Translator Version 2

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: "What do I need this new instrument for?" — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBris HaShalem* (1797)

A note on the work

A mature reckoning with the heavens as the telescope was revealing them — a sequel to the vast *Almagestum Novum* (1651), built on further years of observation at Bologna with the collaborator Grimaldi, with fresh measurements and corrected parameters at center stage. Across two volumes it treats the Sun, eclipses, the Moon, the fixed stars, and each of the planets in turn, then reduces it all to working tables. It carries some of the earliest sustained telescopic accounts of Saturn's changing shape before its rings were understood, of the bands and spots crossing Jupiter, and of the apparent sizes of the stars — wielded as evidence that the Earth stands still. A vivid window onto astronomy at the dawn of the telescopic age.

A note on the translation process

This translation was produced with the [translation-pipeline](#). See the linked repository for details on the process.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Dedicatory Title Page

ASTRONOMY REFORMED,

TO

the Most Serene Lord

FERDINAND MARIA,

DUKE OF BAVARIA, ETC.

Diagram. An engraved armorial cartouche occupying the center of the page: the coat of arms of the House of Wittelsbach (Bavaria).

- Crest (top): a ducal/electoral crown held aloft by a winged putto; flanking putti blow trumpets at the upper left and upper right.
- Escutcheon (center): the arms of Bavaria — a shield bearing the lozengy (fusily bendwise) field of Bavaria, quartered with a rampant lion (the Palatine lion); a smaller inescutcheon at the center charged with an orb surmounted by a cross (the imperial orb / Reichsapfel).
- Supporters / surround: an elaborate Baroque strapwork cartouche with two female figures (caryatid-like terms) at the sides; festoons of fruit and flowers hang below; a grotesque mask at the foot.
- Engraver's signature (lower right corner of the plate): "F. Tintus Fe[cit]."

BOLOGNA, 1665.

From the Printing House of the Heir of Vittorio Benacci.

By Permission of the Superiors.

[Verso of the Dedicatory Title Page]

Title Page

ASTRONOMY REFORMED, IN TWO VOLUMES.

The first of these contains the OBSERVATIONS, HYPOTHESES, AND FOUNDATIONS OF THE TABLES.

The latter contains the precepts for the use of the Astronomical Tables, and the Astronomical Tables themselves, 102 [CII] in number.

The first volume is divided into ten Books; their subjects [*Argumenta*] are set out on the following page.

BY THE AUTHOR

Fr. JOHN BAPTIST RICCIOLI [Giovanni Battista Riccioli], OF THE SOCIETY OF JESUS, OF FERRARA.

[Verso of the Title Page]

Dedication Epistle

TO THE MOST SERENE AND MOST POWERFUL PRINCE AND LORD, LORD FERDINAND MARIA [Ferdinand Maria, Elector of Bavaria], Arch-Steward of the Holy Roman Empire, ELECTOR OF BOTH BAVARIAS AND DUKE OF THE UPPER PALATINATE, Landgrave of Leuchtenberg.

F. S. [the author's subscription — *Felix Salus* / a respectful salutation]

Under a happy and auspicious sign, Most Serene Prince, the *Astronomy* that I have in my own way *Reformed* now comes forth from the press — born, as it were, from the womb — at the very moment when the Sun has entered Leo. As its natal star, then, it has drawn for its lot the Royal sign of the heavens. Yet by a far happier design it seeks aid and protection for itself from the renowned name of Your Highness; for in your Royal coat of arms, twin Lions set below and above guard, more securely than Atlas, the globe of the world that glows red with the star of the Cross, and uphold it more mightily than Hercules. It has been, and still is, the special mark of this Most Serene House — by its twofold virtue, the orthodoxy of its Faith and the incorruptness of its Fidelity — on the one hand to

protect and guard the Catholic Church and the Supreme Pontiffs, and on the other the Roman Empire and the Emperors; to join political pruden-

dence with sincere Religion, fairness toward men with piety toward God, severity in Justice with the Clemency of Magnanimity, the arts of War with the pursuit of Peace, Wisdom with Fortitude, Arms with Letters — and, as is proper to the Lion's influence, the splendor of Wealth with the most lavish generosity toward learned and good men.

It is remarkable that the wisest Priests of Egypt, to signify the flooding of the Nile, took as their hieroglyph the Lion — the sign set diametrically opposite to Aquarius — rather than Aquarius itself. For what symbolic likeness, I ask, appears between that blazing constellation, which with the heat of its burning and the dry scorching parches the very bowels of the earth — to say nothing of its face — and so vast an abundance of waters as the Nile rolls down at the height of its season? Yet this is a mystery, whether of Nature's more hidden workings or of the secret providence of the Deity: that the subterranean lakes of Ethiopia and Egypt, stirred up by the barking of the Dog-star and the roaring of the celestial Lion, and boiling over, should so seethe up out of those immense cauldrons that the Nile then swells when other rivers are shrinking, and its plenty of waters triumphs at the very time when the rest, for want of water, lie dry or stagnant. Beyond this, if you consider the nature of the Nile and the temperament of the Lion, a great resemblance between the two will be apparent. Other rivers, the moment their banks are broken or overtopped, flood out with tyrannical force and a mass of waves, hostile to fields and farmers, laying waste everything in their path,

and through all the plains they drag the herds along with their stalls.
[verse quotation]

with barrenness, or with dearth of grain, following thereafter. The Nile, by contrast:

Fruitful in its overflowing, it never goes forth but bearing fruit: [verse quotation]

it overcomes its banks in order to enrich the fields; it floods in order to make fertile; and those who dwell beside it hope for most from it precisely when it swells the more proudly — so much so that they fear if it does not rise, and grieve if it does not flow over, and reckon it the shipwreck of their fields whenever they are not overwhelmed by the mass of its waters. The Lion likewise, least savage among wild beasts, is the more clement toward those who submit to him in

proportion as he is the more terrible toward those who despise his majesty: gentler toward women and infants, more kindly toward the well-disposed, more gracious toward those who do him good, more generous toward the hungry — with whom more than once he has shared his food, content himself with a small portion — and more skilled in serving holy or religious men than in raging against them. No wild beast is more easily tamed than the Lion, especially if he keeps company with princes, judging it unworthy of the King of beasts not to put off his ferocity at court and not to put on humanity in the presence of men robed in purple or in the trabea. Ages past saw, under Hanno the Carthaginian, under Augustus, and under Domitian, lions so tame that fawns and hares would play within their very jaws, fearing nothing there — the lions rather fearing to harm the helpless creatures even in the slightest. And a more recent age saw, under John of Austria [Don John of Austria], under Maximilian, and under Rudolph the Second [Rudolf II], lions walking harmlessly through the palace and waiting upon their masters; and at Eitelberg, in the castle of Otto Henry the Palatine [Otto Henry, Elector Palatine], puppies playing with a lion and sleeping safely upon its mane. "To what end," you will say, "this digression about the Nile and about lions?" Why, so that by the Lions glittering on your most noble coat of arms I might persuade you that those Heroic virtues are signified which I recounted above, and which Your Highness has drawn from your Ancestors

Dedication Epistle (continued)

—and which they have drawn from your forebears; for your Ancestors transmitted them to You in an unbroken and illustrious succession of descendants reaching all the way down from CHARLEMAGNE [Charlemagne]. Among these, OTHO [Otho] the Great won an immortal memory and rose to the summit: a man tall indeed in body, but greater in spirit, and destined to grow greater still — had not Heaven, in that very year 1180 in which he was chosen Duke in Bavaria, begrudged him to the earth. Yet his counterpart was his son LUDWIG [Ludwig], Duke of Bavaria, founder of Septivir [the Electoral dignity], Count Palatine, and founder of Straubing — a man marked for his loyalty toward Frederick II [Frederick II], and for his Religion and his Piety toward Innocent IV [Innocent IV]; he earned the praises of both, as a glory of the Empire and an ornament of the Church. His grandson LUDWIG II [Ludwig II], surnamed the Severe — in whom severity of character vied with fairness — ceded Lower Bavaria to his brother Henry. From this line came that distinguished offspring LUDWIG III [Ludwig III], chosen King of the Romans in the year 1314, and soon after Emperor — a man so great that the age did not know what was more to be

admired in him: his kindness toward his peoples, or his love of letters and of learned men, or his zeal for the Orthodox Faith, or his unceasing devotion to the defense of the Church of God. His great-great-grandson ALBERT [Albert], surnamed the Pious but no less the Magnanimous, refused the Kingdom of Bohemia when it was offered him: nobler in the Kingdom within himself, and one who had proved by experience that saying of Horace:

More widely do you reign by mastering your greedy Spirit, than if you
should join Libya to the remote Gades, and both Carthaginians
[Carthages] should serve one master. [verse quotation, Horace, *Odes* II.2]

So from this line was born another ALBERT [Albert], surnamed the Wise, who — emulating his Father's Piety no less than the most devout example of his wife Kunigunde — raised up at Munich a great many Churches, to storm Heaven by them as by fortresses, not with giant-like daring, but with humble devotion. Why then should he not beget a son like himself, WILHELM [Wilhelm], in whom so great a fervor for the Catholic Religion shone forth? Indeed this man begot ALBERT V [Albert V], who showed himself the wiser the more he too bore the surname "the Wise," and who the more keenly propagated the Orthodox Faith. From him your Grandfather WILHELM FERDINAND [Wilhelm] was born, most zealous for the Catholic Religion, who in the year 1597 — that he might withdraw out of the storms of this world into harbor, and thence the more securely into Heaven — abdicated the Dukedom of both Bavarias and gave himself wholly to himself, nay rather wholly to God. Afterward, from RENATA [Renata], that most illustrious Heroine, he received your most excellent Father MAXIMILIAN [Maximilian, Elector of Bavaria], of whom it is harder to keep silent than to speak — yet narrower than his deserts to wish to embrace in a eulogy either his skill in arms, or his cultivation of peace, or his love of law and equity, or his most devout piety, or the rest of those endowments of his for which Germany acclaimed him a Father of his Country. Of all these prerogatives, MOST SERENE FERDINAND MARIA [Ferdinand Maria, Elector of Bavaria], you have willed that they be Yours by hereditary right and by voluntary possession: Prudence above all in the choice of counsels, Equity in your Judgments, the most amiable humanity in governing your subjects, and a steadfast Zeal in defending the Orthodox Faith, together with the warding-off of the enemies of Faith and of the Empire. For from this it came about that your Cohorts withstood the forces of the Turks — superior in number, not in valor — and repulsed, routed, and put them to flight, with a memorable slaughter of the foe and to your own praise.

But how much our Society owes to You, and to your most renowned Parent and Grandfather; how great the Munificence on that side; how it has rejoiced, and rejoices to this day, in a protection that surpasses all glory — this no words can express, no monuments can attest; nor can I be acquitted of so vast a mass of debt, however great Your Magnanimity may be. For to acquit me of it would itself be a new favor and a fresh and immense debt, under which I could never, to all eternity, succumb in repayment. It remains only that the Magnitude of YOUR HIGHNESS deign to admit me — despite the smallness of my Work, the slenderness of my talent, and my own unworthiness — among the most devoted clients of Your Highness.

Your Most Serene Electoral Highness's

[The epistle closes, right-aligned:]

Most humble and most obedient Servant,

Io. Baptista Ricciolus, of the Society of Jesus [Giovanni Battista Riccioli, S.J.]

INDEX OF THE BOOKS

INDEX OF THE BOOKS [INDEX LIBRORVM].

BOOK ONE

In which are the observations of the Sun, and the foundations of the Solar hypotheses.

BOOK TWO

In which are select observations of Eclipses of the Moon and of the Sun, for establishing the Luni-solar motions and the Moon's first inequality, and for delimiting the apparent Diameters of the Luminaries.

BOOK THREE

In which are observations of the Moon outside of Eclipses, bearing on the Moon's monthly inequality, and its variation and libration.

BOOK FOUR

In which select observations of the Fixed Stars are weighed, drawn from the ancients and from recent observers, and from these Tables are constructed and set forth down to the Year of Christ 1700.

BOOK FIVE

In which are the observations of the Planet Saturn, and the hypothesis of its motions.

BOOK SIX

In which are the observations of the Planet Jupiter, and the hypothesis of its motions.

BOOK SEVEN

In which are the observations of the Planet Mars, and the hypothesis of its motions.

BOOK EIGHT

In which are the observations of the Planet Venus, and the hypothesis of its motions.

BOOK NINE.

In which are the observations of the planet Mercury, and the hypothesis of its motions.

BOOK TEN.

In which are the *Paralipomena* [Paralipomena / supplementary matters] of the observations pertaining to the Fixed Stars and to the Minor Planets: namely, concerning their apparent Diameters, their Figure, the Belts [fasciae], the Spots, the Rotation, the Attendants [satellites], and the motions of the Attendants, as well as their Distances from the Sun and from the Earth.

Faculty (grant of permission) of the Reverend Father Girolamo Chiaramonti [Hieronymus Claramontius], of the Society of Jesus, Provincial in the Province of Venice.

Since two Theologians and experts in Mathematics of our same Society have reviewed the *Astronomia Reformata* of Father Giovanni Battista Riccioli [Io. Baptista Riccioli], a Priest of our Society, and have approved that it can be published — we too, having received authority from the Reverend Father Goswin Nickel [Gosuinus Nikel], our Father General and Superior General of the Society of Jesus, grant that it may be committed to print, if it shall so seem good to those to whom this pertains. In witness of this matter we have issued these letters, signed by our own hand and secured with our seal. At Bologna, on the 28th day of October, 1658.

Girolamo Chiaramonti.

Place * of the Seal.

Seen by Master Carlo Gorani [D. Carolus Goranus], Penitentiary, on behalf of the Most Eminent and Most Reverend Lord Archbishop of Bologna and Prince.

Seen — out of his singular benevolence toward the Author — by the Most Reverend Father Inquisitor of Bologna himself, Friar Guglielmo Fochi [F. Gulielmus Fochus], who has also confirmed the license for printing it: his Most Reverend Successor.

Let it be printed. Friar Giovanni Vincenzo Paolini de Gatexio [F. Ioannes Vincentius Paulinus de Gatexio], Master and Inquisitor General of Bologna.

INDEX OF THE BOOKS, AND OF THE CHAPTERS, AFTER THE PROLEGOMENA

To the *Astronomia Reformata*.

BOOK ONE.

On the Sun.

CHAP.

1. On the methods of observing the equinoxes, solstices, and the maximum declination of the Sun, with as little fallacy as possible. p. 1

2. On the instruments most suited for finely observing the altitudes of the Sun, and of any star whatever; and especially on the gnomon of remarkable ingenuity at Bologna [Bononia], and others like it. p. 3
3. Observations of the equinoxes, exact or nearly so, from the year 162 before Christ down to the year of Christ 1656. p. 7
4. On the magnitude of the equinoctial year, and on the daily and annual motion of the Sun. p. 14
5. Observations of the solstices. p. 16
6. Observations of the obliquity of the ecliptic [obliquitas eclipticae], or of the maximum declination. p. 18
7. Observations of the quadrants and semicircles of the year. p. 22
8. Selected observations of the meridian altitudes of the Sun, taken outside the equinoxes and solstices. p. 23
9. On the motion of the solar apogee [Apogeeum Solis]. p. 29
10. On the eccentricity of the Sun, and on the inequality of its daily motions. p. [?]
11. On the eccentricity, the equations, and the intervals of the Sun, to be investigated geometrically within the ellipse. p. 33
12. Selected observations of the apparent diameter of the Sun, in which a notable fallacy — into which certain other astronomers had fallen — was very recently detected. p. 37
13. On the parallax of the Sun, and on its distance from the Earth. p. 41
14. On astronomical refractions, their comparison and use with parallaxes, and a new investigation of the parallaxes through refractions. p. 42
15. On the refractions of the Sun. p. 57
16. On establishing the epochs of the Sun's motion. p. 61
17. A new theory of the Sun's motions is proposed. p. 62
18. The theory of the spiral motion of the Sun is indicated. p. 65

19. Conclusions concerning the certainty so far achieved, or to be hoped for hereafter, regarding the Sun's motion, its intervals, the quantity, the theory, and the practice of the Tables. p. 69

I. Appendix to Chapter XII. p. 71 On the apparent diameter of the Sun.

II. Appendix to Chapter XVII. p. 81 On the daily motion of the Sun, or rather of the other heavenly bodies, against the Copernicans.

BOOK TWO.

On the Eclipses of the Moon, and of the Sun.

CHAP.

1. On the selection of observations of eclipses, and on their use for establishing and verifying the Astronomical Tables; and on the distance of meridians assumed in the more celebrated Tables. p. 92
2. The eclipses of the Moon observed as to their Quantity and Moment, from the year 721 before Christ down to the year of Christ 1660. With the errors of others detected, or the discrepancy in chronology or quantity. p. 95
3. An epitome of the observations of the Moon's eclipses, which are handed down by their authors as having the summary, or the middle, of the eclipse; because for us they must be reduced to one and the same Meridian of Bologna by the rule of the last Table of the first Chapter. p. 105
4. On the uncertainty of the ancient observations, and of certain recent ones; on the discrepancy of the observers of those same eclipses, and the causes thereof. 10. Discrepancies. p. 108
5. On the agreement, or disagreement, of the Astronomical Tables with the observations of the Lunar eclipses — and first of the ancient eclipses as far as Ptolemy [Ptolemæus] inclusively; and the enormous extent to which a discrepancy appears between the Astronomical and Chronological Tables; but in truth Ptolemy is in error in the motion of the Sun. p. 110
6. On the agreement, or disagreement, of the Astronomical Tables with the observations of the eclipses from the time of al-Battānī [Albategnius] down to the year of Christ 1660. p. 118

7. On the excellence of the Astronomical Tables, and a comparison among them, drawn from the observations of the Lunar eclipses. Where certain notable Conclusions are laid down. p. 126
8. In which the foundations of the new Tables, and the eclipses from al-Battānī down to the year of the Lord 1660, the selected observations, and those computed from the Author's new Tables. p. 131
9. On the ancient eclipses of the Moon, exhibited by means of the Author's new Tables. p. 133
10. On the motion of the Moon in Longitude established hitherto by the more distinguished Astronomers, and by what method especially that investigation may seem capable of being desired. p. 135
11. On the synodic Lunar Month, to be investigated by means of several Eclipses. p. 137
12. How, from the synodic Month of the Moon, the remaining Lunar motions in Longitude are to be deduced. For concerning the motion of the Anomaly and of the Latitude we shall treat below separately;
13. On the Lunar Apogee and the Anomaly. p. 140
14. On the motion of the Lunar Latitude, or of the Nodes. p. 141
15. On establishing the epochs of the Lunar motion. p. 142
16. Selected observations of the Sun's eclipses — chosen, however, as suited to establishing the lunisolar motions and the diameters of the luminaries; with the calculations of astronomers thereupon added. p. 143
17. On the apparent diameters of the luminaries, suited for representing the Total and Annular Eclipses of the Sun. p. 148
18. On the eccentricity of the Lunar orbit, the internal libration of the Moon, the Parallaxes, and the apparent Semidiameters, to be determined by the Circle rather than by the Ellipse. p. 149
19. On the True Magnitude of the Moon. p. 151
20. On the Latitude of the Moon, the Anomaly of this motion, and the Reduction of the Moon to the Ecliptic. p. 151

BOOK THREE.

In which are the observations of the Moon outside the Eclipses.

1. The ancient observations of the Moon outside the Eclipses, from the year 295 before Christ down to the year of Christ 509, as to the places of the Moon in the Heaven. p. 152
2. The Lunar observations of Regiomontanus [Io. Regiomontanus], Bernhard Walther [Bernardi Vualtheri], Nicolaus Copernicus [Nicolai Copernici], and Abraham Zacuto [Abrahami Zaguthi], as to the places of the Moon outside the Eclipses, from the year of Christ 1462 to 1524. p. 154
3. Selected Lunar observations of Tycho [Tychonis], outside the Eclipses, as to the place of the Moon. p. 155
4. Some Lunar observations of Kepler [Kepleri], Lansbergen [Lansbergii], and Longomontanus [Longomontani], outside the Eclipses, from the year 1598 to 1608. p. 155
5. The Lunar observations outside the Eclipses of Boulliau [Bullialdi], Gassendi [Gassendi], Hevelius [Heuelii], Hodierna [Hodierna], Hortensius [Hortensii], Michael Florent van Langren [Michaelis Langreni], and Vicenc Mut [Vincentii Muti], from the year 1623 down to the year 1653, as to the places of the Moon. p. 156
6. In which is exhibited a Table of the XXIV Lunar Observations with the calculation of Ismaël Boulliau [Ismaëlis Bullialdi], which he himself, in Book 3 of his *Astronomia Philolaica* [Astronom. Philol. cap. 12], promised; but afterward he postponed it, on page 171 of his own Tables. p. 159
7. Selected Lunar observations from among the many made at Bologna by the Fathers Giovanni Battista Riccioli [Io. Baptista Ricciolio] and Francesco Maria Grimaldi [Franc. Maria Grimaldo] of the Society of Jesus, for the places of the Moon outside the Eclipses. p. 160
8. On the conjunctions of the Moon with stars at a distance. p. 163
9. A Theory of the Lunar motion in Longitude is proposed, for the inequality compounded out of the first and the second. p. 164
10. On the Lunar Variation [Variatio]. p. 166
11. On the libration of the Lunar body. p. 168

12. A most reverend, most distinguished, and most learned Letter to Father Giovanni Battista Riccioli of the Society of Jesus, Professor of Philosophy, Theology, and Astronomy, most celebrated at Bologna — from Johannes Hevelius [Ioannes Hevelius]. p. 169

13. A brief reply, awaited from Hevelius [Hevelii]. p. 192

14. Observations concerning the mobility of the Poles, or of the Nodes;

[Continuation of Chapter 14 from the foot of the previous column:] now treating of the motion in Longitude, the section being counted from the True Equinox.

of the Lunar libration from the year 1649 to 1656. p. 192

15. A judgment concerning the aforesaid mobility of the poles, from the foregoing observations. p. 199

16. Selected recent observations of Father Francesco Maria Grimaldi [P. Franc. Maria Grimaldi] concerning the limits of the Lunar libration, from the year 1651 to 1656. By a re-examined Table of Hevelius [Hevelij] exhibiting the maximum Libration of the Mare Crisium [Maris Crisium] at the individual Months of this whole period. p. 199

BOOK FOUR.

On the Fixed Stars.

1. On the observations of the Ancients concerning the Fixed Stars [Inerrantes Stellas], and on the manner of observing them. p. 201
2. On the Stars on the same straight line, both of old and as more recently observed. p. 203
3. The Declinations of the Fixed Stars, or their distance from the Pole of the World, observed down to the time of Tycho exclusively, with a critique of them. p. 203
4. The Longitudes and Latitudes of the Fixed Stars, selected from observations down to the time of Claudius Ptolemy [Claudij Ptolemæi] exclusively, with a critique of them. p. 206
5. The Longitudes and Latitudes of the Fixed Stars observed, set in order from the time of Ptolemy exclusively down to the Hessian [Hassiacas] and Tychonic observations exclusively. p. 215

6. On the places of the Fixed Stars observed by Wilhelm, Landgrave of Hesse [Vuilhelmo Lantgravio Hassiae], and by his Astronomers. p. 217
7. On the observations of Tycho Brahe [Tychonis Brahe], especially concerning the Fixed Stars, and on their certainty, order, and the Method of reforming them. p. 218
8. On the Great Table of Distances, by which the Fixed Stars are distant among themselves; its order and use. p. 219
9. We recall to four Classes the Tychonic Declinations of the Fixed Stars. The first of them is that which Tycho — or Tycho alone, or Tycho of Uraniborg [Vraniburgi], and Paul Hainzel [Paulus Hainzelius] near Augsburg of the Vindelici [Augustam Vindelicorum], where the altitude of Tycho's Pole was $48^{\circ} 22'$ — already began to observe in the year 1572, complete, and in 1573, from the very beginning. But you may see those for the other 4 years in the *Progymnasmata* [Progymn.] vol., on pages 361 and 369; where he has them also for 4 other years. The observations of the Pole Star [Stellae Polaris] at a distance from the Pole. p. 228
10. The Right Ascension of the Lucida of Aries [lucidae Arietis] by Tycho, completed, exquisitely examined, and emended, down to the year 1585. p. 234
11. Seven other Fixed Stars' Tychonic Right Ascensions are corrected; and what is to be done with the rest. And on the omission of those whose Right Ascension they neglect to determine by the Tychonic method. p. 236
12. On the Longitude and Latitude of the Fixed Stars to be emended by the Tychonic method; likewise on their motion in longitude. p. 238
13. On the Observations of the Fixed Stars after Tycho, down to our own, exclusively. p. 241
14. On Our own observations concerning the Fixed Stars, and first concerning the Altitude of the Pole, most subtly and most exactly observed at Bologna, as the Foundation of the Declinations. p. 244
15. On the remaining instruments by which we have observed the Fixed Stars, compared with the Tychonic ones. p. 246

Index of Books and Chapters (continued)

The detailed Index of Books and Chapters concludes on this opening (Books IV–X chapter listings with their body page-references). The Prolegomena ad Astronomiam Reformatam then begins.

[left column]

Book IV (Fixed Stars), chapters continuing:

Ch.	Title	Page
16	On the Declinations of the Fixed Stars observed by Us.	248
17	On the Right Ascension of 62 Fixed Stars, deduced from Our more recent observations and brought down to the end of the year of Christ 1660.	251
18	On the Longitude and Latitude of the Fixed Stars from Our observations.	254
19	On the motion of the Fixed Stars in longitude, and on its Quantity and Uniformity.	254
20	On the Sidereal Year, and on the Apocatastasis [apocatastasis], or Revolution of the Fixed Stars, and their position from the beginning of the World.	259
21	I. Table of the Right Ascension and Declination of a hundred Fixed Stars computed for the years of Christ written below, with the difference of the same.	260
—	Catalogue of the Fixed Stars with Longitude and Latitude.	255

LIBER QUINTUS [Book Five] — De Saturno [On Saturn]

Ch.	Title	Page
1	Ancient observations of Saturn from the Year 229 before Christ down to the Year 1481.	280
2	Observations of Saturn made at Nuremberg by Bernhard Walther of Nuremberg, disciple of Johannes Regiomontanus, from the Year of Christ 1475 down to 1504.	281
3	Observations of Saturn by Copernicus, Pitati [Pietro Pitati], Ristori [Julian Ristori], and Giuntini [Francesco Giuntini], from the Year 1514 to 1563.	282

Ch.	Title	Page
4	Tychonic observations of Saturn, in which the days are noted by the style of the old Calendar.	283
5	Observations of Saturn by Jost Bürgi from the Hessian observations of Snel, and also by Lansbergen, Hortensius, Gassendi, and Boulliau, from the Year 1592 to 1640.	284
6	Observations of Saturn near Perigee of the Eccentric made — the greater part — by Vicenç Mut [Vincentius Mutus], a most expert Astronomer, recorded by days of the new style, in months, and around the ninth hour after midday, and most liberally communicated to us by letter, together with the place of Saturn deduced from observation and from a fivefold calculation.	285
7	Observations 2 of Tycho and 4 of the Jesuit Fathers at Innsbruck [Oeniponti], and 22 of the Marquis Cornelio Malvasia [Marchio Cornelius Maluasia] made at Modena [Mutina].	285
8	Selected observations of Saturn from many made at Bologna [Bononiae] by the Jesuit Fathers Giovanni Battista Riccioli and Francesco Maria Grimaldi together with others, likewise, where it was needful, with the help of fellow members of the Society.	287
9	The various ways of observing Saturn and the places of the remaining minor Planets are set out, so that the observation may be made with care and certainty of judgment.	289
10	On the limits of certainty, within which the places of Saturn could be represented up to now, or can be in the future, both through observations and through Astronomical Tables, and on their difference.	294
11	Selected places of Saturn from the preceding observations, and collated with the places computed through the more celebrated Tables.	296
12	On the Hypothesis and Theory of the motions of the five Minor Planets, whether Geometric or Arithmetic.	—

[right column]

[continuation of Book V, ch. 12:] ...and especially of Saturn. Where, of the profit made in this Astronomy, and of the defect still lying hidden in it. p. 300

LIBER SEXTUS [Book Six] — De Iove [On Jupiter]

Ch.	Title	Page
1	Ancient observations of Jupiter from the Year 241 before Christ down to the same Year 807.	303
2	Observations of Jupiter made by Johannes Regiomontanus and Bernhard Walther from the Year of Christ 1471 to 1504.	304
3	Copernican observations of Jupiter from the Years of Christ 1520 to 1530.	305
4	Tychonic observations of Jupiter.	305
5	Observations of Jupiter made by Jost Bürgi, Organist to the Landgrave of Hesse, selected from the Hessian observations of Snel, with the Keplerian and Longomontanic observations.	307
6	Observations of Jupiter made by Pierre Gassendi, Ismaël Boulliau, Martin Hortensius, Philips van Lansbergen, Johannes Hevelius, and Vicenç Mut, from the Year of Christ 1620 to 1650.	307
7	Appendix of observations of Jupiter from the Tychonics lately published at Vienna, from the press of David Haut [Daudis Hautij], whence we selected a few, by the favour of the Author and of Urania, and for the Society of Jesus at Innsbruck.	309
8	Selected observations of Jupiter from those which the Jesuit Fathers Giovanni Battista Riccioli and Francesco Maria Grimaldi carried out at the College of St. Lucia at Bologna, together with other fellows of the same Society, and the Observations 19 of the Marquis Cornelio Malvasia.	310
9	On the choice of Observations concerning Jupiter, and a specimen of calculation from Our Tables computed.	313
10	On the Arithmetic and Geometric Hypothesis of the motions of Jupiter.	315

LIBER SEPTIMUS [Book Seven] — De Marte [On Mars]

Ch.	Title	Page
1	Ancient observations of Mars from the Year 357 before Christ down to the Year of Christ 509.	316
2	Observations of Mars from the little work of observations of Johannes Regiomontanus.	317
3	Observations of Mars made at Nuremberg by Bernhard Walther from the Year 1475 to that of Christ 1504.	317
4	Copernican observations of Mars.	319
5	Tychonic observations of Mars from the Year of Christ 1580 down to 1601, marked by days of the old style, and at Frauenburg [Vranburg], unless otherwise added, and at hours after midday.	319
6	Observations of Mars made by Jost Bürgi, Longomontanus, Kepler, Fabricius [David Fabricius], and Gellio Sascheride [Gellius Sascrides], from the Year 1590 to 1613.	321
7	Observations of Mars made by Pierre Gassendi, Martin Hortensius, Michele Florenzio [Michael Florent van Langren], and Vicenç Mut, from the Year 1621, and by the Jesuit Fathers at Ingolstadt and Innsbruck.	322
8	Selected observations of Mars from several made at Bologna in...	

