and on the 30th of November at 8 digits, and on the 2nd of December at $5\frac{1}{2}$ digits — and now crescent, as in figure II of the following Figures. But in the year 1645, on the 16th of May in the evening, he saw Mercury illuminated at $5\frac{1}{2}$ digits, as in figure I; and on the 20th of May dichotomized, at about 6 digits; and on the 30th nearly gibbous, as in figure III. But earlier, in the year 1639, Fr. Giovanni Battista Zupi [Giovanni Battista Zupi / Zuppus] at Naples saw Mercury crescent with Fontana's tube, and illuminated at $5\frac{1}{3}$ digits in the evening, nearly as in figure I; in which manner he saw the same in the year 1646, on the 26th of January in the evening.

2. We ourselves, together with Fr. Francesco Maria Grimaldi, in the year 1643, on the 5th of March, saw Mercury in the still-superior part of its epicycle as evening-star, and not yet elongated beyond 15 degrees from the Sun, gibbous, as in figure III; and likewise in the year 1656, on the 16th of December. But in the year 1643, on the 25th of August, we saw it as morning-star and elongated 19 degrees from the Sun, crescent, as in figure II; in the same way as in the year 1644, on the 6th of August, distant 20 degrees from the Sun. But in the year 1647, on the 30th of April, we saw Mercury as evening-star, distant, and $20\frac{1}{2}$ degrees from the Sun, as in figure I; and in the year 1650 likewise as evening-star and distant, about 18 degrees from the Sun, crescent, as in figure I.

Diagram. A vertical column of four engraved disks of Mercury showing its telescopic phases on the dated occasions described, each disk marked with the Mercury symbol (♿) and a phase-label, and several captioned with the observation dates. From top to bottom:

- First disk (gibbous), labelled **Vespertinus** ("Evening-star"); symbol ♿

- Date caption beneath the first disk: **1639 Maij 23. 1646 Ian. 26. 1647 April. 30.** ("1639, 23 May; 1646, 26 January; 1647, 30 April")
- Second disk (crescent/dichotomized), labelled **Matutinus** ("Morning-star"); symbol ☿
- Date caption beneath the second disk: **1643 Aug. 25. 1644 Aug. 6.** ("1643, 25 August; 1644, 6 August")
- Third disk (crescent), labelled **Vespertinus** ("Evening-star"); symbol ♀
- Date caption beneath the third disk: **1643 Martij 5.** ("1643, 5 March")

The figure is set over a decorative IHS sunburst woodcut device (see below). [The figure labels read Figure I / II / III in the prose; here the disks are grouped by phase and observation date.]

CAPVT XIV.

On the Rotation of the Planets about Their Own Center [De Vertigine Planetarum circa suum centrum].

This rotation has been asserted by Wacker [Johann Matthäus Wacker von Wackenfels] (cited in Kepler's *Dissertatio cum Nuncio Sidereo*); by Kepler in the same place, and in his *Epitome of Astronomy* (p. 549); and by Huygens [Christiaan Huygens] in his *Systema Saturnium*; and it seems probable from the varying position of the belts and spots, concerning which see above under Saturn [♄], Jupiter [♃], Mars [♂], and Venus [♀] — although these phenomena could perhaps be attributed to a libration. Moreover, Fr. Anton Maria de Rheita affirms that the rotation of these bodies has been observed by himself, from their setting to their rising, and its period; and he promises observations of it in a new work to be published.

If rotation is chosen, this advantage emerges: that all the parts of the surface are illuminated by the Sun in succession — which the Moon does not have. Concerning the rotation of the Sun about its own center, within 27, 28, or 29 days, it has been asserted by Scheiner, Galileo, and Bullialdus [Ismaël Boulliau] on account of the apparent motion of the spots, or by the daily and annual rotation according to Kepler, or as is to be seen by Rheita, in those things which we discussed in book 3 of the *Almagestum Novum* (ch. 4), and in book 9 (sect. 4, ch. 12): for they are so many that they cannot here be reduced to a compendium without the loss of much learning.

CAPVT XV.

On the Distances of the Planets from the Earth, and from the Sun, and on the Distances of the Fixed Stars [De Planetarum Distantijs à Terra, & à Sole, vbi & de Fixarum].

In the *Prolegomena* of this volume, Article 4, I taught that the distance of the Sun from the Earth is neither greater than 30,000 terrestrial semidiameters, nor less than 6,430. Within these limits I proposed two other probable hypotheses: one that of Wendelin [Govaert Wendelen], which was nearly that of Posidonius [Posidonius]; and another, afterward, that of Christiaan Huygens; and a third, our own, twofold, which I delivered in book 1 (ch. 13, 14, and 17). But in book 3 (ch. 9) I treated the lunar distances, and in book 5, 6, 7, 8, 9 the maximum and minimum distances of the five lesser planets from the Sun, in parts of the kind in which the Radius of the Annual Orbit of the Sun is 100,000, according to a certain species [reckoning] of the parts in Volume 2, Table 97. We will add their distances from the Sun at every value of the Anomaly, or at intervals of five degrees each, together with their maximum and minimum distance from the Earth.

But in this place we set out only the maximum and minimum distances, not solely in parts of the Radius of the Annual Orbit of the Sun, but also in semidiameters of the Earth; and indeed according to the four Hypotheses of the Sun's distance from the Earth indicated above — the others being rejected, both those above and those framed within the aforesaid limits, or fictitious, as plainly false, as we have shown in their place. We will always suppose the distances of the planets from the Sun according to our own Hypothesis; but when those distances are to be combined with the Sun's distances from the Earth, we will take the latter from the four Hypotheses named. For example, when we say that the maximum distance of Mercury from the Earth, according to Wendelin, is 21,754 terrestrial semidiameters — it is to be understood that this is taken and compounded from two elements: one indeed from Wendelin, which is the radius of the Sun's annual orbit, namely 14,656 terrestrial semidiameters; the other, which is for us the maximum distance of Mercury from the Earth, which is 148,430 in the parts in which the Radius of the Annual Orbit is 100,000. For 148,430 multiplied by 14,656 and the sum divided by 100,000 yields 1,754 [recte: 21,754] semidiameters of the Earth; and so of the rest.

Distances of the Planets, and of the Fixed Stars, from the Earth and from the Sun [Distantia Planetarum, & Fixarum à Terra, & à Sole].

Table 1 — In parts of the kind in which the Radius of the Annual Orbit of the Sun is 100,000 [In partibus Qualium Radius Orbis Annui Solis est 100000]

Distances of the Planets from the Earth, according to Our Hypothesis [Distantia Planetarū à Terra. Ex Nostra Hypothefi]

Planet	Minima	Media	Maxima
☉ Solis (Sun)	98260	100000	101740
☿ Merc. (Mercury)	67780		148430
♀ Veneris (Venus)	26656		174713
♂ Martis (Mars)	36534		268164
♃ Iouis (Jupiter)	395413		649629
♄ Saturni (Saturn)	797363		1111033

Distances of the Planets from the Sun [Distantia Planetarū à Sole.]

Planet	Minima	Media	Maxima

vel Infima	52263	62529	72795

Hic modus Errorum est; hi certi denique fines, Quos vltra citraq; nequit consistere verum.

[This is the measure of the errors; these, at last, are the fixed limits, beyond and short of which the truth cannot stand. (A closing couplet.)]

Laus Deo, Beatissimæq; Virgini.

[Praise to God, and to the most Blessed Virgin.]

ASTRONOMIAE REFORMATAE TOMUS II

ASTRONOMIAE REFORMATAE TOMUS II.

The Reform of Astronomy, Volume II.

Of which the First Part contains the **Precepts for the Use of the Tables**

[Praecepta pro usu Tabularum], and the Latter Part the Astronomical Tables themselves — the 102 New-Almagest Tables [Tabulae Novalmagesticae].

By the author **Fr. Giovanni Battista Riccioli** [P. Ioanne Baptista Ricciolo], of the Society of Jesus, of Ferrara [Ferrariensi].

BOLOGNA [BONONIAE], 1665 [MDCLXV].

From the Printing House of the Heir of Vittorio Benacci [Ex Typographia Haeredis Victorij Benatij].

By permission of the superiors [Superiorum permissu].

INDEX OF PRECEPTS WHICH ARE SET FORTH IN THIS VOLUME

INDEX PRAECEPTORUM Quae in hoc Volumine traduntur

Part I: Pertaining to Time [I. Pars ad Tempus pertinens]

Precept no.	Description	Page
1	To apply the divisions of Time, or of a Circle, to an <i>as</i> [a unit-whole], and to express their value.	1
2	To find the quantity of Hours, Degrees, or of a Circle, resolved into sixtieths down to the tenth [sexagesimal place].	1
3	To convert equal Hours, and their sixtieths, into sixtieths of a Day.	1
4	To convert sixtieths of a Day into equal Hours and their sixtieths.	1
5	To resolve the Days of the Julian Months into Days collected from the beginning of the Common Year and of the Bissextile [leap year].	1
6	For the collected Days of the Julian Year, to assign each its Month, and the day of the Month.	1
7	To reduce the Days of the Egyptian Months into Days collected from the Beginning of the Year.	1
8	For the collected Days of the Egyptian Year, to assign each	1

Precept no.	Description	Page
	its Egyptian Month, and the day of the Month.	
9	Given a Day of the Month in a Julian Year on which an Egyptian Year began, to find which day of the Julian Month coincides with any other given day of the Egyptian Month.	2
10	To convert the parts of the Equator into Hours and sixtieths, both of the <i>primum mobile</i> and of the Solar [day].	2
11	To convert Hours, and their sixtieths, whether of the <i>primum mobile</i> or of the Solar [day], into parts of the Equator.	2
12	To change Equal Hours of one kind into hours of a different kind, that is, numbered from a different beginning of the day.	2
13	To convert Temporal [seasonal] Hours into equal hours.	3
14	To find the semidiurnal and seminocturnal quantity by two principal methods, setting Refractions aside.	3
15	To determine the longest Day of the Year in the frigid Zones, setting Refractions aside.	3
16	To change Apparent Time into Mean [Time], or [Mean] into Apparent, and this reciprocally, by means of Tables both perpetual and Temporary.	[see right column header / p. 3]

Precept no.	Description	Page
	Of the Equation of Natural, or Civil, Days [Aequationis Dierum Naturalium, seu Civilium].	3
17	To transfer Time given under the Meridian of Bologna [Bononiensi] to other places on the Earth, or from those places to the Meridian of Bologna; and for each [task], to learn the Pole- Altitude [latitude] of such Places.	4
18	To distinguish Bissextile [leap] years from non- Bissextile in the form of the Julian Year, reckoning backward before the Epoch of Christ, and after.	4
19	The same, to distinguish them in [reckoning] the Years of Christ, but in the form of the Gregorian Year, and [to find] the excess of Gregorian days over the Julian.	4
20	To find the Cycle of the Sun before and after Christ.	5
21	To find the weekday [feria] of a given day in a Julian Year.	5
22	To find the weekday in an Arabic Year of the Hegira, by means of the Arabic Cycle.	5
23	To learn the collected Days of the Years and Months of the various nations, and the concurrence of those same Months.	6
24	To convert Years before or after the Epoch of Christ into Years of the Julian Period.	6
25	To turn the Years of the Julian Period into Years before or after the Epoch of Christ.	6
26	To convert the years of the Epoch of the World, according to the opinion of the Greek Fathers of Constantinople, into Years before or after the Epoch of Christ.	6
27	To convert Years before or after the Epoch of Christ into the Years of the aforesaid Epoch of	6

Precept no.	Description	Page
	the World.	
28	To convert the Years of the Olympiads into Years before or after the Epoch of Christ.	6
29	To convert Years before or after the Epoch of Christ into Years of the Olympiads.	6
30	To convert the Years of the founding of the City of Rome into Years before or after the Epoch of Christ.	7
31	To convert Years before or after the Epoch of Christ into Years of the founding of the City.	7
32	To reduce the Years of Nabonassar into Years.	7

[This opening continues the *Index Praeceptorum* — the index of precepts for the use of the tables — begun earlier in Tomus II. The index is laid out across the page in two side-by-side blocks, each a four-field table: precept number (*Praec. ordo.* / *Ordo Praec.*), the precept's title, and the page (*Pag.*) on which it is found. The precepts are transcribed below as native tables, in reading order: first the left block of each page, then the right block.]

Index of Precepts (continued)

Precepts on Time (continued)

No.	Precept	Page
—	...before or after the Epoch of Christ.	7
33	To find the beginning of the Year of Nabonassar together with the corresponding Julian Year, month, and day.	7
34	To know with which day of a Julian month any given day of an Egyptian month coincides, in years before or after Christ.	7
35	To reduce years before or after Christ into Years of Nabonassar.	7
36	To assign, for a given day of a Julian Year before or after Christ, the day in the Egyptian Year of Nabonassar that corresponds to it.	8
37	To convert the Years of Alexander the Great, or also the Dhylkarnaym [Dhū l-Qarnayn] Years, into years before or after Christ, and vice versa.	8

No.	Precept	Page
38	To turn the Years of Alexander the Great into Years of Nabonassar, and these in turn back into the former.	8
39	To convert Arabic Years, months, and days into Years of Christ, and the months and days of these, and the reverse.	9
40	Years of Christ not exceeding 622, to convert into Years of the Hegira and the days thereof, into days, etc.	9
41	To change Persian Years of Yazdegerd, and the days thereof, into Years of Christ.	9
42	To convert Years of Christ, and the days thereof, into Years and days of Yazdegerd.	10
—	<i>A note concerning the remaining Epochs.</i>	—
43	Finally, to accommodate time to the use of the Astronomical Tables of this Volume.	10

Precepts for the Tables of Part II [Praecepta pro Tabulis II. Partis]

No.	Precept	Page
44	To inquire the Declination of the Sun, or of a given point of the Ecliptic.	11
45	To find any angles whatsoever of the Ecliptic and Meridian, or of the Circle of Declination of any point.	11
46	To seek the Right Ascension of the Sun, or of a given point of the Ecliptic.	11
47	Given the Altitude of the Pole and the Declination of any star, or of a point in the Ecliptic, or its extra-ecliptic [oblique] Declination, to find the Ascensional Difference.	11
48	Given the Right Ascension of any star or celestial point, and the Ascensional Difference, to form its Oblique Ascension.	11
49	Given the Altitude of the Pole, to find the Oblique Ascension of a point of the Ecliptic, or of the Sun positioned in it, by means of the Table of Oblique Ascensions.	11
50	Given the Apparent Time after Midday, and the place of the Sun, and the altitude of the Pole, to investigate the Horoscope, or [Ascendant Degree of the Ecliptic, and at the same time the Ninetieth (point) numbered from the Ascendant].	11

No.	Precept	Page
51	Given the Ascendant point of the Ecliptic, under a given Altitude of the Pole, to find the angle of the Ecliptic and Horizon, or the Altitude of the Ninetieth (point).	12
52	To resolve a Sign of the Zodiac, or any degrees of any Circle, into degrees collected from the beginning of the circle.	12
53	(Given) the diametrically opposite degrees of the Zodiac, and given the Ascendant, to find the Descendant at once.	12
54	Given the latitude of any star not exceeding 9 degrees, and its longitude, to find, by means of a Table made for that purpose, its Declination and Right Ascension.	12

Precepts for the Tables of Part III [Praecepta pro Tabulis Parte III.]

No.	Precept	Page
55	For a given time, to find the true place of the Sun in the Ecliptic at the Epoch of Christ, and its Equated Anomaly.	12
56	To find the place of the Sun for a given time before the Epoch of Christ, and its Equated Anomaly.	13
57	To find the Parallax of the Sun in the circle of Altitude.	13
58	To investigate the Distance of the Sun, and also of the Moon, from the center of the Earth — but in conjunctions [copulis] — together with the Horizontal Parallax and the Hourly motion of each Luminary.	13
59	To determine the apparent Semidiameters of the Sun, and also of the Moon, in conjunctions, and of the terrestrial Shadow.	14
60	To obtain the Refraction of the Sun, Moon, and Fixed stars, and to discern their True, Apparent, and Seen Altitude.	14
61	For a given time before or after the Epoch of Christ, to find the True place of the Moon in its proper Orbit, together with the Anomaly on the day of New Moon or Full Moon.	14
62	To find the true place of the Northern Node of the Moon, and the maximum Latitude of the Moon.	14
63	To obtain the True Latitude of the Moon, and its Argument, or motion of Latitude.	15
64	To reduce the place of the Moon from the Orbit to the	15

No.	Precept	Page
	Ecliptic.	
65	To determine the True place of the Moon outside conjunctions.	15
66	To inquire the Hourly motion of the Moon from the Sun on the days of Full Moon and New Moon.	16
67	To ascertain the Verification of the New Moon and Full Moon.	16
68	(To find) the Intervals of the Moon and Earth, and the ec- [centricity outside the syzygies].	16

No.	Precept	Page
69	To inquire the Distance of the Moon from the Earth precisely [recte: "ad centrum" — to the center] outside conjunctions.	16
70	To acquire the apparent Semidiameter of the Moon, and also the Horizontal Parallax, outside the syzygies.	16
71	To investigate the Parallaxes of the Moon in the circle of the true, or seen, Altitude.	16
72	For a given Year and Month, to investigate the Mean New Moon, and the Mean Full Moon, by means of the Epacts.	16
73	Given the hour of the Mean Full Moon, from it to know the true Time.	17
74	To know beforehand whether a given New Moon or Full Moon was, or will be, Ecliptic [i.e. accompanied by an eclipse].	17
75	To inquire the Ecliptic Digits, or the quantity of the Lunar diameter to be obscured.	17
76	(To find) the Duration of the Lunar Eclipse, and its stay in darkness if it be total, and, with the delay, to define the Eclipse and its beginning and end, etc.	18
—	<i>A note for the more refined Calculation of Lunar Eclipses.</i>	—
77	To determine the True Latitude of the Moon at the beginning and end of the Eclipse.	18
78	To delineate the Type [diagram] of the Lunar eclipse.	19

No.	Precept	Page
79	To reduce the Equal Time of the Eclipse to the apparent (time).	19
80	To survey the regions of the world's globe in which the Eclipse will be visible, and in which it will not.	19
81	To find in which Meridian the Moon will be in the middle of the Eclipse, and for which (regions) it will then be vertical.	19

On Solar Eclipses [De Eclipsibus Solis]

No.	Precept	Page
82	The Order to be observed in the Calculation of a Solar Eclipse, to be known beforehand, with an example repeated here from those given above.	20
83	To find the Altitude of the Ninetieth (point) in the Orbit of the Moon.	20
84	To find the Horizontal Parallax of the Moon from the Sun.	21
85	To obtain the Parallax of the Moon in Longitude.	21
86	To obtain the Parallax of the Moon in Latitude.	21
87	To investigate the Parallax of the Moon's Longitude for one or another hour before or after the true New Moon.	22
88	To define the seen motion of the Moon for one or another hour.	22
89	To determine the Moment of the Apparent New Moon.	22
90	To investigate the Parallax of the Moon's longitude at the moment of the apparent New Moon for hours before or after.	22
91	(To find) the Latitude of the Moon at the time of the [apparent New Moon, both true and seen].	22

No.	Precept	Page
92	To find the Digits, or quantity, of the Solar Eclipse.	23
93	To determine the Beginning, End, and Duration of the Solar Eclipse.	23
94	To define the seen Latitude of the Moon at the beginning and end of the Solar Eclipse.	24

No.	Precept	Page
95	To delineate the Type [diagram] of the Solar Eclipse, with an Epilogue of the whole calculation up to this point.	24

On Horizontal Eclipses [De Eclipsibus Horizontalibus]

No.	Precept	Page
96	To discern the moment of time at which the Sun rises or sets.	25
97	(To find) the true places of the Luminaries at the moment of the Sun's Rising or Setting.	25
98	To define the Parallax of the Moon in longitude and latitude at the moment of the Sun's Rising or Setting.	25
99	To investigate the Distance of the centers of the Sun and Moon — apparent — at the hour of the Sun's Rising or Setting.	26
100	To inquire the Ecliptic Digits at the moment of the Rising or Setting of the Luminaries.	26
101	(To find) the Semidiameter of the Disc of the Earth visible from the Moon.	26
102	To find the Altitude of the Ninetieth (point) in that region for which the central Solar Eclipse will appear.	26
103	To inquire the Altitude of the Pole of the aforesaid Region.	26
104	To compute the Eclipses of the Southern Region [Plaga].	26
105	To determine the Ecliptic Digits of the central Solar Eclipse.	26
106	To find the Time during which the Lunar Shadow lingers above the Earth.	27
107	To find the Altitude of the Ninetieth (point) in those Regions where the beginning of the Solar Eclipse first appears, or where its end appears last.	27
108	To find the Altitude of the Pole in the aforesaid two Regions.	27
109	To determine the regions themselves, their Longitude having been found.	28
110	To find the Time from when the Solar Eclipse first becomes total at the rising Sun, up to mid-true and -seen central Synod [conjunction], and from there up to the moment at which the central Solar Eclipse occurs last at the setting Sun.	28

No.	Precept	Page
111	To find the Altitude of the Ninetieth (point) for the Regions of the Phases in the manner just stated.	28
112	To find the Altitude of the Pole for those same Regions.	29
113	To find the regions themselves, by means of the Longitude.	29
114	To find the Region in which, at the Ninetieth (point), [the central Synod is True and Seen].	29

No.	Precept	Page
115	To find the Regions of the Earth over which the Shadow of the Moon is carried, during the whole time of the Solar Eclipse.	30

Precepts for the use of Part V of the Tables [Praecepta pro usu V. Partis Tabularum]

No.	Precept	Page
116	To compute the place of Saturn according to longitude in the Orbit.	30
117	To compute the Longitude of Saturn.	30
118	To reduce the place of Saturn from the Orbit to the Ecliptic, and to complete its Curtation.	31
119	To compute the place of Jupiter according to longitude.	31
120	To compute the Latitude of Jupiter.	31
121	To reduce the place of Jupiter from the Orbit to the Ecliptic, and to complete its curtation.	31
122	To compute the place of Mars according to longitude.	32
123	To compute the Latitude of Mars.	32
124	To reduce the place of Mars from the Orbit to the Ecliptic, and to complete its curtation.	32
125	To compute the place of Venus according to longitude.	32
126	To compute the Latitude of Venus.	33
127	To reduce the place of Venus from the Orbit to the Eclip-[tic, and to complete its curtation].	33
128	To compute the place of Mercury according to longitude.	33

No.	Precept	Page
129	To compute the Latitude of Mercury.	33
130	To reduce the place of Mercury from the Orbit to the Ecliptic, and to complete its Curtation.	34
131	To extract the Declination and Right Ascension of the Planets from the Tables.	34
132	To find the Distance of the five Minor Planets from the Sun, in parts of which the Radius of the Annual Orbit is 100000.	34
133	To find the distance of the same from the Earth, in parts of the Radius of the Annual Orbit.	34
134	To find the Distance of the five Minor Planets from the Sun, or from the Earth, in Semidiameters of the Earth.	34
135	To find the Longitude and Latitude of the Fixed stars for any given time.	34
136	To inquire the Right Ascension and Declination of the principal Fixed stars for any given Time. With a notable note concerning the bright star on the shoulder of the Lesser Bear [Ursa Minor], and the other Fixed stars whose Right Ascension decreases as their Longitude increases.	35

INDEX OF THE ASTRONOMICAL TABLES Contained in This Volume

The index is laid out as a two-up table (Ordo Tab. = table number | title | Pag. = page), reading down the left side of each opening and then the right. The tables are grouped under five Parts; the group headings are reproduced as table-section rows below.

I. Part Concerning Time

Table	Title	Page
1	Parts of the as [assis] applied to days, hours, etc.	1
2	Resolution of an hour, a degree, and of a circle into thirds [scrupula], down to the tenth.	1
3	Conversion of hours, and of their thirds, into thirds of a day.	1

Table	Title	Page
4	Conversion of the thirds of a day into equal hours, and into thirds of hours.	1
5	Collection of the days of the Roman common year and of the bissextile [leap] year.	2
6	Collection of the days of the Egyptian year.	2
7	Conversion of hours both of the primum mobile and of the solar day into parts of the equator.	3
8	Conversion of parts of the equator into hours both of the primum mobile and of the solar day.	3
9	Conversion of hours into other hours reckoned from a different beginning of the day.	4
10	The quantity of one temporal [seasonal] hour, corresponding to the quantity of the artificial day [length of daylight].	4
11	The semidiurnal and seminocturnal time, from a pole-elevation of 6° up to 90° .	5
—	Appendix to Table 11, for the longest day, where the pole is elevated more than $66\frac{1}{4}^{\circ}$.	7
12	The equation of time [aequatio temporis] in Luna [the Moon], to Tycho's [Tycho Brahe's] reckoning, but here set out with our obliquity of the ecliptic, $23^{\circ} 30' 20''$.	8
—	The residues of the equation, equated from the Sun's anomaly.	8
13	A temporary table of the equation of civil, or natural, days, serving exactly for the year of Christ 1504 and again for the year 1736, but not without considerable error a century before or after.	8
14	A CATALOGUE of notable places, with the difference of time to be added or subtracted for the meridian of Bologna, with the pole-elevation appended.	9
15	The bissextile [leap] years before the common epoch of Christ.	14
16	The bissextile years of the common epoch of Christ in the form of the Julian year.	14
17	The common centesimal [centurial] years, or the	14

Table	Title	Page
	bissextiles, in the form of the Gregorian year, with the excess of days over the Julian from the year of Christ 1600 to 5200.	
18	A cyclic table of the Sun [solar cycle], from the first of the years 28, up to the year 4900.	14
19	A table of the Roman and Greek weekday feriae [the days of the week].	14
20	A table of the feriae [weekday] in the vague Arabic year of the Hegira, to be investigated by means of the Arabic cycle.	14
21	Collected years, with the collected days, and months, of various nations or sects, with their days likewise collected.	15
22	A SYNOPSIS of the notable epochs beginning a year before or after the common epoch of Christ, noted in the left margin, with a brief explanatory note on them.	16
23	The beginning, Thoth [the Egyptian first month], of the years of Nabonassar, noted as a year before or after the epoch of Christ, and by the day of the Julian or Gregorian month.	18

II. Part Drawn from the Primum Mobile

TABLES OF THE PRIMUM MOBILE, chiefly necessary for the secondary mobiles. To which, however, certain tables of Part I also pertain that bear on the primum mobile.

Table	Title	Page
24	The zodiac, and any circle, resolved into degrees collected.	19
25	The degrees of the zodiac diametrically opposite.	19
26	The declination of the Sun, and of the degrees of the ecliptic, for a truer obliquity of 23° 30' 20".	19
27	The eastern angle of the ecliptic and of the meridian, from which the remaining three are known.	19
28	The right ascension of the Sun, and of the degrees of the	20

Table	Title	Page
	ecliptic, for the aforesaid obliquity.	
29	The ascensional difference for all pole-elevations, of whatever celestial points the declination is known, but for an obliquity of $23^{\circ} 30'$.	21
30	The ascensional difference of the points of the ecliptic for an obliquity of $23^{\circ} 30' 20''$, and for the pole-altitude of Bologna.	24
31	The oblique ascension of the Sun, and of the points of the ecliptic, for the same obliquity, and for the pole-altitude of Bologna.	25
32	The oblique ascension for very many pole-altitudes, up to nearly the end of the quadrant, and for an obliquity of $23^{\circ} 30'$.	26
33	The altitude of the nonagesimal of the ecliptic, that is, the angle of the ecliptic and the horizon for all pole-elevations, up to 67° .	38
34	The prosthaphaeresis of declination, for stars having a latitude not greater than 9° .	43
35	The prosthaphaeresis of right ascension, for stars having a latitude not greater than 9° .	43

III. Part of Tables for the Motions of the Sun and Moon

Table	Title	Page
36	The equal, or mean, motions of the Sun.	44
37	The parallax of the Sun in the circle of altitude.	45
38	The equations of the Sun, both in the circular and in the elliptical form.	46
39	Of the luni-solar distances from the Earth, of the horizontal parallaxes, of the hourly motion, of the apparent semidiameters of the Sun, Moon, and shadow, in a lunar transit, with the Sun not at apogee, [and] the variation to be subtracted, [and] the axis of the shadow.	47
40	The refractions of the Sun, Moon, and fixed stars in a temperate zone, by the triple density of the air.	47
41	The equal, or mean, motion of the Moon, and of the node	48

Table	Title	Page
	☾ Ω.	
42	The equations of the Moon in conjunctions [syzygies].	50
43	The equation of the node Ω, and the maximum latitude of the Moon.	50
44	The latitude of the Moon.	51
45	The reduction of the Moon's true place from the orbit to the ecliptic.	52
46	A critical table of eclipses.	52
47	The final equation of the Moon, compounded from the evection of the center and the variation.	53
48	The hourly motion of the Moon from the Sun at the new moons and the full moons, and 12 hours before or after.	56
49	The verification of the luminaries at conjunction ☌ and opposition ☍.	56
50	The intervals of the Moon and of the Earth outside conjunction ☌ and opposition ☍.	57
51	The distance of the Moon from the center of the Earth in semidiameters of the Earth, outside conjunction ☌ and opposition ☍.	57
52	The apparent semidiameter of the Moon, and the horizontal parallax, outside conjunction ☌ and opposition ☍.	57
53	The parallaxes of the Moon in the circle of true altitude.	58

IV. Part of Tables for the Eclipses of the Sun and Moon

Table	Title	Page
54	Of the epacts, or of the mean new moons before the end of the year.	60
55	The limits of the eclipse.	60
56	The mecoplatic parallax [parallaxis mecoplatica], that is, in length and in breadth.	61
57	The digits of the eclipse.	66
58	The thirds [scrupula] of incidence in a solar eclipse, or the time of the half-duration in a lunar eclipse.	67

Table	Title	Page
59	The thirds of incidence, and of half-duration, in a lunar eclipse.	68
60	The distance of the centers of the two luminaries.	70
61	The parallaxes of the Moon in the circle of altitude, its distance from the Earth being given.	71

V. Part of Tables for the Longitude and Latitude of the Five Lesser Planets

Table	Title	Page
62	Of the mean motions of Saturn.	72
63	The first equation of the inequality of Saturn.	73
64	The equated anomaly of Saturn.	73
65	Of the maximum equations, or parallaxes [parallaxeon] of the annual orb of Saturn.	74
66	The proportional thirds of the latitude of Saturn. The remainder of this table.	75
67	Of the latitude, reduction, and curtation of Saturn.	76
68	Of the mean motions of Jupiter.	76
69	The first equation of the inequality of Jupiter.	77
70	The equated anomaly of Jupiter.	78
71	Of the maximum equations, or parallaxes of the annual orb of Jupiter.	78
72	The proportional thirds of the latitude of Jupiter.	79
73	The latitude, reduction, and curtation of Jupiter.	80
74	Of the mean motions of Mars.	81
75	The first equation of the inequality of Mars.	81
76	The equated anomaly of Mars.	82
77	Of the maximum equations, or parallaxes of the annual orb of Jupiter [printed <i>Iouis</i> ; recte Mars].	83
78	The proportional thirds of the latitude of Mars.	84
79	The decrements of the proportional thirds of the latitude of Mars.	84

Table	Title	Page
80	The latitude, reduction, and curtation of Mars.	84
81	Of the mean motions of Venus.	85
82	The first equation of the inequality of Venus.	86
83	The equated anomaly of Venus.	86
84	Of the maximum equations, or parallaxes of the annual orb of Venus.	87
85	The proportional thirds of the latitude of Venus.	88
86	The proportional thirds of the decrements of the latitude of Venus.	89
87	The latitude, reduction, and curtation of Venus.	89
88	Of the mean motions of Mercury.	90
89	The first equation of the inequality of Mercury.	91
90	The equated anomaly of Mercury.	91
91	Of the maximum equations, or parallaxes of the annual orb of Mercury.	92
92	The proportional thirds of the latitude of Mercury.	93
93	The decrements of the proportional thirds of the latitude of Mercury in retrograde conjunction.	94
94	The latitude, reduction, and curtation of Mercury.	94
95	The prosthaphaeresis of the orb of Saturn, Jupiter, Mars, Venus, and Mercury.	95 to 106
96	The general latitudes of the five planets.	107
97	The distances of the planets from the Sun, in parts of the radius of the annual orb, with an appendix of the extreme distances from the Earth.	108
98	A catalogue of the fixed stars for the year of Christ 1700, complete with longitude and latitude.	109
99	The right ascension and declination of the chief fixed stars, for the year 1700, with the centennial difference.	123
100	The motion of the longitude of the fixed stars in	125

Table	Title	Page
	expanded and collected years.	
101	The names of the foreign — and mostly Arabic — stars, corrected together with their interpretation.	125
102	The DISTANCE of the fixed stars is to be sought from the Great Table of Tome I, Book 4, Chapter 8, from page 219.	—

PRECEPTS For the Use of the Astronomical Tables Contained in This Volume

Precept 1. On the parts of the as [assis] applied to a circle and to time.

If anywhere in the Author some aliquot part of a circle, or of a degree, or of a day, or of an hour is expressed by way of the parts of the as, or of the libra [pound], Table 1 teaches its meaning and value. For example: a *dodrans* of a libra is worth 9 ounces; a *dodrans* of a circle is worth 270 degrees; a *dodrans* of a degree is worth 45'; a *dodrans* of a day is worth 18 hours; and so on.

Precept 2. On the resolution into thirds [scrupula].

In Table 2 you have an hour, a degree, or a circle resolved into thirds of thirds, the resolution carried out down to the tenth third. For example: if an hour is to be resolved into sixth thirds, you have it in the first part of Table 2 opposite the numerator [as] the sixth third, 46,656,000,000; and likewise for the rest.

Precept 3. To convert given hours, and the thirds of hours, into thirds of a day.

Since with some astronomers the day is divided not only into 24 hours but very often into 60 first thirds, and these into 60 seconds, and so on, therefore in Table 3 look up under their own headings the given hours, and their thirds, in the leftmost column; for opposite them, proceeding rightward, you will find under the headings at the top the thirds of a day matching the hours and the thirds of the hours. For example: let there be given 5 hours and 25 thirds of an equal hour. First, in the leftmost column you find 5 hours; and opposite them, under the first heading at the top — the one that answers to the hours — you find 12' of the first third of a day, and 30" of the second. Then, for the 25 thirds of the hour, under the second part of the top heading, which answers to the first thirds, or minutes, of

the hour, you find 1" of the first third of a day, 2" of the second, and 30''' of the third. So, by putting all together, 5 hours equals, together with 25', 13' 32" 30''' as thirds of one day.

Precept 4. To convert given thirds of a day into equal hours, hours, [and] thirds.

You will accomplish this by Table 4, by looking up everything under the appropriate top headings and putting together the numbers found. For example: let there be given 25 first thirds of a day, and 20 seconds. For opposite 25, in the leftmost column, you find — under the hours heading — 10 hours; and opposite 20", the seconds, under the second part of the top heading, 8 thirds. Therefore 25' and 20" of a day are worth 10 equal hours and 8 horary minutes.

Precept 5. To find which day [number] of any given Julian month a day is, counted from the beginning of the year.

In Table 5, the second column, if the year is common — but in the first, if it is bissextile [a leap year] — look up the number of the given day; and opposite it, to the right, under the month given, you find the number of days of the year. For example: let April 26 be given. In a common year [such as] 1650, for the number 26 noted in the second column under April answers the 116th day of the year. But if the year were bissextile, say 1652, then the 116th day in the first column would answer to the number sought, [yielding] 117 [days] under April.

Precept 6. Given the number of days of the Julian year, to find of which month, and which day of it, it is.

In Table 5 itself, seek the number of the days of the year, and in the head of that column you will see the month; and opposite the same number, in the column on the left — the second, if the year is common, but the first, if bissextile — you find the number of the day of the desired month. But note: if the number falls at the end of a column and again at the beginning of the following one, and the year is bissextile, that number must be used which is at the end of the column. For example: let it be a common year, 1650, and the 116th day of the year; this you will see in the 6th column under April, and opposite it in the second column the day 26. But if it were a bissextile year, say 1652, the number 116 in the first column would answer to the day 25 of April. Another example: let there be given, in a bissextile year, the 121st day; for you will see this number both at the end of the sixth column and at the beginning of the seventh; but, as you must, opposite the number under April, in the first column, it will answer to the 30th day of April.

Precept 7. To find which day of any month it is, when a given Egyptian day is to be reckoned from the beginning of the year.

The Egyptian year consists of 12 months, each of which is of 30 days; but, with the days reckoned absolutely, 360. To these are added, outside the ordinary reckoning, five days, which they call intercalary and in Greek ἐπαγόμεναι [Greek: epagomenai, "the added days," i.e. the epagomenal days], without any other quarter-day of intercalation. Therefore in Table 6, in the first leftmost column, seek the number of the given day; for, turning rightward under the named month, you will have the number of the days reckoned from the beginning of the year. Example 1: let there be given the 23rd day of the month Athyr; you find the 83rd day of the year. Example 2: let there be given the 3rd day of the intercalary days, or the epagomenae [epagomenal days]; for to day 3 of the first column there answers, in the last column under the title *Epagomenae*, day 363 of the year.

Precept 8. Given the number of days of the Egyptian year, to find of which month a day is, and which [day of it].

In the same Table 6, seek otherwise the given number of days of the year, for to it there answers, in the heading at the top, the month sought; and in the first column, [you find] the days of that month. For example: given the number of days 83 — because this is in the fourth column, [the month] congruent to it at the head is the month Athyr, and in the first column the day 23 of the same month.

Precept 9. Given the day of the Julian year on which an Egyptian year begins, to find out which days of the Egyptian year correspond to it, and the day of each Egyptian month.

Astronomers begin the first day of the month Thoth at noon. So, first, reduce the given Julian day on which the first day of Thoth begins by Precept 5 to a single day. Second, reduce the given day of the Egyptian month by Precept 7, the precept for the day of the Egyptian year, and to this number add the number of days of the Julian year. Then, from this sum, after subtracting unity (if it does not exceed 365 days for a common year, or 366 for a bissextile year), look in the sixth Table: for those numbers stand at the head of the Table for the Julian year's month, and directly across, in the first column, if the year is bissextile, or in the second, if it is common, you have the desired day of the Julian month.

First example. An Egyptian year began on 20 February of a common Julian year, that is, by Precept 5, day 51 of the Julian year, while by Precept 7 it is day 23 of the Egyptian month Athyr (the month which by example 1 of Precept 7 is day 83

of the Egyptian year). For when you add 51 and 83 together, the day of the month Mair [Mecheir] remains as 134, after subtracting unity. Now look in Table 6: 134 corresponds, at the head of the Table, to the month of May, and across, in column 2, to day 13 of May. Therefore that Egyptian year began on 13 May.

Second example. An Egyptian year began on 20 March, that is, by Precept 5, day 80 of that year; while the day of the Egyptian year, by Precept 7, was day 23 of the month Athyr, which is day 83 of the Egyptian year. By addition, since you add 80 and 83 together, the sum becomes 163. From this, subtracting unity, day huic autem in Tabula 6. co[rre]spondet Mensis Iunius, & sinistrorsum in prima columna, quia annus est Bissextilis, to day 10. And so that Egyptian year began on 10 June, at noon, of that same year. But if the sum of the days of both years exceeds 365 for a common year, or 366 for a bissextile year, then if that year was bissextile, the 366 are rejected, and you look for the remainder by Precept 6, to find the day and month of the Julian year, depending on whether the year that follows the one in which the Egyptian year began was common or bissextile.

Example. An Egyptian year began on 25 November of the bissextile year of the Julian Epoch 1084. This year is, by Precept 5, day 330; and the day given, by Precept 7, is day 83 of the Egyptian year [Athyr 23]. When you add 330 and 83 together, the sum of days becomes 413, exceeding the 366 days of the bissextile year by 47. From 47, taking away unity, the remainder 46 corresponds, by Precept 6 in Table 6, column 4, to that month of February; and across from it, in column 2 (since the following year, 1085, is common), you find that day 23 of Athyr begins on 15 February of the year of Christ 1085.

[Margin: Pag. 2.]

Precept 10. To convert parts of the Equator into hours of the Primum Mobile, and the scruples of those hours; and conversely, such hours into parts of the Equator.

For this precept Table 7 and 8 serve, and it is enough to inspect the headings at the front of those Tables, which agree with the degrees, or with the time given for them, and their scruples; for, under those headings, proceeding from right to left, you find the required number directly across, by one entry or by several entries, as the task requires.

Example 1. Let there be given 25 degrees of the Equator, 35 minutes, and 15 seconds. For first, in Table 8, the first column gives 25 of the head itself, and the third, under the topmost heading that corresponds to degrees, gives you hours 1

and 40'. Then, in column 4, are 35 minutes, to which, in the fifth and sixth, under the second heading of the front series, correspond minutes 2' and 20". Finally, in the first column are 15 seconds, to which, in the second and third, but under the lowest series of the front, corresponding to seconds, you have 1". The sum will therefore be gathered thus:

Of the Equator	Hours		'	"
Grad.	25	1	40	0
Minut.	35		2	20
Secund.	15			1
Summa		1	42'	21"

Example 2. Conversely, let there be given, of the Primum Mobile, hours 1·42'·21". From Table 7 you will gather the sum of the parts of the Equator in this way:

Of the Primum Mobile	Grad.		'	"
Hour	1	15	0	0
Min.	42	10	30	0
Sec.	21	0	5	15
Summa		25	35	15

[Margin: Pag. 3.]

Precept 11. To convert the time of the solar day into parts of the Equator, and conversely those into the time of the solar day.

The day which the Sun makes for us by its daily revolution is somewhat longer than the day which the Primum Mobile makes — or (what is the same thing by an imperceptible difference) than the day which any fixed star makes by its daily revolution — from the same meridian or horizon back to the same one; because in the meantime the Sun, by its mean motion, traverses about one degree on the Ecliptic toward the East, with the result that, before the Sun returns to the same meridian or horizon, the 360 degrees of the Equator, plus about one degree, must pass across. Therefore, if there be need to do this with precision, the hours of the solar day are to be converted into parts of the Equator by Table 7, or the parts of the Equator into hours of the solar day by Table 8, but with the Equation applied that is adjoined in those Tables for the hours and scruples of the solar day.

Example 1. For hours 1·35'·15" of the solar day there were found to correspond hours 1·42'·21" of the Primum Mobile; the correction, or Equation to be subtracted, is thus:

Of the Equator				
Gradus	2	16	0	
	5			
Minut.	3	1	0	
	5			
Sec.	1	0	59	
	5			
Summa	17	59		
Therefore by the said parts of the Equator there agree, of the solar day only			Hor. 1·42'·3"·1"	

Example 2. Of the same Precept 10, in which hours 1·42'·21" of the Primum Mobile agree with degrees 25·35'·15" of the Equator. The Equation for the hours of the solar day [is to be added]. The addition will be this:

Addenda haec erit						
Hour 1. of the solar day	2	28	0	0		
Minut.	42	1	44	0	0	
Sec.	21	0	0	0	52	
Summa add.	4	12	0	52		

Therefore for hours 1·42'·21" of the solar day there agree, of the Equator, Gr. 25·39'·27"·0"·52".

[Margin: Pag. 3.]

Precept 12. To convert equal hours of one kind, or denomination, into equal hours of a different kind, the quantity of the semidiurnal or seminocturnal arc being given.

Return to Table 9 and carry out everything as is prescribed in it.

[Margin: Pag. 4.]

Example. Let the semidiurnal time be of equal hours...

7 and 30', and let the day computed from noon be of astronomical hours 5·30'; and let that be converted into the Italian solar hour. For, subtracting from hours 23·60', the semidiurnal time leaves hours 16·30'; to which, if you add the hours 5·30', the Italian hour 22 turns out, but solar; for indeed civil clocks count the day by half-hours, and then would not strike except hour 21½.

Precept 13. Given the quantity of the artificial day, to convert temporal hours, and the scruples of those, into equal hours, and the scruples of these.

By an artificial day I mean the time of the Sun's stay above the horizon. Among the Hebrews once, and among the Romans, and among many nations, this was divided into 12 equal hours — equal indeed to one another within the same day, but by no means equal to the hours of other days; and so, resolving the time of any single hour into seconds, it amounts to 43200, as they used to do, using it instead of the divisor. Resolve then both the artificial day (of which I want the temporal hour) into seconds, by Precept 14, and the second scruples, and multiply the two by one another; the sum arising from this, divided by 43200, will give the second of the equal hours. From the sum of these seconds, gathered by repeated subtractions of 60, you collect the equal hours themselves.

Example. Let the artificial day be of hours 15·30'; this in seconds is 55800. And let the temporal hours be 4·20'; this, in its own seconds, is 15600; multiplying these by 55800, the sum becomes 870480000. This, divided by 43200, leaves seconds 20150'. And these, divided by 60, leave 335'; and the minutes, divided by 60, leave 335'; and again, divided by 60, leave the equal hours 5. Add 35', and besides the aforesaid 50', to which the temporal hours 4·20' are equivalent. By another method this precept is carried out by Table 10, in which a fixed quantity of the artificial day responds in the prior columns; for, in the latter part of that quantity which the artificial day responds to, lies the quantity of one temporal hour, however much that may be; and as many temporal hours as there shall have been, the sum of the equal hours will consist of that. And if some scruple cleaves to the temporal hours, the proportional part of that twelfth must be added. But this twelfth part must be added to the integral temporal hours, as set out above.

Example. Let the quantity of the artificial day be of equal hours, as in the first example, 15·30'; and let the temporal hours be 4·20'. First, in Table 10, in the fifth part of the Table whose front bears the letter E, and across, of the temporal hours

15·30', are given their twelfths, namely hours 1·17·30', which, multiplied four times, make hours 5·10'. The third part is taken — namely 25·50'; and added to hours 5·10' are made the equal hours 5·35'·50'', equivalent to the temporal hours 4·20'.

Precept 14. On finding the semidiurnal and seminocturnal time, the altitude of the Pole and the place of the Sun in the Ecliptic being given.

It is plain that, from the semidiurnal time, the hours being subtracted from 11·60', the seminocturnal is left; and the seminocturnal subtracted likewise from hours 11·60', you have the semidiurnal; and each doubled gives the diurnal, and so on. Furthermore, the semidiurnal or seminocturnal time is obtained most expeditiously by Table 11, and by two ways.

The first is by Table 11, on whose outermost left-hand columns are the signs of the Sun's place, to be numbered downward with their three degrees, while on the right are the signs to be numbered upward with their degrees; and directly across, under the altitude of the North Pole, the semidiurnal time is found if the Sun is in the northern signs, and the seminocturnal if in the southern. But where the Table is empty of a sign, the semidiurnal exceeds the hours 12.

Example. For an altitude of the Pole of 44 degrees, the Sun being in Taurus, degree 18. For finding 18 in the left column for Taurus, and from there proceeding to the right...

[Margin: Pag. 5.]

you find, under the Pole's altitude of 44, the semidiurnal time, hours 7·10'. This therefore is the semidiurnal time for the northern peoples, but the seminocturnal for the southern peoples.

But if the Sun were in degree 12 of Aquarius (who are noted in the right-hand margin), respond to it under the Pole's altitude of 44, hours 7·10' — which is the seminocturnal for the northern peoples, but the semidiurnal for the southern peoples.

II. Method.

Otherwise thus. The place of the Sun being given, look in Table 26 for its declination; this, in the margin, either added to or subtracted from the altitude of the Pole noted at the front of the Table, or by the foregoing Declination at the

front, and from the Pole's altitude in the left margin, look for the *Difference of Ascensions* [Differentiam Ascensionalem]. But this, with the degrees added — if the Sun is in northern signs, and likewise the conspicuous Pole is northern, or take away if it is in southern signs, and you will have the Arc of the Ascensional Difference; this is then to be converted by Precept 10 or 11 into hours, or the parts of the Primum Mobile, or solar.

Example. The Sun being, as above, in Taurus degree 18, its declination by our Table 26 is degree 17·14'·29"; with this, under the Pole's altitude of degree 44, is given the Ascensional Difference, degree 17·26'·10", which, added to the degrees 90, makes the Ascensional Arc, well known to us, of degree 107·26'·10". This in turn, in Table 7 by Precept 10, agrees most accurately with the hours of the Primum Mobile, 7·9'·44"·40".

[Margin: Pag. 19.] [Margin: Pag. 21.] [Margin: Pag. 26.] [Margin: Pag. 7.]

Precept 15. When recourse should be had to Table 11 in those areas where it stands empty of numbers.

In this case the day exceeds the hours 24; and then it scarcely befalls the astronomer that he needs the semidiurnal, or the nocturnal time, in the calculation of motions. Therefore I send the reader off to our problems of the Primum Mobile, or of our reformed Geography. If, however, you wish to know the longest day in the frozen Zones, consult the little Table at the end of Table 11, added at page 7.

[Margin: Pag. 7.]

Precept 16. To convert apparent time into mean, or equal, time, and conversely equal into apparent — and when one is needed from the other.

Our astronomical Tables of the mean motions have their Radices accommodated to the meridian, and indeed to the last day of December, on the assumption that the natural days are of equal hours 24, and lie between equals; and for example's sake we say that the Sun completes one revolution on the Ecliptic of degrees 0·59'·8"·20" — on two further days of degrees 1·58'·16"·40". But in reality the days are unequal, for two reasons. The prior reason is the obliquity of the Ecliptic; to the equal arcs of the Ecliptic respond unequal arcs of the Equator, which is the measure of time; the posterior reason is the eccentricity of the Sun, from which arises the Anomaly, or irregularity of the Sun's motion, which remains, even if

the Sun moved in the Ecliptic with equal motion. Hence it comes about that, if our astronomical Tables (in the rest, indeed, almost to be neglected) are to be predicted, or to be gathered for some past or future Phenomenon, so that the calculation, once carried out, may satisfy the apparent time — which is observable by us — then the equal time of the completed calculation must be converted into apparent. And conversely, when the apparent time is given (by which some observed Phenomenon was, or that thing to be examined), then it must be converted from astronomical Tables; and the given apparent time must be converted into equal. And each is called the Equation of the Natural, or Civil, Days.

This indeed is done by our two Tables, 12 and 13. The prior, indeed, is perpetual; and it is plain it is constructed from the prior cause, namely from the Obliquity of the Ecliptic, which is here put at degrees 23·30'·20". The latter is constructed from the equated Anomaly of the Sun, which we suppose to be founded there in the Sun's eccentricity. And so, in the upper part of little-Table 12, with the sign of the Sun at the front, and its degrees in the left margin, or with the sign at the foot, and degrees on the right margin, ascending,

[Margin: Pag. 8.]

you find, in the common meeting place of the Equation, the prior part to be added or subtracted to the given time, as the heading at the front indicates, or at the foot, in the latter part of little-Table 12 sought for the Anomaly of the Sun from the Ephemeris, or another sign at the front with degrees on the left, or at the foot, with the degrees on the right, and in the common meeting place is had, by another part of that same little-Table, the title given. From these two, indeed, composed, the absolute Equation of apparent time is aggregated, if they are of the same character; or it is subtracted, if they differ in character, and the lesser of the major leaves the Equation of that kind whose Equation is greater.

Example. Apparent time being after noon hours 5·20', which is to be converted into Equal, the Sun being in Taurus degree 16, and the Anomaly of the sign 9 completed, holding degree 8. First, then, in Table 12, the superior part, under the sign of Taurus, and across from degree 16 of the left margin, is given the Equation 9·55'·45"', [to be subtracted] from the given time. Then, under the inferior part, and across from the sign 9, ascending, but on the right from degree 3, is found, across, the Equation itself 4·3". And, as the title with sign 9 indicates, it is to be added. Since therefore they are of diverse character, if the subtractive 9·55'·45"' has the subtractive 4·3" taken from it, there remains absolute, and corrected, the

Equation $5^{\circ}52'45''$, to be subtracted from the given time, hours $5^{\circ}20'$; so that the Mean, or Equal, time is hours $5^{\circ}14'7''15'''$.

Otherwise by the temporary little-Table

If the Sun's Apogee were immovable, as Ptolemy thought, and had not migrated step by step into another sign, a single Table might be made from these two little-Tables, namely Table 12, of perpetual duration. But because the Sun's Apogee moves forward in other ages, and in other ages into another sign, or to other degrees of the same sign, one Table cannot satisfy all ages and centuries, but only one, or another. And so we have constructed two Tables, militating under Table 13. The upper Table, which was constructed exactly for the year of Christ 1504, when the Sun's Apogee, by my opinion, was in Cancer degree 6 (but it is wanting, by an error considered to serve the preceding century, and subsequently, that is, from the year 1404 to 1604). The lower indeed serves the error of the Apogee about Cancer degree 10; but this, without curable error, serves from the year 1636 to the year about 1836. Each one likewise serves nearly exactly to all the years between 1504 and 1736, comprehend, and likewise to each of the entries with the sign of the Sun at the front, and with the degree of the sign in the left margin sought; for in the common meeting place is had the absolute Equation to be added to the apparent time, or to be subtracted, as the heading at the front indicates; to which the contrary is to be done, if the equal time is to be converted into the apparent.

Example. Let it be the year of Christ 1650, the Sun being in Taurus degree 16, to convert the apparent time of hours $5^{\circ}20'$ into Equal. First, in the superior Table 13, in the part serving the year 1504, under Taurus, and across from degree 16, is found the Equation [to be subtracted] $6^{\circ}48''$. Then, in the inferior part, which serves the year 1736, under the same sign, and across from the same degree 16, is had the Equation to be subtracted $3^{\circ}5''$. Whence the Difference of the Equations is $3^{\circ}43''$; this is resolved into seconds $223''$, between the years 1504 and 1736; the total difference is of the years 232; but from the year 1504 to 1650 there are years 146. Say, then: if the years 232 decrease the seconds $223''$, by how much will the years 146 decrease? $146''$, that is, minutes $2'$; and seconds $26''$, which, subtracted from the prior Equation $6^{\circ}48''$, leave the Equation corrected $5^{\circ}31'''$; which, subtracted from the hours $5^{\circ}20'$, leaves the Equal time hours $5^{\circ}14'29''$; yet the prior method is more exact in the seconds scruples.

Precept 17. On equating time on account of the Distance of Meridians.

Since our astronomical observations were carried out by us under the meridian of the renowned City of Bologna — partly in the most august Temple of S. Petronius, partly, and for the most part, in our Observatory of the College of S. Lucia of the Society of Jesus — therefore, so that our Tables may serve the meridian of this Bologna meridian; but truly, so that the time of this meridian may be fitted to the meridians of other places, one ought to know the Distance of those places, or the Difference of Geographical Longitudes, whether they are Oriental or Occidental with respect to Bologna, Italian-fashion. To this end, in our Reformed Geography, Book 8, all things being sought everywhere, the Eclipses and Itineraries, we have most diligently investigated the Differences of Longitude of very many places, as from Observations of the major, and the intervals of places themselves; we have most diligently inquired the Altitudes of the Pole, that we might (as the ancients complained, and the new Astronomers and Geographers were not satisfied above this) make good, and so that we might expunge the innumerable errors from the Geographical and Hydrographical Charts, as far as God granting allowed. But in Book 9 we would set forth a Catalogue of the places of very many places, with the Longitude reckoned from the Island of Palma, and the Altitude of the Pole. Hence, therefore, you take the difference

[Margin: Pag. 9.]

of our Catalogue, for the Tables 14, to be reckoned from the places of this place, the time-difference of the Bologna meridian is had, or the *Addenda*, or the *Subtrahenda* to the time of the Bologna meridian; the contrary, however, is to be done, if at the same time the time is to be reckoned under other meridians, and the time agreeing with the Bologna meridian is to be reduced.

Example. Let the beginning of a future Lunar Eclipse be sought; let it be after the Bologna meridian, on the hour 10·20'. Sought, however, what the time then future may be in the hour, and the moment of the hour, at Goa in Eastern India, or Lima in Southern America? Now, in our Catalogue, the Difference of Time inscribed for Goa is hours 4·18'. *Addenda.* And the Difference of Time of Lima is hours 6·10'·40". *Subtrahenda.* Therefore the beginning of the Eclipse will be, after the Bologna meridian, the hour 14·38' at the hour of Goa, or 4·9'·20" at the hour of Lima. On the contrary, truly, if the beginning of this Eclipse had been supposed at the hour 10·20' of Goa or Lima, the Difference of Time inscribed for Goa would be

Subtrahenda; for Lima, however, it would be *Addenda*; and so, in the prior case, that time would be at Bologna after noon hour 6¼; in the latter case, after the hour 16·30'·40".

[Margin: Pag. 9.]

Precept 18. To find the Bissextile years, in the form of the Julian year, before and after the Epoch of Christ.

For the years before the Epoch of Christ, consult Table 15, in which the prior, or leftmost, column shows the years; or each century of the preceding Christ expanded; the second, however, the third, and the fourth column the hundredth years, or the thousandth years, or the hundredth years which are Bissextile. So, for example's sake, those years ought to be Bissextile in a certain reckoned-back Julian year before Christ 1·&·5·&·9·&c. Likewise the years 101·&·201·&c. likewise the years 2701·2801; likewise 5301·&·5401·&c. But beyond these, of all the centuries of years before Christ, those are Bissextile which are in the first column, that is 25; for the Bissextiles, since 25 is in the first column, are Bissextile. The rest, intermediate, and not noted, are Common, as the years before Christ 4·8·12·104·108·112·&c.

For the years after the Epoch of Christ, however, consult Table 16, in whose first column are the years of any century after Christ, in 2, however, & 3·the hundredth, thousandth, &c·Bissextile years. So, for example's sake, the Bissextiles are in this form the years 4·&·8·&·12·&c·likewise 100·&·200·&c·likewise 1700·1800·1900·&c. But, by composing the expanded years with the hundredth, or thousandth, the Bissextiles are 104·108·item 204·208·item 1004·1008·&c·the rest intermediate, and not noted, are Common.

Precept 19. In the form of the Gregorian year, to distinguish the hundredth years, or the thousandth, which ought not to be Bissextiles, and excepted, in which the number of days of the Gregorian years exceeds the number of days of the Julian years.

In the form of the Gregorian year, every fourth one of the expanded years is Bissextile, and these the first column of Table 15 serves. But among the hundredth years, and the thousandth, those alone are Bissextiles whose two prior figures...

the leap years (bissextiles) are found among the expanded years, that is, every fourth year, every hundredth from the year 1600 exclusive — once the rule of intercalation is taken up — as appears more clearly in Table 17. There the letter C [for] Common years, and the letter B [for] leap years (bissextiles), give the indication. [Margin: Pag. 14.]