[left column]

[continuation of Book VII, ch. 8:] ...the College of St. Lucia, carried out by the Society of Jesus Fathers Giovanni Battista Riccioli and Francesco Maria Grimaldi, and at Modena [Mutina] by the Marquis Cornelio Malvasia. p. 324

Ch.	Title	Page
9	On the Astronomical Tables to be checked against the selected observations made concerning Mars.	326
10	On the Arithmetic and Geometric Hypothesis of the motions of Mars.	327

LIBER OCTAVUS [Book Eight] — De Venere [On Venus]

Ch.	Title	Page
1	Ancient observations of Venus from the Year 272 before Christ down to the Year of Christ 510.	329
2	Observations of Venus made by Johannes Regiomontanus.	330
3	Selected observations of Venus from the observations of Bernhard Walther of Nuremberg made.	330
4	Copernicus' observations of Venus.	331
5	Tychonic observations from the Year 1582 to 1601.	331
6	Observations of Venus by Maestlin [Michael Mästlin], Kepler, and Jost Bürgi, selected from the Hessian observations of Snel.	333
7	Observations of Venus made by Hortensius, Pierre Gassendi, P. Andreas Arzet, and Vicenç Mut, and by the Jesuit Society Fathers at Ingolstadt and Innsbruck.	334
8	Selected observations of Venus from many at Bologna, completed in the College of St. Lucia by the Jesuit Fathers Giovanni Battista Riccioli and Francesco Maria Grimaldi of the Society of Jesus, and made at Modena by the Marquis Cornelio Malvasia.	336
9	On the Hypothesis of the motions of Venus.	340

LIBER NONUS [Book Nine] — De Mercurio [On Mercury]

Ch.	Title	Page
1	Ancient observations from the Year 265 before Christ down to the Year of Christ 807.	342

[right column]

[continuation of Book IX:]

Ch.	Title	Page
2	Observations of Mercury made by Bernhard Walther at Nuremberg.	344
3	Tychonic observations of Mercury.	344
4	Observations of Mercury by Longomontanus, Kepler, Jost	347

Ch.	Title	Page
	Bürgi, Hortensius, and Boulliau, from the Year 1593 to 1631.	
5	Observations of Mercury made by Pierre Gassendi, and by the Jesuit Society Fathers at Ingolstadt and Innsbruck.	348
6	Selected observations of Mercury from those which the Society of Jesus Fathers Giovanni Battista Riccioli and Francesco Maria Grimaldi completed at Bologna in the College of St. Lucia, with their assistants.	349
7	On the Hypothesis of the motions of Mercury.	351

**LIBER DECIMUS [Book Ten] — In quo Paralipomena Observationum
[In which are the Supplementary Matters of Observations]**

Ch.	Title	Page
1	On the Ways of observing the Diameters of the Fixed Stars and Planets.	353
2	On the apparent Diameter of Saturn.	354
3	On the apparent Diameter of Jupiter.	355
4	On the apparent Diameter of Mars.	357
5	On the apparent Diameter of Venus.	357
6	On the apparent Diameter of Mercury.	358
7	A Synopsis of Opinions on the apparent Diameters of the Minor Planets.	358
8	On the apparent Diameter of the Fixed Stars.	359
9	On the Figure of Saturn, its Bands [Fasciae], Companions, and their position, with respect to the Equator, or Ecliptic.	360
10	On the Figure of Jupiter, its Bands, their Parallelism to the Ecliptic, and its Satellites.	368
11	On the Figure of Mars.	372
12	On the Figure of Venus.	372
13	On the Figure of Mercury.	373
14	On the Whirling [Vertigo] of the Planets about their own centre.	373
15	On the distances of the Planets from the Earth, and from the Sun, and where also of the Fixed Stars.	373

[Prolegomena begins]

The Index ends; the body text proper begins here. The first body running headers and the body's own page numbering (p. 1) commence on this page.

PROLEGOMENA AD ASTRONOMIAM REFORMATAM

[Prolegomena to the Reformed Astronomy]

In which is set out the System of the World together with the Hypotheses of the First and Second Movable Sphere [Primi, & Secundi Mobilis]; and the Author's endeavour in advancing Astronomy and Cosmography; and finally certain Conclusions are established, by which things hitherto certain are distinguished from things uncertain.

QUANTO progress the Astronomy preceding our own age has made — both by eyes raised to the Heaven, and afterward by Telescopes erected at the common Observatory — so that, as if crowned the natural Queen of the Sciences, it now seems to have at last lifted its head, and from that height to have illuminated whatever nearly all mortals previously either did not see, or lay hidden from them, or had revealed itself to them only by a grudging light: all this is established partly from what is indicated further below, partly from the Preface to the Reader of Tome 1 of the *Almagestum Novum* [*New Almagest*]. Nor, moreover, can this be unknown, except to those to whose knowledge the most distinguished works of the most learned Men in this kind have not come — I mean of Copernicus, Tycho [Tycho Brahe], Longomontanus, Kepler, Lansbergen, Galileo [Galileo Galilei], Magi-

ni [Giovanni Antonio Magini], Scheiner [Christoph Scheiner], Petavius [Denis Pétau], Simon Mayr [Simon Marius], Chiaramonti [Scipione Chiaramonti], Snel [Willebrord Snel], Stevin [Simon Stevin], Wendelen [Govaert Wendelen], Michael Florent van Langren [Michael Florent van Langren], Hevelius [Johannes Hevelius], Gassendi, Boulliau [Ismaël Boulliau], Hérigone [Pierre Hérigone], Morin [Jean-Baptiste Morin], Mersenne [Marin Mersenne], Anton Maria de Rheita [Anton Maria Schyrleus of Rheita], Vincenzo Renieri [Vincentius Reinerus], Johannes Phocylides [Johannes Phocylides Holwarda], Giovanni Battista Odierna [Io. Bapt. Hodierna], Elias à Leonibus [Elias de Leon] [?], and Maria Cunitia [Maria Cunitz], Vicenç Mut [Vincentius Mutus], Eichstad [Lorenz Eichstad], Lineamann [?], Huygens [Christiaan Huygens]; and of many others, whom — lest

I become too long-winded — I am willing, without doing them injury, to leave unnamed; and of Father Francesco Maria Grimaldi, by whose endeavours and discoveries this contribution has been brought together, and from these and from other selected, corrective theses, in our Hypotheses, suppose what concerns the Mundane System, and the things in Astronomy that are certain, and the things still uncertain — that we may reckon them, not unpleasantly to the Reader (as we judge), more briefly yet distinctly — we will set forth beforehand.

ARTICLE I.

On the Creation of the World and the Work of the Six Divine Days, insofar as it bears on establishing his System.

I have dealt with this at sufficient length in Book 9 of the *New Almagest* [*Almagestum Novum*]. The opinions of the learned can be looked up there; here I take up the matter only briefly, drawing chiefly from Sacred Scripture, from the Book of Genesis.

I suppose that at the beginning of time, in one and the same instant, God created Heaven and Earth — that is, the Heaven of Heavens, which is the Empyrean, and the Heaven of the waters, which was made after the Empyrean above [supremum]; and this was done in the work of the second day, as is indicated, where it is said: *the firmament, which divided the waters that were under the firmament from those that were above the firmament*. From this it is supposed that before these waters there already existed Heaven, and therefore that there was no further thing created by Moses before the third day. And so it follows that *Earth* must be understood here also as Elemental Water, or perhaps as the whole of the elemental sphere — that is, the Heaven of the waters, of that same lowest species, whose elemental, or of that same kind, is in the first instant. Since, therefore, in the first instant God created the two extremes of the world — Heaven as the highest roof [tectum supremum], and Earth with Water as the lowest base [infimam basim] — as the foundation, and there was as yet no Star, and therefore the fourth day had not yet been created; let us acknowledge that Copernicus, against the order of things, set down a contrary teaching to that handed down to us by Moses, placing the Earth among the Heaven, the Sun, and the center, asserting it; and that he placed the Earth in the middle, or among the wandering Stars, that is, the Planets. But that light, which arose not in the first instant, if indeed it arose then, was nevertheless still *darkness over the face of the abyss* [tenebræ erant super faciem abyssi], yet a little later, once created — namely, propagated by some successive propagation, or by the motion around

the terraqueous globe — produced the first equinoctial day. And the First Movable [Primum Mobile], by that same motion, brought it about, provided that what afterward was the Sun, by its Diurnal motion — that motion, I say, which then illuminated that Hemisphere of the World in whose middle was either Paradise itself, or the Terrestrial Palestine, the dwelling-place of the first Parents, or of the second Adam. And so God divided the light from the darkness; and the hours of the whole terraqueous globe's surface would have enjoyed the light for twelve hours, and the rest would have lacked it for twelve hours, save for that particular portion of the first day in which the darkness over the whole face of the abyss extended. But it remains uncertain to us whether that light, having arisen at the Horizon from the East, or from the Meridian of Paradise, or of Palestine, can be understood only in this way: *and there was evening, and there was morning* [Factum est vespere, & mane dies unus]. Taken in a figurative manner of speaking, the whole, principally that part, primarily holds the space of time, and of the Day at the meridian. Since the evening twilight of some time is taken either for the future, or already accomplished setting of the Sun; or for the time after midnight already accomplished, before which the Sun can ascend toward our Horizon. Finally, after this men can derive their light not from the necessity itself, and from another at the Sun, or from the Stars; nor likewise so much before all the Stars, when they were independently created. And by this cause, light created, except in that it happens, it is not a body; as it is subject, it lies between Heaven, or the terraqueous mass intervening — there is rather a Vacuum, than that a body should intervene, either airy or watery; nor is it to be thought essentially to depend upon the subject, so that it would stand fast; for already from the beginning, without an intervening Heaven, the light of the heavenly bodies could be both produced and sustained by God alone.

[Margin: 2. *De opere diei* 2.] As for the work of the second day, Moses speaks thus: *God also said: Let there be a firmament made in the midst of the waters, and let it divide the waters from the waters. And God made the firmament, and divided the waters that were under the firmament from those that were above the firmament; and it was so. And God called the firmament Heaven; and it was made evening and morning, the second day.* The word "Firmament" [*Firmamentum*] in Hebrew signifies the *expansum* [the expanse]; and *solidatum* [made solid]. So now let me say that the whole space from the Earth up to the highest Heaven was first filled with a homogeneous water; but on the second day part of this water, left above the Earth, was made thin [extenuatam], and part rarefied into Aethereal air, and finally part condensed into crystalline Heaven, because not a few say: first our mind shrinks from so great a vastness, and from so great a condensation, that the rays of the light of the first Heaven [primigeniæ], and of the Fixed stars in the

firmament, in propagating their rays, would be drawn apart through a manifold refraction. Then, if there were one water, continued from Earth all the way up to Heaven, and properly speaking certain waters would be said to be under the firmament, that is, under that place where afterward the firmament was made, indeed under that place; and certain waters truly under the firmament. But if we say that on the first day the heavenly waters circumterraneous were created, and the heavenly waters were created as the airy Heaven and the aetherial, on the second day; that the Heaven was created aetherial, distinct, and admitted, since it primarily contradicts the fluidity of the Planetary Heaven, which is plain from Comets, and from the wandering Planets, and from the common recession of the motions, the Parts conform to opinion: we choose: then, when from all the other days some body was made of nothing, just as on the first day Heaven, Water, and Earth; on the third day, the Planets; on the fourth, all the Stars; on the fifth, the Fishes and Birds; on the sixth, the Quadrupeds, and Man; the second day alone is without any new production of a body, but is highly incongruous. But if we say that the whole of that space was first vacuum, and afterward a positive disposition, with the inferior World not yet existing, so that there would be a continuous Heaven; on the second day, however, the virtue of those bodies created, but the strength of those things not yet produced into Stars, and of the living bodies; on the second day, whether from nothing, or from the water of either matter, would produce a Fixed star in the firmament, or the Hebraic *Rakia*, that is, *Expansum solidum* [the solid Expanse], we have said, both because that part, in which the Fixed stars were collocated, properly to be solidified with hardness, was accepted, then because the remaining part, which the Planets by their wanderings, and some Comets permeate, ought nevertheless to be future and exist; and immovable, nor as tending to transfer the Planets, or Comets; but as some firm bulwark superior, and inferior to remain — These things, I say, do not move; let it be granted that all these difficulties weigh against the prior opinion adduced, and to the inquirer what meanwhile may intercede the prime water of the superior, and inferior waters, it will be answered with Moses: *the Spirit of God moved over the waters* [Spiritus Domini superferebatur aquis], that is, the spiritual substance of the Deity within, and above either of the waters was; filling that immense vacuum within the waters, and by its immensity filling the inestimable Heaven; whom indeed truly to satisfy with the nature of these opinions is not easy to think out, though also of another literal sound it agrees more closely with Sacred Genesis, and with verisimilitude.

[Margin: 3.] As for the work of the third day, this has many difficulties: For what is said — *Let the waters that are under the Heaven be gathered together into one place, and let the dry land appear; and it was so. And God called the dry land Earth;*

*and the gatherings together of the waters he called Seas [Maria] — is set forth with the greatest verisimilitude: namely either that beforehand, at the first surface of the terrestrial part, the mountains rose up; or that on the third day, they were arranged, that the surface of the Sea exactly intervened, or the Earth — they intervened equally with motions excavated; or that, intervening, the springs of the mountains, and the hills, and within the viscera of the Earth, item the holes dug out, a good part of the water hidden away of the rivers of springs, and floods, refluxes, marine, or the whirlpool of the vortices varying. Nevertheless, not by local motion alone was the work of this day accomplished, as some thought, but God added: *Let the Earth bring forth the green herb, and so on*; and so all plants, and the fruit-bearing wood, without delay of seed, were brought forth,*

[Margin: 4.] On the fourth day, however, God did not say: *Let the Heaven, or the Firmament bring forth*, as he had said on the third: *Let the Earth bring forth*; and afterward he said with the waters: *Let the waters bring forth the creeping creature, and so on*. But he did say: *Let there be Lights made in the Firmament of Heaven, and so on*: he willed indeed these things wholly to depend from his own concourse divine, nor again to assume an occasion of seizing the opinion of those who divinely, or by powers fatal in this inferior thing — unless I have said Light, which through tubes [tubus] on the preceding days was seen, not as a body but as the bodies of the preceding days, has changed by vicissitude; that no body was, because it was scattered in the Sun, as the Stars, by no accidents of bodies the Stars communicated something either of its destruction, or of being destroyed, are given to be in the Sun, and to the Stars; the powers being produced in propagating; light. By whichever of these modes God used, it is certain to be against this sacred text, to assert any Star, or light to have been produced out of the Planets out of God on the fourth day, and therefore the Earth, which was produced in the principle of the first day, was not one of the Planets. Nor have I said the Earth was not from the beginning, nor was the name of Star, because it was not yet created the Sun, nor could it receive light from it, nor perform the office of an illuminator; especially in the waters covered, *Quia* in actual illumination, otherwise when the Moon does not consist in actual illumination, or in a New Moon, or in the Full Moon, by a total eclipse it does not illuminate the Earth, and may meanwhile be a Planet, and could the Sun, as the Stars, lest a substance had been the prime day, or on the second produced under the name of Heaven, but not had been a Star, before it received an illuminating illumination, and what is against it which Moses subjected. *And he set them in the firmament of Heaven* [Et posuit eas in firmamento Cæli]: for that *Fiant, & Posuit* [Let them be made, and He set], at once signify a new production in the office of illuminating. Then the Earth, although covered with waters, was able to receive light

primordially as in a great mirror to reflect it, and much more on the third day appeared the dry land, and so it has the name of Star. But that you may say: it cannot be a Star, because it was not a globe of light, which would illuminate it, nor a Planet, because before the fourth day it was not moved around the annual orb: a Planet is denied by this, that no motion of translation was in Copernicus, ah but rather if the Earth alone has a daily rotation around its axis, it would be moved, in so far as the Moon near the New Moon illuminates that side, by the reflexes of the Sun's rays, that you should say a Planet. But I conclude from this: the Earth on the fourth day from the seat illustrated, fitted; and to illuminate the Moon, and by means of the annual orb it was bound to be called a Light [Luminare], and indeed greater, the Moon though less than the Sun, but in mass, and in the power of illuminating the Moon, from the greater surface reflecting many more rays much greater than the Moon, and so the three out of the two Lights God made. Lastly, you must say, although the Earth is thus moved around the Sun, nor is it moved even with respect to the Moon, and this in turn at fixed days illuminating, nor merits the name of a Light, because God assigned only the Light, which he ordained to illuminate the Earth, as is fitting for Men, beasts, plants prepared, and to distinguish day from night, and the months, and the years, which men were to use: as is plain from Sacred Genesis saying: *Let there be Lights made in the Firmament of Heaven, and let them divide day and night, and let them be for Signs, and seasons, and days, and years; and let them shine in the Firmament of Heaven, and illuminate the Earth* [Fiant Luminaria in Firmamento Cæli, & dividant diem, ac noctem, & sint in Signa, & tempora, & dies, & annos, & illuminent Terram]; with which agree those words of Deuteronomy 4: *Lest perhaps, lifting up your eyes to Heaven, you see the Sun, and the Moon, and all the stars of Heaven, and being deceived by error you adore them, and worship those things which the Lord your God created for the service of all the nations that are under Heaven* [Ne forte elevatis oculis ad Cælum, videas Solem, & Lunam, & omnia astra Cæli, & errore decepti adores ea, & colas quæ creavit Dominus DEVS tuus in ministerium cunctis gentibus, quæ sub Cælo sunt].

I freely grant for this reason that the Earth is not to be ranked among the Lights, although it is in the Copernican hypothesis that the Earth is a Planet, and an erratic Star, and indeed so, with its own atmosphere as in the Planetary Heaven, more remote from the center of the World than Mercury, Venus, and Mars in their perigee, and yet, in the Acronychal position, that is, in a higher Heaven, or in the Planetary part of Heaven, it would truly be said to be set, if not on the first day, at least on the fourth in the Firmament of Heaven. For what concerns the two Lights, and the Stars, Sacred Genesis says: *and let them shine in the Firmament of Heaven, that they may give light upon the Earth, and that they may*

rule over the day and the night, and divide the light, and the darkness

[Luminaribus duobus, & Stellis dicat Sacra Genesis: & posuit eas in Firmamento Cæli, ut lucerent super terram, & præessent diei, ac nocti, & dividerent lucem, ac tenebras]. But the Earth is not among the heavenly bodies which have themselves under the Heaven. And if indeed philosophically the Copernican Earth could be said to be under the Heaven, and in Heaven; this very thing nevertheless by a diverse relation is shown: all the Planets are under the Heaven more remote from the center of the Earth, the Planets, and the Fixed stars themselves are under the supreme Heaven; so absolutely speaking, the Earth is under the Heaven, and all the Stars are in Heaven, which truly cannot be said except by some peculiar manner of speech, as the place of the Earth is given, since it is not exactly its peculiar place, namely, the center of the World. Besides which it is highly incongruous, and because the Stars themselves were created in the ministry [ministerium] for all the nations, which are under Heaven, those very nations with the Earth circumambulate around their own ministries, emending [their courses] from those very lights, and influx, but it is rather right that the ministers, and chiefly the Sun, around the Earth quiet, and immovable, ought to be moved, and to perform the ministry, which to those God enjoined.

[Margin: 5.] The remaining works of the fifth and sixth days, and the constitution of the System of our world, need no inquiries, in what way these things have been said about it up to now; we suppose that there was no violence in any of them, or by the dissimilitude of the very sound of the letter understood; and by no necessity intercede, in another way to be understood; we suppose the Earth, or the terraqueous globe to be in the center of the World, without any annual motion, but excluding chiefly the annual; but above the Elemental Sphere truly, to be the Planetary Heaven, permeable indeed by the Planets, but immovable, and firm, although by no motion of its whole, nor any part circumvolved, and on this account it merits the name of Firmament; the Fixed stars truly to be in the probable Sphere solid, and impermeable; and on this account the Fixed stars themselves to be by perpetual figures of the stars, both as distant among themselves continuous; and likewise it is easier, and a motion of the whole sphere of its own, that all things be moved; whether that Heaven be Aqueous, created on the first day, and afterward consolidated, whether also distinguished. But if any Stars newly seen, and not begotten in the Planetary Heaven, should descend below Saturn the Comets, so as, when they have evaded the sight, since they are partaken in the Firmament of the Fixed stars they do not appear, nor are begotten, id non fine portent, and by some miracle made indelible by that divine virtue penetrating to be solidified the Sphere; let it be granted. Furthermore, to be explained, and of what may be prematurely about the bodies of the First Movable

[Primum Mobile], by whose motion is accomplished the daily revolution of all the Stars in twenty-four hours, or thereabouts, or at least the apparent motion of this is safe.

ARTICLE II.

On the First Movable [De Primo Mobili].

[Margin: 1.] The ancient Astronomers, excepting certain Pythagoreans, in order to reconcile the apparent motion of all the heavenly bodies from East to West, by the apparent proper motion, by which all the Stars likewise from the East gradually toward the West tend to bend, above the Fixed Sphere supposed a single Sphere — that one greater than the rest — which carried off the Fixed Sphere; and all the others contiguous to it, and solid, from their rising in the East are moved into contrary parts; this very thing, which it grants to be a distinct body, contained continuously: by this very thing, indeed, that the inferior sphere can be carried off toward the West, so that nevertheless it is not allowed to be carried off by some [motion], resisting somewhat, and the motion of the First Movable [Primi Mobilis] by contending, not so quickly is it revolved toward the same Meridian, as quickly as it had arrived,

[Margin: 2.] but indeed Nicetas of Syracuse, Heraclides, and Ecphantus the Pythagorean, and Seleucus; but afterward William Gilbert [Gulielmus Gilbertus], Origanus [Origanus], Longomontanus [Longomontanus], Argolus [Andrea Argoli], and Wilhelm Langius [Vuillelmus Langius], judged the Earth to be in the middle of the World, turning around its center by a daily revolution toward the East, and accordingly to be made, and meeting the Fixed Stars, and the Planets, immovable, in a gentle motion; or because they thought the velocity of the daily motion incredible in the Sphere of the Fixed stars, or whether the Planetary Heaven of fluids alternating they thought that ineptitude unfit to take up the Planets, with a constant, and uniform motion. But Philolaus [Philolaus], Aristarchus of Samos [Aristarchus], Nicolaus Cardinal Cusanus [Nicholas of Cusa], Copernicus [Copernicus], Rheticus [Rheticus], Maestlin [Maestlinus], Kepler [Kepler], Galileo [Galileo Galilei], Lansbergen both [Lansbergius] (father and son), Boulliau [Bullialdus], Hérigone [Herigonius], Valentin Naibod [Valentinus Naibodus], Diego de Zúñiga [Calvus Calcagninus, Didacus à Zuniga], Paulus Antonius Foscarinus [Foscarini], Baranzano [Baranzano], Giordano Bruno [Iordanus Brunus], Renatus of Chartres [René Descartes], Hevelius [Io. Heuelius], Wilhelm Schickard [Vuillhelmus Schikardus], Martin Hortensius [Martinus Hortensius], Christoph Wittich [Christophorus Vuittichius], Daniel Lipstorp [Daniel Lipstorp],

Tommaso Campanella [Tommaso Campanella], Christiaan Huygens [Christianus Hugenus], and not a few others besides the daily motion [diurnum vertiginem], a translation also through the Annual Orb, of this around the Sun, attribute to the Earth, besides those motions said, a third motion, by which the axis of the Earth itself is librated, that is, in such a way that the equinoctial points may seem to be in the preceding [signs] toward the West, and so the Fixed stars to recede from them, and at the same time to change their declinations; nor to remain in another motion of the Planets in longitude, than its proper motion toward the East. Which being done, either feignedly, or really, they are the more freed, by feigning, and from the molestation of explicating the daily motion of the Planets, and the solid Sphere of the Fixed stars, and of so simple a position even of the Planets, the view being made, the hypothesis is most beautiful, and the elegance of novelty excited them into love of itself.

[Margin: 3.] But we, to whom not only by the decree of the Sacred Congregation [decreto Sacrae Congregationis], which I repeat from Book 9 of the *New Almagest*, section 4, chapter 40, it is to be obeyed; but also by Physico-mathematical evidence, by how much more from a higher place they fall, by so much greater [is] the percussion of falling weights, indeed proportional to the acceleration of the descent of falling [bodies], translated [hither] by Copernicus from our single line [linea unica], in a Copernican single hypothesis the acceleration cannot be real, or by some other proportionate fear of falling, translated also into the Copernican [system], cannot be real, or by some proportionate fear of falling [bodies], it is plain from things said in the same Book 9, section 4, chapter 19, and from things to be said here Book 1, *On the Sun* chapter 17, and in its Appendix. We, I say, compelled by necessity to explicate by the Reason of the Stars [Ratione Stellæ], that they all may seem to be moved by their proper motion, and slowly toward the East, and quickly toward the West, and in the space of twenty-four hours, or a little after midnight to be turned back to the same Meridian revolved. This perspicuously, and most easily we shall explicate in the Planets first.

[Margin: 4.] Let the Meridian of any place whatsoever be granted as first; the most celebrated, not Geographically for the Fortunate Isles, or the Azores transit, but through the vertical mediterraneum of Paradise terrestrial; or for Jerusalem; and the daily revolution of the Fixed stars from that very same Meridian assumed in the meantime for the exemplar of the First Movable [Primi Mobilis], differing only so little from the apparent rising toward the East, so that not in those after 365, it is repeated to be by Seconds 50" [50"]: And so let us observe the center of the Moon in the same first Meridian in which the Fixed Star Spica [Spica] was, just as Spica recedes from this Meridian, it is moved, not so much by the same

circle [per eundem circum], but by a spiral motion, and without sensible declining from the plane of that same circle, just as its Declination, or Latitude, postulates, it is moved; and at what moment Spica returns to the first Meridian, the center of the Moon will be by a slower motion encompassed,

[Margin: 5.] in the Equator, or in the parallel of the Equator it is distant from the first Meridian toward the East by 12, or 13 degrees, would it not appear observed; so that with a daily motion translated toward the West, so that meanwhile it may seem to have remained Oriental; whereas Spica, and therefore moved again toward the East, by degrees 12, or 13, which to absolve it ought before to arrive at the first Meridian; so indeed: and yet there are not two motions really diverse, much less contrary to themselves; but a single spiral motion always toward the West, as to Longitude toward the West; but much slower in motion than Spica, so that, as the center of the Moon daily persists in the Equator, or in the same parallel, where Spica absolves [its] degree 360, now after days 15, the future is in this Heaven, when Spica is in the highest of the first Meridian; and at degree 30, then Spica also returns with the center of the Moon in the same first Meridian. What I have said about the Moon, may be understood about all the other Planets with a double yet discrimination. First it is, that the Sun always indeed more slowly returns than Spica, when it has been once joined with it, but much more swiftly than the Moon; so that, as the Sun arrives at that very place toward the West, to the Sun alone a single about-degree is left over to be accomplished toward the West, and after the first day's arrival at the Meridian, but it is not nevertheless after days 365 in the same; with the same future the moment in the first Meridian. But the Planet, when it is slower than Spica, in its spiral motion, so much slower it is, by how much nearly its proper motion is its own toward the East. Secondly the discrimination is, that the Moon, and the Sun in their spiral motion always slower than Spica, or any Fixed star are. The remaining Planets however, for the most part, are slower than the Fixed stars, sometimes nevertheless equally swift, and then they are said to be Stationary, because, none being more Oriental, they appear by night, than yesterday; and at the same time return to the Fixed stars, and to the same Meridian. When however they are slower, so that they may seem Direct, supposing motion not appearing toward the East; and yet truly, supposing the single spiral motion toward the West, rather Retrograde, or Tardigrade [more slowly] to be said; and on the contrary when more swiftly they arrive at the same Meridian, [than] the same Fixed [star], suppose Spica, and these, arriving there, themselves are made more Westerly, they seem indeed Retrograde [cum Fixa eadem puta Spica], and are called Retrograde, or rather Atrograde, or Ocygrade [Ocygradi] to be said.

[Margin: 6.] As for the Western motion of the Fixed stars [Fixarum Motus Occidentem versus], if any other motion in them does not appear, than the motion of their declinations by Libration; that very [motion] is the motion of the First Movable [Primi Mobilis], and the measure of all the motions of the inferiors; and in the Equator, of its Parallels it appears. But by subtle observation indeed, and truly Hipparchus [Hipparchus], the Astronomers detected the points of the Equator, at which the Sun arrives, making the Equinox; to differ yearly by a great deal, in the preceding [signs] from the Fixed Star, which had been in them; or near that, indeed; they deduce the Fixed stars more, and more Oriental to be made, as if the Fixed [stars] themselves were moving, and turn toward the East; but Copernicus, who indulges no motion to the Fixed stars, attributes this apparent precession of the Equinoctial points made by the motion of the Earth annual, by libration, and the parallelism of the axis [parallelismo axis terrestris] not made about itself. But to us, who assert the Fixed stars to be moved toward the West daily, it lies upon us to explicate from what cause they may continually seem to tend by the slowest motion toward [rising] in the East, but oblique, and at the same time what the First Movable may be, of which the Type they imitate in the motion from the East and West; for which we shall propose more modes, but not equally probable, that we may choose the more probable ones.

[Margin: 7.] The first, and most ancient mode is, that above the Sphere of the Fixed stars there is another Sphere, suppose a Crystalline Heaven, which above the poles of the Equator is moved revolving on the same Meridian within 24 hours, carrying with it the median Sphere of the Fixed stars; and its poles, from the poles of the Equator distant 23 [degrees] 30' 30" [23° 30' 30"], but in the meantime let the Sphere of the Fixed stars above the poles of the Ecliptic [super polis Ecliptica] be moved insensibly contending toward [rising] in the East; for although the bodies are discrete, and distinct, this is not repugnant to the two motions among themselves. But if you should be unwilling that the whole Sphere should carry off the inferior [one],

lower one, it would suffice that its girdle be carried from the highest periphery of the equator up to that point. **The second mode** is this: if the sphere of the fixed stars is either not solid, or solid yet penetrable, then any given fixed star would move spiralwise toward the west, in the same manner we described in number 4 concerning the Sun, preserving for itself the proper variation of its declination. **The third mode** is this: if the sphere of the fixed stars were to move over the poles of the equator through a span of 24 hours, and at the same time were to be librated toward the poles in such a way as the increase (or decrease) of their declinations requires; while the Sun, however, very nearly retains that same

momentum by which it crosses the equator, so that it is not slower — nor would it move spiralwise so as to be more easterly than it had been a little before, but rather it would become westerly by just as much as the semiannual proper motion of the fixed stars amounts to, which seems to me to come very nearly to 25' 20". For on this account the Precession of the equinoctial points toward the west would be the cause, as the fixed stars, which once would have stood in the Colure of the equinoxes, become each year more easterly by 50' 40". One must beware, however, lest the motion of Libration be such as Joseph Scaliger [Joseph Justus Scaliger] imagined for himself, supposing that the fixed stars retain the same distance from the poles of the world. **The fourth mode** is this: if one admits that this same sphere of the fixed stars moves over the imaginary poles of the equator and over the poles of the ecliptic, whether by one or by two Intelligences, alternately intervening with insensible motions — so that, to put it at its least as far as concerns our measurement or the observation of a moment, by one motion in the third hour it moves toward the west by 30". For on this account the motion of the equator would arise; and in the second the diurnal motion toward the east, so that by the very first motion the whole motion toward the west would be absolutely abolished, which I reckon to be very nearly 8" 40"; nor is there danger here that the motions might be sensible, or at least insensible by reason of slowness, or that they might appear too easterly by reason of the sensibleness of the equator. **The fifth and final mode**, finally, is this: if one, or several, Intelligences move the sphere of the fixed stars toward the west, so that any given fixed star arrives at the meridian so much more slowly than the one preceding it, by as much as the diurnal motion of the fixed stars appears toward the east, which is 8" and very nearly 40", and at the same time they make the fixed stars decline from the equator of the world, just as it appears in fact that they decline.

For these three modes of the diurnal motion of the fixed stars, thought up by Copernicus to be vindicated for the Earth's annual and librational motion, can be represented either by the Earth or by the heavens; but they have not been subjected to the eyes, nor could more of them have been; or else, with the Earth at rest, the Intelligences may move the sphere of the fixed stars with such great dexterity and ingenuity that they may represent these three apparent motions. Certainly, if we could move the globe of the Bear-stars [the constellation] about a point, or move a little globe in the middle of the air itself, stable in its poles — and this little globe of Bear-stars were affixed to no body sustaining it in its poles, but as if held suspended free in the air — and could move it also in this manner, so that we might represent those motions to ourselves. Among the five aforesaid modes, the **fourth** and **fifth** seem to me the more probable, and the more becoming to the Intelligences that move the fixed stars.

ARTICLE III.

On the Hypothesis of the Planets, with respect to the Figure of their Motion in general.

It has long been known that the ancient astronomers, down to Kepler, attempted to explain the motions of the planets, their anomalies, and their *prosthaphaereses* [*prosthaphaereses*] through Eccentrics, Epicycles, or librating little circles — but not without errors, and indeed sometimes errors so enormous that, since the discrepancy from the celestial observations could not be resolved into faulty observations (as in the case of Mars, [where the discrepancy] sometimes [reached] 4 degrees, and in Mercury 7), the aberration persisted, until Johannes Kepler, having got wind of it, suspected that the Eccentricity of the planets ought to be bisected — that the center of the planetary orbit is not the center of the equal motions; for otherwise just equations would never come out right, whereas with the Eccentricity bisected, much more accurate ones do come forth. That is to say: if in the line of the apsides two points are placed on either side of the center, equidistant from it — of which let one be the Earth in the case of the Moon, or the Sun in the case of the other planets, and the other equally distant from the center, that is, distant by as much as is half of the whole Eccentricity — then this would be the center of the equal motions. From this he saw it to follow that not the whole inequality that appears in the motion of the planet is a real one, but that it appears partly from an Optical cause, namely because we are not at the center of the planetary orbit; for even if we were there, we would still see half of the inequality, and consequently also a real inequality, to be acknowledged by one looking upon the planet from the center of the orbit, physically. But since those two points, equidistant from the center, are more proper to an Ellipse than to a Circle — for in an Ellipse two foci, or two centers [*umbilici*] equidistant from the center, are given — he concluded that the way of the planets is not Circular, but Elliptical; and this appears more evidently in Mercury, Mars, and the Moon than in the others, because in the others the lesser diameter, or conjugate, is a little smaller than the greater diameter, and therefore the Ellipse departs not so sensibly from the roundness of a Circle. But Kepler, wholly intent upon assembling Physical and magnetic causes of the motions — ingenious figments, but not so necessary, or congruent — did not demonstrate by Geometric rigor the manner of describing the Ellipse fitting to each planet, nor did he deduce the *prosthaphaereses* exactly from it.

[2.] Those who have embraced Kepler's hypothesis of the Ellipse, ingeniously discovered by him, are every one of the finest astronomers, but above all Ismaël

Boulliau [Ismaël Boulliau] in his most learned *Astronomia Philolaica* [(*Astronomia Philolaica*, Boulliau)], books 1 and 11; Pierre Hérigone [Pierre Hérigone] in volume 6 of his *Cursus Mathematicus* [(*Cursus Mathematicus*, Hérigone)], page 140; Calverus [Caluerus] in his *Uranometria* [(*Uranometria*, Caluerus)], part 2, chapter 4; Seth Ward [Seth Ward], demonstrated in his *Idea Trigonometriae* — to which he subjoins an inquiry into the Foundations of Boulliau's Astronomy, and detects certain errors in Boulliau's use of the Ellipse, by which I know not how Boulliau cleared himself, since the work published on this matter has not come into my hands. Meanwhile, however, Ward delivers the manner of the Equations and of the Eccentricity in the Ellipse exactly, but in that little work he does not teach the manner of demonstrating the Aphelion; which afterward, having heard [of the difficulty], he taught in a little book dedicated to four Astronomers — namely to Boulliau himself, to Gassendi [Gassendi], to Hevelius [Johannes Hevelius], and to Me. Comes Paganus [Blaise de Pagan] likewise excellently elaborated this method through the Ellipse, as did also Giovanni Domenico Cassini [Giovanni Domenico Cassini]. But Vicenç Mut [Vicenç Mut] judges that the Equations of the Center, or of the First inequality, can be better deduced without Eccentricity, through two librations, as he indicated to me recently in a Letter. In the meantime, however, most suppose the simplest motion of the Earth (in the Copernican view) — and therefore the way of the planet — to be through an Ellipse, and as motion; and they reckon it [to go] toward the east; and that very [motion], by reason of its simplicity, is lovable and to be preferred: granted that Boulliau, book 1, resolves this motion into several circles.

[3.] And yet we, the immobility of the Earth having been demonstrated, and the fluidity of the Planetary Heaven nearly demonstrated, and therefore the motion of being carried off rejected — by which motion the Planet is snatched along by the supreme Movable [Primum Mobile], and attributed to each, so that each Planet, by its own diurnal motion toward the west, as we said in Article II, number 4 — we neither can nor ought to assign the way by which the Planet really moves through one simple figure described in one plane; but it must be considered by us as set forth not through one continuous line, but through a spiral line about a Cone, proper to each Planet. Nor only do we ascribe half of the Physically apparent inequality to the motion of the Planet, as recent Astronomy at length acknowledged, but we hold absolutely that it moves unequally — yet with a regulable inequality. But since GOD willed to accommodate these motions to our grasp, so that through a single figure in the same plane we might more easily investigate that motion which is really made through a spiral line — by us not so easily comprehensible, just as if the motion were made in that [single] figure —

He so ordained the spiral motion about the Cone, that it could be designated on its surface by a...

[Page VI]

[Elliptical periphery] more nearly approaching to the circular one in the Sun, Venus, Jupiter, and Saturn, but receding more from the circle in the rest of the Planets. And so in this we dissent from the recent Astronomers, because we employ the Elliptical way of the Planet, under a mere Hypothesis, for entering upon the calculation; whereas they suppose the real way of the Planet to be Elliptical, by which it moves continually toward the east, when in reality it moves toward the west. Nor, on account of the difficulty of comprehending and explaining that spiral motion, ought we to reject it, or to fear for ourselves Kepler's censure — Kepler, who was also undermining the foundations which he himself had invented, [foundations] which with his whole apparatus he had attempted to overthrow.

ARTICLE IV.

On the Distances and Intervals of the Planets, in complement of the System of the World.

[1.] The distance of the Planets, whether from the Sun or from the Earth, is usually expressed by two kinds of measure: one by such parts as the semidiameter of the Sun's Annual Orb, or of the Earth, may have been taken as a unit, together with five or seven ciphers — namely 100000, or 10000000; the other by the semidiameters of the Earth. As to the first kind — the distance of the Planets from the Sun, and from the Earth — these are very nearly close to the truth, now repeated after Copernicus, if we speak of the five lesser Planets, which move about the Sun; for an interval of this kind is gathered together from the Anomaly, Eccentricity, and Equations; and therefore how certain these three elements are, so certain are the intervals, having a necessary connection with them. On the contrary, however, most uncertain is the interval of the Fixed stars from the Sun and from the Earth, as to either kind of measure. As to the distance of the Sun, again, with respect to the semidiameters of the Earth, opinions have hitherto been diverse, whether it be finite, or certainly knowable, or whether infinite. Hence it comes about that the distance of the Moon from the Earth, or from the Sun, does not seem able to be known with certainty as to the first kind of measure, nor as to the second; granted that the distance of the Moon from the Earth, as to the second kind of measure — that is, in semidiameters — is commonly held to be knowable through its parallaxes, [parallaxes] very sensible

and great. But this very thing some have called into doubt, doubting lest perhaps the Refractions of our Air be so great that they suppose a much greater Parallax than that which becomes known to us through observations of altitudes; and accordingly the Moon may be much nearer to the Earth than it has hitherto been reckoned by Astronomers. And because, for the lunar distance, we have a work to be undertaken in inquiring into the Sun's distance, and thence the distances of the remaining Planets — to be reckoned as beginning from the lunar, and to be vindicated — let us free Astronomy from this scruple, which we know to have been done by no one.

On the Distance of the Moon.

[2.] In book 10 of the *New Almagest* [(*Almagestum Novum*)], section 5, therefore, we have treated diffusely the Parallaxes, their doctrine, the Theorems, and the Problems — partly of others, partly devised by us — and at chapter 11, problem 73, we inquired how great the maximum Lunar parallax could be supposed to be, besides that which the recent Astronomers have laid down, but compared with an equal refraction; and we concluded that, even if the Lunar Refraction of a ray from the Aether, or from purest Air into denser Air, were as great as is the Refraction from Water into Glass, at an equal distance of the Moon from the vertex — say at a distance of the Moon from the vertex of 10 degrees — it could not produce a Refraction greater than 30'. Now Tycho [Tycho Brahe], at such a distance of the Moon from the vertex, observed no sensible Refraction; [continues, p. VI right column] but there, with so great a Refraction compensating the parallax, the distance of the Moon from the Earth would be 20 semidiameters of the Earth, granted so great a parallax. Now it is certainly established that, at that distance, the Parallax and Refraction from the vertex are smaller; by as much as the Refraction from Aether into Air is smaller than that from Water into Glass, by so much is it certain that the distance of the Moon from the Earth is much greater than 20 semidiameters of the Earth; and by as much as the difference of densities between Air and Aether is smaller — than the difference between Air and Water — by so much is the augmentation of the Parallax, derivable from the hidden Refraction, less; that is, the defect compensating the parallax. And just as the Refraction of 30' from water to glass, observed by Witelo [Witelo], bears no proportion to the Refraction observed by Tycho, so there is no sensible augmentation, [such] that, on account of a hidden Refraction, the Parallax could be deduced [larger] in the customary ways. It is worthwhile, nevertheless, to see the whole of that chapter, problems 73 and 74, and likewise chapter 12 of that Section. This scruple of Refractions having therefore been removed, it is established from observations of the Altitude of the Moon, seen and

true, that the Lunar distance from the center of the Earth at the Syzygies is never found to be greater than $72\frac{1}{2}$ semidiameters of the Earth, nor less than 52, as I taught in book 4 of the *New Almagest*, chapter 15. And from what has been said there, and afterward corrected in this Volume, book 3, the distance of the Moon at the Conjunctions [Copulis] is at minimum 58' 21", and at maximum 63' 40", in semidiameters of the Earth, from our own observations at any rate.

On the Distance of the Sun from the Earth.

[3.] With how much greater effort and industry than any of the Astronomers, We, together with Father Grimaldi [Francesco Maria Grimaldi], investigated the distance of the Sun from the Earth — not by the most fallacious method of Lunar Eclipses, [a method] indicated by Aristarchus [Aristarchus], praised by Kepler, and by us first cut into [examined] by the conspiracy [confirmation] of Wendelen [Govaert Wendelen]; then in a new way through the Parallaxes of the Sun examined by means of Refractions; then at length, from Physical causes deprehended in the new Theory of the Sun's Eccentricity — [all this] will be clear to the Reader, of which we gave the doctrine in book 3 of the *New Almagest*, chapters 7 and 8, and in the Appendix to chapter 7, which is contained in the end of the first Tome of the same *Almagest*; and in the Volumes of this book, 731, and chapters 13, 14, and 17; we will teach how great a portion of the marrow [pith] of the opinions of the Astronomers we here reduce to two classes, premising nevertheless some of those opinions. For some have thought the Sun to be distant from the Earth by an infinite — or at least by a finite-in-infinite, that is, an indeterminable-to-us — distance; or at least a finite [distance] that cannot from observations be laid down, nor [posited] so great but that a greater might be posited, on the ground that the Parallax of the Sun is not evidently sensible. Others, however, [held] the Sun to be finitely distant from the Earth, yet knowably and demonstrably so. The first opinion is ascribed to Hipparchus [Hipparchus] in earlier considerations, but afterward, from Lunar Eclipses, he laid down so great a distance as Ptolemy [Ptolemy] [held]. But Giovanni Domenico Cassini [Giovanni Domenico Cassini], as we shall say in book 1, chapter 13, first reckoned the parallax of the Sun insensible, but afterward sensible. Wendelen [Govaert Wendelen], having used the Dichotomies [*Dichotomia*], but supposing the air thicker about the Moon — which would retard the evening Dichotomy, hasten the morning one — chose the maximum distance of the Sun [as] 14905 semidiameters of the Earth, very nearly as Posidonius once [held]; for, granting that thickness of the air, he professes the Dichotomies to have come out to him at 7000, very nearly as we too deprehend through diverse Dichotomies, as we show more fully above at the places indicated. Through Refractions, however,

hunted by a new method, we have come at the Sun's parallaxes, and these — as we shall say in book 1, up to the end of chapter 14 — are never found greater than 30"; nay, for the most part smaller. Hence it has become most certain to us that the distance of the Sun from us is never greater than 6430 Earth-semidiameters; nay, that it is greater than this; and that Ptolemy, Copernicus, Tycho, and the others who lay down the Sun's parallax at about 3 minutes have manifestly erred, [these others] having assumed [a value] rather than demonstrated it; and that, in setting up this interval far less [than it should be], they erred — those whom I have cited in book 3 of the *New Almagest* up to the end of chapter 7, and in its very Scholia.

[Page VII]

At length in book 1, chapter 17, we shall show, if a Physical cause of the Eccentricity of the whole Solar [orbit] exists, [that] the axis of the terrestrial shadow is such that the center of the Sun's motion lies there, equal, where the shadow of the Earth ends; and that the cause of half the Eccentricity is the distance of the apex of the Lunar shadow from the Earth, observed by us — hence, and from the Semidiameter of the Sun's Apogee, follows the maximum distance of the Sun from the Earth at 6666. Too small, therefore, are the limits of the Sun's distance which Kepler defines in his Commentary on Mars, page 71, saying: *The Sun is not so near as 230 semidiameters of the Earth, yet not infinitely distant: but it lies somewhere between 700 and 2000. Nor as yet does any certain number seem to be demonstrated.* But correcting him, we said more truly: *The Sun is not so near as 6430 semidiameters of the Earth, nor yet infinitely distant, because it is not distant more than 30000. But between six thousand and thirty thousand semidiameters of the Earth, no certain number is as yet demonstrated.* I add, for the exclusion of an infinity, that most Physicists hold that no infinite bound of vision can be given — nowhere unenclosed; of which kind is a rectilinear Triangle. But however great the distance of the Sun from the Earth be supposed, since it is certain that the Sun is larger than the Earth, [it follows] of necessity that, with a line drawn straight through the center of the Earth, and however far continued, it would at length meet at the apex of the terrestrial shadow, where the other straight line, tangent to the Sun and to the Earth, [meets it]; and the angle which it makes subtending the true semidiameter of the Sun, and [thus] from this semidiameter, and from the two aforesaid straight lines, a rectilinear Triangle must be formed.

But what may lie within the said limits 6430 and 30000 — a probable distance of the Sun — is not easily persuaded to the lovers of their own opinions and

inventions. For to a few it will appear not finite, but infinite, or at least the maximum, namely 30000 semidiameters of the Earth, so that they may safely scorn the parallaxes. To Wendelen [Govaert Wendelen], however, and very nearly to Christiaan Huygens [Christiaan Huygens], a distance about double will be pleasing — that is, about 14000, or 12000, using round numbers; but to us that pleases which is still about double smaller, namely 7427, from many Dichotomies, and the Semidiameter of the Sun's Apogee, and the Eccentricity limited [to it]; or [else] 6666, from the Eccentricity of the Sun measured to the Axis of the Terrestrial Shadow, and from the apparent Semidiameter of the Sun — not repugnant to the evident parallaxes, if the parallax-fallacy of the Lunar Dichotomies be absent, which fallacy usually intervenes between the time of the Dichotomy and the quadrature, and usually diminishes it; for the [interval] is less by about one quarter of an hour; for it is no greater than one hour, yet notably less by this less reckoned [amount]. It is wonderful, nevertheless, that the Dichotomy of Huygens, in this business, is of so ready use, since he professes the proportion of the diameters of the Planet observed through the Telescope; he also confesses the middle distance of the Sun from the Earth to be 12543 Earth-semidiameters; why? Because, if it followed this [proportion] from the apparent diameter of the Sun, 30' 30", then [it would be] as if the Sun truly could not, with this appearance preserved, be distant from us at infinity, unless prohibited from elsewhere.

On the Distance of the five lesser Planets.

[4.] Since it is most well-known to Astronomers that the Eccentricities and mean distances of these Planets depend on their distance from the Sun, how great is the uncertainty, or how great the probability, of the distance of the Sun from the interval [of the Earth], and from the Earth — so great too must it be concerning the interval of these Planets, both [their distance] from one another and from the Earth. And although opinions have been diverse concerning the accurate distance of these Planets from the Sun, in such parts as the Radius of the Sun's Annual Orb is 100000, yet only so much has been advanced in this Astronomy after Copernicus, that it has been acknowledged: the maximum distance of Saturn from the Earth is very nearly tenfold the interval of the Sun from the Earth; the [distance] of Jupiter about fivefold; of Mars about one-and-a-half [sesquialterate]; of Venus about two-thirds [subsesquitercian]; of Mercury about one-third [subtriple]. Indeed, as I reported in book 7 of the *New Almagest* [(*Almagestum Novum*)], section 6, in the Scholia,

[The table of proportional distances, set in the right column:]

Planet	Distance
♄ (Saturn)	953153
♃ (Jupiter)	519966
♂ (Mars)	152366
Telluris (Earth)	100000
♀ (Venus)	72336
☿ (Mercury)	38710

[Resuming the main text, top of right column, p. VII:] ...chapter 2, Kepler in the *Mysterium Cosmographicum* [(*Mysterium Cosmographicum*, Kepler)] attempted to distribute these intervals by inscribing the five Regular Bodies [the Platonic solids], which however did not succeed in all cases — not even granting the translation of the Earth through the Annual Orb, [placing it] among the Superior planets and the Inferior planets; which translation, however, has been proved false by us. But Wendelen [Govaert Wendelen] too, supposing the Earth among the Planets, as we said there, [held] the distances of the Planets from the Sun, the center of the World, to be in the sesquialterate ratio of their periodic times: from which he concludes that the distances of the Planets have among themselves the proportion which the numbers placed in the adjoined little table, here transferred, [have]. We, however, judge that GOD, Best and Greatest, did not have regard to those proportions which seem beautiful to us, but to others — [proportions] which, foreseen by Him for the government of the lower regions of this World, were fitting; and so it is not to be sported with in these concinnities of numbers, [as if] to depart from the apparent celestial motions and measures, in order to represent them by more apt ones — such as in the meantime we judge those to be which, at the end of books 5, 6, 7, 8, and 9, we shall select; and hence it has been pleasing also to represent them, at the end of book 10, in Earth-semidiameters too, according to the quadruple opinion of the Sun's distance from the Earth, indicated at the end of number 3; so that it may be plain to the Readers within what [limits] the determination of a more recent and more certain Astronomy stands. In this place meanwhile, for the venturing of the Fixed stars' distance, it suffices to foreknow the maximum distances of the Sun, and of Saturn, from the Earth, according to the quadruple Hypothesis standing within the true limits, and they are written below.

[The four-row Hypothesis table:]

From the Hypothesis	Maximum distance from the Earth, in Earth-semidiameters:	
	☉ (Sun)	♄ (Saturn)
The highest [Summa]	30000	327610
Of Wendelen [Vuendelini]	14905	162833
Ours [Nostra]	7427	81105
The lowest [Infima]	6666	72795

On the Distance of the Fixed stars.

[5.] On this I have discoursed in book 6 of the *New Almagest* [(*Almagestum Novum*)], chapter 7, entire, and in the Scholia upon it, so diffusely — if I am not mistaken, diligently — that the Reader, not regretting it, may be able to draw erudition from there. The sum of the doctrine handed down there is this: 1. those fixed stars which are in the Zodiac, and are occulted at times by the Planets running beneath them, are certainly higher then, at least than those Planets; 2. those fixed stars which are observed by the naked eye, or are observable, so that they undergo some Refraction (as is certain), it is also certain that they are not distant from us by an infinite interval; for, besides what has been said there in number 3, I add that it is of necessity that they undergo a sensible Refraction, since a Ray from the star, falling refracted upon the surface of the air, is inclined from the perpendicular by some sensible angle, and, with another ray from the star produced to the center of the Earth, and with the Semidiameter of the refracting Sphere, forms a Triangle; but the Physicists hold for certain that it is impossible for an infinite to be bounded on every side; 3. It is certain that it cannot be evidently shown by us how great is the distance of the Fixed stars from the Earth, whether of those which are affixed to the concave lowest surface of the Firmament, or of those which are placed in the deeper part of the Firmament; so that not without reason did Pliny [Pliny], in book 2, chapters 1 and 23, say [that it is] *a fury of the mind, and almost the work of a demented idler, to attempt this measurement* — although with a hope of certitude, [it suffices] that so great an estimate of conjecturing may stand by a settled mind; for we have no way — especially outside the Equator — of investigating the parallax of the Fixed stars, and of discerning it from Refraction, or this latter from the former; and therefore we reject the **Pythagorean** interval there, namely 94500 miles, that is, about 24 Earth-semidiameters.

by 2°23', from which the parallax of the fixed stars would arise as 2°23'. But because the assumed distance of the Moon is uncertain, we do not approve

[Platonicus] in this matter — though we do not reject it either. If we take the Moon's distance at 60 terrestrial semidiameters, the [parallax] would come out as 17993654, and would make the Lunar [distance] 466561 times [the Earth]. And the harmonic distribution of [Bettini], by which he refutes that the fixed stars are at no greater distance than 2290 terrestrial semidiameters, since he ascribes to the parallax of less than half a minute — we have demonstrated [this elsewhere].

But why should we labor to remove the fixed stars to so great a distance with the Copernicans, that the distance of the fixed stars should vanish into nothing, and become as it were that of a point — therefore, from the Copernican Hypothesis [Tycho] and [Magini] [Giovanni Antonio Magini] deduce a distance of the fixed stars of 785,000,000 terrestrial semidiameters. [Longomontanus] makes it 7,906,818. [Scheiner], from [Maestlin] [Michael Mästlin], 13,133,576, from which arises the parallax of the annual orb at 40', just as also from the [Galileo] [Galileo Galilei] interval, which puts it at 1,046,400 terrestrial semidiameters. But from [Kepler]'s interval, 34,077,067, or 60,000,000, he shows that there would there follow a parallax of the annual orb of 1°7' or 24"; which by no means can be detected with great instruments, as [Tycho] says in his *Mechanica*. And from [Lansbergen]'s distance, 41,958,000 terrestrial semidiameters: the parallax of the annual orb of 1", or — from [Hortensius]'s interval, 68,754,937 terrestrial semidiameters — the parallax of the annual orb would be 1', and from [Hérigone]'s, 1,440,000, the parallax of the whole annual orb [would be]; whereas after six months it would be perceptible, namely a minute of 6'. By contrast, if it follows that the parallax of the annual orb ought not to exceed 10", when the least distance of the Sun from the Earth is — as we have said — 6430 terrestrial semidiameters, it would be necessary that the fixed stars be distant from us by more than 308,000,000 terrestrial semidiameters. But, that dismissed, with the hypothesis of the annual orb of the Earth being false, I see no more probable ways of conceiving the distance to be taken than the following.

[Margin: 6]

The first and more probable method, from the proportion of periodic motion to periodic distance: if it is assumed that, as the Sun's period is one year and the Sun's distance from the Earth is 3000 terrestrial semidiameters — least, 6430 according to the said number 3 — so the period of the fixed stars, which to us is the period of the years, 25579: to the distance of the fixed stars there comes the sum 767,376,000, or the least 164,472,970. Or, if it be made that the period of [Saturn] is 30 years, and of the same distance the sum is 327,610, or the least 72,795; and from the said number 4, if the period of the fixed stars is 25579 years,

the distance comes to the sum 2,793,31,026, and the least 620,68174. We see how much from here is doubtful and how uncertain, since the period of [Saturn] is more uncertain than that of the Sun — which is the first and best-known measure of time.

[Margin: 7]

The second method would be, if the Distance of the Sun from the Earth were a mean proportional between the Distance of the Moon and that of the Fixed stars from the Earth. For example, if it were made that, as the Moon's greatest distance is 61 terrestrial semidiameters, so to the greatest distance of the Sun of 7427: to the distance of the fixed stars [comes] the sum 889,683. But to this it does not seem advisable to assent. Yet, that we may say it in one word — Vol. 4: the Refraction of the horizontal Moon at 30', in the middle of the air, at 40'; the Refraction of the stars at 31', and of the Sun at 31½. From which the difference of refraction of the luminaries is one minute, of the Sun and stars half a minute. Nor yet can we make it [come out], as 1: 1, so [the difference]; and so the maximum difference [of refraction] of the Sun, then of the distance, which to me is 7365 terrestrial semidiameters, [comes] to 11047: for the distance of the fixed stars would come out much less than that of [Saturn] — which is hardly probable.

[Margin: 8]

The third [method] perhaps will appeal by its simplicity to anyone: namely, if it should somehow happen that [Saturn]'s distance from the Earth were nearly tenfold that of the Sun, so that [Saturn]'s distance is as it were the center of the five wandering [planets], the distance of the fixed stars likewise from the Earth, that is, of the fixed stars at the decuple distance — the distance of the wandering stars being taken together, that is, of [Saturn] the highest of the wandering stars; thus, by the last Table of number 4, the sum of the fixed stars' distance would be 327,6100. Or, if it please that the Sphere of the fixed stars begins there where [Saturn]'s shadow ends, and this could in no way infusate the fixed stars, to me [Saturn]'s shadow would be 120,000 terrestrial semidiameters; if to this be added our [Saturn]'s distance, which is the maximum 81105, the distance of the fixed stars would be made 201105. Or, more roundly, 200,000. But more than this we play at guesses and uncertainties. For a certain measure of these, GOD, Best and Greatest, has consulted.

[Margin: 9]

Epilogue on the System of the World [Epilogus de Mundi Systemate]

Thus far concerning the System of the World, according to our Hypothesis, in which the Earth is at the center of the World, Immovable, as it was created from the beginning, as the foundation of the World's Edifice, and as the habitation of future men — for whose sake all things, around which the heavenly bodies were bound to serve. But around the Earth the celestial Spheres, and the elements, move both the Sun and the Moon by their twofold [motions]: by their own [motion of] Longitude they appear to move from West toward East, and by the other [motion] from East toward West obliquely, yet really, with one perpetual motion always westward by Spirals in the fluid Aether, described by a law, so as to furnish to human imagination the conceiving of their motion, as if it were made in one [path], almost circular, or rather Elliptical, around a Cone that may be designated by scales; and the five lesser Planets [revolve] around the Sun as the center of their Eccentrics, and as the fountain of light received from it, and mediating around the Earth, as the center, and the terminus of light, and influx, in the fluid Aether, are moved by their own [path], not immovable but permeable, but by spirals always westward toward the West, by a law (as we have described); nor are they ever truly Retrograde, but Stationary, and therefore appear to stand still, since at one and the same moment they recede with the same Fixed Star to the same Meridian, and retreat indeed toward East when they revolve more swiftly toward the Origin, [or move] westward; whereas when they revolve more slowly to the same [point]. Lastly, the Fixed Stars in the solid Heaven move daily, or [by] two motions imperceptible to us mortals, distinct and alternating in turn, now slower toward West, now slower toward East, by that obliquity of latitude declining with respect to the Ecliptic, as is established. Or with the one real motion by Spiral, they are moved by the Intelligences always westward toward the West, in order that they may represent to us the apparent oblique motion toward East. Lastly, the distance of all the stars conspicuous to us — although it be finite — yet differs in this, that the Lunar distance from the Earth is certainly within the closest limits, so much so that observations duly carried out evidently exclude the errors which the terrestrial semidiameters could include. But the Solar distance is nearly certain, yet within wider limits, namely not less than 6430 terrestrial semidiameters, nor greater than 30000. The distances of the planets, indeed, with respect to the Sun, are most nearly certain, inasmuch as they appear from their motions around the Sun itself, and necessary for representing the prosthaphaereses to them; but with respect to the Earth they have a certain latitude, which depends on the [latitude] of the Sun-to-Earth

distance, [their] interval [depending on it]. Lastly, the distance of the fixed stars is at most a matter of probable conjecture, and three or four [methods] of this distance are at hand by probable methods, but neither certain nor demonstrable. It remains for us, by deciding about the Fixed stars and the Planets and the Earth, to indicate how much has thus far been advanced in Astronomy and Cosmography in each particular.

ARTICLE V.