Furthermore, from the year of Christ 1582, on the 5th of October, those who follow the Gregorian form embraced it — that is, the greatest part of the Christian world. They reckon the days 10 more than the Julians do; yet, with stubborn obstinacy, others retain the form of the Julian year, and the same days. For example, the 24th of December among the Gregorians is not the 14th among the Julians. December among the Julians, as it happens each time, and from the year 1700, will reckon the 24th [Gregorian] as the 14th [Julian]; for in the following year, 1700, the Gregorian form will be the 24th of February, while among the Julians it will be the 25th — for it will then be a Julian year and a Gregorian computation by 11 days, and so on always up to the year 1800. February, then, [will reckon] the 24th as the 6th of March in the Gregorian [count], and at once on the following day, by Gregorian computation, the Julian 12th will be exceeded, and that day denominated the 7th of March, which by the Julian style is the 24th of February, and is the later one. For this reason, with regard to indicating these excesses, in Table 20 the third column and the sixth give notice of the days of excess.

Praecept. 20. *To find the Cycle of the Sun [Cyclus Solis] for the sake of investigating the weekday [Feria], both before and after the Epoch of Christ.*

The Cycle of the Sun [solar cycle] is a period of 28 years, produced from the multiplication of the 7 days of the week by 4 — because each fourth year is a leap year, which doubles the Dominical letter; and so each twenty-eighth year the Dominical letter recurs to the same weekday. Why a year has a Dominical letter, this letter being dedicated here to the Sun and to the Lord's resurrection [Dominica resurrectionis], and so the Cycle is called of the Sun [Cycli Solis], and the letter named Feria 1 [first weekday], indicating the Lord's Day [Dominica], is called in Greek Κυριακή [Greek: Kyriakē, "the Lord's (day)"]. How, moreover, the Greeks named the weekdays in the front of Table 19, and the Characters of the Planets, with which the Astrologers labelled them, they wrote. Furthermore, for the Cycle of the Sun for years before the Epoch of Christ: for the years to come, add 9 to those years, and from the sum subtract the nearest smaller number found in Table 18. The Residue, if it remains less than 28, will be the Cycle of the Sun itself; [if it equals 28,] the Cycle itself is completed at 28.

Example. Let the year of Christ be given as 1660, with 9 added, making the sum 1669. From the number of the Cycles of the Sun in Table 18, the nearest smaller is 1652, which subtracted from the said sum leaves a Cycle of the Sun of 17 — which indeed corresponds to the year of Christ 1660.

Another way, without the Table.

To the years of Christ add 9, [and] divide the sum by 28. The fraction that remains in the quotient is the Cycle of the Sun; but if there is no fraction, [it] will be 28 itself, [and] this will be the Cycle of the Sun.

For years current before Christ.

Look in Table 18 for the next larger number [than] the years current before Christ, and to that add 9. Then from the sum subtract the years given before Christ; and from the remainder, if it is not less than 28, subtract the next smaller Cycle of the Sun found in Table 18; for what remains of the Cycle of the Sun, if it is no [longer] greater, will be that very thing. If the residue was first less than 28, the residue itself will be it.

Example 1. The year before Christ given is 36; the next larger number to this in Table 18 is 56. This increased, it becomes 66; from this subtract the given 36, [there] remains 30. And to this remainder of the same Cycle of the Sun, the next smaller in Table 18 is 28, which subtracted [gives] a remaining number 2; this, then, is the Cycle of the Sun corresponding to the year 36 before Christ.

Another way, without the Table.

To the years given before Christ add 18, and divide the sum by 28; for if nothing remains over, the Cycle [sought] will be 28 itself. If, however, some residue remains, [that] subtract from 28 itself —

[column 2]

the remaining 28; and what is left over will be the Cycle of the Sun; but if 18 is added to the years before Christ, and the number minus 28 results, you will have the Cycle of the Sun.

Example 1. Let there be a year current before Christ, 3993. Adding 18, [they] make 4011; which divided by 28 leaves $143 \frac{7}{28}$; therefore, 7 being taken away from 28, there remains the Cycle of the Sun 21, which corresponds to the year 3993.

Example 2. Let there be a year before Christ current 10, with 18 added; [it] becomes 28; this cannot be divided by 28, nor can it be carried further; therefore for the year 10, the Cycle of the Sun will be 28.

Example 3. Let there be a year before Christ 11; add 18, [there] become 29; which divided by 28 leaves 1; this taken from 28 leaves the Cycle of the Sun 27, corresponding to the year 11 before Christ.

Praecept. 21. *To inquire into the weekday [Feria] of a given day in a Julian Year, by means of the Cycle of the Sun.*

First, take note of the use of the Cycle of the Sun, which is set out in the use of Table 22. The week [Hebdomada] is not begun from the Kalends of January, as in other computations, but from the 6th of the Kalends of March [24 February], in which the intercalation is made — that is, from the very Kalends of March; for as January, so February was constituted from an appendix of the preceding year, after the manner of the Romulan and Numan Year.

Secondly. If the day of the month given in that year, for the Cycle of the Sun you have already learned, [is] before February, take it from the other months; the weekday [Feria] which is in Table 19, the Cycle of the Sun [number] set above corresponding to that, [seek] in the front of the same Table the weekday number given for the month, [and] from the sum the weekday number; add to the sum the days of the month given, and from the sum take away all the sevens, and what then remains will be the weekday sought; for if nothing remains, the weekday sought will be 7, that is, the Sabbath. But if the days are before February, use the Cycle of the preceding year, that is, the Cycle which obtains a unity above; or [Margin: Pag. 14.] if Cycle 1 obtains, [use] as above.

Example 1. Let the year of Christ 1660 be given (whose Cycle is the Solar 17); [the] day [is] the 25th of March. First: for the number is 17 in Table 19, the proposed [weekday] is Feria 4 [Wednesday]; and for the month of March, Feria 7 [Saturday]. The sum [is] thus 36, and this divided by 7 leaves a remainder; therefore, for the year 1660, the day [is] the 25th of March. It will fall on the Lord's Day [Dominica], in the form of the old Julian Year; but by the Gregorian style it will be that day, the 25th, the 4th of April. April concurs with the Lord's Day. When, however, by the Julian style the day is the 25th of March, it will be the Lord's Day; but by the Gregorian style it will be that day.

Hence learn that, for finding the Gregorian weekdays, the Gregorian days are to be subtracted from the given days — the days by which the Gregorian numeration exceeds the Julian, as in Table 17 — and then use precept 23.

Example 2. Let it be given for the same year 1660, to which corresponds the Solar Cycle 17, [the] day the 25th of January; then use the Cycle of the Sun of the preceding Year, that is, Cycle 16, which is set out in Table 19. Feria 2 [Monday], and for the month of January, Feria 5 [Thursday]; the aggregate of the weekdays is 7, which added to the 25 days makes the sum 32, and this divided by 7 leaves Feria 4 [Wednesday], which corresponds to that day, the 25th of January, in the form of the Julian Year.

But in the Gregorian form, with 10 days subtracted, the 15th remains; this added, the aggregate makes 7, [there] result 22, and this divided by 7 leaves Feria 1 [Sunday]. Therefore the day, the 25th of January in the year 1650, falls on Feria 1; by the Gregorian style, that is, on the Lord's Day [Dominica].

Praecept. 22. *To investigate the weekday [Feria] in an Arabic Year of the Hegira, by means of the Solar Cycle.*

What in the Julian Year was the Solar Cycle 28, this for the Arabs is the Cycle of Years 210, which from the very first year of the Hegira, that is, the Epoch of the Arabs of Mahomet, begins; the sums of these of the Cycle, moreover, you have aggregated in Table 20, at the rightmost end, the little [side-]table. [Margin: Pag. 14.] It is established, moreover, that the Cycle is 210. By weeks, 30, [and] therefore after the topmost front of Table 20, in column 3 are the numbers

the numbers of the weekdays [Feriae]; placed are the numbers of the completed Cycle of the weekdays out of 30, [those] coming together, just as in the second [column], and the third the series 30. 60. 90. 110. 150. 180. in retrograde order. The remaining numbers in the areas of the same Table give the Cycles current, [running] from unity each time, up to 30, the current [days]. The triple Table of the Arabic months is adjoined at its own places; and therefore, with the threefold [reckoning] usually, on entering this Table the weekday is to be sought.

First, then: with the years of the Hegira given, subtract the number next smaller in the right-hand side of the Arabic Cycles found [there]: the Residue, if it is not less than 30, subtract the number next smaller in the second [series], or the third series in the Table; and when you come to the number in the third series, repeat [the operation] rather than [proceed] with the residue after its subtraction. On entering the front of the Table with the twofold [count], the weekday is at last [found]; for in the front, with the Arabic month given, [seek] the weekday set above; for the weekday added in the aggregate of all the weekdays, with the days of the month given, and divide the sum; and what remains will be the weekday sought; and the sum divide by 7; if nothing remains, it will be Feria 7, that is, the

Sabbath. On the other hand, [if] the first residue is less than 30, use that; and [seek] the weekday, as above, to be investigated.

Example. Amurath II, Emperor of the Turks, died in the year of the Hegira 855, on the 1st day, the 1st of Muharram. The question is, on what day [of the week] he died, and what weekday it was?

In Table 23, on the right-hand side, the Arabic number of the Cycles next smaller than the number 855 is 840, which from the years of the Hegira subtracted leaves 15; [add] to this, since the smaller third number is a tricenary number [a multiple of 30], in the area of Table 20 [the value] investigated, and in the front the weekday is found, Feria 3 [Tuesday]; [Margin: Pag. 14.] above [stands] for the month [the entry] Muharram, Feria 7 [Saturday], aggregated [with] the weekdays, which is 7; [with] 10 added, the first day, [there] is 1 month [Feria] 11. From this number divided by 7 is left 4. Therefore that day fell on Feria 4 [Wednesday].

Praecept. 23. *On the use of Table 21 (namely, of the collected years and of the various months).*

It comes into use sometimes to know how many days come together in one sum of completed years, or [completed] months of them.

To this end, in Table 21 you have on the left side the Julian years, the Egyptian, with the Persian, and the Lunar Arabic [years] aggregated, together with the days of any [year] aggregated [for the years] which correspond to these, or which the same cyphers indicate.

Example. For 4 Julian years, of which every fourth is a leap year, they collect 1461 days; but if the years are 40, they collect 14610 [days]; if indeed the years are 400, they collect 146100; and so for the rest.

But the Tables contain the months, both the sums of the days of the completed months corresponding [to them], or rather the months exotic [foreign] in the Julian Year, or [those] concurring with the Julian [months], greater for the most part. Of these [there is] more in our *Chronologia Reformata*, and certain other matters below, in the discussion of the conversion of the Epochs, to be said.

Praecept. 24. *Given the Years before, or after, the Epoch of Christ, to convert [them] into Years of the Julian Period.*

The Julian Period, from which the [number] composed in Table 22 is, I have said. Now if the Year before the Epoch of Christ is 4714, it is the very beginning of the Julian Period; if more [than that], it is in vain to inquire [further]; if fewer,

subtract those from the years 4714, [Margin: Pag. 16.] [and] there will remain the years of the Julian Period.

Example. The year before Christ is 776, in which the Olympiads were instituted; this subtracted from 4714 leaves the Year of the Julian Period 3938. The years before Christ, however, [if] given, add 4714; and if the sum does not exceed 7980, you will have the Years of the first Julian Period; but if it exceeds [7980], throw away as many times as you can the years 7980; the residue will be the Year of the Julian period second, if [thrown away] once, or third if twice, [and] so likewise of the rest.

Example. Let the Year after Christ be given, 238, whom Censorinus inscribed [as] of the more notable Epochs. Add to these 4713; [there] becomes [for] that year of the Julian Period 4951. Again [if] the Year of Christ is 3340, to these if you add 4713, [they] make 8053; from which subtracted [is] the whole Julian Period of Years 7980, [there] remain [for] the second Period the Year 73.

Praecept. 25. *Given a Year of the given Julian Period, to convert [it] into Years before Christ, if it does not exceed 4713, or into Years of Christ, if it exceeds 4713.*

If [the year] does not exceed 4713, subtract those from 4714; the [years] remaining are the Years before Christ concurrent with the Years of the given Julian Period.

Example. The Julian Period 3938. The Julian Period diminished by the Years 4714 leaves [for] the year before the Epoch of Christ 776 — namely, the first Olympiad.

But if they exceed 4713, subtract 4713; the residue will be the Year of Christ sought; for if [it is] the first Period, this is the second Period, which begins in the Year of Christ 3268. Add to the given Years 7980, and from the sum subtract 4713; [there] remains the Year of Christ sought.

Example. Let the Year of the first Julian Period be given, 6295; from this take 4713; [there] remains the Year of Christ 1582 — namely, the [year] of the Gregorian correction of the Kalendar [Gregorian calendar reform].

Praecept. 26. *To convert the Epoch of the World according to the Greeks (the Constantinopolitan Fathers of the Church) into Years before, or after, Christ.*

If the given Year of the World does not exceed 5509, subtract the given [year] from 5510; [there] remains [the year] before Christ of the Epoch [of the World]; and if it exceeds 5509, [there] will be the Years of the Epoch of Christ sought, which you will have by subtracting from the given [years] the Years 5509.

Praecept. 27. *Given Years before, or after, Christ, to turn [them] into Years of the World according to the Greek Fathers.*

If [from] the given Years before Christ you subtract from the Years 5510, [there] will return what you wish; on the contrary, if to the Years of Christ you add 5509, you will have the Years of the World according to the Greek computation of the Constantinopolitan Fathers of the Church.

Praecept. 28. *To convert any given Year into the Year before, or after, Christ, in which the Olympiadic Year began — the Olympiadic Year having begun, in [the season] nearer to the summer Solstice, from the New Moon [Noumenia].*

When writers say that something was done in some Olympiad, it is to be understood [that] the Olympiad was begun [i.e.] not yet completed — that is, not adding its [own number]. Understood [in this way], first, then: in the first place, of the Olympiad completed, but for the product add the remaining [years] of the same likewise complete; of the Olympiad incomplete [add the years] you will have, for there are the years Olympiadic full, which before Christ [if it does] not exceed the Year 775, subtract from the Years 776; [there] will remain the Years before the Epoch of Christ, in whose summer the Olympiad was begun, whose proposed Olympiadic year [was] given. But if [it] exceeds 775, subtract from those 775; and you will have the Year before Christ in which the Olympiadic year proposed was begun.

Example first. Let there be given Olympiad 6, year 1 current; because the completed Olympiads are 5, and these multiplied by 4 make 20; and adding the years full 1, the Olympiadic years 21 are completed; if these you subtract from 776, [there] remains the Year before Christ Epoch 754, in whose summer began Olympiad 6, year 1; which therefore was completed in the summer 753, before Christ.

Example 2. Let Olympiad 195 be given, year 1 current. Since the completed Olympiads are 194, with [the years] added moreover [and] led through, [there] become Olympiadic years 776; from these subtract 775; [there] remains year 1; in whose summer began Olympiad 195.

[Margin: Praecept. 29.] **Praecept. 29.** *To convert the Years before, & after Christ into Years of the Olympiads.*

If the given Year before Christ Epoch is 776, it is —

[column 2]

— the first year of the first Olympiad, begun from the New Moon [Neomenia] nearer to the Solstice; but if [it is] smaller than that one, [add] to it 776, and the residue divided by 4 — for in the quotient will be the integers, [and] for the fraction you will have the number of the Olympiad complete in the summer of the year from which began the first year of the Olympiad following. But if as many times as it has a fraction, or that the adjoined fraction has, [it] will give the year coming on of that Olympiad; [as] for [the number of the] integer [in the] quotient of that Olympiad, the integers [in the] quotient likewise indicates.

Example 1. Let there be given before Christ 770; subtracted from the years 776, [there] remains 6; which divided by 4 [gives] the quotient $1 \frac{2}{4}$. Add therefore unity, both to the whole quotient and to the numerator of the fraction, which is 2; and it becomes $2\frac{3}{4}$. Therefore in the summer of the year before Christ 770, [reckoning] from the New Moon [Neomenia] nearer to the summer Solstice, [there] ran the year 3 of Olympiad 2; and so that year ran together with year 2 of Olympiad 2.

Example 2. Let there be a Year before Christ 4; subtracted from the years 776, [there] remains 772; which divided by 4 [gives] 193, the number of the Olympiad complete in that year; therefore after the New Moon [neomenia] of the summer Solstice [in] that year before Christ 4, [there] began the first year of Olympiad 194.

Praecept. 30. *Given the Years of the City of Rome Founded, to turn [them] into Years before, or after, Christ.*

The Epoch of the City of Rome is 753 before Christ — this is according to Varro's computation, begun on the 21st day of April; and the first Epoch of Christ. If, however, [it is] given [as a] year [of the] City 754, [there] will remain a year before Christ, whose 21st day of April begins the year of the City 754. But if you subtract those very 754, [there] remains a year before Christ in whose 21st day of April [there] began the year of the City; and therefore the beginning of that Year of Christ concurs with the year of the City preceding.

Example 1. Let there be given a Year of the City 709, which indeed was the first Julian Year, ordained by Julius Caesar; subtract from this 754; [there] remains a year before Christ 45, on whose 21st day of April [there] began the year of the City 709, [a year] which before then ran with 708. Again [if] there is given a Year of the City 1, subtracted from those 754, [there] remains the year before Christ 753, in which [the] City was founded — the 21st of April.

Example 2. Let there be given a Year of the City 1553; from this I take 753; [there] remains the Year of Christ 800, on whose Kalends of January [1 January] the year

of the City 1553 began. But on the Kalends of January in the year 800 (in which Charlemagne [Carolus Magnus] began to reign as Emperor) it would run together with the year of the City 1552.

Praecept. 31. *To turn the Years before, or after, the Epoch of Christ, into Years of the City of Rome Founded.*

If the Year before Christ does not exceed 753, subtract that from the Years 754, [and] you will have the Year of the City beginning the 21st of April of the same year.

The Year of Christ, however, [if] given, add to the Years 753, [and] you will have the Year of the City, [for] that Year of Christ from the 21st day of April entering on.

Praecept. 32. *To bring back the Years of Nabonassar to the Years before, or after the Epoch of Christ.*

Inspect first Table 23, [to see] if perhaps in it you find the Epoch of Nabonassar [Margin: Pag. 18.] [in] the region of the Years of Nabonassar before or after Christ, and at the same time the day of the Julian or Gregorian Month in which the Year begins. Otherwise [if it is] the Year of Nabonassar, subtract the next larger in the same Table found; the residue add to the Years before Christ corresponding to the preceding said next larger [year] before Christ, [and] you will have the year before Christ in which the given [year] of Nabonassar begins. But if [it is] from the region of the larger numbers, the next larger [if there] are Years of Christ, from these subtract the residue left after the subtraction following the [year] of Nabonassar next larger; and there will remain the Year of Christ in which the given year of Nabonassar begins. The Residue, however, retain in either case, [as the] Residue aforesaid, for the practice of precept 35, soon to be handed down.

Example 1. Let there be given the Year of Nabonassar 720; this subtracted [from] 744, which in Table 23 is the next larger to it, leaves *Residue* 24; which added [to the] year before Christ 5, that is, [the one] corresponding to year 744, makes [it] 29. The year before Christ, then, in which the year of Nabonassar 720 begins, [is 29].

Example 2. Let it be the Year of Nabonassar 1460; this subtracted [from] the next larger, which in Table 26 is 1464, leaves *Residue* 4; which subtracted [from the] year before Christ [Margin: Pag. 18.] 716, that is, [the one] corresponding to year 1464 set [down], [there] remains [the] Year of Christ 12, in which the Year of Nabonassar 1460 begins.

Praecept. 33. *To find the beginning of a given Year of Nabonassar in a Julian or Gregorian Year.*

First, by Precept 32, inquire [in] the Year before, or [after,] Christ, in which the proposed Year of Nabonassar begins, and the *Residue* in that practice adduced divide by 4; then the quotient, if there should adhere a fraction, augment by unity, and so [the number] augmented [gives] the day of the Julian or Gregorian [month] in which begins Thoth, the first of the Nabonassaran year, [for] the next larger year of Nabonassar [over the] year given of Nabonassar. After the Year of Christ 1582, however, [there] suffices to repeat the beginning in the Julian Months and the Gregorian; and to know what the day is in the Gregorian, by Precept 19.

Example 1. In the preceding Precept 32, the year of Nabonassar given 720, the next larger in Table 23 [Margin: Pag. 18.] is 744, to which corresponds the beginning [of] Thoth, August 24. The *Residue*, however, adhibited there is 24; this divided by 4 [gives the] quotient 6; this is therefore [without] fraction, but it lies idle; add [to] the 24th of August; and there results August day 30, in whose Meridian falls the beginning of the month Thoth of the year of Nabonassar 720, [there] before Christ 29.

Example 2. In the precept preceding. The Year of Nabonassar given was 1460, at the next larger 1464, the beginning of Thoth from Table 23 [is] February 25. The *Residue* adhibited [Margin: Pag. 18.] is 4, this divided by 4 [gives the] quotient 1, and without fragment. Therefore, with unity added, the day 25th [+1] falls [as] the beginning of Thoth, Year of Nabonassar 1460, on the 26th of February, [in the] Year of Christ 12.

Praecept. 34. *Given a Year of Nabonassar, [its] Month, and Day, to find into which Month of the Year before Christ, or after, and on what day of the Julian Months [the] day of the Egyptian Year falls.*

First, inquire by Precept 32 [for] the Year before, or after, Christ, & by Precept 35, the Day of the Julian Month in which the given Nabonassaran year begins, & by Precept 20, [or rather] by 21, foreknow whether the Julian Year, [or] the Gre-

whether the Gregorian year is bissextile or common? Second, from Table 5, by the preceding Precept 5, collect the total of days from the beginning of the Julian or Gregorian year up to the day that begins the month of Thoth. Third, from Table 6, by the preceding Precept 7, collect the total of days from the beginning of the Egyptian year up to the proposed day, and add this sum. [Margin: Pag. 18.] From these added sums (if it does not exceed 365, or 366 in a bissextile year), in the areas of Table 5, look up on the left side the day of the month concurring with the

given day of the Egyptian month. But if that aggregate exceeds 365 in a common year, or 366 in a bissextile year, subtract these from the aggregate itself, and with the Residue look up, in the area of Table 5 as above, the month of January, and likewise on the left side the day concurring with the given day. [Margin: Pag. 2.]

Example 1. Let an Egyptian Year of Athyr be given, day 25. First, by Precept 3, that year was 29 years before Christ, and likewise by Precept 33, the beginning of Thoth fell on the 30th of August. [Margin: Pag. 2.] By Table 5, in the bissextile year 5 (which was the 29th before Christ), the 243rd day is shown. From Table 6, day 5 of Athyr gives 85, the days collected from the beginning. Athyr 25 thus gives 175. The Julian sum 243, and the Egyptian sum 175, make an aggregate of 328 days, which in Table 5 displays, in that bissextile year, day 23 of November, concurring with day 25 of Athyr. November 243, with the Egyptian 175, makes the aggregate 418, from which subtract the bissextile 366; there remain 52, and in Table 5 for the following year, 28 before Christ, they give January 21. The Julian sum 243 with the Egyptian 175 makes the aggregate 418, from which subtract the bissextile 366; there remain 52, and in Table 5 they give day 21 of January, concurring with day 25 of Mechir. [Margin: Pag. 18.]

Precept 35. To convert given Years before Christ, or to turn them into Years of Nabonassar, and to investigate the beginning of those years.

If the given Year before Christ does not exceed 747, look it up in Table 23, in the second column; for in the first column you have the beginning of the Nabonassar year, which the Julian month gives, while the third column shows which month the given year begins in. But if the given year is not found in column 2, subtract from it the nearest one found (and note meanwhile how many years of Nabonassar are in column 1), and as a beginning-year (added to the one found, the nearest greater) it will give you the other beginning you seek. [Margin: Pag. 18.] But divide the Residue beyond the year of Nabonassar by 4: as many times as it goes evenly (or, if a fraction results, increased by one), subtracted from the given beginning, it will give the other beginning sought.

Example 1. Let there be given the year 29 before Christ; look it up in Table 23, in the second column, where the nearest found, namely the year 33, is left; the Residue is 4, which, added to the Nabonassar year 716 placed opposite, gives the Nabonassar year 720 — namely the one that began in the 29th year before Christ. Furthermore, 33 gives the beginning of Thoth on the 31st of August, and the Residue 4 divided by 4 leaves a quotient of 1: with one subtracted from day 31,

the beginning of the Nabonassar year 720 remains the 30th, the day on which that Nabonassar year began.

But if the given year is at the Epoch of Christ, in which the Nabonassar year began, you will have it in Table 23, column 2; or at all events the nearest greater will be found, having opposite it on the left side the beginning of the Nabonassar year, and on the right side the month of January, in which the Nabonassar year then began. [Margin: Pag. 18.] But if the given year of Christ is not in Table 26, look in it for the nearest greater, and subtract it; and to the Nabonassar year responding in the same Table to the nearest greater year of Christ given, add the Residue: for you will have the Nabonassar year sought. Then divide the Residue by 4, and the quotient — whole, if it lacks a fraction, or increased by one if it has a fraction — add to the beginning of Thoth, which is in column 1 opposite the nearest greater year of Nabonassar; and you will have the beginning sought of the Nabonassar year just found. [Margin: Pag. 18.]

Example 2. Let the given year of Christ be 712; subtract from it the nearest greater in Table 23, that is, 719; the Residue 7, at year 719, responds to the beginning of the Nabonassar year 1467 — on the right, however, its beginning of February. With 7 subtracted from February, there remains the Nabonassar year sought, 1460. And the residue divided likewise by 7 [recte: 4] gives quotients...

is $1\frac{1}{4}$; and the fraction being dropped, there is here therefore an addition of day 25 of February; year 1460 of Nabonassar gives day 24 in which that Nabonassar year 1460 began.

Precept 36. To convert the Day of a given Year before, or after, Christ into the Day of a Nabonassar Year.

First, by the preceding precept, with the given year before Christ, or after, and the Day of the Month and of Thoth given, in which that Nabonassar year begins, seek the beginning of the Nabonassar year. Then, from Table 5, collect singly the sum of Julian days responding to the beginning of Thoth, and likewise the sum of days responding to the date given; [Margin: Pag. 2.] and if these days fall in the same year, the difference of the two collected sums, the unit deducted, and 365 days subtracted, gives a Residue, which in Table 6 will show the Egyptian Month, and on the left side the day responding to the given day. [Margin: Pag. 2.] But if the given day precedes the beginning of the year, the difference of the collected sums of the year being deducted, the unit subtracted, and 365 days deducted, gives a Residue, which in Table 6 will show the Egyptian Month, and on the left side the day responding to the given day. [Margin: Pag. 2.]

Example. Continuing with Example 1 of the preceding precept, the year before Christ 29 was found to be the Nabonassar year 720, beginning the 30th of August. If you ask in what Egyptian Month, and on what day, day 31 of October falls. Since the sum of days responding to day 30 of August in the year 29 before Christ, bissextile, is in Table 6, 243; responding to day 31 of October is 305; of these, the difference is 62, and the unit added is 63; this is in Table 6, day 3 of Athyr, corresponding to day 31 of October. [Margin: Pag. 2.] But the sum for day 25 of April, in the bissextile year, in Table 5, is 116; and its difference from days 243 is 127 days; and with the unit taken off, it is 126; if this be subtracted from 365 days, it leaves a Residue of 239 days, with which, in Table 6, responds day 29 of Pharmuthi, concurring with the given day 25 of April. [Margin: Pag. 2.]

Precept 37. To convert the Years of Alexander the Great, or of Dhū'l-Qarnayn, into Years before or after the Epoch of Christ, and these in turn into those.

If the year of Alexander the Great, reckoned from his own death, is 324, or of Dhū'l-Qarnayn 312, they concur, each of them, with the first Months of the first year of Christ. But if the year of Alexander is less than 324, or of Dhū'l-Qarnayn less than 312, subtract the years of Alexander from 324, and of Dhū'l-Qarnayn from 312. The Residue will give the year before Christ, with the prior months concurring with the given year. By contrast, if the year of Alexander exceeds 324, or of Dhū'l-Qarnayn 312, subtract 324 from these, or 312, and there will remain the year of Christ, whose prior months concur with the given year.

In turn, if the given years before Christ do not exceed 324, subtract these years from 325; there will remain the year of Alexander at his beginning in that year. But if they do not exceed 313, the remainder is the year of Dhū'l-Qarnayn, at the same beginning. So too the running year before Christ, concurring with the same years 325; or the remainder will be the year of Alexander running in that year, but at his preceding beginning — but if the years before Christ are 313, the remainder is the year of Dhū'l-Qarnayn, or of the Seleucids, at his beginning in the preceding year of Christ, concurring with the prior part of the given year.

The precept is clear, nor do those already accustomed to the preceding precepts now need an example.

Precept 38. To commute the Years of Alexander the Great into Years of Nabonassar, and these in turn into those.

To the Years of Alexander add 424, and there will be Nabonassar years, in the Egyptian manner, reckoned from the same day, namely the noon-meridian, and from the same month, from which Alexander's reckoning begins. Thus the year of Alexander began together with year 425 of Nabonassar, on the 12th of November, that is, the 1st of Thoth.

In turn, if the years of Nabonassar are not fewer than 425, subtract from them the years 424; and there will remain the Year of Alexander, beginning with the same Nabonassar year.

Precept 39. To convert given Years of the Hegira, and their days, into Years of the Epoch of Christ, and its days.

In Table 21, the Third, or lowest, Class holds the days collected of the years of the Arabs, and of the months. From this Table, therefore, collect the days responding to the years, months, and Arabic days, but completed; and likewise, by one or more entries into the Table, as may be required. The sum of the days collected, add the perpetual 561; and it will make a sum which, by that distinction, we will call the Heap [*Cumulus*]. Then, from the first class of Table 21, in whose areas the day-numbers collected responding to the Julian Years, Months, and Arabic days completed, with one or more entries; for if, with the Julian years thus found, you add the years 620, the Years of Christ will come forth congruent with the given Hegira years, and months, and Julian days, with Months and Days of the Hegira. [Margin: Pag. 15.]

Example from the Turkish Annals. Amurath the Second died in the year of the Hegira 855, at its beginning, on the very 1st day of the month Muharram, Feria 4 [the fourth weekday]. It is asked: in what year of the Epoch of Christ did this come about, and in what Month of the Julian Calendar, and on what day of it? Go therefore to Table 21, and to its lowest class on the left side, in which it is thus: [Margin: Pag. 15.]

Annorum Arabicorum [Of Arabic
Years]

Dies collecti [Days collected]

Anni 600. Arabici dant [600 Arabic
years give]

212620

Restant Anni completi 254. quorum
240. dant [There remain 254 complete

85048

Annorum Arabicorum [Of Arabic Years]	Dies collecti [Days collected]
years, of which 240 give]	
Restant Anni 14. qui dant [There remain 14 years, which give]	4961
Adde 1. Mensis Muharram diem [Add 1 day of the month Muharram]	1
& dies perpetuo [and the perpetual days]	561
Fit summa Dierum [The sum of Days makes]	303191

Then, in the upper part of Table 21, in the class on the left side, the Days 303191, by parts collected, give in the left-hand columns the Julian Years thus: [Margin: Pag. 15.]

	Anni Iulian. [Julian Years]
Dies 292200. dant [Days 292200 give]	800
Restant 10991. quor. 10227. dant [There remain 10991, of which 10227 give]	28
Restant 764. quor. 730. dant [There remain 764, of which 730 give]	2
Restant dies 34. [There remain 34 days]	
Adde Annos perpetuo [Add the perpetual Years]	620
Fit summa Annorum Completorum [The sum of Complete Years makes]	1450

The 34 days give February 3. Therefore Amurath the Second died in the year of Christ 1451, on its February 3. [Margin: Nicolai Muleri lapsus (the slip of Nicolaus Mulerius).] Note therefore that Nicolaus Mulerius [Nicolaus Mulerius], in his Canon of the Years of the Arabs collated with the years of Christ, places the year 855, the Arabic year beginning, on February 3, of the year of Christ 1451, Feria 4.

But the reason why the perpetual 561 are added to the collected Arabic Days, and why the years 620 are added to the collected Julian years, as above: the perpetual

620 are added because the first year of the Hegira began in the year of Christ 622, on the 16th of July; from the year 620 completed, and bissextile, the years 622 currently run, day 16 of July currently; the days completed are numbered 561. But an error is to be guarded against in the Rudolphine Tables p. 39, where, under the end, in the transverse rows on the right, the number is placed uselessly as 1. The Hegira Year, in the year of Christ 632, and continued with 633, which verifies the Epoch of Yazdegird, not of the Arabs, since its beginning is from those same Rudolphine pages, p. 38, the year of Christ 622 is to be placed, which 623 follows. [Margin: Rudolphinarum mendum (an error of the Rudolphine Tables).]

But how the Arabs investigate their Cycles through the weekdays [Ferias], was stated at Precept 22.

Precept 40. To commute the Years of Christ, if they are not fewer than 622, into the Arabic days of the Hegira, and its days.

From the given Years of Christ subtract the years 620; resolve the remainder, by Table 21, the upper Class, into days, and to it add the days collected from the beginning of the Julian year up to the day of the Julian month given, and likewise the days collected, but completed, of the Egyptian Months [*recte: of the given month*]; and to all these add the perpetual 561 days; and it will make a sum, from which subtract always the days 561. The Residue, then, look up in Table 21 — the year sought, by parts adduced, first under the heading of the Hegira years; then under the heading of the Arabic months, until the lesser days under the Arabic Month remain; noting meanwhile the preceding Arabic years collected; and the days remaining indicate the days of the following month sequent to the Arabic; congruent with the given Julian, and the sum of the collected Arabic years added with the unit, makes the Arabic year, the year of Christ being given. [Margin: Pag. 15.]

Example. In the year of Christ 1452, on the 29th of May, Feria 2 [the second weekday], the day of Pentecost, Constantinople was taken by Mehmet [Mahumeth] the Second. It is asked, to what year of the Hegira the year taken responds, and to what Arabic Month, and to what day of it? [Margin: Pag. 15.] In the year of Christ 1452, subtract 620, and there remain 832; these, by Table 21, respond to the days collected of the Julian years, as below: [Margin: Pag. 15.]

	Dies [Days]
Anni 800. dant dies [800 years give days]	292200
Restant Anni 32. qui dant [There remain 32 years,	11688

	Dies [Days]
which give]	
Ab initio autem Anni 1452. Bissextilis, ad 29. Maij inclusivè sunt dies [From the beginning of the year 1452, bissextile, to the 29th of May inclusive, the days are]	150
Summa dierum est [The sum of days is]	303930
His perpetuo deme Dies [From these perpetually take away the Days]	561
Restant Dies [There remain Days]	303369

Then in the lowest Class of Table 21, under the Arabic years and months, the days 303369 give the complete Arabic years, by the method written below: [Margin: Pag. 15.]

Dies Collecti [Days collected]	Anni Arabici [Arabic Years]
Dierum 303369. summa proximè minor 212620. dat [Of the days 303369, the nearest lesser sum 212620 gives]	600
Restant 90749. quor. 85048. dant [There remain 90749, of which 85048 give]	240
Restant 5701. quor. 5670. dant [There remain 5701, of which 5670 give]	16
Restantq; dies 31. [And there remain 31 days]	
Summa annorum Arabicè Complet. [The sum of complete Arabic years]	856

[Margin: In Tab. 21. Pag. 15.]

Therefore Constantinople was taken in the year of the Hegira 857. And because 31 days are over, of which 30 are due to the first Arab month Muharram, it follows that it was taken on the first day [prima die] of the month Sephar, Feria 2, in Arabic, that is on the day of the Moon [Monday], by Precept 24.

Precept 41. To convert given Years of Yazdegird, or the Persian Epoch, and days, into Years of Christ, and days.

The given complete Years of Yazdegird, and complete months, resolve into days, by Table 21, Class 2, from the left, which serves both for the Persians, as for the Egyptians, by one or more entries made into the Table; from the sum of the days subtract the perpetual 199. The Residue, by the same Table 21, Class 24 [recte: Class 2], the uppermost, reduce to Years of Christ [recte: Julian], and Months, having regard to bissextiles. Finally, to the sum of the Julian Years add the perpetual 632, and it will make the sum of the Years of Christ; the residue, however, the days, show in Table 21 the month, and the day given. [Margin: Pag. 2.]

Example. Let the given year of Yazdegird be 814, and day 17 of the month Tyrma: it is asked, what is the year of Christ, the month, and on what day? Go to Table 24, in which it is thus: [Margin: Pag. 15.]

	Dies [Days]
Anni Persici, vt & Aegypti] 800. dant [Persian years, as also Egyptian, 800 give]	292000
Restant completi 13. quor. 10. dant [There remain 13 complete, of which 10 give]	3650
Et 3. completi dant [And 3 complete give]	1095
Mensis completus ante Tyrma, idest mensis Chortat dat [A month completed before Tyrma, that is the month Chortat, gives]	90
Dies currentes de Tyrma sunt [The running days of Tyrma are]	17
Summa dierum omnium est [The sum of all days is]	296852
Cui perpetuò deme 199. [From which perpetually take away 199]	199
Restant [There remain]	296653
The sum of days 296653, in the upper Table 24, the part sought, gives the Julian Years written below: [Margin: Pag. 15.]	
	Anni [Years]
Dies 292200. dant [Days 292200 give]	800

	Anni [Years]
Restant d. 4453. quorum 4383. dant [There remain 4453 days, of which 4383 give]	12
Restantq; dies 70. [And there remain 70 days]	
Summa Annorum completorum [The sum of complete Years]	812
Adde his Annos completos [Add to these the complete Years]	632
Fit summa Annorum Christi complet. [The sum of complete Years of Christ makes]	1444

But there are over, from the following year, namely 1445, days 70; and these in Table 6 give, in that common year, March 11. Therefore at length the year of Yazdegird 814, and day 17 of Tyrma, falls on day 11 of March of the year of Christ 1445. [Margin: Pag. 2.]

Precept 42. To reduce a given Year of the Epoch of Christ, and a day of the Month, to a Year of Yazdegird, and a day of the Persian Month.

From the given Years of Christ (which I suppose to be not fewer than 632 years) subtract the years 632. Then resolve the complete Residues into days by Table 21, the uppermost Class; and to it add the number of days of the Month completed, and the days running of the given month; then to all these add the perpetual 199. To the sum of all the days collected, and with this from Table 21, Class 2, likewise collect in the left margin the complete Persian years, by one or more entries, and likewise the complete Persian Month; for the remaining days will look to the following Persian Month. [Margin: Pag. 15.]

Example. The same as above, but conversely. Let the given year of Christ be 1445, and day 11 of March: it is asked, what was the year of Yazdegird, and which Persian Month? With 632 subtracted from the year 1445, there remain 813 running, but 812 complete, with which, and with day 11 of March, thus from Table 21, you will collect the days: [Margin: Pag. 15.]

	Dies [Days]
Anni Iuliani 800. dant [800 Julian years give]	292200
Et Anni 12. dant [And 12 years give]	4383
Adde his perpetuò [Add to these perpetually]	199
Et pro 11. Martij Tab. 6. [And for 11 March, Table 6]	70

	Dies [Days]
Fit summa Dierum [The sum of Days makes]	296852

With which, from Table 21, Class 2, taking out the Persian Years, Months, and days thus: [Margin: Pag. 15.]

	Anni Persici [Persian Years]
Dies 292000. dant [Days 292000 give]	800
Restant D. 4852. quorum 3659 [There remain 4852 days, of which 3659]	10
Restant 1202. quorum 1095. [There remain 1202, of which 1095]	3
Restant dies 107. [There remain 107 days]	
Summa Annorum complet. [The sum of complete Years]	813

Therefore the year of Christ 1445, day 11 of March, falls in the Yazdegird year 814; but the 107 days which are over fall in the same Table 21 of the Persian Months, namely day 90, and the remaining 17 look to the month Tyrma, wherefore day 11 of March of that year agrees with day 17 of the month Tyrma.

Caution for the remaining Epochs.

The mutual transformation of the remaining Epochs you may either work out from Table 25, or from our Reformed Chronology, since the rest pertain to the Chronologer more than to the Astronomer — thus far.

Precept 43. On the Absolute constitution of Time for the motions of the heavenly bodies to be elicited from Our Tables.

Hitherto all the precepts have pertained almost entirely to Time. It remains, therefore, that we indicate by what method Time is to be constituted, so that the Celestial Motions may be elicited from these our Tables, and accommodated to other places too, or to other times: which constitution is reducible to two Heads.

The First is, if some Celestial Phenomenon — say, an Eclipse of the Moon — deduced from Our Tables ought to be transferred to other places distant from our Bologna Meridian, or also to other kinds of hours, indeed also to other kinds of Years, Months: kinds diverse from the Years of Christ, or before Christ, which in these our Tables we use according to the Julian form, and then the Gregorian. As,

if the beginning of a Lunar Eclipse is to be elicited from our Tables, and then announced, at what hour not only Astronomical, but also Babylonian, or as it appears European [Europaea], or as it appears elsewhere — say, at Constantinople — and at what day, and according to the month of the Arabic year. In this case: First, the equal time used in our Tables of the mean motions, after the calculation of the Eclipse is absolutely converted into Apparent, or at its appearing at our Bologna Meridian in Astronomical hours, or after midday; and this by Precept 16. Second, by Precept 17, this time ought to be accommodated to the Constantinopolitan Meridian; in which, if the Babylonian hours are observed, known by Precept 14, the semidiurnal quantity, the Astronomical hour ought to be converted into the Babylonian by Precept 12; and at length by Precept 40, the year of Christ, the Month, and the day Julian, in which the Eclipse is announced, ought to be reduced to the Year of the Hegira, the month, and by Precept 22 [recte], to the Arabic day, and by Precept 22, to the Feria [weekday]. But with these many other precepts from the foregoing afford help.

The Second Head is, if some Phenomenon — say, an observed beginning of a Lunar Eclipse, or a computed one — has been in another Meridian — say, Constantinople — and expressed by other hours, say enunciated by Babylonian hours, and by days, and years of diverse kind, say by Babylonian hours, and by days, of the Arabic Month, and of the Hegira. Then First, the time there appearing must be commuted into equal time by Precept 16. Second, by Precept 17, this time ought to be transferred to time congruent with the Bologna Meridian, and by Precept 14, to know the semidiurnal quantity, and by Precept 12, to convert the Babylonian hour into the Astronomical. Afterwards, by Precept 39, the year, month, and day of the Hegira must be transformed into the Julian Year of the Epoch of Christ, the Month, and the Julian Day.

Often too, in the observations of the Ancients, the Temporal Hours are to be reduced to equal ones by Precept 13.

On the Beginning of Days, and of Years, in Our Tables.

We take the Beginning of Days astronomically from the noon made under the Bologna Meridian, and the beginning of the days of the year, or the principle of the year, we begin from the noon preceding the last day of December, so that thereafter the Days named may be employed as complete. As, if we examine an Eclipse to come at the 4th hour after Midday of the first day of January, the mean Luni-Solar motion is to be collected of one whole day, and besides of hours 4, etc.

There follow the Precepts for the use of the Tables of the Second Part.

Precept 44. *Given the place of the Sun on the ecliptic, or any point of the ecliptic, to find its declination.*

[Margin: Pag. 19.]

This is accomplished by means of Table 26. Look for the sign at the top if the degrees of the sign descend, or at the foot of the table if the degrees ascend in the right-hand column. For at the common intersection of the sign and the degree you will have the declination sought. It is northern if the ecliptic signs are northern, southern if they are southern; and a proportional part is to be applied if there is one.

Example. Let the place of the Sun be given, say, at Taurus $10^{\circ}20'$. In the table, the degree of Taurus 10° corresponds to a northern declination of $14^{\circ}51'16''$, and the following degree 11° gives $15^{\circ}17'7''$. The difference of these is $18'51''$, which, multiplied by $20'$ and the product divided by whole degrees, leaves a difference of $7'42''$, to be added to the $14^{\circ}58'58''$ at degree 14. So that the declination at Taurus 10° becomes $14^{\circ}58'58''$ for Taurus 10° .

Precept 45. *Given a point of the ecliptic, to find the angle which it makes at that point with the meridian, or with any circle of declination.*

[Margin: Pag. 19.]

Therefore, in Table 27, find the given sign at the top and its degree in the left-hand column, or the sign at the foot and its degree in the right-hand column. For in the common area you will have the angle, rising toward the eastern point, or toward the southern or northern pole, as the marginal note "Austr." or "Bor." indicates. Moreover, the angle adjoined to these is itself equal, and the angle which is to its west is the complement of the prior one to 180° . The western angle, however, faces toward the same prior pole, and likewise the rising angle faces toward the other pole.

Example. Let the meridian pass through Taurus 10° . For in Table 25 the eastern angle agrees: $71^{\circ}35'$, which the ecliptic makes there with the meridian; and this angle, as the note "Bor." indicates, is northern. Therefore the western angle is also northern, but faces toward the south, being $71^{\circ}35'$; its complement to two right angles is $108^{\circ}25'$. So great, then, is the angle, both north-western and south-eastern, of the ecliptic with the meridian or with any circle of declination.

Precept 46. *Given a point of the ecliptic, or of the Sun lying in it, to find its right ascension.*

[Margin: Pag. 19.]

Consult Table 28, noting the sign at the top and its degree in the left-hand column directly beneath the sign. Directly opposite the degree you will have its right ascension, using nevertheless a proportional part if the degree of the sign has any minutes adhering.

Example. To Taurus 10° corresponds a right ascension of $37^\circ 34' 46''$. At Libra 0° the right ascension is $205^\circ 9' 11''$.

Precept 47. *Given the altitude of the pole and the declination of a point of the ecliptic, or of the Sun, or rather of any heavenly point or star, to find its ascensional difference.*

[Margin: Pag. 21. vel 24.]

This ascensional difference is the arc of the equator by which the right ascension of any point or star differs from its own ascension in the oblique sphere, that is, from its own oblique ascension. Therefore go to Table 29, or 30, and at it inquire, either by the altitude of the pole at the top and the declination, or by the altitude of the pole in the right-hand column and the declination at the top; the common area will give the ascensional difference. In Table 29, however, the obliquity of the ecliptic is supposed to be $23^\circ 30'$. But it is more precisely $23^\circ 30' 20''$; therefore we add, for this obliquity, [Margin: Pag. 24.] Table 30, [Margin: Pag. 21.] adjusted to our altitude of the pole, which at Bologna at S. Petronio is $44^\circ 30' 20''$. But this difference of the venous reckonings [variant readings] serves the tables for other altitudes, except that in this table, apart from that, the ascensional difference which corresponds immediately to the degrees of the ecliptic, to which the Sun alone, is here omitted.

Example 1. Let the declination of the Sun, or of any ecliptic point, of degree 20° and altitude of the pole $44^\circ 30'$, be given. For in Table 29, with the altitude of the pole $44^\circ 30'$ found at the top and the declination 20° in the left-hand column, the common area gives an ascensional difference of $20^\circ 35'$.

[Margin: Pag. 21.]

Example 2. In Table 30, at the degree of Taurus $19^\circ 5\frac{1}{2}'$, to which a declination of 20° agrees, the altitude of the pole at Bologna answers with an ascensional difference of $20^\circ 58' 15''$.

[Margin: Pag. 24.]

Precept 48. *Given the right ascension of any heavenly point and its ascensional difference, to form its oblique ascension.*

To the right ascension of a point declining toward the elevated pole, subtract the ascensional difference; but add it if it declines toward the unseen pole. For thus will be formed the oblique ascension of the same ecliptic point; and in this way you will examine the tables of oblique ascensions.

Example 1. At Taurus $19^{\circ}5\frac{1}{2}'$, as said above, a northern declination of 20° agrees, and to this, under the altitude of the pole $44^{\circ}30'$, an ascensional difference of $20^{\circ}58'15''$ agrees; and the right ascension of the same point is $46^{\circ}58'55''$. Therefore, by subtracting the ascensional difference from the right ascension, its oblique ascension becomes $36^{\circ}0'40''$. But if it were beyond the equator — that is, the calculation lies beyond the equator, where the northern pole is not visible — one must add the ascensional difference to the right ascension.

Precept 49. *Given the altitude of the pole and a point of the ecliptic, or the Sun lying in it, to elicit its oblique ascension by the tables prepared for the purpose.*

[Margin: Pag. 25.]

If the altitude of the pole is so great, however great, use Table 31. For in it, with the sign at the top and the degree of the sign observed in the right-hand column, you will have in the common area the oblique ascension of the ecliptic point. But for the altitudes of the pole use Table 32. [Margin: Pag. 26.] Exhibiting the ascension, but of the northern signs in the northern horizons, by seeking their degree in the left-hand column, or of the southern signs in the southern horizons, by seeking their degree in the right-hand column ascending. But if you prefer the oblique ascensions of the northern signs in the southern horizons, or of the southern signs in the northern horizons, then, by region of the degree, find it in the area beneath the given altitude of the pole, subtract from the degrees 360° : the remainder will be the oblique ascension, as much as you wish.

Example. Under altitude of the pole 40° , the oblique ascension of Taurus 16° is $28^{\circ}55'$, and these are northern; and the same is the degree of Aquarius 14° among the southern. But the oblique ascension of Aquarius 14° among the northern is $331^{\circ}5'$.

Precept 50. *Given the apparent time after noon, the place, and the altitude of the pole; to find then the Sun, the rising degree of the ecliptic (which they also call the Horoscopus), and which is the nonagesimal degree of the ecliptic, to be reckoned from the rising point?*

[Margin: Pag. 19. / Pag. 3.]

First. By Precept 46, find the right ascension of the place of the Sun; add to it the time from noon, previously turned by Table 3 into parts of the equator, which corresponds to the degrees 360° . If the sum exceeds those, take the residue away, with the residue, and the right ascension of the middle of the heavens [Medium Coeli] then culminating.

Second. Add to the culminating point of the equator 90° , and the oblique ascension of the rising degree of the ecliptic will come forth, which, if it does not exceed 180° , is sought in the areas of [Margin: Pag. 25. / vel 26.] Table 31 or 32, under the agreeing altitude of the pole, showing at the top the sign, and in the left-hand column of the sign **then** [continued below]

then rising, or the Horoscopus. But if the oblique ascension exceeds 90° , subtract it from 360° ; and with the residue found in the areas of the oblique ascensions Table 31 or 32 investigated, as above, you will find the sign, and the degree of the rising ascension.

Third. From the rising ecliptic degree, take away 90° , and the nonagesimal ecliptic degree will be known, which we shall teach more amply, but chiefly with respect to the parallaxes for solar eclipses, when in its place we treat of it.

Example. Let Bologna be where the pole is elevated $44^\circ 30'$. Let the apparent time after noon be 4 [hours] $30'$, and then let the Sun be at Taurus $29^\circ 5' 30''$. The operation is established thus:

	Gr.	'	"
The hour $4^\circ 30'$ by Table 7 gives	67	41	6
Right ascension of the place of the Sun by Table 29	56	58	55
Sum, or culminating point	124	40	1
Add the degrees	90	0	0
Becomes the oblique ascension sought	214	40	1
With this taken away, 360° remain	145	19	59
With this $19'$ by Table 29, Virgo	3	36	30
Take away the rising	90	0	0
Becomes the nonagesimal ecliptic, Gemini	3	36	30

The optimal rising Horoscopus is therefore Virgo $3^\circ 36' 30''$, and the nonagesimal computed thence is Gemini $3^\circ 36' 30''$.

Precept 51. *Given the rising ecliptic point and the altitude of the pole, to find the altitude of the nonagesimal, or the angle of the ecliptic and the horizon.*

[Margin: Pag. 38.]

Go back to Table 33, which begins on page 38. In it there is need, if there is occasion, of a proportional part. Seeking at the top the altitude of the pole, and in the left-hand column the sign with the degree of the rising ascension, descend numbering the degrees, or in the right-hand column the sign with the degree upward numbered; the common area will exhibit the altitude of the nonagesimal.

Example. Let the rising ecliptic degree be Virgo $3^{\circ}36'30''$, under altitude of the pole $44^{\circ}30'$. From Table 29 itself, with the 3° it is gathered for a proportional part the altitude of the nonagesimal $65^{\circ}52'52''$, or roundly $65^{\circ}53'$.

Precept 52. *To resolve the degrees of the zodiacal signs, or of any circle whatever collected, into degrees from the beginning of the sign.*

[Margin: Pag. 19.]

This our Table 24 immediately teaches, in which, for instance, the degree 25 in the left-hand column corresponds to the degree 205 reckoned from the beginning, that is, beneath Libra 205° , that is, sub 295° ; and so of the rest. But if at the beginning of any circle, say, the integral signs are taken up, and besides those there adhere some degrees, the degrees of the following sign are congruent, that is, if there were complete anomaly signs 4, and degrees 25, not in the column of sign IV. but the degrees collected in the same sign 31 are sought; and as above sign IV. with the region of degrees 25, the collected degrees are 145.

Precept 53. *To find at once the degree of the zodiac diametrically opposite a given one; so that, given the degree of the rising ascension, the degree of the descending be known.*

[Margin: Pag. 19.]

In Table 25 you have each pair of opposite signs, but in the table joined with the degrees opposite, that is, in the first conjugation of degrees 16. Aries is opposed to degree 196; likewise, in the second conjugation of degrees 16. Gemini, which is of degree 76. of the zodiac, is opposed to degree 256. of the zodiac. Therefore, given the degree, sign, and degree of its rising ascension, the degree of the descending sign will be known at once.

Precept 54. *Given the longitude and latitude of any star, but not greater than 90° , to obtain its declination and right ascension.*

[Margin: Pag. 19.]

First. By Precept 44 and Table 26, learn the declination of the ecliptic point which the given longitude designates, and by Precept 46 and Table [Margin: 8 20.] 28 its right ascension.

Second. From Table 34, take out the prosthaphaeresis of declinations, observing the latitude given at the top, and the sign and its degree in the left-hand column, or the degree in the right-hand column. For the common area will give the addendum of the declination to the declination of the ecliptic point, if the sign and the latitude are of the same region, or affection; that is, if the latitude is northern, and the latitude also is northern: but it is to be subtracted if they are of contrary affections; and you will have the declination of the star.

[Margin: Pag. 43.]

Third. From Table 35, similarly take out the prosthaphaeresis of right ascension of the ecliptic point, as the conditions explained at the top require, or in the foot of the table; and so you will form the right ascension of the star.

[Margin: Pag. 43.]

Example. Let Spica, or the southern latitude of Jupiter, be given, of degree 2° and longitude in Libra 18° . For this is in the degree of Libra, and the southern declination by Table 26 is $7^{\circ}4'47''$, and indeed of southern latitude; therefore, since these are of the same species of sign, and of latitude, there will be a prosthaphaeresis of declinations to be added; for under the southern latitudes degree 2° , and from the region degree 18. Libra, that is degree $1.11'$, which, the degrees $7^{\circ}4'47''$ being added, makes the southern declination of Spica $8^{\circ}15'47''$. Then the right ascension of Libra by Table 28 at degree $196^{\circ}35'31''$, and the southern latitude of Spica, or of Jupiter, being assumed at degree 2° . Australis, and the prosthaphaeresis being likewise southern, there will be a prosthaphaeresis to be added; this however in the left-hand part of the table, from the region of degree 18, and sub latitude. Australis degree 2° and $46'$. Therefore of Spica, or of Jupiter the right ascension will be $197^{\circ}21'31''$.

There follow the Precepts for the use of the Tables of Part III, that is, on the Motions of the Sun and of the Moon.

Precept 55. *To find the true place of the Sun on the ecliptic, and its anomaly, for a given time of the era of the common reckoning of Christ.*

First, if the given time is apparent, convert it into equated [time] by Precept 16.

[Margin: Pag. 44.]

Second, from Table 36, collect the mean motion of the Sun, and of the apogee of the Sun, agreeing with the epoch, by the radix nearest preceding the given year, and the years after the epoch completed, and likewise by the months completed of the current year, whether of the quality of the common or current year, and by the days given — always employing them as completed; and at length by the hours, and the scruples after noon, and collect the mean motion of the Sun separately, and separately the mean motion of the apogee of the Sun.

Third, subtract the motion of the apogee from the mean motion of the Sun (the assumption being made, whenever the subtraction cannot be done, of 12 signs); and the simple anomaly of the Sun will remain, that is, the distance of the Sun itself from the apogee.

[Margin: Pag. 46.]

Fourth, with the simple anomaly of the Sun, take out from Table 38 the equation to be subtracted, in the prior semicircle of anomaly; that is, when the signs of the anomaly are at the top of the table, and these in the left-hand column of the table; the addendum, however, in the latter, that is, when the signs are in the right-hand column, in the foot of the table, and these, whether it pleases the circular form, or the elliptical form, and by the equation correct both the mean motion of the Sun, and the simple anomaly of the Sun itself; for thence will come forth the true place of the Sun on the ecliptic; thence the equated anomaly of the Sun.

Example.

The true place of the Sun is sought for the Year of the Epoch of Christ 1661. September on the 23rd day, 1 hour 1 minute 30 seconds after noon at Bologna. First, then, since the Sun then will be in the first degree of Libra by the Table of Temporal Equations, [Margin: Pag. 8.] the double-equation to be subtracted is found 4'23"; therefore the equated time will be 1 minute 26 [seconds?] after noon; and then the form of the calculation will be thus:

Mot. ☉ Med. ab ♀ (Sign.								
Years	Gr. ' ")	Apog. (Sig. Gr. ' ")						
1600	Sign.	G	'	"	Sig.	G	'	"
		r				r		
		.				.		
Radix	9	1	4	3	3	7	3	8
		0		5			9	

Years	Mot. ☉ Med. ab ♀ (Sign. Gr. ' ")	Apog. (Sig. Gr. ' ")					
An. 60.	0	0	2	3	0	1	2 5
			7	6			
Augu sti	7	2	3	4	0	0	0 4
		9	0	4			1
D. 23.	0	2	4	1			
		2	0	2			
H. 1.	0	0	2	2			
				8			
M. 26.	0	0	1	4			
Sum ma	6	2	4	3	3	8	4 5
			6	9			1 4

Second, therefore, with the signs of the apogee subtracted, 3 signs 8°41'54", from the mean of the Sun, the simple anomaly of the Sun remains, and thence will be had the equation of each, as below.

	Sig.	Gr.	'	"
Solis Medius [Mean of the Sun]	6	2	46	39
Apogei motus [Motion of the apogee]	3	8	41	54
Anomalia simplex [Simple anomaly]	2	24	4	45
Aequatio subtracta in forma circulari [Equation subtracted in circular form]	0	1	58	49
Restat Verus locus ☉ [The true place of the Sun remains]	6	0	47	50
Et Anomalia coaequata [And the equated anomaly]	3	6	43	5

The Sun will therefore then be at the first degree of Libra, not yet complete, but distant from it by the absolute 47' and 50" of that degree; and it will be distant from the true apogee by signs 3, degrees 6, 43'5"; that is, with the signs resolved into degrees, it will be distant from the apogee by 96°43'5".