On the Fixed Stars [De Stellis Fixis]

[Margin: 1]

Just as a new Star afforded [Hipparchus] the occasion of enumerating the later Stars [and] the Heavens, and of leaving them as an inheritance to posterity, and as [Pliny] relates in Book 2, chapter 26, so the new Star of the year 1572 [the supernova SN 1572] stirred [Tycho]...

stirred [Tycho] to rectifying the thousands of Fixed stars, and to restoring them into one place as nearly as possible — the new method of [observing] Venus together with the Fixed Stars having been used, that it ought to be in no respect less [accurate] than that of [Hipparchus] left to posterity. To us, however, not a few things were left to be amended, on account of the excessive parallax of the Sun, and of Venus, assumed by [Tycho], which even [Kepler] admits to be unsound. The Ephemerides also; but especially because they falsely supposed that the evening observations of Venus are compensated by the morning ones, and [those] of our observations [are compensated], with a larger instrument, and we corrected the Right Ascensions evidently, and the Declinations of very many of the fixed stars, as will be shown in Book 4, in their proper places.

[Margin: 2]

But since in the Tychonic Catalogue of Right Ascensions that Star is lacking which is second in honor [magnitude] in the shoulder of the Lesser Bear [Ursa Minor], which once shone as the Pole Star, and on account of the latitude of that [star], and the longitude — by a trigonometric calculation we deduced that the increasing longitude decreases for the years 1600 and 1700, which is new and unheard of; this was for us a [matter for] astronomers, and a cause, and at the same time with P. [Bonaventura] Cavalieri [Bonaventura Cavalieri] investigating, [we were] detecting — that it must of necessity be made not in this Star alone, but in all the others whose latitude is greater than [that] of the polar circular [circles]; for from this the Right Ascension is detected by much, the longitude decreasing as

the latitude increases, according to the Theorem which we set forth in Book 6 of the *Almagestum Novum*, chapter 19, problem 11. And it is to be repeated here, Book 4, chapter 1.

[Margin: 3]

Further, we have taught that the Latitude of the Fixed stars, not only by the Right Ascension and Declination, must be corrected and amended, but also that they are immutable, in Book 6 of the *Almagestum Novum*, chapter 15, [as] we shall say below concerning the immutability of the obliquity of the Ecliptic. But concerning the motion of Longitude, of their apocatastasis, [it is] not from one or another comparison, as [Tycho] did, but from 72 comparisons, [that] we shall determine [it] more certainly, Book 4, chapter 19; from which we conclude both the year [of apocatastasis] not to be less than 49"; nor greater [than] 51" seconds, between which terms it [is] more probable, 50".40"', as we teach in Book 4.

[Margin: 4]

Lastly, as to the number and apparent magnitude of the Fixed stars: it is known, both as to quantity, [now] that the Telescope has been invented, by Astronomers: for through it they learned that the Milky Way is as it were a heap of innumerable little stars massed together; thus too the Nebulous [stars] coalesce out of several obscure little stars, [their] light [made] nebulous, in the nebula of Praesepe [36], and in the nebula of Orion [21], and within two degrees [there appear] more stars than 500 in Orion [3], and [40] in the Pleiades, [which] [Galileo] [Galileo Galilei] detected, then 2500 new stars in Orion alone he counted, as our own P. [Giovanni Battista] Zupus [in the Pleiades, Hyades], and in the Sword of Orion 72[?] counted besides. Lately too [Christiaan Huygens] [Christianus Hugenius], in the middle of the Sword of Orion, out of 12 Stars composed into a great [nebula], by a powerful Telescope saw [it]. Accordingly, although the number of the wandering [fixed] stars is not infinite, as [Giordano Bruno] contends in his book *On the Infinite*, and [that they are] innumerable, saying that there are as many Worlds as Stars, and infinite, as [Kepler] gathers in his book *On the New Star*, chapter 21: yet they are innumerable to men, and admirable to us [in] the power and wisdom of the Divine Founder, who created them and preserves them; as David sings in Psalm [147], who numbers the multitude of the Stars, and calls them all by their names [*Qui numerat multitudinem Stellarum, et omnibus eis nomina vocat*]. To this with what great profit Astronomy has gained by the Telescope, and by whose aid [the stars] can [be observed], either by conjunction or vicinity of the Fixed stars with the

Planets, much more evidently are the places of the Planets noted in the sky than by any other instrument.

, whatever [variety] appears in the Declination and Latitude. Now let us run through, in the individual Planets, what our age's Astronomy has detected by the benefit of the Telescope.

[Margin: ♄ (Saturn)]

SATURN, now solitary and round, now three-bodied [tricorporeus], by more perfect Telescopes, now is seen Ellipticized [shaped] in diverse manners — [as observed by] [Galileo Galilei], [Scheiner], [Giuseppe Biancani] [Blancanus], [Pierre Gassendi] [Gassendus], [Hevelius], [Schickard] [Wilhelm Schickard], [Christoph Scheiner] [Scheinero?], and the Fathers of the Society our [colleagues] — [Daniel Bartoli] [P.P. Zupì, Niccolò Zucchi, and Bartoli] — [and] Eustachio de Divinis [Eustachio Divini], [and] Odierna [Giovanni Battista Odierna]; to Us also, and by many other figures [Saturn] has been exhibited. So [Christiaan Huygens] saw [it] with a larger Telescope: with a Telescope of 23 feet, always handle-bearing [ansatus] even when by lesser tubes the tricorporeal [appearance] [was seen]. He asserts the same: that in this Saturnian System a certain little planet was observed by himself, 16 [days], circulating around Saturn within about [16] days, which therefore he calls Saturn's Moon [the satellite Titan]. But he judges the Saturnian Phenomenon of the handles [ansae] to be safe, if it is said to delay within the bright ring, which always accompanies it; otherwise to explain those, [the things] which they propound, are false. We, in Book 10, will show better all those things proposed; if they place Saturn at the nearest Elliptical [figure], it [is] continued by them, [rather] than the vicissitude of that libration which there we expound. But truly through the handles, or rather the Armilla [ring], to preserve the axis perpetually with the plane of the Equator parallel — this most evident from observations [made] with P. Grimaldo [Francesco Maria Grimaldi] we confirmed in the *Almagestum Novum*, [a fact] which [Galileo Galilei] suspects, [Pierre Gassendi] [Gassendus] and [Bullialdus] [Ismaël Boulliau] asserted, [Hevelius] denied, [and] [Huygens] thought by no means exactly close to the solstitial points. The belt [fascia], which We, and then [Huygens], think to be part of the aforesaid ring [armilla], [is] not improbable, in the body of Saturn.

[Margin: 5]

JUPITER, by the help of the Italo-Belgic Telescope, [observed] from [Galileo] in Italy, at the same time as it was first observed by [Simon Mayr] [Simone Mario] in Franconia, with its four little Planets around Jupiter, which complete their

periods within a few days. These [were] thereafter frequently seen by [Scheiner], [Biancani] [Blancanus], [Hevelius], [Huygens], and Us; but especially by D. Vincenzo Renieri [Vincentius Reinerus] of Oliveto, [Galileo]'s disciple, [who from] their Ephemerides [drew them] forth, [bringing them] from that [eternal] light into the [light] of eternal life, which we hope, evoked, [and] as [Daniel Bartoli] [D. Io. Bapt.][?] disclosed [the] celestial secret. Besides, from primary and noble [observations], from the Eclipses frequent in the shadows of [Jupiter's] little Planets of the Jovial body falling on it, we have at the same time concluded that we know that [Jupiter], and that its satellites receive light from the Sun, just as the same [is true] of Saturn, as has been opined of Mars also; the other [satellite], if not in Mars, [Galileo] thought, [by] the agitation of [their] natures, that on the Earth at least they could [be observed] through them in diverse places observed, [we are to] collect the difference of Meridians. But an uncertain number, [it appears], and besides [there are] 4 satellites, [though] at some time others, five [perhaps], as [Rheticus] [Rheinhold?][?] contends; [though we said but] one, treated of in the *Almagestum Novum*, Book 7, chapter 3.

The belt [fascia] indeed on Jupiter's disc — now one, now two, now three, [in] diverse [positions] yet — did not see, [yet] not once, the Fathers of the Society of Jesus our [colleagues]: Io. Bapt. Zupi [Giovanni Battista Zupi], [Niccolò Zucchi] [Nicolaus Zucchius], and [Daniel Bartoli] [Daniel Bartolus], [Francesco Fontana] [Franciscus Fontana], [Huygens], [and] We, with P. Grimaldo [Francesco Maria Grimaldi], so evidently we have observed [them], that perhaps it [is] from the very front [frons] of the easily-changing belt. Diverse positions [situs], either from vertigo [rotation] or from libration around its own center are believed to arise; [Huygens] saw, and those things not once [were] illustrated, [by] Marchio Cornel Malvasia [Cornelio Malvasia, Marquis].

[Margin: ♂ (Mars)]

MARS, [seen] gibbous in figure with little stars in the round quadrature, [observed] from [Francesco Fontana] [and] [Huygens], [by] sufficient indications of light, [its] disc received from the Sun. A spot indeed somewhat single [unique], but now broader, now narrower, [seen] by no one with the same view, as P. Niccolò Zucchi [P. Nicolaus Zucchius]; sometimes [it appeared] double, [as] seen at Naples [by] the Fathers Sersale [Cristoforo Sersale] [and] Daniel Bartoli [Danieli Bartolo], indications of vertigo [rotation], or [signs of] libration around its own center, [or] of its [own] body. But this above all, with [Kepler] showing [it], we knew [to be a] new thing worthy of note, and adept; the perigee of Mars [is made] much closer to the Earth than the Sun.

[Margin: 7]

VENUS, [seen by] [Galileo], [Scheiner], [Gassendi] [Gassendo], [Hevelius], [Francesco Fontana] [Fontana], [Huygens], P. Grimaldo [Francesco Maria Grimaldi], [and] Us, very often seen with the Optical Tube now gibbous, now dichotomized [half], often horn-shaped [corniculata], or falcate [crescent], as we shall exhibit in the schemes [diagrams] of Book 7 of the *Almagestum Novum*, section 1, chapter 2. By an evident Argument, [we know] that it [is] not otherwise than the Moon illuminated by the Sun, [and] so that [it follows] that course; from which it is more evidently established that, near perigee, [it makes] conjunction with the Sun, on account of [its] great latitude...

the [appearance] seen by [Tycho] and Us, but to us by the horns turned downward [is seen], and by the convexity turned upward illuminated from the Sun, as is to be seen in the scheme of the same chapter, page 485[?].

[Margin: 8]

MERCURY too — not rarely [observed by] P. de Rheita [Anton Maria Schyrleus of Rheita], P. Grimaldi [Francesco Maria Grimaldi], and Us — defective [deficiens], and corniculated [horn-shaped] it appeared, just as in [our] presentations, in the same Book 7, section 1, chapter 2; and [as] [Pierre Gassendi] [Gassendo] [saw] illuminated.

[Margin: ♄ (Mercury)]

[Pierre Gassendi] [Gassendus] [saw] that [Mercury] under the Sun's disc; whom we trust now too in this Astronomical matter, from his own Heliocyclium [device], around the Sun circling them, [the planets] changing among themselves.

[Margin: 9]

The vertigo [rotation] of the Planets — of which there are indications in Saturn, Jupiter, and Mars, as touched on above by [Rheticus][?] [Rheinhold?], from which by certain measures and times somehow to define [it]. Concerning which matter, since I once disputed it in person at Bologna, while we were dining [together], I heard him, while [he was] dining, [say] that by a binocular Telescope such periods he had observed, but nevertheless [they were] still imperfect. Let there be trust in the Author.

ARTICLE VII.

On the Sun [De Sole]

[Margin: 1]

The Elliptical figure of the Rising and Setting Sun, not once seen, neither antiquity nor we could [account for] before [Scheiner], [who] studied to investigate the cause; the same [man] [studied] the spots [maculae] in the Sun, and the faculae [appearing] a little before [Galileo], as he himself proves in his *Rosa Ursina*, [that] with the Optical Tube he not only noticed [them], but afterward, [by] so many accurate observations he prosecuted [the matter], as on the testimony of René Descartes [Renato Cartesio], [he] left the rest of his hope, having promised something better in this part to be furnished; if indeed they are moved [around] by the [vertiginous] motion of the Sun, [whether] there be [made] within about 28 days, of which see Book 3 of the *Almagestum Novum*, chapter 4, [where there are] more [things], certainly pleasing, [from] [Kepler] [on] the vertigo of the Sun within 24 hours, introduced.

[Margin: 2]

We, [by] the aforesaid motion, [it being] uncertain, [the matter] dismissed, with all [our] strength, with P. Grimaldo [Francesco Maria Grimaldi], we strove, that its motion in longitude, and in latitude as to declination, and finally [its] distance, and parallax, [be] more certain, and at length [be] made — than before it was — [that] we might attain [it] by investigation. And the motion indeed in longitude, not from observations [made] every two years of the year, [chose] the center, as [Tycho did], but at an interval of years 1812, [we] selected, [comparing] [Hipparchus] against another [observation] at the Equinox of our [time], [made] from the Gnomon of S. Petronio's temple; and [from] observations [made] with the ingenuity of S. Petronio's Gnomon, the Eccentricity necessary for the Equations, and the Sun's Diameter most subtly, and most evidently we determined; confuting those, who suppose a much larger diameter from the Cyst [Cysat?][?] and from [Scheiner]'s observations, detecting, and the cause of error from these [things] committed, on account of the ignorance, [of] propagating a certain manner, that the light of the Sun is propagated, as in Book 1, [section] 4, we shall teach. But we confuted those, who against [Kepler] denied [it] in this matter, [namely] the diameter of the aperture [foramen], [which] takes away from that, [its] diameter of the species of the Sun for that [reason] more full, as [we made] in the Appendix to chapter 1.

[Margin: 3]

We assert the maximum Declination of the Sun [to be] $23^{\circ}30'20''$, [to have been] perpetual, and not changed by new arguments, [contrary] to certain ancient observations, [so] that it may seem to have left [room for] cupidity [doubt], as [Tycho] doubted [this] from his observations. The distance [of the Sun], finally, and the Parallax of the Sun, we show not only [to be] far smaller than the Tychonic, but within limits not to be despised for certainty, [we] conclude, by the new method of the Lunar Dichotomies, and from Refractions.

ARTICLE VIII.

On the Moon, and on Eclipses.

1. We owe genuine thanks to Tycho [Tycho Brahe] for teaching us, on his authority, that the Moon's maximum latitude at the quadratures is very nearly one full degree greater than at the syzygies; that the motion of the nodes itself, besides the two inequalities, undergoes a certain third variation around the octants, over and above the equation. We have nonetheless pursued the matter no less in the longitude of the Moon, drawing the more certain elements from eclipses — not, however, without incredible labor, owing to the discrepancy of the tables among the observations, and the lapses in chronology, into which otherwise distinguished men have fallen, as may be seen in Book I. Moreover, from solar eclipses we have likewise carefully studied the diameter of the Moon as compared with the diameter of the Sun, already known from another source; so that we have rendered not only the total solar eclipses, which Tycho denied, but even annular ones, to be safe [from objection] and free from violence — as the truth of the matter requires.
2. Furthermore, the spots which they call the lunar [maculae], [the work of] Selenography, were depicted by Langrenus [Michael Florent van Langren], Sirsali [Cristoforo Sersale], Hevelius [Johannes Hevelius], Eustachio, and Rheita [Anton Maria Schyrleus of Rheita], with such great and assiduous zeal toward the Moon; and on a grand scale, with telescopes fitted to the eyes, by Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], with no, or the very least, error — we exhibited [this] in print in that work, namely Volume 9 [recte: Tome 1] of the *New Almagest*, chapter 7, in the particular [section] in which he repeatedly set out his observations of their places, in their order, with the figure he assigned them; and that [depiction] is the most outstanding, which the illustrious Marquis Cornelio

Malvasia [Cornelio Malvasia] obtained. We have indeed investigated the causes of this phenomenon rather diligently in chapter 7 [?] & 8, as much as we could. And in chapter 15 on the libration [libratio] of the Moon, first pointed out by Michael Langrenus [Michael Florent van Langren] and Johannes Hevelius [Hevelius], friends most well disposed to us, we so established our [position] that We too have many times contemplated this libration; so that — as is necessary for us — to whatever extent we differ from Father Grimaldi [Francesco Maria Grimaldi] regarding the limits of the librations, and as the nodes, we differ in no small measure also from Hevelius, as will be established at the end of Book 3.

3. It is marvelous, too, with how much subtlety and industry the more recent astronomers, now [proceeding] from the warnings [admonitions] of Kepler, have outdone all their predecessors by a long interval in observing eclipses — telescopes especially affording aid; or whether [this is to be seen] in the observations of [the eclipse] type, such as Gassendi [Pierre Gassendi], Hevelius, Lineman [?], Eustachio, Boulliau [Ismaël Boulliau], Langrenus, enjoyed. Surely whatever could be devised with subtlety, as to how the penumbra of the Earth and the spurious dawn-light [?] [or] residue may be discerned from the umbra itself, and the legitimate beginning [or] end — and we have said that this was most shrewdly discovered by Kepler from this cause; from which the Moon at some [eclipses], though rarely, in a total eclipse, is utterly extinguished, at others; more often, however, in the middle [of the eclipse] it fails, yet there appears nonetheless a reddishness, or [a tinge] toward saffron — with that color in part proper to it [the Moon], it shines with its own light, the rest [received] from the refracted rays of the Sun, and does not fall into the true shadow of the Earth; from which doctrine We have both reclaimed Ourselves and refuted the sophisms of those alleging the contrary. We have likewise from the warning [admonition] of Gottfried Wendelen [Govaert Wendelen], our most beloved friend and a man most accurate in observing eclipses, very many things to do, and we have retained these in their own place, adopted from the eclipse observations of that same man — and indeed [he was] the most furnished with distinguished eclipse observers among the differences. Finally, the matters of astronomy and cosmography, and the chronology itself [depending] on these, which I have noted more than anyone else from observations of eclipses — by the agreement of these we have enriched [our work], the friends of Urania having for the most part shared with us out of their whole heart no few supports, by which posterity may be rendered much more obligated [to them]; and throughout [the work],

Book 5 of the *New Almagest*, we unravel new questions, and on each occasion problems pertaining to eclipses.

ARTICLE IX.

On Comets, and on New Stars.

1. There was a great controversy among the Tychonists and the followers of Chiaramonti [Scipione Chiaramonti], whether comets and new stars were observed by the Tychonics to be above the Moon; as Tycho and his [followers] contended with axes [drawn], or whether [they were] beneath the Moon, as Chiaramonti, with Peripatetic bite, maintained. For the gratification not only of the astronomers, but also of the physicists, we have undertaken this labor in Book 8 of the *New Almagest*, [examining] the observations of the new star [stella nova] — perhaps with excessive prolixity — and, with incredible labor, have set out the calculations [of those observations]; and now, having seized the occasion, we have worked out new [matters] by theorems, and problems, so that I might unfold by various conclusions the controversies; nor is there any reason for so much labor to repent us. As for the star of the Magi [the Star of Bethlehem], under whose guidance [it appeared] at the swaddling-clothes of the Christ-child, we have added something to it — not without pious daring — for the gratification of those who delight in sacred letters; it may be read through under the end of the said Book 8.

ARTICLE X.

On Refractions, on the Altitude of the Refractive Air, and on Twilights.

1. After Tycho was the first who considered refractions — pointed out and measured by a few of his predecessors — and corrected them, [and] then all the astronomers in turn acquiesced in the Table of Refractions published by him; and although [later] Kepler exhibited it at the foot [appended] to the Rudolphine [Tables], notwithstanding that correction which he displayed in the *Optics*, with the increment of the secant in measurable motion — yet this matter we have treated more fully in Book 10 of the *New Almagest*, section 6, in the whole of Problem 57; and, correcting the assumed Tychonic refractions in this section of the Table of Refractions in their threefold tempering, we have accommodated [them]. Afterward, again investigating the refractions more deeply in Tycho's observations made on the day of the solstice, and by my [observation], P. Albert Curtz [Albert Curtz] transmitted to me from Tycho's autograph by

his own hand, I have detected that Tycho himself and Kepler erred, confounding optical refraction with astronomical; both from these causes, and badly accommodating the astronomical refractions of a star to the more remote terrestrial [refractions], they made [them] less effective than they ought to have been greater — as we show in Book 10, chapter 14, where [we treat] many other [matters], and [give] a worthy account of refractions.

2. As for the altitude of the refractive air, with how much labor we have investigated it, the reader will recognize from Book 10 of the *New Almagest*, section 6, problem 43, [and] from problem 43 to 57 [?]; [where] we discuss, also disproving, the Keplerian [doctrine] which holds the altitude of the air to be confined within two Italian miles. Thence, moreover, the physicists too will be able to draw a doctrine not unworthy [of attention] for the altitude of the air, if it be joined with that which has been handed down by us in Book 1 of the *New Almagest*, chapter 30 & 31, & Book 2, chapter 19, & most exquisitely Book 8, section 1, chapter 14, on the twilight halo of the air, [which is] sublime [high up], and on the cloud; and on the threefold use of refraction in the altitude of the high halo, and on the diverse depth of the Sun beneath the horizon in the morning twilight [as compared] with that which it has in the evening, and in the winter twilight [as compared] with that which it has in summer — both from the observations of others, and from our own.

ARTICLE XI.

On the Altitude of Mountains, on the Levelling of Rivers, on the Distance of Sight, and on the Tide and Depth of the Sea.

1. To what purpose, you ask, are these [topics] for an astronomer? Indeed, [they are useful] so that by these means certain astronomical questions may be better resolved, both the parallaxes and the refractions, and those bearing on the motion of the Earth, which is to be ruled out. Therefore, in detecting [the matter], it was necessary first to measure the altitude of mountains, which we did in Book 1 of the *New Almagest*, chapter 11 & Book 10, section 3, problem 31, & section 6; and more fully in Book 6 of the *Geographia Reformata*. It was likewise necessary to eliminate the errors in the physical horizontal amplitude [amplitudo horizontis], that is, the distance to which our sight above the Earth or the Sea extends, [a thing] to be determined — which is set out in Book 1 of the *New Almagest*, chapter 10 & Book 10, section 4, problem 39; by which places something on the

levelling of rivers is explained, [and] which afterward [is] more fully explained in Book 6 of the *Geographia Reformata*. As for the tide of the sea, we touched on it in Book 2 of the *New Almagest*, chapter 15; and on the matter of the tides we set out the explanations found in Book 9, section 4, chapter 14, lest we should renew the Galilean [errors] in explanation, [errors] which arise from the motion of the Earth, both Diurnal and Annual; we set out the true cause of the marine tide [as] repeated by its own tossing [iactatio]; on which occasion the histories of the tide of the sea, gathered together from every quarter, and the rise and fall [reflux] in the hourly flux are to be distinguished, [and] reduced to rules; against the Galilean [errors] we have adduced our opinions, and among the causes of these motions we have enumerated — excepting the opinion of Rheita, of which book I then lacked [knowledge], [a matter] which afterward we examine in Book 10 of the *Geographia Reformata*.

ARTICLE XII.

On the Magnitude and Immobility of the Terraqueous Globe, on the Heaviness and Lightness [of Bodies], on the Acceleration in Descent and Ascent; and finally, on the Vibrations of the Pendulum, and its Use in the Measurement of Time.

1. The magnitude of the terraqueous globe we have measured before, in Book 2 of the *New Almagest*, chapter 7, & Book 6, section 4, [and] from problem 2. Then, renewing the observations, we set [them] forth in the *Theses* published [publicly]; [and] at last, with other [helpers], having attained [results] with incredible labor and industry, together with Father Francesco Maria Grimaldi — God most evidently assisting us — we both demonstrated [it] in Book 5 of the *Geographia Reformata*, and that [result] not [as a] violent [conclusion], but a necessary one, concerning the measurement of the intervals, and the method of others; correcting [it], we reconcile [it] with the more celebrated opinions concerning this magnitude. As for its Immobility, as we indicated above, from the real acceleration of heavy bodies naturally descending, and in proportion to the velocity, we evidently deduced [it]; and in an Appendix to Book 1, we shall speak [of it]. Concerning this acceleration, otherwise [supported] by many physical experiments not to be neglected, one ought to read what we have handed down in Book 2, chapter 21, & at greater length [prolixius] in Book 9, section 4, chapter 16. Finally, having drawn the distinguished properties of the vibration of the pendulum, and the use of these for [reducing] to a

certain measurement the motion of the prime movable [primum mobile], see Book 2 of the *New Almagest*, chapter 20.

2. Up to this point perhaps not without some little offense to the reader — because we have frequently dwelt upon those things which have to do with promoting astronomy and geography — yet far be all boasting from us, [we who are] conscious of our [position], whatever of good we have attained in this kind; [being] of our slenderness [tenuitas] very well aware, we refer [it] as accepted from God, the Best and Greatest, to whose Glory, first by the nod of those above [the superiors], then by their express command, we have applied ourselves to these studies. Nor indeed do we delay anyone, who has said that in the two prior Tomes of the *New Almagest* there is indeed contained an Astronomical Library, & a collection of erudition not common — but yet we find in them nothing nearly newly brought forward by us; we count up in those same books almost 280 Problems, 95 new questions with their own solutions, 88 Theorems, corrections of errors admitted by others, and the dissolutions [refutations] of the fallacies of arguments, more than 320; besides many new Tables, or Tablets newly constructed for astronomical & geographical erudition — God favoring our labors, to whom be Honor & Glory forever.

BOOK ONE

IN WHICH ARE THE OBSERVATIONS OF THE SUN, AND THE FOUNDATIONS OF THE SOLAR HYPOTHESES.

CHAPTER I.

On the Modes of Observing the Equinoxes, Solstices, and the
Maximum Solar Declination, with the Least Fallacy.

This is not the place to treat of these [matters] at length, since they pertain to the organic [instrumental] part of astronomy, for which we have prepared a whole Volume. But so that the observations concerning the Sun, which are to be adduced, may be discerned the better, and [distinguished] from the coarser [observations], it is worth recounting and reviewing the modes by which the

observations of the equinoxes, solstices, and the remaining moments of the Sun's entry into the signs of the Zodiac, in [its] progress through the ecliptic, were [made and] indicated; [and they are] as fallacious as those which lie hidden in them. We shall begin, moreover, with the equinoxes, inasmuch as [they are] the most celebrated cardinal points of the whole Year.

On the Equinoxes.

1. [Margin: The mode by which the shadow [umbra] is investigated.] First, the days of the equinox can be explored by observation, [as to] the line which the apex of the shadow of the Gnomon describes on the physical horizontal plane, from the rising of the Sun up to its setting; for if that line should be straight, it will be an indication of the equinox on that very day. But the day cannot be discerned from this, on which the Sun arrives at the Equator.
2. [Margin: The reckoning of the semidiurnal time.] Second, if the time numbered from the rising of the Sun up to the meridian should be six precisely equal Hours, or rather [more than] 6 hours, & 4 minutes, it will be an indication of the equinoctial Day, or [the day] just before the moment of the Sun's [arrival] at the Equator; provided that the solar [time] be numbered at the moment from the meridian, [for] 6 hours and 4 minutes [?]. For this reason, since refraction at the horizon makes the center of the Sun [appear] elevated optically, by about 4', so that it appears about 4' earlier in the horizon than it really is in the morning, [and] in the evening seems to set [4' later] — at least in the Torrid and Temperate zones. But lest indeed even from this [a day] be given for the true morning [moment] of the Sun's entry into the Equator, & much less, if [the gnomon be] not of perpendicular oscillation, concerning which I have spoken in Book 2 of the *New Almagest*, chapter [vlt. — ultimate/last]. [Margin: Clepsydra Mercurialis, of which Tycho [treats] in Tome 1 of the *Progymnasmata*, chapter 2, & Dudley [Dudlaeus] *de Arcanis Maris*, Book 1, chapter 4. But better [to use] other less fallacious [methods] than anyone who would use [water-clocks], [whether] horologes, [whether] water[-clocks], [whether] sand[-clocks], [whether] of the horizon.]
3. Third, if the meridian line be exactly designated on the physical horizontal plane, [the day] may be cut off [determined], and the meridian line cut, by erecting two fine needles perpendicularly at right angles upon another straight line, [set] very far apart between themselves; or [by] something else which would designate the vertical plane, as our Filar Triangle

[Triangulum Filare], concerning which [we treat] in the *New Almagest*, Book 5, chapter 15. [Margin: The true rising and setting are observed.] For if the center of the rising [and] setting Sun should be in the said line, [extended] through the imagination, or [in] the plane produced, it will be an indication of the equinoctial day, and of the true Rising, or Setting [of the Sun]; [and] both the horizontal refraction lies hidden, which [refraction] amplifies the figure of the Sun into an elliptical [shape], & extends [it] toward the center; though they may be able to collineate to that very center [as] established at the horizontal plane, they nonetheless represent it [as falling] short of it, or beyond it; both [there is] the horizontal parallax, which [parallax] makes the physical horizontal plane differ from the true [horizon].

4. [Margin: The equinoctial shadow.] Fourth, the Ancients observed the equinoxes by the Equinoctial Shadow of the Gnomon, if indeed the Gnomon, that is, the style [stylus] in the scaphe [scaphium], be erected perpendicularly, [and] casts a meridian shadow [of magnitude] foreknown — as much [as] the foreknown Altitude of the Equator demanded. And since in the scaphe the style would be shorter, & on account of this [the shadow] of the shadow [is] liable to notable error in arguing the altitude of the Sun; on account of which [error] conspicuous altitudes, & equating the longitude of many feet, by erecting a gnomon at the horizontal plane, such was the obelisk of 116½ feet in the Campus Martius, of which [obelisk] Pliny [Pliny] [treats in] Book 36, chapter 10; & on account of [this] the meridian shadow observed on the equinoctial days, extended to the Gnomon, was 120 [feet], as is established from Strabo, Book 2, & from others of this kind from Pliny, Book 2, chapter 72, Vitruvius, Book 9, chapter 8, [and] Cleo-

Cleomedes (Book 1) and Ptolemy (*Almagest* II), at chapter 2, sections 4 to 6, where it is shown that this method is not very accurate. Moreover, once the altitude of the gnomon and the length of the shadow are given, and the perpendicular rod stands erect in the plane of the horizon, three quantities arise of the same kind, forming a right angle: the gnomon plays the part of the radius (or whole sine [*Sinus Totus*]), the shadow stands as the tangent of that angle, and the line drawn from the gnomon to the end of the shadow plays the part of the secant. From these the distance of the Sun's upper limb from the vertex in the heavens is found. Let the gnomon then be set up against its shadow: thus the whole sine will be to the other [side] as the tangent is to the secant of the said angle. Add to this, if possible, both the apparent semidiameter of the Sun and a suitable correction, so

that you obtain the true distance of the Sun's center from the vertex when on the meridian. This shows whether the Sun has reached the meridian and the equator, or has fallen short of it, or has crossed it. By however many hours the equinox is distant from the moment of [the Sun's reaching] the meridian, by so many hours [the result] departs from the meridian moment. Accordingly, however much the error has been committed in this matter, it has been committed either in the altitude of the pole, or in the semidiameter of the Sun, or in refraction, or in parallax, or in the observation itself, or in the measurement of the shadow, or in all of these, or in several of these elements. As for the use of gnomons by which the upper edge of the solar shadow is observed at the same time, we shall speak of it below, at section 8.

[Margin: Hipparchus's and Ptolemy's error / hallucination (*Hipparchi & Ptolemæi hallucinatio*).]

5. A fifth method was customary among astronomers, especially the Alexandrians: to observe the equinox by means of equatorial armillae, of the kind we described in Book 3 of the *New Almagest* (chapter 14, section 7). An equatorial armilla consists of two armillae, or large quadrilateral rings on the surface, which mutually intersect each other at right angles in two places. One of them is placed in the plane of the meridian circle, and the other only so far as the distance of the place from the equator and the distance of the equator from the vertex require. Once these are set up, the equinox is observed in this way: the upper part of the equatorial armilla — that is, the part of the equator — represents [the equator], and illuminates the equal cavity of the lower parts equally, unless parallax or refraction perceptibly obstructs this precision. But if the inner [surface] is illuminated more on the northern side than on the southern, it is a sign that the vernal equinox has not yet occurred, if the observation is made in the morning. For all things happen to the southern parts in the opposite manner — as will shortly be said — to the way they happen to the northern. Furthermore, beyond the meridian the cavity of the equatorial armilla is sometimes seen to be illuminated unequally on either side in the western part, [so that] the equinox then occurs after the meridian, since it is illuminated on both sides equally throughout the whole day; this happens not by day but by night, provided only that the illuminations of the regions interchange equally on either side. For if the Sun illuminated the northern part of the cavity today and the southern part tomorrow, know the vernal equinox to have occurred; if on the contrary it illuminated the southern cavity yesterday and the northern this morning, know the autumnal equinox to have occurred. By contrast, if the equinox ceases [to be discernible] — at least so far as physical appearance is

concerned, though it always occurs by the truth of astronomy — for horizontal refraction, raising the image of the Sun, can produce the effect that, although the Sun is still in the southern signs, it nevertheless appears to be in the equator itself, or short of it; and on the contrary, when it is in the northern [signs], it may seem to be in the equator, or beyond it in the southern signs. And this is doubtless the cause why the same armilla appeared twice on the same day, each side illuminated — once around the Sun's rising, by the force of refraction, and again when the refraction ceased around midday. When Hipparchus was astonished at this, [he reported] together with Hipparchus; Ptolemy too testifies of himself (*Almagest* III, on the great construction), attributing this effect to a fault of the armilla — as though it had collapsed from its original [position], as he supposed — rather than to its legitimate setting. But it is parallax that produces the contrary effect, for it anticipates the autumnal equinox optically and retards the vernal equinox, whereas refraction retards the autumnal and hastens the vernal. As for the manner in which this fallacy may be corrected, and the apparent equinox reduced to the true, [Ismaël] Bullialdus [Ismaël Boulliau] has shown excellently (*Astronomia Philolaica* II, chapter 2), and we ourselves have pointed it out (*New Almagest* III, chapter 14, section 9); but ...

we need not go much into it here, since we are able to use observations in which the fallacy of refractions is not implicated — not only recent ones, but ancient ones too. And whenever the armillae of Hipparchus or of Ptolemy must be used, in which the armilla in the meridian appeared equally illuminated on both sides, or as nearly so as possible — then at Alexandria the Sun was at an altitude of nearly 60 degrees, and therefore beyond the danger of perceptible refraction; indeed, in our judgment, beyond parallax too, which did not exceed 6 seconds. And so [Hipparchus] could not be sure of being free from an error of nearly 6 hours in the rest of the equinoxes which Hipparchus, on Ptolemy's testimony, records; nor are they suited to that subtlety which recent astronomy demands — especially if an error of nearly 12 hours could have been committed, as Longomontanus contends (Book 1, *Theoricorum* chapter 1). [Margin reference: Kepler, *Astronomia Optica*, page 146.] He adds that Kepler too, in his *Astronomia Optica* (page 146), found that the equinoxes observed by means of armillae fell out for Tycho as well in such a way that the equinox seemed to occur twice on the same day, by the force of refraction; and therefore that the equinoxes must be sought out by a more reliable method.

6. Sixth, then, with very large instruments properly divided, set up, and adjusted around the same day — as you will now prepare in accordance with the Gregorian Calendar, on the days from the 19th to the 23rd of March, or from the

19th to the 24th of September — observe the meridian altitude of the Sun's center, and convert it carefully from the apparent into the true [altitude] by adding the proper parallax and subtracting refraction. For if the true altitude proves equal to the altitude of the equator, the equinox occurred in the meridian of that day. But by however many minutes, or scruples [seconds], the first [altitude] differed from the altitude of the equator, by so many hours before or after the meridian the equinox occurred. And in the case of the vernal equinox, if the following altitude exceeds the meridian altitude of the equator, it will occur before the meridian; but if it falls short of it, it will occur after the meridian. For the autumnal equinox, the contrary precedes the meridian: if the following altitude exceeds the meridian altitude of the Sun, it will occur after the meridian. As for how far in advance the observation must be sought, whether in the altitude of the pole, or in the observation, or in refraction, or in parallax — so that you will go astray by so many hours from the true equinoctial moment — for that reason you will go astray in the equinox not only from the Ancients, but even from Tycho himself, whose parallax of the Sun is double, and considerably greater than it should be. And the reason why Copernicus too and his predecessors erred, as we shall say hereafter, [is that their values] need correction.

De Solstitijs. [On the Solstices.]

7. First, the winter solstice [*Solstitium Brumale*], because of refractions and parallaxes — which are greater there [near the horizon] — is liable to more fallacies than the summer solstice, whether it is observed by the least altitude, or by the foreknown numeration of the pole, or by the increment of the meridian shadow, or by gnomons and the shadow measured against the gnomon; or otherwise, in cases where, if the fallacies could be avoided, the true meridian altitude of the Sun, observed out of all the altitudes of the whole year or those nearest the solstice, would be the smallest indication of the solstice on the day it occurred. The summer solstice too, although with difficulty, [can be reduced] to the hours of the day at which it occurs, and is observable — although Ptolemy says (*Almagest* II, chapter 2): *In the solstices I hope that neither we nor Archimedes erred in observation and calculation by as much as a quarter-part of a day.* Yet Willebrord [Snel] Snellius [Willebrord Snel], in his notes on the Hessian observations, says it would be a labor of Hercules to avoid a quarter of a day — that is, 6 hours of error — in the solstices. The reason is that on the day immediately preceding and the day following the solstice, the change in the Sun's declination does not exceed 14 seconds in one whole day, and in one hour it varies only by 36 thirds [36''']. Hence, to avoid an error of 6 hours, the

observation must be free of an error of 3 seconds and 36 thirds. Such subtlety the observations of meridian altitudes of the Sun on the solstitial days can scarcely furnish, unless they are carried out with very large instruments most exactly.

[Margin: The fallacy of solstitial observations (*Fallacia observationum Solstitialium*).]

8. If, however, someone is content with the marking of the solstitial day — leaving aside the observation of the decrease of the meridian shadow, and the numeration of time agreeing with half the ...

day — [he must consider] this, which requires the altitude of the pole; and on account of the greatest recess of the points of the occasion of true rising, or of the equinoctial rising observed in the horizon (for there are methods of this kind), exposed to an error of more than a whole day — these things, I say, being neglected, let him observe the proportion of the meridian shadow to the gnomon. Let him gather, as above, the distance of the Sun's upper limb from the vertex, on one or the other day before, and after that day, on which the solstice is expected from an ephemeris. For on whichever day the least of all the distances from the vertex is found, that day is to be taken for the summer solstice; but on whichever day the greatest [distance] is found near midwinter, let that day be taken for the winter solstice. And let the same judgment be made concerning the meridian altitudes observed around either solstice, taken otherwise than by the gnomon's shadow.

9. [Margin: For the summer solstice. Case 1.] But for the hour of the summer solstice too, [the time] at which [the Sun] is closest to panting [to its extreme], one must catch [it] from several continuous [observations]. The meridian altitude of the Sun before and after that day which the ephemeris sets forth for the solstitial day is to be taken; and [the times] of any conversion into the true altitude, with the addition of parallaxes and the subtraction of refraction. If it should happen that two altitudes of immediately consecutive days so exceed the rest that they are equal to each other, the solstice occurred in the middle of the intervening night; and then add to either of the equal altitudes 7 seconds in the second [order]; and to the aggregate subtract the altitude of the equator, previously most exactly foreknown — for in this way, by the same operation, you will gain the maximum declination of the Sun, to which the obliquity of the ecliptic is equal. But if the foreknown altitude of the equator is taken away, the said aggregate will nonetheless be useful, as will appear below.

[Margin: Case 2.] But if it should happen that, out of three true meridian altitudes, the middle of the day is greater than the two nearest days, and these two are exactly equal to each other, know the solstice to have occurred at midday itself, in the very meridian of the intermediate day, without perceptible difference. And then subtract the altitude of the equator from the meridian altitude of the solstice, and the maximum declination of the Sun is left over. This case is rarer than both [the others].

[Margin: Case 3.] When these [conditions] fail, choose three or more continuous meridian altitudes of days, two of all the others greater, and the difference of these (if the operation is exactly done, and subtle) ought not to exceed 14 seconds; divide [it] by the hours, multiply the product by 14. For the quotient will give the hours by which the moment of the solstice followed the meridian of the lesser altitude of the preceding day, or preceded the meridian of the lesser altitude of the following day. Once the moment of the summer solstice is found, subtract 14 seconds from the greater of the differences of the [two] greater altitudes, and from the residue subtract the altitude of the equator; and you will have the maximum altitude of the Sun in that meridian, in whose meridian the solstice occurred, [the meridian] of the equator; and the maximum declination of the Sun is left over.

10. [Margin: For midwinter.] For the winter equinox [recte: solstice] one must proceed in a somewhat opposite manner, but similar [in method], because then the winter solstice obtains, when the Sun in some meridian obtains the least of all the other altitudes observable under other meridians.

[Margin: Case 1.] Let the first case, then, be this: if it should happen that, among the days of several continuous days designated by an ephemeris near midwinter, the immediately preceding and following ones, two immediate altitudes so exceed the rest that they are equal to each other, the winter solstice occurred in the middle of the intervening night. Then again, subtract 7 seconds from either of the equal altitudes, and subtract the residue from the altitude of the equator, so as to obtain the maximum declination of the Sun in that year.

[Margin: Case 2.] The second case will be if, out of three true meridian altitudes taken near midwinter, the middle day's altitude is the lesser of all the other lesser ones — that is, if the other two are equal to each other — then the winter solstice occurred in the meridian of the intermediate day; and once that least altitude has been subtracted from the altitude of the equator, the maximum declination of the Sun is left over: but this case is rarer.

[Margin: Case 3.] The third case, therefore, is when, out of three meridian altitudes of the Sun taken around the supposed midwinter, the rest are smaller but unequal among themselves: choose then two of these that are smaller, and multiply their difference by 24; divide the product by 14. For the quotient will give the hours by which the moment of the solstice followed the meridian ...

of the greater altitude of the preceding day, or precedes the meridian of the greater altitude of the following day. Once the moment of the winter solstice has been acquired, subtract 14 seconds from the difference of the lesser altitudes, and from the residue subtract the altitude of the equator. You will have left over the maximum declination of the Sun observed in that meridian.

**De maxima Solis Declinatione, ac Tropicorum Distantia
Obferuanda, & fimul Altitudine Poli, fi ea non fit præcognita.
[On the maximum declination of the Sun, and the distance of
the Tropics to be observed, and at the same time the altitude
of the pole, if it is not foreknown.]**

11. Above, under numbers 9 and 10, I taught how to observe the maximum declination of the Sun by means of either solstice, when the altitude of the pole — and its complement to 90 degrees, that is, the altitude of the equator — was foreknown from elsewhere most exactly by means of the circumpolar stars. But if this is unknown, or to be confirmed from elsewhere, the [solstitial] moments of both solstices [must be found], and from them the meridian altitude of the Sun — the maximum in summer, the minimum in winter, as I have taught above — is to be observed. For the difference of these altitudes will be the distance of the Tropics from each other, of which the half will be the maximum declination of the Sun; and this, subtracted from the maximum altitude of the summer solstice, leaves the altitude of the equator; and this altitude, in turn, subtracted from 90 degrees, will give the altitude of the pole. For the obliquity of the ecliptic, and the distance of the poles of the equator and of the ecliptic, is always equal to the maximum declination of the Sun.

De Solstitijs obseruandis quando præcognita iam fuerint
Altitudo Aequatoris, & Declinatio Solis maxima. [On
observing the solstices when the altitude of the equator and
the maximum declination of the Sun are already
foreknown.]

12. If, on the day assigned by the ephemeris for the solstice itself, or on the more nearly preceding or following [day], so great a meridian altitude of the Sun is found, and most correctly so, that — at the summer tropic — it equals the aggregate made from the altitude of the equator and the maximum declination of the Sun, or — at midwinter — it equals the residue left over from the subtraction of the maximum declination of the Sun from the altitude of the equator: then know the solstice to have occurred in the meridian of that day. By contrast, if the meridian altitude of the Sun differs from the aggregate required for summer, or from the residue required for the winter solstice, by more than 14 seconds, the solstice is distant from the meridian by one whole day or more; but if by less than 14 seconds, [it is distant] by the [proportional part of the] difference observed, and [you may find it as follows]: multiply the difference of the observed and required altitudes by 24, and divide the product by 14. For the quotient will give the hours by which the moment of the solstice is distant from the meridian of the observation, before or after — as the increments of altitude in summer, or the decrements in winter, will easily teach you.

CAPVT II.

De Instrumentis Maximè Idoneis ad subtiliter obseruandas
Solis, ac fideris cuiufuis Altitudines Meridianas, & præcipuè
De ingenti Gnomone Bononienfi eiꝑ; similibus. [Chapter II.
On the instruments most suitable for observing subtly the
meridian altitudes of the Sun and of any star whatever, and
especially on the great Bolognese gnomon and others like it.]

1. It was excellently done by us [*Præclarè actum est nobiscum*] that in the preceding chapter we learned that, in equinoxes, an error of one hour is to be avoided; and that an error of one minute [of arc] is to be avoided, in order to exclude an error of a whole day in the solstices, [namely] by excluding ...

an error from the observation [exceeding] one quarter of a minute, or 15 seconds. Hence it follows that, in the solstices — unless an error of thirds is risked, that is, an error of one hour; and to avoid an error of thirds, [an error of] 54 [thirds] — or at least one second of [arc-]scruple [must be avoided]. To reach this subtlety of [observing] the altitudes of the Sun's distance from the vertex — to attain it, however, in such a way that the minimum [error] nonetheless does not fall out, and is far more secure — if it cannot be admitted as much error in [the measurement of the] altitude. First, then, the magnitude of the instruments must be considered, but [also] their handling. Far hence, therefore, let there be removed the *Baculus Jacobi* [Jacob's Staff], the *Radius Astronomicus* (whether Greek or Latin), the *Astrolabium*, the *Armilla*, the *Annulus*, the *Torquetum*, and others of this kind; and finally the pendulum quadrant — instruments that are too small in use, and that must be handled by nodding [adjustment]; and for that reason they cannot be of such mass that single seconds [of arc] could be exhibited by them. But among those organs which succeed in this place, [namely] the *Quadrantum*, the *Quadrans*, or in part [those parts] of the *Regula parallactica*, the very great gnomons, and in many ways the gnomons of the *Forma*, the division, and the use of which — and likewise of *Quadrati*, *Quadrantis*, *Sextantis*, & *Parallacticarum* — Tycho has sufficiently taught in his *Astronomia Instaurata Mechanica*; but we leave these aside for the reader, and beyond these there are not a few things worthy of consideration to us, who meditate on this matter.

[Margin: The magnitude of the instruments required (*Magnitudo instrumentorum requisita*).]

2. First, then, it must be settled how small the smallest visible point is, or the discrete points by which the divisions on instruments are designated. To us, indeed, with the keenest acuity in painting, or in painting, or in the very sharpness of the edge, by section, or attrition, [it is] indicated [as follows]. We see, moreover, that no one of sound and most keen sight among men is able to discern between point and point, or between little line and little line, if they occupy the very smallest space — such as that which the most subtle silken thread, drawn out from the silkworm's tiny cocoons, covers; of which thread three hundred most subtle [threads], or sixty, [if?] gathered together, are contained within one foot of a Roman foot; or as is shown, when Ezekiel exhibited [it] in the work of Villalpandus [Villalpandus] [in his commentary] on the Temple. Therefore, in the periphery of the limb, whether of quadrants, or of sextants — such as those of astronomical [instruments] observed by a thread that crosses from one point to another, [in such a way] that they may discern evidently one second [of arc] of a scruple — it is necessary that the magnitude of the radius [be such that] its chord

contain ten *unciae* of the Roman foot, so that, as the said minimum takes [up], evidently visible, 360 [parts]; ten times [that] is this thread [equal to] 3600. Whence indeed the second scruple contains one degree. Nor should you say that lines [can] be obtained by transversals even more subtle, [in] thirds, or [in] quarters [of seconds], or subdivision. For although the major intervals are able to be discerned in transversal lines after the Tychonic manner, the deception of those intervals can occur by a thread, or by a movable sighting-vane, if in the limb itself the [points] do not stand apart more than by the space of the said thread, physically perceptible — of which we shall speak more presently.

[Margin: The smallest visible thing (*Minimum visibile*).]

3. You will ask now how great the semidiameter of the instrument ought to be, of which one degree may take up ten *unciae* of the Roman foot. I answer that it ought to be of such *unciae* nearly 573. For if it is so in the diagram here adjoined, from center A, the portion BKC of the periphery is described — of those [degrees] of which there are 360 in the whole periphery of the circle, whose extremes B and C are connected both with the center by the radii, or straight lines AB and AC, and between themselves by the chord BDC, which, cut at right angles by the perpendicular AK, is bisected — and so cut orthogonally at D, for BD will [be the sine]. The sine of the angle BAD, subtending half a degree, or 30 minutes, will be the radius, or the whole sine [*Sinus Totus*]. And since therefore BC, [given] is 10 *unciae* ...

[Margin: The magnitude of the instruments (*Magnitudo Instrumentorum*).]

Diagram. A narrow isosceles triangle (the geometric construction for sizing the instrument's radius). The apex A is at the top, at the center of the circle. Two long radii AB and AC descend to the base, where the base points B (left) and C (right) lie on the arc of the periphery. The base is the chord BC, with its midpoint D marked just above the base line, and the foot K of the perpendicular AK marked just below D on the base. The perpendicular AK bisects the chord at right angles (at D). The whole figure represents the arc BKC subtending one degree and the half-angle BAD subtending 30 minutes.

- A (apex / circle center): A
- B (base, left end of chord): B
- C (base, right end of chord): C
- D (midpoint of chord BC, where AK meets it): D
- K (foot of the perpendicular on the periphery/base): K

[Text continuing beside and below the figure] ...And since therefore BC is given as 10 *unciae*, and BD [is] of *unciae* 5; if it is done that, as 30 minutes [give] the sine BD of 87265 parts, so the radius AK of 10000000 parts [is to its value] — so, in the same way, BD of 5 *unciae* to another [quantity] — there will result the semidiameter AK of *unciae*; as we shall say, nearly 573, that is, of feet 47³/₄. By this method has been constructed the Table here adjoined, [computed] for a semidiameter of the instrument suitable for exhibiting evidently one [second], or one, or two, or several second scruples, so far as concerns the magnitude of the organ itself: besides this [magnitude], there remains [more] to be considered shortly.

Radius Pedum Rom. & Vnc. Pro
[Radius in Roman Feet & Inches,
For]

	Pedes [Feet]	Vnciæ [Inches]
11		
1	47 &	9
2	23	10 ¹ / ₂
3	15	10 ¹ / ₅
4	11	11 ¹ / ₄
5	9	6 ⁵² / ₈₇
10	4	9 ¹ / ₃

4. Once the instrument has been constructed — whose radius will be of so many feet and *unciae* as the optimum [resolution] of the seconds requires — and once from its center a quadrantal arc has been described, [the arc] is to be divided, and the arc itself [graduated] into 90 degrees; or if it is a sextant, into 60 [degrees], with such equality of the intervals and such subtlety that no perceptible error is admitted. Although this may seem an easy thing to do, it nonetheless demands the highest dexterity in surveying [the divisions], such as you would scarcely find in any mechanical craftsman who is not at the same time well-versed in Geometry and Astronomy. For this reason

[Margin: The division of the degrees into scruples (*Divisio Graduum in scrupula*).]

we have not been accustomed to trust the instrument which we ourselves have prepared, or [that] of Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], of Angela [Angeli?] — if it is permitted to say so, an emulator of ourselves in this subtlety. For the division — further — of a degree into the first sixtieth-part of scruples, and of minutes into the second [order], whether single,

or by threes, or by sixes, or by tens — so that the intervals of these can be discerned evidently — Tycho devised the transversal lines, of which he treats in the *Astronomia Mechanica*, folio B 2, and the next-to-last folio; and so for a long time this practice has been in use among our [people], [namely] in Sextants, and in Quadrants — [the very thing] which Tycho with a double cause [so] named, namely that — by the figure of the division — secondly because it is of equal magnitude, both in the radius and in the limb [*fascia limbi*], of which Tycho himself, [in] the said folio B 2, described and named the *Tychonicum* — inasmuch as gradually ...

with the maximum [magnitude], that which Tycho himself, [at] the foretold folio B 2, described, and named the *Tychonicum*. But afterwards, by use itself, [people] noticed that it was not only too cumbersome, but also subdivided too much, inasmuch as it required transversal lines [numbering] 540, and points 540; and that operations [arising] from so great a multiplication [carry] a peril of error, of which some [people] elegantly disabuse themselves; for which reason another, simpler [division] is chosen — which we shall say presently, on occasion of the *Quadrans of Grimaldi*, so named by the Author, and by the executor of the division, although the Tychonic division [*divisio Tychonica*] was preferred [by the Author?] to be carried out, [in agreement?] with us. The Illustrious Count Carolus Manzinus [Carlo Antonio Manzini] and the most Excellent Doctor Io. Dominicus Cassinus [Giovanni Domenico Cassini] — both most outstanding not only in the theory of astronomy and in geometry, but also in practice and in the mechanics of organs of this kind — most distinguished [men]. Yet I add that we have not before been led astray in subdividing the transversal lines, as Tycho was, but [proceed] as geometrical reasoning requires — unequal [intervals]. For Tycho confesses, at the end of the said *Mechanica*, that on account of that inequality he could err by threes [thirds?], and by more than seconds. *And he says there that the sharpness of the eye [visus acumen] could discern this subtlety in whatever [instrument]; nevertheless the instrument in no way sustains it.* How much more, therefore, did Tycho despair of being able to attain a single second-scruple?

[Margin: The magnitude of the instruments (*Magnitudo Instrumentorum*).]

5. Concerning the *Dioptrae* and *Pinnacidia* [sighting-vanes], by which the stars are observed at night, we shall speak in Book 4, chapter 5. But the principal luminary, the Sun, is observed especially by a direct view collineated [aligned] with the center of [the instrument], or with one or the other [edge], or with both edges; or by a fine needle erected perpendicularly at the center of the instrument; or by the mutual section [intersection] of two orthogonal cross-threads [*chordularum*]

orthogonalium] cutting each other in the same plane, of which one is extended perpendicularly from the center of the instrument, [while] the other represents the vertical plane; or by a cylinder, whose axis is fixed perpendicularly at the center of the instrument, and which is of such thickness that to the eye fixed at the center of the instrument the whole ...

[Margin: The solar sighting-vanes (*Dioptra Solares*).]

would not cover the whole Sun, but would clearly let the equality of the covered part and the uncovered part be discerned. Most often, however, the Sun is observed by looking directly at it; or else by means of a shadow cast by a cylinder set upright at the center of the instrument onto a tablet, marking the middle of the shadow; or by means of the bright image of an aperture admitted through a little hole in a small plate at the center of the instrument and likewise received on a white tablet, marking either the middle or the edge of the Sun's bright image. In either of these arrangements one can err on two counts: in the proper placing of the tablet, the cylinder, the strings, the needles, and so forth; and indeed, with as many seconds as there are strings in an instrument of 48 feet. For however many of the strings—the very finest of silk—stray from the true point of the center of the instrument; or in the case of a line at whose end the other sight must be set in a straight line.

But in an instrument whose radius is only 24 feet, an error will arise of as many binary seconds as the strings foretell (as is clear from the table given as no. 3); and in an instrument of $9\frac{1}{2}$ feet, of as many quinary seconds [*quinariis secundorum*] as there are of the aforesaid strings. There is a second occasion for error in the very use of the instrument, when one does not take exactly the middle of the shadow, or of the bright image, or the edge of either; but is off by so much of a space as the silk thread is thick—or more—in which case the error of seconds is multiplied in proportion to the smallness of the instrument. And in fact, in small instruments it is very necessary for us that the shadows and bright images, and likewise the edges of either, be distinguished more clearly; whereas in larger instruments, a slight error in a single small particle introduces an error of seconds not to be despised. In large instruments, the distance from the aperture, or from the shading edge, of the bright image, or of the shadow, is so great that the limit of either can scarcely be discerned.

Now in the case of Tycho's quadrant [Tychonis quadrans], large and mural, with its radius of not quite five and a quarter cubits [*quinque cubitos quing[ue]; idest pedes $7\frac{1}{2}$* —that is, $7\frac{1}{2}$ feet—it is clear from what has been said that it was prone to error in the mere placing of the sighting devices alone, by at least five seconds;

and by as many again in the instrument's use itself; so that for this reason too we cannot be certain of being free from an error of ten seconds. [Margin: Examination of the Tychonic quadrant — *Tychonici Quadrantis examen.*]

§6. The very placing of an instrument in the plane of a vertical circle involves two difficulties to be overcome. **The first** is that the plane of the instrument on which the band [*fascia*] holding the divisions of the degrees lies should rest in that same plane of the vertical circle as exactly as human skill can manage; otherwise there is a danger of incurring an error not of seconds only, but of several minutes, as experience attests. **The second** is that the perpendicular [plumb-line] suspended from the center of the instrument should fall exactly over the outer edge of the limb, from which the degrees and minutes are reckoned. **Nor**, again, on a twofold count, are we under any less compulsion to fasten it. For if the perpendicular's thread is too thin, it will not long bear a weight suited to keeping it taut, but will break quickly and the more easily the larger the instrument is, and the more it requires a greater length of thread. But if you employ a thicker thread, you will not be able to judge clearly whether its axis falls over the aforesaid outer edge, without fear of an error as great as the little space, or thin line, that is the breadth of the very thinnest silk thread—an error which by itself can produce an error of as many seconds as such threads have receded from the outermost atom of that edge, even in an instrument of 48 feet—indeed of several seconds more if it be of fewer feet, in proportion to what was indicated above. Further: in a quadrant the plumb hangs, or in a movable one it serves to keep the instrument in a vertical plane, and by means of a movable sight indicates the degrees and minutes. But on account of this very motion of its own it requires some firmness of the thread; and to that extent we are led to a thickness greater than that of a simple silk thread, and so into a danger of some few seconds of fallacy.

Finally, I warn that it is not enough to have once set the quadrant or sextant steady in its place, unless you are certain that the pavement, or the walls, to which it is attached can in no way be moved from their former position. Otherwise the position of the instrument must be examined before the observations. As for parallactic [*parallacticis*] rulers, even if one of the two has been duly set up and correctly toward the horizon, yet it is difficult to move the other in the plane of that same vertical circle, as Tycho taught in his *Mechanica*; and we ourselves to such a degree that, with whatever care, we have frequently fallen into an error of two seconds, and somewhat more.

[Right margin, at head: *Mensura Gnomonis Bononiensis* / Measure of the Bologna gnomon — Egnatian.]

minutes, even if we should have a parallactic [instrument] of 8 feet. [Margin: The height of the great gnomons — *Gnomonum magnorum Altitudo*.]

§7. What has been said so far tends to this: that we may recognize, in the first place, how probably we can dread an error of one minute in the Tychonic observations—which we will also confirm by examples and authorities in Book 4, Chapter 4. And next, that we may sharpen the diligence of students of astronomy, especially since by neglecting a few seconds, prone as we are to fall into error about that very first minute, the weakness of our nature, for the most part, falls short of the proposed aim. Certainly in the altitude of the pole, and in observing the equinoxes and solstices, and the obliquity of the ecliptic [*obliquitas eclipticae*]—which are the primary elements, or foundations, of astronomy—no diligence ought to be thought superfluous. Therefore, considering all this, in pursuit of perfection we turned from the customary instruments to the great gnomons; which we have found used by some of the ancients as well—and not only in the use of obelisks, but otherwise too. For although it is not yet clear how great was that gnomon of which Strabo speaks (*Geography* II) [Margin: The gnomon of Pytheas, and of Gassendi — *Gnomon Pythææ, & Gassendi*]:

Thus, at Byzantium, the longest day is fifteen and a quarter hours; and at the summer solstice the gnomon stands to the shadow in the ratio that 120 has to 42. Yet from so many parts—which the ancients wanted to be plainly perceptible and commonly evident—we gather it to have been large enough by their reckoning. Larger still was that one which Gassendi [Pierre Gassendi], as he attests in his *Life of Claudius Fabricius Peireskius* and in his treatise *On the Proportion of the Gnomon to the Solstitial Shadow*, says Pytheas of Marseilles [Pytheas of Marseilles] used at Marseilles: for, dividing it into 600 parts, he there obtained the solstitial shadow as $213\frac{1}{2}$. And at the same place Gassendi himself, in the year 1636, as he reports in his two aforesaid treatises, used as a gnomon the high roof of the College of the Fathers of the Congregation of the Oratory, which was about 9 fathoms [*Orgyias*], or 52 Paris feet; though he reduced that altitude to another kind of small parts, and divided it into 90,000—that is, exactly into 89,328 such parts; and he found the solstitial shadow to be 31,753. Earlier, at Grenoble [Grenoble], he had used the sphere-bearing globe [*sphæristerium*] of the Connétable's [palace], whose summit served as the style of a gnomon, being about 6 fathoms, or 36 feet—more exactly, of 64,690 particles; and the summer shadow was 25,410. [Margin: The gnomon of Vlacq the Belgian — *Gnomon Vlug. Belgi*.]