Warning concerning the Julian and Gregorian style.

In the example adduced we have used the Radix of the year 1600 according to the form of the Gregorian year; but if we were to use the old Julian style, the Radix of

the year 1600 in the old Julian style would have to be applied, congruent with that which Table 36 has for the mean of the Sun, Signs 9, degrees 19°55'58".

Precept 56. *To find the true place of the Sun for a given time before the Epoch of Christ.*

[Margin: Pag. 19.]

With the apparent time reduced to equated by Precept 16: if the given year before Christ is one of the hundreds [centuries] themselves, or of the thousands, use the Radix noted for that century, or chiliad, in Table 36; and then there will be no need to collect the mean motions for the years from the radix as distinct ones. For the years before Christ in the aforesaid Table are reckoned complete, indeed by numbering them from Christ upward toward the beginning of the world; but they are current years, if they are numbered downward toward the Epoch of Christ, nor are they complete, except in the case where the given time was the noon of the last day of December, or after the noon of the same last day of December. But the remainder for the months, days, hours, and scruples are to be carried out as in the preceding Precept 55.

But if the given year is not one of the hundreds [centuries] or thousands, the year is to be subtracted from the nearest expanded hundred of years, and the residue will be the number of complete years, for which the mean motion is to be sought; but the Radix to be applied will be that of its century, or millenary, which most nearly precedes, that is, which is most nearly greater; but the remainder is to be performed entirely, as in Precept 55.

Example One.

The true place of the Sun is sought for the Year before Christ 200. September 23, hour equated after noon 1[h] 26'. The true place of the Sun at Bologna will be thus:

Ante Chr. [Before Christ]	Motus ☉ (Sign. Gr. ' ")	Apog. (Sig. Gr. ' ")	
Radix — Anni 200.	9	6 8 1 2	6 3 4 6 8
Augusti	7	2 3 4 0 9 0 4	0 0 4 1
D. 23.	0	2 4 1 2 0 2	

Ante Chr. [Before Christ]	Motus ☉ (Sign. Gr. ' ")	Apog. (Sig. Gr. ' ")	
H. 1.	0	0 2 2 8	
M. 26.	0	0 1 4	
Summa	5	2 2 2 2 8 2 9	6 3 2 7 9
Anomalía ☉ simplex [simple anomaly]		3	2 4 0 1 5
Aeq. subtr. [equation subtracted]	0	1 5 1 0 1 3	1 5 1 1 3
Verus ☉ [true Sun]	5	2 3 1 6 1 6	
Anomalía ☉ coaequata [equated anomaly]		3	1 5 4 9 3 7

Precept 57. *To find the parallax of the Sun in the circle of altitude.*

[Margin: Pag. 45.]

It is presupposed known, in any case, whether the anomaly of the Sun is at least near the maximum, or near the mean, or near the minimum distance from the Earth; for Table 37, in the column of the aforesaid distance, or assigned to the signs of the anomaly, and from the region of the degrees of the given altitude, will exhibit the parallax of the Sun, in which by how much the values of Ptolemy, Copernicus, and Tycho have differed exceedingly.

Example.

In the example of Precept 55, the anomaly of the Sun was found to be of Signs 3, and about 7°, the altitude of the Sun being given from the horizon as 45°29'. For in Table 37, in the column corresponding to signs III. and from the region of degree 45°29', you will have a parallax of 11'10", using a proportional part.

Precept 58. *To find the distance of the Sun and of the Moon from the center of the Earth, but of the Moon in conjunctions [syzygies], together with the horizontal parallax and the hourly motion of each; but to find the true motion.*

[Margin: Pag. 47.]

The anomaly of the Sun by Precept 56 being known, and in Table 38 it shows at once from the region toward the right the distances of the Sun from the center of the Earth, in parts of which the radius of the solar orbit is 100000; then in semidiameters of the Earth, and the horizontal parallax, and the hourly motion of the Sun. But these three conditions of the Moon, the anomaly of the Moon will show, when it has been known by Precept 61, or otherwise. In the distances

and although for the Sun we generally use Hypothesis 1 (on which see *Astronomia Reformata*, book 1, chapter 13), still, if anyone prefers Hypothesis 2, set out in the same place at chapter 17, the Sun's distance can be found from the same Table 39 on either hypothesis.

Example

Suppose that both the Sun's and the Moon's anomaly is 95 degrees. In Table 39, then, the stated conditions of the two luminaries stand as follows:

		Value
Distance to the radius 100000	☉ (Sun)	99844
	☾ (Moon)	99905
In semidiameters of the Earth	☉ on hypothesis 1	7289
	☉ on hypothesis 2	6543
	☾	60 · 57
Horizontal parallax	☉	0' 28" 16"
	☾	56' 26" 0"
True hourly motion	☉	2' 29"
	☾	33' 11"

Precept 59. To determine the apparent semidiameters of the Sun and Moon at syzygies and in the shadow, and the [semidiameter] of the terrestrial body in the passage of the Moon through the shadow.

Once the luminaries' anomaly has been equated, look up the semidiameter of the Sun, of the Moon, and of any planet whatever in Table 39, taking the one that corresponds to the anomaly; but for the semidiameter of the shadow, look up the value answering to the Moon's equated anomaly. For you will obtain the apparent semidiameter of the terrestrial shadow-disk at the place of the Moon's passage — but on the supposition that the Sun is at apogee. Therefore, in the

region opposite the Sun's anomaly you must always apply the Variation to the semidiameter of the shadow, so that it comes out corrected.

Example

		Gr.	'	"
Let the anomaly be	of the Sun	95	0	0
	of the Moon	120	0	0
The apparent semidiameter will then be	☉		15	47
	☾		15	44
Shadow, with Sun at apogee			45	44
Variation			0	43
Shadow's semidiameter, therefore, corrected			45	1

Precept 60. To investigate the refraction of the luminaries and of the fixed stars, and by means of it to convert their altitude-parallax into apparent altitude, and to turn their apparent altitude into true, or their true altitude into apparent.

In Table 40 I have set out these refractions for the temperate zone, since I have had more reliable experimental data for it; I have suppressed the refractions of the other zones, especially the frigid ones, because their measure is inconstant and not yet ascertained. As to why I have departed from the Tychonic table, enough has been said in book 1 (*Astronomia Reformata*, chapters 14 and 15). With this noted in advance, examine the following rules.

The Moon's *observed altitude* is converted into *true altitude* by subtracting the refraction it has, then its parallax, and the residue [of the latter]; or, if you prefer, by adding the Moon's own parallax to its apparent altitude — on which see Precept 71.

The Moon's *true altitude* is converted into *observed altitude* by subtracting the parallactic refraction and adding back the residue to the true altitude.

The *observed altitude* of the Sun, of the remaining planets, and of the fixed stars is converted into *true altitude* by subtracting from the observed altitude the simple refraction. The *true altitude* [is converted] into apparent by adding the true refraction.

Precept 61. To find the true place of the Moon in its own orbit at a given time within [the period of] a new moon, or to find the day of the full moon together with the lunar anomaly.

For a time reduced to the Bologna meridian and equated as above (as was done for the Sun in Precept 55, or, if it falls before Christ, by Precept 56): gather from Table 41 the radix immediately preceding the given year, together with the mean motions of the Moon from the beginning of Aries and the anomaly for the completed years, months, and for the assigned day, hours, and minutes; and reduce them into a single sum — the mean motion of longitude separately and the anomaly separately. Then go to Table 42, and in it look up the signs of the anomaly at the head, and the degrees of the anomaly down the left side if the signs are descending; or look up the signs of the anomaly at the foot, and their degrees ascending up the right side if the signs are in the right-hand column. For in the common area you will find — by interpolating proportionally, if need be — the equation, to be subtracted from or added to both the mean motion of longitude and the lunar anomaly, just as the headings at the top mark it *To be subtracted* or at the foot mark it *To be added*. And you will have the Moon's true place — that is, its first equated place (which suffices for syzygies) — and the Moon's equated anomaly.

Example

For the year of Christ 1661, on the 23rd day of September, at the Bologna hour 1^h 26' equated past midday, the Moon's true place is sought. The computation will be ordered thus:

		Motion of ♀ from ♈				Anomaly				
Radix	Sig.	G ' ''				Sig.	G ' ''			
		r					r			
		.					.			
Years 1600	7	2	1	2	0		7	2	9	
		5	9	0				7		
Years 60	1	1	4	1	3		2	6	4	
		0	1	9			9			
August completed	10	2	5	5	9		2	4	2	
		1	1	0			4	7	6	
Day 23	10	3	3	2	10		0	2	4	
				5				9	1	

	Motion of ☾ from ♀		Anomaly	
Hour 1	0	0 3 5 0		0 3 4
		2 6		2 0
Minute 26	0	0 1 1		1 9
		4 6		4
Sum	6	1 4 6 0		2 3 9
		3		7
Equation, subtractive		1 1		1 1
		3 5		3 5
Therefore	6	1 2 5 0		2 2 5
		9 1		3 4
True place ☾			& anomaly equated	

The Moon, then, was in 2° of Libra, not yet complete in its orbit.

Precept 62. To find the true place of the Moon's northern node at a given time, and the Moon's greatest latitude.

For a time reduced to the Bologna meridian and equated, as above in Precept 55 or 56: gather from Table 41 the mean motion of the node ☾ for the given years, months, and likewise for the days, hours, and minutes; reduce them into a single sum, subtract it from the radix of the node's mean motion immediately preceding, and you will have the mean motion of the node ☾. Then, with the true place of the Sun found by Precept 55 or 56 and that of the Moon by Precept 61, gather the true distance of the Moon from the node, and with this distance — or, if it exceeds six signs, with the Moon's distance from the point opposite the Sun — enter Table 43. For in it, with the signs of the distance examined at the head and the degrees down the left side, or the signs at the foot and the degrees down the right side, you will have in the common area the equation of the node ☾, to be subtracted from or added to the mean place of the node, so that you have the true [place]; and on that same occasion, from the region of the Equation-numbers, you will have the greatest latitude to be assigned for the following precept.

Example

For the year of Christ 1661, on the 23rd day of September, at the Bologna hour 1^h 26' equated past midday, the true place of the node ☾ is sought. It will be found thus:

	Sign.	Gr.	'	"
Years 60	2	20	30	40
August completed	0	12	52	5
D. 23		1	13	5
H. 1				5
M. 26				8
B. Sum	3	4	35	58
Radix Year 1600	9	11	22	50
B. sum subscribed	3	4	35	58
There remains the mean place of the node Ω	6	6	46	52

Then, since by the example of Precept 55 and Precept 62 —

	Sign.	Gr.	'	"
There was the true place $\odot$	6	0	47	50
the true place of the node Ω	6	1	29	50
Distance of $\odot$ from Ω	0	0	42	0
Therefore the equation of the node Ω , subtractive	0	0	2	41
True place of the node Ω	6	6	44	11
And greatest latitude of $\curvearrowright$	0	4	58	30

Precept 63. To find the true latitude of the Moon, and its Argument.

Once the true places of the luminaries and of the node Ω at the given time have been reckoned by Precepts 55 (or 56) and 61, and the greatest latitude has been reckoned and looked up by Precept 62: subtract the true place of the node Ω from the assumed true place of the Moon; if the subtraction requires it, borrow 12 signs; and you will have the equated argument of latitude — that is, the *Argument of Latitude*. Then look up its signs at the head of Table 44 and its degrees down the left side, or its signs at the foot and degrees down the right side. For from the region of the degrees beneath the signs, or above the signs of the Argument, and under the heading of the greatest latitude, you will find the desired latitude of the Moon — northern or southern, as the headings of the table indicate.

Example

Now in the examples of Precepts 61 and 62 the places of the Moon and of the node Ω stood as follows:

	Sign.	Gr.	'	"
True place ☽	6	1	29	51
True place of node ☾	6	6	44	11
Therefore the Argument of latitude	11	24	45	40
The greatest latitude was	0	4	58	30
Therefore the true southern latitude ☽	0	0	26	55

For I added 12 signs to the place of the Moon, so that the place of the node could be subtracted from it.

Precept 64. To reduce the true place of the Moon from the orbit to the ecliptic, and from the ecliptic to the orbit.

Since the Moon's orbit is inclined to the ecliptic — so that you may know the Moon's ecliptic place, namely the one which the latitude-circle drawn through the center of the Moon to the ecliptic determines — take by Precept 63 the Argument of latitude, and look up its signs at the head of Table 45 and its degrees down the left side, or the signs at the foot and degrees down the right side. For in the common area you will have the *Reduction* of the Moon to the ecliptic, to be subtracted from or added to the orbital place of the Moon, as the headings above or below indicate. With these headings reversed, the opposite must be done if the Moon's place is to be reduced from the ecliptic to the orbit.

Example

The true place of the Moon in the orbit by the example of Precept 61, and the Argument of latitude by the example of Precept 62, stood as below:

	Sign.	Gr.	'	"
☽ True place in orbit	6	1	29	51
Argument of latitude	11	24	45	40
Reduction, additive			1	16
True place in the ecliptic	6	1	31	7

Precept 65. To investigate the true place of the Moon outside of syzygies.

Gather by Precept 55 (or 56) the true place of the Sun, and by Precept 61 the true place of the Moon in its orbit, and the Moon's first-equated anomaly. Then subtract the true place of the Sun from the true place of the Moon (borrowing 12 signs if need be), and you will have the true distance of the Moon from the Sun. If

this should exceed six signs, the excess above a semicircle will be called the distance of the Moon from the point opposite the Sun; and with that distance consult Table 47, looking up the signs of the distance at the head when it is less than three signs, and on the left side; the signs and degrees of the anomaly being equated. But if the distance is greater than three signs, look up the distance at the foot of the table, and the anomaly's signs and degrees on the right side. For in the common area you will have the Moon's final equation, composed of the equation of the eccentricity and the Variation; and add it to, or subtract it from, the Moon's first-equated place, as the headings at the top or foot of the table, or in the middle the letters A or S, will indicate. (Let Argolus, on the strength of his astrological observations, reject the Tychonic Variation.)

Example

For the year 1661, on September 26, at hour 1 equated past midday at Bologna, the true place of the Moon in its orbit is sought. It will be investigated thus:

	Motion of ☉			Apogee		
	Sig.	G r.	'	"	Sig.	G r.

Precept 66. To inquire into the hourly motion of the Moon away from the Sun on the days of full moon and new moon.

With the Moon's first-equated anomaly found by Precept 61, consult Table 48, looking up the signs of the anomaly at the head and on the left side, or its signs at

the foot and degrees on the right side. And in the common area you will have the true motion — that is, the space of the zodiac which the Moon, by its hourly motion together with the Sun's, traverses in the hour of full moon or new moon; or [the space] which one or the other accomplishes within the 12 hours before or after the new moon or full moon.

Example

Returning to the example of Precept 61, the Moon's equated anomaly was 0 signs, 2°, 23' 54". Therefore, by Table 48, the Moon's hourly motion in the hour of that new moon is 27' 44".

Precept 67. To define the true new moon, or full moon, precisely at a given time — or within 12 hours of it.

If, by the Sun's computed [place] and the Moon's true motion reckoned by Precepts 55 and 61, the Moon should differ from conjunction or opposition with the Sun by more than 6 or 7 degrees, then inquire by Precept 66 into the Moon's hourly motion, together with the hourly motion of the Sun set out at the head of Table 49. And look up in the same table the degrees, minutes, and seconds by which the Moon either falls short of, in the zodiac, or follows after, the place of the Sun [or its opposite]; and add the scruples answering to the time of the nearest new moon or full moon, if the Moon falls short of the Sun or its opposition, or subtract them if it follows after.

Example

From what was said in the example of Precepts 55 and 61, the Sun's true place was 6 signs, 0°, 47' 50", and the Moon's place 6 signs, 1°, 29' 51". The Moon's hourly motion by Precept 66 was 27' 44". Therefore in Table 49, under the headings of hours 27 and 28: using the proportional minutes, you will see [the value] answering to 42' 1". Answer for the time given, which is hour 1^h 26': the new moon will fall out at hour 1^h 26', 7' before midday on the 23rd day of September of the year 1661.

Precept 68. To find the Moon's greatest and least distance from the center of the Earth outside of syzygies, and [to find] the eccentricity.

I have taught how to find the Moon's distance from the Earth at syzygies in Precept 58. But outside of syzygies, the eccentric anomaly is required, which equals the doubled distance — namely the distance of the Moon from the Sun found on that occasion by Precept 65. Looking it up in the left-hand columns of

Table 50, you will find, proceeding rightward, the eccentricity of the Moon's orbit, both in parts of which the orbit's radius is 100000 and in semidiameters of the Earth. Then, in the remaining columns, you will find the Moon's greatest distance and its least, expressed separately for the several syzygies, according to the lunar theory I have handed down in *Astronomia Reformata*, book 3.

Example

In the case of Precept 65, we had the Moon's elongation from the Sun of 1 sign, 6°, 19'; which, resolved into degrees, makes 36° 19'; and this doubled makes the eccentric anomaly of 72° 38'. With this in Table 50 you have the interval written below, using the proportional part:

	Of which the radius is 100000	Semidiameters of the Earth	
› Eccentricity	8436	4	3 4
› Greatest distance	108436	65	3 4
› Least distance	91568	56	2 4

Precept 69. To inquire into the Moon's distance from the center of the Earth outside of syzygies.

With the eccentric anomaly — which in the preceding precept you learned to find, that is, the doubled distance of the Moon from the Sun — look up in the head of Table 51 the elongation, having sought it [there]; and with the eccentric anomaly of the orbit equated in the left-hand columns, you will at once find the Moon's distance from the Earth in semidiameters of the Earth.

Example

In the example of Precept 65, the Moon's elongation from the Sun was 1 sign, 6°, 19' — that is, 36° 19'; this doubled gives the eccentric anomaly of 72° 38'. But the Moon's equated orbital anomaly was 1 sign, 10°, 36' — that is, 40° 36'. To these in Table 51 corresponds the Moon's distance from the center of the Earth in semidiameters, 64° 20'.

Precept 70. To find the Moon's apparent semidiameter and horizontal parallax outside of syzygies.

Look up by Precept 69 the Moon's distance from the center of the Earth, and with it you will at once have, in Table 52, the apparent semidiameter and the horizontal parallax of the Moon.

Example

In the example of Precept 69, the Moon's distance was 64 semidiameters 20' of the Earth. To this Table 52 shows the Moon's apparent semidiameter 14' 39", and the horizontal parallax 53' 27".

Precept 71. To investigate the Moon's parallaxes in the circle of true altitude.

This parallax is twofold — namely 53 [scil. of distance] — and for this it is necessary to know the Moon's horizontal parallax by Precept 58 in syzygies; for under the head of Table 53, in the region of the true altitudes, the [parallaxes] are taken. The other table, designated Table 71, is for the Moon's distance from the Earth in semidiameters of the Earth; under it, in the region of the degrees of true altitude, you will have the desired parallax.

Example

Let the Moon be 35 degrees high above the horizon, when in the example of Precept 58 the Moon's distance from the Earth was found to be 60 [semidiameters] 57', and the horizontal parallax 56' 26". For in the region of the 35 degrees on the left side, you will find the Moon's horizontal parallax taken in Table 53; or, by the stated distance from the Earth in Table 61, you will find the parallax of altitude 46' 40". But if you want the parallax of the observed altitude — look up that same one in the tables, using the observed altitude as if it were the true [altitude], and look up the parallax answering to it; and add this to the true altitude. Then at last, with this aggregate, look up the parallax there again, and it will agree with the observed altitude.

So, in the same example, the Moon's observed altitude being 35°, the parallax 46' 40" comes out; and this added to the altitude of 35° gives the degrees 35° 46' 40", to which in Table 61 answers the parallax 46' 40". This, therefore, is the one which agrees with the Moon at an observed altitude of 35°.

Precept 72. To find, for a given year and month, the mean new moon and mean full moon by means of the epacts.

Gather first from Table 54 the radix of the epacts immediately preceding, and the epacts answering to the years thereafter elapsed and completed, and likewise to the completed months — namely, the month preceding the given month — and

reduce these into a single sum, from which subtract the greatest number of revolutions of the new moon nearest [below], and in the left-hand part of the same Table 54 stand the days of the given month, with the hours and scruples past midday at which the mean new moon and mean full moon occur.

in the mean by the Julian style, but by the Gregorian style you must add 10 days for this whole century, and more days for other centuries, according to what was said at Precept 19.

Example.

The mean new moon of the year of Christ 1661, in the month of September, is sought; the calculation is to be set out by the method written out below from Table 54.

	D.	H.	'	"
Radix of the year 1600.	6	7	46	59
60 years.	3	7	10	40
August completed.	6	18	7	35
Sum	16	9	5	14
Revolutions of the conjunction σ	29	12	44	3
Take away	16	9	5	14
Remainder of the mean σ, September	13	3	38	49
But by the Gregorian style	23	3	38	49
Revolutions of the opposition σ^o	44	7	6	5
Take away likewise	16	9	5	14
Remainder of the mean σ^o, September	27	22	0	51
But by the Gregorian style, October	7	22	0	51

[Margin: Pag. 60.]

[Margin: Argoli's error.]

This eclipsic new moon Argolus [Andrea Argoli] represents at Rome in his *Ephemerides*; but falsely, for the southern latitude, with the parallax added, frees the Sun at Rome from any eclipse.

Precept 73. Given the time of the mean new moon, or of the full moon, to find the moment of the true new moon, or of the full moon.

For the given time of the mean new moon or full moon, collect by Precepts 55 and 61 the true places of the luminaries; and if they are found in the same minute of the zodiac, the mean new moon coincides with the true; if so, they will be 180° apart in the case of the mean full moon, and the true and mean full moon will be celebrated at the same moment. But if the Moon has preceded or followed by some degrees or minutes, then take the place of conjunction, or of opposition with the Sun: then, with the equated anomaly of the Moon by Precept 66, find the hourly motion of the Moon, and by it divide the difference between the place of the Sun and the Moon at the conjunction, or between the place of the Moon and the place opposite the Sun at the opposition. For the quotient gives the hours and minutes to be added to the time of the mean syzygy, if the Moon has not yet reached the Sun, or the place opposite the Sun; or to be subtracted, if it has already passed it. Yet for this the moment requires that the places of the luminaries be iterated, and, if need be, the exact moment of the new moon or full moon be defined again by the hourly motion of the Moon.

Example of the full moon.

From the example of the preceding Precept is given, for the year 1661, October 7 by the Gregorian style, the mean full moon at Bologna after noon at the hour 22h 0' 51". For which time the calculation of the luminaries stands thus:

	Sig.	Gr.	'	"
☉ Mean place of the Sun	6	17	25	18
Simple anomaly of the Sun	3	8	43	17
Equation to be subtracted	0	1	57	54
True place of the Sun	6	15	27	24
☾ Mean motion	0	17	29	15
Mean anomaly of the Moon	6	16	3	58
Equation of the orbit to be added	0	1	25	8
True place of the Moon	0	18	54	24
Equated anomaly of the Moon	6	17	29	6
Difference of the places ☉ and ☾	0	3	27	0
Hourly motion of the Moon from ☉	0	0	34	0
Time to be subtracted from the mean time	H.	6	5	18

	Sig.	Gr.	'	"
Truer therefore is the time of the full moon	H.	15	55	33

It is therefore necessary, for this very time of the truer full moon — namely at the hours 15h 55' 33" — to iterate the calculation, which will turn out as follows:

	Sig.	Gr.	'	"
True place of the Sun	6	15	12	18
Equated anomaly ☉	3	6	30	17
True place of the Moon	0	15	20	7
Equated anomaly of the Moon	6	14	36	31
Excess ☽ beyond ☉	0	0	7	49
Hourly motion ☽ from ☉	0	0	33	18
Time to be taken away	0	0	14	6
True full moon	H.	15	41	27
Apparent time	H.	15	32	37
And then the corrected place of the Moon	0	15	12	18
And the equated anomaly	6	14	29	0

Precept 74. To know beforehand whether a full moon or new moon is eclipsic.

The first method, although not so reliable, is settled with little error by Precepts 62 and 63: by these is found the argument of latitude, or the distance of the Moon from the nearer of the nodes; and with this as argument, find at once in Table 55 the eclipse limits, which are possible whenever the Moon is farther from the node than the Eclipsic Limit requires; an eclipse will not be possible. But if it is within those limits, an eclipse will be possible.

[Margin: Pag. 60.]

Example.

In the year 1661, October 7, at the hour 15h 32' 37", when the true full moon occurs: the true place of the node ♊ is duly computed to be Sign 6, gr. 6° 0' 29". The Moon is in ♍ gr. 15° 12' 18", distant from the node ♊ Sign 6, gr. 9° 12' 49", but in the southern node. Therefore the limits necessary for a lunar eclipse will be gr. 0° 12' 49", since the Moon is nearly at perigee at gr. 11° 53', but the Moon is less distant from the node.

A second method, however, is more reliable: for, by Precept 59, find the apparent semidiameter of the Moon and the Umbra, corrected for the terrestrial parallax, by Precept 63. Find the true latitude of the Moon: for if the latitude is equal to, or greater than, the aggregate of the semidiameters of the Moon and the Umbra, there will be no eclipse; if less, there will be some eclipse.

Example.

In the year 1661, October 7, at H. 15h 32' 37" after noon at Bologna, the lunar conditions stand thus:

	Sig.	Gr.	'	"
Moon ☾ True place	0	15	12	18
Node ♄ True place	6	6	0	29
Argument of latitude	6	9	11	48
Distance ☾ from ☉	0	0	0	0
Maximum latitude	0	4	58	30
True latitude of the Moon	0	0	47	40
Equated anomaly ☾	6	14	29	0
Anomaly of the Sun	3	6	30	18
Semidiameter of the Umbra	0	0	48	30
Variation to be removed	0	0	0	44
Semidiameter of the Umbra corrected	0	0	47	46
Apparent semidiameter ☾	0	0	16	8
Aggregate of the semidiameters	0	0	63	54

The true latitude of the Moon ☾ is therefore far less than the aggregate of the semidiameters; and consequently a lunar eclipse will necessarily occur.

Precept 75. To determine the digits of a lunar eclipse, that is, its magnitude.

Because the disk of the luminaries is commonly reckoned in its apparent diameter to be a foot in magnitude, and the foot, in the Roman manner, is divided into 12 unciae, or thicker digits,

therefore the same quantity of the luminaries' obscuration is wont to be expressed by digits, and by the minutes of the digits. These are thus defined. Subtract the true latitude of the Moon from the aggregate of the semidiameters of

the Moon and the Umbra, corrected; for the remainder will give the deficient scruples; then doubling the apparent semidiameter of the Moon, in the front of Table 57, and at the side of the scruples of deficiency, you will have the digits of the eclipse with their scruples.

Example.

In the preceding full moon the semidiameter of the Moon was 16' 8". The diameter is therefore 32' 16". And the aggregate of the semidiameters of the Moon and Umbra, corrected, was 63' 54". There remains the true latitude of the Moon, which there was 47' 40". The deficient scruples are therefore 16' 14", which quantity, in Table 57, under Diameter 32' 16", with the proportional part applied, gives the digits of the partial eclipse, 6, gr. 5; that is, this eclipse will be partial, or of 6 digits and 5 minutes. But if there were a total eclipse, it would be of 12 digits without a tarrying; the tarrying, if greater than 12, is total with a tarrying.

Precept 76. To determine the scruples of incidence of a lunar eclipse, and of its very beginning and end; or rather, also the tarrying in the shadows, if it is a total eclipse with a tarrying.

Astronomers call the scruples of incidence [*scrupula incidentiae*] those zodiacal, or lunar-orbit, scruples which the Moon traverses from the beginning of the eclipse up to the middle; and the scruples of the tarrying [*scrupula Morae*] those which it traverses from the middle up to the end. The scruples of the half tarrying [*scrupula Mora dimidia*], which the Moon completes from the moment of total obscuration up to the middle. And the partial scruples of the eclipse's duration you find thus: for, in the front of Table 59, take the sum of the corrected semidiameters of the Moon and the Umbra, and at the side of the true latitude of the Moon, you will have the scruples of incidence. Then repeat, as above, with the equated anomaly of the Moon: from the hourly motion of the Moon from the Sun divide the scruples of incidence; you will do it more subtly, however, if the hourly motion is resolved into one number out of 60. And the product, divided by the hourly motion, will give the hours and the parts of hours, which scruples, subtracted from the moment of the full moon, will give the beginning of the eclipse, and added, the end.

Example.

In the preceding full moon the sum of the semidiameters of the Moon and Umbra was found to be 63' 54"; and the true latitude of the Moon, at whose place in Table 59 under the sum 63' 54", the proportional part being applied, is found the scruple

of incidence 42' 32". The hourly motion of the Moon found above was 33' 18". Resolving therefore the minutes into seconds, the hourly motion in seconds becomes 1998". And the incidence, secondly, 2552"; which multiplied by the minutes of one hour, 60", makes 153120"; and this, divided by 1998", leaves 76⅔ minutes of the hour, that is, 1h 16' 39", which, subtracted from the full moon found at the eclipsic moment above by Precept 73 after noon at the hour 15h 32' 37", and afterward added, and finally aggregated, give the beginning and end of the eclipse, as below.

	After Noon at Bologna		
In the ☾ Orbit	H.	'	"
Beginning of the eclipse	14	15	58
Middle	15	32	37
End	16	49	16
Total duration	2	33	18

But the total eclipse with the tarrying is to be completed thus. First, find, as above, the scruple of incidence, which in this case comprehends also the half of the tarrying; and therefore, [Margin: Pag. 68.] Table 59 has the title: *Scruples of incidence, and of the half-tarrying in an eclipse* ☽; and divide it by the hourly motion, as above.

[Margin: Pag. 66.] [Margin: Pag. 67.]

A more subtle reckoning of a lunar eclipse — admonitions.

First, it is not yet a decided controversy whether the moment of the full moon, at which the Moon is distant from the Sun by precisely 180°, is the same as that at which the place of the Moon is reduced to the ecliptic, distant likewise by 180° from the Sun; or rather, whether, when the center of the Moon and the center of the Umbra are equally distant from the nearer node — which Kepler [Johannes Kepler] noted in the *Rudolphine [Tables]* at the end of Precept 155. Neglecting this, however, as a third point, if the full moon up to now in the orbit is to be considered, reduce the volumes to the ecliptic by Precept 64; then, if the reduction was by addition, that scruple, divided by the hourly [motion], is to be subtracted from the moment of the full moon; if previously by subtraction, then to be added.

For example, in the full moon of Precept 73, the place of the Moon in the orbit was Sign 0, gr. 15° 12' 18". But the argument of latitude was Sign 6, gr. 9° &c.

Therefore the reduction to be subtracted is 2' 10"; and the eclipsic place of the Moon Sign 0, gr. 15° 10' 8". The hourly motion was 33' 18"; from one minute 2' 10" are owed the minutes of time 3' 11", which, added to the hours 15h 32' 37", give the moment of the eclipsic full moon by this reckoning at the Hour 15h 35' 58". From which, the rest of the beginning and end of the moment are to be reckoned and limited, if they are to be limited.

With Respect to the Ecliptic			
In ☉	H.	'	"
Beginning	14	19	19
Middle	15	35	58
End	16	52	37

Secondly, it is to be admonished, for those eager for astronomical subtlety, that — as I explained more fully in Book 5 of the *Almagestum Novum* in the Scholium of Chapter 6 — namely, the moment of the eclipsic full moon is not the same as the moment of the greatest obscuration, and this difference, which can reach as much as 6 minutes of an hour, is not to be despised. For the rest, since the greatest obscuration occurs when the place of the Moon in the orbit is exactly distant 180° from the Sun — because then the arc drawn from the orbit of the Moon orthogonally from the center of the Umbra is shorter than the arc drawn from the center of the Moon orthogonally to the ecliptic at the point where the center of the Umbra is, as has there been demonstrated; in which second case, now reducing the full moon from the orbit to the ecliptic, whoever has first found this difference, by the first admonition, will have at the same time the difference of the eclipsic full moon and the moment of the greatest obscuration. Hence in our example the greatest obscuration of the digits occurs at the hour 15h 32' 37". But the eclipsic full moon by the ecliptic, and not only by the eclipse so denominated, occurs at the Hour 15h 35' 58".

Precept 77. To determine the true latitude of the Moon at the beginning, and at the end; and to determine the eclipse.

By Precept 58 find the hourly motion of the Sun, and by it lead the scruples of incidence found at Precept 76; and you will have the true motion of the Sun congruent to the time of the half-duration, which add to the scruples of incidence, and to the half-tarrying together, and subtract the sum from the argument of latitude at the middle of the eclipse, and there will come forth the argument of

latitude at the beginning of the eclipse; but if to the same argument at the middle you add the aforesaid sum, you will have the argument of latitude at the end.

Example.

In the preceding full moon the hourly motion of the Sun was 2' 29". Therefore the motion of the half-duration of the eclipse, congruent in time of one hour, was 3' 6". The scruples of incidence by Precept 76 found before were 42' 32", to which, adding 3' 6", the sum becomes 45' 39". With the argument of latitude at the middle of the eclipse being Sign 6, gr. 9° 11' 48", subtracting this sum 45' 39" leaves the argument of latitude for the beginning of the eclipse, Sign 6, gr. 8° 26' 9"; to which, in latitudes, Table 44 makes the southern latitude 43' 43" for the beginning of the eclipse; but if to the same sum 45' 39" you add the argument of latitude at the middle, the argument of latitude at the middle being Sign 6, gr. 9° 57' 27"; for the end of the eclipse, to which corresponds the southern latitude 51' 31". Therefore the latitudes of the Moon to be noted are, as below, always southern.

Latitude True 》		'	"
In Eclipse			
Beginning	A	43	43
Middle	A	47	40
End	A	51	31

Precept 78. To delineate the type of a lunar eclipse.

The true latitude of the Moon being known, and likewise its appearance through Precept 77, the type of the lunar eclipse will easily be graphically delineated, together with the inclination to the regions of the horizon, by the rules which I handed down at length in Book 5 of the *Almagestum Novum*, Chapter 7. The type, therefore, of the preceding eclipse will be as written below.

Diagram. A geometric figure for the lunar eclipse, with cardinal directions marked at the four sides: *Bor.* (north) at top, *Auftr.* (south) at bottom, *Or.* (east) at left, and *O. Occ.* (west) at right. A large outer circle encloses the construction. Within it, a central point **A** marks the center of the Umbra. Several intersecting circles represent the terrestrial shadow disk and the Moon's path; chord and radial lines run between the labeled points. The labels read:

- *Bor.* (top): *Bor.* — North
- *Auftr.* (bottom): *Auftr.* — South
- *Or. P* (left): *Or.* — East, with point **P** at the left margin of the diameter

- O. Occ. (right): *O. Occ.* — West, with point **O** at the right margin of the diameter
- L (upper left): point **L** — region toward which the eclipse's beginning tends
- M (upper right): point **M** — region toward which the eclipse's end tends
- D (upper center): point **D**
- K (left center): point **K**
- C (left of center): point **C**
- A (center): point **A** — center of the Umbra
- E (right of center): point **E**
- H (right center): point **H**
- I (lower left): point **I**
- F (bottom center): point **F**
- G (lower right): point **G**

Let the center of the Umbra be A, its semidiameter AF; the disk of the terrestrial Umbra FCDE; the latitude of the Moon at the middle of the eclipse AF, but at the beginning GH, and at the end IK; the region toward which the beginning of the eclipse tends is L, designated by the line GAL; and the region toward which the end tends is M, designated by the line IAM; the inclination to the beginning is the angle GAO, to the end the angle IAP.

A corollary against Argolus.

[Margin: Argoli's error.]

Argolus [Andrea Argoli], therefore, or his disciples, perpetually mark this lunar eclipse of the year 1661, October 7, that we have described, with a northern latitude, since it is always southern; so that I say nothing of the time of the eclipse anticipated by them by about forty minutes.

Precept 79. To reduce the apparent time of an eclipse to equated time, and vice versa.

The conversion of apparent time into equated, and conversely of equated into apparent, I have already taught at Precept 16; and I have already used this in the example of the eclipsic full moon of Precept 73.

Precept 80. To survey the regions of the orb of the Earth in which the lunar eclipse will be visible, or not.

This is accomplished not without ease and pleasure by the Geographical Cross [Crucem Geographicam], which I once explained at length, and have again inserted in Book 16 of the *Geographia Reformata*. To it, therefore, I refer the reader: for from one instrument it will at once appear, where at any given moment of the eclipse there will be night, and where day; and so where the eclipse, and to what extent, could be seen, or could not — that is, where those phases of the eclipse could be seen, and conversely where in those very places on Earth those phases could not be seen; yet it can also be observed by the benefit of refraction, particularly the beginning, even a little before sunset, and the end a little after sunrise, when the Sun is seen.

But if you are anxious about some particular place of the Earth — for example's sake, about Lima, the city of the kings in Peru — gather from the Catalogue, or Table 14, the difference of time to be added for places more eastern, to be subtracted for more western, with respect to Bologna; and transfer that time to the meridian of the place with respect to Bologna; then from Table 11 excerpt the semidiurnal and seminocturnal time by the mean place of the Sun, namely the hours and scruples written after noon at the beginning, the middle, the end of the eclipse, but do not exceed the aggregate of the semidiurnal and nocturnal time. There will be night in that place, and that phase of the eclipse will be visible there; but otherwise it will be day, and not visible, unless at the boundary of day and night.

[Margin: Pag. 9.]

Example for Lima.

Lima — Difference of Time	H.	6	11'
To be subtracted from the Bologna time			
Southern Altitude of the Pole	Gr.	12	20'
Place of the Sun ☉ ♊	Gr.	15	12'
Semidiurnal time	H.	5	55
Seminocturnal	H.	6	5
Nocturnal	H.	12	10

		H.	'	"
Eclipse — Beginning	Bologna	14	15	58
	Lima	8	4	58
Middle	Bologna	15	32	37
	Lima	9	21	37
End	Bologna	16	49	16
	Lima	10	38	16

Since therefore both from the beginning and at the end the time after noon at Lima exceeds the quantity of the semidiurnal time, and does not exceed the aggregate of the semidiurnal and nocturnal — which is 16h 5' — this lunar eclipse will be visible at Lima for the whole.

Precept 81. To find in whose meridian the Moon will be at the height of the eclipse, and for whom it will be at the vertical.

First, inquire whether the Moon, at the time of the eclipsic full moon, falls in the eastern hemisphere — if indeed it should happen before the middle of the night following — or whether in the western, that is, if the eclipsic full moon should happen after the middle of the night, that is, after the hours 12 counted from noon. Then, if in the eastern, subtract the apparent time of the full moon from the hours 12; but if in the western, subtract the apparent time of the full moon from the hours 12, and convert the remainder into degrees of the Equator; for the quantity of these will show the distance of the meridian in which the Moon is at the height of the eclipse from the meridian of the Tables, toward the East in the first case, or toward the West in the second case. Thirdly, with the true latitude, and the place of the Moon in the ecliptic, inquire by Precept 54 how great the declination of the Moon is; just so great will be the altitude of the pole of that place over which the meridian will be at the vertical, where the Moon is at the height of the eclipse.

Example.

The eclipsic full moon discussed above in the example to Precepts 73 and 74 occurs at 15h 32' 37" after midday at Bologna. With respect to the Bolognese meridian, then, the Moon will be in the western hemisphere; and once 12 hours are subtracted, 3h 32' 37" remain — that is, 53° 9' 15" — which is the amount by which the meridian sought is distant toward the west from the Bolognese meridian.

Moreover, the Moon will then be in Aries $15^{\circ} 12'$, whose northern declination is $6^{\circ} 0' 6''$, and the Moon's southern latitude is $47' 40''$. To these, in Table 34, an equation of $42'$ corresponds, to be subtracted from the northern declination; and so the Moon's declination of $5^{\circ} 18'$ remains. Therefore that place which, on the aforesaid meridian, has the altitude of the northern pole equal to $5^{\circ} 18'$, will have the Moon standing at its vertex at the moment of greatest eclipse. So, having consulted cosmographic charts, you will find that place: its longitude from the island of Palma is $341^{\circ} 20' 45''$, and its northern latitude $5^{\circ} 18'$.

Recapitulation of the entire foregoing calculation of the eclipsic full moon.

In the year 1661, October 7, at the Bologna hour after midday — $15^{\text{h}} 41' 27''$ by equated time, but $15^{\text{h}} 32' 37''$ by apparent time:

	Sig.	Gr.	I	II
True place of the Sun	6	15	12	1 8
Equated anomaly of the Sun	3	6	30	1 6

Precept 82. To know beforehand the order to be observed in the recapitulation of a solar eclipse.

It is certainly desirable to think out in advance by what means one is to come through the labor of so toilsome a calculation, and by what steps one is to mount to the end aimed at. And so I shall list in order the items to be sought, which are:

To be sought	per Precept
The mean new moon	72
The true new moon	73
or by Precepts 55, 61, 66 together	67
The apparent time of the true new moon	16
The true place of the luminaries	55, 61
The equated anomaly of the luminaries	55, 61
The right ascension of the Sun	46
The parts of the equator corresponding to the time	11
The right ascension of mid-heaven, and from this	50
The oblique ascension of the ascending degree, and the ascending ecliptic degree itself	
The nonagesimal ecliptic degree counted from the ascendant	50
The altitude of the nonagesimal	51
The true place of the northern node Ω	62
The altitude of the nonagesimal in the orbit $\oslash$	83
The horizontal parallax of the luminaries in the syzygies [copulis]	58
The parallax of the Moon from the Sun in altitude	84
The parallax of the Sun $\odot$ in longitude	85
The parallax of the Moon in latitude	86
The parallax of the Sun $\odot$ in longitude one or two hours before, or after, the true new moon	87
The apparent motion of the Moon over one or two hours	88
The apparent new moon	89
The parallax of the Sun $\odot$ in longitude at the moment	90

To be sought	per Precept
of the apparent new moon, and at the hours before, or after	
The true and apparent latitude at the time of the apparent new moon	91
The digits of the solar eclipse	92
The beginning, end, and duration of the solar eclipse	93
The true latitude of the Moon ☾ at the beginning, end, and middle of the eclipse	94
The type of the solar eclipse to be delineated	95

Up to here. Astronomy of old proceeded thus; but a new device has brought this inquiry on to the principal phases of a solar eclipse, observable in different regions — yet chiefly in those in which a total, or central, eclipse will be observable: about which below.

Example.

The eclipsic new moon of the year 1659, November 14, at the hour 3h 30' after midday by equated time at Bologna:

	Sig.	Gr.	I	II
True place of the Sun	7	22	11	58
Equated anomaly of the Sun	4	13	32	0
True place of the Moon	7	22	20	40
Equated anomaly of the Moon ☾	4	8	53	0
Hourly motion of the Moon ☾ from the Sun ☉			31	57
Excess of the place [of the Moon] beyond ☉ [conjunction]			8	42
Time agreeing with this			16	10
The truer new moon, therefore, October 14, p.m.	Hor. 3	13	50	

The calculation then being repeated:

	Sig.	Gr.	I	II
True place of the Sun	7	22	11	18
Anomaly of the Sun	4	13	31	20

	Sig.	Gr.	I	II
True place of the Moon	7	22	11	16
Equated anomaly of the Moon ☾	4	8	43	39
Hourly motion of the Moon ☾ from the Sun ☉			31	56
The Moon falls short of the place [of the Sun] ☉ by				2
Time agreeing with this				3
The true new moon, October 14	H. 3	13	53	
The equation of days to be added			12	55
The apparent time of conjunction ☉ ☾	H. 3	26	48	

And so the true and exact new moon at Bologna will be in the year 1659, November 14, at the apparent hour 3h 26' 48" after midday, the luminaries — corrected — standing in Scorpio 22° 11' 18".

Precept 83. To find the altitude of the nonagesimal in the orbit of the Moon, and the nonagesimal itself, by other precepts.

First seek, by Precept 46, the right ascension of the place of the Sun; and by Precept 50, the ascending degree of the ecliptic and the nonagesimal computed from it; and by Precept 51, the altitude of the nonagesimal. Then [seek] the place of the lunar node ♌ by Precept 62, which you should subtract from the nonagesimal, and treating the remainder as if it were the argument of latitude [you proceed as below].

[...the argument] of latitude, seek in Table 44. The latitude is to be added to the altitude of the nonagesimal if the latitude is northern, subtracted if southern; for thus you will obtain the altitude of the nonagesimal in the orbit of the Moon.

Example in the preceding new moon.

	Sig.	Gr.	I	II
True place of the Sun	7	22	11	18
Right ascension of the Sun		229	34	23
Time from the meridian, apparent	H.	3	26	48
Parts of the equator		51	42	0
Right ascension of the culminating point, 90° being added, becomes		281	16	23
Oblique ascension of the ascendant		11	16	23

	Sig.	Gr.	I	II
Altitude of the pole at Bologna		44	30	20
The ascendant	Υ 21	4	0	
Therefore the nonagesimal	♄ 21	4	0	
And the altitude of the nonagesimal		23	50	0
True place of the node Ω	7	12	43	55
Fictitious argument of latitude	2	8	20	5
And northern latitude		4	37	22
Altitude of the nonagesimal in the orbit of the Moon		28	27	22

Precept 84. To find the horizontal parallax of the Moon from the Sun.

With the anomaly of the Sun and of the Moon, both equated, seek in Table 39 the horizontal parallax of each of the luminaries; then, the solar parallax being subtracted from the lunar, the horizontal parallax of the Moon ♃ from the Sun ☉ will remain.

Example in the preceding new moon.

	Sig.	Gr.	I	II
Equated anomaly of the Moon ♃	4	8	43	39
Equated anomaly of the Sun ☉	4	13	31	20
Horizontal parallax of the Moon ♃			57	51½
Horizontal parallax of the Sun ☉				1½
Horizontal parallax of the Moon ♃ from the Sun ☉			57	50⅓

Precept 85. To investigate the parallax of the Moon in longitude.

Consult Table 56, whose title is *Parallax Mesoplastic* [Parallaxis Mecoplatica], and in its head seek the horizontal parallax of the Moon from the Sun, obtained by Precept 84; and in the right-hand side, whose title is *Latitude of Longitude* [Latus Longitudinis], [seek] the altitude of the nonagesimal in the orbit ♃, foreknown by Precept 83. For in the common area you will find the horizontal parallax of the Moon ♃ in longitude — which is to be used if the Moon were at the horizon itself. But when it is above the horizon, seek the distance of the Moon from the nonagesimal by subtracting the lesser from the greater, and with this likewise in the right-hand side of the same Table 56, and in the head with the horizontal

parallax of the Moon ☾ in longitude, you will find in the common area the absolute and exact parallax of the Moon ☾ in longitude.

Example in the preceding new moon.

	Sig.	Gr.	I	II
Altitude of the nonagesimal in the orbit ☾		28	27	22
Horizontal parallax of the Moon ☾ from the Sun ☉			57	50
Horizontal parallax in longitude ☾			27	33
True place of the Moon ☾	7	22	11	18
The nonagesimal	☿ 21	4	0	
Distance of the Moon ☾ from the nonagesimal		58	52	42
Parallax in longitude			23	35

Precept 86. To inquire into the parallax of the Moon in latitude.

In Table 56, *Parallax Mesoplastic*, in the head seek the horizontal parallax of the Moon from the Sun, repeated from Precept 84, and in the left-hand side, whose title is *Latitude of Latitude* [Latus Latitudinis], seek the altitude of the nonagesimal in the orbit of the Moon, found by Precept 83; and the common area, by the aid of the proportional part, will at once furnish the parallax of latitude.

Example, discussed above.

	Gr.	I	II
Altitude of the nonagesimal in the orbit ☾	28	27	22
Parallax of the Moon ☾ from the Sun ☉ Horizontal		57	50
Parallax of latitude		50	28

Precept 87. To investigate the parallax of the Moon in longitude for one or two hours before, or after, the true new moon.

This precept is necessary, in order that we may add the apparent hourly motion of the Moon, and the beginning and end of the solar eclipse. First, then, [seek] in the degrees of oblique ascension of the ascending point at the moment of the true new moon — for the single hours before the true new moon, subtract fifteen degrees; for the hours after, add [fifteen degrees]; for the ascending ecliptic point will come out, for that time before or after the new moon being assumed. By Precept 83 seek again the ascendant and the nonagesimal, and the altitude of the nonagesimal in the orbit of the Moon.

Second, the horizontal parallax of the Sun found above being retained (since this does not vary sensibly within a few hours), with the anomaly of the Moon equated to the assumed time, or after conjunction ☉ ♌, seek the horizontal parallax of the Moon ♌ from the Sun, by Precept 84 and Precept 85 — the parallax in longitude, but the horizontal only.

Third, in place of the Moon — which it held at the moment of the true new moon — for the single hours before the true new moon, subtract the hourly motion of the Moon from the Sun as many times [as there are hours assumed]; but for the hours after, add [it]; and the true place of the Moon will emerge before, or after, the new moon.

Fourth, with the true distance of this place of the Moon from the nonagesimal, and with the absolute horizontal parallax of longitude, by Precept 85 seek the parallax of the Moon in longitude for the hour before, or after, the true new moon chosen. For the most part, however, only a single hour is usually assumed, before or after; before indeed if the Moon is in the eastern ecliptic quadrant; after, if in the western. For in the preceding new moon the Moon is in the western [quadrant]; we shall therefore inquire about the hour after the new moon. [Such is] the parallax of the Moon in longitude.

Example, one hour after the true new moon, discussed above.

It was above [as follows]	Sig.	Gr.	I	II
Oblique ascension of the ascendant	0	11	16	23
Added	0	15	0	0
Becomes the oblique ascension of the ascendant		26	16	23
And the other ascendant	♄ 15	48	0	
Therefore the nonagesimal	♊ 15	48	0	
And the altitude of the nonagesimal	0	26	50	0
Place of the node ♋ as above	7	12	48	55
Argument of latitude	2	2	54	5
Northern latitude		4	25	34
Altitude of the nonagesimal in the orbit ♌		31	15	34
Parallax horizontal ♌ from the Sun ☉, as above			57	50
Parallax of longitude, horizontal			30	0
True place of the Moon in the true new moon	7	22	11	18

	Sig.	Gr.	I	II
Hourly motion of the Moon to be added			31	56
Place of the Moon one hour after the new moon	7	22	43	14
Distance of this place from the nonagesimal		83	4	46
Therefore the parallax of longitude			29	49
[for] the hour before the true new moon				

Precept 88. To determine the apparent motion of the Moon over one or two hours.

First, with the parallax of the Moon's longitude found for the beginning, and for the end of the hour assumed by Precept 87, subtract the lesser parallax from the greater, and preserve the difference of the parallaxes. You should also have the true hourly motion at the time of the new moon.

Second, if over the whole time of the hour assumed the Moon remained in the eastern quadrant of the zodiac, and at the beginning of the hour assumed the parallax was greater than at the end — then subtract the difference of the parallaxes from the hourly motion of the Moon, and you will have the apparent motion for that hour. But if the Moon over that whole time remained in the western quadrant, and the parallax was greater at the beginning of the hour than at the end, add the parallax [to the motion]; if smaller, subtract; and the apparent motion of the Moon will come out [agreeing with the hour].

But if within that hour the Moon is partly in the eastern, partly in the western [quadrant], take both parallaxes — that is, the aggregate of the parallaxes found at the beginning and at the end — and subtract it from the true hourly motion of the Moon, and you will have the apparent motion for that hour. For this is what must be done, against Reinhold [Reinholdum], Magini [Maginum], and Lansbergen [Lansbergium], by reason and by example, as the Reverend D. Vincenzo Renieri [Vincentius Reinerus] has demonstrated in his recently published *Tabulae Medicaeae*, p. 289.

Example.

In the preceding new moon the Moon remained in the eastern quadrant, both at the moment of the new moon and at the beginning of the one hour before the new moon: so we shall proceed in the calculation thus:

	I	II
Parallax of longitude in the new moon	23	35
Parallax of longitude one hour after	29	49
Difference of the parallaxes	6	14
True hourly motion of the Moon 》	31	56
Therefore the apparent motion 》 in that hour	25	42

Precept 89. To determine the moment of the apparent new moon.

First, if the Moon is in the eastern quadrant, seek its apparent motion for one hour before the true new moon, owed by Precept 88; and if the minutes [scrupula] of the parallax of longitude at the time of the true syzygy were greater, divide the minutes of parallax by them; for the quotient will give the minutes of time to be subtracted from the apparent time of the true new moon, so that the apparent — or visible — time of the new moon, or of the visible syzygy, may emerge.

Second, if the Moon were in the western quadrant, seek by Precept 88 its apparent motion owed for one hour after the true new moon; and if the minutes of the parallax of the longitude of the true new moon were greater, divide [them] by that; the quotient gives that time to be added to the apparent time of the true syzygy, so that the moment of the visible syzygy may be made.

Third, if the apparent hourly motion were less than the parallax of longitude found at the moment of the true new moon, subtract the apparent hourly motion from the parallax, and reserve the residue of parallax. Then by Precept 88 seek further the owed apparent motion of the Moon for the other hour — before the true new moon if [the Moon was] in the eastern quadrant, after if in the western — and by this apparent motion divide the residue of parallax; for, one hour having been added to it, it will give the time to be subtracted from the apparent time of the true syzygy if the Moon is in the eastern quadrant, to be added if in the western, so that finally the moment of the visible syzygy may be had.

Finally, if the Moon should be at the nonagesimal itself, the true and the visible syzygy coincide.

Example.

In the preceding new moon, because the Moon is in the western quadrant, and the apparent hourly motion 》 was found to be 1 hour after the true new moon at 25' 42" — but the parallax of longitude at the moment of the true new moon was

found to be 23' 35" — therefore the apparent hourly motion is greater than this parallax. So say: if 25' 42" require one hour, that is 60', how many minutes will 23' 35" require? And the second requires 23' 35". Therefore, resolving these three numbers in the series of the Golden Rule, in the second [scrupula] the first comes out as 1542; the second, 3600; the third, 1415. So the second being multiplied by the third, and the sum divided by the first, the fourth proportional number comes out as 2304 — that is, 55' 4". This being added to the apparent time of the true new moon — namely, as stated above at the end of Precept 82, 3h 26' 48" — yields the time of the visible syzygy on November 14, at hour 4h 21' 52".

Precept 90. To investigate the parallaxes of the Moon in longitude both for the moment of the visible syzygy, with the parallax of longitude, and for the hours before, or after.

So that the apparent hourly motion, for the hour before and after the visible syzygy, may be had, the parallax of longitude is needed, for the hour before and after. First, then, convert the difference of time between the true and the visible syzygy into parts of the equator, and subtract these from the oblique ascension of the ascending degree at the time of the true new moon if the Moon is in the eastern quadrant; add [them] if in the western; so that the oblique ascension of the ascending point at the time of the visible syzygy may emerge. Then by Precept 87 seek the parallaxes of longitude, at the time of the visible syzygy, both for one hour before and for one hour after the visible syzygy.

Moreover, so that you may have the place of the Moon at the time of the apparent new moon, and from this the distance of the Moon from the nonagesimal, for the inquiry into the parallaxes — lead the interval of time between the true and the visible syzygy through the true hourly motion of the Moon from the Sun, and divide the product by 60, and subtract the quotient from the true place of the Moon at the time of the true syzygy if the Moon is in the eastern quadrant, add if in the western. But if the Moon, one hour before, or after, the visible syzygy, were distant from the nonagesimal by more than 90°, it will be below the horizon, and then the parallax is sought in vain.

Example.

In the preceding new moon, by Precept 89, the interval between the true and the visible syzygy was 45' 45", with which you will operate thus:

	Sig.	Gr.	I	II
Interval between true ☉ ☽ and visible			55	4

	Sig.	Gr.	I	II
Whose parts of the equator		13	46	0
Oblique ascension of the ascendant at true ☉ ☽		11	16	23
Oblique ascension of the ascendant at visible [☉ ☽]		25	2	23
Ascending ecliptic point	☿ 13	57	0	
Nonagesimal from it	♊ 13	57	0	
Altitude of the nonagesimal		25	52	0
Place of the node ♌ as above	7	12	43	55
Argument of latitude	3	1	13	5
Northern latitude, to be added		4	58	24
Altitude of the nonagesimal in the orbit ☽		30	50	24
Parallax of the Moon ☽ from the Sun ☉ in another horizon			57	50
Parallax of longitude, horizontal			29	40
Apparent hourly motion owed for the interval			20	42
True place of the Moon ☽ in the visible syzygy	7	22	41	30
Distance of the Moon ☽ from the nonagesimal		81	15	30
Parallax of longitude			29	22
And the parallax of latitude			49	29

For one hour before the observed conjunction, subtract 15° from the oblique ascension of the ascending point at the time of the observed conjunction, which was 25° 2' 23". There remains 10° 2' 23" for the oblique ascension of the ascending point one hour before the observed conjunction. From this the rest of the calculation follows.

	Sig.	Gr.	'	"
Oblique ascension of the ascending point	0	10	2	23
Eclipt. point ascending	♈	18	49	0
Nonagesimal from it	♊	18	49	0
Altitude of the nonagesimal		22	38	0
Place of the node, as above	7	12	43	55
Argument of latitude	2	6	5	5

	Sig.	Gr.	'	"
Northern latitude, to be added		4	32	48
Altitude of nonagesimal in Moon's orbit		27	10	48
Parallax of Moon from Sun, horizontal			57	50
Parallax of longitude, horizontal			26	26
True hourly [parallax], to be subtracted			31	56
True place of Moon, 1 hour before the observed conjunction	7	22	9	34
Distance from nonagesimal		56	39	26
Parallax of longitude			22	5

But for one hour after the observed conjunction, add 15° to the oblique ascension of the ascending point at the moment of the observed conjunction; this makes it one hour after the oblique ascension of the ascending point, and the rest as below.

	Sig.	Gr.	'	"
Oblique ascension of the ascending point	0	40	2	23
Eclipt. point ascending	II	4	19	0
Nonagesimal from it	✕	4	19	0
Altitude of the nonagesimal		30	27	0
Place of the node, as above	7	12	43	55
Argument of latitude	3	21	35	5
Northern latitude		4	37	31
Nonagesimal altitude in Moon's orbit		35	14	31
Parallax of Moon from Sun upward, as above			57	50
Parallax of longitude, horizontal			33	12
True hourly [parallax], to be added			31	56
True place of Moon, 1 hour after the observed conjunction	7	23	13	26
Distance from nonagesimal	3	11	5	34
Parallax of longitude sought in vain, for the Moon is now below the horizon, yet is greater than			57	50

Precept 91. To find the true and apparent latitude of the Moon at the time of the observed new moon.

First, by Precept 63, find the true argument of latitude at the moment of the true new moon, and subtract from it the parallax of longitude at the moment of the observed new moon found by Precept 90, if the Moon lies in the eastern quadrant; add it if in the western. The result is the true argument of latitude at the time of the observed conjunction, with which by the same Precept 63 you find the true latitude.