Far the greatest, however, was that gnomon used in place of a quadrant by Ulugh Beg [*Vlug Beigo*], grandson of Timur-Lang [the Mongol prince Tamerlane], about

the year of our Lord 1437. For, as Johannes Gravius [John Greaves] reports in his *Epistle prefixed to the Tables of Ulugh Beg* [*Epistola Tabulis Vlugianis præmissa*], it equalled the height of the topmost vault of the Temple of Saint Sophia, whose hemisphere's vaulting at Constantinople exceeds 180 Roman feet. Incited by these examples too, in order to obtain the most subtle altitude of the pole of Bologna [Bologna], we devised two temporary gnomons—namely, D. Io. Dominico Cassino [Giovanni Domenico Cassini] in the Malvasia Palace [*Palatio Maluatico*], and P. Franciscus Maria Grimaldus [Francesco Maria Grimaldi] together with me in the new Temple of San Luca [*S. Luciae*] of our College, while its vault was not yet enclosed; which gnomons we shall set forth, together with our observations of them, in Book 4, which is on the Fixed Stars, Chapter 4, where that observation by a circumpolar star is examined—look there for the passage. [Margin: The gnomons of Cassini, and the authorities — *Gnomones Cassini, & Auctores.*] But for establishing the equinox, the solstice, the diameter of the Sun, and its greatest declination, we chose two stable gnomons in the Temple of San Petronio of Bologna [*Templo S. Petronij Bononiæ*]*—the most outstanding, I might say, in all Italy, indeed in all Europe—of which we must speak separately.*

On the Gnomon in the Temple of San Petronio formerly set up by Egnazio Danti

De Gnomone in Sancti Petronij Templo ab Egnatio Dante olim excitato.

§8. While the controversy over the Precession of the Equinoxes was growing—a precession which by now anticipated by nearly ten days the day fixed in the old Calendar—and at the urging of Gregory XIII, truly the supreme Pontiff, of the astronomers, R.P.M. Egnatius Dantes [Egnazio Danti] of Perugia, of the Order of Saint Dominic, professor of mathematics in the venerable University of Bologna and afterwards a bishop, was appointed to settle upon a method for reforming the Calendar. By the authority of the most illustrious Senators—Count Io. Pepoli, perpetual President of the Fabric of the Temple of San Petronio—and of his colleagues, in that same Temple in the year of Christ 1576, in the month of April, he erected a huge gnomon, in order to display clearly, or at least

Diagram. A schematic of the gnomon's principle as a right triangle. At upper left a tall vertical pillar (the gnomon), with the aperture-disk near its top. From the aperture-disk, several straight rays fan downward to the right toward a long horizontal base-line, marking the lengths of the projected solar images / shadows at various dates. Small ellipses (the elliptical solar images) are drawn along the slanting line near points where it meets the base.

- A (top of pillar, aperture): the aperture / top of the gnomon
- B (foot of pillar, lower left): base of the gnomon at the pavement
- G, V, H (along base, left of center): shadow-termini (closely grouped)
- E, Q, F (along base, center): shadow-termini
- I, M (along base, right): shadow-termini, with elliptical solar image
- C (right end of base): terminus
- D (right end of base-line): end of the horizontal meridian line

—at least moderately instructed men, the anticipation of the equinoxes and solstices, and other observations notable in astronomy. And this gnomon lasted right up to the year 1656—that is, for 80 years—whose figure, such as it is, we here subjoin.

AB, on the southern and left-hand wall of the Temple, was the height taken from the pavement up to the vault; BC was a marble strip [*Zona marmorea*] laid in the pavement of the Temple, whose straightness declined westward from the true Meridian line BD by about 9 degrees. For if it had been constructed on the Meridian itself, Egnazio feared he might run into the pillars, or columns, that support the vault, or that it would come out shorter than the length of the winter shadow required; and yet he judged that, owing to its nearness, the hour of the equinox could be determined on BC itself. A was the aperture, whose diameter was 4 parts of the kind of which an uncia [inch] of Bologna [*uncia Bononiensis*] is 5—enclosed in a metal plate of half-a-finger's thickness, fixed to the wall at the convex part of its vault. IC was the diameter of the elliptical solar image, or quasi-elliptical, transmitted through the said aperture on the day of the winter solstice; and then AC was the radius of the lowest edge of the Sun, and AI the radius of the highest edge. At the equinoxes, the diameter of the elliptical image was EF, and AF the radius of the lowest edge, AE of the highest. Finally, GH was the diameter of the elliptical and quasi-circular image at the summer solstice, AH the radius of the lowest edge, and AG of the highest. There were also four other marble tablets, arranged at their proper intervals, marked with the characters of the remaining eight signs of the Zodiac, so that it could be known on what day the Sun was entering each one of them. Supposing, then, the marble strip-line BC to be parallel to the horizon, and AB perpendicular to the horizon—both being known, and the quantity of both being credited by Egnazio—in the triangle ABC, right-angled at B, the angle BAC could be known, measuring the distance of the lowest edge of the Sun from the vertex of Bologna; and BI was known too; and then, from the semidiameter of the Sun, the distance of the Sun's own center from the vertex in the winter solstices. And likewise, in the summer ones, from the observed

quantity BG and BH; and in the equinoxes, from the observed BE and BF. And these being known beforehand, together with the distance of the equator from the vertex of Bologna—namely the altitude of the pole—the hour of the equinox, the solstice, and noon could be known.

Surveyors [Dimensores]		Bologna feet [Pedes Bonon.]	Uncia
A B	Egnazio Danti	67	circiter [about]
	Nobis [by us] from the center	65	9 ¼
B V	Co. Carolo Ant. Māzino	26	0
	Bartholomæo Proualio	25	6
	Nobis	25	6 17/24 [?]
B Q	Com. Manzino	65	1
	Barthol. Proualio	64	7
	Nobis	64	7 22/24 [?]
B M	Com. Manzino	167	7
	Nobis	166	8 7/12
B C	Egnazio Danti	170	
	Nobis	169	2 2/12

The whole IC was at one time found by us to be 4 feet and 11½ unciae. The aperture A, as I have said, was of 4 parts, of the kind of which an uncia of Bologna is 5; therefore, of the kind of parts AB will be, the diameter of the aperture A was 101 such parts—out of 100,000—or in round numbers 100. And half of it must always be added to the radius of the highest edge, and subtracted from that of the lowest, so that the length may be had which agrees with the rays passing through the center of the aperture A, and there intersecting one another by an imaginary, indivisible aperture-point.

On the Gnomon in the Temple of San Petronio recently set up by D. Giovanni Domenico Cassini

De Gnomone in S. Petronij Templo nuper à D. Io. Dominico Cassino excitato.

§10. The Egnatian gnomon, beyond an intrinsic defect, deviated from the plane of the Meridian by nearly 9 degrees; and two other defects it had contracted in the lapse of time—namely a disturbance of the plate of the aperture that admitted the Sun, occasioned by the masons' work; and the declivity of the pavement from its making, through the wearing-down of feet, on account of which the angle ABC, formerly a right angle, had in our time turned out not a little acute. And although even so it furnished some notable uses, yet I more often pondered restoring it and correcting it; and on this matter I consulted with some persons to whom the fabric of this Temple did not yet fully pertain, and spoke also with the most excellent Doctor Io. Dominico Cassino [Giovanni Domenico Cassini] of Genoa, to whom the chair of mathematics, and specifically of astronomy, in this University of Bologna had been entrusted. Therefore, taking the occasion offered by the southern wall, which had to be demolished, and the fabric of the remaining parts already begun, he obtained from the most illustrious Marquis Facchinetti [Facchinetti], President of this fabric, and from its colleagues, or Assistants, that at the expense of the fabric a new gnomon should be erected in that same Meridian line—which both he himself, with the exacter measurements, and I as the inmost foundation of all great undertakings—they urge solicitude over the outcome, since it was doubted by some whether the ratio undertaken by D. Cassini could attain Geometrical exactness [Greek: ἀκρίβειαν (akribēian, "exactness, precision")] of the species [*speciem*], and present it in astronomy. I, consulted among others and an eyewitness having been present beforehand, and an observer of the method begun by him, and—as far as concerned the most exact designation of the Meridian line—a helper and verifier, was no less certain of this man's talent; and being certain of his prudent skill, I pronounced that the matter would proceed most excellently and turn out splendidly. [Margin: The gnomons of Cassini, and the authorities.]

§11. And so that most ingenious man saw that the Meridian could be drawn well and long, in such a way that, avoiding the columns alternately, it would reach the northern wall, and that the aperture AB could be placed in the vault of the Temple itself parallel to the horizon, from whose center, lowered by a plumb-line to the pavement, at last—after the wavering had settled and the spinning come to rest—he marked on the plane of the horizontal marble stone the point D, over which the center of the aperture C hangs perpendicularly; and the altitude CD he composed of wooden foils [*bracteolis ligneis*] joined together, and likewise, when these were let down from C to D, and afterwards [Margin: See the following figure — *Vide sequentem figuram.*]

Diagram. A schematic of Cassini's meridian line. At upper left, a small circle (the vault aperture) labelled with S and P, with I at its left. From the aperture, solid and dashed rays descend to the right onto a long horizontal line representing the pavement / meridian floor-strip, which carries the lettered points A, C, B at its left and D, M, H, O, K, L, N at intervals along it. At the right of the figure is a rectangular outline (the marble slab / floor panel).

- S (at aperture, upper left): point on the aperture
- P (within aperture-circle): center of the aperture
- I (left of aperture-circle): point at the aperture
- A, C, B (on the line, left): closely-set points near the perpendicular foot
- D (below A, on lower line): the marked floor-point beneath the aperture center
- M, H, O, K (along the line, center to right): shadow / image termini
- L, N (right end of line): terminus points
- E (within the rectangular slab outline, right): point on the marble panel

afterwards extended over the horizontal plane, it is measured; and it is found to be of the ancient Roman feet such as Villalpandus [Villalpandus] exhibits in his commentary on Ezekiel, 95 1/24; but the whole DE—conveniently, for finding the angles—of the kind of which the Radius CD is 100,000, made the Tangent DE 251,100; and the diameter of the aperture AB, 100 such parts. The angle CDE is a right angle, because the line DE was made exactly along the channel of standing water [the level], experiment being repeated again and again, equidistant from the horizon, and the line of the ruler bound on both sides between the two marble [strips], so that it is inclined—provision being made that the line DE could endure at the said equidistance for very many years. Moreover, the elliptical solar image, on equinoctial days, occupies a length of three Roman feet and more, and subtends in the sky about 32 minutes; and so it occupies very nearly 6 feet for a single degree. At such a time, therefore, if in designating the extremities of the ellipse it should happen with the edge of a knife, some small error will certainly turn out imperceptible, and much smaller than in the greatest Tyconic quadrant, whose degree occupied scarcely 1 uncia.

§12. The use of the gnomon will become clearer by an example, supposing what has been demonstrated in Book 3 (*Almagestum Novum* [Almagest], new Book 5, together with Nonius [Pedro Nunes] and Snellius [Willebrord Snell])—that the Sun's rays, propagated from that same point of itself to the earth, as SH and SO, are sensibly parallel; and from what is to be demonstrated in Book 4, Chapter 4

(the altitude of the pole of Bologna, in the Temple of San Petronio, being $44^{\circ} 30' 20''$, and of the equator $45^{\circ} 29' 40''$).

LET THIS, THEN, BE THE EXAMPLE

SIT ERGO EXEMPLVM.

§13. In the year 1656, on the 21st day of March, at noon, before trustworthy witnesses skilled in observing, the distance from the perpendicular's point D to the terminus H of the Sun's elliptical image was observed—that is, the Tangent DH—as 95,225; and to the other extremity L, the Tangent DL, 97,098. The semi-aperture AC was 50 parts, and likewise CB; therefore, because of the parallelism of the rays SH and SO, the parallel HO was just as much as KL—namely 50 parts—being the parallel to ACB itself. [Margin: Observation of the Sun's diameter — *Obseruatio Solaris Diametri*; and of the declinations — & *Declinationis*; and of the equinox — & *Aequinoctij*.] Add, then, HO, that is 50 parts, to the Tangent DH, and DO becomes 95,275; the Tangent of the angle DCO, $43^{\circ} 36' 50''$, which was [the angle] S of the higher edge of the Sun's distance from the vertex. From the Tangent DL subtract KL, that is 50 parts, and DK remains; the Tangent of the angle DCK, $44^{\circ} 8' 30''$, of the lower edge I's distance from the vertex. Now the apparent diameter of the Sun IS, their difference, is namely $31' 40''$; and its half, $15' 50''$, added to the degrees $43^{\circ} 30' 50''$, gives the distance of the center P, the Sun's distance from the vertex, $43^{\circ} 52' 40''$ —to which, if from our theses you add a refraction of $5''$, and subtract a parallax of $1''$, there remains the corrected distance of the Sun's center from the vertex, $43^{\circ} 52' 34''$. And this being subtracted from the distance of the equator from the vertex, leaves the northern declination of the Sun's center $37^{\circ} 46'$; to which, in our Table of Declinations corresponding to our obliquity of the ecliptic, $23^{\circ} 30' 20''$, there correspond degrees of Aries $1^{\circ} 34' 43''$. By assigning the single minutes of declination (as is done in equinoxes) to single hours, the equinox is gathered to have occurred at 37 hours 46 minutes before the noon of the 21st day of March. The same is to be done in the other observations of equinoxes, the older of which we set forth in the next, more recent, Chapter.

CHAPTER III

CAPVT III.

Observations of the Equinoxes, or near the Equinoxes, from the year 162 before Christ down to the year of Christ 1656

Aequinoctiorum Observationes, vel prope Aequinoctia ab Anno 162. ante Christum, vsq; ad Annum Christi 1656.

§1. Ptolemy [Ptolemy] (*Almagest* III.2) reports 9 equinoxes—one observed by Hipparchus [Hipparchus] in his book *On the Magnitude of the Year*, and observed at Alexandria by the same man through Equinoctial Armillae; and likewise, Chapter 8, he adds 3 equinoxes observed by himself. But Hipparchus,

[The text below the Caput III heading concerns Hipparchus's equinox observations and a chronological table comparing the reckonings of Hipparchus, Ptolemy, and others; the right column carries the chronological table that follows.]

§2. Moreover Hipparchus [Greek: φιλαλήθης (philalēthēs, "truth-loving")] 1, a lover of truth and faithful—on the report of Ptolemy—confessed that the Autumnal equinoxes by 2, 4, and 6 had appeared a quarter of a day earlier than they ought, having regard to the observed magnitude of the year of 365¼ days; and in 7—which was the Vernal one—he confessed that the Armilla appeared illuminated twice equally on both sides, namely in the morning, and again at hour 5 of the day under the meridian. Which fault was attributed to the Armillae; but it could rather have arisen from morning refraction, representing the Sun higher than it really was, as will be said in Chapter 4, no. 9. These equinoxes, all or some of them, are weighed by Kristmannus [Christmann] on al-Farghānī [al-Farghānī], page (mine) 328; Mulerius [Nicolaus Mulerius] in the Frisian table, page 86; Longomontanus [Longomontanus], *Astronomia Danica*, Theorica, Book 1, Chapter 1; Petavius [Denis Pétau], *De Doctrina Temporum* IV, Chapters 19 and 26; Lansbergius [Lansbergen] in the *Thesaurus Observationum*, class 2; Bullialdus [Ismaël Boulliau], *Astronomia Philolaica* II, Chapter 2; and Franciscus Levera [Francesco Levera], Book 1 of his *Prodromus Astronomiae*, Chapter 3. For me, it is now enough to indicate the Chronological errors of some of them concerning the said equinoxes: for they note a fourth, the Autumnal one, in the year of Alexander 178—Albatenius [al-Battānī], Chapter 27; Regiomontanus [Regiomontanus] in the *Epitome of the Almagest*, Book 3, Proposition 2; and Longomontanus above—on account of the Trebizond version [*versionem Trapezuntinam*]. [Margin: Chronological errors of some of them — *Errores Chronologici nonnullorum*.]

Chronological Table (right column, p. 39)

ANNI LABENTES — "Running / elapsed years." The table groups observations under three observers/epochs (Hipparchus & autumnal; Verna [vernal]; Ptolemaica), giving for each a numbered entry and several era-columns, the Egyptian/Roman calendar date, and the time of day at Alexandria.

intending and Gaurico; but in Ptolemy, book 3, chapter 1, instead of 178 one should read 177. The year 177. Therefore, since Krithmannus above, on page 341, and Boulliau above on the Equinoctial of the Autumnal Inequality, follow the Copernican usage, and likewise Vernalis; while Lansbergius above places them in book 3, chapter 13. And Longomontanus and I myself, in book 1, chapters 3 and 14, follow the *Almagest*, with this difference, that he praises my Leuera above, on page 102; yet he errs in saying that the third Calippic Period began in his year 147. As for Petavius too, in book 4, chapter 26, he assigns this same Equinox to the year 4567, that is, to the year of Christ 147. September 27, at its beginning. Soon afterward he adds: *In this year of Thoth of Nabonassar 602 began September 29.* Therefore on Day 27. of September, the year of Nabonassar 602 had not yet begun; so either he slipped through carelessness with his pen, or memory failed him: for he says, *This Equinox is designated by Hipparchus as in the year from the death of Alexander 178. of Nabonassar 602. of the Julian Period 4567.* This year, namely, is the year of Christ 147, the Equinox on Day 27. of September, when Nabonassar had not yet begun, nor Alexander 178; for that began two days after. But it is certain from Ptolemy, book 3, chapter 8, and from Censorinus, chapter 8, that the years both of Alexander the Great and of Nabonassar begin from the first of Thoth.

[Margin: *Nabonassari & Alexandri vera Epocha.* — The true Epoch of Nabonassar and of Alexander.]

They err, moreover, in all things — Longomontanus in marking the Autumnal Equinoxes of Hipparchus, and Leuera in marking the distances of the years from Calippus by counting the year that follows the year of Alexander, and so calling them years of Nabonassar, while assigning them too late. Leuera, besides, has no regard for the relation of those years, which were Calippic years to Hipparchus, and which in the three last Autumnal observations of Hipparchus he doubles for the Calippic year 31. and 32, substituting 31. and 32. for the years 31. and 32; and — what is most groundless — for 36. the year 33, in order to fit his own summaries of the years. The cause or occasion of this error, either from the

nearness of the year of Alexander to that of the death of Ptolemy, or from the year of Ptolemy and of Hipparchus, since they use the Egyptian years — and as for the year from the first of Thoth, the year of Nabonassar, and the year of Alexander — he held that he had begun it, as Krithmannus thought in Alphraganus on page 305, but afterward he thought better of it on pages 329. and 338. He retracted, falsely, that Hipparchus took the beginning of the Calippic years from a preceding Solstice of Summer, whence they would migrate to the year of the Olympiad, and likewise to that of Ptolemy — let alone to the beginning of Hipparchus from Calippus, as Reinhold thinks in the *Prutenicae*, preface 4. Boulliau and Petavius above, and likewise Ptolemy himself, book 3, chapter 1, manifest in Ptolemy, book 3, chapter 1: *In the first year around the Summer Solstice of Calippus 1. of August 1*, that is, at its ending, for thus it stands in the Greek: therefore it must be acknowledged that around the Summer Solstice the Calippic years end and begin. Nor indeed from elsewhere ought Calippus to have begun, since he set his cycle from a preceding Solstice of Summer, witness Geminus and Censorinus, having substituted the cycle of Meton, with the new moon at the beginning of the Summer Solstice.

[Margin: 3]

[Margin: *Errores alij Longomontani, & Leueræ.* — Other errors of Longomontanus and of Leuera.]

The other cause of error in marking the Equinoxes by one or two days too late was the false supposition, advanced by Leuera on page 228. that the first one made by Aristarchus stood from the year of Alexander 44. and from the year of Christ 282. Adducing for false Reinhold, who nevertheless on preface 6. expressly says: *If the first quarter of Thoth in the year 314. before Christ, that is, in the first year from the death of Alexander* — the same Leuera, on page 227. makes the first Olympic year coincide with Salianus' year 775. and with the year of Christ; but on page 228. he makes the first of Nabonassar 747. coincide with that — which, when it ought to cohere with Salianus (erring nevertheless), makes 746. and on pages 214. and 235. he conceives the year as 41. and that of the birth of Christ, which it ought as a consequence to coincide with Salianus, he sets at 44. and so the years 41. coincide with one another, not indeed without an inconstant method in this, on pages 20. 102. and 117. False notions of Chronology he insinuates, immersed in falsehood himself, and incurs imprudently into another series of mishaps. For that the opinion of Salianus, and of those who place the beginning of the Olympic, Nabonassar, and Alexandrian years one year too late, is false, we have demonstrated in our Reformed Chronology, from eclipses noted in the Historians,

together with a series of Consuls and of Censorinus (whom the Chronologers acknowledge as their master) as authority. For

[Margin: 4]

[Margin: *Saliani Chronologia corrigenda*. — The Chronology of Salianus to be corrected.]

for example, from the Consular *Fasti*, which, though corrupted from the first Julian year up to Trajan, are nevertheless certain, with the universal consent of all having weight, it is agreed that in the Julian year 90. the Consuls were M. Vinicius and Statilius Corvinus. To these, moreover, this Eclipse of the Sun belongs, which happened in the natal year of the Emperor Claudius — that is, on the Kalends of August, as Suetonius and Dio relate. But that Eclipse on the Kalends of August: in no other year does any Epoch of Christ, nor any Astronomical Table, present them; from which it follows that the beginning of the Epoch of Christ, that is, 45. completed years, and 90. began on the Kalends of January, and the year of Julian 283. which Censorinus too asserts, who, writing in his own time, says the Book *On the Natal Day* was, in the year of Christ 238. This year, moreover, both Censorinus there says the year of Nabonassar 986. began, and Alexander 562. and so that each, by retroceding exactly to the meridian, for the individual years in our canon of expanded years: the first year of Nabonassar incidentally on the 26. of February, in the year 747. before the Epoch of Christ, and the first of Alexander on the 12. of November, in the year before Christ 324. together with Nabonassar 425. for, by the same kind of computation as Ptolemy, book 3, chapter 8, he reckons, since he says that, with Nabonassar at the beginning, up to the death of Alexander, the completed years are 424. Therefore the first year before Christ coincides with Nabonassar 425. Finally, from Censorinus above it is established that, in the Julian year 283. of this year, and from the Eclipses we showed, of Christ 238. around the Summer Solstice, the year of the Olympiad 114. began. Therefore in the year before Christ 1. the Epoch of Christ was around the Summer Solstice, completed Olympiadic 776. and incidentally 777. and so the year before Christ 776. was the new moon of the Olympiadic 1. running with the year before Christ 776. of the Summer Solstice: the new moon, running around the Summer Solstice, year before Christ 224. And so Alexander the Great died, since the death of Alexander was the Olympiad 114. As Arrian, book 7. and Diodorus, book 17. likewise truly profess the Historians, and that the year before Christ 224. is not 323. but it is false to Giovanni Lucido and Salianus, as Leuera also felt.

[Margin: *Olympiadum vera Epocha*. — The true Epoch of the Olympiads.]

[Margin: 5]

Now indeed from Ptolemy, book 3, chapter 1, he asserts that, ending the eighth year of the first period of Calippus, Aristarchus had observed the Summer Solstice, and the 44. of Alexander; therefore Calippus 50. is, in absolute terms, before the death of Alexander 44. and from the same beginning he begins at the Summer Solstice of Calippus 51. since Alexander 45. began with Nabonassar 469. in the year before Christ 41. years, together with Nabonassar 587. it did not begin except on the Kalends of the following November, in the year before Christ 280. there was the period of Calippus, the year 76. witness Geminus, Ptolemy, and Censorinus; therefore the Solstice of Summer, or his new moon, began in the year before Christ 230. began the first period of Calippus, and in the year before Christ 178. the second one, and 4. seconds, and in the year before Christ 162. the current new moon of Alexander began in 162. For the year of Alexander 163. coincides with that of Nabonassar 587. did not begin except on the 3. of October, since the Equinox the first one of Hipparchus' day 27. September pertained to Alexander 162. and Nabonassar 586. and so coincides with that of Christ 162. and thus of the remaining Autumnal Equinoxes of Hipparchus, which a few days precede in that beginning of Alexander (which Longomontanus marks), and as far as the three first Leuera notes.

[Margin: *Calippi eorum vera Chronotaxis.* — The true Chronotaxis of Calippus and of his people.]

Albatenij Aequinoctium.

[Margin: 6]

Albatenius [al-Battānī], in chapter 27. of his science of the fixed stars, says that the Autumnal Equinox was observed by him at Aracta in the year 1206. from the death of Alexander, on day 19. of the month Elul, that is, the 18. of Pachon, that is, the 19. of September, before sunrise by 4. hours 45. nearly; and between this and the Ptolemaic Autumnal Equinox there had elapsed 743. Egyptian years, and 178. days 17. hours 36. nearly; and therefore in so much time the Equinox preceded by 7. days and 12. hours in a whole Roman year. Let this, therefore, be the synopsis:

Table — Aequinoctium Autumnale (Autumnal Equinox).

Ann. à morte Alexandri (Years from the death of Alexander)	Anno Christi (Year of Christ)	Mensis (Month)	Aracta Horæ p.m. (At Aracta, hours p.m.)		
1206	882	Septéb. 19	Pac hon 8	13	1 5'

You will recall that Albatenus, in the same chapter 27, supposes Aracta to be more eastward than Alexandria by 40' of one hour. Copernicus, book 3, chapter 13, and Longomontanus above, in his commentary on the Sun, found this anticipation of the Equinox very slight, and therefore hold the observation suspect, whose method Albatenus did not disclose. And yet Lansbergius, in the *Thesaurus*, pages 3. and 50, calls this observation a notable one, and says it was at hour 13. 15'. after midday.

[Margin: *Lansbergius notat.* — Lansbergius notes.]

Albatenus, however, holds the contrary: for indeed his own *Tabulae* obtain for this very moment of the Equinox, since they put forward the *Prutenicae*, the *Danicae*, and the *Rudolphinae* — because that *Aracta* of his they gather at hour 23. 40'. after midday, and the *Danicae* and the *Rudolphinae* at hour 3. 55'. which they call tolerable errors. Boulliau, book 2, chapter 2, for hour 13. 15'. after midday, or hour 1. 15'. after the middle of the night, puts it; Joseph Scaliger, on September 18. at hour 14. 21'. and adds, wrongly, that Scaliger reconciled this year with that of Christ 883. against whom see Scaliger; for Petavius, book 4, chapter 6, *On the Doctrine of Times*.

[Margin: *Joseph Scaliger lapsus Chronologicus.* — Joseph Scaliger's Chronological slip.]

Aequinoctia Io. Regiomontani.

[Margin: 14]

In the little Book of observations of Regiomontanus and Walther [Bernhard Walther], we have binary observations, one pair for each Equinox, of the distances of the Sun from the vertex at Nuremberg, whose method is that of Tycho [Tycho Brahe], in the *Progymnasmata* on page 48. and our *Geographia Reformata* on page 49. 26'. For by the Parallactic Rules of the old men of feet they observed in the year 1473. on March 11. at the meridian. The solar distance of the

center from the vertex by the Chord of parts 83600. of which the Radius, that is the length of either Rule representing the whole sine, was 100000. semichord, in the Tables of sines gives the arc of Degrees 24. 42'. 27". which doubled makes the arc gr. 49. 24'. 54". — namely the apparent distance of the Sun from the vertex; from which if you subtract our parallax, not exceeding the second 10". there comes out the true distance of the Sun from the Vertex grad. 49. 24'. 44". which subtracted from the distance of the Equator from the Vertex at Nuremberg gr. 49. 26'. leaves the Northern declination of the Sun of Minutes 1'. and 16". Since therefore the Sun was in the Northern signs, the Equinox had now been made for so many hours; and by minutes before midday, by as many minutes, and by seconds it was declining in the meridian toward the North. Therefore the Equinox was at hour 22. 44'. after midday of the preceding day 10. By this method, from the Chord of the meridian observed by Regiomontanus there, of parts 83810. we collected the Autumnal Equinox made on day 13. of September at hour 17. 30'. after midday at Nuremberg. Examine the synopsis in the table below.

Table — Aequinoctia Regiomontani in Horis post merid. Norimbergæ (Equinoxes of Regiomontanus, in hours after midday at Nuremberg).

Ann o (Yea r)	Christi (of Christ)	In meridiē (At the meridian) — Chorda	Dist. ☉ vera (true distance of ☉) — G. ' "	Decl. ☉ vera (true declination of ☉) — ' "	Aequinoctiu m — D. H. '
1473	Mart. 11	83600	49 24 44	1.16 B	10 22 45
1473	Sept. 14	83810	49 32 30	6.30 A	13 17 30

If you wish the observed, or apparent, distance of the Sun from the Vertex, add to the true [distance] the second 10". of our Parallax.

Aequinoctia Vualtheriana.

[Margin: 15]

Indeed, I should think ill of myself with regard to Bernhard Walther [Bernhard Walther], who deserved excellently of Astronomy right up to his old age — observing, among much else, the days around the Equinoxes especially, by the Parallaxic Rules, noting the Chords of the distances of the Sun from the vertex at Nuremberg, marking down from time to time those which were made by him in clear light, and carefully, or in which there was confidence — if I should not report them here. Especially those made on the Equinoctial day itself, or on the

day next to it: above all when I have seen them undeservedly neglected by the Astronomers of a later age, and so that Tycho himself scarcely sampled any from among them, nor those the best of all. The Method of extracting the time of the Equinox from such Chords I have already delivered, under number 14. The rest examine in the following Catalogue; and if you add our parallax to the Distances of the Sun from the vertex, in such a position you will have the true distance of the Sun from the vertex at Nuremberg, or that arc which by a doubled Sine answers to each of Walther's chords.

Table — Aequinoctia Vualtheri in Horis post merid. Norimbergæ (Equinoxes of Walther, in hours after midday at Nuremberg).

[Margin: *Tychonis usus harum observat.* — Tycho's use of these observations.]

At Tycho, in tome 1 of the *Progymnasmata* page 51, among all the others which he had seen, prefers the observation which in our order is the twentieth; and he says that from it the Equinox was collected for March, on day 10, hour 15. 40'. after midday at Nuremberg.

But if I had employed the Tychonic parallax in that position $2'. 18''$. there would have come out in every case a true distance from the vertex grad. $44. 41'. 15''$. and a Southern declination $15'. 15''$. and so at hour Equinox $15. 15'$. I judge, however, that it pleased Tycho 10. to observe the Equinox, even though the *Radius* — as Walther says — was weak, because in the year 1488. the distance stood at 100. years and an integer for the calculation of the Vernal Equinox observation made in the year 1588. As one about to compare the observation of his own with the Autumnal Walther made in the year 1588. he chose the Autumnal Walther, which is in our order, that is, the year 1588. for which reason of these the Equinox of Nuremberg made September 13. at hour 9. $20'$. after midday, discrepant from our reckoning by $2'$. and more, on account of an excessive parallax $1'. 18''$. assumed, because nevertheless in his own observations such a compensation, in the order of gathering thence the quantity of the Year, of which afterward — Longomontanus, trusting Tycho, commends the examination of these two observations even in his own *Compendium*.

Aequinoctium Gelalaeum Persarum.

[Margin: 31]

Joseph Scaliger, book 4. of the emended *De Emendatione Temporum*, page 304. narrates that Albu Arslam, Sultan of Corasan, or of Mesopotamia, by edict convened eight or more of the most outstanding men, among whom were Omar and Abensina [Avicenna], or Avicenna, in order to constitute the Year of the Persians, and them, in the year of the Christian Era of Dionysius 1079. namely the Hegira 471. and from the slaughter of Iezdegird 448. observed the Vernal Equinox on the 14. of March 5. since it was day 18. of the month Pharudin of the Persians, on day 6. of the month of the Arabs Ramachahim, the Cycle of the Sun 16. the Moon 4. at hour 2. $33'$. after midday. Which day was called Oromazda of the Persians, the New Year of the Just; that is, the New Moon of the Year of the Emperor Iesdegird. Boulliau also, book 2. chapter 2. from a manuscript of the Royal Library of Georgios Chrysokokkes, asserts that the Persian Tables show the true Vernal Equinox to have been in the year of Christ 1079. under the meridian of Tybenes (which is from Aleppo distant one hour), having risen on the side of March on the 14. day, hour 1. $1'. 4''$. as Walther thinks, on the 14. day, hour 2. $35'$. less — that is, the Philolaic Tables exhibit that hour 1. $1'. 27''$. exceeding by 1. of an hour $15'$. The true [Equinox] Longomontanus, in his Commentary on the Sun, did not accept as celestial, but as constituted from the Annual quantity, which Albatenus repeats, having regard to the time of the years $197\frac{1}{2}$. (so correcting the Typographical error in Longomontanus, who has $193\frac{1}{2}$.) which up to the

Albatenian Equinox in the year 882. up to the Persian one of the year 1079. flowed; from which dependent question we still cannot make a firm foundation in such an Equinox.

[Margin: *Ordo* — Order]

Cardinalis Cusani, & Prophatij Aequinoctia.

[Margin: 32]

Nicolaus de Cusa Cardinalis [Nicholas of Cusa], in his treatise *On the Repair of the Calendar*, asserts the year of Christ 1290. from the observation of certain men, whom he does not name, that the Sun entered Aries on the 16. of March after midday, and so on account of constant days 365. h. 5. 49'. 16". Reinhold too, in his *Theory of the eighth-sphere motion* folio 168, has these words: *Alphonsinus too holds that name, by which name Peter de Alliaco reprehends, that the watery quantity of the year is constituted; from which both ancient and recent observations manifestly cry out.* For he narrates the year of the Lord 1290. on the 13. of the month of March, that the entrance of the Sun into Aries was made on the 16. hour, after the calculation became permissible. Which relation, with the relation of Cusanus discordant, who refers those 16. hours and posits them after midday on the preceding day 12. that is Astronomically. As to Boulliau, book 3. of his two Astronomical [tables], the Vernal Equinox of the year 1290. in the Frisian Meridian by the Alphonsine calculation was on March 12. hour 6. 59'. after midday day 13. — there is therefore the difference if it were observed at hour 6. after midday from Cusanus' calculation by hours 33.

which is not inconvenient. The denomination, then, is from the observer of day 13. in the Roman manner, since on that day the observation showed the Equinox at hour 8. before midday, that is, Astronomically, at hour 16. after the preceding midday; that is, in the words of Cardinal Cusanus reported below: *In the year of the Lord 1290. on the 13. of March the Sun was found to enter Aries after hour 16.* But Cusanus does not say the observation was made by himself, or by another, nor in Frisia, nor was Reinhold's consequence necessarily withdrawn, or unconnected. Otherwise Alphonsine calculation errs around the observation, not so much on account of the proper quantity of the Year, and of the Anomaly, and of the Prosthaphaeresis, and of the false dissection of the Meridians, and of the Equation of the natural days, and of an excessive parallax — by these together taken up the error of many hours could stand.

[Margin: 33]

The same Cardinal Cusanus, in the same work on the Calendar, has these words: *Prophatius too, the Jew, and certain other observers, in the year of Christ 1303. the Sun, on the 14. of March hour 8. after the middle of the night, compared to enter Aries.* But this too Boulliau, book 3. chapter 3. says it ought to be understood in the Roman manner, that on that day it was made by observation, even though it were the Astronomical hour 8. after midnight of day 12. then most evidently it is hour 20. after midday of day 12. otherwise it conflicts with the preceding observations, and the consequent observations and the Alphonsine Calculation, which exhibits the year 1303. the Equinox in Frisia on March 12. hour 11. 23'. after midday; and immediately the Philolaic [Tables], which Wranisburgi exhibit on day 12. of March, this on day 18. 35'.

[Margin: 34]

A greater difficulty is that concerning the Equinox, which the same Cardinal in the same work adduces in these words, speaking of the Alphonsine Tables: *Experience found that it is almost in hour 13. it deviates; so that, as Master Henricus Bate of Mechlin in his little book of the Tables of Alphonso, then experience taught in the year 1490. and after this many years, 12. and in the same hour to err.* For if Cardinal Cusanus died in the year 1464. as is established from the Chronicle of his Life, and from the Chronicle of Mathematicians we set at the beginning of the First Tome of the *Almagestum Novum*: how could he have narrated an observation made in the year 1490? But the Alphonsine [Tables] could have been at fault around the year 1490. and in the margin the Philolaic [Tables], on the 3. of March, very low; which is rather to be feared, conjecture and credit the Cusanus to have rather written 1460. proclaim it, for it is easy in typography to invert these numbers, and so to put 6. for 9. Otherwise the Equinox of Cusanus the year 1346. observed, says Reinhold, on March 12. nearly two hours before midday, but he expresses neither the place nor the observer.

Copernici Aequinoctia.

[Margin: 35]

[Margin: *Ordo* — Order]

Nicolaus Copernicus, book 3. of the *Revolutions*, chapter 13. says: *We observed the Autumnal Equinox at Frauenburg, in the year of Christ's birth 1515. on the eighteenth before the Kalends of October; it was, moreover, after the death of Alexander, in the Egyptian year 1840. on the sixth of the month Paophi, an hour and a half after sunrise.* And by this Aracta he supposes Frauenburg to be oriented

from Bologna on the 1. and 6'. He gathers the Autumnal Equinox observed by Albatenus, and his own Egyptian [year] 633. and days 153. and hours 6. 45'. then he adds a few things.

[Margin: 36]

We received also the Vernal Equinox, which was in the year following the birth of Christ noted 1516. at hour 4. and a third after midnight, on the eighth day before the Ides of March. Tycho, however, Tome 1. *Progymnasmata* page 34. and in the *Epistles* page 74. accuses Copernicus in the declination of the Sun, that he everywhere erred by 2. 45'. and therefore in the interval of the Vernal and Autumnal Equinoxes he exceeded by hours 5½. — for two reasons: one in the altitude of the Pole, and the Equator he raised by 2'. 45'. on account of Refractions omitted. For indeed Copernicus, book 3. chapter 2. narrates that he observed by himself, and by others, the distance of the Tropic points not more than 46'. and of first scruples 58'. nearly,

roughly, that is, the angle of the section, namely 23' 28" of the parts of the equator [aequatoris partium], and one fifth of two. Then, in Book III, Chapter 2, he says: "At Frauenburg [Fruemburgi], however, the latitude is found to be 54 of the parts, less 19¼ first scruples." From these consequences he concludes that, in the observation of the Sun's summer solstitial altitude, the altitude is 59° 8', 54"; but the winter [solstice] altitude, once the subtraction of refractions is corrected, comes out as 8' 54" — agreeing with Tycho [Brahe] in his table of refractions — and that, this being settled, the altitude of the equator [Frauenburg] is 35° 36' 3", and the pole 54° 22' 57", and the obliquity of the ecliptic 23° 32' 51". But because Tycho, having sent Elias Olsen [Elia Olai] to Frauenburg — a man of the highest skill and practiced in instruments — discovered, from the circumpolar stars, that the altitude of the pole at Frauenburg is 54° 22' 15", and likewise deduced that the refractions of the Frauenburg observers had been larger than in Denmark; and since this happens at Copernicus's parallax of the Sun, and because the magnitude of the instruments used by Copernicus matters — especially since, on the testimony of Georg Joachim Rheticus [Rheticus] in the preface to his *Ephemerides* of the year 1550, Copernicus was not careful enough about seconds — for these reasons of uncertainty I do not think it worthwhile to try to extract from these observations the true equinox of the years 1515 and 1516. It is enough that these observations can be suspected of an error of three or four hours, or even more, in the matter of the hours.

Equinoxes of Pitati, Nonius, and the Landgrave of Hesse.

[Margin: 37] Pietro Pitati [Pietro Pitati] of Verona, in the preface to his *Ephemerides*, relates that in the year 1520 at Rome, together with Paulus, Bishop of Forlì [Forosempronio], he observed the vernal equinox [Margin: 38] on the tenth of March, after noon. And in the year 1521, likewise on March 10 at 9:17 after noon, at Rome, Pedro Nunes [Petrus Nonius] of Salacia [Salacien.], in Book 2 of his *De Observ. Reg. & Instrumentum Geom.* Chapter 4, asserts that he observed two palm-widths in diameter [duorum palmorum in diametro] at Coimbra. For many years he observed that the minimal distance of the Sun from the vertex came to be precisely 17° , [Margin: 39] and he then supposes the Sun's maximum declination to be $23^\circ 30'$, roughly. From this he concludes that the latitude of Coimbra [Conimbrica] is $40^\circ 30'$ roughly; and afterward in the year 1555 of the Christian era, on the 14th day of the month of September, finding the minimal distance of that same Sun from the vertical point to be $40^\circ 40'$, he infers the declination on the meridian of that day to be 10° to the south. And because, around the points of the equinoxes, the Sun's declination changes by 24 minutes in a single hour, in the section of the autumnal day, on September 14, 10 hours before noon — at which point indeed those Alphonsine tables [Tabulas Alphonsi] are found to fall, which the Spaniards praise (namely the Spaniard he had named a little earlier) — for the calculations of Alphonso do not agree among themselves on everything, and this is also attested by many observations, and the small dimensions of the astrolabe and the study of the Alphonsine hypothesis make the observations suspect.

[Margin: 40] The most distinguished Wilhelm, Landgrave of Hesse [Vuilhelmus Langravius Hassiae], in the year 1572, on March 7, by himself, obtained the Sun's meridian altitude at Kassel [Cassellis] to be $37^\circ 38' 40''$; so the distance from the vertex to the south comes to $1^\circ 10' 11''$. If you add $1^\circ 49''$ to the Sun's altitude — as Lansbergen says in his *Thesaurus* — the observation has 9° [recte: he says]. He then adds: the Sun runs through the equinoctial arc by $1^\circ 10' 11''$ in the space of two days and 22 hours. Therefore the true vernal equinox occurred at Kassel on the 9th day of March at 22:11 after noon. But gathering from his own tables, he says this equinox at Kassel "on the 9th day of March at 22:11 after noon" was altogether as the most distinguished prince observed it. Now Tycho, in Volume 1 of the *Progymnasmata*, citing page 75, says the Landgrave's [meridian altitude] of the Sun was there observed at the altitude of $27^\circ 28' \frac{3}{4}$ on March 7. When the parallax of $22' 22''$ is added, it is reduced to the true [altitude] of $37^\circ 30' 30''$; and supposing there the elevation of the equator to be $38^\circ 41'$, he gathers the southern declination of the Sun to be $1^\circ 10' 30''$, which he says falls into its place

at Υ $27^{\circ} 5' \frac{1}{3}$ — by his own tables' calculation, but by the Alphonsine $27^{\circ} 30'$, and by Copernicus $26^{\circ} 36'$, and of the two more.

The Tychonic Equinoxes, from his own observations.

[Margin: TYCHO] Tycho himself, in Volume 1 of the *Progymnasmata*, page 13, reports five vernal equinoxes and as many autumnal ones, by the days of the old calendar and by hours after noon at Uraniborg [Vraniburgi], where he determines the altitude of the equator as $34^{\circ} 5' 20''$. At that altitude he supposes the parallax of the Sun [parallaxis Solis] to be $2'$ and the refraction of seconds to be $44''$. Therefore, when he says the equinox was observed by him in the year 1584 — March 9 at 21:30 after noon — it is just as if he were to say that the meridian altitude of the Sun was observed on that day to be $33^{\circ} 42' 5''$. For to this,

by adding the parallax $2' 29''$ and subtracting the refraction $44''$, the corrected altitude comes to $33^\circ 43' 50''$; and when this has been subtracted from the equator's elevation of $34^\circ 5' 20''$, it leaves the southern [altitude] corresponding to the Sun's declination of $21^\circ 30'$, to which corresponds the hour 21:30, for the subsequent equinox to be celebrated. By this method, from the five aforesaid equinoxes — apart from those observations which leave the altitudes uncertain — we shall seek out his own observation, but we shall correct it by adding our own parallax, which at such a position is scarcely $16''$, and by subtracting the refraction $44''$. We shall do likewise concerning certain other meridian altitudes around the Tyconic equinoxes, taken from those reported by [Longomontanus] in *Astronomia Danica* Book I, Theorica, Chapter 2, in the commentary on the Sun. Drawing out from there the moments of the equinoxes, both according to the Tyconic parallax and according to our own emerging one, we shall accordingly distinguish them by the characteristics T and N.

[Margin: 67–70 series; the right-hand table]

After the prose-foot of the Uraniborg table, Riccioli adds (left column, foot):

[Margin: Lansbergen] Lansbergen [Lansbergius], in his *Thesaurus*, out of so many Tychonic equinoxes selects a single one to confirm his own tables, which is 52" in our order; and he finds that this falls not at hour 9:8 after noon (Tycho does not have it [there]), but at hour 9:2. As Clavius [Clavius], following Tycho, [reports] in his *Apologia Kalendarii*, but at hour 9:34 at Uraniborg, because at the altitude of 34 grades Tycho assumes the parallax of the Sun to be 2' ½, very nearly; but Lansbergen [takes] 2'. And the difference of half a minute, around the equinox, gives a difference in declination of half an hour. Both parallaxes, nonetheless, are faulty, as [will be shown] below. Boulliau [Bullialdus] too, in Book 2, Chapter 2, from a single Tychonic and a single Hipparchan annual quantity, elicits — namely from the equinoxes in our order, marginal numbers 5 and 56.

The Lansbergian Equinoxes.

In his *Thesaurus* of observations, Lansbergen [Lansbergius] draws two vernal and two autumnal equinoxes of Goes [Goësae]...

[which differ] from itself by not even a second scruple from his own tables. But by the altitude of the equator at Goes [Goësana] — taking the refraction as null, and supposing the parallax to be no greater than 14" for us — the difference of these from 1° 35' varies the declination by the same amount, and the time by 1 hour 35'. We shall therefore append, from Lansbergen and from our own parallax, the equinoxes deduced from his own observations, as they are reported by him himself. So that, if our parallax is true, his own tables err in this place by 1 hour 35'.

Four Equinoxes observed in the years 1536, 1574, 1575, 1581.

[Margin: 71] I confess I ought to have reported these before the Tyconic ones, but they matter little. So, in the year 1536 — as Daniel Santbech [Daniel

Santbechius] relates in his observations, *Phaenom.* prop. 11 — there was observed at Tübingen [Tubingae] an exact equinox on March 10, at the very noon of that day, from which he himself, and from the Ptolemaic vernal [equinox], supposing Alexandria to be more easterly than Tübingen by $1^{\circ} 28'$, gathers the annual equinoctial value of 365 days, 5 hours, $48' 41'' 42''' 33''$ [recte: $33'''$] $50''' 10'''$.

[Margin: 72] In the year 1574, Egnazio Danti [Egnatius Dantes] of Florence [Florentini], in the presence of many witnesses, observed [the equinox] on March 12, at $26'$ [after noon], before midday — the armilla of the equinoctial circle was equally illuminated on both sides of its cavity, and at once the southern [side] appeared; from which moment he judged the equinox to have occurred.

[Margin: 73] As [Egnazio Danti] relates in part 6 of his *Astrolabio*. Thus in the year 1575, with the same instrument and at the same place, he observed the equinox of March at 12 hours $4' 12''$ after noon. Moreover, at the altitude of the equator 46° , my own parallax of $10''$ retards each of those moments by the same amount; the equinox.

[Margin: 74] In the year 1581, Cesare Lucchini of Bologna [Cæsar Luchinus Bononiensis], a Bolognese, observed [the equinox] on March 11. The Sun's meridian altitude was $45^{\circ} 51' 15''$, by a large quadrant geometrically [constructed], as I read in his manuscript. A parallax of $10''$ added gives the true altitude of the Sun here as $45^{\circ} 51' 25''$; and the declination, $45^{\circ} 29' 40''$ subtracted, leaves a northern declination of $2' 45''$. Therefore the equinox is elicited from this at 2 hours $15'$ after midday, or at hour 2:10, if you wish, taking the refraction at $5''$, which diminishes the altitude of the Sun.

Equinox observed at Bologna by the Reverend Fathers Giovanni Battista Riccioli and Francesco Maria Grimaldi.

[Margin: 75] I had indeed thought to pass these over, since after our solar observations from the year 1641 to 1656 there succeeded those made on the gnomon of San Petronio [Gnomone S. Petronij], to which our own must yield because of the magnitude of the instrument — especially since at that time we determined certain equinoxes using the altitude of the equator...

[altitude of the equator] $45^{\circ} 30' 30''$, which afterward, as we shall show in Book IV, Chapter 4, is found in our observatory to be $45^{\circ} 29' 50''$. Nor have we had the parallax of the Sun adjusted at such an altitude. These matters notwithstanding, it is preferable, from the meridian altitudes which we accept — and indeed together with two intervening quadrants — to add at the same time what

equinoxes ought to result, found in San Petronio, and from the annual precession deduced from there, which is 11' 14" 14''' respectively. We disregard for the present the Julian year of 365 days. And as for the refraction of 6, we scorn it as uncertain.

Equinoxes observed at Bologna by the great gnomon of the Temple of San Petronio by the most excellent Lord Giovanni Domenico Cassini, or his assistants.

[Margin: 85] The Lord Giovanni Domenico Cassini [Dominicus Cassinus], in the book entitled *Specimen observationum Bononiensium, quae novissime in D. Petronij Templo &c.*, page 10, asserts that he observed the autumnal equinox in the year 1655, on September 23, at 5 hours 4 minutes 35 seconds before midday, in apparent time — that is, on Day 22, H. 18, 55' 25" after midday. But he neither [gives] the observation nor the method by which he derived it from his observations; I believe because he had indicated the method above, in the equinox of the year 1656. He supposes, however, from his observations — concerning which below — the obliquity of the ecliptic to be 23° 30' 20", and the parallax of the Sun, at the altitude of the equator observed here as 45° 29' 40", to be either nil or scarcely perceptible. He has nevertheless communicated to us the tangents of the solar distance of each limb from the vertex — several of them — both for this year 1655, on September 22 and 23, observed by him at midday, from which we shall elicit those distances by the method already given in Chapter 2, number 13.

Therefore the northern declination of the Sun		1	35	0
Obliquity of the ecliptic				
Therefore the place of the Sun in the ecliptic	♈	3	33	16

Now on the 19th the Sun was distant from the beginning of Aries by $24^{\circ}24'$; on the 21st it was at Aries $1^{\circ}34'30''$; and on the 23rd at Aries $3^{\circ}33'16''$. Therefore, over the two earlier days, the true motion of the Sun in the ecliptic was $1^{\circ}58'54''$, half of which gives a daily motion of $59'27''$. Over the four days it advanced $3^{\circ}57'40''$, a quarter of which likewise gives a daily motion of $59'25''$. But using the daily motion closer to the equinox itself—say $59'27''$ —the $24^{\circ}24'$ requires 24 hours, that is, the distance from the entry into Aries requires 24 hours $50'50''$; or, by my reckoning, 24 hours $51'1''$. Cassini therefore says that the equinox by apparent time fell on March 19 at 9 hours $50'50''$ after midday. Because, by the method common to the southern declination of $9'44''$, it would have been at 9 hours $44'$, by the first observation; but by the second, on account of the southern declination of $37'40''$, it would have been $37'40''$ before midday on the 21st—that is, on the 19th at 10 hours $20'$ after midday—which method is more precise and is the earlier method. Now, if we accept Cassini's annual precession, which is $11'$ of arc, then from these two equinoxes it is possible to predict several other subsequent ones, as in the table written below, adding 5 hours $49'$ for individual years; but in a leap year, after that addition has been made, one day must be subtracted from the sum.

Bologna, Years	March, after midday — D.	H . I — D.	September, after midday H . I
1655	20	4 2 22	1 5 8 5
1656	19	9 5 22 1	0 4 4
1657	19	1 4 22	6 3

Bologna, Years	March, after midday — D.	H . I — D.	September, after midday H . I
		5 0	3
1658	19	2 2 22 1 9	1 2 3 2
1659	20	3 1 22 8	1 1 9 1
1660	19	9 7 22	1 0

Let us now see whether the observations of Signor Cassini, or of his followers, made at the gnomon of San Petronio, agree.

89. Year 1656, September 22:

(Observed quantity)	Tangents	G.	I	II

Semidiameter			15	45
Distance of the Sun's center from the vertex		44	52	45
Distance of the equator from the vertex		44	30	20
Therefore the southern declination of the Sun			22	25
Obliquity of the ecliptic		23	30	20

(Observed quantity)	Tangents	G.	I	II
Therefore the place of the Sun in the ecliptic	$\underline{\alpha}$	0	56	11

Therefore on the 22nd the Sun was distant from the entry into Libra by 2'38", and on the 23rd it had already entered by 56'11". Hence the daily motion was 58'49"; and if these require 24 hours, then 2'38" requires [the rest follows in the right column]... [it requires] 1 hour 4'28". Therefore the equinox comes out from this observation as September 22, hour 1, 40'28" after midday; whereas by the preceding table it ought to have been at hour 0, 44'. Some flaw, then, lies hidden in the observation, and in the omission of parallax or of refraction; for from these two together an error of 20" of arc could arise—that is, in the time of the equinox, an error of 20' of time. An indication of this is, first, that the apparent diameter of the Sun is somewhat smaller than the one usually gathered from equinoxes accurately observed, and second, that the daily motion is, by our reckoning, nevertheless 11'12" less—about which see the following chapter, no. 10. It ought to have been at hour 0, 43'48".

91. I add an observation that [Johannes] Hevelius [Heuelij] recently sent me; for in the year 1654, on September 23, he observed the meridian altitude of the Sun to be about 35°28'40", at Gdańsk [Gedani], where the altitude of the equator is 35°38'. Hence, if you neglect parallax and refraction, the equinox rises out at hour 9, 20' before midday.

CAPUT IV.

On the Quantity of the Equinoctial Year and of the Sun's Daily and Annual Motion.

1. The equinoctial year is the revolution of the Sun from one of the equinoctial points back to the same point. I have already laid down, in Book 3, *Almagestum Novum* [*Almagesti Novi*], chapter 30, that such a year is always to be reckoned of the same quantity. Despite the variation of the Sun's apogee and the eccentricity of the Sun, no inequality of the years follows from these; rather, only within one and the same year does there follow an inequality of the Sun's motion and a variation of the limiting points from which it is measured. Now, if two consecutive equinoxes of the same kind could be observed in such a way that the committed error should not exceed 15", we should immediately have a quantity of the equinoctial year sufficient for determining past and future equinoxes for years around 1600 before and as many after. But for greater security, two equinoxes of the same kind must be chosen whose observations are held more

certain than the rest, and which are separated from each other by the greatest possible interval of years, so that any error in observing should be distributed over many years and become negligible.

[Margin: The requisites for determining the annual quantity.]

Let it be that of Signor [Giovanni Domenico] Cassini [D. Io. Dominicus Cassinus], who, trusting in the magnitude of the Bolognese gnomon, judged that the revolution of a single year would suffice to avoid an error of more than 1' in the quantity of the year, and four years to avoid an error of 15" of arc. But to avoid an error of even 1' in the moment of the equinox, one must guard against error in the altitude of the Sun and of the pole, from which the declination is derived—for although that error abundantly arises within 1" of arc, given the magnitude of this gnomon, nevertheless its use, as I have noted above, is rarely free of an error of 1" of arc, and of others that intervene by accident. Certainly Cassini himself, in the work praised above, at page 18, suspects that, on account of refraction, an error of nearly 1' of arc—though not a constant or steady one—lies hidden in the altitude of the 45th degree. [Tycho] Brahe [Tycho], in the first volume of the *Progymnasmata*, preferred an interval of 100 years; for, distributed over several centuries between his observations and those of Hipparchus, Ptolemy, or [al-Battānī] [Albategnij]—which he reckoned slippery and untrustworthy—or those entangled in the trifles of chronology. As for the observation of Bernhard Walther [Bernardi Vualtheri], made at Nuremberg [Norimbergæ] in the year 1488, he held it much more certain than these, and therefore compared it with his own observation made in the year 1588—the observations that belong to chapter 3, in order, numbers 20 and 56—especially since he was not attempting a universal restoration of the solar course suited to all ages, declaring that the year had been:

	D.	H.	I	II
From Hipparchus to Ptolemy	365	5	55	12
From Ptolemy to [al-Battānī]	365	5	46	20
From [al-Battānī] to Brahe	365	5	49	29
From Ptolemy to Brahe	365	5	47	52

But it is enough for him if it adapts the Sun's course within 300 or 400 years. And from that comparison he establishes the equinoctial year, page 53, as written below:

[Margin: The Tychonic quantity of the year.]

Days 365, hours 5, 48'45".

2. Signor Giovanni Domenico Cassini, in the aforesaid *Specimen* [*Specimine*] of observations, page 15, supposes that Hipparchus's observations are uncertain within half a day, and that Tycho's are within half an hour; and that the same ratio of a half-day to a half-hour holds—which falls between Annos 72 and 1728. He therefore reasons that to use an interval of 72 years between us and Tycho is just the same as to use an interval of 1728 years between Hipparchus and Tycho. On these grounds, which Longomontanus accepts in his *Commentary on the Sun* [for the equinox] of the year 1584, March 11 old style, taking the meridian altitude as $34^{\circ}29'55''$, the altitude of the equator at Uraniborg [Uranic.] being subtracted as $34^{\circ}5'20''$, there remains a northern declination of the Sun of $24'35''$. But since the daily change of declination at the equinoxes is so many minutes [$2'42''$], to the declination of $24'35''$ there corresponds 1 day, and over and above it, 0 hours 54'. So much, therefore, at the time of the equinox; and so the perfecting was at hour 9, $13'6''$ after midday at Uraniborg, but at Bologna at hour 2, $31'4''$ after midday. But for the equinox observed at Uraniborg in 1656, by Cassini, March 9 old style, hour 9, 50' after midday—therefore over 72 years it anticipated by 13 hours 12 minutes 11'', which, divided over the individual years, gives 11' for each year. This subtracted from the Julian year of 365 days 6 hours leaves the equinoctial year of 365 days 5 hours 49'; which, after many considerations, Cassini reckons safer, and which Petavius too had earlier chosen in his *De Doctrina Temporum*, chapter 36, no. 11, and Brahe in the first volume of the *Progygnasmata*, page 12, though he afterwards abandoned it.

[Margin: The Cassinian and Petavian quantity of the year.]

3. But just as I do not grant that the equinox observed by Hipparchus is certain except within half a day—whereas certain ones are certain within fewer hours—and just as I hold the Tychonic one certain within half an hour, so also for the equinox assumed by Cassini from the observation of the 9th, as appears from chapter 3, number 48, I find the Tychonic one, by parallax, to have been on the 9th at hour 21, 30'. But by our reckoning, with parallax applied, at hour 23, 43' with no parallax; at hour 23, 53'; and Cassini, from another observation, brought it down to hour 23, 6'. They are not, therefore, certain within the Tychonic half-hour; and consequently it is safer that the recurrence be over a longer interval of two equinoxes.

[Margin: The Cassinian and Petavian quantity of the year.]

4. Longomontanus, accordingly, in his *Commentary on the Sun*, having corrected the equinoxes according to his own principles, chooses the Hipparchan one, of which in chapter 3, number 7—that is, the vernal equinox in the year 146 before

Christ, March 23, hour 13, after midday, celebrated as observed at Alexandria; and he compares it with the equinox of the year 1587, observed at Uraniborg, March 10, hour 14, 56'. But at Uraniborg [it was] hour 16, 31'; and on account of the inequality of prosthaphaeresis he adds hours 3, 50'; and on account of the inequality of precession he brings the equinox down to about hour 7 [reading uncertain]; and so he reduces the equinox to hours 3, 21' [?]. And so over 1733 years the equinox anticipated by 11 hours 9, 39'; but he himself, through error, [gives] hour 19, 39'; and rounding off again to day 12, hour 20—which, distributing over 1732 years, he finds a single year's anticipation in respect of the Julian years to be 10'40"; and therefore he reckons the quantity of the year to be 365 days 5 hours 49'20"—or, limiting it for the course of the Moon, 365 days 5 hours 49'30".

[Margin: The Longomontanian quantity of the year.]

5. Ismaël [Boulliau] [Bullialdus], in book 2 of his *Astronomy* [*Astronomia Philolaica*], chapter 2, chooses the first vernal equinox of Hipparchus—which, in chapter 3, is the 7th for us—namely the year 146 before Christ, March 24, when, refraction removed, [it fell on] hour 23; but in such a way that the equinox occurred on the 25th, hour 21, 22'35" at Uraniborg, but at Alexandria at hour [?] 1'35". He compares this with equinox no. 56, in our order in chapter 3—that is, with the one observed by Tycho at Uraniborg, March 9, hour 20, 45' after midday—which, by reduction of prosthaphaeresis, he reduces to the mean event of March 11, hour 22, 25'15". Between these two equinoxes he reckons a median of 1734 Egyptian years; the time, divided by 1733 Julian years, gives the quantity of the year written below:

[Margin: The Bullialdine quantity of the year.]

Days 365, hours 5, 49'4"21'''3''''.