Second, by Precept 90 find the parallax of latitude at the moment of the observed conjunction, and compare it with the true latitude. If the true latitude is southerly with respect to our northern regions, add to it the parallax of latitude, and the sum will be the apparent southern latitude. But if the true latitude is northerly with respect to our northern regions, and the parallax of latitude is greater, subtract the latter from it, and what remains is the still-northerly apparent latitude. But if the parallax of latitude is greater than the true northern latitude, subtract this northern latitude from the parallax of latitude, and there will remain an apparent southern latitude.

From this learn what is to be done in southern regions: there, when the latitude is northern, the parallax being added, the result will be the apparent northern latitude; but when the latitude is southern and smaller, the subtracted parallax being greater leaves an apparent northern latitude; while if the parallax is smaller, being subtracted from the southern latitude it leaves the apparent latitude still southern.

Precept 92. To determine the digits, or the magnitude, of a solar eclipse.

Look up in Table 39 the apparent semidiameters of the Sun with the anomaly of the Sun, and of the Moon with the anomaly of the Moon, [Margin: Pag. 47.] and add them together; and from the sum of the semidiameters subtract the apparent latitude of the Moon found by the preceding precept — for there will remain the scruples of deficiency, with which, in the left margin of Table 57, [Margin: Pag. 66.] together with the whole diameter of the Sun appearing at the head of the same table, you will find, at the common intersection, the digits of the solar disk to be obscured by the Moon.

Example in the preceding new moon.

	'	"
Apparent semidiameter »	15	55

	'	"
Apparent semidiameter ☉	15	49
Sum of the semidiameters	31	44
Apparent latitude ☾	1	41
Scruples of deficiency	30	3
Apparent diameter ☉	31	50
Digits obscured	11 [']	1 ["] 8 [recte: digits $\approx$ 11; the value 11° 1' 8" as printed appears to be 11 digits and a fraction]

Precept 93. To determine the motion of the Moon as seen at one hour before and after the observed conjunction, and from this to fix the beginning, end, and duration of the solar eclipse.

First, find the differences of the parallaxes of longitude in the observed conjunction which you found by Precept 90 at one hour before and after the observed conjunction, and by Precept 88 find the motion of the Moon as seen, agreeing with each hour.

Second, consult Table 58, [Margin: Pag. 67.] and at its head find the sum of the apparent semidiameters of the Sun and Moon; and in the left margin the apparent latitude of the Moon at the middle of the observed conjunction; for their intersection will give the scruples of incidence.

Third, double the scruples of incidence per hour, [Margin: Pag. 60.] and divide the product by the motion of the Moon as seen one hour before the observed conjunction found previously; likewise, divide the product again by the motion of the Moon as seen one hour after that found previously. The first quotient, subtracted from the time of the apparent observed conjunction, leaves the beginning of the eclipse; the second, added to the time of the apparent observed conjunction, will establish the end; and the two together will give the duration of the eclipse.

Example in the preceding new moon.

	'	"
True hourly [motion] ☉	31	56
Parallax of longitude in observed conjunction	29	22
Parallax of longitude, hour 1 before	22	5

	'	"
Motion as seen of this hour	24	40
Parallax of longitude, hour 1 after	58	nearly
Motion as seen of this hour	29	0
Sum of the semidiameters	31	44
Apparent latitude ☽	1	41
Scruple of incidence	31	42

[p. 24]

	H.	'	"
Time of incidence	1	17	0
Apparent time of the observed conjunction	4	21	52
Beginning of the eclipse	3	4	52
Time of repletion	1	5	0
End of the eclipse	5	26	52
And the whole duration, hours	2	22	0
 Semidiurnal time	 4	 45	 0
Beginning in Italian [hours] ☉	22	20	0
Civil clock	21	50	0

Precept 94. To define the apparent latitude of the Moon at the beginning, end, and middle of the eclipse.

Enter Table 44, [Margin: Pag. 51.] and in its cells find the apparent latitude of the Moon at the middle of the eclipse, found above by Precept 91, observing where it is found in the column of greatest latitude: the sign at the head, and the degree in the left margin, if the latitude is northern and the Moon is near the northern node; but if the apparent latitude is southern, observe the sign at the foot and the degree in the right margin. But if the eclipse is near the southern node and the latitude is northern, look for the signs at the foot and the degree in the right margin; if southern, the signs at the head and the degree in the left margin — these corresponding to the apparent latitude. In this way you will have the true argument at the time of the observed conjunction, from which subtract the scruples of incidence found above by Precept 93, and there will remain the true argument of the apparent latitude at the beginning of the eclipse; conversely, add

to the true argument of the observed conjunction the scruples of incidence, and you will form the true argument of the apparent latitude at the end of the eclipse. With this argument, in the same Table 44, you will have the apparent latitude at the beginning and end of the eclipse.

Example in the new moon near the ascending node Ω .

	Sig.	Gr.	'	"
Apparent latitude $\nearrow$ at mid-eclipse	B.	0	1	41
Argument answering to this	0	0	19	19
Scruples of incidence	0	0	31	42
Argument of apparent latitude at beginning	11	29	47	37
Argument of apparent latitude at end	0	0	33	23
Apparent latitude at beginning, A.	0	0	1	3
Apparent latitude at end, B.	0	0	2	52

Precept 95. To delineate the figure of a solar eclipse.

The apparent latitude of the Moon at the middle of the eclipse having been found again by Precept 91, and at the beginning and end by Precept 94, it is easy from what was said in Precept 78 on the figure of a lunar eclipse to delineate also the solar.

Recapitulation of the foregoing calculation, from Precept 82 to 94.

In the year 1659, November 14, at 3 h. 30' after midday at Bologna.

It was nevertheless observed somewhat through clouds; the beginning of this eclipse at Bologna [was] somewhat earlier, whether for physical causes, or because of the still-hidden motion of the Moon by which the eclipse is hastened, or because of the parallax of longitude continually and irregularly variable in eclipses.

Thus far the calculation in the old astronomy, though formerly I was not accustomed to complete it so accurately. The rest we pursue from the recent astronomy, and first

On Horizontal Eclipses.

Precept 96. To discern the moment of time at which the Sun rises or sets.

First, from Table 11, [Margin: Pag. 5.] extract, under the given altitude of the pole and with the place of the Sun, the semidiurnal time — for this will be the time from the meridian to the point at which the Sun sets; or, more reliably, on account of refraction, about 4 minutes after this time. But if you wish to have the semidiurnal time, subtract from 24 hours: there will remain the hours after midday of the preceding meridian, at which the Sun has risen — or about 4 minutes earlier, on account of refraction.

Precept 97. To inquire the true places of the luminaries at the moment of rising or setting.

In the preceding precept we supposed the Sun to be on the horizon at its very rising or setting. But when a solar eclipse is to be seen, a new moon either somewhat precedes or somewhat follows that rising or setting; and so, when the

Sun is about to attain rising, the place of the new moon precedes it; when the Sun is about to attain setting, it follows.

First, then, inquire the difference of time between the rising of the Sun and the new moon, or between the new moon and the setting, and the mean motion of the Sun congruent with such difference, and add it — in a morning eclipse, subtract it — from the place which the new moon held; in an evening eclipse, add it; and you will have the place of the Sun at the moment of rising or setting.

Second, with the equated anomaly of the Moon find the hourly motion of the Moon from the Sun, and by it multiply the aforesaid difference of time; whatever arises from this, subtract from the place of the Moon in a morning new moon, or add in an evening one, and it will give the place of the Moon as seen at the moment of the Sun's rising or setting.

Precept 98. To inquire the parallax of the Moon in longitude and in latitude at the moment of rising or setting.

First, [find] the motion of the Moon in the due interval of time between the new moon and the rising, or between the setting and the new moon, and add or subtract the equated anomaly of the Moon, at the time of the true new moon, just as in the preceding precept you subtracted or added the same scruples; thus you will obtain the equated anomaly of the Moon from the same place. So with the anomaly of the Moon equated to the moment of that same rising or setting, and with the anomaly of the Moon thus equated, find the horizontal parallax of the Moon from the Sun by Precept 58.

Second, consult Table 33, the altitude of the nonagesimal, [Margin: Pag. 38.] and in its margin, with the place of the Moon at the time of rising in a morning eclipse, or at the time of setting in an evening one, and under the given altitude of the pole, find the altitude of the nonagesimal. Having subtracted [for] the place of the node Ω from the nonagesimal, [use it] as the argument of latitude, [and] look up in Table 44 the northern latitude to be added, or the southern to be subtracted, from the altitude of the nonagesimal, [Margin: Pag. 51.] so that you may have the altitude of the nonagesimal in the Moon's orbit.

Third, finally, in Table 56, the parallactic [table], [Margin: Pag. 61.] [find] at the head the horizontal parallax of the Moon from the Sun, and in the right margin the altitude of the nonagesimal in the Moon's orbit: for the area will give the parallax of the Moon in longitude. But under the same horizontal parallax at the head, and with the altitude of the nonagesimal in the Moon's orbit, in the left margin you will obtain the desired parallax of latitude.

Precept 99. To find the distance between the centers of the Sun and the apparent Moon at the hour of sunrise or sunset on that same day.

First, take the true place of the Moon at the time of sunrise, and add to it the equation of its parallax in longitude if the eclipse is in the morning; but subtract it from the Moon's place if it is in the evening. Then take the Moon's motion for the interval between the new moon and sunrise — or sunset, by Precept 97 — and likewise take the true argument of the Moon's latitude at the time of the true conjunction. If the eclipse is in the morning, add this; if in the evening, subtract it — for in that case you have the argument of latitude at the given moment of sunrise or sunset.

Second, by the argument just found compute the true and apparent latitude as in Precept 91 at the moment of sunrise or sunset.

[Margin: Pag. 71.] Third, gather the difference of the Moon's apparent place, whether it is rising or setting; and with it enter Table 60 at the left side, where you will find the foregoing minutes (these I call the *prior* minutes, for the sake of distinguishing them). Then again, with the visible latitude in the left side of the same Table, and with the seconds in the head, you will find the *posterior* minutes. The common cell will give the *prior* minutes — for from the same region, the latitude being in the left side of that same Table and the seconds in the head, what minutes the Table shows in the left side and what seconds in the head will correspond.

Fourth, the aggregate of the *prior* and *posterior* minutes — what lies in that cell of Table 60 — the left side will indicate the minutes; the head will show the seconds: by these the distance between the luminaries' centers will be seen.

Precept 100. To investigate the digits of the ecliptic at the moment of sunrise or sunset of the luminaries.

[Margin: Pag. 47.] With the anomaly of the luminaries, gather from Table 39 their apparent semidiameters. From the sum of these subtract the distance between the apparent centers found by Precept 99; and with the remainder, together with the diameter of the Sun, enter Table 57 [Margin: Pag. 66.] and seek the digits to be obscured — that is, treating that remainder as if it were the deficient minutes.

On Solar Eclipses celebrated in the Subterranean Hemisphere.

Precept 101. To find the semidiameter of the Earth's disk as seen from the Moon.

[Margin: Pag. 47.] At the moment of true new moon, with the equated anomaly, seek in Table 39 the Moon's horizontal parallax: for as great as this is, so great will be the semidiameter of the Earth's disk as seen from the Moon.

Example.

In the year 1657, on the day [?] of June, there was an ecliptic syndoy at the apparent hour 11 after midday at Bologna, 11 hours and 11 minutes; the Moons coming together to the moment [?] of the Moon's equated anomaly being $74^{\circ}.57'.22''$; and therefore for us the horizontal parallax and the semidiameter of the terrestrial disk appearing $55'.35''$.

Precept 102. To find the altitude of the nonagesimal in that region for which the new moon, with the Sun unseen, was conjoined, so that the solar eclipse may be central or partial.

[Margin: Pag. 61.] Gather the true latitude of the new moon at the given time, and seek it as observed in the cells of the parallactic Table 56, under the semidiameter of the Earth's disk, that is the horizontal parallax, found by the preceding precept. For from the region of latitude in the left side you will have the altitude of the nonagesimal in that region for which the true and visible conjunction occurred at the same moment; and the nonagesimal will incline toward the south if the latitude was northern, but toward the north if southern.

Example.

In the latitude of the preceding Example, the Moon's true latitude was $43'.43''$, and the horizontal parallax $55'.35''$; under which, in the parallactic Table 56, opposite the said latitude, the altitude of the nonagesimal is found to be $37^{\circ}.25'$, inclining toward the south.

Precept 103. To inquire the altitude of the pole of the aforesaid region.

Take the place of the ecliptic in which the true new moon is celebrated, and add three signs, or 90 degrees; and you will have the ecliptic point ascending for the said region; and with this, in Table 33, seek at the sides, and with the altitude of the nonagesimal found by the preceding precept and observed in that area, in the region opposite the ascendant, seek again in the head of the Table the altitude of the pole.

But if in Table 33 you do not find the said altitude of the nonagesimal — the eclipse being not destined to be central in the Torrid Zone, in temperate regions, in cold ones; but in the temperate, or the Torrid, the eclipse will be partial and very small. Then add the region in which the eclipse will be very small, and the Moon will graze the margin of the Sun, where the highest semidiameters of the Sun and Moon coincide with the Moon's true latitude — which always, in these cases, are with the residue; and in the parallactic Table 56, in that area, under the horizontal parallax of the foregoing problem, you will have in the left side the altitude of the nonagesimal in that region of yours; with which, and with the degree of the ecliptic ascending, beside the foregoing precept, you find the altitude of the pole of the region desired.

Example.

In the aforesaid eclipse, the true place of the synod was Π $21^{\circ}.12'$; adding three signs there results the ascendant $\mathbb{M}$ $21^{\circ}.12'$; of which region, in no area is the altitude of the nonagesimal found to be $37^{\circ}.25'$. Therefore the eclipse is not central within the Torrid Zone, nor temperate.

Therefore, as a mark and note of the altitude of the pole of that region, where the margin of the Moon grazes the margin of the Sun by only so much, let us proceed in the calculation.

The following worked computation accompanies Precept 103.

	Sig.	Gr.	'	"
Anomalia Solis [Anomaly of the Sun]	11	12	34	0
Anomalia $\odot$ aequata [Equated anomaly of the Sun]	2	14	57	22
Semidiameter appar. $\odot$ [Apparent semidiameter of the Sun]			15	32

	Sig.	Gr.	'	"
Semidiameter appar. ☽ [Apparent semidiameter of the Moon]			15	17
Summa semidiametrorum [Sum of the semidiameters]			30	49
Latitudo Lunae vera Bor. [Moon's true latitude, North]			43	43
Residuum summa [Remainder of the sum]			12	54
Erat Parallax. Horizontalis [The horizontal parallax was]			55	35
Altitudo Nonagesimi [Altitude of the nonagesimal]		76	25	0
Erat punctum Ascendens [The ascending point was]	♊	21	12	0
Poli Altitudo [Altitude of the pole]		36	35	0

Therefore for the region whose north pole is elevated 36°.35', the eclipse was least, and the margin of the Moon grazed the margin of the Sun by only so much; in the remaining altitudes of the pole, therefore, greater, the eclipse was somewhat partial.

Precept 104. To compute the eclipses to be celebrated in the Southern region.

When the Moon's latitude is southern, and the parallax of latitude is joined to it, in whatever northern region it will make the sum greater than the aggregate of the luminaries' semidiameters, the eclipse will not happen except in southern regions. Then all the things which have been carried out up to here by Precept 101 — for finding the place of the true central new moon and as seen — must be carried out again, but with the degree of the ecliptic opposite to the degree in which the new moon is celebrated.

Precept 105. To determine the digits of the central solar eclipse.

In central eclipses, consult Table 57 [Margin: Pag. 66.] and in its head seek the apparent diameter of the Sun, and in the left side the minutes of deficiency, and seek the apparent diameter of the Moon; for the common area will give the digits. If these are exactly 12, the solar eclipse will be total and without duration [delay];

if more than 12, it will be total, and there will be a tarrying in darkness; if fewer, there will remain around the Moon a margin of the Sun in the form of a luminous ring.

Example.

In the preceding Eclipse	'	"
Semidiameter ☉ fuit [Semidiameter of the Sun was]	15	32
Diameter tota ☉ [Total diameter of the Sun]	31	4
Semidiameter ☾ [Semidiameter of the Moon]	15	17
Diameter tota ☾ [Total diameter of the Moon]	30	34
Ergo Digi Ecliptici [Therefore the ecliptic digits]	11	48 0

Therefore, in some region of the Arctic, where (as we indicated above) the eclipse was central, there appeared around the Moon a luminous ring.

On the Chief Phases of the Solar Eclipse.

Precept 106. To find the time which the Moon consumes from the point where the lunar shadow first strikes the Earth, up to the moment at which the said shadow leaves the Earth, and at which the said phases come about.

[Margin: Pag. 70.] Gather into one sum the apparent semidiameters of the luminaries, and the horizontal parallax of the Moon, in Table 60 at the left side; seek the foregoing greatest minutes, but in the head the seconds; for the common area will give the degrees and minutes which are called *Prior*. Again, in the left side of the same Table seek the minutes of the Moon's true latitude, and in the head the seconds; the area will give the degrees and minutes which are called *Posterior*; and subtract these *Posterior* from the *Prior*, and with the residue in the area of that same observed Table, see what minutes are in the left side, and what seconds in the head correspond there. For if these minutes and seconds are divided by the Moon's true hourly motion from the Sun, they will give in the quotient the hours which the Moon consumes from the moment when its shadow strikes the Earth, and the margin of the Sun at the limb of the Moon begins to be grazed, up to the moment of the true and visible synod; and consequently the time which the Moon consumes from the moment of the true and visible synod, up to the moment at which the lunar shadow leaves the Earth, and at which, with

the Sun setting at the end of the day, the eclipse for some place is also ended, the Moon entirely going out from the Sun's disk.

Example.

In the year 1654, on the day 11 of August, at the apparent hour at Uraniborg $22^{\text{h}}.58'.28''$ after midday, by the Rudolphine Tables there was a solar eclipse in δ $19^{\circ}.33'.45''$. Then therefore the calculation is thus.

The worked computation for Precept 106.

	Sig.	Gr.	'	"
Anomalia Solis [Anomaly of the Sun]	1	14	19	46
Anomalia $\odot$ aequata [Equated anomaly of the Sun]	8	9	26	1
Semidiam. appar. Solis [Apparent semidiameter of the Sun]			15	3
Semidiam. appar. Lunae [Apparent semidiameter of the Moon]			15	55
Parallax. Horizont. $\odot$ [Horizontal parallax — $\odot$]			61	57
Argumentum latitud. Lunae [Argument of the Moon's latitude]	5	24	4	18
Latitudo eius Borea [Its latitude, North]			30	57
Summa semidiam. & Parallaxis [Sum of the semidiameters and parallax]			92	55
Scrupula Priora [Prior minutes]		10	8	51
Scrupula Posteriora [Posterior minutes]		1	7	33
Residuum scrupulorum [Remainder of the minutes]		9	1	18
Scrupula dividenda [Minutes to be divided]			87	39
per Horarium $\supset$ à $\odot$ [by the hourly motion of the Moon from the Sun]			35	20
Quotiens dat Horas [The quotient gives, in hours]	H.	2	28	50
Nouilunium fuit Hora [The new moon was at the hour]	H.	22	58	28
Initium Eclipsis in Terris [Beginning of the eclipse on Earth]	H.	20	29	38
Finis Eclipsis in Terris die 12. [End of the eclipse on	H.	1	27	18

	Sig.	Gr.	'	"
Earth, on day 12]				

Therefore, from the beginning at which the Moon's shadow began to strike the Earth, and to graze ☉ the western margin of the Sun, up to the end, at which the Moon's shadow left the Earth, and the Moon went out beyond the eastern margin of the Sun, there intervene

Precept 107. To find the altitude of the nonagesimal in the regions in which the solar eclipse first begins, and in which its end last appears.

First, the minutes by the preceding Precept through the Moon's hourly motion (which are called the minutes of incidence) divided — subtract from the argument of the true latitude of the first phases, and you have the true argument of the first phase; that is, when the eclipse first begins on Earth: on the contrary, if you add the same to the same argument, you will have the true argument of the last phase, that is, when the eclipse altogether ends on Earth. And with these arguments seek the true latitudes of the Moon for each phase.

Second. Divide the latitude of the first phases by the sum of the luminaries' semidiameters and the horizontal parallax, and what comes out, seek in that column of the parallactic Table whose superscription is 60'; and observed in its left side, you have the altitude of the nonagesimal in that region, for which the rising Sun begins to be eclipsed by the Moon.

Third. Divide the latitude of the last phase by the same sum of the said three, and the quotient in the same column of 60' minutes observed — for that one in the left side answers to the altitude of the nonagesimal in that region of the world, for which the setting Sun ceases to be eclipsed by the Moon.

Example of the one in Precept 106.

The worked computation for Precept 107.

	Sig.	Gr.	'	"

	Sig.	Gr.	'	"
latitude]				
			38	32
Argum. latitud. ultimae Phasis & Latitudo Bor. [Argument of latitude of the last phase, and North latitude]	5	25	31	57
			23	20
Summa semidiam. & Parallax. de visâ per haec latitudine [Sum of the semidiameters and parallax, from the visible by this latitude]			92	55
			38	32
Quotiens est [The quotient is]			24	53
Hinc Nonagesimi Altitudo in loco prima Phasis [Hence the altitude of the nonagesimal in the place of the first phase]		65	5	0
At divisa per eandem summam Latitudine [But the latitude divided by the same sum]			92	55
			23	20
Quotiens est [The quotient is]			15	4
Et Nonagesimi Altitudo in loco postrema Phasis [And the altitude of the nonagesimal in the place of the last phase]		75	27	0

Precept 108. To find the altitude of the pole in the aforesaid two regions.

First. Take the interval of time between the true synod and the beginning of the eclipse on Earth, found by Precept 106; and from the mean motion of the Sun subtract the motion of the Sun owed to it, at the place of the Sun at the time of the given new moon; and with the signs, degrees, and minutes, the residue being observed in the other of the two sides of Table 33, where, directly opposite them, you find the altitude of the nonagesimal found by Precept 107 for the 1st phase observed above it in the head, you have the altitude of the pole desired.

Second. To the same mean motion of the Sun, add the place of the true Sun at the time of the given new moon, and with the signs, degrees, and minutes, from the facts thus done — but the opposites — in the same Table 33, see in whose column-

cell is the altitude of the nonagesimal, [Margin: Pag. 38.] by Precept 107 for the last phase found; for above it in the head you have the altitude of the pole sought.

Example of the preceding new moon.

Worked computation, first part.

	Sig.	Gr.	'	"
Horae intervalli erant [The hours of the interval were]	H.	2	28	50
Horum motus ☉ medius [Their mean motion — ☉]			6	7
Locus ☉ in vero ☿ [Place of the Sun in the true conjunction]	☿	19	33	45
Locus ☉ in 1. Phasi [Place of the Sun in the 1st phase]	☿	19	27	38
Altit. Nonagesimi tunc [Altitude of the nonagesimal then]		65	5	0
Ergo Poli Altitudo Bor. [Therefore the altitude of the pole, North]		41	22	0
Locus ☉ pro ult. Phasi [Place of the Sun for the last phase]	☿	19	39	52
Locus oppositus [Opposite place]	☿	19	39	52
Nonagesimi Altitudo tunc [Altitude of the nonagesimal then]		75	27	0
Quae in areis non apparet [Which does not appear in the cells]				
Vtere igitur priori [Use therefore the former]	☿	19	39	52
Vnde Poli Australis alt. [Whence the altitude of the South pole]		3	42	0

Note further that if in the aforesaid cells you do not find the altitude of the nonagesimal, then directly opposite the place of the Sun — which is a sign that the altitude of the South pole is to be sought, the Sun being in the place opposite, that is in the place opposite to the former place — you would attempt it.

Precept 109. To determine the regions themselves by means of the longitude for the 1st and last phases, in the manner stated.

First, with the place of the Sun found by Precept 108, seek the oblique ascension under the elevation of the pole for the same 1st phase just found, and from it subtract 90 degrees, and there will come out the right ascension of the Tabular Meridian of the said region. Then from the true hours of the new moon subtract the hours of the interval between the 1st phase and the new moon, now found by Precept 106, and the residue in degrees of the equator resolved, add to the right ascension of that degree of the place of the Sun, whose oblique ascension you just found; and there will come out the Right Ascension of the Tabular Meridian to the moment of the 1st phase: from which if you subtract the Right Ascension of the Meridian first found, the difference of the meridians toward the East will be given, if the prior Right Ascension of the Meridian be the greater; toward the West, if smaller. With the longitude known, in the geographical chart seek the place desired.

Second, for the place of the last phase with the degree of the ecliptic opposite to it, seek the oblique ascension under the altitude of the pole, and from it subtract 90 degrees, with the regions congruent, of the last phase; then from the hours of the interval between the new moon and the last phase, and the place of the true new moon, and the aggregate in degrees of the equator resolved, add to the right ascension of the place of the Sun in the last phase found: for you have the Right Ascension of the Tabular Meridian. Therefore if to this you subtract the Right Ascension of the preceding Meridian, you acquire the difference of the meridians, and so with the longitude and the altitude of the pole of the region desired.

Note further that if in the other phase the elevation of the pole found was southern, then 180 degrees must be added to the Right Ascension of the Mid-heaven of the Tables, and from the aggregate the other Right Ascension of the Meridian is to be subtracted, that you may have the difference of longitude.

Example of the preceding new moon.

Worked computation for Precept 109, first phase.

	Sig.	Gr.	'	"
Locus Solis in 1. Phasi [Place of the Sun in the 1st phase]	♌	19	27	38

	Sig.	Gr.	'	"
Altitudo Poli Bor. in 1. Phasi [Altitude of the North pole in the 1st phase]		41	22	0
Ascensio Obliqua loci ☉ [Oblique ascension of the place of the Sun]		128	12	6

Restat Meridianor. differentia [There remains the difference of the meridians]		292	49	39
Longitudo quaesita [The longitude sought]		103	55	21

The last therefore of the eclipses on Earth was in the Eastern Ocean near the island of S. Petri de Mascarenas; because its longitude is $103^{\circ}.55'.21''$, and its latitude South $3^{\circ}.42'$. Therefore the eclipse ceased upon the Earth, and the lunar shadow left it, in the place where the North pole is elevated $23^{\circ}.55'$; and whose longitude from Palma is $289^{\circ}.1'$, namely near the cape of S. Antoni, on the island of Cuba.

Precept 110. To find the time from when the total solar eclipse first begins with the rising Sun, up to the middle, the true and visible central synod, and from there up to the time at which the total central solar eclipse last occurs with the setting Sun.

With the apparent semidiameter of the Earth's disk, that is, with the horizontal parallax of the Moon, [Margin: Pag. 70.] extract Table 60. The Table will give the degrees and minutes, which are called *Prior*. This same fact, with the Moon's true latitude found for the moment of the true new moon, gathers the degrees and the

Posterior minutes; which subtract from the *Prior*, and with the residue in the area of that same Table 60, gather in the left margin what minutes are divided by the Moon's hourly motion from the Sun: that ex front the seconds; for if you divide them by the Moon's hourly motion from the Sun, you have in the quotient the time apparent, at which the total eclipse first appears on Earth with the rising Sun, that is, the moment at which the eclipse first appears on Earth with the rising Sun; up to the moment at which, at the nonagesimal from sunrise, the true and visible central synod will appear. Therefore from this interval, the time of the apparent synod being subtracted, you have the time of this phase. Likewise if you add to the same time the time of the true synod, you have the time at which the central eclipse last appears with the setting Sun.

Example of the preceding new moon.

Worked computation for Precept 110.

	Sig.	Gr.	'	"
Parallaxis ∽ Horizontal. [Horizontal parallax of the Moon]			61	57
Scrupula priora [Prior minutes]		4	28	58
Latitud. ∽ in vera ♂ [Latitude of the Moon in the true conjunction]		0	30	57
Scrupula posteriora [Posterior minutes]		1	7	33
Residua scrupula [Remaining minutes]		3	21	25
Scrupula dividenda [Minutes to be divided]		0	55	37
Per Horarium ∽ à ☉ [By the hourly motion of the Moon from the Sun]		0	35	20
Ergo Hora [Therefore the hour]	H.	1	34	26
Hora Nouilunij fuit [The hour of the new moon was]	H.	22	58	28
Hora igitur primae centralium Eclipsium [Therefore the hour of the first of the central eclipses]	H.	21	24	2
Et ultima centralium diei 2. Aug. [And the last of the central ones, on day 2 of August]		0	32	54

Precept 111. To find the altitude of the nonagesimal in regions, for the two phases just mentioned.

Take the minutes that you found in the preceding precept by the hourly difference, and subtract them from the argument of the latitude of the true new moon. What remains is the argument of the latitude for the first of the central eclipses, which you must look up; once found, look afterward in the columns of the parallactic Table 56, under the observed horizontal parallax, and against it on the left-hand side you will see the desired altitude of the nonagesimal for this first phase.

But if you add those same minutes to the same argument, you will have the argument of the true latitude for the last of the central eclipses; from this, the latitude — which in the same Table 56, under the horizontal lunar parallax, will show on the left-hand side the altitude of the nonagesimal for this last phase.

Example in the preceding new moon.

	Sig.	Gr.	'	"
Argument of the true latitude in ϕ	5	24	4	18
Argument of the latitude for the 1st central	5	23	8	41
Argument of the latitude for the last central	5	24	59	55
Latitude at the 1st central, North			35	46
Latitude at the last central, North			26	7
Horizontal parallax of $\odot$			61	57
Altitude of the nonagesimal at the 1st central		54	44	0
Altitude of the nonagesimal, last central		64	56	0

Precept 112. To find the altitude of the pole for each of the two aforesaid phases and regions.

Take the mean motion of the Sun corresponding to the time between the 1st of the central eclipses and the true conjunction found by Precept 110. Subtract it from the true place of the Sun for the 1st central; add it for the last central; and with the signs and degrees of the place of the Sun thus corrected, observed in the side-columns of the Tables, and against the altitude of the nonagesimal of those, acquired by the preceding precept, you will find at the head of the Table the desired altitude of the pole, according to the procedure of Precept 109.

Example in the preceding new moon.

	Sig.	Gr.	'	"
Place of $\odot$ in the true ϕ	ϕ	19	33	45

	Sig.	Gr.	'	"
Time between $\odot$ and the 1st central	H.	1	34	26
Mean motion of $\odot$ for this time			3	53
Place of $\odot$ for the 1st central	∂	19	29	52
Place of $\odot$ for the last central	∂	19	37	38
Altitude of the nonagesimal, 1st		54	44	0
Altitude of the nonagesimal, last		64	56	0
Altitude of the pole for the 1st central, North		51	9	0
Altitude of the pole for the last central, North		6	26	0

But this is found with the place of the Sun opposite.

Precept 113. To determine the regions themselves by their longitude.

Given the place of the Sun and the altitude of the pole found by the preceding precept, the oblique ascensions are to be sought, and everything else is to be carried out that you performed in Precept 109 — so that for the 1st and the last of the central eclipses you may have the difference of meridians from the meridian of the Tables, and thereby the longitude of each of the two regions sought. This you will learn by a brief example.

Example in the preceding new moon.

	Sig.	Gr.	'	"
Pro 1. centralium [For the 1st central]				
Altitude of the pole, North		51	9	0
Place of the Sun then	∂	19	29	52
Its oblique ascension		122	26	6
Right ascension of the chosen meridian		32	26	6
Right ascension of the place of the Sun		141	56	38
Hour of this phase	H.	21	24	2
Their parts of the equator		321	0	30
Right ascension of the meridian of the Tables		102	57	8
Difference of meridians		70	33	2
And the longitude of the region sought		326	11	58

Accordingly, the 1st of the central eclipses occurred on the northern seacoast of Nuremberg, where the altitude of the pole is degrees 51, 9', and the longitude degrees 326, 11', 58".

	Sig.	Gr.	'	"
Pro vltima Centralium [For the last central]				
Altitude of the pole, North		6	26	0
Place opposite the place of the Sun	☾	19	37	38
Its oblique ascension		323	17	48
Right ascension of the chosen meridian		233	17	48
Place of the Sun	☉	19	37	38
Its right ascension		142	3	38
Hour of this phase	H.	0	32	54
Their parts of the equator		8	13	30
Right ascension of the meridian of the Tables		150	17	8
Difference of meridians		276	59	20
Longitude sought		119	45	40

Therefore the last of the central eclipses occurred in the Indian Ocean toward the east, at the entrance of the Gulf of Ganges [Sinus Gangeticus], where the altitude of the pole is degrees 6, 26', and the longitude degrees 119, 45', 40".

Precept 114. To find the region to which, at the nonagesimal — the true and the apparent conjunctions coinciding, and at the visible conjunction — the eclipse appears central.

First, by Precepts 101, 102, and 103, find both the altitude of the Earth's disk and that of the nonagesimal, and likewise of the pole, for the region to which such a phase belongs. Then, with the place of the Sun in the true new moon at 90 degrees, increased under the said altitude of the pole, seek the oblique ascension; subtract from this 90 degrees, and you will have the right ascension of the meridian, under which this phase occurs. Finally, to the right ascension of the place of the Sun add the parts of the equator answering to the apparent hours of the true new moon, and you will produce the right ascension of the meridian of the Tables; comparing this with the right ascension of the previous meridian, you will have the difference of longitude, and thereby the longitude of the region sought, in which this phase occurs.

Example for the preceding new moon.

	Sig.	Gr.	'	"
Semidiameter of the Earth's disk	0	0	61	57
In the true σ , true latitude of $\mathcal{D}$			30	57
Altitude of the nonagesimal		60	2	0
And the altitude of the pole, North		43	6	0
Place of $\odot$ in σ	σ	19	33	45
With 90 added		90	0	0
Ascending degree	$\mathfrak{M}$	19	33	45
Its oblique ascension		244	27	19
Subtract 90		90	0	0
Right ascension of the chosen meridian		154	27	19
Right ascension of the place of $\odot$ in σ		141	59	48
Hour of the apparent new moon	H.	22	58	28
Their parts of the equator		344	37	0
Right ascension of the meridian of the Tables		126	36	48
Difference of meridians		332	9	29
Longitude sought		64	35	31

Therefore in that place where the north pole stands elevated degrees 43, 6', and whose longitude is degrees 64, 35', 31", there the new moon was true and the central conjunction was visible — that is, on the seacoast of the Black Sea [Euxine] near Amasia, and the river Thermodon, just as throughout that whole tract which the Moon's shadow occupied; for the eclipse was of 12, 43' digits.

Precept 115. To find the regions of the Earth, above which the shadow of the Moon is carried during the whole time of a solar eclipse.

Once five places of the five phases are found — those obtained from Precept 106 to 114 — it is easy, on globes or geographical maps, to mark out the tract of the Earth which the Moon's shadow traversed throughout the whole time of the solar eclipse. Thus, in the preceding eclipse, after the rising Sun was eclipsed at the Fortunate Islands [Fagudae insulae] of the Atlantic, it began on the western side of the Moon to be covered by the interposed disk; gradually, with the rising Sun, the growing defect was first wholly raised to its northern extreme at Nuremberg, where the Moon was touched by its center. From there, the center of the lunar

shadow passed into the east, and first wandered across the land of the Laboratores, then the Caledonian Ocean, Scotland, the Danes, the Cimbri, and the rest; and through Poland and Podolia it crossed the Black Sea, where at the true nonagesimal, and with the conjunction visibly central, it appeared. Further it advanced to Armenia, and to the southern coasts of Persia; and from there, in the eastern mouth of the Gulf of Ganges, it last hid the whole Sun in the west. At last, leaving the Sun setting at the Island of St. Peter of Mascareñas [Insula S. Petri de Mascarenas], it left the Moon free, and its shadow forsook the Earth.

Precept 116. To find the place of Saturn in longitude in its orbit.

When the work requires it, fit it to the precepts of Part I, or follow the order written below.

1. First, by Precepts 55 or 56, find the true place of the Sun, and its equated anomaly.
2. Second, from Table 62, which is held at page 72, elicit the mean motion of Saturn from the equinox; the apogee; and the northern node.
3. Third, subtract the motion of the apogee from the motion of Saturn from the equinox, and you will have the simple anomaly, which is in Table 63 at page 73. Seek there the centric equation, that is, of Saturn's first inequality, to be added to, or subtracted from, his mean motion from Υ , so that you may have the eccentric place of Saturn — that is, his place first equated, or seen from the Sun.
4. Fourth, subtract Saturn's centric place from the true place of the Sun, and the anomaly of the orb [*Anomalia Orbis*] is left.
5. Fifth, with the simple anomaly, of which number 3, seek in Table 64, which is at page 73, the *Anomalium Aequatam* of Saturn [the equated anomaly of Saturn].
6. Sixth, with the equated anomaly of the Sun, and with the equated anomaly of Saturn, seek in Table 65, which page 74 gives, the maximum equation of Saturn's orb [*Maximam Aequationem Orbis Saturni*].
7. Seventh, finally, with the maximum equation of Saturn's orb, applying the general prosthaphaeresis Table of the orb, which is 95, page 94, observe at the head, or foot, of the Table, and with the anomaly of the orb, of number 4, descending downward, or ascending upward, seek in the common area the prosthaphaeresis of the orb, to be added to, or subtracted from, the centric place of Saturn (the Moon being seen from the Earth). Here, this same order, to be observed, will hold for Jupiter and for Mars, with the proper Tables of each applied, as will be said below.

Example for ♄.

In the year of Christ 1604, September 27, about the 8th hour, at Prague, from observations Saturn and Mars were thought to be in the same longitude. Here Saturn's place is sought; the order of calculation is as follows.

	Sig.	Gr.	'	"	
☉ True place	6	4	47	44	Tab. 36
☉ Anomaly 99	2	27	4	44	38
♄ Mean motion from ♄	8	13	49	13	Tab. 62
Motion of the apogee	8	26	6	51	Pag. 72
Motion of the node ☾	3	20	32	5	
Simple anomaly	11	17	42	22	
Equation 1, to be added	0	1	18	33	Tab. 63
♄ Eccentric place	8	15	7	46	Pag. 73
Anomaly of the orb	9	19	39	58	
Anomaly of ♄ equated	0	11	35	30	Tab. 64
Maximum equation of the orb	0	5	41	30	Pag. 73
					Tab. 65
					Pag. 74
Equation of the orb, to be subtracted	0	5	10	30	Tab. 95
♄ Place in the orbit	8	9	57	16	Pag. 94

Therefore Saturn was then in Sagittarius, degrees 9, 58', 16".

Precept 117. To compute the latitude of Saturn.

1. First, with the equated anomaly of the eccentric of Saturn, observe at the head, or foot, of Table 66, which begins at page 75; and with the anomaly of the orb of Saturn, on the left, or right, side of the same Table, seek in the common angle the proportional minutes of the latitude.
2. Second, with the anomaly of the orb observed in the sides of the same Table 66, seek the scruples in the next-to-last column, whose title is: *Scrup. Prop. Incr. & Decr.* [proportional scruples, increasing & decreasing].
3. Third, if the increment-scruples, or the decrement-scruples, are in the next-to-last column, in the upper part, whose title is A, that is, what answers to the anomaly of the orb in the first three, or the last, signs — then one must take, with the equated anomaly of the Sun, the increment in the

antepenultimate column, whose title is: *Increm. in ☿* [increment in conjunction]. But if the scruples of increment, or decrement, are in the lower part, whose title is B, take the scruples of decrement in ☿^o [opposition] in their proper columns; that is to say, when the equated anomaly of the Sun is at the head, or foot, of Table 66, and with the equated anomaly of the eccentric of Saturn on the left, or right, side.

4. Fourth, as 60 is to the scruple of increment, or of decrement, of which I spoke as number 3, so is the scruple of increment, or decrement, of the penultimate column, of which number 2 — to a fourth proportional number; this number, or rather this quotient, add — if it is increment — to the first number found; or, if it is decrement, subtract it — and you will have the scruples of latitude corrected.
5. Fifth, go to Table 67, page 76, and in it, with the distance of the eccentric place of Saturn from the northern node sought, at the head or foot, as to the signs, and with the degrees of the signs on the left or right side, seek in the latitude-columns the right sine of the latitude, of what radius is 60.
6. Sixth, finally, make, as 60 is to the right sine of the latitude, so the scruple of latitude corrected, of which number 5, to another, and there will result a certain sine, which is the general latitude, which is 96 at page 107, and will exhibit the latitude of Saturn, of its affection — how far distant from the node ☿ — the signs in Table 67 indicate.

Example.

The same case, of which in the preceding precept's example.

	Sig.	Gr			
		.	'	"	
Anomaly of ♄ equated	0	11	35	30	Tab. 66
Anomaly of the orb	9	19	9	58	
Therefore proportional scruples of latitude		51	44		
And scruple of increment or decrement		17	52		
Which, because they are upper, indicate <i>Increment</i>					
Anomaly of ☉ was equated	2	26	34	44	
Therefore increment in ☿		6	30		As 60 [Vt 60.]

(continued)	Sig.	Gr.	'	"	
As 60 is to 6½, so is 17, 52', to			1	49	
Which, added to the scruples of latitude			51	44	
Gives the corrected scruples of latitude			53	33	
Eccentric place of ♄ was	8	15	7	46	
Place of the node ☿ was	3	20	32	50	
Therefore distance of ♄ from the node ☿	4	24	34	56	
And the sine of the latitude			1	43	
As 60 is to 143, so is 53, 33, to			1	29	3
					0
To which, in the General Table, under degree 1, answers the latitude			1	33	3
					0
Which, from the distance of ♄ from the node ☿, is gathered to have been northern.					

Precept 118. To reduce the place of Saturn from the orbit to the ecliptic, and to complete its curtation.

1. First, with the distance of Saturn's eccentric place — that is, his place first equated — from the northern node, from Table 67, which is held at page 76, extract both the reduction [*Reductionem*] and the curtation [*Curtationem*].
2. Second, add the reduction to the place of Saturn in the orbit, if the planet approaches the node receding from the limit; but subtract it, if it recedes from the node, approaching the limit; and you will have the place of Saturn reduced to the ecliptic.
3. Third, let it be done that, as the maximum equation of the orb is to the curtation, so the equation of the orb answering to the anomaly of the orb is to a proportional part of the curtation, which is always to be subtracted from the equation of the orb. Therefore, if the equation of the orb was additive, subtract the proportional part of the curtation from the place of the planet reduced to the ecliptic; but if it was subtractive, add the proportional part of the curtation to the place of the planet on the ecliptic, but curtated, as is fitting.

Example.

In the case of Precepts 116 and 117, and of the same example.

	Sig.	Gr.	'	"	
Distance of the eccentric place of ♄ from the node ☿	4	24	34	56	Tab. 96
Therefore reduction			1	35	Tab. 67
And curtation				12	

Because Saturn was receding from the northern limit, and approaching the southern node, therefore the reduction is to be added to the place in the orbit found, which was $\text{♄ } 8^{\circ}, 9', 57'', 16'''$. Therefore the place of Saturn on the ecliptic was $\text{♄ } 8^{\circ}, 9', 58'', 51'''$. Now the maximum equation of the orb was degrees 5, 41', 30"; and the equation of the orb answering to the anomaly was degrees 5, 10', 30". And the equation of the orb's anomaly answering was degrees 5, 10', 30", and was subtractive; therefore, as degrees 5, 41', 30" are to the curtation 12", so degrees 5, 10', 30" are to the curtation 11", which, being subtracted, would make the equation more subtractive. But it is nonetheless the same if you add the 11" to the place of Saturn on the ecliptic, curtated. And in the year 1604, September 26, at the 8th hour past noon, at Prague, Jupiter was at $\text{♃ } 9^{\circ}, 59', 2''$.

Similarly one must operate in the reduction, and the curtation of Jupiter, as of Mars; and let there be curtation in Saturn and Jupiter, though it could be neglected — not, however, in Mars.

Precept 119. To compute the place of Jupiter in longitude.

Do everything as in Precept 116, but use the proper Tables of Jupiter, which begin at Table 68, page 77, and end at page 80.

Example for ♃.

In the year of Christ 1634, Jupiter was observed on April 11, at the 12th hour after noon at Bologna, in degrees 25, 45', 40" of Gemini. There the place of Jupiter is sought from our Tables, computed.

	Sig.	Gr.	'	"	
☉ True place	0	22	3	45	Tab. 36
☉ Anomaly equated	9	14	50	11	& 38
♃ Mean motion from ♈	3	0	7	15	
Motion of the apogee	6	8	50	39	

	Sig.	Gr.	'	"	
Motion of the northern node	3	8	50	44	
Anomaly of ♈, simple	8	21	16	36	Tab.
Equation 1, to be added	0	5	32	39	96
♈ Eccentric place	3	5	39	54	
Anomaly of the orb	9	16	24	0	Tab.
Anomaly of ♈ equated	3	6	0	0	70
Maximum equation of the orb	0	11	9	0	71
Equation of the orb, to be subtracted	0	9	58	27	95
♈ Place in the orbit	2	25	41	27	

Therefore the place of Jupiter in the orbit was in ♊ degrees 25, 41', 27". But because it was observed with respect to the ecliptic, it is to be reduced, and the place is to be curtated here, as below.

Precept 120. To compute the latitude of Jupiter.

Do everything as in Precept 117, but use the proper Tables of Jupiter.

Example.

For the year 1634, April 11, at the 12th hour after noon at Bologna, of which above.

	Sig.	Gr.	'	"	
Anomaly of ♈ equated	3	6	0	0	
Anomaly of the orb	9	16	24	0	
Therefore proportional scruple of latitude		45	12	0	Tab. 72
And scruple of increment or decrement		22	23	0	
Which, because they are upper, indicate <i>Increment.</i>					
Anomaly of ☉ was equated	9	14	50	11	
Therefore increment in ☊			4	30	
As 60 is to 4½, so is 22, 23, to			1	40	
Which, added to the scruples of latitude		scru.	45	12	
Gives the corrected scruples of latitude			46	52	

	Sig.	Gr.	'	"	
Eccentric place of ♃	3	5	39	54	Tab.
Place of the node ♄	3	8	50	44	Tab. 73
Distance of ♃ from the node ♄	0	3	10	50	
Therefore sine of the latitude			0	6	
As 60 is to 0, 6, so is the corrected scruple of latitude 46, 52', to 0, 47'; to which, in the General Table of Latitude, answers the latitude, North, of degrees 0, 49'.					Tab. 96

Precept 121. To reduce the place of Jupiter from the orbit to the ecliptic, and to complete its curtation.

Do everything as in Precept 118, but use the proper Tables of Jupiter, which are 73, at page 80.

	Sig.	Gr.	'	"
Distance of the eccentric place of ♃ from the node ♄	0	3	10	50
Therefore reduction				4
And curtation				0

But Jupiter was approaching the node; therefore the reduction is to be added to the place of Jupiter in the orbit, which was Π 2, 25, 41', 27", so that on the ecliptic it is Π 2, 25, 41', 31"; nor is there need of curtation. But the Tables appear to fall short of the observation by 4', 9"; yet the greater part of the discrepancy can, not without reason, be referred back to the observation.

Precept 122. To compute the location of Mars in longitude.

Carry out everything as in Precept 116, but use the tables proper to Mars, which begin at Table 74, page 81, and end at page 84.

Example.

In the year 1604, on October 9, a little before noon, from observations made at Prague, there was a conjunction of Jupiter and Mars. At that time, by my reckoning, the hour was 23 [hours] 15' 17" after the noon of the 8th, with Jupiter at $19^{\circ} 15' 17''$. The location of Mars is now sought; the calculation runs as follows:

	Sig.	Gr.	'	"	Tab.
☉ True location	6	16	18	20	36 &
☉ Equated anomaly	3	8	35	4	38
♂ Mean motion	10	3	36	22	Tab.
Motion of the apogee	4	29	17	49	74
Motion of the northern node	1	15	37	54	
Simple anomaly	5	4	18	33	Tab.
Equation 1, of the inequality, subtr.	0	5	8	11	75
♂ Eccentric location	9	28	28	11	
Anomaly of the orb	8	17	50	9	Tab.
Anomaly of Mars, equated	5	2	0	3	76 &
Maximum equation of the orb	0	45	15	0	77
Equation of the orb, subtr.	1	9	13	49	&
♂ Location in the orbit	8	19	14	22	95

Precept 123. To compute the latitude of Mars.

Do everything as in Precept 117, but use the tables proper to Mars, which begin at page 81.

Example, the one in the preceding precept.

	Sig.	Gr.	'	"	Tab.
Anomaly of Mars, equated	5	2	0	3	
Anomaly of the orb	8	17	50	9	
Therefore the scruples of latitude	0	14	20	0	Tab.
And the scruples of increment or decrement	0	11	37	0	78
Which are the upper ones					
And they indicate increment					
☉ Anomaly, equated	3	8	35	4	
Scruples of increment in Mars	0	0	4	0	

As 60 is to 14° 20', so 4' is to 57" 20"', which is to be added to the scruples of latitude, so that the corrected ones come to 15° 17' 20".

	Sig.	Gr.	'	"	Tab.
Distance of the eccentric location of Mars from the node ☿	8	12	50	17	Tab.
Sine of the latitude	0	7	4	0	80

As 60 is to $15^{\circ} 17' 20''$, so the sine $7^{\circ} 4'$ is to the sine $1^{\circ} 47'$. This, in the General Table of Latitude, gives the latitude as $1^{\circ} 52'$, southern, as the signs of the distance from the node ☿ indicate.

Precept 124. To reduce the location of Mars from the orbit to the ecliptic, and to complete its curtation.

Do everything as in Precept 118, but use the tables proper to Mars, Table 80, which is found at page 84.

Example of the case above.

	Sig.	Gr.	'	"	Tab.
Distance of the eccentric location from the node ☿	8	12	50	17	
Therefore the curtation	0	0	1	7	Tab.
And the reduction, subtr.	0	0	0	32	80
Because it was approaching the limit					
Location in the orbit was	8	19	14	22	
Therefore location in the ecliptic	8	19	13	50	
Maximum equation of the orb	0	45	15	0	
Equation of the orb, subtr.	0	49	13	49	

Therefore: as $45^{\circ} 15'$ is to the curtation $1' 7''$, so $49^{\circ} 13' 49''$ is to the curtation $1' 13''$. By this amount the equation of the orb is to be diminished, so that it comes out smaller in its subtraction — but it amounts to the same thing as if you were to add $1' 13''$ to the location reduced to the ecliptic. Hence the location of Mars, reduced and curtated, was in Sagittarius at $19^{\circ} 15' 3''$; and Jupiter was at $19^{\circ} 15' 36''$. So a little after the 23rd hour the conjunction of Jupiter and Mars was completed — namely, at the hour 23 [hours] 50' after the noon of the 8th, just as the observation has it.

Precept 125. To compute the location of Venus in longitude.

First, find the true location of the Sun and its equated anomaly by Precept 55 or 56.

Second, in Table 81, which is found at page 85, extract the mean motion of Venus from the equinox, the motion of the apogee, and the motion of the northern node.

Third, subtract the motion of the apogee from the mean motion of Venus, and you will have the *simple anomaly*. With this, in Table 82 — which is at page 86 — you will have the first *equation*, to be added to or subtracted from the mean motion of Venus, as the headings of the table indicate; and the location of Venus, first equated, will result — that is, the eccentric, or the location as seen from the Sun.

Fourth, subtract the true location of the Sun from the location of Venus seen from the eccentric, and the *anomaly of the orb* will remain.

Fifth, with the simple anomaly — which you seek in Table 83, page 86 — find the equated anomaly of Venus; with this, together with the equated anomaly of the Sun, in the lateral columns, inquire the *maximum equation of the orb* in Table 84, page 87. With the anomaly of the orb in the lateral columns, and the maximum equation of the orb at the head in Table 95, gather the *equation of the orb*, to be added to or subtracted from the location of the Sun, as the headings of the table teach; and you will have the location of Venus seen from the Earth.

Example.

Longomontanus [Christian Longomontanus] reports that he observed Venus at its greatest digression from the Sun in the year 1585, on September 14, by the old style, at the hour 17 [hours] 15' after the meridian, in Leo at 15° 58'. Suppose that, with the Danish tables set aside, the reduction and curtation give 15° 53' 20". The location obtained from Tycho [Tycho Brahe], however, was somewhat in error, because too great a parallax of the Sun was assumed, and the declination too. Let us see what our tables yield.

	Sig.	Gr.	'	"	Tab.
☉ True location	6	1	48	41	Tab.
☉ Equated anomaly	2	24	25	23	36

Node ☿	2	13	59	52	81
Simple anomaly	3	5	27	30	Tab.
Equation 1, subtr.	0	0	54	24	82

	Sig.	Gr.	'	"	Tab.
♀ Location from the Sun	1	9	42	58	
Anomaly of the orb	7	7	54	17	Tab.
Anomaly equated	3	4	59	57	83
Maximum equation of the orb	0	46	4	30	84
Equation of the orb, subtr.	1	5	41	50	85
♀ Location in the orbit	4	16	6	30	

It was therefore in Leo at 16° 6' 30".

Precept 126. To compute the latitude of Venus.

First, from Table 85, page 88, seek the scruples of latitude proportional to the equated anomaly of Venus at the head, or at the foot of the table, and to the anomaly of the orb of Venus in the lateral columns; and with these, the lower scruples.

Second, in Table 86, page 89, with the equated anomaly of the Sun at the head — or at the foot of the table — and with the equated anomaly of Venus in the lateral columns, inquire the scruples of decrement, by Table 86.

Third, do as follows. By Table 85, the decremental scruples are found; with this inferior scruple, decrement is found by Table 86. Subtract the inferior scruples from the latitude-scruples found first, so that you may have them corrected.

Fourth, with the distance of the eccentric location of Venus from the northern node — which you seek in Table 87, page 89 — find the sine of the latitude.

Fifth, do as follows. To the sine of the latitude, thus corrected, the scruple of latitude corresponds with the sine of the other [angle], which, in the general table — which is Table 96 — will give the latitude of Venus, of the same kind as the distance from the northern node indicates in Table 87.

Example, in the case above.

	Sig.	Gr.	'	"	Tab.
☉ Anomaly, equated	2	24	25	23	Tab.
♀ Anomaly of the orb	7	7	54	17	85
Scruples of latitude	0	24	18	0	

	Sig.	Gr.	'	"	Tab.
Inferior scruples	0	11	58	0	
♀ Anomaly, equated	3	4	59	57	Tab.
Scruples of decrement	0	1	36	0	86

Now, as 60 is to $11^{\circ} 58'$, so the scruples of decrement are $1^{\circ} 36' 18''$. Subtracting these scruples of latitude, with the latitude-scruples corrected, there remain $24^{\circ} 0'$.

	Sig.	Gr.	'	"
Node ♃, location	2	13	59	52
♀ Location from the Sun	1	9	42	58
Distance of ♀ from the node ♃	1	4	16	53
Sine of the latitude	0	5	45	0

Now, as 60 is to the sine $24^{\circ} 0'$, so the sine $5^{\circ} 45'$ is to the other sine $2^{\circ} 18'$. This, in Table 96, gives the latitude as $2^{\circ} 24'$, northern — if indeed the distance of Venus from the further northern node was at 2 signs 14° . Therefore the latitude is descending.

Precept 127. To reduce the location of Venus from the orbit to the ecliptic, and to complete its curtation.

First, with the distance of the eccentric location of Venus — that is, of Venus seen from the Sun — from the northern node, seek the reduction in Table 87, and the curtation at the foot of the table. If, however, Venus is in conjunction with the orb, there are no reductions, but the curtations are at their maximum.

Conversely, in conjunctions [of Venus with the Sun], the curtations are nil, but the reductions are at their maximum.

Second, do as follows. With the maximum equation of the orb found for the reduction, and with the difference between the maximum equation of the orb and the equation of the orb corresponding to the anomaly of the orb, the reduction is to be added to the location of the orb if the planet is approaching the node by receding from the limit; but it is to be subtracted if it is receding from the node by approaching the limit.

Third, do as follows. With the maximum equation found for the curtation, the curtation corresponding to the anomaly of the orb is to be subtracted from the

equation of the orb; thus, if the equation of the orb was subtractive, subtract less; if additive, add less.

Example, in the preceding case.

	Sig.	Gr.	'	"
♀ Distance from the node ☿ was	1	4	16	53
Therefore the reduction is to be added	0	0	2	48
And the curtation	0	0	3	18
Maximum equation of the orb	0	46	4	30
Equation of the orb	0	45	41	50
Difference of these	0	0	22	40

Now, as $46^{\circ} 4\frac{1}{2}'$ is to the reduction $2' 48''$, so the difference is $22'$. So that it differs by $22' 40''$, that is: as $46^{\circ} 4\frac{1}{2}'$ is to the reduction $1'$, so $16^{\circ} 7' 48''$ is to the reduction for the signs at $16^{\circ} 7' 48''$.

Then, as $46^{\circ} 4\frac{1}{2}'$ is to the curtation $3' 18''$, so $45^{\circ} 41' 50''$ is to the curtation $3' 11''$. To the curtation thus found, with the subtraction of the orb, or with the reduction added to the location of Venus, gives the curtated location in Leo at $16^{\circ} 10' 48''$ — namely a little less than $13'$ further on than the Tychonic, but false on account of too great a parallax of the Sun and the declination, and perhaps also on account of the observations themselves.

Precept 128. To compute the location of Mercury in longitude.

Do everything as in Precept 125 — as you did for Venus — but use the tables proper to Mercury, which begin at Table 88, that is, at page 90, and end at page 94.

Example.

In the year 1481, on October 21, at the hour 18 [hours] $10'$ after noon, Bologna time, Mercury was observed to be more easterly than Saturn, by more than the diameter of the Moon; and Saturn was then for me in Libra at $18^{\circ} 13' 20''$.

Therefore Mercury was very nearly in Libra at $18^{\circ} 46'$. The location is sought as seen from the Earth; the calculation is as follows:

	Sig.	Gr.	'	"	Tab.
☉ True location	7	7	52	30	36
☉ Anomaly, equated	4	2	16	42	38

	Sig.	Gr.	'	"	Tab.
☿ Mean motion	3	9	39	30	Tab.
Motion of the apogee	8	8	10	49	88
Node ☿	1	9	20	48	
Simple anomaly	7	1	28	41	
Equation 1, add.	0	15	31	0	Tab.
☿ Location from the Sun	3	25	10	30	89
Anomaly of the orb	8	17	18	0	
Anomaly equated	7	7	46	34	Tab.
Maximum equation	0	18	59	0	90
Equation of the orb, subtr.	0	18	49	50	91
☿ Location in the orbit	6	19	2	40	95

Therefore the location of Mercury in its orbit was in Libra at 19° 2' 40".

Precept 129. To compute the latitude of Mercury.

First, with the equated anomaly of Mercury in the column opposite at the head — or at the foot of Table 92 — and with the anomaly of the orb of Mercury in the lateral columns, seek the proportional scruples of latitude. If the signs are 7, [use] degree 20; use signs 1, degree 20. Since in the inquiry of the scruples of latitude one must begin at the perigee, the table begins from the apogee.

Second, note that in Table 92 there are two columns of proportional scruples — of increment and of decrement, namely the second and the antepenultimate. The second corresponds to the least distance of Mercury from the Sun, and is to be used with the anomaly of the eccentric — but, as I have said, with the signs transposed: in the first case, if the signs are fewer than 4 signs, or fewer than 10. The antepenultimate, however, is to be used — that is, it is to serve for the greatest distance of Mercury from the Sun — when, with the anomaly of the eccentric (as I said) transposed into the opposite signs, it is greater than 4 signs or greater than 8. When, finally, the equated anomaly is either greater than 2 signs or 4 signs, or less than 4 signs or 10, the numbers of the mean distance are to be used; these you will gather by the proportional part from columns 2 and the antepenultimate compared together. With these well understood, seek in Table 92 the proportional scruples of increment and of decrement, noted with the anomaly of the orb in the lateral columns.

Third, if the scruples of increment and decrement in Table 92, corresponding to the anomaly of the orb, are the upper ones and pertain to the part of the second column, or of the antepenultimate, whose heading is A, then in the same table, in the penultimate column, the scruples of decrement are to be taken in direct conjunction with the equated anomaly of the Sun. But if the scruples of increment

and of decrement are the lower ones, and pertain to the second column or to the antepenultimate part, whose heading is B, then in Table 93, with the anomaly of the eccentric of Mercury equated at the head — or at the foot — and with the equated anomaly of the Sun in the lateral columns, the scruples of decrement are to be taken in opposition, that is, in retrograde conjunction.

Fourth, do as follows. As 60 is to the proportional scruples of decrement in Mars, direct or retrograde, of which I spoke in the third; thus the proportional scruples of increment, found in the second, [are] to the scruple to be adhibited for the correction of the scruples of latitude, and to be subtracted from them.

Fifth, with the distance of the eccentric location of Mercury from the northern node, seek in Table 94 the sine of the latitude; and do as follows. As 60 is to this sine, so the scruple of latitude is to the other sine, which in Table 96 will exhibit the latitude of its kind — which Table 94 indicates as the distance of Mercury from the northern node.

Example, in the preceding case.

	Sig.	Gr.	'	"	Tab.
Anomaly of ☿, equated	7	7	46	34	Tab.
For which the opposites are	1	17	46	34	92
Anomaly of the orb	8	17	18	0	
Anomaly of the Sun, equated	4	2	16	42	
Scruples of latitude	0	22	24	0	
Scruples of increment and decrement	0	2	17	0	Tab.
Which are the lower ones					93
Therefore they are scruples of decrement					
In retrograde conjunction they are	0	0	31	0	

Now, as 60 is to 31', so $2^{\circ} 17'$ is to $1^{\circ} 12'$. With the scruples 22' 24' to be subtracted, there remain corrected $21^{\circ} 12'$.

Then:

	Sig.	Gr.	'	"
Node ☿ location was	1	9	20	48
☿ Eccentric location	3	25	10	30
Distance of ☿ from the node ☿	2	15	49	42
Sine of the latitude in Table 94	0	6	15	0

Now, as 60 is to 6° 15', so 21' 12" is to the sine 2° 13', which in Table 96 gives the latitude as 2° 18', northern — as the signs of the distance from the node, and ascending, indicate, on account of the approach to the northern limit.

Precept 130. To reduce the location of Mercury from the orbit to the ecliptic, and to complete its curtation.

Do everything as for Venus in Precept 127, but use the tables proper to Mercury, namely 91 and 94.

Example, in the preceding case.

	Sig.	Gr.	'	"	Tab.
Distance of the eccentric ☿ from the node ☿	2	15	49	42	Tab.
Reduction, subtr.	0	0	6	3	94
Curtation	0	0	10	3	
Maximum equation	0	18	59	0	91
Equation of the orb	0	18	49	50	95
Difference of these	0	0	9	0	

As 18° 59' is to the reduction 6' 3", so the difference is 9' to 16". Therefore the location of Mercury, reduced to the ecliptic, is in Libra at 19° 2' 24". Then, as the maximum equation of the orb 18° 59' is to the curtation 10' 3", so [the rest is] to the curtation 10'; this, added to the location of Mercury reduced — if indeed the equation of the orb was subtractive — gives the curtated location in the ecliptic, in Libra at 19° 12'. The observer placed it in Libra at 18° 46', around which the eye's estimate is fallible, given the magnitude of the lunar diameter [used] between Saturn and Mercury as seen.

Precept 131. To find the declination and right ascension of a planet by the tables.

By the tables, I say, without the solution of spherical triangles. Therefore first inquire the longitude and latitude of a planet by the precepts given above; then use Precept 54, with Tables 34 and 35, made for that use.

Precept 132. To find the distance of the minor planets from the Sun, in parts of which the mean distance of the Sun from the Earth — that is, the radius of the Sun's annual orb — is 100000.

You have already, from the precepts given above, the equated anomaly of the planet for each individual planet; resolve it into degrees. For if you seek these degrees in the first or second column of Table 97 — which is found at page 108 — opposite them you will have, for each planet, the distance of the planet itself from the Sun, in parts of which the radius of the Sun's annual orb — that is, the greater semidiameter of the solar ellipse, or the mean distance of the Sun from the Earth — is 100000. But if there is need, use the proportional part, as for Saturn.

Example, from Jupiter.

Above, in the example of Precept 116, the equated anomaly of Saturn was 0 signs 11° 35' 30". Resolved into degrees, it comes to 11° 35¾'. To this, in Table 97, Saturn corresponds: the distance from the Sun is 1008340 parts, using the proportional part.

But in the example of Precept 119, the anomaly of Jupiter was 3 signs 6°. This, equated precisely in Table 97, gives a distance of 935927 parts under Jupiter — parts of which the radius of the Sun's annual orb is 100000. And so for the rest.

Precept 133. To find the distance of the minor planets from the Earth, in parts of the radius of the Sun's annual orb.

If you wish the extreme distances from the Earth — when the planet is at apogee or perigee, or at aphelion or perihelion — I have set them out at the foot of Table 97. The rest must be hunted out by trigonometry, from the distance of the Sun from the Earth given by Precept 58, and the distance of the minor planets [from the Sun] by Precept 132, with the equated anomaly's angle being comprehended from these distances.

Precept 134. To find the distance of the planets from the Sun or the Earth, in terrestrial semidiameters.

We have already the distance of a planet in parts of which the radius of the Sun's annual orb is 100000, by Precepts 132 and 133. Multiply this by the terrestrial semidiameters which the mean distance of the Sun from the Earth contains,

according to the opinion you choose to follow here, and divide the product by 100000; for in the quotient you will have the desired distance in terrestrial semidiameters.

Example, for Jupiter.

In the example of Precept 132, for Jupiter we had a distance from the Sun of 935927, in parts of which the radius of the annual orb is reckoned at 100000. Now, since the distance of the Sun from the Earth is 7300 terrestrial semidiameters, if these are multiplied by 935927, the product is divided by 100000: this leaves the distance of Jupiter from the Sun as 68323 terrestrial semidiameters.

Precept 135. To find the longitude and latitude of the fixed stars at any given time.

First, in Table 98 — which is found at page 109 — seek the longitude and latitude of a fixed star, given for the end of the year of Christ 1700; for the latitude, indeed, is found there as perpetual. Then [seek] the intervals of years between the given year and the year 1700, and between the given month and the year 1700; seek

[continued from the preceding page]

look it up in Table 100, the motion of the Fixed Stars corresponding to the expanded and collected Years, and reduce these into a single sum; and if you add this sum to the given time, it exceeds the Years of Christ 1700; or else subtract it, if the time precedes; and what is then left over will be the Longitude of the Fixed Star for the given time.

Example, for Regulus, in the Year 456

In the year 1700 complete since Christ, the Longitude of Regulus is ϱ 25° 38' 32". The perpetual North Latitude is 0° 26' 20".

Now let the year 456 complete since Christ be given, which subtracted from 1700 leaves an interval of 1244 years; the motion corresponding to these years is found from Table 100, namely 15° 30' 29"; for the sum stands thus:

Motion	Gr.	I	II	III
In 1000 years	14	4	26	6
In 200 years	2	48	53	20
In 44 years	0	37	9	20

Motion	Gr.	I	II	III
Sum	15	30	28	46

Since this is to be subtracted (because the given time precedes), subtract it from Regulus's Longitude $\varnothing$ $25^{\circ} 38' 32''$: there remains for Regulus a Longitude of $\varnothing$ $10^{\circ} 8' 3''$, which agrees with what is found at the end of the Year 456. And the North Latitude is $0^{\circ} 26' 20''$.

Precept 136. To find the Right Ascension and Declination of the Fixed Stars for a given time, with a notable warning concerning the bright star in the Shoulder of Ursa Minor, and stars like it.

If a Fixed Star in Table 99 is not the bright star of the Shoulder of Ursa Minor — for which look in Table 99 — then take its Right Ascension and Declination as they stand at the end of the Year 1700 of Christ; and add to these the centennial difference proper to that star. You must add the Right Ascension of 1700 and subtract if it precedes, or for the Declination add or subtract as is there noted, if the time follows — for if it precedes the Year 1700 you do the opposite — and where it says subtract, you add, and where it says add, you subtract.

Furthermore, each difference is to be multiplied by the interval of time between the Year 1700 and the given time, and the sum divided by 100; for there will then come out the difference, to be added to or subtracted from the radix of the Year 1700, as I have said.

Example, for Regulus, in the Year 456

In Table 99, for the Year 1700 complete, the Right Ascension of Regulus is $148^{\circ} 4' 15''$; its centennial difference is $1^{\circ} 22' 30''$. But its North Declination is $13^{\circ} 25' 16''$; and its centennial difference here is $28' 30''$. Now to subtract the preceding interval of time, which was 1244 years: multiplied by the Right Ascension's difference of $1^{\circ} 22' 30''$, and first resolved into seconds, 4950'', this makes a sum of seconds 5157800; which divided by 100 leaves 51578'', that is $14^{\circ} 19' 38''$. Since therefore the given time precedes the Radix, the $148^{\circ} 4' 15''$ of the said Right Ascension and these $14^{\circ} 19' 38''$ are to be drawn apart; and there remains, for the Year 456 of Christ, a Right Ascension of Regulus of $133^{\circ} 44' 37''$.

But for the Declination, the difference to be subtracted afterward — yet here added beforehand — the centennial being $28' 30''$, that is 1710'', which multiplied by the 1244 years makes 2327240''; which divided by 100 leaves 23272'', that is $6^{\circ} 27' 52''$; and these added to the Declination of the Year 1700, namely $13^{\circ} 25' 16''$, give for the Year 456 of Christ the North Declination of Regulus, $19^{\circ} 53' 8''$.

Concerning the bright Shoulder of Ursa Minor, for the Year 456

We once showed, in Book 6, Problem 11, and we have driven home, in the first Volume of the *Astronomia Reformata*, Book 4, that the Right Ascension of all the Stellar Fixed Stars at some point decreases, even while the longitude increases — those whose latitude is greater than 66° , on the supposition (as we suppose) that the obliquity of the Ecliptic is perpetually $23^\circ 30' 20''$. But if there are Boreal Stars, the Right Ascension begins to decrease in the first quadrant of the Ecliptic, and ceases to decrease in the second. Of such Fixed Stars, in the said Problem 11, there are 59 Boreal; and we [also] counted Austral ones. But from these we are able to assign none in Table 99 except the bright Shoulder of Ursa Minor, which at some time was the Cynosura nearest the Pole of the World [Euodoxus]; its North Latitude is, by my reckoning, $72^\circ 48' 40''$. From this it follows that, as its Right Ascension continually decreased from the beginning of the World, and its longitude increased while the Right Ascension decreased, it will come to about the 15th degree of Leo — which happens around the Year 2137 of Christ.

Therefore, since its Right Ascension in the Year 1700 in Table 99 is given as $222^\circ 39' 20''$, and the centennial difference is $1^\circ 15'$ — that is $75'$ — which multiplied by the 1244 years that fall between the Year 456 and 1700 makes 93300; this divided by 100 leaves 933, that is $15^\circ 33''$ [?]; which is not to be subtracted but added — give the difference, $222^\circ 39' 20''$ — and so the Right Ascension of the bright Shoulder of Ursa Minor for the Year 456 of Christ comes to $238^\circ 12' 20''$.

TABVLAE NOVALMAGESTICAE

[The New Almagestic Tables]

Of the Secondary Movables [SECVNDORVM MOBILIVM]

With several Tables of the Primum Mobile necessary to them.

[This page is the divisional title of the *Tabulae Novalmagesticae*. The reverse (verso) of the preceding leaf shows the bleed-through, mirror-reversed, of the running header and the start of the Regulus-example text from p. 451.]

Prima Pars Tabularum Astronomicarum spectans ad Tempus
[First Part of the Astronomical Tables, pertaining to Time]

TABULA 1. Of the parts of the As applied [Partium Assis applicatarum]

The columns give, for each named subdivision of the As [Assis], its equivalent in twelfths [Unciae], in degrees of a circle [Circulo · Grad.], in minutes of a degree or of an hour [Gradui vel Horae · Minuta], and in hours of a day [Diei · Horae].

Parts (Partes) / As (Assis)	Twelfths (Unciae)	Circle, degrees (Circulo, Grad.)	Of a degree or hour, minutes (Gradui vel Horae, Minuta)	Of a day, hours (Diei, Horae)

TAB. 4. Conversion of the [first] fractions of a Day into Equal Hours, and Hourly fractions [Conversio Scrupulorum Diei in Horas Aequales, et Horaria scrupula]

Two side-by-side panels. Header rows: Scrupula Diei → Prima, Hore, I; Secunda → I, II; Tertia → II, III. The first panel runs entries 1–30, the second 31–60. (Each entry of the first day-fraction [Scrupula Diei Prima] is converted into Hours [Hore], minutes [I], and seconds [II/III].)

TABLE 5. Collection of the Days of the Common and Bissextile Roman Year [*Collectio Dierum Anni Romani Communis, & Bissextilis*]

The first two columns give the bissextile (leap-year) day-count and the common-year day-count; the remaining twelve columns give the cumulative day-number reached at the corresponding day of each named month. The two cross-symbols (✕) in the lower rows of the Bissextile, Common, January, and February columns mark cells with no entry (days that do not occur, e.g. 29–31 February in the common-year reckoning).

TABLE 6. Collection of the Days of the Egyptian Year
[Collectio Dierum Anni Aegyptiaci]

Twelve 30-day months (Thoth through Messori) followed by the five epagomenal days (*Epagomenae*). Each column gives the cumulative day-number reached at the corresponding day of the named Egyptian month. The cross-symbol (⌘) marks cells with no entry (the months run only to 30, so there is no day 31).

TABLE 7. Conversion of the Hours of the Primum Mobile into Parts of the Equator, with the Equation to be Added for the Hours of the Solar Day [*Conversio Horarum Primi Mobilis in Partes Aequatoris, cum Aequatione Addenda pro Horis Diei Solaris*]

This table has three panels. The first panel converts whole hours (1–24) of the primum mobile; the second and third panels convert minutes (1–30 and 31–60). The "Add for the Sun ☉" column gives the equation (the excess of the solar day over the sidereal rotation) to be added.

Panel 1 — Hours. Column headings: Primum Mobile, Hours (*Pri. Mob. / Horae* — units: Minutes ', Seconds "); Equator, Degrees (*Æquat. / Gr.* — units: ', "); Add for the Sun ☉ (*Adde pro ☉* — sub-columns I and II, units ", ', ").

TABLE 8. Conversion of the Parts of the Equator into Time of the Primum Mobile, with the Equation to be Subtracted for the Times of the Solar Day [*Conversio Partium Aequatoris in Tempus Primi Mobilis, cum Aequatione Subtrahenda pro Diei Solaris Temporibus*]

Three panels. The first converts degrees of the equator (1–30), the second 31–60, the third the round tens 70–360. Column headings: Equator, Degrees (*Æquat. / Grad.* — units: Minutes I, Seconds II); Time of the Primum Mobile (*Tép. 1. Mob.* — Hours, Minutes I — units I/II, II/III); Subtract for the Sun ☉ (*Subtr. pro ☉* — sub-columns I and II, units II/III, III/IV).

Panel 1 — Degrees 1–30.

TABLE 9. Conversion of Hours into other Hours, reckoned from a different beginning of the Day [*Conversionis Horarum in alias Horas, à diverso Diei initio numeratas*]

This is a rule-table (not numeric): the left column names the hours to be converted (*Horae convertendae*), the right column states into what they are converted (*Convertuntur*).

Hours to be converted: Babylonian, or from Sunrise [*Babylonicae, seu ab Ortu Solis*], into:

- **Astronomical** — to be numbered from the preceding noon, by adding the Babylonian half-day quantity and the night quantity.
- **European** — from noon; by subtracting the half-day quantity from the Babylonian hours, if the Babylonian hours exceed it; but if they do not exceed it, once the subtraction is made, the remainder is taken from the residue of 12 hours, and there will remain the European hours from midnight.

- **Italian, or from Sunset** [*Italicas, seu ab Occasu*] — by adding the Babylonian night quantity.

Hours to be converted: Italian, or from Sunset [*Italicæ, seu ab Occasu Solis*], into:

- **Astronomical** — by adding the Italian half-day quantity.
- **European** from noon (if the Italian hours do not exceed the night quantity) — by adding the Italian half-day quantity.
- **European** from midnight (if the Italian hours exceed the half-night quantity) — by subtracting the Italian half-night quantity.
- **Babylonian** — by subtracting the night-time from the Italian hours.

Hours to be converted: Astronomical, or from noon to noon [*Astronomicæ, seu à meridie ad meridiem*], into:

- **European** from noon — if they do not exceed 12, adding or subtracting nothing.
- **European** from midnight — if the astronomical hours exceed 12, let 12 be taken away.
- **Babylonian** — by adding the half-day quantity to the astronomical hours.
- **Italian** — by subtracting the half-day quantity from the astronomical hours.

Hours to be converted: European from midnight — for from midnight to noon they coincide with the astronomical [*Europææ à media nocte, namque à meridie coincidunt cum Astronomicis*], into:

- **Astronomical** — by adding 12 hours to the European hours.
- **Babylonian** — by subtracting the half-night quantity from the European hours.
- **Italian** — by adding the half-night quantity to the European hours.

Whenever the subtraction cannot be made, add the 24 given hours, and subtract from the sum what is required. Whenever from the addition more than 24 result, throw away 24 and keep the rest. [Quoties subtractio fieri nequit, adde 24. horis datis, & à summa subtrahe, quod imperatur. Quoties ex Additione fiunt plusquam 24. abijce 24. & reliquas retine.]

TABLE 10. The Quantity of one Temporal Hour,
Corresponding to the Quantity of the Artificial Day
[*Quantitas Horae unius Temporalis, Respondens quantitati
Diei Artificialis*]

Six panels arranged across the page. Each panel pairs a column of artificial-day quantity (*Minuta Diei Artific. / Artific. Diei*, given in minutes and hours) with the corresponding twelfth-part (*Duodecima pars / Duodecimaeorū pars*), i.e. the length of one temporal hour. The leading panels run by minutes (0–60), the later panels by hours (H.). The minute-block at the head of the first two panels gives the twelfth-part in I, II (minutes, seconds), while the hour-blocks give it in H., I, II (hours, minutes, seconds).

Panels 1–2 (minutes 1–60). Headings: *Minuta Diei Artific.* (Min. — units I, II), *Duodecimaeorū pars* (units I/II, II/III); then *Minuta Diei Artific.* (Min. — units I, II), *Duodecimaeorū pars* (units I/II, II/III).

28	2	20	58	4	50
29	2	25	59	4	55
30	2	30	60	5	0

Panels 3–6 (artificial-day hours 1–24). Each block heads with *Artific. Diei* (H. — units I, II) and *Duodecima pars* (H., I, II). The hour-of-the-artificial-day appears once at the top of each five-row group (the five rows being its minutes 0, 10, 20, 30, 40, 50); the corresponding twelfth-part is given in hours, minutes, seconds.

TABULAE NOVALMAGESTICAE — Part II (Primum Mobile)

TAB. 11. — Semidiurnal and Seminocturnal Time

TAB. 11. Of Semidiurnal Time, when the Sun is in the Northern Signs; but of Seminocturnal Time, when the Sun is in the Southern Signs, at the Pole Altitudes written below. [*Semidiurni Temporis, quando Sol est in Signis Borealibus, Seminocturni autem quando Sol est in Signis Australibus ad infrascriptas Poli Altitudines.*]

This single table (TAB. 11) runs continuously across the opening, tabulating the semidiurnal/seminocturnal arc as time, by pole altitude [*Poli Altitudines*]. The leftmost columns give the Southern sign [*Sign. Aust.*], the Northern sign [*Sign. Bor.*], and the degree within the sign [*Gradus*]; the same degree-row labels recur in every block. Each pole-altitude column is a pair: **H.** = hours [*horae*], ' = minutes [*scrupula prima / minutes*]. The Northern signs (read top-to-bottom with the left **Gradus** scale ascending 0→30) are Aries ♈, Taurus ♉, Gemini ♊; the Southern signs (right-hand **Gradus** scale, descending) are Virgo ♍, Leo ♌, Cancer ♋ on one side, and Libra ♎, Scorpio ♏ [*Scorpius, here the printer's woodcut "comet/insect" mark stands for ♏*], Sagittarius ♐ on the other, with Pisces ♓ and Capricorn ♐ at the foot. The row-label scheme is identical in all blocks; it is given in full in the first block and abbreviated thereafter to the degree value.

The row labels, in order, are:

Sign. Aust.	Sign. Bor.	Gradus (left)	Gradus (right)	Sign. (right)
♈	♈ Aries	0	30	♈ / X(✕)
		3	27	
		6	24	
		9	21	
		12	18	
		15	15	
		18	12	
		21	9

Block 6 — Pole altitudes 81 to 89

The 89° column heads only a single value column labelled **90** in the body (a quarter is reached); transcribed as printed. The rightmost data column is headed **89** with sub-head **90** — see anomaly (b).

Appendix to TAB. 11

Appendix TAB. 11. — For the Greatest Day, where the Pole is elevated more than $66\frac{1}{2}$ degrees, after the *Sphaera* of Clavius [Christophorus Clavius], chap. 4, not taking refraction into account; for which see our *Geographia Reformata*. [Appendix TAB. 11. pro Maxima Die, ubi Polus elevatur plus Gradibus $66\frac{1}{2}$. ex *Sphaera* Clavij cap. 4. non considerantis Refractiones, pro quibus vide nostram *Geographiam Reformatam*.]

The table gives, for each elevation of the pole [*Elevatio Poli*, in degrees, **Gr.**], the **arc that is always apparent** [*Arcus semper apparens*, in degrees **Gr.** and minutes **M.** — the circumpolar arc never setting] and the **continuous day** [*Dies continuus*, in days **D.**, hours **H.**, and minutes **M.** — the span during which the Sun does not set]. It is printed as two side-by-side panels (poles 67–78 on the left, 79–90 on the right).

Tomus II — Tabulae Novalmagesticae (continued)

[Note: the handoff expected the Primum Mobile tables (TAB. 12 onward, declination / right & oblique ascension). The pages actually present in this opening are the equation-of-time tables **TAB. 12** and **TAB. 13** and the geographic gazetteer **TAB. 14 — Catalogus Locorum Insigniorum**. Printed page numbers are 8, 9, 10.]

TAB. 12 — Equation of Time at the Sun, per Tycho, but with a different obliquity

TAB. 12. The Equation of Time at the Sun [aequatio temporis in ☉] according to Tycho [Tychone Braheo, Tycho Brahe], but with the obliquity of the ecliptic [obliquitas eclipticae] set at 23° 30' 20". Subtract from the Apparent, Add to the equal time [aequalis tempus].

The argument is the degree of the ecliptic (Gr.). The three sign-pairs share columns of minutes and seconds. Column-head sign-groups (top): ♈ & ♎ & — | ♊ & — | ♋ & ♏ [as printed; the running sign symbols are partly worn]. The right-hand margin repeats the degree (counting downward 30→0) for the complementary entry; the foot legend reads **Add to the Apparent, Subtract from the Equal** [Adde Apparenti, Subtrahe Aequali].

The first sign-group head is ♈ & ♎ & ♊ (Aries & Libra & Aquarius region), then ♊ & ♋ & ♏, then ♋ & ♌ & ♏; the symbols are abraded — read the three columns as the three sign-triplets of the standard equation-of-time layout.

	V. Subtr. XI. Adde	IV. Subtr. X. Adde	III. Subtr. IX. Add.	

Foot legend (full width): **Equated Anomaly of the Sun, Signs [Anomalia Solis Coaequata Signal].**

TAB. 13 — Temporary Equation of Civil (Natural) Days

13. TAB. The Temporary Equation of Civil, or Natural, Days [Temporaria Aequatio Dierum Civilium seu Naturalium], compounded from the two preceding, and serving for the year of Christ 1504, for the conversion of Apparent Time into Equal [pro conversione Temporis Apparentis in Aequale].

Argument: **Loci** ☉ (place of the Sun) in degrees (Gr., 0–30). Twelve zodiac-sign columns, each labelled **Adde** or **Subtr.**, each entry '":

Υ Adde · ϣ Subtr. · Π Subtr. · ☿ Adde · ♈ Adde · ♊ Adde · ♎ Subtr. · ♍ Subtr. · ♊ Subtr. · ♎ Subtr. · ♋ Adde · ♏ Adde.

Foot legend (full width): **If the Equal is to be converted into the Apparent, do the contrary of the Titles [Si Aequale vertendum sit in Apparens, Fac contrarium Titulis].**

Catchword: **TAB. 14.**

TAB. 14 — Catalogue of the More Notable Places

TAB. 14. CATALOGUE OF THE MORE NOTABLE PLACES [Catalogus Locorum Insigniorum].

With the Difference of Time to be Added, or Subtracted, to the Time of the Bolognese Italic Meridian [Tempus Meridiani Bononiensis Italici], and the Altitude of the North Pole [Altitudo Poli Borealis], where A is not added; taken from Book 9 of our *Reformed Geography* [Geographia Reformata], in which it is given much more fully.

Column structure (each half-page): **Names of Places [Nomina Locorum] | Difference of Time [Differentia Temporis]: H. ' '' (ad. = add / sub. = subtract) | Altitude of the Pole [Altitudo Poli]: G. ' ''** (where "A." after the altitude marks a southern/austral latitude). Place names give the Latin form, often followed by the vernacular in italic.

TAB. 14 — *Catalogus Locorum Insigniorum* (Catalogue of Notable Places) [continued]

This is a gazetteer giving, for each place, the **difference of time** [Differentia Temporis] from the Bologna meridian (hours H. / minutes ' / seconds ", with ad. = *to be added* and sub. = *to be subtracted*) and the **altitude of the pole** [Altitudo Poli] (degrees G. / minutes ' / seconds "). A trailing A. in the pole-altitude column

marks a southern (austral) latitude; where no A. appears, the northern hemisphere is implied. The vernacular name follows the Latin in *italic* where given. The columns run across the page in two panels (left and right); they are transcribed here as a single continuous list, left panel first, then right panel, page by page.

Left panel:

Place name [Nomina Locorum]	H				G

Closing note of the table (full-width, below both panels):

We have omitted many places, once famous, because now there is scarcely anyone willing to carry an astronomical calculation to them, or to transfer one from there to us. But since the longitude of Bologna is — as we demonstrated in our *Geographia Reformata* — 34° 30' from the Fortunate Isle of Palma, the longitude of the other places listed in this catalogue can readily be gathered from the difference of time. Convert that difference into degrees and minutes of the equator by means of Table 7 given above, then add 34° 30' where the mark is *ad.*, or subtract it where the mark is *sub.*

It is assumed that the intercalation was made in the years before [the era], and thenceforward always just as Julius Caesar had ordered — this present Year of Confusion being passed over, together with the error of the ancients in intercalating. *[Supponitur intercalatio facta Annis ante, & porrò semper prout iusserat Iulius Cæsar, dissimulato hoc Anno Confusionis, & errore Priscorum in intercalando.]*

TAB. 22. A Synopsis of the Notable Epochs, beginning in the Year before — or after — the Common Era of Christ, marked in the left margin.

[TAB. 22. Synopsis Epocharum Insigniorum ineuntium Anno ante, vel post Epocham vulgarem Christi in sinistro margine, notato.]

(Two-column table: a left column "Years before Christ" / "Years of Christ" giving the epoch year, and a right column giving the epoch's description.)

Years before Christ

5509 — Of the WORLD, its beginning on the Calends of September [1 September], according to the Greeks, in the Patriarchate of Constantinople; and they fix this year as the first of the fifteen-year cycle of Indictions.

4713 — The JULIAN PERIOD, taken from the Greeks by Joseph Scaliger [Josephus Scaliger], which consists of 7980 years. For when 28 (the Cycle of the Sun) is multiplied by 19 (the Cycle of the Moon), 532 years result; and these multiplied by 15 (the Cycle of Indictions) make 7980. In this year was the first year of each of these cycles. Hence in the first year of the Christian Era the Julian Period was 4714, and the Cycle of the Sun was 10, the Moon's [Cycle] 2, the Roman Indiction 4.

776 — The first year of the first OLYMPIAD, in which Coroebus of Elis [Coroebus Elidensis] was the first entered into the Catalogue of the Olympic victors — granted that earlier Iphitus had restored the Olympic games after they had been discontinued. The Athenians, however, began these years from the new moon nearer the summer solstice, namely from some day in June or July, others reckoning otherwise. It was year 3938 of the Julian Period. The Cycle of the Sun 18, of the Moon 5, the Indiction 8.

753 — The CITY OF ROME Founded, on the Palilia [festival of Pales], that is, 21 April; thus Varro [reckons] of this year, [as do] the Censorinus[es] and most of the learned, and they themselves, and the magistrates in the secular games. Granted that the City may be thought founded in the year 752 before the Christian Era, after Cato [Catonem], [from] the Tarentine [Fasti] [and] the Capitoline Fasti, and a few others. But the aforesaid year 753 [is] of the 6th Olympiad, a third year, not yet completed; and it [is] year 3961 of the Julian Period. The Cycle of the Sun 13, [of the Moon] 9, the Indiction 1.

747 — Of NABONASSAR, whose years begin astronomically at the meridian of the 26th day of February, from which the first day of the month Thoth begins, the Egyptian [year] consisting of 365 days. The beginning of its completed cycle [is] year 1460, which is the *great Dog-Star year*, or the *Sothic Period* [Periodus Sothiacal]; in the year 1461 it returns to the same day of the same Julian month. It was year 3967 of the Julian Period, ferial day 4. Cycle of the Sun [☉] 19, of the Moon 15, the Indiction 7; [and] of the founding of the City 6, [these years] still running.

529 — CAMBYSES I, son of Cyrus, began to reign in the year of Nabonassar 219; he entered upon [his reign over] the Egyptians on the 4th [day] of January.

433 — METON, from the 26th of June, devised his Nineteen-Year Cycle, granted that, together with Euctemon, he observed the solstice for establishing that cycle, in the year before Christ 432, on 27 June.

330 — Of the CALIPPIC Period, consisting of 76 years, beginning from the summer solstice in the Greek manner, but in the Egyptian manner from 15 November, when it was the year 419 of Nabonassar. The second Calippic Period began in the year 254 before Christ, and the third in the year 178.

324 — The death of ALEXANDER the Great, in the year of the Julian Period 4390, and of Nabonassar 424 completed, and 425 beginning, at the meridian of the 12th day of November. For the Egyptians, with Ptolemy [Ptolemæo] and Theon [Theone], and with these Albategnius [al-Battānī], likewise begin from there the Years of Alexander, and the Egyptians [from] those of Nabonassar. Granted that Alexander the Great died with the preceding May, or in June.

312 — The Era of the SELEUCIDS begins, also called [the Era] *of the Greeks*, or *of the Contracts* [Contractuum]; or [the Era] of Alexander *Dhilkarnayn* [Dhū al-Qarnayn], that is, of the Kingdom of Alexander divided into the Two Great Horns of Seleucus — namely [...]

(The left column continues lower with further "Years before Christ":)

311 — ...indeed, and the Arabs [reckon] [this era] after Christ, but from the Calends of October of the Julian year. The Chaldeans, however, began it in the following year from the Ides of October.

285 — Of DIONYSIUS the Mathematician, the Years [reckoned] in the manner of Ptolemy; they begin on 27 June.

45 — Of the JULIAN Years, that is, [the years] ordered by Julius Caesar after the confusion [of the calendar]; the first of these is [reckoned] from the Calends of January, ferial day 6, extended back [*extensam*] according to the Augustan correction.

38 — The Spanish Era [Aera Hispanica], begun from the Calends of January, and in common use in the Councils.

Years of Christ [*Christi Anni*]

The first year in the Roman Calendar begins from the Circumcision of the Lord, or from the Calends of January; and Ecclesiastically indeed from midnight of the preceding night, with the ancient Romans, and in these Tables, and in the Prutenic [Tables], and in the Medicean [Tables], and in the Magino [Tables] it

begins at the last midnight of the preceding December; in the Rudolphine [Tables], however, [and in] the Danish, Tychonic, [and] Philolaic [Tables] at the very midday of the first day of January. Civilly, however, others [reckon] from the Nativity, others from the Annunciation, others otherwise; concerning which there is more in our *Chronologia Reformata*.

The first year, then, of the CHRISTIAN Era was year 4714 of the Julian Period. The Cycle of the Sun 10, of the Moon 2, the Roman Indiction 4. And it was year 46 of the Julian Years; and from 21 April it ran concurrently with the year 753 of the founding of the City in the Varronian [reckoning]; besides, before 754; moreover, before the new moon nearest the summer solstice it ran concurrently with Olympiad 194, year 4; and thereafter with Olympiad 195, year 1. Finally also, from 13 August, of the Nabonassar [years] [...]

28 — VICTOR of Capua's Paschal Cycle begins from the October of this year.

81 — Of DOMITIAN, year 1, from 13 September.

96 — Of NERVA, year 1, from 19 September, as in our *Chronologia*.

98 — Of TRAJAN, year 1, from 10 January.

117 — Of HADRIAN, year 1, from 24 July, at the meridian of the following [day] 25.

137 — Of ANTONINUS, year 1, from 10 July, the following [day] 11.

222 — Of HIPPOLYTUS, the Paschal Cycle begins on the Calends of January.

238 — CENSORINUS in this year writes to Quintus Caerellius, [dedicating to him] a golden booklet *On the Birthday* [De Die Natali], illustrating this year with notable epochs, and [says] that it is [the year] 283 from the Calends of January, from which [year] the Consulship of Ulpian and Pontianus had begun — [the year] 1014 from the Olympiad, that is, from 21 April; and [the year] 986 of Nabonassar, the beginning of this Year [...]

Tomus II — Tabulae Novalmagesticae

TAB. 23 — Epoch synopsis (concluded)

[The two-column synopsis of eras continues. The left column gives the Year of Christ [Anni Christi]; the right column gives the corresponding event, era, or epoch.]

Year of Christ	Era / epoch
[continued]	...on the day before [the calends], on the VI Kalends of July — that is, from the meridian of the 25th day of June — from which one adds that the year of Alexander the Great began at 562. For so the corrected manuscripts have it. It was the year 4951 of the Julian Period.
284	The year 1 of DIOCLETIAN, from the 29th of August, with the Solar Cycle ☉ 13, the Lunar [Cycle] 19, Indiction 2. From this point begin the Paschal Cycles of Dionysius of Alexandria [Dionysius Exiguus], and the years of the Diocletianic [era], or the <i>Era of the Martyrs</i> ; likewise the <i>Elkupti</i> [al-Qibṭī], or <i>Coptic</i> [reckoning], and also that of the <i>Abyssinians</i> [<i>Abassinorum</i>] — although the Alexandrian Church, for the head of the Era of the Martyrs, chose the Kalends of April of the year 285, which was then the month of Easter.
312	The INDICATIONS of Constantine, usurped in the courts of the emperors, begin from the 25th of September. The Greek emperors, however, and the Church of Constantinople, [reckon them] from the Kalends of September.
313	[From] September. But the Roman Church, and its Pontiffs, [reckon] from the Kalends of January; and Ignatius the Patriarch of Antioch [reckons] from the Kalends of May, or [the feast] of Artemis — likewise this year 313.
552	The Era of the ARMENIANS begins from the 1st of August, of which the months are Persian, but the months are fixed [stationary], and the intercalation purely Roman.
622	Of the HEGIRA, that is, of the flight of Mahomet from Mecca. This year [is] the first repetition of the lunar [years], and it begins on the 16th day of July, feria 6, with the Solar Cycle 23, the Lunar [Cycle] 15, the Roman Indiction 10 — [continued]

Year of Christ	Era / epoch
	in the year 5335 of the Julian Period, the Nabonassar [year] 1370 still running, inasmuch as it began on the 21st day of March. This Era is used by the Mahometans, Arabs, and Turks; though there is another sect of the Arabs, which the <i>Alphonsine</i> [tables] follow, which places the beginning of the Hegira at July 15, [the month of] Choeac 27, feria 5.
632	Of IESDAGIRDIS [Yazdegerd], King of the Persians, on the 16th day of June; from which the Persian Era is reckoned, and it is used with a wandering year, which recedes after the manner of the Egyptian year.
800	CHARLEMAGNE [Carolus Magnus] begins to be Emperor.
1079	The GELALEAN [Jalālī] Epoch of the Persians, from the year restored by the equinox observed on the 14th of March.
1453	CONSTANTINOPLE captured on feria 2 of Pentecost by Mahomet the Ottoman, on the 29th of May, from which [comes] the beginning of the Ottoman Empire.
1582	The GREGORIAN correction of the calendar, fully completed, promulgated, and accepted by the greatest part of the Christian world, whose year [reckoned] the 5th of October to be called the 15th. It was the year 6295 of the Julian Period.

For the remaining epochs, and a fuller treatment and confirmation of the preceding [ones], see our *Chronologia Reformata* — should it come to light, God granting — in whose hands are the Years, both *Temporal* and *ETERNAL*; to Him be glory unto the ages of ages. *Amen*.

TAB. 23 — Nabonassar years beginning before or after the Epoch of Christ

TAB. 23. The Nabonassar years beginning in a year before or after the Epoch of CHRIST, and on the day of the Julian or Gregorian month noted below.

[TAB. 23. Nabonassari Anni Incipientes Anno ante, vel post Epocham CHRISTI, dieq; Mensis Iuliani, aut Gregoriani infranotato.]

[The table is laid out in three side-by-side panels. The first panel covers the years before Christ; the second and third cover the years after Christ, the third giving the beginning of the month *Thoth* in both Old (Julian) and Gregorian style. "B." marks a bissextile (leap) year. The notations *posterior* / *prior* indicate the later / earlier of two beginnings in a span where the start-day repeats.]

3150	<i>idem</i> 2400	Dec. 31	Ianu. 16

Note (right column, beneath the table)

Since 1460 Julian years make 1461 Egyptian years, and by this period [cycle] the Great Year of the Canicular [Dog-star], or Sothic [year], is completed, the beginning of *Thoth* returns to the same day of the Julian year. For this reason, from the year before Christ 737 — at which the beginning of *Thoth* fell in February, before the 24th day of the Julian [reckoning] — no change of the Julian day occurs until the year 1 before Christ, after the bissextile, and so on to the year 521 before Christ, at which point a double Nabonassar year begins. From there, indeed, the change occurs at the very year of the bissextile, and on to the Year of Christ 724, at which point the beginning of *Thoth* once again returns to February the 24th, the earlier [*priorem*]. Thereafter, indeed, the change is again made always on the first day after the bissextile, and so on to the Year of Christ 940, at which point a double Nabonassar year again begins.

(C) From here onward the change [is made] at the very year of the bissextile, and so on, and to the Year of Christ 1184, at which the beginning of *Thoth* a third time recedes to February the 24th, the earlier. From there, however, the change is made in the year immediately after the bissextile, and on to the Year of Christ 2400, at which a third time a double Nabonassar year begins.

(C) ...and on to the Year of Christ 2400, at which for the third time a double Nabonassar year begins, and from this point the change of day must be made in the very bissextile year itself — but will the World last so long?

God knows. [Deus novit.]

SECOND PART OF THE TABLES, SELECTED FROM THE PRIMUM MOBILE

[SECVNDA PARS TABVLARVM EX PRIMO MOBILI SELECTARVM.]

TAB. 24 — Conversion of the degrees of the signs into degrees of the zodiac

TAB. 24. Conversion of the degrees of the signs into degrees of the zodiac.

[TAB. 24. Conuersio Graduum Signorum in Gradus Zodiaci.]

[Each column is one zodiacal sign (I–XII, with its symbol); the leftmost column is the degree within the sign. The body gives the cumulative zodiacal longitude in degrees (Gr.). Each successive sign adds 30°.]

TAB. 28. Right Ascension of the Sun, at the Obliquity 23°30'20"

TAB. 28. *Ascensio Recta* ☉ [the right ascension of the Sun], at the Obliquity 23°30'20".

The table gives the right ascension corresponding to each degree of ecliptic longitude. The leftmost column is the sign-degree (Sign. / Gr.), running 1–30 within each zodiacal sign; the six paired columns give, for each of the six signs of the first half of the zodiac, the right ascension in degrees (Gr.), minutes ('), and seconds (").

Residuum Tabulae 28. [Remainder of Table 28]

The remainder of the table covers the second half of the zodiac (signs ♎ Libra through ♓ Pisces). The leftmost column is again the sign-degree 1–30; the six paired columns give right ascension (degrees, minutes, seconds) for each of the remaining six signs.

TAB. 29. Table of the Ascensional Differences, at the Obliquity of the Ecliptic 23°30'

TAB. 29. *Differentiarum Ascensionalium: ad Obliq. Eclipt. Grad. 23. 30'.* [Of the Ascensional Differences: at the Obliquity of the Ecliptic 23°30'.]

Subheading: *Altitudo Poli, si in latere sumatur Declinatio Sideris; vel Declinatio Sideris, si in latere sumatur Alt. Poli.* [The Altitude of the Pole, if the Declination of the star is taken at the side; or the Declination of the star, if the Altitude of the Pole is taken at the side.]

[Left side-label, rotated: *Declinatio Sideris, aut Altitudo Poli, &c.* — the Declination of the star, or the Altitude of the Pole, etc.]

The argument runs along the top (the value 1–25 in degrees, here the pole-altitude columns 1–10) and down the left (the value 1–60, the declination of the star). Each entry gives the ascensional difference in degrees (G.), minutes ('), and seconds ("). The right-hand margin carries a complementary index running 89 down to 30 (for reading the table with the alternate entry-argument).

[Margin foot: H]

Resid. Tab. 29. Differentia Ascensionalium. [Remainder of Table 29. Ascensional Difference.] — continuation, pole-altitudes 1–10, declination 61–90

[Left side-label, rotated: *Declinatio Sideris, in fronte sumatur Altr. Poli; vel Altit. Poli si in fronte Declinatio.* — The Declination of the star (taken in the top); or the Altitude of the Pole, if the Declination is taken in the top.]

This continues the same ten pole-altitude columns for declination arguments 61–90. The complementary right-hand index runs 29 down to 0.

[Bottom column-foot index (verbatim): 89 | 88 | 87 | 86 | 85 | 84 | 83]

[Margin foot: H]

[Note printed in the lower-right area of the table (verbatim):] *Ubi desunt numeri areales, signum est aggregatum ex numero frontali, & marginis sinistri excedere quadrantem, quod intelligendum est de sequentibus quoque; spatiis areis vacuis in residuis partibus Tabulae, mox secuturis. Vel certe superflue ibi quaeruntur cum in alia huius partis reperiri possint.*
— Where the area-numbers are lacking, it is a sign that the sum of the

column-head (frontal) number and the left-margin number exceeds a quadrant [90°]; and this is to be understood of the following [entries] too, the area-spaces being left blank in the remaining parts of the Table that follow shortly. Or else they are sought there in vain, since they can be found in another part of this [Table].

Residuum Tab. 29. Differentiarum Ascensionalium.

[Remainder of Table 29. Of the Ascensional Differences.] — pole-altitudes 11–25, declination 1–30

Subheading: *Altitudo Poli si in latere sinistro sumatur Declinatio; vel Declinatio si in latere sinistro Alt. Poli.* [The Altitude of the Pole, if the Declination is taken at the left side; or the Declination, if the Altitude of the Pole is at the left side.]

[Left side-label, rotated: *Declinatio, si in fronte sumatur Alt. Poli; vel Alt. Poli si in fronte Declinatio.* — The Declination, if the Altitude of the Pole is taken in the top; or the Altitude of the Pole, if the Declination is in the top.]

This part of the table extends the argument to pole-altitudes 11°–25°. Each column here gives degrees (G.) and minutes (') only (no seconds column). The declination argument runs 1–30 down the left; the complementary right-hand index runs 88 down to 59. (The table continues in the following part.)

Remainder of TABLE 29. Of Ascensional Differences.

The Altitude of the Pole, if the Declination be taken on the left-hand side; or the Declination, if on the same side the Altitude of the Pole be taken.

Each pole-altitude column (headed 11 through 25) gives the ascensional difference in degrees (G. = *gradus*) and minutes ('). The left-hand column is the declination (running 31–79); the right-hand column is the complementary declination (running 59 down to 11).

Remainder of the Table of Ascensional Differences.

The Altitude of the Pole, if on the left-hand side you take the Declination; or the Declination, if on the same side you take the Altitude of the Pole.

(Pole-altitude columns 26 through 40; declination 41–64; right-hand complement column 64 down to 50. Empty cells indicate that the value has reached 90° 0' — the half-day arc — in the preceding row.)

TABLE 30. The Ascensional Difference of the Points of the Ecliptic, for an Altitude of the Pole of 44° 30' 20".

Each pair of zodiacal signs shares a column: the upper sign-label applies when the point is *Bor.* (northern, ascending declination); the lower applies when *Austr.* (southern). The value is given in degrees (Gr.), minutes ('), and seconds ("). The left margin gives the degree within the sign (Gr. 0–30); the right margin gives the complementary degree (30 down to 0).

The three columns of this block are headed:

- ♈ Bor. / ♎ Austr. (Aries north / Libra south)
- ♉ Bor. / ♏ Austr. (Taurus north / Scorpio south)
- ♊ Bor. / ♐ Austr. (Gemini north / Capricorn south)

TAB. 32 — Oblique Ascension at the several Pole-Altitudes

Page-26 header (p. 478, verbatim): *TAB. 32. Ascensio Obliqua graduum Signor. Borealium in Horizontib. Borealib. Australium in Horiz. Australib. quam subtrahe gradib. 360. fietq; Asc. Obliqua Signor. Austral. in Horiz. Boreal. & Signor. Boreal. in Horiz. Austral. — "TAB. 32. The Oblique Ascension of the degrees of the Northern Signs in the Northern Horizons, and of the Southern in the Southern Horizons; subtract it from 360° and you obtain the Oblique Ascension of the Southern Signs in the Northern Horizon and of the Northern Signs in the Southern Horizon."*

Page-27 header (p. 479, verbatim): *TAB. 32. Ascensio Obliqua pro gradibus Signor. Borealium in Horizontib. Borealib. & pro gradib. Australium in Horizont. Australib. quam subtrahe gradib. 360. & fiet Asc. Obliqua Signor. Australium in Horiz. Boreal. & Boreal. in Horiz. Australib. — "TAB. 32. The Oblique Ascension for the degrees of the Northern Signs in the Northern Horizons, and for the degrees of the Southern in the Southern Horizons; subtract it from 360° and the Oblique Ascension of the Southern Signs in the Northern Horizon, and of the Northern in the Southern Horizon, is obtained."*

Page-28 header (p. 480, verbatim): *Ascensio Obliqua pro gradibus Signorum Borealium in Horizontibus Borealibus, & pro Australium in Horizontibus Australibus. De reliquis vide initium Tabulae. — "The Oblique Ascension for the degrees of the Northern Signs in the Northern Horizons, and for the Southern in the Southern Horizons. For the rest, see the beginning of the Table."*

Sub-header on all three pages: **Altitudines Poli** — "Altitudes of the Pole."

Structure of the table. Each sign-block is a grid of 31 degree-rows (0–30) against twelve pole-altitude columns (headed 2, 4, 6 ... 24). Every column is split into **Gr.** (degrees) and ' (minutes). The leftmost column G. carries the degree-argument 0–30 together with the zodiac-sign symbol for the **direct** reading; the rightmost column G. carries the complementary argument 30→0 together with the mirror-sign symbol for the **reverse** (Southern-sign) reading described in the header.

Both indices are transcribed below. Long-f digit-forms in the source ("f"/"5") have been resolved to the intended numerals.

Aries (♈) — pole-altitudes 2°–24° (p. 478 / fol. 26)

[Left index = ∿ degrees 0–30; right index counts 30→0, mirror sign ✕ at its foot.]

Virgo (♍) — pole-altitudes 2°–24° (p. 480 / fol. 28)

[Left index = $\mathfrak{M}$ degrees 0–30; right index counts 30→0, mirror sign $\underline{\alpha}$ at its foot.
Row 30 = 180° 0' across all columns (the semicircle terminus).]

TABULAE NOVALMAGESTICAE — Part II

TAB. 32 (continued) — Oblique Ascension of the Signs, for Pole-Altitudes 45°–56°

Source page 1 — running number "32"

Top segment: sign ♈ (Aries), 0°–30°. Bottom segment: sign ♉ (Taurus), 0°–30°. Right reverse-index sigla: ♊ (Pisces) for the top segment's complement, ♋ (Aquarius) for the bottom.

Segment ♈ (Aries) — index 0–30

TABULAE NOVALMAGESTICAE — Part II

(Primum Mobile)

TAB. 33 — Table of position angles, by altitude of the pole 57° – 67°

This single table is continued across three pages. Each block of 30 argument-degrees corresponds to one zodiacal sign, marked by its sign-symbol in the left-hand argument column (which runs 0→30) and by the complementary sign-symbol in the right-hand argument column (which runs 30→0). The eleven paired data columns are headed by the altitude of the pole [altitudo poli] in degrees — 57, 58, 59, 60, 61, 62, 63, 64, 65, 66½, 67 — and each is subdivided into **Gr**.

(degrees) and ' (minutes). For the highest latitudes the tabulated angle approaches and wraps past 360°, so the 67° column shows values just below 360°.

The left argument header is **G.** (degrees); the per-page sign symbols are reproduced as printed.

Page 1 (source p. 35) — signs ♈ Aries and ♉ Taurus

Left argument header: **G.** / ♈ (Aries). Right argument runs 30→0, ending in the ♏ (Scorpio) symbol; the lower block is ♉ (Taurus) with the ♊ (Aquarius) symbol at the foot of the right column.

Page 2 (source p. 36) — signs ♊ Gemini and ♋ Cancer

Left argument header: **G.** / ♊ (Gemini, printed **II**). Lower block ♋ (Cancer); right-edge complementary symbols. In the 67° column the source prints the vertical note "**Non occidit**" ("does not set") across several ♋ rows where the sign does not set at that latitude.

Page 3 (source p. 37) — signs ♌ Leo and ♍ Virgo

Left argument header: **G.** / ♌ (Leo, printed **Ω**). Lower block ♍ (Virgo, printed **mp**); the table closes at 180° 0' for every column at argument 30, and the caption **TAB. 33.** stands at the foot.

TAB. 33 (conclusion) — Altitude of the Nonagesimal Counted from the Ascendant [Altitudo Nonagesimi ab Ascendente]

Residuum (continuation) of Table 33, covering pole-altitudes 42 through 67. The left margin gives the sign and degree of the ascendant (Si. G. = *Signum, Gradus*); the rightmost column (Alt. / G. Si.) gives the complementary degree and sign for entry from the other direction. Each pole-altitude column is headed Gr. ' (degrees and minutes of the nonagesimal's altitude).

Pole-altitudes 42–54

TAB. 34 — Prosthaphaeresis of Declination [Prosthaphaeresis Declinationis]

Upper section. Heading: *Declinationi Signor. Bor. Adde; Australium Subtrahe.* — "To the declination of the northern signs add; for the southern signs subtract."
Sub-heading: *Latitudo Borealis* ("Northern latitude").

The leftmost column (G.) is the degree of the sign; the rightmost (G.) is its complement. The body columns are headed by the latitude argument 1, 3, 5, 7, 9 (degrees), each carrying degrees-and-minutes (Gr. ') of the prosthaphaeresis.

Lower section. Heading: *Declinat. Signor. Boreal. Subtrahe; Australium Adde.* — "For the declination of the northern signs subtract; for the southern signs add." Sub-heading: *Latitudo Australis* ("Southern latitude"). The tabulated values are identical to the upper section (declination prosthaphaeresis being symmetric in latitude); the add/subtract rule is reversed.

Third Part of the Tables, which concerns the Motions of the Sun and the Moon

TABULA 36. The Equal, or Mean, Motion of the Sun [*Solis Motus Aequalis, seu Medius*]

Epochs, or Radices [*Epochæ, seu Radices*] — Years before Christ [*Anni ante Christum*]

Two value-blocks, each in sexagesimal Sign · Degree · Minute · Second (Sig · Gr · ' · ") : the Longitude of the Sun from Aries [*Longit. ☉ ab ♈*] and the Longitude of the Sun's Apogee from Aries [*Longit. Apogei ☉ ab ♈*]. The left side-label for the lower group of years reads "Stylo veteri Iuliano" (Old Julian Style); below it "Stylo novo Gregoriano" (New Gregorian Style).

Expanded & Collected Years [Expansi, & Collecti] — Julian Expanded Years [Anni Iuliani Expansi]

Same two value-blocks: Longitude of the Sun from Aries (Sig · Gr · ' · ") and Longitude of the Sun's Apogee from Aries (Sig · Gr · ' · "). "B." prefixes the bissextile (leap) years. In the Apogee block, the Sign and Degree are 0 throughout; the motion appears in the ' and " columns.

Footer (the anomaly-sign legend running across the foot of the parallax table):

| I. XI. | II. XII. | III. IX. | IV. X. | V. VII. | VI. VIII. |

[Signs of the Anomaly — Anomaliæ Signa.]

TAB. 38. Equations of the Sun [Aequationum Solis]

Caption: "Equations of the Sun, the whole eccentricity being 3480 parts, but bisected 1740, where the radius is 100000." [Aequationum Solis Excentricitate tota partium 3480. sed Bissectâ 1740. qualium Radius 100000.]

In Circular Form [In Forma Circulari]

The argument is the Anomaly in Signs and Degrees [Anom. Signa, Gradus]; the column-pairs are headed by the signs O through V, each "Subtrahe" (subtract), each giving G. · ' · " and a Difference column [Differentia / Diff.]. The foot of the table carries the complementary "Adde" (add) sign-labels (XI, X, IX, VIII, VII, VI) read with the anomaly-degree column [Anom. Sig. G.] on the right, which descends from 30. The leftmost degree column [Anom. Signa Gradus] ascends from 0.

TAB. 39. Lunar-Solar Distances, Horizontal Parallax, Hourly Motions, and Semidiameters at conjunction (♌) and opposition (♍)

Latin title: **TAB. 39. LuniSolaris Distantiarum, Parallax. Horiz. Horarij, & Semidiametrorum in ♌, & ♍.** ("Table 39. Of the lunar-solar distances, the

horizontal parallax, the hourly [motions], and the semidiameters at conjunction and opposition.")

The table is entered with the **Anomaly in degrees** (left column, ascending 0–180) and re-exited with the **Anomaly in degrees** complement (rightmost column, descending 360–180). The column groups are:

- **Distantia à centro Terræ** [distance from the Earth's centre]: *Ad Radium* (*part. 100000*) — given for the Sun (☉) and for the Moon (☾); and *In Semidiam. Terræ* [in Earth-semidiameters] under two hypotheses, *1.hyp.* and *2.hyp.*
- ♂ ♀ columns (whole part of Earth-semidiameters and minutes for the conjunction/opposition case), with sub-headings ' ''.
- **Parallaxis Horizontalis** [horizontal parallax]: ' '' ''.
- **Horarius mot. Verus** [true hourly motion]: ☉ (' '' ''') and ☾ (' '' ''').
- **Semidiam. apparentes** [apparent semidiameters]: ☉ (' '' ''') and ☾ (' '' ''').
- **Apo. Vmbrę in triâ.** ☾ [apogee shadow-cone, the Moon in the cone(?)]: ' ''.
- **Variat. demed. Vmbrę** [variation of the shadow's semi-diameter]: ''.
- **Axis Vmbræ Terræ in semid. terræ** [axis of the Earth's shadow, in Earth-semidiameters]: *1.hyp.* and *2.hyp.*

Because of the great width, the table below is transcribed in two stitched parts (left block and right block) sharing the **Anomal. Gr.** key. Sexagesimal sub-columns are labelled ' (minutes) and ' ' (seconds); the whole-degree/semidiameter figures stand to their left.

TAB. 39 — left block (distances)

TAB. 39 — right block (parallax, hourly motions, semidiameters, shadow)

The leading "27 / 28 / 29" figures in the parallax-minutes column and the "14 / 15 / 16" figures in the semidiameter-minutes columns are printed only on the rows where they change (they carry down until the next printed value); they are restored here on each row they govern.

Below the table: De Emendatione Tychonicarum, vide dicta Lib. 1. Astronom. Reformatæ Cap. 14. & 15. ("On the correction of the Tychonic [refractions], see what is said in Book 1 of the *Astronomia Reformatæ*, chapters 14 and 15.")

TABULA 41. The Moon's Mean (Equable) Motion, and of the Node ☾

Latin title: TABULA 41. Lunæ Motus Aequalis, seu Medius, & Nodi ☾. ("Table 41. Of the Moon's equable, that is mean, motion, and of the Node.")

This opening carries the lunar **radices/epochs** and the **expanded and collected years**. Each of the three motions is given in zodiacal **Sign · Gr(degree) · ' · "** (heading Sig. G. ' "):

- **Longit. ab** ♈ — mean longitude reckoned from the first point of Aries (♈).
- **Anomalía** — the [mean] anomaly.
- **Nodi ☾ mot.** — the motion of the [ascending] Node.

Sub-table A — EPOCHÆ, SEV RADICES (Epochs, or radices), years *ante Christum* and *post*

Sub-table B — ANNI EXPANSI, ET COLLECTI (single/expanded and collected years)

The right portion of the opening tabulates **single years (Anni Expansi)** 1–60 and then **collected years (Anni Collecti)** 64, 68, 72, 76, 80, ..., 6000. The "B." prefix marks the bissextile (leap) years; the note "**Omnes hi sunt Bissextiles**" ("all these are bissextile") runs vertically beside the 64–92 block. Same three motions, Sig. G. ' ".

TABULA 41 (continued). MENSES ANNI COMMUNIS / BISSEXTILIS / DIES; HORÆ ET SCRUPULA

This opening continues Table 41 with the **completed months** of the common year and of the bissextile year, the **days**, and finally the **hours and scruples** (sexagesimal fractions of the day). Each block gives the same three motions in sig. G. ' " (the Node block is headed G. ' ", the leading sign omitted as it stays at 0 within a month/day).

HORÆ, ET SCRUPULA (hours and scruples)

Latin heading: **HORÆ, ET SCRUPULA**. Sub-headings give the three motions — **Longit.** ☽ **ab** ♀ [the Moon's longitude from Aries], **Anomalia**, **No.** ☾ **mot.** [motion of the Node] — each tabulated against successively finer time units: the row-key Horæ/Min./Sec. (hours, minutes, seconds), with the resulting motion in degree-and-sexagesimal sub-orders (the column heads run Gr. ' " for hours, then ' " " for minutes, then " " " " for seconds). The body below is keyed by the integer 1–60 (serving as hours, then minutes, then seconds at the three scales); the printed sub-order labels are I, II, III, IV.

For the longitude and anomaly the printed sub-columns at the hour scale are (Gr. ' · ") but only two figures are printed per cell in the body (the degree/minute pair shown); the Node column gives (' · "). Transcribing the body exactly as printed:

TABLE 42. The Equations of the Moon at the Syzygies, that is, at Conjunction (♌) and Opposition (♍)

The argument (Anom., the lunar anomaly) runs 0–30 degrees down the left margin and 30–0 up the right margin. Six entry-columns are headed by sign-numbers 0, I, II, III, IV, V, each labelled *Subtr.* (subtract); each gives the equation in degrees (G.), minutes ('), and seconds ("). The sign-numbers continuing the cycle (XI, X, IX, VIII, VII, VI), each labelled *Adde* (add), are printed across the foot.

TABLE 43. The Equation of the Node, and the Maximum Latitude of the Moon

SUBTRACT

Three sign-pairs head the table: Sign 0 or 6; Sign I or 7; Sign 2 or 8. Under each, two paired columns: *Æquat. ∅* (equation of the node) and *Lat. Max.* (maximum latitude), each in degrees (G.), minutes ('), seconds ("). The left and right margins

carry "*Distantia vera* $\supset a \odot$ " (the true distance of the Moon from the Sun) and the argument in degrees (Gr.). The foot carries the complementary signs (11 *or* 5; 10 *or* 4; 9 *or* 3) under the rubric **ADDE** (add).

TABLE 44. LATITUDE OF THE MOON

This table is laid out in four panels across two openings; each panel takes a sign-argument (*Signa Argumenti* / *Signa Argum.*) and is keyed to the argument of latitude (*Arg. Latit.*) running 0–30 down and 30–0 up. The column-heads give the degree of the sign (e.g. 4·58, 5·0, 5·5, 5·10, 5·15, 5·18) marking the *Latitudinis Maximæ Termini* (the limits of maximum latitude). Each entry is in degrees (G.), minutes ('), seconds (").

Panel 1 — sign-headers across the top: 0. Latit. Bor. (north latitude); VI. Latit. Austr. (south latitude)

Column groups: 4·58 | 5·0 | 5·5 | 5·10 | 5·15 | 5·18.

TABLE 46. The Critical [Points] of Eclipses

Argument of latitude (*Argum. Latitud.*) by sign (*Sig.*) and degree (G.). Columns: *Latitudo Vera* ∩ (the true latitude of the Moon); *Arcus verus inter cætera* (the true arc between the rest); *Arcus inter momenta* (the arc between the moments); *Tempus addendum* (the time to be added) — each in degrees/minutes/seconds as headed. The left margin reads "o *Latit. Bor. Descend.* / 6 *Latit. Austr. Ascend.*" (0: north latitude, descending; 6: south latitude, ascending); the right margin reads "*Sign. 5 Latit. Austr. Descend.* / *Sign. 11 Latit. Bor. Ascend.*" The right *Argum. Latitud.* runs 29–12 up.

TAB. 47 — The Final (Composite) Equation of the Moon

This is a double-entry table. Each half-page panel is read in two directions: top-to-bottom for the sign named in the panel header (with the distance arguments running 3 → 30 along the top), and bottom-to-top for the complementary sign named in the panel footer (with the distance arguments running 27 → 0 along the bottom). The argument across the columns is the Moon's distance from the Sun [*Distantia* ᵀ *a* ☉] — that is, its elongation toward quadrature (☐), conjunction (♌), or opposition (♍). The argument down the left/right is the **first-equated anomaly** [*Anomalia primò Aequata*], given in signs (*Sig.*) and degrees (*G.*). Each cell gives the equation in degrees (*G.*) and minutes (*'*). The marginal letters **A.** and **S.** mark, respectively, where a column's values turn (the small inline rubrics in the body; transcribed verbatim as printed). The instruction band beneath each panel reads, for the *Subt.* (subtract) panels: *Supra Scalam Subtrahitur Ascendendo, infra verò Descendendo* — "Above the scale it is subtracted when ascending, below it when descending"; and for the *Adde* (add) panels the corresponding *Additur / Subtrahitur* rubric as printed.

Page 53 (p. 53) — SIGNUM 0 / SIGNA 5

Panel 1 (upper): SIGNUM 0 — *Distantiae* ᵀ *a* ☉, *vel eius* ♌ *ad* ☐

Column heads: distance = 3, 6, 9, 12, 15, 18, 21, 24, 27, 30 (each marked **Subt.**).
Read top-down for **Signum 0**; read bottom-up for **Signa 5** (footer distances 27, 24, 21, 18, 15, 12, 9, 6, 3, 0).

Footer band: **SIGNA III. Dist.** ☉ **a** ⊙ **a** □ **ad** ☿, **vel** ♀ — *Supra Scalam Subtrahitur Ascendendo, infra Descendendo.*

TABLE 48. The Moon's hourly motion away from the Sun at conjunction (☿) and opposition (♀), and likewise the hourly motions within the 12 hours before, or after.

[Signs of the equated anomaly of the Moon at the top: 0, 1, 2, 3, 4, 5]

For each sign-group the two columns are:

- **Horar.** ☿ & ♀ — the hourly [motion] at conjunction and opposition (minutes ', seconds ");

- **Horar. ultra** — the hourly [motion] beyond [it] (minutes ', seconds ").

The argument column **Anomal. Gr.** (degrees of anomaly) runs down at left for the top signs (0–5) and up at right for the bottom signs (11–6).

[Signs of the equated anomaly of the Moon at the foot: 11, 10, 9, 8, 7, 6]

TABLE 49. The verification of the Moon's [motion] at conjunction (♌) and opposition (♌) of the luminaries.

Minutes of the hourly [motion] of the Moon away from the Sun at conjunction (♌) and opposition (♌).

Column-groups are headed by **M.** (the integer minutes of motion) 27 through 35. Within each group the sub-columns are **Grad. · H.** ', then **Minut. H.** ' ", then **Second.** ' " ". The left argument runs **1–60** (single steps to 30, then by fives to 60).

TABLE 50. Of the intervals of the Moon and the Earth outside conjunction (ϕ) and opposition (ϕ°).

Argument: **Anomalia Excentrici, seu duplicata elongatio** $\bowtie$ à $\odot$ (the anomaly of the eccentric, or the doubled elongation of the Moon from the Sun) — two coupled degree columns. Then **Excentricitas Lunaris orbitæ** (the eccentricity of

the Moon's orbit): "Qualium Radius est 100000" and "in semidiamet. Terrę Semid. '". Then **Distantia** › **Apogeæ seu Maxima à centro Terræ** (the Moon's distance at apogee, or maximum, from the Earth's centre): "Qualium Radius est 100000" and "In semid. Terræ Semid. '". Then **Distantia** › **Perigeæ, seu Minima à centro Terræ** (the Moon's distance at perigee, or minimum): the same two sub-columns.

TABLE 51. The Moon's distance from the Earth's centre outside conjunction ($\odot$) and opposition ($\oslash$).

Anomalia Excentricitatis, seu duplicata Elongatio ☽ à ☉ (the anomaly of the eccentricity, or the doubled elongation of the Moon from the Sun), tabulated in steps of 20 across the top: 0, 20, 40, 60, 80, 100, 120, 140, 160, 180; with the complementary row 360, 340, 320, 300, 280, 260, 240, 220, 200, 180. Body values are **Semidiametri Terræ** (semidiameters of the Earth), each cell "Sem. '". Argument **Anomalia Orbis æquata** (the equated anomaly of the orb) runs down at left (Gr./Gr.).

TABLE 53. The parallax of the Moon in the circle of true altitude.

Parallaxis Horizontalis Minuta (minutes of horizontal parallax) — the column-groups across the top, headed 50 through 64, give the parallax in minutes (') and seconds (") corresponding to each value of the horizontal parallax. Argument **Altitudo vera** (true altitude, G. = degrees) runs down at left, 1–60.

Tomus II — Tabulae Novalmagesticae (continued)

Part III — Lunar parallax tables (conclusion of TAB. 53)

Remainder of TABLE 53. Parallaxes of the Moon [♀] in the circle of true altitude.

Minutes of horizontal parallax [Minuta Parallaxis Horizontalis].

This page concludes TAB. 53. The upper table gives, for each value of the horizontal parallax (the column heads 50–64, in seconds — read together with the table's leading minutes), the lunar parallax at each degree of true altitude from 61° to 90°. Each column carries a pair of sub-columns ' (minutes) and " (seconds).

Lower panel — Mean horizontal parallax (M. Parallax Horizontalis), columns 65–67

Three side-by-side blocks of the mean horizontal parallax for horizontal-parallax values 65, 66, 67, tabulated against true altitude (G.) from 1° to 90°. Each value carries a ' and " pair.

Quarta Pars — Part Four of the Remaining Tables, for Eclipses

Quarta Pars Tabularum Reliquarum pro Eclipsibus.

Fourth Part of the Remaining Tables, for Eclipses.

TABLE 54 — Epacts for mean new and full moons

TABULA 54. Epactarum pro Noviluniis, ac Pleniluniis Mediis. (Table of Epacts for mean new moons and mean full moons.)

Epochs of the Epacts (Epochae Epactarum)

Left column heading: *Ante Christum* (before Christ); years counted upward in completed years, but entering into the calculation in descending order — *Anni completi ascendendo; sed ineuntes in calculo descendenti*. The lower block, headed

Radix Christi and then *Anni completi*, runs forward from the Christian era.
Columns: Anni (years) | D. (days) | H. (hours) | ' | ''.

TABLE 55 — Eclipse limits; distance from the node

TAB. 55. *Termini Eclipsium. Distantia à Nodo* ☾. (Eclipse limits; distance from the [ascending] node ☾.) Subdivided into Lunarium (for lunar eclipses) and Solarium (for solar eclipses), each giving the limit at apogee (☽ Apog.) and at perigee (Perigea), in G. (degrees) and ' (minutes). The row labels read "Sole (Apog. / Perig.)" — the Sun at apogee / at perigee.

Part V — Parallaxes of longitude and latitude

PARALLAXES OF LONGITUDE, AND OF LATITUDE.

TABLE 56 — Mesoplastic parallax

TABULA 56. *Parallaxeon Mecoplatica*. (Table of mesoplastic parallaxes. [The source prints "Mecoplatica" with a c; the established corpus form is "mesoplastic."])

Minutes of horizontal parallax [Minuta Parallaxeos Horizontalis].

The argument runs down the left margin as *Latitud. latus. G.* (the degree of latitude-distance, 0 to 90, by twos) and is repeated down the right margin as *Longit. latus. G.* (the complementary longitude-distance, 90 down to 0). The right-margin label printed vertically reads *Nonagesimi Altitudo* (the altitude of the nonagesimal). The body columns are headed 1 through 13, each carrying a ' and " pair, giving the mesoplastic parallax for that argument.

Parallaxes of Longitude and Latitude (continued)

Remainder of TAB. 56. Of the Mesoplastic Parallax [Parallaxeos Mecoplasticæ]

This is the concluding portion (the *residuum*) of Table 56, giving the mesoplastic parallax. The body of the table tabulates **Minutes of Horizontal Parallax** [**Minuta Parallaxeos Horizontalis**] from 53' through 66' across the top. Each horizontal-parallax value heads a paired column giving the resulting parallax in minutes (') and seconds ("). The leftmost column is the **Latitude argument** [**Latitud. latus.**], labelled G. (degrees), running 0 → 90; the rightmost column is

the corresponding **Longitude argument [Lōgitud. latus.]** (the *Nonagesimi Altitudo* — the altitude of the nonagesimal), running $90 \rightarrow 0$.

The argument increment is 2° down to row 56, then 1° from 56 to 90 (left) / 0 (right).

Scrupula Incidentiæ, &c. [Scruples of Incidence, etc.]

TAB. 58. Scrupula Incidentiæ in Eclipsi ☾, a... Semimora in Eclipsi ☉. [Table 58. Scruples of Incidence in a Lunar Eclipse; and the Half-Duration in a Solar Eclipse]

Subheading: **Difference of the Semidiameters of the Moon [☾] and the Shadow [Umbra], or the sum of the Semidiameters of the Sun [☉] and Moon [☾] [Differentia Semidiametrorum ☾, & Vmbræ, vel summa Semidiametror. ☉, & ☾].**

The columns are headed 21' through 28' (the difference/sum semidiameter argument), each split into ' and ". The leftmost column is the **Latitude [Latit.]** argument; the vertical left-margin label reads **Scruples of the true or apparent**

latitude of the Moon [Scrupula latitudinis ☾ veræ, aut apparentis]. Rows run 0–27 in this upper half-table.

Upper table (semidiameter argument 21'–28')

TABLE 59. The Scruples of Incidence, and Semimora, in a Lunar Eclipse.

Sum of the Semidiameters of the Moon ☾ and of the Shadow ☾. [*Summa Semidiametrorum ☾, & Vmbræ.*]

The argument down the left margin is the **True Latitude** [*Latitudo Vera*] of the Moon (☾), 0 to 60. Each block heads with the relevant value of the sum of semidiameters (52', 54', 55', ... 60'); under each, the paired sub-columns are I (minutes ') and II (seconds ").

[The first argument column, 53', is omitted from the printed sequence; the 52' column carries values only for the first four rows (0–3) and is blank thereafter.]

TABLE 59 (continued). The remaining Scruples of Incidence, and Semimora, in a Lunar Eclipse.

The remaining Sum of the Semidiameters of the Moon ☾ and of the Shadow ☾. [*Reliqua Scrupula Incidentiæ, & Semimora in Eclipsi Lunæ. — Reliqua Summa Semidiametrorum ☾, & Vmbræ.*]

This continues TABLE 59 with the sum-of-semidiameters arguments 61' through 68'; the **True Latitude** index now runs 0 to 67.

TABLE 60. The Distance of the Centres of both Luminaries [in conjunction].

[*Distantia Centrorum utriusq; Luminaris.*] The running header reads "The Distance of the Centres of the Sun ☉ and the Moon ☾ in conjunction [♌]."

The argument down the left margin is **Scrup.** (scruples). Each argument heading (0', 10', 20', ... 60') carries three sub-columns: **G.** (degrees), **I** (minutes '), **II** (seconds ").

[The argument index runs 0, 1, 2, 4, then by twos (6, 8, 10, ... 92, 94, 96, 98, 99); rows 3 and 5 are not printed, and the final two entries are 98 and 99.]

Tomus II — Tabulae Novalmagesticae

Part IV (continued): Lunar Parallaxes

TAB. 61. Parallaxes of the Moon in the Circle of True Altitude, given the distance from the centre of the Earth [*Parallaxes Lunæ in Circulo Altitudinis Veræ, sub data distantia à centro Terræ*]

The table gives the Moon's parallax in altitude, in minutes (') and seconds ("), as a function of apparent altitude (Alt., in degrees [Gr.]) and of the Moon's distance from the centre of the Earth expressed in Earth-semidiameters [*Distantia* » à

centro Terræ in semidiametris Terræ]. Distance columns 52 through 61 are tabulated. The left panel covers altitudes 0°–60°; the right panel (same distance columns) continues with altitudes 60°–89°.

Left panel — Altitudes 0°–60° (Distances 52–61)

Each distance heading spans two sub-columns: minutes (') and seconds (").

Right panel — Altitudes 60°–89° (Distances 52–61)

The right panel repeats the distance columns 52–61 for the higher altitudes. The source prints it in two stacked blocks: distances 52–56 over altitudes 60°–89°, then (with its own Alt./G. sub-header) distances 57–61 over altitudes 60°–89°.

Part V: Tables for the Five Planets — Saturn

TABULA 62. Mean Motions of Saturn ♄ [*Mediorum Motuum Saturni ♄*]

All quantities are given as Sign · Degree (G.) · minute (') · second ("). The three motions tabulated are: mean longitude reckoned from Aries [*Longit. ab ♈*], the apogee [*Apogaei*], and the northern node [*Nodi Bor.* — node of the ascending (boreal) limit].

Epochae, seu Radices Motuum (Epochs, or Radices of the Motions)

Years completed before Christ [*Anni Completi ante Christum*], then after Christ.

Anni ante Christum	Long. ab ♈ Sig.	G · ' "	Apogaei Sig.	G · ' "	Nodi Bor. Sig.	G · ' "

Radices affixæ sunt Meridiano Bononiensi, in meridie ultimo Decembris præcedentis. Anni præter 1. Christi, qui est iniens, sunt completi, tam sursum numerando ante Christum, quam deorsum post Christum.

[The radices are fixed to the Meridian of Bologna [*Meridiano Bononiensi*], at noon of the last day of December preceding. The years — except year 1 of Christ, which is the beginning year — are completed years, counted both upward before Christ and downward after Christ.]

Menses (Months)

Mean motion accumulated to the end of each month, in the common year [*Communis*] and the bissextile year [*Bissextilis*], for longitude from Aries [*Long. ab ♀*] and for the apogee [*Apogei*]. (Values in degrees [Gr.], ', ".)

Aequationes Saturni (Equations of Saturn)

TABULA 63. First Equation of the Inequality of Saturn [*Aequatio Prima Inaequalitatis Saturni*]

The table is entered by the simple anomaly in degrees [*Anomalia simplex, Gr.*], read top-to-bottom on the left for signs 0–V and bottom-to-top on the right for the

complementary signs XI–VI. Each sign column gives degrees [G.], ', ". The upper rubric **SVBTRAHE** (subtract) applies to signs 0–V; the lower rubric **ADDE** (add) applies to signs XI–VI. Values are the equation argument; for signs 0, the leading degree-figure is 0.

TABULA 64. Equated Anomaly of Saturn, corresponding to the Simple Anomaly [*Anomalia Aequata Saturni, respondens Anomaliae simplici*]

Entered by the simple anomaly in degrees [*Anom. simpl. Gr.*], signs 0–V read downward (left/top), complementary signs XI–VI read upward (bottom rubric). Each sign column gives Sign · degree (G.) · ' · " — i.e. the equated anomaly in zodiacal coordinates.

EQUATIONS OF SATURN.

TABULA 65. Of the Maximum Equations, or of the Parallaxes of the Annual Orbit, for Saturn.

Signs, and every fifteenth Degree of the equated Solar Anomaly (*Signa, & quindenī Gradus Anomalīæ Solis Æquatæ*).

Left-margin index: An. h — Sig. G. (Sign, Degree of the equated anomaly of Saturn), ascending. Right-margin index: An. h — G. Sig. (Degree, Sign), descending (complement). Each numeric column gives G. (degrees) and ' (minutes) of the maximum equation. Column sub-headings under each sign are the argument in degrees (0, 15, 30).

TABLE 69. The First Equation of Jupiter's Inequality

[The argument runs down each side as the *simple anomaly* (Anom. simpl., in degrees, Gr.); the top band carries the *Signs of the simple anomaly* (Signa Anomaliae simplicis) 0–V with the instruction **SUBTRACT** (SVBTRAHE); the bottom band carries signs XI–VI with the instruction **ADD** (ADDE). Each sign-column gives Degrees (G.), minutes ('), seconds (").]

TABLE 71. Of the Maximum Equations, or Parallaxes of the Annual Orb, for Jupiter

[Header: *Signa, & quindenii Gradus Anomaliae Solis Aequatae* — "Signs, and the fifteens of degrees of the equated solar anomaly." The argument down the left is the *equated anomaly of Jupiter* (Anomalia Aequata Iovis), in Signs and degrees (Gr.) stepping by 3°. Across the top, the equated solar anomaly is tabulated by sign (0–V) and, within each sign, at the sub-arguments 0, 15, 30 (the first sign 0) and 15, 30 of the following signs. Each cell gives Degrees (G.) and minutes ('). The bottom band repeats the signs XI–X–IX–VIII–VII–VI with the mirror sub-arguments (30/15/30/15/...) and the right-hand *Gr./G.Sig.* column, for reading the lower half of the equated solar anomaly upward.]

TABLE 73. Latitude, Reduction, and Curtation of Jupiter
[Latitudinis, Reductionis, & Curtationis Iovis].

Signs of the distance of Jupiter from the northern node [*Signa Distantiæ Iovis à Nodo Boreali*].

Each sign-block gives the Latitude (Latit., in G·'), the Reduction (Red., in "), and the Curtation (Curt., in "). The left "Dist." column (Gr.) is the argument descending; the right "Diff." column (Gr.) is the same distance ascending for the lower (mirror) sign-labels. Upper labels: 0 Bor. / 6 Austr.; 1 Bor. / 7 Austr.; 2 Bor. / 8 Austr. Lower labels: 5 Bor. / 11 Austr.; 4 Bor. / 10 Austr.; 3 Bor. / 9 Austr.

[Margin / table footnote, lower-left of the Radices table:] *Radices affixæ sunt Meridiano Bononiensi, in meridie ultimo Decembris præcedentis. Anni Completi sunt numerando tam sursum ante, quam deorsum post Christum.* — The radices are fixed to the meridian of Bologna, at noon of the last day of the preceding December. The completed years are reckoned both upward (before Christ) and downward (after Christ).

EQUATIONS OF MARS

TABLE 75. The first equation of the inequality of Mars
[*Aequatio Prima Inæqualitatis Martis*].

Signs of the simple, or mean, anomaly [*Anomaliae simplicis, seu Mediæ Signa*].

The left "Anom. simpl. Gr." column is the argument (degrees) descending; the right "Anom. simpl. Gr." is the argument ascending for the lower (mirror) sign-labels. Upper sign-headers (each "Subtr." — subtractive): 0, I, II, III, IV, V; each gives G'.". Lower headers (added quantity): "Adde XI, X, IX, VIII, VII, VI."

Lower sign-labels (right-hand argument, the "Adde" quantities): Adde XI, X, IX, VIII, VII, VI.

TABLE 76. The equated anomaly of Mars, corresponding to the simple anomaly [*Anomalia Aequata Martis, respondens Anomaliæ simplici*].

Signs of the simple, or mean, anomaly [*Anomaliæ simplicis, seu Mediæ Signa*].

The left "Anom. simpl. Gr." is the argument (degrees) descending; the right "Anom. simpl. G." is the argument ascending for the lower sign-labels. Upper headers: 0, I, II, III, IV, V (Sig:G'.''). Lower headers (read with the right argument): XI, X, IX, VIII, VII, VI.

Lower sign-labels (right-hand argument): XI, X, IX, VIII, VII, VI. (Footer: *Anomalice simplicis Signa* — Signs of the simple anomaly.)

EQUATIONS OF MARS.

[Margin (left and right, rotated): *Anomalia Æquata Martis* — the equated anomaly of Mars]

TABLE 77. Of the Maximum Equations, or of the Parallaxes of the Annual Orb, for Mars.

[Top heading spanning the seven double-columns: *Signa Anomaliae Solis Æquatæ Completa* — Completed signs of the equated anomaly of the Sun]

The left index gives the completed signs (Sig.) and degrees (G.) of the equated anomaly of the Sun; the seven double-columns headed **0, I, II, III, IV, V, VI** each give degrees (G.) and minutes (') of the maximum equation; the right index gives degrees (G.) and the descending sign (Sig.) read from the foot of the table (XII, XI, X, IX, VIII, VII, VI), where the bottom heading repeats *Signa Anomaliae Solis Æquatæ Completa*.

[Foot heading: Signa Anomaliae Solis Æquatæ Completa — Completed signs of the equated anomaly of the Sun]

LATITUDES OF MARS.

TABLE 78. Of the Proportional Minutes of the Latitude of Mars.

[Heading spanning the central double-columns: Signa Completa Anomaliae Æquatæ Excentrici Martis — Completed signs of the equated anomaly of the eccentric of Mars]

The left index gives the commune (orbital) anomaly of Mars [Anomal. orb. seu commun. ♂] in signs (Sig.) and degrees (G.); the column **Scrup. propor. increm. & decrem.** gives the proportional minutes of increase and decrease (G./'); the seven double-columns headed **0, I, II, III, IV, V, VI** give the proportional minutes (G./'); then a second **Scrup. propor. increm. & decrem.** column (G./') on the right, a **Scrup. incr. in ♂** column (the scruples of increase in Mars, '), and a right index **Anomal. orb. ♂** in degrees (G.) and signs (Sig.). The marker "A." marks the maximum (60) and "B." the inflection. The bottom sign-row reads XII, XI, X, IX, VIII, VII, VI.

[Foot heading: Signa Completa Anomaliae Solis Æquatæ — Completed signs of the equated anomaly of the Sun]

TABLE 80. Of the Latitude, Reduction, and Curtation of Mars.

[Heading: Signa Distantiæ à Nodo Boreali — Signs of the distance from the northern node]

This table is read against the **distance from the northern node** [Distantiæ à Nodo Boreali]. The left index **Distant.** gives degrees (Gr.). Each block of three columns gives **Latit.** (latitude, G./'), **Red.** (reduction [Reductio], "), and **Curt.** (curtation [Curtatio], "); the block headings give the bordering sign-pair (e.g. "0

Bor. 6 Austr." = 0 of Boreal / 6 of Austral). The right index **Distant.** (Gr.) counts down, with the foot headings completing the southern signs.

[Foot heading: Signa Distantiæ à Nodo Boreali — Signs of the distance from the northern node]

MEAN MOTIONS OF VENUS.

TABLE 81. Of the Mean Motions of Venus ♀.

[Margin: Distantiæ à Nodo Boreali — distance from the northern node]

Epochs, or Radices of the Motions [EPOCHÆ, seu RADICES MOTUUM]

Left index **Anni Completi ante Christum** (completed years before Christ; below "Christi," it counts forward, with the running side-labels **Stylo veteri** [old style] and **Stylo novo** [new style]). Three triple-column groups give the **Longitude from Aries** [Longit. ab ♈], the **Apogee** [Apogæi], and the **Northern Node** [Nodi Bor.], each in signs (Sig.), degrees (G.), minutes ('), and seconds (").

Tomus II — Tabulae Novalmagesticae — Equations and Latitudes of Venus

TABLE 82. Of the Equations of the First Inequality of Venus.

(TABULA 82. Aequationum Primae Inaequalitatis Veneris.)

Signs of the simple, or mean, anomaly (*Signa Anomaliæ simplicis, seu Mediæ*).

The top band of each block gives the sign-headers **O Subtr. ... V Subtr.** ("Subtract"); the bottom band gives the complementary sign-headers **Adde XI ... Adde VI** ("Add"). The left **Anom. simpl. G.** column ascends 0–30; the right **Anom. simpl. G.** column descends 30–0. Each block has two subcolumns, minutes (') and seconds (").

Bottom band (complementary sign-headers): **Adde XI** | **Adde X** | **Adde IX** | **Adde VIII** | **Adde VII** | **Adde VI**.

Foot: Signs of the simple anomaly (*Signa Anomaliae simplicis*).

TABLE 83. The Equated Anomaly of Venus, corresponding to the Simple Anomaly.

(TAB. 83. *Anomalia Aequata Veneris, respondens Anomaliae simplici.*)

Signs of the simple anomaly (*Signa Anomaliae simplicis*).

Top sign-headers **O ... V**; bottom sign-headers **XI ... VI**. Left **Anom. Gr.** ascends 0–30; right **Anom. Gr.** descends 30–0. Each block: Sig. (sign), G. (degrees), ' (minutes), " (seconds).

Bottom sign-headers: **XI | X | IX | VIII | VII | VI.**

Foot: Signs of the simple anomaly (*Signa Anomaliae simplicis*).

TABLE 84. Of the Maximum Equations, or of the Parallaxes of the Annual Orb of Venus.

(*TABULA 84. Maximarum Aequationum, seu Parallaxeon Orbis annui Veneris.*)

Signs of the equated, completed anomaly of Venus (*Signa Anomaliae Veneris Aequatae Completa*).

This is a double-argument table. The left margin reads vertically **Anomalia Solis Aequata** ("Equated anomaly of the Sun"); the right margin likewise **Anomalia Solis Aequata**. The body argument is the equated, completed anomaly of Venus, given as **Sig.** (sign) + **G.** (degree) at the left, in steps of 3° (0, 3, 6, 9, 12, 15, 18 ...). Across the head run the sign-blocks **O, I, II, III, IV, V, VI**, each carrying a **G.** (degrees) and **'** (minutes) of the maximum equation; the running G. value is printed only where it changes. The right-hand **G./Sig.** pair counts the complementary solar-anomaly argument downward (12, 11, 10 ...). The foot sign-headers run **XII, XI, X, IX, VIII, VII, VI**.

The value entered in each sign-block is **degrees ' minutes** of the maximum equation. Within each 6-row group the degrees figure (45, 46, 47) is printed once at the group head and carries down until it changes.

Foot sign-headers: **XII** | **XI** | **X** | **IX** | **VIII** | **VII** | **VI**. Foot: The completed signs of the equated anomaly of Venus (*Anomaliae Veneris Aequatae Signa Completa*).

TABLE 85. Of the Proportional Scruples of the Latitude of Venus.

(*TABULA 85. Scrupulorum Proportionalium Latitudinis Veneris.*)

Completed signs of the equated anomaly of the Sun (*Signa Completa Anomaliae Solis Aequatae*).

Double-argument table. The left margin reads vertically **Anomalia Orbis Veneris** ("Anomaly of the orb of Venus"); the right margin likewise **Anomalia Orbis Veneris**. The body argument is **Sig.** + **G.** at the left. Across the head run the sign-blocks **O, I, II, III, IV, V, VI**, each with **G.** (degrees) and **'** (minutes) of the proportional scruples. To the right of the VI-block stands a separate column **Scrup. decr.** ("decrement scruples") with its own **G./**, captioned vertically *Scrupula proportionalia Decrementi in ♂ retrograda* — "Proportional scruples of

the decrement, in the retrograde σ (Mars)". The right-hand **G./Sig.** pair counts the complementary argument downward (12, 11, 10 ...); the foot sign-headers run **XII, XI, X, IX, VIII, VII, VI.**

LATITUDES OF VENUS [LATITVDINES VENERIS] (p. 89)

TABLE 86. Proportional Minutes for the Decrement of the Latitude of Venus [TABVLA 86. Scrupulorum Proportionalium Decrementi Latitudinis Veneris.]

Argument: Equated anomaly of Venus [Anomal. Æq. ♀], in Signs (Sig.) and Degrees (G.), read down the left margin and up the right margin. Top column-headers (Signs of the completed equated anomaly of the Sun [Signa Completa Anomalizæ Solis Æquatæ], read at top): O, I, II, III, IV, V, VI. Bottom column-headers (read from below): XII, XI, X, IX, VIII, VII, VI. Each sign-column gives Degrees (G.) and minutes (').

TABLE 87. Of the Latitude, Reduction, and Curtation of Venus
[TABVLA 87. Latitudinis, Reductionis, & Curtationis Veneris.]

Argument (both margins): Distance of Venus from the [ascending] Node [Dist. à ☿], in Degrees (Gr.). Top sign-labels: Signs of the distance of Venus from the boreal Node [Signa Distantiæ Veneris à Nodo Boreali] — the three displayed blocks are headed **O Boreal.** / **VI Austral.**, **I Boreal.** / **VII Austral.**, **II Boreal.** / **VIII Austral.** Each block has three sub-columns: Latitude [Latitudo.] (Degrees G., minutes '); Reduction [Reductio.] (minutes ', seconds "); Curtation [Curtatio.] (minutes ', seconds "). Bottom sign-labels (read from below): **V Boreal.** / **XI Austral.**, **IV Boreal.** / **X Austral.**, **III Boreal.** / **IX Austral.**

Block: **O Boreal.** / **VI Austral.** — **I Boreal.** / **VII Austral.** — **II Boreal.** / **VIII Austral.**

[Below the EXPANSI table:] The roots are fixed to the meridian of Bologna, at noon of the last [day] of the preceding December. The years are Completed [years], whether you count upward before Christ or downward after Christ. [Radices affixæ sunt Meridiano Bononiensi, in meridie ultimo Decembris præcedentis. Anni sunt Completi, sive numeres sursum ante Christum, sive deorsum post Christum.]

EQUATIONS OF MERCURY [ÆQVATIONES MERCVRII] (p. 91)

TABLE 89. Of the Equations of the First Inequality of Mercury
[TABVLA 89. Aequationum Prima Inaequalitatis Mercurij.]

Argument (both margins): Simple anomaly [Anom. simpl.] in Degrees (Gr.), descending 0→30 on the left and 30→0 on the right. Top caption: Signs of the simple anomaly of the eccentric of Mercury [Signa Anomaliæ simplicis Excentrici Mercurij]. Column-blocks O–V, each labelled **Subtract** [Subtr.], in Degrees (G.), minutes (′), seconds (″). Footer signs (the complementary "Adde" signs): **Adde XI, X, IX, VIII, VII, VI.**

[illegible]

Mercury Equation and Latitude Tables (Tabulae 91–93, 87)

TABLE 91. Of the Maximum Equations, or Parallaxes of the Orb of Mercury (*Maximarum Aequationum, seu Parallaxium Orbis Mercurij*)

[Left side-label: Anomalia Aequata Mercurij (Equated Anomaly of Mercury). Right side-label: Anomalia Aequata Mercurij.]

Top argument heading: **Signa Completa Anomaliae Solis Aequatae** (Completed signs of the equated solar anomaly), running 0–VI across the top and XII–VI across the bottom.

The left double argument is *Sig.* (sign) and *G.* (degree); the right double argument is *G.* and *Sig.* read from the bottom. Each completed-sign column gives the maximum equation in *G.* (degrees) and ' (minutes). A degree value carried in a column applies down the column until the next printed degree value.

Bottom argument heading (right-to-left): XII | XI | X | IX | VIII | VII | VI — **Signa Completa Anomaliae Solis Æquatae.**

TABLE 92. Of the Proportional Minutes of the Latitude of Mercury (*Scrupulorum Proportionalium Latitudinis Mercurij*)

Top argument heading: **Signa Completa Anomaliae Excentrici Mercurij Æquatae** (Completed signs of the equated eccentric anomaly of Mercury), running O–VI across the top and XII–VI across the bottom.

Left double argument: *Anom. orbis* ☿ — *Sig.* and *G.* Adjacent to it, *Scrup. propot. incr. & decr.* (proportional minutes, increasing and decreasing) in *G.* and *'*. The central blocks give *G.* and *'* per completed sign. To the right, a second *Scrup. propot. incr. & decr.* column, then *Decr. in ♂ directa* (decrement in direct Mars [motion]) in *'*, then *Anom. orbis* ☿ — *G.* and *Sig.* (read from below).

TABLE 87. Of the Latitude, Reduction, and Curtation of Mercury (*Latitudinis, Reductionis, & Curtationis Mercurij*)

Each block is headed by a Boreal sign (top) and an Austral sign (bottom): *Latitudo.* in *G.* and *'*; *Reductio.* in *'* and *"*; *Curtatio.* in *'* and *"*. The outer columns are *Dist. Gr.* (distance in degrees), ascending on the left, descending on the right.

Bottom argument heading: V Boreal. / XI Austral. — IV Boreal. / X Austral. — III Boreal. / IX Austral. — **Signa Distantiae Mercurij à Nodo Boreali.**

TABULA 95 — Prosthaphaeresis of the Orb (Saturn, Jupiter, Mars, Venus, and Mercury)

TABVLA 95. Prosthaphaeresis of the Orb [Prosthaphaeresis Orbis] for ♄ [Saturn], ♃ [Jupiter], ♂ [Mars], ♀ [Venus], and ☿ [Mercury] — devised by the most distinguished Dn. de S. Legier of Avignon [à Clariss. Dn. de S. Legier, Auenion.], and exactly computed.

Sub-heading: **Maximum, or composite, equation** [Æquatio maxima, seu composita]. — **ADD** [ADDE] (across the top); **SUBTRACT** [SVBTRAHE] (across the foot).

This is a single continuous table spanning the three pages of this opening. The left-hand argument column (S | G.) gives the degree of argument 1–30 within each sign-block; the descending argument (S | G.) on the right edge gives the complementary degree 29...0 with its own sign-number. The body columns are headed by the whole-degree value of the argument's sign-position (5, 6, 7, 8, 9, 10, 11, 12, 17, 18), each subdivided into G. (degrees) · ' (minutes) · " (seconds). Read the top sign-headers and "ADD" when the argument enters from the top; read the foot sign-headers and "SUBTRACT" when it enters from the bottom.

argument-blocks (top header signs 5–18; foot header signs 5–18)

Top sign-headers (degrees): 5 · 6 · 7 · 8 · 9 · 10 · 11 · 12 · 17 · 18. Right-edge sign marker: 12. Foot sign-headers (degrees): 5 · 6 · 7 · 8 · 9 · 10 · 11 · 12 · 17 · 18. Bottom legend: **SVBTRAHE**. Catchword/signature foot: R 2, PRO-.

[Table continues — the lower portion of p. 99 runs the argument 4–30 down columns 5°–18° to the foot legend **SVBTRAHE**. and the foot sign-headers 5·6·7·8·9·10·11·12·17·18. The lower-block cells crowd toward the binding gutter and ink show-through; many seconds digits there are not separable at native resolution and The foot-block descending argument runs 27...0 on the right edge.]

Tabulae Novalmagesticae — TAB. 95 (Prosthaphaeresis of the Orb), continued

TABVLA 95. *Prosthaphaeresis Orbis* ♄, ♃, ♂, ♀, ♁ **et** ☉. [The composite prosthaphaeresis (parallax) of the orb for the five planets and the Sun.]

Æquatio maxima, seu composita — The maximum, or composite, equation.

Sub-heading **ADDE** (Add) at the top of each page; **SVBTRAHE** (Subtract) at the foot.

The table is a double-entry equation table. The interior columns are headed by the degree of the argument (19, 20, 21, 22, 23, 24, 25, 26, 27, 28), each subdivided into G(°) | ' (minutes) | " (seconds). The leftmost rail gives the sign-number **S** and the argument-degree **G**. (1–30); the rightmost rail gives the complementary descending degree and sign. Read top-down under the upper sign and **add**; read bottom-up under the lower sign and **subtract**.

top sign **S 0** / foot **S 11**

Upper block (argument 1–30, sign S 0; complement at right S 11)

Foot of page 2: **SVBTRAHE**.

top sign S 4 / foot S 7 (descending branch)

On this page the print is fainter and several leading degree-digits failed to ink; where the degree integer is dropped from the type it is reconstructed from the smooth column progression and flagged, or marked [?] where not recoverable.

Foot of page 3: **SVBTRAHE**.

PROSTHAPHAERESES OF THE ORB [PROSTAPHÆERESES ORBIS]

TAB. 95. Prosthaphaeresis of the Orb ♄, ♃, ♂, ♀, & ☿ (*continued*)

[Margin / column-band labels: across the top of each page the operation marker reads **ADDE** ("ADD"); along the bottom it reads **SUBTRAHE** ("SUBTRACT"). The leftmost banner reads **Æquatio maxima, seu composita** ("The maximum, or composite, equation"). The running header reads **PROSTAPHÆERESES ORBIS**.]

These three pages continue the composite prosthaphaeresis table (TAB. 95) introduced earlier, now carrying the high-degree argument columns for the maximum (composite) equation common to the five planets (Saturn ♄, Jupiter ♃, Mars ♂, Venus ♀, and Mercury ☿). Each page is a single table: the left-hand index gives the sign **S** and degree **G.** of the argument (1–30), and each value cell is a triple **G. ' "** (degrees, minutes, seconds) of the equation. The descending index and sign-block on the right edge serve the inverse reading (argument-complement), with the operation reversing from ADD (above) to SUBTRACT (below). The body argument columns are headed **29, 30, 34, 35, 36, 37, 38, 39, 40, 41** (degrees of the argument).

Page 1 (source PDF p. 553; printed p. 101)

[Left sign-block index: rows 1–30 under **S 0**, then rows 1–30 under **S 1**. Right descending index: **S 12** at top down to **S 11**. Operation: ADDE above, SUBTRAHE below.]

Argument-degree columns: 29 · 30 · 34 · 35 · 36 · 37 · 38 · 39 · 40 · 41 (each cell = G ' '')

Sign block S 0 (left index G 1–30)

[Table-foot argument-degree labels: **29 0 · 30 0 · 34 0 · 35 0 · 36 0 · 37 0 · 38 0 · 39 0 · 40 0 · 41 0**. Operation below: **SUBTRAHE**. Right descending index runs **S 10 ... S 9**.]

Page 3 (source PDF p. 555; printed p. 103)

[Left sign-block index: rows 1–30 under **S 4**, then rows 1–30 under **S 5**, then the start of **S 6** at the foot. Right descending index: **S 8** at top down through **S 7** to **S 6**. Operation: ADDE above, SUBTRAHE below. This page carries the descending half of TAB. 95, where each column declines toward 0° 0' 0".]

PROSTHAPHÆRESES OF THE ORB

TABLE 95. Prosthaphæresis of the orb for ♄ [Saturn], ♃ [Jupiter], ♂ [Mars], ♀ [Venus], & ☿ [Mercury]. *(continued)*

Maximum equation, or composite [Æquatio maxima, seu composita]. — ADD [ADDE].

The argument runs across the top in whole degrees (42, 43, 44, 45, 46, 47, 48); each column entry is given in **G.** (degrees) ' (minutes) " (seconds). The outer index columns carry **S** (the sign-block marker) and **G.** (the degree of argument). The left index ascends 1–30 within each block; the right index descends. Read **ADD** when entering the table from the top; **SUBTRACT [SVBTRAHE]** when entering from the bottom.

Source PDF p. 556 (printed p. 104)

Left block-marker S column reads (top to bottom of the major divisions): **0**, then **I [1]**, then **II [2]**. Right block-marker S column reads **12**, then **11**, then **10**. Right G-index descends from 29.

Foot of table: SUBTRACT [SVBTRAHE].

Source PDF p. 558 (printed p. 106)

Left block-marker S column reads 4, 5, 6. Right block-marker S column reads 7, 6. On this page the degree-of-argument figure is printed only in the first row of each minor block of several columns (the printer leaves the leading whole-degree blank where it repeats); the blanks are reproduced below as a blank degree cell where the source omits it. The table reaches its terminus at the foot, where every column reads **0 0 0**.

Foot of table: **SUBTRACT [SVBTRAHE].**

TABLE 96. General Latitude of the Five Planets.

Degrees of the circle up to 10.

The argument runs down the left edge in minutes of arc (1–60, labelled *Scrupula Graduum* — minutes of degrees), and across the top in whole degrees of the circle (the ten column-groups headed 0 through 9). Each column-group gives the latitude as G. (degrees) and ' (minutes). The tabulated entries are the sines of the degrees-and-minutes, in the measure where the radius is 60.

The numbers distributed through the columns are the sines of the degrees and of the minutes, in the measure where the radius is 60.

TABLE 97. Distance of the Minor Planets from the Sun, in parts where the radius of the Sun's annual orb is 100000.

The argument is the equated anomaly of the planets [*Anomalia Æquata Planetarum*, given in the left margin], stepping by 3 degrees in the first column (0

to 180) and by its complement to 360 in the second (360 down to 180). The remaining columns give the distance for Saturn (♄), Jupiter (♃), Mars (♂), Venus (♀), and Mercury (☿).

TABLE 98.

OR, THE UNIVERSAL CATALOGUE OF THE FIXED STARS, COMPLETED FOR THE YEAR OF CHRIST 1700.

And reduced to four Classes, or Degrees of Certitude; transcribed here from Book Four.

The **First Class** contains the stars observed by us together with Father Francesco Maria Grimaldi [P. Franciscus Maria Grimaldus], most often, whose longitude and latitude — in accordance with what was said in Book IV — we reckon as certain in the first degree; and to these we have added the Pleiades observed by D. Vicenç Mut [D. Vincentius Mutus] and by Michael Florent van Langren [Michael Florentius Langrenus].

The **Second Class** holds the remaining stars observed by Tycho [Tycho Brahe] or by Kepler [Johannes Kepler], as they stand in the Rudolphine Catalogue [Catalogo Rudolphino] — the numbers nevertheless corrected so far as the differences

between our own values and the Tychonic values of the same constellation require, or those near to them, which we place in the second degree of certitude.

The **Third Class** comprises the remaining stars, observed neither by us, nor by Tycho, but by Hipparchus [Hipparchus] and Ptolemy [Ptolemy] — looking, however, to those same constellations, or to neighbouring ones, of which some Fixed stars are by us, or by Tycho, observed; the numbers corrected so far as the differences between the Ptolemaic values and our own, or the Tychonic values of the same constellation, require. And these, in the third degree of certitude, we do not place so as evidently to exclude an error of 10 minutes. As Kepler says: *that they were corrected by themselves from the numbers, after the example of the surrounding Tychonic ones.*

The **Fourth Class** extends to stars observed neither by Hipparchus, nor by Ptolemy (so far as we know), nor by Tycho — nor among those observed by them, but looking to wholly new constellations, observed by the navigators [Naucleri]. Their longitude only we have reduced to the end of the year 1700, adding to the Rudolphine longitude the motion of 100 years, which for us is $1^{\circ} 24' 27''$. The latitude, however, we have transcribed from the Rudolphine Catalogue wholly unchanged. We reckon these, moreover, to be of the fourth degree of certitude; and, given the cross-staff [Radius], or astronomical staff [Baculo Astronomico], which the navigators use, and which we have found by experience to be liable to an error of some few minutes, we do not judge them to be more reliable than the Ptolemaic ones, until they shall have been observed by another and more accurate method.

PART ONE. Of the Fixed Stars of the Twelve Signs of the Zodiac.

ARIES.

Name of the Fixed star	Sig n	G r.	'	"	Lat. Gr.	'	"	B/ A	Ma g.
<i>1st Class.</i>									
The first in the Horn, preceding [Prima in Cornu præcedente]	Υ	2 8	5 9	2 7	7	8	0	B	4

CATALOGUE OF THE FIXED STARS FOR THE YEAR 1700 (continued)

Universal table of the fixed stars (TAB. 98), continued. Each entry gives the star's name, its ecliptic longitude (zodiac Sign | degrees | minutes | seconds), its ecliptic latitude (degrees | minutes | seconds, with B = Borealis/northern, A = Australis/southern), and its magnitude. Within each constellation the stars are grouped by certitude class (1.–4. Classis). The longitude "Sign" column gives the zodiacal sign in which the longitude falls; it is reproduced here by name.

(Continuation of TAURUS, 2. Classis)

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
In the right shoulder [In armo dextro]	Gemini	3	2	3	8	4	5	A	5
			1	0		0	0		
The preceding of the three below the Hyades [Trium infra Hyadas præced.]	Gemini	3	5	0	6	5	2	A	5
						6	0		
The middle of them [Media earum]	Gemini	4	5	0	7	4	2	A	5
			1				0		
The following of them [Sequens earum]	Gemini	6	1	0	6	1	2	A	6
			8			7	0		
The little one in the southern horn [Parvula in cornu austr.]	Gemini	1	2	0	1	3	5	A	6
			6	5			0		
The following in the same horn [Sequens in eodem cornu]	Gemini	1	1	3	1	1	5	A	6
			8	8	0	9	0		
The little one following the four in the section [Parvula sequens quatuor in sectione]	Taurus	8	5	0	9	3	2	A	6
			6				0		
Of the two in the square of	Gemini	0	4	3	6	3	5	A	5

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
the neck, the preceding [Duarum in quadrato colli præced.]		5		0		2	0		

3. Classis. — Informes [the unformed/scattered stars]

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
Below the foot and the right shoulder [Sub pede, & armo dextro]	Taurus	1	4	0	17	2	3	A	4
		7	3			9	0		
The preceding, above the southern horn [Præced. supra cornu austr.]	Taurus	1	2	0	1	5	3	A	5
		2	3			0	0		
Below the extreme southern horn, more to the north [Sub extremo cornu australi borealior]	Gemini	2	2	0	5	5	3	A	5
		1	3			9	0		
Below the same, more to the south [Sub eodem australior]	Gemini	2	2	0	6	5	3	A	5
		1	3			9	0		
Preceding by 5°, below the northern horn [Ex 5 sub cornu boreo præced.]	Gemini	1	2	0	0	4	3	B	5
		9	3			0	0		
Following this one [Hanc sequens]	Gemini	2	2	0	1	2	3	B	5
		1	3			0	0		
Again behind this one [Hac iterum posterior]	Gemini	2	2	0	1	4	3	B	5
		3	3			0	0		
The more northern of the last two [Vltimarum duarum borea]	Gemini	2	4	0	3	4	3	B	5
		4	3			0	0		
The southern of them [Earum australis]	Gemini	2	4	0	1	3	3	B	5
		5	3			5	0		

GEMINI.

1. Classis.

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
Head of Castor [Castoris caput]	Cancer	1	1	4	10	2	5	B	2
		6		7			0		
Head of Pollux [Pollucis caput]	Cancer	1	4	5	6	3	3	B	2
		9		3		8	0		
The bright star in the foot of Gemini [Lucidus pes ♊]	Cancer	4	5	4	6	4	0	A	2
			1	7			8		

2. Classis.

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
Left hand of the preceding Twin [Sinistra manus præcedentis Gemini]	Cancer	6	5	5	10	5	3	B	5
			4	0		8	0		
In the left arm [In sinistro brachio]	Cancer	1	1	5	7	4	3	B	4
		1	6	2		3	0		
In the same shoulder-blades [In eiusdem scapulis]	Cancer	1	4	0	5	4	0	B	4
		4	7			3			
In the same, the right shoulder [In eiusdem humero dextro]	Cancer	1	1	0	5	1	3	B	5
		7	0			0	0		
In the left shoulder of the following Twin [In sinistro hum. sequentis Gemini]	Cancer	1	2	0	3	3	3	B	4
		9	9				0		
In the right side of the preceding [Gemini] [In latere dext. præced. ♊]	Cancer	1	4	0	2	5	3	B	6
		4	1			6	0		
In the left elbow of Castor [In sinistro cubito Castoris]	Cancer	1	3	0	6	1	0	B	6
		5	3						
In the northern and topmost knee [In boreal. & supremo genu]	Cancer	5	4	0	2	1	3	B	3
			5			1	0		

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
In the left, the following knee [In sinistro genu sequentis]	Cancer	1	4	0	2	7	0	A	3
		0	9						
In the belly of Pollux [In ventre Pollucis]	Cancer	1	1	5	0	1	0	A	3
		4	8	0		4			
In the same one's hough [In eiusdem poplite]	Cancer	1	3	0	5	4	3	A	4
		4	6			1	0		
In the foot preceding Castor [In pede antecedenti Castoris]	Gemini	2	1	0	0	5	3	A	4
		9	4			8	0		
The heel of the same foot [Calx eiusdem pedis]	Cancer	1	4	5	0	5	3	A	3
				0		3	0		
In the extreme right foot of Castor [In extremo pedis dextri Castoris]	Cancer	2	3	0	3	8	3	A	4
		5				0			
In the lowest foot of Pollux [In imo pede Pollucis]	Cancer	6	5	2	10	9	3	A	4
		0	0			0			
In the heel of Pollux [In calce Pollucis]	Cancer	9	1	0	9	4	3	A	6
		7				1	0		
At the top of the knee of Pollux [Suprema genu Pollucis]	Cancer	7	4	5	1	1	2	A	6
		3	0			2	0		
In the thigh of Castor [In femore Castoris]	Cancer	9	5	2	1	3	2	B	6
		8	0			1	0		
Below the head, in the hand of Pollux [Infra caput in manu Pollucis]	Cancer	2	5	5	5	4	3	B	5
		1		0		4	0		
The little one between the heads [Gemini] [Parvula inter capita II]	Cancer	1	2	2	7	2	2	B	5
		8	5	0		4	5		
At the ear of Castor [Ad aurem Castoris]	Cancer	1	4	5	9	4	3	B	5
		4	3	0		2	0		
Preceding the topmost foot, nearer it [Præcedens summum pedé, seu Propus]	Gemini	2	4	5	0	1	3	A	4
		6	2	0		3	0		
The lowest of the five	Cancer	1	2	2	5	5	2	A	6

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
preceding stars among the Twins [Præcedétium quinque inter Geminos infima]		8	3	0		2	5		
The following one above this [Sequens supra hanc]	Cancer	1	2	5	3	4	0	A	6
		9	6	5		9			
The third of them [Tertia earum]	Cancer	2	5	2	2	4	3	A	6
		0	1	0		2	0		
The fourth of them [Quarta earum]	Cancer	2	4	5	0	5	0	A	6
		2	8	0		8			

3. Classis.

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
The bright star that precedes the front knee [Quæ præcedit genu anterius Clara]	Gemini	2	7	0	6	1	3	B	4
		9				0	0		

CANCER.

1. Classis.

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
The Nebulous Manger [Nebulosa Præsepe]	Leo	3	8	2	1	1	3	B	ne b.
				3		4	0		
The Northern Ass [Asellus Boreus]	Leo	3	1	5	3	8	3	B	4
			8	3			0		
The Southern Ass [Asellus Australis]	Leo	4	2	5	0	3	3	A	4
			9	3			0		

(Right column of page 110 — continuation of CANCER, 2. Classis)

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
In the northern of the preceding square [Borea in □ præcedentium]	Leo	1	1	0	1	3	0	B	5
			1			2			
The southern of the same [Australis earumdem]	Leo	1	3	3	0	4	0	A	5
			4	0		7			
In the southern arm [In Brachio austrino]	Leo	9	2	3	5	7	3	A	3
			5	0			0		
In the northern arm [In Brachio boreo]	Leo	2	6	0	10	2	3	B	5
						3	0		
In the extreme northern foot [In extremo pedis borei]	Cancer	2	1	0	1	1	0	B	5
			5	8		6			
In the extreme southern foot [In extremo pedis austrini]	Cancer	2	2	0	7	4	3	A	6
			6	6			0		
The brighter one at the root of the tail [Lucidior in radice caudæ]	Cancer	2	7	3	2	1	0	A	4
			7	0		8			
The next one following, in the back [Sequens proximé in dorso]	Cancer	2	3	3	1	3	3	A	6
			9	4	0		0		
In the southern arm, [the more] northern [In brachio australi borea]	Leo	3	9	3	1	5	3	A	6
				0		3	0		
In the same, the southern [In eodem austrina]	Leo	1	5	0	5	3	2	A	5
			1	8		5	8		
In the northern claw [In rostro borealis]	Leo	6	4	0	7	1	3	B	6

LEO.

1. Classis.

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
The Heart of the Lion, Regulus [Leonis cor, Regulus]	Leo	2	3	3	0	2	2	B	1
		5	8	2		6	0		
The bright star of the tail [Leonis caudæ lucida]	Virgo	1	2	4	12	1	2	B	1
		7	6	7		6	0		
The bright star of the mane, or of the neck [Iubæ, seu colli lucida]	Leo	2	1	1	8	4	4	B	2
		5	8	9		5	0		
The top of the neck [Suprema cervicis]	Leo	2	1	4	11	4	4	B	3
		3	6	7		8	0		
The bottom of the neck [Infima cervicis]	Leo	2	3	1	4	5	4	B	3
		3	9	7		0	0		
The bright star in the loins [Lucida in Lumbis]	Leo	7	7	3	14	1	3	B	2
				2		8	0		

2. Classis.

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
Those in the nostrils [Quæ in naribus]	Leo	1	1	3	10	2	4	B	4
		1		0		1	0		
In the gape of the mouth [In hiatu]	Leo	1	3	3	7	5	4	B	4
		3	6	0		0	5		
The more northern of the head [Capitis borealior]	Leo	1	1	0	12	1	5	B	4
		7	1			9	0		
The more southern of the	Leo	1	2	0	9	3	4	B	3

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
head [Capitis australior]		6	5			8	0		
In the more southern breast [In pectore australior]	Leo	2	1	3	1	2	4	A	5
Preceding Regulus, very near [Antecedens Regulum proximé]	Leo	2	5	3	0	0	2	B	4
		3		0			5		
Preceding this, in the right knee [Hác præced. in genu dextro]	Leo	1	1	3	0	1	5	B	5
		9	6	0		5	0		
In the right ear [In aure dextra]	Leo	1	2	0	3	1	1	A	4
		7	9			0	0		
Following on the other foot [Sequens in altero pede]	Leo	2	2	0	3	4	1	A	4
		0				7	0		
In the left ear [In aure sinistra]	Leo	2	8	0	3	5	1	A	4
		5				5	0		
In the left armpit [In sinistra Axilla]	Virgo	2	1	0	0	7	5	B	4
			0				0		
In the belly, the preceding of three [In ventre trium anteced.]	Leo	2	4	0	2	9	5	B	6
		3	6				2		
The more northern of them [Earum borealior]	Virgo	3	2	0	5	5	5	A	6
			8			5	0		
The more southern of them [Earum australior]	Virgo	5	2	1	2	4	2	A	6
			7	0		9	0		
Preceding the two in the loins [Præcedens duarum in lumbis]	Virgo	4	3	0	12	5	5	B	5
			6			2	0		
In the haunch, the preceding northern [In clune præcedens borea]	Virgo	9	1	0	9	4	2	B	3
			2			1	0		
The following southern [Sequens austrina]	Virgo	1	3	0	7	5	2	B	6
		0	0			0	5		
In the thigh [In femore]	Virgo	1	2	3	6	6	5	B	3
		3	0	0			0		

Name of the star	Long. Sign	G	'	"	Lat. G	'	"	B/ A	Ma g.
In the hinder knee [In genu posteriori]	Virgo	1	3	3	1	3	5	B	4
		4	0	0		9	2		
The middle one in the foot [Media in pede]	Virgo	1	1	0	0	3	1	A	4
		7	9			3	0		
The lowest one in the foot [Infima in pede]	Virgo	2	5	0	3	2	4	A	4
		0	0				0		
In the hoof of the left foot [In vngula pedis sinistri]	Leo	1	5	0	4	4	3	A	6
		7	5			9	0		
In the hoof of the preceding right foot [In vngula pedis præced. dextra]	Leo	1	2	3	5	4	3	A	5
		7	4	0		4	0		
In the middle of the body [In medio corpore]	Virgo	1	3	3	10	1	3	B	6
			7	0		5	0		
The little one in the head [Parvula in capite]	Leo	1	3	0	10	4	1	B	6
		7	3			6	0		
Preceding the two in the hinder left foot [Præcedens duarum in sinistro pede posterior]	Leo	1	1	0	7	4	3	A	4
		7	5			0	0		
Tycho's other codex [Tychonis alter codex]	Virgo	2	1	0	5	4	3	A	5
		0	2			2	0		
Of the unformed stars above the back, the preceding [Informium supra dorsum præced.]	Leo	2	4	3	17	3	4	B	5
		7	5	0		8	0		
Following them [Sequens earum]	Virgo	1	2	0	16	2	5	B	5
			0			8	0		
The topmost of the bright stars of the back [Suprema lucidarum dorsi]	Virgo	6	1	3	16	4	4	B	5
			6	0		5	0		
Above the tail [Supra caudam]	Virgo	1	4	0	17	1	5	B	4
		4	5			7	0

Catalogue of the Fixed Stars for the Year 1700

(TAB. 98. Each page carries two side-by-side table panels; reading order is the left panel top-to-bottom, then the right panel top-to-bottom. The columns are: **Names of the Fixed Stars** [Nomina Fixarum] | **Longitude** [Longitudo: Sign · Degrees · Minutes · Seconds] | **Boreal Latitude** [Latitudo B.: Degrees · Minutes · Seconds] | **Magnitude** [Magnitudo]. In the latitude column, **B** = boreal/northern, **A** = austral/southern.)

Pars Prima — concluded (Pisces, with the Northern Triangle informes)

The following rows conclude the Pisces section of Pars Prima (the zodiac).

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The middle one in the boreal knot	♈	2	3	3		5	2	3	B	4
		2	8	0			1	0		
The northern one, and the last of the cord	♈	2	5	0		9	2	2	B	5
		2	9				4	8		
The northern one in the mouth of the boreal Fish	♈	2	3	3		2	0	3	B	6
		4	7	0		2		0		
The southern one in the same place	♈	2	1	0		2	4	2	B	5
		4	2			0	3	8		
The northern one of the triangle of the head	♈	2	4	0		2	5	3	B	6
		0	5			0	5	0		
The southern one of the said triangle	♈	1	2	0		1	2	3	B	6
		9	9			9	4	0		
The middle one, and	♈	1	2	0		2	2	2	B	6

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
preceding the triangle		8	6			0	4	9		
On the southern spine, near the left elbow of Andromeda	Υ	1	1	0		1	2	3	B	5
The middle one after it	Υ	9	9			3	1	0		
		1	2	0		1	2	0	B	6
		9	5			2	2			
The lowest of them	Υ	1	3	3		1	2	3	B	6
		9	1	0		1	1	0		
The northern of the two in the belly	Υ	2	4	2		1	2	2	B	5
		4	0	9		7	6	9		
The one more toward the south	Υ	2	2	0		1	3	2	B	5
		2	1			5	0	8		
The following middle one of the three on the southern spine	Υ	2	2	3		1	2	0	B	5
		9	2	0		2	8			
The one following, northward in the belly, toward the north	Υ	2	3	2		1	3	3	B	6
		5	3	8		8	1	0		
On the back of the head of the boreal fish	Υ	2	3	3		2	3	2	B	6
		3		0		3		9		

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
Of the informes in the square below the Fish, the preceding one on the first boreal side	⋈	1	3	3		1	3	3	A	4
		9	2	0		5	9	0		
The following one	⋈	2	3	2		2	2	3	A	4
		4	2	9			4	0		
The preceding one of the southern side	⋈	2	3	3		5	3	2	A	4
		3	7	0			4	9		
The following one	⋈	2	5	2		5	2	3	A	4
		4	2	8			9	0		
The preceding one of those following this square	Υ	2	3	3		4	3	2	A	5
			7	0			5	9		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The posterior one	Υ	7	3	2		4	2	3	A	5
			3	9			3	0		

PARS SECUNDA — Astra Borealia extra Zodiacum

(The northern constellations outside the zodiac.)

URSA MINOR — The Lesser Bear

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The last of the tail, now the Pole star [Polaris]	Π	2	2	4		6	5	5	B	2
			4	6			5	9		0
The bright one of the shoulder, formerly the Pole star in the time of Eudoxus	Ϡ	8	4	7		7	4	4	B	2
			5				2	8		0

Or, the upper one of the two preceding in the square.

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The next-to-last of the tail	Π	2	6	0		6	4	3	B	4
			7				9	6		0
The one at the root of the tail	Ϡ	4	5	0		7	4	0	B	4
			4				3	6		
The upper one of the two in the following square	Ϡ	2	5	0		7	5	0	B	4
			2	9			4	6		
The lower one of them	Ϡ	2	2	0		7	3	3	B	5
			6	2			7	4		0
The lower one of those preceding, in the square	Ϡ	1	1	0		7	1	3	B	3
			6	1			5	9		0
The informis at the head of the more southern Bear	Ϡ	4	2	0		7	2	0	B	6
			4				1	0		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one above this	♄	2	5	0		7	1	0	B	6
		8	0			0	5			
The first of the informes, in a straight line with the Pole	♄	1	4	0		3	4	0	B	6
		8	7			5	7			
The second	♄	1	5	0		3	1	0	B	6
		8	8			7	7			
The third, obscure	♄	1	1	0		4	1	0	B	6
		9	7			0	0			
The fourth	♄	1	3	0		4	5	1	B	6
		9	3			2	3	0		
The first of the informes near the Pole star	♄	2	8	0		5	5	0	B	6
		3				7	2			
The second	♄	2	2	0		7	3	0	B	6
		3	5			0	9			
The third	♄	2	1	0		6	0	0	B	6
		6				9				
The fourth	♄	1	3	0		6	1	0	B	6
		6	7			8				
The fifth	♄	8	5	0		6	4	0	B	6
		2				7	0			
The sixth	♄	1	2	0		6	1	0	B	6
		1	7			7	9			
The one nearest the Pole	♄	2	0	0		6	5	0	B	6
		8				3	2			

URSA MAIOR — The Greater Bear

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the shoulder, Dubhe [α Ursae Maioris]	♈	1	5	2		4	4	1	B	2
		0	9	7		9	0	0		
The bright one of the side,	♈	1	7	5		4	5	4	B	2

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
below Dubhe		5		7		5		0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the posterior haunch	♏	2	1	1		4	8	4	B	2
		6	0	2		7		0		
The bright one of the back, toward the tail	♏	2	4	5		5	3	1	B	2
		6	9	7		1	7	0		
The root of the tail, or the first one	♏	4	3	2		5	1	4	B	2
			6	7		4	7	5		
The middle one of the tail	♏	1	2	5		5	2	1	B	2
		1	1	3		6	1	0		
The last one of the tail	♏	2	3	7		5	2	1	B	2
		2	7			4	4	0		
The one following it on the neck	♏	2	3	0		4	3	1	B	4
						2	6	8		
The one following below this	♏	5	3	3		3	1	4	B	4
				0		8	5	5		
The one on the left fore-foot, anterior	♏	1	5	3		3	3	4	B	3
			7	0		4	4	6		
On the right foot, the more northern one	♏	2	2	0		2	1	4	B	3
		7	1			9	5	8		
The southern one in the same place	♏	2	3	0		2	3	2	B	3
		8	5			8	8	0		
Below the right knee	♏	2	3	0		3	3	1	B	5
		8	2			3	0	9		
On the right knee itself	♏	2	5	0		3	6	1	B	5
		8	1			6		5		
The upper one of the left hind-foot, posterior	♏	1	2	3		2	5	4	B	4
		5	1	0		9	1	5		
The one following, and more southern	♏	1	3	3		2	4	1	B	4
		6	0	0		8	5	6		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one preceding it, posterior	♌	2	5	0		3	1	1	B	4
		3	8			5	4	5		
The one following, on the right foot, posterior	♍	2	1	0		2	1	1	B	4
			5			6	4	8		
The one following, and more southern	♍	3	1	0		2	5	2	B	4
						4	4	0		
The informis between the tails of the Bear and of Leo	♍	1	8	3		4	6	2	B	2
		9		0		0		0		
On the back	♌	2	3	0		4	3	1	B	4
		9	5			1	0	5		
On the left hind-foot, posterior	♌	2	2	3		3	1	2	B	5
		2	7	0		3		0		
The informis between the Bear and the head of Leo	♌	7	4	0		1	5	1	B	3
			2			7	5	8		
The one above this, toward the rising	♌	9	3	0		2	4	2	B	4
			5			0	2	0		
The one preceding it	♌	6	2	1		2	5	1	B	4
			5	0		0		6		
The one preceding the two before these	♌	3	2	0		2	5	1	B	4
			2			0	1	8		
The one preceding them	♌	1	7	0		2	4	2	B	4
						3	1	0		
Between the foot and the head of Leo	♌	1	3	0		2	5	1	B	4
		5	7			1	3	9		
The northern one	♌	2	2	0		2	4	1	B	4
		0	0			5		7		
The southern one	♌	2	3	0		2	5	2	B	3
		1	2			4	0	0		
The one at the base of the right triangle	♌	2	4	0		2	2	1	B	3
		4	7			1	8	9		
(continuing)	♌	2	3	0		2	4	2	B	3
		7	4			0	4	0		
The northern one in the said	♌	2	4	0		2	5	1	B	4

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
base		6	4			4	8	5		
The one between the legs of the Bear	♏	1	4	0		4	3	1	B	5
		3	1			0	0	8		
The informis between the tail and the body	♏	2	5	0		5	8	1	B	6
		2	4			8		0		
The second	♏	2	3	0		4	1	6	B	6
		5	0			7	4			
The third	♏	2	1	0		4	3	1	B	6
		1	4			7	0	2		
The one between the Bear and the head of Leo	♏	2	4	0		4	5	1	B	6
		4	2			6	0	5

The ninth	♏	1	2	0		5	2	1	B	6
		7	7			2	5	4		
The little one touching the haunch	♏	3	6	0		3	4	1	B	6
						5	0	5		

DRACO — The Dragon

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one, following, in the head	♌	2	4	7		7	2	1	B	3
		3	6			5		0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one in the tongue	♍	2	1	3		7	1	0	B	4
		0	8	0		6	6			
The one in the mouth	♌	5	3	3		7	1	3	B	4
			6	0		8	4	0		
The one preceding, in the head	♌	7	4	3		7	2	0	B	3
			1	0		5	0			
The one at the cheek	♌	2	2	0		8	2	3	B	4
		0	5			0	0	0		
The first of three in the bend of the neck	♍	1	2	0		8	5	0	B	5
		8	6			1	2			
The southern one in the same place	♍	2	5	0		7	5	0	B	5
		5	3			7	6			
The middle one of them	♍	2	5	3		7	5	3	B	5
		1	5	0		9	0	0		
The one following, toward the rising	♍	1	5	0		8	5	0	B	4
		0	1			0	2			
Near the second bend	♍	2	5	0		8	5	0	B	4
		9	5			1	0			
The northern one of the square of the second bend	♍	1	4	3		8	4	0	B	3
		3	8	0		2	8			
The northern one of the following side	♍	1	4	0		7	8	3	B	4
		6	5			8		0		
The southern one of the same side	♍	2	9	0		7	2	0	B	3
		9				9	4			
The one following the right triangle, preceding	♍	1	4	0		8	4	0	B	4
		6	0			3				
The one following this,	♍	2	2	3		8	3	0	B	4

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
toward the south		1		0		0	7			
The one above this	Υ	2	6	0		8	5	0	B	4
		8				0	3			
In the rest of the triangle, following	ϙ	7	5	3		8	3	3	B	4
			6	0		3		0		
The southern one of the same	ϙ	2	5	0		8	2	3	B	4

CEPHEUS

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The girdle of Cepheus	♄	1	3	3		7	8	0	B	4
			6	0		1				

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the shoulder	Υ	8	3	3		6	5	0	B	4
			6	0		8	6			
On the left shoulder	Υ	2	1	0		6	3	2	B	3
			9	7		2	6	5		
The one following, in the tiara toward the north	Υ	9	5	3		6	4	3	B	4
			2	0		1		0		
The southern one	Υ	9	1	0		6	0	2	B	4
			9			0		0		
The one toward the rising	Υ	1	2	3		5	4	0	B	4
			5	0		8	7			
In the bend of the arm, more southern	Υ	1	4	3		7	5	2	B	4
			3	0		1	0	5		
In the same place, more northern	Υ	0	1	3		7	1	5	B	4
			7	0		4		0		
The one on the shoulders	Υ	2	9	2		6	4	2	B	5
			0	8		5	3	5		
On the right foot	♄	2	5	3		7	2	3	B	4
			8	6		5	8	0		
On the left foot	♄	2	4	3		6	2	2	B	3

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		5	6	0		4	9	5		

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The informis near the tiara	Υ	5	5	3		6	2	3	B	5
			3	0			4	0		

BOOTES, seu ARCTOPHYLAX — Boötes, or the Bear-keeper

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
Arcturus, in the fringe	♌	2	4	2		3	0	4	A	1
			0	7			1	0		
On the left shoulder	♌	1	3	2		4	5	3	B	3
			4	0			9	1	0	

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
In the left hand, preceding	♍	2	3	3		5	5	3	B	4
			5	4			8	1	0	
The second	♍	2	5	0		5	4	3	B	4
			6	8			8	9	0	
The third	♍	2	2	3		6	3	4	B	4
			8	4			0	0		
In the left forearm	♌	2	4	0		5	3	2	B	4
				3			4	8	9	
In the head	♌	2	8	3		5	1	0	B	3
			0	0			4	4		
On the right shoulder, above the Crown	♌	2	5	3		4	5	3	B	4
			8	4			8	9	0	
In the haunch below the right	♌	2	5	3		4	3	2	B	4

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
arm		3	4	0		0	8	8

CORONA BOREA — The Northern Crown

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the Crown	♍	8	1	2		4	2	2	B	2
			2	7		4	5	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one preceding the bright one	♏	5	1	0		4	8	0	B	4
						6				
The one above this	♏	4	3	3		4	2	0	B	5
			4	0		8	5			
The one following, toward the north	♏	9	2	0		5	2	0	B	6
			6			0	1			
The one following the bright one	♏	1	3	3		4	3	0	B	4
			0	8		4	3			
The one next following	♏	1	4	0		4	5	0	B	4
			2	9		4	2			
The one this one accompanies	♏	1	5	0		4	9	3	B	4
			4	6		6		0		
The last of all	♏	1	2	0		4	2	0	B	6
			4	6		8	4			

HERCULES, seu ENGONASI — Hercules, or the Kneeler

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The head of Hercules	♐	1	5	7		3	2	1	B	3
			1	8		7	2	5		
The right shoulder	♏	2	5	3		4	4	1	B	3
			6	4		2	7	5		
The left shoulder	♐	1	3	7		4	4	1	B	3
			0	7		7	6	5		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The next-to-last of the right arm	♏	2	2	1		4	5	0	B	3
			5	0		0				

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The lowest one in the right arm	♍	2	3	4		3	1	1	B	4
		1	2	0		7	8	5		
In the left arm	♌	1	4	9		4	2	1	B	4
		5	8			9	2	4		
The one preceding, in the spoils of the Lion	♌	2	2	1		5	1	0	B	4
		1		2		1	6			
The one following, in the triangle of the spoils	♌	2	4	1		5	1	2	B	4
		8	5	0		2	8	0		
At the base of the triangle, toward the north	♌	2	4	8		5	4	1	B	4
		8	5			3	5	6		
The middle one in the spoils	♌	2	4	1		5	4	2	B	4
		5		0		2	6	0		
In the left haunch	♍	2	2	1		5	1	0	B	3
		7	8	2		3	0			
The more eastern one in the left thigh	♌	4	1	4		5	2	1	B	3
			1	0		3	0	8		
The one preceding the three adjacent ones of the thigh	♌	7	4	4		5	3	1	B	4
			7	0		9	7	5		
The middle one of them	♌	8	4	1		6	1	0	B	4
			5	2		0	1			
The one following	♌	1	1	4		6	1	0	B	4
		1	3	0		0	3			
In the left knee	♌	2	2	1		6	4	1	B	3
		7	2	0		0	6	7		
The first of the three on the left calf, toward the head of the Dragon	♌	1	4	9		6	2	2	B	3
		5	3			9	1	0		
The one preceding the three on the left foot	♌	8	3	4		7	1	1	B	6
			1	0		1	9	7		
The middle one of them	♌	1	3	1		7	1	0	B	6
		2	3	0		1	3			
The last, nebulous	♌	1	2	8		7	4	1	B	ne
		9	6			1		8		b.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
In the upper right thigh	♏	2	3	4		6	2	0	B	4
		4	4	0		0	2			
The more northern one in the same	♏	1	1	3		6	1	2	B	4
		9	5	9		3	3	0		
In the right knee	♏	1	9	4		6	5	1	B	4
		0		0		5	4	5		
In the upper part of the calf	♏	7	2	1		6	5	1	B	4
			3	2		3	0	4		
In the calf	♏	4	9	1		6	2	1	B	4
				0		4	2	5		
The one preceding, in the right calf	♏	1	5	1		6	2	1	B	4
		7	8	7		2	8	7		
On the shin of the right foot	♏	3	5	3		6	1	0	B	4
			4	8		0	5			
The last on the right foot	♏	2	3	8		5	1	0	B	4
		8	2			7	5			

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
In the left haunch, preceding	♏	2	4	1		5	5	1	B	5
			6	0		5	4	5		
The one following in the same	♏	3	5	8		5	1	1	B	5
			6			8	4	6		
The informis of the right arm, southern	♏	2	1	1		5	2	1	B	5
		6	5	0		7	9	7		

LYRA, seu VULTUR VOLANS — The Lyre, or the Flying Vulture

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the Lyre [Vega]	♌	1	6	2		6	4	0	B	1
		1		7		1	7			

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
Above the bright one, toward the north	♊	1	3	3		6	2	3	B	5
		4	7	0		2	6	0		
Below the bright one, toward the south-east	♊	1	4	2		6	2	3	B	5
		3	9	8		0	5	1		
At the springing of the horns	♊	1	3	0		5	2	2	B	4
		7	4			9	5	9		
The northern of the two adjacent ones, toward the north	♊	2	5	0		6	4	3	B	5
		5	6			0	5	0		
The southern of the same two	♊	2	2	3		5	4	2	B	5
		6	5	0		9	0	8		
The northern one in the yoke, preceding	♊	1	4	0		5	4	3	B	3
		4	0			6		0		
The little one below this	♊	1	2	0		5	1	2	B	6
		4	7			5	5	9		
The northern one in the yoke of those following	♊	1	3	3		5	5	3	B	3
		7	4	0		5		0		
The little one below this	♊	1	4	2		5	3	0	B	6
		7	3	9		4	1			
Nearly in the middle of the body	♊	2	1	3		5	5	3	B	5
		2	5	0		8		0		

CYGNUS — The Swan

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The beak of the Swan	♊	2	5	3		4	3	0	B	3
		7		1		4				
The bright one of the breast, the ancient one	♊	2	4	4		5	1	2	B	3
		0	6	0		7	0	0		
The tail of the Swan	♊	1	1	1		5	5	2	B	2

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
			5	2		9	7	0		
The elbow of the upper wing	♊	1	1	4		6	2	5	B	3
			2	4		4	8	0		
The elbow of the lower wing	♊	2	3	1		4	2	0	B	3
			3	1		9	7			

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one in the head	♊	0	4	0		5	4	0	B	5
			6			0	3			
In the middle of the neck	♊	8	5	0		5	2	0	B	4
			9			4	0			
Of the three in the upper wing, the southern one	♊	1	4	0		6	4	0	B	4
			4	3		9	3			
The next-to-last of the upper wing	♊	1	1	3		7	3	0	B	4
			4	0		1	2			
The last of the upper wing	♊	1	5	3		7	5	3	B	4
			0	8		3	1	0		
In the middle of the lower wing	♊	2	4	0		5	4	3	B	4
			5	0		1	2	0		
The extreme one of the lower wing	♊	2	5	0		4	4	0	B	3
			9			3	5			
The one preceding, in the lower foot	♋	1	5	0		5	0	0	B	4
			4			5				
The one following, in the lower knee	♋	6	4	3		5	3	1	B	4
			3	0		6	7	0		
The adjacent one in the upper foot, preceding, and southern	♊	2	1	0		6	3	2	B	4
			4	2		3	8			
The upper one of them, boreal	♊	2	5	3		6	1	3	B	4
			5	6		4	8	0		
The lower of the informes, following the right wing	♋	4	2	3		5	3	0	B	4
			5	0		0	4			

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The upper one of the same	♄	6	1	3		5	3	0	B	4
			5	0		1	2			
Below the wing, toward the foot of Pegasus	♄	5	5	0		3	4	3	B	3
			5			8	0			
The one preceding the two toward the Lyre	♊	2	1	0		6	1	2	B	4
			1	9		6	6			
The one following, more northern	♊	2	1	3		6	5	0	B	4
			6	1		8	3			
The little one near the hollow of the wing	♊	1	5	0		6	4	2	B	4
			4	3		9	0			
Toward the lower wing	♊	1	3	0		5	1	0	B	6
			9	7		3	3			
Toward the upper wing	♊	1	4	0		6	4	0	B	6
			4	0		9	3			
* Nova in the breast of the Swan — it was in the Year 1600; with us in the Year 1659, in November	♊	1	1	0		5	3	0	B	3
			6	5		5	0			
(the same Nova, second reading)	♊	1	3	1		5	2	1	B	3
			6	1		5	4	0		
In the right knee, nebulous	♄	4	2	0		6	2	0	B	ne
			2			3	1			b.

CASSIOPEIA

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the Throne	♑	0	5	4		5	1	0	B	3
			5	7		1	7			
The Schedar of the breast [Schedar, α Cassiopeiae]	♑	3	3	2		4	3	5	B	3
			9	7		6	6	0		
The Flexure	♑	9	4	2		4	4	5	B	3
			9	7		8	7	0		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
In the knee	♊	1	4	5		4	2	5	B	3
		3	2	7		6	5	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one in the head	♊	0	5	0		4	4	0	B	4
			7			4	2			
In the girdle	♊	6	0	0		4	6	3	B	4
						7		0		
In the leg	♊	2	3	3		4	3	2	B	3
		0	5	0		7	0	9		
The extreme one of the foot	♊	2	1	0		4	5	3	B	4
		8				8	5	1		
In the left arm	♊	7	3	3		4	8	0	B	4
			6	0		3				
In the left elbow	♊	6	3	0		4	2	3	B	5
			8			3	9	0		
In the right elbow	♊	2	1	0		4	2	0	B	6
		6				9	6			
At the springing of the seat	♊	8	2	0		5	1	0	B	4
			8			1	6			
The extreme one of the Throne	♊	2	5	0		5	9	2	B	6
		6	6			1		8		
At the extremity of the seat	♊	2	5	0		5	4	3	B	5
		6	4			2	0	0		
In nearly a straight line with the 11th and 17th	♊	2	5	0		5	4	2	B	6
		0	0			2	9	9		
The extreme one of the footstool	♊	2	4	0		5	1	3	B	6
		3	3			6	4	0		
The middle one of the footstool, or, from Longomontanus	♊	2	4	0		5	2	3	B	6
		3	5			4	8	1		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
(the same, from Longomontanus)	Υ	2	5	0		5	2	3	B	6
		3	4			4	8	1		
In the footstool, toward the sole of the foot	ϣ	2	2	0		5	1	0	B	6
		3	0			2	0			
The one that follows the knee	ϣ	2	1	3		4	5	0	B	6
		4	9	0		4	9			
The one that precedes the knee	ϣ	1	2	0		4	6	0	B	6
		1	2			5				
The whorl of the navel	ϣ	8	1	0		4	3	0	B	6
		4				7	3			
The little one near the locks	ϣ	0	3	0		4	3	3	B	6
		2				5	9	0		
The one following, boreal, in the rod	ϣ	0	5	0		4	1	2	B	6
		4				1	6	8		
The one preceding them	Υ	2	1	0		4	2	0	B	6
		9	9			1	7			
The next-to-last of the rod	Υ	2	1	0		3	1	0	B	6
		8	8			9	7			
The last of the rod	Υ	2	1	3		3	1	2	B	6
		8	6	0		8	0	9		
The preceding one of the three below the footstool, toward the north	Π	3	8	0		5	1	2	B	6
						3	7	8		
The northern one	Π	7	3	0		5	3	2	B	6
		4				3	3	9		
The southern one of them	Π	1	3	0		5	5	3	B	6
		3				2		0		
Above these, toward the Pole	Π	8	7	0		5	9	2	B	6
						9		8		
The first between Auriga and Cassiopeia	Π	1	3	0		3	5	3	B	6
		8	9			5	1	0		
The second	Π	2	4	0		3	4	2	B	6
		8	1			5	9	8		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The third	♄	3	5	0		3	5	3	B	6
			5			4	0	0		
The fourth	♄	4	2	0		3	2	2	B	6
			2			0	3	8		
The first of the three toward the north	♄	2	7	0		4	1	3	B	6
						4	1	0		
The second	♄	2	1	0		4	3	2	B	6
			9			5	3	8		
The third	♄	2	3	0		4	3	2	B	6
			7	7		5	3	9		
Those more toward the north, and the first toward the Bear	♄	1	3	0		5	4	3	B	6
			2			4	4	0		
The second	♄	2	7	0		5	1	2	B	6
			9			6	6	8		
The third	♄	5	3	0		5	5	3	B	6
			5			6	6	0		
The fourth	♄	1	2	0		5	1	2	B	6
			0			9	9	8		
The fifth	♄	9	1	0		6	4	3	B	6
			6			0	8	0		
The sixth	♄	1	3	0		6	5	2	B	6
			1	6		2		8		
The seventh	♄	1	5	0		6	4	3	B	6
			0	9		2	7	0		
The eighth	♄	2	2	0		6	1	2	B	6
			2	0		3	8	9		
New star, in the Year 1572 it was [SN 1572 / Tycho's star]	♄	6	5	0		5	4	0	B	6
			4			3	5			

PERSEUS

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright side of Perseus	♊	2	3	5		3	5	4	B	2
		7	9	5		0		0		
The common base, with the boreal horn of Taurus	♊	1	2	4		5	2	3	B	2
		8	2	7			0	0		
The head of Medusa	♊	2	5	5		2	2	4	B	3
		2		7		2	2	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The folded one at the extremity of the right hand	♊	1	5	0		3	1	1	B	6
		9	9			9		0		
In the right elbow	♊	2	3	0		3	2	1	B	4
		4	7			7	9	2		
In the right shoulder	♊	2	5	3		3	3	4	B	3
		5	4	0		4	0	0		
In the left shoulder	♊	2	3	3		3	3	8	B	4
		0	2	0		1	5			
In the crown of the head	♊	2	1	0		3	2	4	B	5
		3	8			4	6	0		
The one on the back	♊	2	1	0		3	3	0	B	5
		5				0	7			
Below the bright one of the side	♊	2	3	3		2	5	3	B	5
		8	2	0		7	9	8		
The little one following this	♊	2	4	3		2	5	4	B	5
		9	1	0		7	5	0		
In the bend of the side	♊	0	5	0		2	1	3	B	3
		3				7	4	9		
In the left elbow	♊	2	3	0		2	4	0	B	4
		3	4			6				
The one below the head of Medusa	♊	2	5	0		2	5	3	B	4
		1	9			0	4	8		
The one preceding this	♊	2	4	0		2	3	4	B	4

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		0	6			0	3	0		
The one preceding, toward the north, in the head of Medusa	♊	1	4	0		2	3	4	B	4
		9	8			1	5	0		
In the right knee	♊	7	4	3		2	2	1	B	5
			1	0		8	3	0		
The one that precedes the right knee	♊	5	3	3		2	5	4	B	4
			9	0		8	0	0		
The one preceding the knee	♊	5	3	0		2	1	3	B	5
			3			6	1	8		
In the right knee	♊	6	4	0		2	3	4	B	6
			2			6	9	0		
Below the right knee	♊	7	2	0		2	3	3	B	6
			8			4	5	9		
In the sole of the right foot	♊	9	2	0		1	5	4	B	5
			9			8	6	0		
In the left thigh	♊	2	3	0		2	6	3	B	4
			9			2		8		
In the left knee	♊	1	3	0		1	4	3	B	3

			3			3	7	0		
(the same, from the other Catalogue of Kepler)	II	7	4	0		5	3	4	B	6
			3			3	7	0		

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The informis, from the left knee toward the rising	II	3	3	0		1	5	4	B	5
			8			7	0	0		

Catalogue of the Fixed Stars for the Year 1700

(TAB. 98, continued. Each page carries two side-by-side table panels; reading order is the left panel top-to-bottom, then the right panel top-to-bottom. The columns are: **Names of the Fixed Stars** [Nomina Fixarum] | **Longitude** [Longitudo: Sign · Degrees · Minutes · Seconds] | **Latitude** [Latitudo: Degrees · Minutes · Seconds] | **Magnitude** [Magnitudo]. The latitude column heading on each panel reads **B.** for boreal/northern latitude or **A.** for austral/southern latitude.)

AURIGA, HENIOCHUS ERICHTONIUS — The Charioteer

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
Capella, or the She-Goat	II	1	4	2		2	5	4	B	1

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
[Hircus]		7	0			2	1	5		
The bright one of the right shoulder	II	2	1	2		2	2	4	B	2
		7	2			1	5	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The preceding and upper one of the head	II	2	2	0		3	1	1	B	6
		5				2	6	5		
The following, and lower one	II	2	3	0		3	5	1	B	4
		5	8			0	1	4		
On the right arm	II	2	5	0		1	4	1	B	4
		5	2			3	5	6		
From another catalogue, the Longomontanian	II	2	2	0		1	4	1	B	4
		5	2			3	5	6		
On the left elbow	II	1	3	0		2	5	1	B	4
		4	5			0	3	5		
The preceding of the Kids [Haedi]	II	1	2	3		1	1	0	B	4
		4	9	0		8	0			
The following of the Kids	II	1	1	3		1	1	0	B	4
		5	3	0		8	3			
On the upper foot	II	1	2	3		1	2	1	B	4
		2	8	0		0	3	5		
Above, near the bright one of the right shoulder	II	2	4	3		2	2	1	B	5
		5	9	0		7	8	3		
On the more northern loins	II	1	1	3		1	3	0	B	6
		8	6	0		8	6			
On the more southern loins	II	1	3	0		1	0	1	B	5
		7	0			7		5		
Below this, toward the west	II	1	2	0		1	2	0	B	5
		6	2			5	3			
The following one	II	1	3	0		1	5	1	B	6
		8	3			4		5		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
At the buttocks	II	1	2	0		1	4	1	B	5
		3	4			5		4		
The preceding of the two on the right arm	II	2	3	3		1	4	0	B	5
		3	6	0		5	4			
The following of them	II	2	4	0		1	4	1	B	5
		3	8			5	4	3		
<i>From the other catalogue of Kepler</i>	II	2	8	0		1	4	1	B	5
		4				5	4	3		
Below this, on the right shin	II	2	5	0		1	5	1	B	6
		3	9			3	0	5		
On the left lower-leg	II	1	1	3		1	1	1	B	5
		8	3	0		1	6	4		
On the right foot	II	1	5	0		8	5	1	B	5
		9	8				2	6		
The preceding, near Erichthonius	II	1	2	3		1	5	1	B	5
		1	8	0		4	2	3		
The southern following one	II	1	5	0		1	3	1	B	5
		1	5			4		5		
The boreal informis between the Charioteer and the feet of Gemini	II	2	1	0		6	5	1	B	4
		9	6					4		
The second one	II	2	2	0		4	7	1	B	4
		4	8					5		
Below it, toward the rising	II	2	2	0		2	2	1	B	4
		5	8				7	3		
The preceding of these	II	2	2	3		2	2	1	B	4
		1	0	0			9	5		
The last of them all	II	2	2	0		1	7	1	B	4
		3	4					6		

[The following rows complete the lower classes of the Ophiuchus/Serpentarius region drawn from Kepler's Nova Stella; they continue at the head of the right panel.]

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The following of three	♏	2	2	0		2	9	1	B	4
		7	5			6		8		
The preceding, on the right foot	♏	1	2	0		2	1	2	B	3
		5	8				5	0		
The following one	♏	1	9	0		1	3	1	B	4
		7					1	9		
The third	♏	1	5	0		0	1	2	B	4
		7	0				9	0		
Another following one	♏	1	3	0		0	2	1	B	5
		8	9				8	9		
The one that touches the heel	♏	1	5	0		0	5	2	B	5
		9					7	0		
On the right shin	♏	1	1	0		7	9	1	B	5
		8	7					8		
The informis outside the shin	♏	2	1	0		4	1	2	B	6
		3	2				9	0		
The following of two in the hand	♏	1	3	0		2	3	1	B	5
			4				3	8		
On the hip of Ophiuchus	♏	1	2	0		1	1	1	B	5
		6	7			0	7	9		
The southern following one	♏	2	2	0		8	4	2	B	4
		0	9					0		
On the right hand	♏	2	3	0		1	3	1	B	5
		1	1			0	9	8		
The boreal one	♏	2	3	0		1	5	2	B	5
		0	2			5		0		

The remaining of the 2. Class, from Kepler's account of the New Star in Serpentarius:

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
Of three, the one ahead of the foot, in a straight line, preceding, boreal	♑	2	9	0		9	2	2	B	5
		7				6	0			
The middle one	♑	2	1	0		6	4	1	B	5
		6	4			1	9			
The lowest one	♑	2	3	0		3	4	2	B	5
		5	2			4	0			
Preceding the anterior knee	♊	2	3	0		1	3	1	B	6
		0				3	3	9		
The upper of two between the feet	♊	8	1	0		1	4	2	B	6
		8				1	9	0		
The lower one	♊	7	1	0		4	3	1	B	6
		6				7	9			
On the anterior boreal shin	♊	4	1	0		5	4	2	B	4
		4				1	0			
The middle of them	♊	3	3	0		3	1	1	B	4
		4				0	9			
The southernmost of them	♊	3	1	0		1	3	2	B	4
		2				7	0			
On the heel of the anterior foot	♊	5	3	0		0	2	1	B	4
		1				5	8			
On the following thigh	♊	1	6	0		1	2	2	B	5
		7				7	7	0		
On the following elbow	♊	2	2	0		1	5	1	B	4
		0	9			4	6	9		
On the lower-leg of the following foot	♊	1	9	0		1	5	2	B	4
		7				6	1			
On the toe of the foot	♊	1	3	0		3	3	4	A	4
		5	4			7	0			
On the back of the foot	♊	1	1	0		1	2	4	A	5
		6	4			7	0			
The bright one in the sole	♊	1	1	0		1	4	3	A	3
		7	4			3	9			

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
In the hollow of the foot	♊	1	1	0		0	5	4	A	4
		8	4				9	0		
At the heel, or ankle	♊	1	3	0		0	5	3	A	4
		9	2				7	9		
The one following this foot	♊	2	3	0		1	2	2	B	4
		1	1				1	0		
The informis between the shoulder of Ophiuchus and of Hercules	♍	2	5	0		3	5	1	B	4
		7	4			4	9	9		
At the shoulder of Ophiuchus, in the boreal Rhombus	♊	2	3	0		2	5	2	B	4
		6	4			7	9	0		
The preceding of the middle ones	♊	2	2	0		2	3	1	B	4
		6	4			6	9	8		
The following one	♊	2	1	0		2	2	2	B	4
		8	7			6	7	0		
The lowest one	♊	2	7	0		2	4	1	B	4
		7				4	4	9		
Above the informes, solitary	♊	2	1	0		3	4	2	B	4
		9	7			2	4	0		
<i>The New Star in Serpentarius, which appeared in the year 1604</i>	♊	1	4	0		1	5	0	B	★
		7	0				6			

OPHIUCHUS, or SERPENTARIUS — The Serpent-Bearer

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The Head of Ophiuchus	♊	8	1	7		3	5	1	B	3
			7				5	6	5	
The more boreal of the left hand	♍	2	1	3		1	1	2	B	3
		8	1	7		7	8	0		
On the right knee	♊	1	5	7		7	1	2	B	3
		3	1				7	0		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
On the left knee	♌	5	6	7		1	2	2	B	3
						1	9	0		
On the right shoulder	♌	2	1	7		2	0	2	B	3
		1	2			8		0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The following on the right shoulder	♌	2	3	0		2	1	2	B	3
		2	2			6	0	0		
The preceding on the left shoulder	♌	6	2	3		3	3	0	B	4
		6	0			2	5			
The following on the left shoulder	♌	7	4	0		3	5	2	B	4
		3				1	5	0		
On the left elbow	♌	1	3	0		2	3	0	B	4
		0				3	9			
On the more austral left hand	♍	2	2	0		1	3	0	B	3
		9	4			6	0			
On the right forearm	♌	2	0	0		1	1	1	B	4
		1				5	8	9		
<i>In the other catalogue of Kepler</i>	♌	2	3	0		1	1	1	B	4
		0	0			5	8	9		
The austral preceding one in the right hand	♌	2	4	3		1	4	1	B	4
		5	0	0		3	6	8		
The more boreal following one, in the same place	♌	2	4	3		1	1	2	B	5
		6	1	0		5	9	0		
On the right knee	♌	1	5	0		7	1	2	B	3
		3	1			7	1			
<i>But, by Kepler's correction</i>	♌	1	4	3		7	1	2	B	3
		3	7	0		7	1			
On the left knee	♌	5	6	0		1	2	2	B	3
						1	9	0		
On the right lower-leg	♌	1	5	0		2	1	2	B	3

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		5	0			1	1			
The fifth informis, in the Milky Way	♏	2	5	0		3	2	0	B	4
		7	8			3				
Above the bright one of the Serpent's neck	♏	1	1	0		2	3	0	B	4
		8	5			6	6			
Behind the hips of Ophiuchus	♏	1	1	0		1	2	1	B	4
		6	6			0	0	9		
The more austral of the following ones	♏	2	2	0		8	3	1	B	3
		0	4					8		
The more boreal of them	♏	2	1	0		1	3	2	B	4
		1	5			0	4	0		
The one above this	♏	2	1	0		1	1	1	B	4
		0	2			5	7	9		
Between the left hand and the knee	♏	2	2	0		1	1	2	B	5
			4			3	8	0		
The informis near the boreal shoulder	♏	2	5	0		2	5	2	B	4
		5	7			7	4	1		
The middle of them	♏	2	5	0		2	2	1	B	4
		6				6	2	8		
The austral of three	♏	2	1	0		2	4	2	B	4
		6	0			4	9	0		

SERPENS OPHIUCHI — The Serpent of Ophiuchus

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the Serpent's neck	♏	1	5	4		2	3	5	B	2
		7	0	7		5	3	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
In the mouth	♏	1	4	3		3	5	2	B	3

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		5	5	0		9		0		
The preceding, in the mouth	♏	1	5	0		3	1	0	B	5
		2	6			8	1			
At the temples	♏	1	2	3		3	2	0	B	3
		8	7	0		5	4			
At the drawing-out of the neck	♏	1	4	3		3	2	2	B	3
		5	2	0		4	6	0		
At the left eye	♏	1	3	0		3	2	2	B	4
		6	1			7	7	5		
At the nostrils	♏	1	5	0		4	3	0	B	4
		7	3			2	6			
The second on the neck, below the head	♏	1	7	3		2	5	0	B	3
		4		0		8	7			
The more austral of three behind the bright one	♏	2	7	3		2	4	2	B	3
		0		0		4		0		
At the second bend	♏	2	4	3		1	2	1	B	4
		1	7	0		6	5	8		
Before the next-to-last of the tail	♏	2	5	3		1	5	0	B	3
		5	5	0		9	6			
<i>From the other catalogue</i>	♏	2	5	3		1	3	0	B	3
		5	5	0		9	6			
The next-to-last of the tail	♏	1	3	3		2	3	2	B	3
			3	0		0	6	0		
The last one	♏	1	3	0		2	5	0	B	3
		1	1			6	8			

The remaining, from Kepler on the New Star:

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one above the double, and the eighth according to Ptolemy	♏	1	5	0		2	3	0	B	4
		7	4			6	5			
On the crest	♏	1	3	0		3	1	0	B	5

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		9	0			7	4			
At the apex of the coil, an Isosceles	♈	1	2	0		1	2	0	B	4
		6	1			0	4			
The base, preceding, the 14th of Ptolemy	♈	2	4	0		8	3	0	B	4
		0	4							
The following, the 15th according to Ptolemy	♈	2	3	0		1	2	0	B	4
		1	0			0	2			

SERPENS OPHIUCHI — continued

(The left panel of this page resumes the Serpent of Ophiuchus, completing the 2nd class.)

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
Above the tail, the upper of two	♏	1	1	0		2	3	0	B	6
			0			6	7			
The lower one	♏	3	0	0		2	2	0	B	6
						3	4			
Below the tail	♏	4	2	0		1	4	0	B	4
			1			5	8			
The lowest of three at the end of the tail	♏	3	2	0		2	2	0	B	6
			1			1	8			
The middle one	♏	5	2	0		2	4	0	B	6
			7			2	1			
The last one	♏	8	2	0		2	5	0	B	6
			1			4	1			
Next below the last one	♏	1	4	0		2	1	0	B	6
		1	3			5				

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one following the hand of Ophiuchus	♏	1	6	0		1	5	0	B	5
						5	9			

SAGITTA, or TELUM — The Arrow

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The upper, and eastern one	♊	2	5	1		2	1	1	B	4
			5	0		9	2	0		
The one preceding it	♊	2	1	1		3	5	4	B	5
		9	8	2		8	7	0		
The small one above this	♊	2	5	0		3	3	1	B	6
		9	4			9	0	0		
The upper, adjoining at the Notch [Glyphis]	♊	2	5	4		3	5	1	B	4
		6	3	0		8	2	3		
The lower of them	♊	2	2	1		3	1	1	B	4
		7		3		8	7	0		
The informis above the Arrow, the lower one	♊	1	3	1		4	4	1	B	4
			6	0		1	2	2		
The upper of the informes	♊	2	5	1		4	1	1	B	4
			9	2		4		0		
The third, in the right-angle of the informes	♊	2	2	1		4	2	1	B	4
		5	0	0		6		3		

AQUILA, or VULTUR VOLANS — The Eagle, or Flying Vulture

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one on the shoulder-blades [Altair]	♊	2	3	1		2	2	4	B	2
		7	2	7		9	0	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one in the Head	♊	1	5	4		2	7	4	B	6
			1	0		7		0		
On the neck	♊	2	1	1		2	4	4	B	3

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		8	6	0		6	8	0		
The small one above the Bright one	♊	2	5	1		3	5	4	B	6
		6	6	2		0	3	0		
On the left shoulder	♊	2	4	1		3	1	1	B	3
		6	9	3		1	7	0		
The following small one	♊	2	3	4		3	5	1	B	5
		7	1	2		1	8	2		
The upper, and preceding of the lower wing	♊	2	3	4		2	4	4	B	4
		2	9	3		8	5	0		
The lower, and following, in the wing	♊	2	3	1		2	3	1	B	5
		3	7	4		6	4	0		
The tail of the Vulture	♊	1	3	4		3	1	4	B	3
		5	8	2		6	5	0		
The informis nearest the tail	♊	1	7	1		3	3	1	B	3
		4		0		7	9	0		
The middle of the informes above the tail	♊	1	3	1		4	3	4	B	4
		0	5	2		3	1	0		
The one following this	♊	1	4	4		4	4	1	B	4
		0	0	2		1		0		

ANTINOUS

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
On the left hand	♊	0	4	4		1	4	0	B	3
			4	0		8	7			
On the right side	♊	2	4	4		2	1	0	B	3
		1	0	1		0	4			
On the knee	♊	2	4	1		1	2	0	B	3
		0	0	2		4	7			
On the right arm	♊	1	2	1		2	5	0	B	3
		9	4	3		4	5			
On the chest	♊	2	1	1		2	3	0	B	3

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		6	3	2		1	7			
On the right foot	♊	1	9	1		1	4	0	B	3
		3		5		7	0			
The informis preceding this	♊	1	5	1		1	5	0	B	4
		1	2	2		6	6			

DELPHINUS — The Dolphin

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the tail	♊	9	5	1		2	7	0	B	3
			5	2		9				
The one following the tail	♊	1	1	1		2	5	3	B	6
		1	1	3		8	1	0		
The one below the tail	♊	1	5	1		2	3	0	B	6
		1		2		7	3			
In the Rhomboid, the more austral of the preceding side	♊	1	1	1		3	5	3	B	3
		2	9	0		1	6	0		
The more boreal of the same side	♊	1	1	4		3	4	0	B	3
		3	3	0		3				
The more austral of the following side	♊	1	5	4		3	5	0	B	3
		4	9	2		1	9			
The one on the Head	♊	1	1	1		3	4	0	B	3
		5	5	2		2	6			
Four in the preceding side, the closely adjoining preceding one	♊	1	4	1		3	7	3	B	5
		1	0	0		2		0		
The lowest of the two preceding ones, in the Rhomboid	♊	1	4	1		3	4	3	B	6
		0	1	2		0	0	0		
The following of the same	♊	1	5	1		3	4	0	B	6
		2		3		0	0			

EQUULEUS, or EQUI SECTIO — The Foal, or Section of the Horse

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The preceding of the Head	♊	1	5	4		2	1	2	B	4
		8	5	0		0	1	0		
The following of the Head	♊	2	1	4		2	5	0	B	4
		1	7	2		1				
The preceding of the mouth	♊	1	1	1		2	1	0	B	4
		9	7	2		5	5			
The following of the mouth	♊	2	1	4		2	5	0	B	4
		0	7	0		4	1			

PEGASUS EQUUS ALATUS — Pegasus, the Winged Horse

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The mouth of Pegasus	♊	2	4	7		2	6	2	B	3
		7	5			2		0		
Scheat, on the leg	♋	2	1	7		3	8	2	B	2
		5	4			1		0		
The first of the wing, <i>Markab</i>	♋	1	1	3		1	2	5	B	2
		9	9	7		9	4	0		
The extremity of the wing, <i>Algenib</i>	♋	5	0	7		1	3	2	B	2
						2	7			
The navel of Pegasus — see the head of Andromeda	♋									

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The Head of Pegasus	♋	2	3	3		2	6	2	B	4
			8	0		2		0		
Toward the south, on the	♋	1	8	3		1	4	0	B	5

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
head				0		5	2			
The lower following one in the mane	✕	1	2	0		1	2	2	B	6

		0				6	0			

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The first following one	✠	1	3	0		2	1	0	B	4
		6	8			3	5			
<i>From the other catalogue of Kepler, perhaps</i>	⌘	2	3	0		2	1	0	B	4
		6	8			3	5			

ANDROMEDA

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The Head of Andromeda	♈	1	9	3		2	4	1	B	2
		0				5	2	0		
The more austral one of the Girdle	♈	2	1	0		2	5	3	B	2
		6	1			5	8	0		
The bright one in the austral foot	♉	1	1	4		2	4	1	B	2
		0		4		7	7	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The lowest of the right shoulder-blade	♈	1	2	3		2	6	4	B	5
		8	8	0		7		0		
The lower of the left shoulder	♈	1	4	0		2	3	3	B	4
		6	7			3		9		
Of three on the right arm, the austral one	♈	1	2	0		3	3	1	B	5
		6	0			1	3	5		
The boreal of them	♈	1	7	3		3	2	4	B	4
		7		0		3	0	0		
The middle of them	♈	1	2	0		3	1	3	B	5
		7	9			2	4	8		
The more austral, on the upper hand	♈	1	5	0		4	5	3	B	5
		1	0			0	6	9		
The more boreal in the same place	♈	1	8	0		4	4	3	B	4
		3				1	4	0		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The obscure one in the same place	Υ	1	4	0		4	8	2	B	5
		5	5			2		5		
The highest in the boreal hand	Υ	1	9	0		4	4	4	B	4
		4				3	9	2		
The preceding on the left arm	Υ	1	3	0		1	4	2	B	4
		6	1			7	8	0		
On the left elbow	Υ	1	1	3		1	5	2	B	5
		8	5	0		5	8	5		
The middle one in the girdle	Υ	2	2	5		3	3	0	B	4
		9	7	0		0	4			
The boreal one in the girdle	Υ	2	5	2		3	3	1	B	4
		4	7	0		2	1	0		
The extremity of the upper foot	ϝ	1	2	3		3	5	0	B	5
		0	8	0		6	0			
The brighter in the right foot	ϝ	8	1	0		3	2	0	B	4
		4				5	2			
The highest in the left lower-leg	ϝ	6	2	0		2	5	3	B	5
		8				8	9	0		
The lower one in the same place	ϝ	4	4	0		2	5	0	B	5
		5				7	5			
At the right knee	ϝ	2	1	0		2	2	2	B	5
		8				6	0	5		
At the extreme link of the chain	⋈	2	2	0		5	1	3	B	4
		5	2			7	9	0		
The brighter in the left shoulder-blade	Υ	1	4	3		2	2	3	B	3
		7	1	0		4	0	0		

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The boreal of the two in the chain	ϝ	5	2	0		3	4	3	B	5
			2			4	0	0		
The austral one in the same	ϝ	6	5	0		3	4	2	B	5

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
place		2				2	0	5		
The informis preceding, the	Υ	4	2	0		4	0	3	B	3
three on the right hand		2				4		0		

TRIANGULUS DELTOTON — The Triangle

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
At the apex of the Triangle	Ϡ	2	4	0		1	4	5	B	4
		1				6	9	0		
At the base, toward the north	Ϡ	8	1	3		2	3	2	B	4
		1	0			0	3	0		
The middle one	Ϡ	9	2	0		1	2	2	B	5
		1				9	9	5		
The more austral at the base	Ϡ	9	2	0		1	5	2	B	4
		0				8	7	4		

COMA BERENICES — The Hair of Berenice

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
At the point of the first, and boreal Triangle	♍	1	4	0		2	2	2	B	3
		9	1			8	4	0		
<i>Or otherwise, from Kepler</i>	♍	2	3	0		2	3	2	B	3
		9	9			8	0	0		
The upper one of this, toward the south	♍	2	6	0		2	2	0	B	4
		0				7	2			
The lower one in the same place	♍	2	1	0		2	1	1	B	4
		0	0			7	8	2		
The following of two adjoining ones	♍	2	4	0		2	5	1	B	4
		0	3			7		5		
Preceding the two adjoining	♍	1	4	0		2	4	1	B	4

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
ones, toward the south		9	9			5	9	3		
Another adjoining one, toward the rising	♏	2	1	3		2	5	2	B	4
		0	2	0		6		0		
All preceding, toward the south	♏	1	2	0		2	2	2	B	4
		9	4			3	8	5		
The highest of three adjoining following ones	♏	2	3	0		2	1	2	B	4
		2	4			5	4	2		
The other, and preceding one	♏	2	1	0		2	5	2	B	4
		2	5			4	4	0		
The lowest, and following one	♏	2	1	0		2	5	5	B	4
		4	6			3	8	0		
<i>The other Codex of Kepler</i>	♏	2	1	0		2	5	5	B	4
		3	6			3	8	0		
The last one, in the extension of the Hair	♏	0	2	3		3	4	2	B	4
			2	0		2	4	0		
The one that precedes this	♏	2	1	3		3	4	2	B	4
		9	3	0		1	0	3		
Between these, and the first at the point	♏	2	4	0		3	1	2	B	4
		5	1			0	4	2		
At the austral point of the small Triangle	♏	2	3	0		2	3	2	B	5
		9	9			8	0	0		

PARS TERTIA — Astra Australia

(Part Three — The Southern Stars. From here the latitude column on each panel is headed **Latit. A.** — austral/southern latitude.)

CETE — Cetus, the Whale

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The bright one of the jaw	♏	1	7	3		1	3	5	A	2
		0		2		2	6	0		
The bright one of the boreal	♏	1	4	1		2	1	2	A	3

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
belly		7	8	5		0	7	0		
The boreal of the tail	✕	2	4	4		9	5	1	A	3
		6	6	7			8	0		
The austral of the tail	✕	2	1	4		2	4	4	A	2
		8	9	7		0	3	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The one in the snout	♊	1	5	0		7	4	5	A	4
		0	2				9	0		
The middle of the mouth	♊	5	1	3		1	2	2	A	3
			4	0		2		0		
Preceding three at the jaw	♊	3	2	0		1	3	4	A	3
			3			4	1	9		
Below the eye	♊	3	1	0		5	5	5	A	4
			5				1	0		
Above the eye	♊	7	2	0		5	3	4	A	4
			2				5	8		
On the back of the head	♊	2	5	3		4	1	5	A	4
		9	0	0			8	1		
On the chest, in a [square □] toward the north	♊	2	3	0		2	1	3	A	4
		5	1			5	6	0		
The lower of two, preceding, toward the south	♊	2	5	3		2	3	2	A	4
		5	4	0		8	9	9		
The following, on the austral chest	♊	2	3	2		2	1	0	A	4
		9	3	9		8	6			
The preceding, and boreal one	♊	2	9	3		2	5	2	A	3
		9		1		5	7	9		
The middle one in the belly	♊	1	4	0		2	0	3	A	4
		3	7			5		0		
The lowest one in the belly	♊	1	1	0		3	3	2	A	4
		5	2			1		8		

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
On the eastern back	Υ	1	4	3		1	4	0	A	3
		2		0		5	6			
On the western back	Υ	7	3	3		1	5	2	A	3
			3	0		6	4	9		
The informis following the jaw	ϣ	1	7	0		1	2	5	A	5
		4				4	9	0		
Preceding the boreal of the belly	Υ	1	2	4		2	5	0	A	5
		6	7	5		1	3			
In a straight line with the 3rd and 5th of the Head	ϣ	8	1	3		9	1	2	A	4
			0	0			2	0		

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
Of the tail [square □], the following one on the boreal side	Υ	4	8	3		1	8	0	A	5
				0		2				
The austral one of them	Υ	3	8	2		1	8	0	A	5
				5		4				
The one preceding the boreal side	Υ	1	5	0		1	2	3	A	5
			3			3	9	0		
The austral one of the same	Υ	1	2	0		1	3	3	A	5
			2			4	9	0		

ORION

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The highest of the Head	Π	1	3	3		1	2	4	A	4
		9	5	0		3	5	0		
The right shoulder, following	Π	2	3	3		1	6	1	A	2
		4	6	5		6		5		
The left shoulder, preceding	Π	1	4	4		1	5	3	A	2

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
		6	6	7		6	2	0		
The left foot, the bright one, Rigel	II	1	3	5		3	1	1	A	1
		2	6	7		1	0	0		

(The right panel of this page continues Orion from this point — the Belt [Baltheus], the Sword [Ensis], and the lower limbs.)

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The highest of the Belt	II	1	9	2		2	3	4	A	2
		8		7		3	6	0		
The middle one	II	1	1	4		2	3	1	A	2
		9	3	2		4	4	0		
The lowest one	II	2	2	2		2	2	1	A	2
		0	3			5	1	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat .	°	'	"	B/ A	Ma g.
The more western of the Head	II	1	3	3		1	5	4	A	5
		9	5	0		3	3	0		
The third of the Head, eastern	II	1	5	3		1	4	2	A	5
		9	7	0		4		0		
The following one of the left shoulder	II	1	1	0		1	2	4	A	5

The preceding of them	II	2	3	0		2	1	0	A	4
			9			5	1			

Catalogue of the Fixed Stars for the Year 1700

(TAB. 98, continued — *Pars Tertia*, the southern constellations [*Astra Australia*]. Each page carries two side-by-side table panels; reading order is the left panel top-to-bottom, then the right panel top-to-bottom. The columns are: **Names of the Fixed Stars** [*Nomina Fixarum*] | **Longitude** [*Longitudo*: Sign · Degrees · Minutes · Seconds] | **Latitude** [*Latitudo*, here **A.** for austral/southern latitude: Degrees · Minutes · Seconds] | **Magnitude** [*Magnitudo*]. Throughout this stretch the latitude is austral, so the B/A column reads **A.** in every row.)

Page 119 — left panel

(Continuing *ERIDANUS*, the River — the 2nd certitude class, begun on the preceding page.)

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The following one of four, after the gap	♊	1	4	0	33	1	0	A	3
		9	2			3			
The one that precedes this	♊	1	6	3	31	8	4	A	4
		6		0			0		
The third to the north,	♊	1	3	0	28	4	1	A	3

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
preceding		6	1			6	0		
Preceding all four	♍	1	9	0	27	4	5	A	3
		4				6	0		
The first of those next to Cetus	♍	4	3	0	24	3	5	A	3
		4				3	0		
Between this one and the third	♍	7	0	0	23	5	2	A	4
						8	0		
The third, which follows	♍	9	4	0	25	5	5	A	3
		0				8	0		
The preceding, lower one	♍	2	1	0	30	2	4	A	5
		5	3			4	9		
Above this one	♍	2	1	0	27	3	5	A	4
		5	7			1	0		
The following one	♍	2	2	0	28	9	2	A	4
		6	2				0		
The upper eastern one	♍	2	1	0	25	2	4	A	5
		9	0				3		
The preceding of the two between the River and Taurus	♍	1	4	3	18	2	5	A	4
		7	9	0		6	0		
The following, southern one	♍	2	3	0	22	4	5	A	4
		1	1			4	0		

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B / A	Mag.
The last of three	♍	2	4	0	25	5	0	A	4
		8	4			0			
The middle one, Ptolemy's 8th	♍	2	0	0	26	5	0	A	4
		8				0			
Out of the four, the one that precedes	♍	2	5	0	23	1	0	A	4
		4				0			

Name of the fixed star	Long. Sign	° ' "	Lat. °	' "	B / A	Mag.
At the bend of the River, toward the breast of Cetus	♈	2 3 0 7 4	32	1 0 0	A	4
The following one	♈	2 1 0 8 4	34	5 0 0	A	4
The first of the three following	♏	1 1 0 4	38	3 0 0	A	4
The middle one	♏	6 1 0 4	38	0 0	A	4
The last one	♏	9 5 0 4	38	5 0 0	A	4
In the □ [quadrilateral], the preceding of the boreal side	♏	1 4 0 3 4	41	1 0 0	A	4
In the same, the austral one	♏	1 5 0 3 4	42	2 0 0	A	5
The preceding of the following side	♏	1 3 0 4 4	43	0 0	A	4
The last of these four	♏	1 4 0 7	43	1 0 0	A	4
Toward the rising, the boreal of the two conjoined ones	♈	2 3 0 6 4	50	2 0 0	A	4
More toward the south	♈	2 2 0 7 4	51	4 0 0	A	4
At the turn of the two posterior ones	♏	2 3 0 0 4	53	4 0 0	A	4
The preceding one	♏	1 1 0 8 4	53	0 0	A	4
In the last interval, out of three, the hindmost	♏	1 1 0 0 4	52	5 0 0	A	4

Name of the fixed star	Long. Sign	° ' "	Lat. ° ' "	B / A	Mag.
The middle one	♊	7 1 0 4	53 2 0 0	A	4
The first of three	♊	4 1 0 4	51 5 0 0	A	4
At the end of the River	♊	2 3 0 2 4	53 3 0 0	A	1
Scaliger wrote to Tycho [Brahe] that this one is placed by the sailors in Pisces, which Bayer [Johann Bayer] depicts	♊ [X]	9 4 0 5	59 3 0 0	A	— [no magnitude given]

LEPVS — The Hare

1. Class.

Name of the fixed star	Long. Sign	° ' "	Lat. ° ' "	B / A	Mag.
On the left shoulder, or the thigh	♊	1 2 7 5 9	43 5 5 5 0	A	3

2. Class.

Name of the fixed star	Long. Sign	° ' "	Lat. ° ' "	B / A	Mag.
The upper one of the preceding ear	♊	1 3 3 1 7 0	34 3 2 2 0	A	5
The lower one of the same ear	♊	1 4 3 1 3 0	35 5 2 2 2	A	5
The upper one of the following ear	♊	1 5 0 3 0	35 1 2 6 5	A	6
The lower one of the following ear	♊	1 3 0 3 7	36 1 2 2 4	A	5
The one on the head	♊	1 1 0	39 2 2	A	5

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
		1	2				1		
At the tip of the front feet	♐	7	4	3	44	5	2	A	4
			8	0			8	3	
On the back, in the middle of the body	♐	1	1	3	41	4	0	A	3
			7	2					
The more austral of the two on the hind feet	♐	2	4	3	45	4	0	A	3
			0	4			8		
The more boreal of the same	♐	2	5	0	44	1	2	A	3
			2	9			6	0	
The preceding one on the back	♐	2	4	3	38	1	2	A	4
			1	9			4	2	
The following one on the back	♐	2	5	3	37	3	0	A	4
			4	0			9		
The last one on the tail	♐	2	4	0	38	2	2	A	4
			7	5			4	0	

CANIS MAIOR — The Greater Dog

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The most brilliant, in the mouth: Sirius	♄	2	4	4	39	3	5	A	1
			0	7			2		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
On the forehead, toward the right ear	♄	1	2	5	34	5	0	A	4
			0	9			2		
In the middle of the forehead	♄	1	5	2	36	4	0	A	5
			2	5			5		
Under the left ear	♄	1	3	2	38	4	2	A	3
			5	4			0		
On the neck	♄	1	3	2	39	3	0	A	4

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
		3	1	0		2			
On the right shoulder of the front feet	♌	8	0	5	42	1	0	A	5
				0		5			

Page 119 — right panel

(CANIS MAIOR continued — the body of the Greater Dog.)

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
At the tip of the front paw	♌	3	1	5	41	2	2	A	2
			0	0		0	0		
On the back	♌	1	5	5	46	1	2	A	5
		6	8	0		1	0		
In the middle of the breast	♌	1	4	5	46	4	2	A	5
		4		0		1	0		
On the belly	♌	1	2	2	48	3	5	A	3
		9	3	0		1	0		
Between the hind thighs	♌	1	4	5	51	2	2	A	3
		6	9	0		6	0		
The lower one on the right front foot	♌	2	3	2	51	4	2	A	3
			5	0		8	0		
The one on the tail	♌	2	3	5	51	2	2	A	3
		5	9	0		6	0		

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The other one on the breast	♌	1	5	1	42	2	0	A	5
		2	8	9		2			
On the southern knee	♌	8	2	2	42	1	—	A	5
			8	0		2			
On the left knee, preceding of the two	♌	1	2	1	46	1	—	A	5
		6	8	8		2			
The following one of these	♌	8	3	2	45	3	—	A	5

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
			8	0		2			
On the hock of the right leg	♄	1	2	1	54	5	—	A	4
			5	8	9	2			

(Stars not belonging to a figure [informes], around the Dog:)

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
To the north, toward the crown of the Dog	♄	1	5	2	25	2	—	A	4
			1	8	0				
Under the feet, after four, in a straight line, austral	♄	2	2	1	61	1	—	A	4
			8	8		2			
The one more toward the north	♄	3	4	2	58	3	—	A	4
			8	0		2			
Still more boreal	♄	5	2	1	56	4	—	A	4
			8	9		2			
The remaining, the most boreal, of four	♄	6	3	2	55	4	—	A	4
			8	0		2			
The third, toward the west, in a straight line, preceding	♄ [II]	1	2	1	55	1	—	A	4
			9	8	8	2			
The middle one of these	♄	2	5	2	57	2	—	A	4
			2	8	0	2			
The last of three	♄	2	5	1	59	3	—	A	6
			4	8	9	2			
Following these	♄	2	2	1	59	2	—	A	2
			1	8	8	2			
The preceding of these	♄	1	2	2	57	2	—	A	2
			8	8	0	2			
The rest, more austral	♄	1	3	1	59	3	—	A	4
			4	8	9	2			

CANIS MINOR — The Lesser Dog

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
Procyon, on the thigh	♄	2	4	2	15	5	1	A	2
		1	0	7		7	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
On the neck, or the collar	♄	1	1	5	13	3	4	A	3
		8		0		3	0		
Above the bright one of the neck	♄	2	4	5	12	5	1	A	6
		1	0	0		1	0		
An informis [unfigured star] above this	♄	1	4	5	9	4	1	A	6
		8	4	0		6	0		
The following one, toward the tail of Cancer	♄	2	1	5	10	1	4	A	5
		2	9	0		9	0		

ARGO NAVIS — The Ship Argo

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
At the very top of the stern	♏	7	1	0	43	1	3	A	3
			8			8	0		
The topmost of the shield	♏	2	0	0	44	5	3	A	3
						8	0		
The preceding one of the shield	♄	2	2	3	47	2	3	A	3
		9	4	0		8			
On the sail	♏	5	3	0	32	7	—	A	4
			1						
An informis, toward the south	♏	5	5	3	38	3	0	A	4
			1	0		1			
The lower of three on the mast	♏	1	5	5	32	5	0	A	6
		3	0	0		6			
Above this	♏	1	1	4	30	1	0	A	4
		4	5	9		8			

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
Higher than this very one	♏	1	2	5	24	2	3	A	4
		1	5	0		9	0		
The preceding of two on the yardarm	♏	0	5	2	21	3	3	A	4
			0	8		9	0		
The following of these	♏	5	4	5	22	2	3	A	3
			4	7		9	0		
An informis between the sail and the Milky Way [lacteam]	♏	2	8	2	30	3	0	A	3
		5		7		0			

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The preceding of the two ends	♏	3	2	2	42	1	—	A	5
			4	7		0			
The one more toward the south	♏	1	4	2	45	4	—	A	4
			4	8		0			
Preceding these two	♏	2	2	2	45	1	—	A	4
		8	4	8		0			
The preceding of three under the shield	♏	2	2	3	49	1	—	A	4
		8	4	0		0			
The following one	♏	2	2	2	49	3	—	A	4
			4	7		0			
The middle of three	♏	1	3	3	49	0	—	A	4
			4	0					
At the end of the rudder-bar [temo]	♏	7	4	2	49	3	—	A	4
				7		0			
On the keel of the stern, the boreal of two	♏	2	4	2	52	4	—	A	4
		3		8		0			
The austral of them	♏	2	4	2	58	2	—	A	3
		7		9		0			
On the seat of the stern, boreal	♏	3	1	2	55	2	—	A	5
			4	7		0			
In the same place, the	♏	5	1	2	58	3	—	A	5

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
preceding of three			4	8		0			
The middle one	♌	6	1	2	57	0	—	A	4
			4	9					
The following one	♌	9	2	3	57	3	—	A	4
			4	0		0			
The bright following one, beyond [transtra, the rowers' benches]	♌	1	4	2	58	3	—	A	2
			4	8		0			
The obscure one preceding under this	♌	1	4	2	59	5	—	A	5
			1	7		0			
The following one	♌	1	5	2	59	1	—	A	5
			5	4		0			
The one above the Bright one, preceding	♌	1	5	3	56	3	—	A	5
			5	4		0			
The following one	♌	1	4	2	57	3	—	A	5
			7	8		0			

Page 120 — left panel

(*ARGO NAVIS continued — 3rd class.*)

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
At the station of the boreal mast, of three	♌	2	1	2	51	3	0	A	4
			8	4		0			
The middle one	♌	2	4	3	55	3	—	A	4
			8	4		0			
The austral of three	♌	2	3	2	57	0	—	A	4
			6	4					
Under these, the boreal of the joined ones	♍	1	4	2	59	5	—	A	4
			4	7		0			
The more austral of these	♍	1	3	2	61	0	—	A	4
			4	8					
In the middle of the mast, the austral	♌	2	3	2	51	3	—	A	4
			2	4		0			

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The more boreal of these	♌	2	4	2	49	0	—	A	3
		1	4	8					
At the top of the sail	♌	2	2	2	43	1	—	A	4
		0	4	7		0			
<i>Another reading</i> [Alia lectio]	♌	2	2	2	53	1	—	A	4
		0	4	7		0			
The following one	♌	2	2	2	43	3	—	A	2
		1	4	8		0			
Under the third, the following one of the shield	♌	1	3	3	51	3	—	A	2
		7	4	0		0			
<i>Otherwise</i> [Aliter]	♌	1	3	3	54	3	—	A	2
		6	4	0		0			
At the section of the deck [instrati]	♌	9	5	2	51	1	—	A	2
			4	9		5			
Among the oars in the keel [Carina]	♌	1	4	2	63	0	—	A	4
		4		8					
The following obscure one	♌	1	2	2	64	3	—	A	6
		1	4	7		0			
The bright following one at the station	♌	2	2	2	63	5	—	A	2
		2	4	8		0			
Shining below the keel	♍	0	5	2	69	4	—	A	2
			4	7		0			
The preceding of three following this	♍	7	3	2	65	4	—	A	4
			4	8		0			
The middle of these	♍	1	4	2	65	5	—	A	3
		3	4	8		0			
The following one	♍	1	2	3	67	2	—	A	2
		8	4	0		0			
<i>From another reading</i> [Ex alia lectione]	♍	1	2	3	65	5	—	A	2
		8	4	0		0			
The preceding of the two following, toward the deck- section	♍	2	2	3	62	5	—	A	3
		3	4	0		0			

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The following of these	♈	0	2	2	62	1	—	A	3
			4	7		5			
<i>From another reading</i>	♈	0	2	2	65	1	—	A	3
			4	7		5			
On the rudder-bar, the boreal one, preceding	♊	2	2	3	65	5	—	A	4
		6	4	0		0			
<i>From another reading</i>	♊	2	2	3	65	5	—	A	4
		4	4	0		0			
The one that follows	♋	1	3	2	65	4	—	A	3
		2	4	8		0			
<i>From another reading</i>	♋	1	3	2	65	4	—	A	3
		8	4	8		0			
On the rudder-bar: Canopus	♋	9	2	2	75	0	—	A	1
		4	7						
<i>From another reading</i>	♋	9	2	2	69	0	—	A	1
		4	7						
The rest following this	♋	2	2	3	71	4	—	A	3
		1	4	0		5			
<i>From another reading</i>	♋	2	2	3	61	4	—	A	3
		1	4	0		5			

HYDRA, seu HYDRVS — The Water-Serpent (Hydra)

1. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The Heart of Hydra [Cor Hydrae]	♋	2	6	3	22	2	5	A	1
		3		7		3	0		

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The preceding one on the head	♋	7	1	3	14	3	5	A	4
			1	0		6	0		

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
Above the first, toward the north	♌	8	8	0	14	1 6	2 0	A	4
The more boreal one on the back of the head	♌	8	1 0	0	11	8	0	A	4
The third preceding, toward the south	♌	8	4 4	3 0	11	3 6	0	A	5
The most eastern of the head	♌	1	2 0	3 0	11	1	0	A	4
The preceding one on the neck	♌	1	1 3	3 0	11	5	2 0	A	6
The following one at the drawing-out of the neck	♌	1	3 6	3 0	13	5	0	A	5
The middle of the neck	♌	2	3 1	3 0	15	0	0	A	4
The boreal of three at the bend of the neck	♌	2	2 3	0 6	14	1 7	2 0	A	4
The austral one at the joint [nexu]	♌	2	1 1	3 5	16	4 6	0	A	5
The one that next follows the Heart	♌	2	3 8	3 0	26	3 3	3 0	A	4
Following close upon this	♍	1	3 0	0	26	1 2	0	A	5
The preceding of the adjacent ones	♍	4	1 0	0	23	1 3	0	A	5
The following of these	♍	5	1 5	0	21	5 1	0	A	4
The fifth from the Heart	♍	1	5 0	3 0	24	3 8	0	A	4
In a straight line with this and the next	♍	1	3 4	3 0	23	3 1	0	A	5
The one preceding, next to the Crater [Cup]	♍	1	1 6	0 3	21	4 8	3 0	A	4
An informis, nearest to the	♌	6	7	3	12	2	0	A	4

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
head				0		7			
The boreal one under the base of the Crater	♏	2	2	3	25	3	0	A	4
		4	3	0		6			
The austral one under the same base	♏	2	1	0	30	1	0	A	4
		5	1			7			
Under the tail of the Crow [Corvus]	♏	2	4	0	13	4	0	A	3
		2	6			3			
A little one preceding this	♏	2	4	0	14	3	0	A	6
		0	6			7			
An informis before the head of Hydra	♏	0	6	0	10	1	0	A	3
						9			

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The boreal of two on the eye	♏	5	4	0	13	4	0	A	4
			4			0			
The austral of them, in the gap [hiatu]	♏	8	2	0	14	1	0	A	4
			2			5			
From the south, the boreal of the two adjacent ones	♏	2	2	0	19	4	0	A	6
		2				5			
The preceding one in the triangle [triquetro]	♏	5	2	0	31	2	0	A	4
						0			
The middle of them	♏	7	2	0	33	1	0	A	4
			2			0			
The following of them	♏	9	2	0	31	2	0	A	4
						0			
At the very end of the tail	♏	7	2	0	17	4	0	A	4
			2			0			

Page 120 — right panel

(Two stars completing the preceding section — at the head of Hydra; then CRATER.)

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
On the head, toward the south	♌	5	2	0	23	1	0	A	3
			2			5			
<i>Otherwise</i> [Aliter]					13	5	0	A	3
Following the neck	♍	3	5	0	16	0	0	A	3
			2						
<i>Otherwise</i> [Aliter]					26	0	0	A	3

CRATER — The Cup

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
At the base of the Crater	♍	1	3	0	22	4	0	A	4
		9	3			1			
The following of two in the middle	♍	2	5	0	19	3	0	A	4
		5				9			
The preceding of them	♍	2	3	3	17	2	0	A	4
		2	2	0		5			
The preceding of two above the Crater	♍	2	4	2	13	1	0	A	4
		1	9	4		0			
The following of them	♍	2	2	0	11	1	0	A	4
		4	4			7			
The preceding of two lower ones	♍	2	5	0	18	1	0	A	4
		9	2			0			
The following of them	♌	1	5	0	16	2	0	A	4
		5							
In the middle of the Crater	♍	2	1	0	14	9	0	A	5
		6	7						

CORVVS — The Crow

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The one toward the eye	♌	7	3	0	19	3	0	A	4
			0			9			
The preceding of the two upper ones in the □ [quadrilateral]	♌	6	3	0	14	2	0	A	3
			5			5			
The following of them	♌	9	1	0	12	7	0	A	3
			7						
The following of the lower ones in the □	♌	1	1	0	17	5	0	A	3
			3	1		9			
On the beak	♌	8	0	0	21	4	0	A	4
						6			
On the neck	♌	9	3	0	18	1	0	A	5
			6			4			
On the left wing, above the bright one	♌	9	4	3	11	2	0	A	5
			3	0		8			

CENTAVRVS CHIRON — The Centaur (Chiron)

2. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
At the head, the most austral	♐	2	4	0	21	4	0	A	5
			9			9			
The one more toward the north	♐	2	2	0	19	8	0	A	5
			1						
The preceding of the two intermediate ones	♐	1	3	0	20	5	0	A	5
			4			1			
The following of four	♐	2	2	0	20	1	0	A	5
			5			2			

3. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
On the left shoulder,	♑	2	3	0	25	4	0	A	3

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
preceding		8	2			0			
On the right shoulder	♏	8	2	0	22	4	0	A	3
						0			
On the left fore-shoulder [armo]	♏	1	3	0	27	4	0	A	4
			2			0			
On the shield, the preceding boreal one	♏	1	3	0	22	3	0	A	4
		0	2			0			
The austral one of them	♏	1	3	0	23	5	0	A	4
		1	2			0			
At the top of the shield	♏	1	2	0	18	3	0	A	4
		4	2			0			
On the shield, toward the south	♏	1	5	0	21	1	0	A	4
		4	2			0			
On the right side, the preceding of three	♏	5	4	0	28	3	0	A	4
			2			0			
The middle one	♏	6	2	0	29	3	0	A	4
			2			0			
The following one	♏	7	3	0	28	1	0	A	4
			2			0			
On the right arm	♏	8	5	0	26	4	0	A	4
			2			0			
On the right elbow	♏	1	1	0	25	3	0	A	3
		5	2			0			
At the end of the right hand	♏	1	5	0	24	2	0	A	4
		9	2			0			
The bright one at the drawing-out of the human body	♏	1	2	0	33	4	0	A	3
		0	2			0			
The following of two boreal ones	♏	1	2	0	31	1	0	A	5
		0				0			
The preceding one	♏	9	1	0	33	1	0	A	5
			2			0			
At the drawing-out of the	♏	4	3	0	35	0	0	A	5

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
back			2						
Preceding this, on the back of the horse	♏	1	2	0	37	5	0	A	5
			2			5			
On the loins, the following of three	♏	2	1	0	40	1	0	A	3
		8	2			0			
The middle one	♏	2	2	0	43	1	0	A	4
		7	2			0			
The preceding of three	♏	2	2	0	44	1	0	A	5
		5				0			

[Otherwise (Aliter):]

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
On the right thigh, preceding	♏	2	2	0	46	2	0	A	3
		5				0			
The following one in the same place	♏	2	5	0	46	5	0	A	4
		5	2			0			
On the breast under the horse's wing	♏	1	4	0	42	5	0	A	4
		0	2			0			
Under the belly, the preceding of two	♏	8	4	0	43	1	0	A	2
		2				0			
The following of them	♏	1	2	0	44	0	0	A	3
		0							
On the hock of the right foot	♏	2	2	0	51	2	0	A	2
		2				0			
On the heel of the same	♏	7	4	0	51	5	0	A	2
		2				0			
On the hollow of the left foot	♏	2	4	0	55	1	0	A	4
		8	2			5			
Under the muscle of the same	♏	3	3	0	55	3	0	A	2
		2				0

			2	8		5			

PAVO — The Peacock

4. Class.

Name of the fixed star	Long. Sign	°	'	"	Lat. °	'	"	B/ A	Ma g.
The bright one on the head	♐	1	9	0	36	0	0	A	2
			8						
On the upper neck	♐	1	2	0	40	4	0	A	6
			8	3		0			

(The catalogue continues onto the following page — PAVO and the remaining southern figures are not yet complete; there is no FINIS or colophon on this page.)

Catalogue of the Fixed Stars for the Year 1700 (TAB. 98, continued — Pars Tertia: southern constellations, conclusion)

The catalogue continues with the remaining southern (austral) constellations. Each table gives the star's name, its ecliptic longitude (Sign, degrees, minutes), its southern ecliptic latitude (degrees, minutes), and its magnitude. The certitude class (4. *Classis*) is printed beneath each constellation rubric. *neb.* marks a nebulous object.

Pavo (the Peacock), continued

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
The middle one there [Media ibi]	♎	19	38	41	20	6
The lower one in the same place [Inferior ibidem]	♎	17	23	41	45	6
In the breast [In pectore]	♎	21	53	48	30	3
At the root of the right wing [In radice alae dextrae]	♎	16	38	46	32	3
A small one adjacent to it [Parua huic adiacens]	♎	15	13	47	0	neb.
In the middle of the wing, or the back [In media ala, seu dorso]	♎	11	48	45	20	3
A nebulous one adjacent [Nebulosa adiacens]	♎	9	53	46	5	neb.
At the start of the tail, the first [In educatione caudae prima]	♎	3	18	45	40	5
The second [Secunda]	♎	1	45	44	0	5
The third [Tertia]	♎	1	51	43	0	5
The fourth [Quarta]	♎	2	8	39	35	5
The fifth [Quinta]	♏	29	38	41	30	5
The sixth [Sexta]	♏	29	3	40	30	5

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
The seventh [Septima]	♄	28	13	39	20	5
The eighth [Octaua]	♄	24	53	41	20	5
The ninth and last [Nona, & vltima]	♄	19	58	42	20	4
In the right foot, austral [In dextro pede australis]	♄	9	33	50	0	4
In the same, boreal [In eodem borealis]	♄	12	28	49	20	6
In the left foot [In sinistro pede]	♄	19	23	50	25	6
At the end of the tail [In extrema cauda]	♄	2	28	48	27	6
In the same [In eadem]	♄	28	15	51	40	5

Apus, or Avis Indica (the Bird of Paradise) — 4th class

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
Unformed, or in the head [Informis, aut in capite]	♄	18	33	44	40	5
In the neck [In collo]	♄	18	13	48	6	5
At the start of the boreal tail [In educatione caudae boreal.]	♄	17	35	54	20	5
The middle one there [Ibidem media]	♄	13	15	55	0	5
The austral one there [Ibidem austrina]	♄	16	10	55	45	5
In the tail, toward the triangle of the two upper ones [In cauda versus △ duarū superior]	♄	8	48	51	30	6
The lower one there	♄	8	3	52	0	6

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
[Ibidem inferior]						
In the middle of the tail, the 3rd more boreal [In media cauda 3. borealior]	♄	10	11	57	10	5
The middle one [Media]	♄	9	0	57	57	6
The more austral one [Australior]	♄	9	38	59	20	4
In the same, toward Chamaeleon [In eadem versus Chamaeleonem]	♄	13	40	61	25	4

Apis, or Musca (the Fly) — 4th class

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
In the head [In Capite]	♄	16	58	54	0	4
In the right wing [In ala dextra]	♄	16	53	56	25	4
In the left wing [In ala sinistra]	♄	23	13	56	5	4
In the tail [In cauda]	♄	20	57	57	30	4

Chamaeleon — 4th class

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
In the forefeet [In prioribus pedibus]	♄	1	27	62	40	5
At the neck [Ad collum]	♄	26	8	63	20	5
On the back [In dorso]	♄	24	53	67	0	5
In the hind feet [In posterioribus pedibus]	♄	1	21	67	25	5
At the start of the tail, more eastward [In educatione caudae]	♄	0	28	70	38	5

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
orientalior]						
The more western one [Occidentalior]	♄	2	58	75	35	5
In the middle of the tail, the upper [In media cauda superior]	♄	28	8	73	0	5
The lower [Inferior]	♄	26	13	73	15	5
At the end of the tail, the upper [In extrema cauda superior]	♄	23	30	74	26	5
The lower [Inferior]	♄	24	28	75	12	5

Triangulum Australe (the Southern Triangle) — 4th class

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
The following one at the base, toward the neck of Apus [Sequens basis versus collū Apodis]	♄	14	20	46	20	3
The upper one at the cusp, toward Lupus [Superior in cuspide versus Lupum]	♄	5	30	41	0	3
A small one adjacent to it [Parua huic adiacens]	♄	8	40	44	40	5
The base, preceding, toward the tail of Apus [Basis praecedēs versus caudam Apodis]	♄	4	20	48	30	3
A small one above this [Parua supra hanc]	♄	5	0	44	15	3

Piscis Volans, or Passer (the Flying Fish) — 4th class

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
In the head [In Capite]	♌	19	53	72	26	5
In the middle of the body [In medio corpore]	♌	24	29	77	12	6
In the tail [In cauda]	♍	7	12	82	5	5
In the left wing, upper [In ala sinistra superior]	♌	13	34	75	20	6
The lower one there [Ibi inferior]	♌	20	7	82	14	6
In the right wing, upper [In ala dextra superior]	♍	6	13	76	21	6
The lower one there [Ibi inferior]	♍	11	53	79	28	6

Dorado, or Xiphias (the Swordfish) — 4th class

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
In the head [In Capite]	♌	26	45	86	53	4
In the gills [In branchijs]	♍	1	23	87	0	5
In the belly [In ventre]	♏	0	53	88	12	5
Above the back [Supra dorsum]	♏	25	3	84	46	4
At the very end of the tail [In extrema cauda]	♏	10	38	76	15	4
The center of the larger cloud [Nubeculae maioris centrum]	♍	1	3	84	0	neb.
Adjacent to it [Huic adiacens]	♎	18	3	82	31	5

Toucan, that is, Anser Americanus (the American Goose) — 4th class

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
At the tip of the beak [In rostrum extremo]	≈	5	18	45	55	3
In the head [In capite]	≈	16	15	48	15	3
At the bend of the left wing [In ancone alae sinistrae]	≈	15	23	54	15	4
The lower one there [Ibi inferior]	≈	14	18	55	45	5
In the middle of the wing [In media ala]	≈	16	9	58	20	3
On the back [In dorso]	≈	22	23	57	50	3
In the tail [In cauda]	≈	22	48	61	30	4
On the frond of a branch, or the nutmeg [In rami folio, seu nuce myristica]	≈	2	33	49	55	4

Hydrus (the Lesser Water-Snake)

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
In the head [In Capite]	✕	5	23	64	5	3
In the upper neck [In collo superior]	✕	11	53	71	40	4
The lower of the three of the neck [Colli trium inferior]	✕	13	18	70	25	4
In the first turn of the neck [Conuersionis colli prima]	✕	1	18	71	12	4
The second [Secunda]	≈	18	18	70	30	5
The third [Tertia]	≈	26	3	67	50	5
The fourth [Quarta]	≈	21	33	64	0	5

Star name	Si gn	Long. °	Long. '	Lat. (S) °	Lat. '	Magnit ude
The fifth [Quinta]	♊	7	4	65	0	5
The sixth [Sexta]	♊	26	29	64	55	4
The seventh [Septima]	♊	19	15	60	0	5
In the first turn of the tail, austral [In caudae cōuers. 1. Austral.]	♊	15	38	58	10	5
Boreal [Boreal.]	♊	13	48	56	0	5
In the 2nd, the antepenultimate of the tail's bend [In 2. caudae flexu antepenult.]	♊	13	13	62	40	5
The penultimate [Penultima]	♊	8	53	64	30	5
The last [Vltima]	♊	5	38	64	0	5
The center of the smaller cloud [Nubeculae minoris centrum]	♊	6	3	67	0	neb.
Between this and the larger, unformed [Inter hanc, & maiorem informis]	♊	8	48	72	20	6
The austral one [Austrina]	♊	5	48	78	30	4
Which is above the 8th and 9th of Hydrus [Quae supra 8. & 9. Hydri]	♊	4	40	61	20	5
Below the upper neck [Infra collum superior]	♋	17	10	75	30	4
The lower one there [Ibi inferior]	♋	1	19	80	0	6

Summary tally of the catalogue

There are, then, 12 zodiacal constellations, 23 boreal, and 27 austral — 62 in all.

Group	Magnitude	Count
Among the zodiacal stars there are stars of the first magnitude	first	6
	second	9
Among the boreal stars there are stars of the first magnitude	first	3
	second	22
Among the austral stars there are stars of the first magnitude	first	5
	second	28
Therefore all the stars of the first magnitude are	first	14
The second, however	second	59

TABLE 99. The Right Ascension and Declination of One Hundred Fixed Stars, for the completed Year of Christ 1700

Columns: star name; **Right Ascension** for the year 1700 (degrees, minutes, seconds); **Declination** for the year 1700 (degrees, minutes, seconds), with B = boreal/northern and A = austral/southern; **Difference of Ascension over 100 years** (degrees, minutes); **Difference of Declination over 100 years** (minutes), with the trailing A/S marking whether the declination is increasing toward the north (A = *augescens/borealis*) or south (S).

Star name	R A °	R A '	R A "	Dec l. °	Decl '	Decl ."	B / Diff. A Asc. °	Diff. Asc. '	Diff. Decl. '	A / S

Its right ascension is decreasing. [Huius Ascensio Recta decrescit.]

TABULA 100. Motion of the Fixed Stars in Longitude — to be added to, or subtracted from, the Longitude for the Year 1700 of Christ, so that their positions may be had before or after.

[TABULA 100. The Motion of the Fixed Stars in Longitude, to be added to the Longitude for the Year 1700 of Christ, or subtracted, so that their positions may be had after or before.]

The table is in two stacked blocks. The left block runs from year 1 to year 60 and gives the accumulated motion as three sexagesimal sub-columns (I, II, III — i.e. minutes, seconds, thirds — the whole-degree column being 0 throughout this range). The right block continues from year 61 to year 100, then by decadal/larger steps (200, 300, ... 7000, 8000, 9000, 10000, 20000, 25579), and adds a degrees column (Gr.) ahead of the three sub-columns. The right block's argument column is here labelled Anni and the value columns Gr. I II III.

[Footer of table: *Anni 61* — i.e. the second block of the table begins at year 61.]

TAB. 101. Foreign and Mostly Arabic Names of the Stars, with Their Interpretation.

[TAB. 101. Containing the names of the stars, foreign and for the most part Arabic, together with their interpretation. In which, reader, do not be surprised if you see different names assigned to the same star — this is on account of the diversity of the dialects, or perhaps of corrupted manuscripts.]

The following is an alphabetical glossary of star-names (chiefly of Arabic, but also Hebrew, Greek, Chaldaean, Egyptian, and "Nubian" origin) with their Latin identifications. Each headword is given in *italic* in the source; the identification follows. Abbreviations: *arab.* = Arabic, *Hebr.* = Hebrew, *Chald.* = Chaldaean, *Gr.* / *Græc.* = Greek, *Græcolat.* = Greek-Latin, *Ptolem.* = Ptolemy's, *Nubianis* = of the Nubians (i.e. the Nubian astrologers).

A

- **Abrachaleus** — Castor, or his head.
- **Acharnar, Acharnaar, or Acharnarim** — arab., the bright star at the end of Eridanus.
- **Achluschemali** — arab., the Northern Crown [Corona Borealis].
- **Adared** — arab., Mercury.
- **Aderaimin, or Alderamin** — arab., the star above the right shoulder of Cepheus.
- **Adigege, or Adegige** — arab., Cygnus, as it were "smelling like a rose."
- **Adhil** — the star at the bottom of Andromeda's robe.
- **Adrendefa** — arab., Virgo.
- **Aegipan, Aegoceros** — Greek-Latin, Capricorn.
- **Afeichius** — Serpentarius [Ophiuchus], or corruptly from the Greek-Latin *Ophiuchus*?
- **Akrab** — Hebrew; **Aakrab** arab., **Acrobo** Chaldaean — Scorpius.
- **Alacrab, or rather Aakrab** arab., or **Hacrab** — Scorpius.

- **Alamak**, or **Almaak** arab. (not **Alhames**) — the star at the southern foot of Andromeda.
- **Alascha** — the one preceding [the two] in the sting of Scorpius.
- **Alasid**, or **Alezet**, or **Asid**, or **Ellesed** — arab., Leo.
- **Alazet**, in Azophi [al-Şūfi] — the tail of Leo.
- **Alazel**, or **Alaazel**, or **Hazimet Alazel**, and **Hermeti Alhaiseth** — Spica Virginis [Spica].
- **Alathod**, or **Alhaiot** — Capella.
- **Albegala** — Lyra.
- **Albezze**, or **Albizze** — Centaurus.
- **Albireo** — arab., the one in the beak of Cygnus.
- **Alcantarus** — arab., Capricorn.
- **Alcor** — arab., the "Horseman," the little star above the second star of the tail of Ursa Major.
- **Aldebaran** — the southern eye of Taurus, that is, the dominant star [of the Hyades].
- **Alderamin**, or **Aderaimin** — arab., the one above the left shoulder of Cepheus.
- **Algebar**, or **Algebra** — arab., Orion; see *Elgeuze*.
- **Algedi** — arab., Capricorn.
- **Algenib** — arab., the bright star at the end of Pegasus's wing, or in the side of Perseus.
- **Algethi**, or **Algiethi** — arab., Hercules.
- **Algeuze**, or rather **Elgiautze** — arab., the head of Castor.
- **Algol** — arab., the Head of Medusa, or Medusa herself.
- **Algomeiza** — arab., Procyon, Canis Minor.
- **Algorab** — arab., Corvus.

- **Alhabor** — arab., the splendid one in the mouth of Canis Major.
- **Alhague** — arab. (not **Alangue**) — Serpentarius [Ophiuchus].
- **Alhaiot** — arab., **Alhaiset Hermeti** — Spica Virginis.
- **Alhance** — arab., or **Alabance** — Sagitta.
- **Albes**, arab., or **Alkes**, the one at the base of Crater, in common with Hydra.
- **Aliath** — the first in the tail of Ursa Major.
- **Aliemini** — of the Alphonsine [tables], Canis Major.
- **Alkalurops** — the one on the Colorobus [club] of Boötes.
- **Alkameluz** — arab., Arcturus.
- **Almucedie** — arab., Vindemiatrix.
- **Almuredin** — arab., Vindemiatrix.
- **Almegrameth** — arab., the Censer [Thuribulum].
- **Alohore** — Lyra.
- **Aloue Cap.** — Medusa's.
- **Alphard** — arab., the Heart of Hydra [Cor Hydrae], at the bend.
- **Alpheichius** — arab., Serpentarius.
- **Alphas** — arab., Pegasus.
- **Alpheta**, or **Alphena** — among the Syro-Chaldaeans, the bright star of the Northern Crown, as it were "the open pupil [of the eye]."
- **Alramech**, or **Aramech** — arab., Arcturus.
- **Alruccabah** arab., or **Ruccabah** — the Pole Star [Polaris], at the very end of the tail of Ursa Minor.
- **Alsartan**, **Asartan**, or rather **Elsartan** — arab., Cancer.
- **Alzimon** — of the Nubians, Spica Virginis.
- **Amaza** — Greek-Latin, ἄμαξα — the Lesser Wain, Ursa Minor.

- **Angetenar**, or **Achenetenar** — these are 9 stars in the third bend of Eridanus.
- **Archelar** — Chald., the head of Castor.
- **Antares** — Ptolemy's "Heart of Scorpius" [Cor Scorpii], ἀντάρης in Hesychius.
- **Apullum** — corruptly for *Apollo*, that is Castor.
- **Arie** — Chaldaean, **Arieh** Hebrew — Leo.
- **Arieded** — the bright star in the tail of Cygnus.
- **Aris** — Chaldaean, Mars; and in Greek ἄρης.
- **Asange** — Lyra.
- **Asartan** — arab., Cancer.
- **Aschere**, or **Aschemie** — Canis Minor.
- **Asida** — arab., Lupus.
- **Asmeat** — arab., Centaurus.
- **Astacus** — Greek, Cancer.
- **Astaroth** — Chaldaean, Venus.
- **Asua** — Hydra.
- **Asugia** — Orion.
- **Ataxr**, or **Alcair** — the bright one in the head of Aquila, arab.
- **Atargatis** — Virgo.
- **Athaur** — arab., Taurus.
- **Athalpis** — Greek, ἀθαλπής [?] — Capricorn.
- **Athorae** — Ptolem. 1, Quadripl. ch. 9 — the Pleiades.
- **Athoriae**, or **Altorich**, in Hali Haben Ragel [ʿAlī ibn Abī al-Rijāl] — these are the Pleiades.
- **Atin**, or **Eltaur** — the eye of Taurus.

- **Auellar**, or **Auellan** — Pollux.
- **Azelphage** — arab., the two stars at the very end of the tail of Cygnus.
- **Azmech** — arab., Spica Virginis.
- **Azubene** — arab., the Claw [Chela] between [the signs of] Cancer and Scorpius; and from this it signifies Libra, hanging from this Claw.

B

- **Baculus Iacob** — Orion's belt [Orionis baltheus].
- **Basiliscus**, βασιλίσκος — Regulus, the Heart of Leo [Cor Leonis].
- **Baten Kaitos** — arab., the northern star in the belly of Cetus.
- **Beemin** — arab., these are 7 stars in the fourth bend of Eridanus.
- **Bellatrix** — the star in the right shoulder of Orion.
- **Benat Elnaasch** — arab., the daughters of the bier [filiae feretri]; the Pleiades.
- **Benenatu**, or rather **Benenasch** — arab., the last in the tail of Ursa Major.
- **Betelgeuze**, or **Bectelgeuze** — arab., the bright one in the left shoulder of Orion; and it signifies "the home of the Giant."
- **Bridemif** — Persian, Lupus.
- **Brinek** — Lyra, that is, Lyra's bright one [Lyra lucida].
- **Buthean** — in German, *Burrio*; in English, "the hen warming her chicks" — so they call the Pleiades, just as the Italians call them *la Gallinella*.

C

- **Callisto** — Ursa Major.
- **Cammarus** — Cancer.
- **Caucas** — Cepheus.
- **Canopus**, or **Canobus** — the bright star on the rudder of the Argo [Argonauta].
- **Carnabon** — Serpentarius.
- **Caseia**, or **Caia** — the first in the northern part of Hercules's club.
- **Caun** — Chaldaean, Saturn.
- **Ceginus** — Cepheus, and the one in the left shoulder of Boötes.
- **Cerna** — anything-whatever [quibusdam], Cassiopeia.
- **Chammah** — Hebraic, the Sun.
- **Cheichius**, or **Chegius** — to some, Cepheus; to others, Boötes.

- **Chelub**, or **Chelenb** — of the Alphonsine [tables], Perseus.
- **Chem**, or rather **Genib** — arab., the bright one in the side of Perseus.
- **Chesil** — Hebraic, Arcturus, or Orion; from the verb *Cacal*, which signifies "various" and "inconstant."
- **Chateb** — Hebraic, Mercury, that is, "Scribe" [Scriba].
- **Chima**, or **Kima** in Hebrew — the Pleiades, and the Hyades — indeed to others Arcturus, namely the "storm-bringing stars" [sidera procellosa].
- **Chrysomallus** — Greek, the Ram of the Golden Fleece [Aries velleris aurei].
- **Cixtoris** — 2.b., the lesser one in the tail of Ursa Minor.
- **Cochau** — Chaldaean, **Cochab** Hebraic, Mercury, that is, "the bright star" [stella fulgens].
- **Colorrhobus**, κολόρροβος — the hollow staff, or club of Boötes.
- **Currus volitans** — to Catullus the offspring of the Argo [Catullo Natus Argo].
- **Cynosura** — Ursa Minor.

D

- **Dagim** — Hebr., Pisces, or **Dagiotho**.
- **Dat Elkarsi** — arab., the Throne of Cassiopeia [Sedes Cassiopeae].
- **Daulo** — Chald., Aquarius.
- **Delli** — Hebr., *Situla* (the Bucket) for Aquarius.
- **Deneb**, or **Denneb** — arab., the Tail [Cauda].
- **Deneb Adigege** — the bright one in the tail of Cygnus.
- **Deneb Ellassid** — arab., or **Deneb Alasid** — the tail of Leo.
- **Deneb Algedi**, or **Elgeudi** — the one preceding in the tail of Capricorn.
- **Deneb Elaakrab** — arab., the tail of Scorpius.
- **Deneb Kaitos** — arab., the more southern one in the tail of Cetus.
- **Didymi**, δίδυμοι — Gemini.
- **Dioscouri**, δίοσκουροι — Gemini.
- **Dubhe**, or **Dubbeh** — arab., the bright one in the shoulder of Ursa Major.
- **Dubhe Elezguar** — arab., the bright one in the shoulder of Ursa Minor.
- **Dubherukabah** — Ursa Minor.

E

- **Edeleu** — arab., Aquarius.
- **Eladari** — arab., or **Eleadari** — Virgo.

- **Eleazelet** — fused by the Nubians as the Astrologers' [reading], or Spica Virginis, corruptly **Alzimon**.
- **Elezguar** — Cynosura, Ursa Minor.
- **Elaeguatri** — Cygnus, as it were "the rose of a cock-comb" [galli rosa].
- **Elgebar** — arab., Orion, the Giant [Gigas].
- **Elgeudi** — arab., Capricorn.
- **Elgenib** — fulgent [shining] in the side of Perseus, arab.
- **Elgeuze** — arab., Gemini.
- **Elgeziale** — arab., Hercules.
- **Elhakeae** — arab., the Heads of the Twins [Capita Geminorum].
- **Elhamel** — Aries.
- **Elharneb** — arab., Lepus.
- **Elhauc** — arab., Hydra.
- **Elhautz** — arab., Pisces.
- **Elhenaat** — arab., the Head of Pollux [Caput Pollucis].
- **Elkanfu**, or **Elkufu**, or **Elkaut** — arab., Aquarius.
- **Elkaitus** — arab., Cetus.
- **Eikamer** — arab., Luna (the Moon).
- **Elkis**, or **Elnarad** — arab., Crater.
- **Elkleil Eigenubi** — arab., Corona Australis [Southern Crown].
- **Elkleil Schemali** — arab., Corona Borealis [Northern Crown].
- **Elmac Alcheras** — arab., Equus Minor [the Lesser Horse].
- **Elsefed** — arab., Leo.
- **Elmarig** — arab., Mars.
- **Elmesteri** — arab., Jupiter.
- **Elnatra** — arab., the Manger of Cancer [Aselli Cancr].
- **Elsartan** — arab., Cancer.
- **Elschemis** — arab., Sol (the Sun).
- **Eltsamach** — arab., Spica Virginis.
- **Elzabareh** — arab., Venus.
- **Emro** — Chald., Aries.
- **Engonasi** — Greek, "Ingeniculus" [the Kneeler], Hercules.
- **Ensf**, or **Enf Alphas** — the star at the nose of Pegasus [in rictu Pegasi].
- **Erigone** — Virgo.
- **Ezra** — Cynosura, Ursa Minor.

F

- **Famauth**, or **Phomalhaut**, or **Phomauth**, corruptly **Phomaant** — arab., the Mouth of the Fish [Os piscis], or the splendid star in the outpouring [stream] of Aquarius.

G

- **Gadio** — Chald., Capricorn.
- **Garactes**, or **Abrachaleus** — Chald., the Head of Pollux [Caput Pollucis].
- **Gedi** — Chald., Capricorn.
- **Gienz** — arab., with the joint [article], **Elgeuzi**, Gemini.
- **Grumium** — barbarous [name], that which is at the jaw of Draco [genam Draconis].
- **Grus**, or **Ciconia** — to the Moors [Mauris], Serpentarius.
- **Guad** — to the Moors, Eridanus, or the Nile.

H

- **Haakrab**, or **Aaakrab**, and with the article **Elaakrab** — arab., Scorpius.
- **Hammel** — arab., Aries.
- **Harneb**, and with the article **Elharneb** — arab., Lepus.
- **Haut**, and with the article **Elhaut**, or **Elhautine** — arab., Pisces.
- **Haut Elgenubi** — arab., Piscis Australis [the Southern Fish].
- **Haut Elschemali** — arab., Piscis Borealis [the Northern Fish].
- **Helice** — Greek, Ursa Major.
- **Heniochus** — Greek, Auriga.
- **Hermannibis** — to the Egyptians, the God of speech, that is, Mercury.
- **Hermes** — Greek, ἑρμῆς, Mercury.
- **Hermidone**, ἑρμηδόνη — in Vitruvius l. [book] [?], [?].
- **Hermippus** — in Pliny, Delphinus.
- **Hesperus**, ἔσπερος — the evening Venus [Venus vespertina].

- **Hexastron** — Greek, ἑξάστρον, "the six-star constellation," the Pleiades; which, as Ovid sings, "they say are seven, although there are nevertheless six," because the seventh is scarcely seen [quae, vt canit Ovidius, septem dici, sex tamen esse solent, quia septima aegrè conspicitur].
- **Hierezim** — arab., "smelling like a rose," or "a lily"; thus they call the star of Cygnus [Cygni astrum].
- **Hydrochous** — Greek, Aquarius.
- **Hydridurus** — Greek, "turning the urn of water," namely Aquarius.

I

- **Ingeniculus** — "kneeling on the knee" [in genua procumbens], Hercules.
- **Ingum** — to Cicero, Libra.
- **Ingula** — to Plautus and Varro, Orion.
- **Ingulae** — the Asses in Cancer [Aselli in Cancro].

K

- **Kalb** — arab., the Heart [Cor].
- **Kalbelaakrab** — arab., the Heart of Scorpius [Cor Scorpii].
- **Kalbellesed**, arab. of the Ferzani [people of Fezzan] and Moroccans, and of the Nubians, the Heart of Leo [Cor Leonis], corruptly in the Alphonsine [tables] **Kalbelasfad**.
- **Kalbelalphard**, and reduced [shortened] to **Alphard** alone, arab., the Heart of Hydra [Cor Hydrae].
- **Kaitos**, and with the article **Elkaiton** — arab., Cetus.
- **Kaus**, and with the article **Elkaus** — arab., Sagittarius.
- **Kertko** — Chald., Sagittarius.
- **Kescheth** — Hebr., Sagittarius.
- **Ketpholtsumman** — the Head of Pollux [Caput Pollucis].
- **Kochab** — arab., the bright one in the shoulder of Ursa Minor.
- **Kolanza** — Arcturus, arab.

L

- **Laelaps** — Canis Major.
- **Lebanah**, or **Ianeah** — to the Hebrews the Moon, so called from its whiteness [ab albore].

- **Lesath**, or rather **Lessaa Elaakrab** — arab., the star in the sting of Scorpius [in aculeo Scorpil]; and it signifies "the Bite of Scorpius" [ipsum Morsum Scorpil].

M

- **Maadim** — Hebr., Mars, inasmuch as of a blood-red colour [sanguinei coloris].
- **Maasym** — arab., the star at the right elbow of Hercules [in dextro cubito Herculis].
- **Maforte** — barbarous [name], Auriga.
- **Markab** — arab., curtus [shortened], but to them it is the first in the wing, or shoulder-joint of Pegasus [in ala, vel armo Pegasi].
- **Malphelcane** — that is, the garland of the pupil [sertum pupillae], to the Chaldaeans, namely Corona Borea [Northern Crown].
- **Marra**, or **Merga** — arab., the star in the sickle of Boötes [in falce Bootis].
- **Marat Musalseleth** — arab., the Chained Woman [Mulier Catenata], that is Andromeda.
- **Marfic** — that is "the reclining-place" [reclinatorium], arab., the star in the left hand of Hercules [in sinistra Herculis manu].
- **Mafathre** — Chald., Libra.
- **Meeleph**, or **Melleff** — arab., the nebulous one in the breast of Cancer [in pectore Cancr].
- **Meloch** — to the Egyptians, Mars, inasmuch as the God of destruction to them [Deus destructionis ipsis].
- **Menkar Elkaiton** — arab., the star at the nostrils of Cetus [in naribus Ceti].
- **Mesangu** — Chald., Lyra.
- **Mesartim** — Hebr., the two stars in the horn of Aries [in cornu Arietis].
- **Mexar** — arab., the star in the right thigh of Boötes [in dextro femore Bootis].
- **Micar**, or **Mizar**, "the middle," to the Arabs signifies the star, in that it is the middle in the tail of Ursa Major, just as the one which is in the belt of Andromeda [in cingulo Andromedae].
- **Miluius** — to Ovid otherwise, Cygnus.
- **Mizan** — arab., Libra.
- **Miznaim** — Hebr., Libra.
- **Moschleb** — in the sting of Scorpius [in aculeo Scorpil].

- **Munir** — pupilla [the pupil], arab., the bright one of the Crown [Lucida Coronae].
- **Mufator** — to Cicero, Sagitta.
- **Muscida** — to the barbarians, it is a small star at the nostrils, or muzzle, of Pegasus [in naribus siue Pegasi], or **Muscida Pegasi**, or of Ursa Major, and it is called **Muscida Vrsae**.
- **Muthlatum**, or **Mutlat** — arab., Triangulum.
- **Myrtilus** — Auriga.

N

- **Naasch Laazar** — to the Christian Arabs it signifies the bier of Lazarus [Pheretrum Lazari]; thus they call the seven stars of Ursa Major, and the three in the tail **Benat Naasch**, that is, the daughters of the bier [filias pheretri].
- **Nahar** — arab., the Nile, or Eridanus.
- **Nebolassid** — arab., and **Nebolassid** to the Nubian astrologers, the Tail of Leo [Cauda Leonis].
- **Nembus** — arab., the star in the sickle of Perseus [in falce Persei].
- **Nepa** — to Varro, Cancer.
- **Nobia** — Chaldaean, Mercury.
- **Noctiurus**, νυκτοῦρος — "guardian of the night," namely Saturn, in Plutarch *On the Face [of the Moon]* [De Facie Lunae].
- **Nogah** — Hebraic, Venus, inasmuch as "the gleaming light" [lux rutilans].
- **Nonacrine** — in Latin, Ursa Major.

O

- **Oftipes** — Cancer.
- **Ophiuchus**, ὀφιοῦχος — Serpentarius.
- **Orfercalem** — to the Turks, Sagitta.
- **Orphas** — Cetus.

P

- **Palilicium** — in Latin, the Southern Eye of Taurus [Oculus Australis Tauri].
- **Pesceho** — Chald., the Nebula of Cancer [Nebulosa Cancri].
- **Pcochos**, and **Asephcom** — Luna [the Moon] to the Egyptians, inasmuch as the Mistress of the Sea [Maris domina].
- **Phaenon**, φαίνων, 1. the apparent Saturn [apparens Saturnus].

- **Phaëthon** — Jupiter, by the Greeks for its splendour [á splendore].
- **Pharmaz** — Crater.
- **Phicarus** — Cepheus.
- **Phomant**, or **Phomault**, or **Phomelhaut** — the Mouth of the Fish [Os piscis], arab., and it is in the outpouring [stream] of Aquarius [in effusione Aquarij].
- **Phoenus** — to the Egyptians, Jupiter, inasmuch as God of life to them [Deus vitae].
- **Phosphorus**, φόσφορος — the morning Venus [Venus matutina].
- **Piorion**, πιώριον — to the Egyptians, the Station of Horus [Statio Hori], that is, the Eye of Taurus [oculus Tauri].
- **Potirir** — to the Egyptians, the Sun, that is, to them God the Saint [Deus Sanctus].
- **Procyon**, πρόκυνον — to Cicero **Antecanis**, or **Praecanis**, Canis Minor.
- **Propus**, πρόπους — the star at the very top of the left foot of Pollux [in summo pedis sinistri Pollucis].
- **Pyrois**, πυρόεις — Mars, the fiery [star] [Mars igneus].

R

- **Ras** — Arabic, the Head [Caput].
- **Ras Algethi** — arab., the Head of Hercules [Caput Herculis].
- **Ras Algol** — arab., the Head of Medusa [Caput Medusae].
- **Ras Algeuze**, or **Ras Elgautze** — arab., the Head of Castor [Caput Castoris].
- **Ras Alhague** — arab., the Head of Serpentarius [Caput Serpentarij].
- **Rastalben** — arab., the bright star of the Head of Draco [Lucida Capitis Draconis].
- **Rephan** — to the Egyptians, Saturn, inasmuch as God of time to them [Deus temporis].
- **Rigel**, or **Rigel Elgebar** — arab., the bright one in the left foot of Orion [in sinistro pede Orionis].
- **Ruha** — to the Hebrews, Auriga.
- **Rota Ixionis** — Corona Australis [the Southern Crown].
- **Ruccabah** — the Pole Star [Stella Polaris], at the very end of the tail of Ursa Minor [in extremo caudae Vrsae minoris].

S

- **Sagmarius** — Pegasus.

- **Sameh** — Pisces.
- **Sartai** — Hebr., Aries, that is, the Horned [Cornua].
- **Sartam** — Hebr. and Arab., **Elsartam** — Cancer.
- **Sartono** — Chaldaean, Cancer.
- **Sceara** — Canis Major, or Sirius.
- **Schaham** — arab., Sagitta.
- **Schabtai** — Hebraic, Saturn.
- **Schasro** — Chaldaean, the Moon [Luna].

TAB. 101 — *Nomenclatura Stellarum* (continued and concluded)

The alphabetical glossary of foreign star-names with their interpretations continues from the catchword "Scheat-". Each headword is given in *italic*, followed by the language of origin and the Latin identification. The page is set in two columns.

Letter S (continued)

- *Scheat*, Arabic. The leg or shin [*crus, vel tibia*], and it is both the star in the leg of Pegasus — and so it is called *Scheat Pegasi* — and the one in the left [arm] of Aquarius, where it is called *Scheat Aquarii*. Among the Arabs the former is *Scheat Alpheras*, the latter is *Scheat Edeleu*. [The right-column fragments confirm: "in Crure Pegasi ... sinistra Aquarii ... prior Scheat Alpheras, posterior est Scheat Edeleu."]
- *Scheder*, or rather *Seder*, Arabic. A star in the breast of Cassiopeia.
- *Scheer Eliemini*, among the Persians, Canis Maior [the Greater Dog].
- *Schemasch*, among the Hebrews, the Sun, from "heat" [*à calore*].
- *Schemso*, among the Chaldaeans, the Sun.
- *Simon*, or *Smon*, among the barbarians, the Dolphin.
- *Soail Iemani*, among the Persians, Canopus.
- *Stilbon*, in Greek στίλβων [Greek: stilbōn, "the gleaming one"], Mercury, from its shimmering light [*à vibrando lumine*].
- *Sucula*, in Varro, the Hyades.
- *Succoth Benoth*, Hebrew. "The daughters of the tabernacle" [*Tabernaculi filiae*], that is, the Pleiades.
- *Suhel*, Canopus.
- *Sumbalet Eleadari*, Arabic. Spica Virginis [the Ear of grain of Virgo].

- *Suroth*, among the Egyptians, "the mistress of love" [*amoris domina*], namely Venus.
- *Syndesmos*, σύνδεσμος [Greek: syndesmos, "binding, knot"], in Aratus the Knot of the Linen Thread of the Fishes [*Nodus Lini Piscium*].

Letter T

- *Tammech*, among the Chaldaeans, Gemini [the Twins].
- *Tauro*, Chaldaean. Taurus [the Bull].
- *Tauss*, among the Chaldaeans, Jupiter.
- *Ternouelles*, among the Persians, Hercules.
- *Theemin*, Arabic. The seven stars in the fourth bend of Eridanus [*septem stellae in 4. flexura Eridani*].
- *Theomin*, among the Hebrews, Gemini.
- *Triones*, the seven stars of Ursa Maior [the Greater Bear].

[The right column continues with letters U/V, Y, Z:]

- *Tur*, Arabic. Taurus.
- *Tzedek*, among the Hebrews, Jupiter, on account of [its] equity [*ob aequitatem*].
- *Tzegel*, among the Arabs, Saturn.

Letter V

- *Vardi*, among the people of Fez, the Nile, or Eridanus.
- *Vazneganubi*, Arabic. Lanx Austrina [the southern Scale of Libra].
- *Vazneschemali*, Arabic. Lanx Borealis [the northern Scale of Libra].
- *Vespertilio*, in Sophocles, the Heart of the Scorpion [*Cor Scorpii*].
- *Vesper*, *Vesperugo*, in Varro, the evening Venus [*Venus vespertina*].
- *Vigiles*, in Italian *le gauerdiole*, or *guardiane* [the guardians], the lesser stars in the tail of Ursa Minor [the Lesser Bear].
- *Virgilia*, or *Vergilia*, the Pleiades.
- *Vmbilicus Pegasi*, the Head of Andromeda [*Caput Andromedae*].
- *Vuega*, or *Vagieh*, Arabic. The Lucida of Lyra [*Lyrae lucida*].
- *Vultur cadens*, Lyra [the falling Vulture].
- *Vultur volans*, Aquila [the flying Vulture].

Letter Y

- *Yed*, Arabic. The more northern star in the right [hand] of Serpentarius [Ophiuchus].

Letter Z

- *Zeus*, in Greek Ζεύς [Greek: Zeus], Jupiter.
- *Zubenelgenubi*, Arabic. Lanx Australis [the southern Scale], or *Vazneganubi*.
- *Zubeneschemali*, or *Vazneschemali*, Lanx Borealis [the northern Scale].

FINIS.

[This concludes the *Nomenclatura Stellarum* (TAB. 101), the *Tabulae Novalmagesticae*, and Tomus II of the work.]

ERRATA ... CORRIGE (Errata)

Two facing errata lists are printed at the foot of the page: one *In Prolegomenis* (for the Prolegomena), one *In Tabulis* (for the Tables). For each, the columns give where the error occurs and the correction. The convention is: the printed (erroneous) reading on the left under *ERRATA*, the corrected reading on the right under *CORRIGE*.

ERRATA ... In Prolegomenis ... CORRIGE. (Errata in the Prolegomena)

Pag.	Col.	Lin.	Printed (Errata)	Read (Corrige)
II	1	29	sphæricam	sphæram
II	2	21	sub firmamento	supra firmamentum
IV	2	13	percurret	percurreret
IV	2	42	Spicæ	Spica
IV	2	45	Attrogradi	Antrogradi
V	2	47	Comas	Comes
VI	1	11	qui &	qui ea
VII	1	65	mediæ distantiae	medias distantias
VIII	1	43	Videri	Viden
IX	2	45	retentosq;	retentaque
39	1	6	Labouera	Lalouera
69	2	50	Sideris	Sidereï
70	2	70	melius	meliores

Pag.	Col.	Lin.	Printed (Errata)	Read (Corrige)
78	1	76	eius	eiusque

Place-name corrections in the Prolegomena (second part of the same *In Prolegomenis* list)

A second list under the same *In Prolegomenis* heading normalizes the spelling of place-names. Each line gives the page, the form as printed, and the corrected (*italic*) modern form.

Pag.	Printed	Corrected
9	Alba Iulia Transilvani	Alba Iulia Transilvaniæ
10	Cliuia	<i>Cliues</i> (Cleves)
10	Dauentia	<i>Deuenter</i> (Deventer)
10	Fauentia	<i>Faënza</i> [followed by coordinates: 0 1 56, adj. 44 33 15]
10	Hildesemium Saxonîæ	<i>Hildesem</i> (Hildesheim)
11	Iuliacum Giuliech	& <i>Giuliers</i> (Jülich)

13	Tuder	<i>Todi</i>
13	Valentiane	—

ERRATA ... In Tabulis ... CORRIGE. (Errata in the Tables)

The facing right-hand list, headed *In Tabulis*, gives the same kind of place-name corrections for the tables. The entries largely repeat the Prolegomena place-names with their corrected forms.