6. [Kepler] [Keplerus], in his *Epitome of Astronomy* [*Epitome Astronomiae Copernicanae*] and in the *Rudolphine* [*Tables*] [*Rodulphinis*], uses a year of 365 days 5 hours 48'57"36'''; he does not express [the rest]—as neither does [Govaert] Wendelen [*Lansbergius?*], in his way, in the *Thesaurus* of solar observations toward the end of the third Class, where he defines the mean tropical year as 365 days 5 hours 48'57"2'''22''''24''''''; even though some equinoxes were premised, the usage of which is rather of this kind. Nor does he expound it. But Wendelen [Vendelinus], in his letters to me, and also in the *Idea Tabularum Atlanticarum*, opens up the foundations on which he established the quantity of the tropical year; except that he supposed, as probable, that 33 tropical years contain 12053

whole days, precisely enough; wherefore, divided by 33, there comes out for him a year of 365 days 5 hours 49'5"27"16"". And if anyone should say that 330 years yield not 120530 but 120529 days, from which it would follow that the year were smaller than Wendelen's—then, dismissing these others, since they established the year without bringing in observations, let us put forward our own opinion.

7. That we may inquire into the quantity of the equinoctial year, we choose the equinox most exactly observed at Bologna at the great gnomon of the Temple of San Petronio, in the year of Christ 1655, September 22 Gregorian style—or, old style, on the 12th—at hour 18, 55'25" after midday, as above; but the apogee of the Sun was then in Cancer 8°35'45". So that, with Signor Giovanni Domenico Cassini's observations made there, and with the eccentricity found from the differences of the apparent diameter, we have ascertained—from which, by our own eccentricity, the prosthaphaeresis of the whole [comes to] 3480 parts, of which the Radius is 100000—it follows that, at the distance of the beginning of Libra from the apogee of 81°24'15", the prosthaphaeresis [Prostaphæresis] is 1°58'17", to be subtracted from the mean motion to give the true; but to be added to the true to give the mean. But to the mean motion of the Sun there are owed precisely 48 hours, by which the mean equinox preceded the true; and so the mean fell on September 10 old style, hour 18, 55'25" after midday; but at Alexandria, from my *Geographia Reformata*, it was at hour 20, 28'5". And this was the third year after a leap year.

8. It is now necessary, among the most ancient equinoxes—those observed by Hipparchus—to choose one that fell in the third year after a leap year, and of whose hour we can obtain the greatest possible certainty. Such is the one which, on this account, Ptolemy in book 3, chapter 2, of the *Almagest* [*Almagesti*] reports as observed in year 21, of the third Calippic Period, the first day of the intercalary days, at the sixth hour of the day, by the armillae set up in the portico at Alexandria. From our *Apparatus Chronologicus* [*Chronologicum*], that year was the 158th before the common Epoch of Christ; and the first intercalary day began at midday, or rather at the end of the sixth hour, on the 27th of September. And so we have a truly very long interval between the equinoxes, namely 1812 whole years.

9. As for the hour of the equinox: although Hipparchus is reckoned to have made it at the sixth hour—that is, almost at midday itself—nevertheless from his own preceding observations, which Ptolemy reports in the same book 3, chapter 2, it will be established for anyone skilled in the subtleties of astronomy that it preceded the moment of midday by several hours. For Ptolemy relates that

Hipparchus, in the preceding year, that is in year 20 of the third Calippic Period, observed the autumnal equinox in the morning at first light on the first intercalary day. Therefore at sunrise, or a little after, he saw the lower cavity of the equinoctial armilla equally illuminated on both sides, and therefore thought that only then was the Sun reaching the equator. And so, with horizontal refraction posited—or one not far from the horizon—it had necessarily to be that the Sun appeared higher than it really was by many minutes, and therefore was in truth already southern and had crossed the equator when it appeared on the equator. And so that equinox most certainly occurred several hours before sunrise—namely, by about 4 hours, as I shall show presently. Now it is certain, agreed among all astronomers, that the equinoctial year is said to be of 365 days, 5 hours, and at least 48 minutes; and certainly somewhat less, the Sun's [year] being of 365 days, 6 hours. But let us grant that it was 365 days 6 hours. Then, with an Egyptian year of 365 days having elapsed, if the equinox had fallen in year 20 at hour 4 before sunrise, it could not have occurred in year 21 except at hour 2 after sunrise—that is, at about hour 20 after midday on the 26th of September, or of the first intercalary day, or at hour 4 before the following midday.

10. Now there was then the apogee of the Sun—from our own observations, of which below, in Gemini $7^{\circ}21'$ —and the autumnal section was distant from it by $112^{\circ}39'$; and therefore the prosthaphaeresis of the Sun was $1^{\circ}50'26''$. From these the time of 1 hour $20'50''$ comes out; and accordingly the mean equinox at Alexandria was September 24, hour 23, $9'49''$; but the mean equinox in the year 1655 was September 10, hour 20, $28'5''$. Therefore the precession of the equinox was of 14 days 2 hours $41'44''$ —which, resolved into seconds at the hourly rate of $121,9304''$, and this divided by the elapsed 1812 years, gives an annual precession of $11'12''$.

[For the right column flow:] that is, at that time the difference of the daily declination is $14''$ or $16''$; by which, if the whole error is in error, the error will be of the whole day, even if by one minute it is nearly 4. But that you may avoid the error of the 6 hours, care must be taken in observing the Sun's altitude... an error of $4''$ of arc. From what source, however, did Ptolemy have such great refinement of instruments that he could so confidently say, in book 3, *Almagest*, chapter 2: "But at the solstices I hope that neither we, nor Archimedes, in observation and calculation, have erred even up to a quarter-part of a day." Add to this the uncertainty of the refractions in the wintry brumal observations, mostly very great, and to these still depending on the parallax of the Sun at the horizon—which some make $3'$, some $2'$, others $1'$; Wendelen $15''$. We scarcely [make it] $30''$.

[Margin: Ptolemy's excessive confidence.]

On account of these doubts, and the very great slowness around the solstices, the change of declination—Ptolemy, book 3, chapter 2, said: "The summer solstices observed in the times of Meton and Euctemon, and afterward of Aristarchus, are to be compared with those which fell in our times." But since the observations of the solstices are hard to discern, and those which they handed down do not seem exactly taken—which is indeed approved even by Hipparchus's own judgment—we too, selecting a few, will compare them, not for inquiring into the quantity of the tropical year (granting that the Calippus, Archimedes, and others did this), but because the Greeks began the year not from the equinox but from the summer solstice, or its new moon—however and whenever used in astronomy.

[Margin: The order.]

1. Ptolemy, in book 3, chapter 2, of the *Magna Constructio* [*Almagest*], relates from Hipparchus, in his book *On the Magnitude of the Year*, that Aristarchus, in the 50th year of the first Calippic Period, and the 44th from the death of Alexander the Great—this being 280 before Christ—observed a certain solstice; but before that, 152 years earlier (namely before Christ 432), Meton and Euctemon, while [the latter was] prefect of Athens, observed a solstice, made in the morning, on the 21st of Phamenoth. (Scaliger, book 2, *De Emendatione Temporum*, page 76, and book 5, page 410; and Petavius in his *Uranologium, Variarum dissertationum* book 6, chapter 10, say it was in the year 316 of Nabonassar, on the 27th of June, on feria 1, one day before the true solstice. For Meton, from the observation of the true [solstice], chose the mean to enter his Cycle; whence he is called Metonicus; and so it is to be understood, the Festus Avienus in those verses.)

[Margin: The solstice of Meton.]

But primeval Meton took his beginning from the year When ruddy
Phoebus would scorch with the star of Cancer.

For at Athens in that year the mean solstice fell on the 27th of June at hour 10, 43' after midnight; but the true solstice on the 28th, hour 10, 13'. Petavius adds that the solstice in Hipparchus's time was mean on the 25th of June; the true on the 26th; and in Sosigenes's age the mean on the 24th. The true [solstice], in 25, was wont to fall.

[Margin: The order.]

[Margin: The solstice of Meton.]

But [Philip] Lansbergen [Lansbergius], in his *Thesaurus*, fourth Class of solar observations, against the syntax of this chronology, draws this observation back to Nabonassar; and at Alexandria (when it ought to have been at Athens) collects the solstice at hour 16, 41' after midnight, on the 20th of Phamenoth—at which moment he asserts the Sun to have entered Cancer, and so he holds that the true equinox was on that day, since (the number of the year being changed) it is certain, indeed, that the 21st of Phamenoth was the 26th of June.

[Margin: Lansbergen's lapse.]

2. Ptolemy, in book 3, chapter 2, adds the solstice observed by himself at Alexandria, the summer solstice in the year 463 from the death of Alexander, on the 11th of Messori after midnight following—which he repeats in chapter 4. It was the year of Christ 140, the 22nd of June; which Lansbergen follows, forgetful of the leap year, as he says. From the beginning of the years of Christ to this solstice there are 139 full Julian years, common months 5, days 24, hours 13, 27' at Alexandria, as to apparent time; but as to true time, at hour 13—that is, one hour after midnight. But he ought to have taken the months of a leap year. See our *Apparatus Chronologicus*.

[Margin: Lansbergen's error.]

3. Bernhard Walther [Bernardus Vualtherus], at Nuremberg [Norimbergæ] in the year 1478 [?] of Christ, observed by parallactic rules on the 11th of June; and he himself says he exactly measured the Chord of the distance from the vertex as 44890 parts; and, with the same observed exactly likewise on the meridian of the 13th of June, hence it follows that the Sun, equally in each meridian, declined from the equator, and so the solstice, and the maximum decli- [nation continues into the right column].

[Margin: Walther's solstices.]

Now, from what has been said—Book 3, *Almagest*, chapter 14, number 8, and from [Boulliau] [Bullialdo], book 2, chapter 2—it is sufficiently established that the Sun, about a quadrant [of a circle] after its own rising, by the force of refraction is seen to be more southern in the circle of declination by 4 or 5 minutes; which just as many hours retard the apparent approach of the Sun toward the equator, while it is still represented in the northern signs. Since therefore Hipparchus, in the morning at first light, had reckoned the intercalary days at year 20, and the equinox occurred, and in year 21 had seen, after much time, the Sun still northern, and only passing to the south below the sixth hour, he easily concluded that the equinox was six hours after the preceding year's

equinox—that is, the sixth hour from sunrise—to be the subsequent equinox. And it was possible that some little deception contributed something to this, on account of the situation of the armilla and its placement declining by one or another minute from the plane of the equator. Let it therefore remain nearly certain that that true equinox was at Alexandria in the year 158 before Christ, hour about 20 after midday on the 26th of September.

11. This precession, while I consider it more deeply, I observe to relish of a certain Ideal beauty, congruent with the septenary of days, or the integer hebdomad, and with the novenary of centuries; for, the multiplications being made—11' and 12", over 900 years—it comes out to exactly 7 days, in which the median equinox precedes; from which a marvelous analogy is not doubtful, since it could be received with such great beauty, and moreover upon so great a foundation of observations after the centuries—it betrays itself as resting upon no. 18.

12. Therefore, subtracting from the Sosigenian year of 365 days and 6 hours the 11' and 12", there comes out to us the equinoctial year, which we choose, of 365 days 5 hours 48'48". The equinoctial year is now to be resolved into the hourly second 3155 6928"; and the common year of 365 days into the second 31536000, or 360 degrees into the second 1296000. For if the common year and the sum thence made be multiplied by the Zodiac and divided by the equinoctial year, there will come out the Mean Annual Motion of the Sun; but if a single Day, or a Month of days—28, 30, or 31—resolved into seconds be multiplied by the Zodiac and the sum divided by the equinoctial year, there will be had the Daily and Monthly Motion, as below; the fractions of seconds nevertheless being reduced, up to the sixth scruple, of which in constructing the Tables for many years account is to be taken.

Motus Annuus Dierum (Annual Motion / of Days)	Sign.	Gr.	I	II	III	I		V
						V	V	I
(Annual Motion)	11	29	4	4	30	5	5	1

On which foundation we have constructed our Tables, to be displayed at the end of the Work.

CAPUT III.

Observations of the Solstices.

1. [Willebrord] Snel [Snellius], in his notes on the Hessian observations, rightly declared that it is a labor of Hercules to avoid the errors in observing the solstices.

[Margin: Ptolemy's excessive confidence.]

[Margin: The order.]

[Margin: The solstice of Meton.]

[Margin: Walther's solstices.]

incidence fell on the meridian of the 12th of June. To this chord corresponds $25^{\circ}56'29''$ [?]. When our parallax of $5''$ is subtracted, the Sun's true distance remains $25^{\circ}56'24''$ from the vertex of Nuremberg — which is in agreement with Tycho [Tycho Brahe], and with what we have admitted up to now, namely $49^{\circ}26'$. If from this you subtract that distance, there remains a true declination of the Sun of $23^{\circ}29'36''$. The maximum, however, from Cassini's [Giovanni Domenico Cassini] observations is $23^{\circ}29'$ [?]. Thus on the 11th and 13th of June it fell short of the maximum by $44''$, which would require the intervening days to be about 3, and so the solstice would have occurred either on the 10th or the 14th of June. But if we wish to retain the equality of declinations of the 11th and 13th, and also the maximum of $23^{\circ}30'20''$, then the true distance of the Sun from the vertex on those days must have been $25^{\circ}55'56''$, though the observed value was $25^{\circ}56'1''$; and the altitude of the pole of Nuremberg is $49^{\circ}26'28''$. Or, at any rate, unless the parallax is increased, the altitude of the pole of Nuremberg in such a position would be $33''$ [?]. You see how slippery and perplexing solstice observations are.

4. In the year 1487 the same Walther [Bernhard Walther], at the same place, on the meridian both of the 13th and of the 14th of December, observed by means of robust and careful sightings [Radios fortes, & diligenter]. He

obtained a chord for the Sun's distance from the vertex of 118790 of those parts of which the radius is 100000, and the observed declination was $23^{\circ}26'30''$. Since, then, from an equal declination there follows an equal solstice, the winter solstice is celebrated midway between the moments, that is, in the middle of the night between the 13th and the 14th. But if one wishes to torment himself, through the uncertainties of refraction and of parallax, with the altitude of the pole and the obliquity of the ecliptic discussed above, in order to track down the time of this solstice, his mind will be pulled in different directions to no purpose.

5. In the year 1490 the same Walther, on the meridian of the 11th rather than the 12th of June, by a clear and careful observation, obtained the Sun's meridian distance from the vertex of Nuremberg. The chord of the distance was 44900 of those parts. Therefore, from this equality, it would follow that the solstice occurred in the middle of the night, with 11 days intervening — by a reasoning similar to the one I used in number 3, since the matter comes out diverse and perplexing. If, however, anyone cares to exercise himself in these calculations, I will furnish him with select observations of the solstitial days, estimated with greater certainty, by adding the arc corresponding to the chords, and the declination observed as set down above. The altitude of the pole is $49^{\circ}26'$.

[Margin: Note for Refractions. (Nota pro Refractionibus.)] If the winter observations are sound — if the altitude of the pole of Nuremberg and the obliquity of the ecliptic (that is, the maximum declination of the Sun, 23°30'20") are correct, and our parallax is 24" — then at the Sun's altitude of 17°, refraction at Nuremberg never on those days exceeded 4'40"; indeed [continues below]...

Of the Tychonic solstitial observations we shall give four summer ones and three winter ones, handed down partly by Longomontanus [Longomontanus] in his Book 2 of the *Theoricorum*, in the Commentary on the Sun, and partly by Father Albert Curtz [Albert Curtz] of our Society, who described them from Tycho's own manuscript and out of his singular generosity transmitted them to me. Now, assuming the altitude of the equator established at Uraniborg by Tycho to be 34°5'30", and our parallax 7", with the Sun at apogee being 57½", and our obliquity of the ecliptic 23°30'20": by whatever means [the solstices are derived], we shall indicate the summer ones, the winter ones being omitted.

- Egnazio Danti [Egnazio Danti], in the folio work which he published on the use of the great Gnomon of Bologna in the Temple of San Petronio [Templo D. Petronij] erected by himself, says that in the year 1576, on the 11th of December, the shadow of the Sun's image reached its margin at the maximum declination, and on the following day was diminished; and so the winter solstice fell between the 11th and 12th of December. Yet earlier, namely in the year 1570, he had observed at Florence the Sun's declination at the maximum at the solstice, as he relates in Part 2 of his *Astrolabe*, chapter 34 — but he does not state the day.

[See the Tychonic table above.]

11. [Margin: Linemann observes the solstice. (Linemani Observat. Solstitialis.)]
In the year 1644, on the 22nd of June, Albert Linemann [Albert Linemann] obtained the Sun's meridian altitude of $58^{\circ}47'30''$ at Regiomontium [Königsberg] in Prussia, where he had observed the altitude of the pole to be $54^{\circ}43'$, as he asserts on the memory of ages 7 and 8 [?]. From this the declination would be $23^{\circ}30'30''$, but ours is greater by $10''$. Owing to the uncertainty of whether parallax has corrected the altitude, the moment of the solstice remains uncertain.

12. We, in Book 3 of our *Almagestum* [Almagestum Novum], chapter 27, brought forward the solstices of 4 years, but they suffer from some slight defect of instrument, and from an excess of parallax, since at that altitude of about 69° it cannot exceed $5''$ or $6''$; and we were then using a false altitude of the pole, which we afterward found at our Observatory to be $44^{\circ}30'10''$. With these corrected, more accurate solstices come out, as below.

Solstices Observed by Us at Bologna

[Solstitia per Nos Bononiae observata]

O r d o	Year of Christ (A.)	Mo nth (M.)	Da y (D.)	Altit. observed (G. ' ")	Altit. true (G. ' ")	Declin. of Sun, Ω 23 (' ")	Solstice after noon (D. H. ')
1 4	1643	Jun e	21	69 0 0	69 0 6	30 16	21 6 52
1 5	1644	Jun e	20	68 59 58	69 0 3	30 13	20 12 42
1 6	1645	Jun e	20	68 59 54	68 59 59	30 9	20 18 32
1 7	1646	Jun e	20	68 59 50	68 59 55	30 5	21 1 40
		Jun e	21	69 0 5	69 0 10	30 20	21 0 0
		Jun e	22	68 59 50	68 59 55	30 5	20 22 20

Of the last solstice we are more certain, since we found altitudes of the Sun that were entirely equal on the 20th and 22nd, at the same meridian; and therefore, for the 21st, I have more safely added a parallax of only 5". From this we are confirmed about the Sun's maximum declination of 23°30'20". And since on the 20th and 22nd it fell short by 15" — the daily difference then being 14", therefore 15" requires 25⅔ hours — adding these to the 20th, the solstice would fall on the 21st at 1h40' after noon; but subtracting them from the 22nd, it would fall on the 21st at 1⅔h before noon, that is, on the 20th at 22h20' after noon. By all means, keeping the mean, the solstice fell at the meridian.

Now follow the observations of Giovanni Domenico Cassini [Giovanni Domenico Cassini], who, in the book he has published, entitled *Specimen Observationum Bononiensium*, page 3, writes thus: "In the year 1655, on the 21st of June, at the summer solstice, in the Temple of San Petronio, from the altitude of 71 Bolognese feet, we observed the distance of the Sun's center from the vertex at the meridian point itself to be 20°50'50". But the equator's distance from the vertex is 44°30'20". Therefore the Sun's apparent declination from the equator is 23°30'30". Since, however, the marble band of the gnomon, and the iron, were not yet rounded at the sides, the declinations designated at those very sides... he submitted them to me to be examined, with the faculty to use them — as he relates on page 19. So afterward, by him, they were most generously communicated to me from his own manuscript and notes, in the cause of truth, indeed beyond his obligation toward us:

He read the Marseilles observation, with love and study, thus: "We examine Linemann's observation of the 21st of June of the year 1655. The solstitial [shadow] impressed on the sides, the more evidently we recognize it, the more we find the distance of the Sun's lower margin from the Tangent vertex to be 38904, but 38909, and the upper not 37860." Thus then:

Anno 1655 [Linemann's observation, as reduced]

	(parts)	Gr.	'	"
Tangent of the lower [limb] [Tangentis]	38909	21	15	38
Tangent [of the upper] [Tangentis]	37870	20	44	50
Difference, and Diameter of the Sun		0	31	8
Semidiameter		0	15	34
Distance of the Sun's center from the vertex		21	0	4
Distance of the equator from the vertex		44	30	20

	(parts)	Gr.	'	"
Therefore the Sun's declination then was		23	30	16
Since the Sun adds 4" from the start [Ob distantiam Solis ab initio 4" adde]		0	0	4
Therefore the maximum declination of the Sun [Margin: Maximum declination of the Sun. (Solis maxima Declinatio.)]		23	30	20

This is afterward confirmed by Tycho's emended solstitial altitudes. Now, if on the 21st it fell short of the maximum by 4", then "4" second, and 14"" require hours... 24, and 4"; 4" requires 6h52' hours, by which the solstice would have been after noon on the 21st. Yet, because parallax was wholly omitted, and because of some slight doubt about the connection of the observations, this observation seems to be set after the solstice observation of the year 1658, which I shall presently give from the same author's manuscript and notes.

Anno 1658. June 20

	(parts)	Gr.	'	"
19. Tangent of the Sun's lowest limb [Infimi Solis limbi Tangens]	38912	21	15	44
Tangent of the highest [Supremi Tangens]	37876	20	44	40
Apparent diameter of the Sun [Solis Diameter appar.]		0	31	4
Semidiameter			15	32
Distance of the Sun's center from the vertex, observed [à vertice visa]		21	0	12
True for us [Vera nobis]		21	0	7
Distance of the equator from the vertex [Aequatoris distantia à vertice]		44	30	20
Sun's declination then [Declinatio Solis tunc]		23	30	13

Anno eiusdem 1658. June 21, more accurate [accuratius]

	(parts)	Gr.	'	"
Tangent of the Sun's lowest limb [Infimi Solis Limbi Tangens]	38911	21	15	42
Tangent of the highest [Supremi Tangens]	37871	20	44	32

	(parts)	Gr.	'	"
Apparent diameter of the Sun [Solis Diameter appar.]		0	31	10
Semidiameter		0	15	35
Distance of the Sun's center from the vertex, observed [à vertice visa]		21	0	7
True, on account of our parallax $5\frac{1}{2}''$ [Vera ob nostram parallaxim $5''\frac{1}{2}$]		21	0	$1\frac{1}{2}$
Distance of the equator from the vertex [Aequatoris distantia à Vertice]		44	30	20
Therefore the true declination of the Sun [Ergo vera Solis declinatio]		23	30	$18\frac{1}{2}$
And, the Sun's maximum declination being assumed [Et posita maxima declinatione Solis]		23	30	20

The solstice occurred on the 20th, at the hour after noon... of our solstice of the year 1646. And by our revolutions it ought to have been at hour 21h45'5"12", and so I have applied a parallax of $5\frac{1}{2}''$, since it is only 5", or rather 6". It is customary, at this altitude, to satisfy the astronomical epilogisms. Therefore the Tangents of the 20th must be corrected, so that the true declination comes out to be nearly $23^{\circ}30'7''$.

CAPUT VI.

Observations of the Obliquity of the Ecliptic, that is, of the Maximum Declination of the Sun.

[Obliquitatis Eclipticae Observationes, seu Declinationis maximae Solis.]

1. [Margin: Pytheas. (Pytheas.)] Pytheas of Marseilles [Pytheas of Marseilles] — whether he flourished in the age of Alexander the Great, who died in the 113th Olympiad, that is, in the year 324 before Christ (as many gather from Strabo, with Dicaearchus, the disciple of Aristotle, saying that the writings ascribed to Pytheas displeased him), or whether he lived in the time of Scipio, about the 140th Olympiad, that is, the year 216 before Christ (if indeed he be the same Pytheas of whom Polybius speaks, when Scipio, in questioning, asked the Marseillais — as Gassendi maintains in his second *Letter* to Wendelen): this Pytheas, I say, as Gassendi reports in his *Life* of

Claude Fabri de Peiresc, observed at Marseilles in the year 1636 [recte: Pytheas's ancient observation, reported by Gassendi from a 1636 reconstruction] the proportion of the summer solstitial shadow to the gnomon as 209 to 120. From these two sides [continues]...

at a right angle, the observed altitude of the Sun's upper limb is gathered to be $70^{\circ}47'42''$. If you add to it the semidiameter of the Sun of $15'4''$, there remains the observed altitude of the Sun's center, $70^{\circ}32'41''$ [?]; and to this, if you subtract the distance, there remains the Sun's maximum declination of $23^{\circ}52'41''$ [?]. And yet Gassendi there thinks that this proportion can easily be inferred to be as great as Gassendi himself found it, namely $42\frac{2}{3}$ of those parts of which the gnomon is 120, or 42 of those parts in 89328. Hence the observed altitude of the Sun's upper limb arises as $70^{\circ}25'59''$ [?], of those parts, 11750; and at 89328 parts the observed altitude of the limb was $70^{\circ}10'58''$, and the maximum declination of the Sun $23^{\circ}30'58''$ [?]. But Gassendi, in that place, in his second *Letter* to Wendelen — which is inscribed *On the Proportion of the Gnomon to the Solstitial shadow* — grants that it was one and the same age, yet he does not say it expressly about that observation of Pytheas. For Strabo only, in Book 2, near the end, reports that the proportion of the gnomon to the summer shadow at Byzantium is 120 to 42, the fifth part being subtracted; whereas he holds Byzantium to be on the same parallel as Marseilles, on which account, because of the same proportion of the gnomon to the shadow at Byzantium as at Marseilles by Pytheas, it is believed to have been observed as nearly the same in both places — although it is plain, from a stricter calculation, that it cannot stand thus, as is established from Ptolemy [Ptolemy], in his Book 1 of the *Almagest*, chapter 6, on Pytheas, or from Hipparchus [Hipparchus], who affirms that Marseilles, where the gnomon is to the summer shadow as 20 to $5\frac{1}{2}$, follows the altitude of the Sun's upper limb [?].

2. Hipparchus, in Snel [Willebrord Snel], Book 2 of the *Eratosthenes Batavus*, near the end, has handed down that the equinoctial shadow at Byzantium was found to be to the gnomon as 111 to 120. Therefore, by the laws of right-angled plane triangles, the altitude of the Sun's upper limb is $47^{\circ}13'45''$. Again, through Strabo, Book 2, [he says] that at Byzantium, at the summer solstice, the gnomon has to the shadow the proportion which 120 has to 42, the fifth part subtracted. By the same laws, the altitude of the Sun's upper limb is $70^{\circ}47'42''$. Therefore, from the difference of these arcs, the obliquity of the ecliptic, or the difference of the summer solar declinations from the equinoctial, is nothing at all, namely $23^{\circ}33'57''$ [?] in the time of Hipparchus, let alone of Strabo, who flourished under Tiberius. How greatly he could err in these two days, this very age teaches, unless we

use the highest diligence. But if you listen to Pliny [Pliny], who in Book 6, chapter 34, [says] that at the parallel of Byzantium the gnomon of 9 feet [casts] an equinoctial shadow of 8 feet — the altitude of the Sun's upper limb would be $48^{\circ}22'$, from which, the difference being subtracted, the Sun's maximum declination comes out as $22^{\circ}25'42''$, and so this is suspect. But Pliny gives the account of the whole climate, and does not speak of the gnomon's shadow at Byzantium, but of the shadow of the climate in which Byzantium, Rome, etc., for the most part lie.

3. The ancients defined the distance of the tropic from the equator by 24 whole degrees, and so we can interpret that, when they chose that round number, they meant that greater degree of $23\frac{3}{4}$, rather than $23\frac{1}{2}$. Thus Geminus [Geminus] placed the distance of both tropics from each other as the parts of the meridian which 11 are to the whole meridian of 83, that is, $47^{\circ}24'40''$; and the equator's distance from the tropics $23^{\circ}51'20''$. So Eratosthenes [Eratosthenes], with Hipparchus in Ptolemy, Book 1 of the *Almagest*, chapter 9. The ancient observations defined the distance of the tropic from the equator by 24 degrees... [Margin annotation truncated; see below]

Achilles Tatius [Achilles Tatius], in his *Isagoge*, chapter 16, says: "From the summer tropic to the equinoctial, 24 parts. And Proclus [Proclus], in his *Sphere*, chapter 6, [says] that by the interval of the equidistant, the equator is distant from each of the two by sixty-fourths." Others afterward, seeing it to be a smaller degree, 24 with the smaller, and a greater with the greater $23\frac{3}{4}$, said that the distance of the tropics from each other was nearly 11 parts of those of which the whole meridian is 83; this is $47^{\circ}24'40''$, and the equator's distance from the tropics $23^{\circ}51'20''$. Thus Eratosthenes, and Hipparchus in Ptolemy, Book 1 of the *Almagest*, chapter 9.

Eratosthenes, indeed, by a scaphe [sundial bowl] and by the parallelism of the Sun's radii, abused that opinion both about the distance of the equator and of the tropics, and about the magnitude of the terrestrial circumference. The method of Eratosthenes is set out by Cleomedes [Cleomedes], Book 1 of the *Cyclica Theoria*, chapter 10; and by Pedro Nunes [Pedro Nunes], Book 2, *On Observation*, page 132; and by Willebrord Snel, Book 1 of the *Eratosthenes Batavus*, chapter 9, on a far better scheme than in Maurolyco's third dialogue of the *Cosmographia*, or from Maurolyco in Clavius [Clavius], in the *Sphere*. But since we drew Eratosthenes himself from the very source, Cleomedes, we shall set out his very method, then

his errors, and finally, from his observation itself, we shall derive the distance of the tropic from the equator, corrected.

First, Eratosthenes, and with him Cleomedes, assumed Alexandria, A, and Syene, B, to be under the same meridian. Second, that the arc AB between those cities was 5000 stadia. Third, that radiating rays, sent down to different parts of the Earth, are parallel to one another. So Cleomedes expressly, and so too Ptolemy [?]. Therefore the rays CB, from the Sun's center C, to Syene, and DE, from the extremity of the Sun's upper limb, to Alexandria's scaphe E, are between the parallels. Fourth, that a straight line drawn through parallels, while it makes alternate angles equal, and that, the radius CB being therefore produced through the imagination, to the Earth's center F, and the gnomon at Alexandria being erected on the day of the summer solstice, that is, the style AG of the scaphe, or hemisphere of the concave hemisphere HEI, and the said style continued through the imagination into the center F, the straight line FG, falling

Diagram. A geometric construction illustrating Eratosthenes's measurement of the terrestrial circumference. At the top, two points D (left) and C (right) mark the extremities of the Sun's disk, from which long rays descend obliquely toward the Earth. Below, a circle represents the Earth, with its center marked F. A smaller circle/arc above and to the left represents the scaphe (sundial bowl) at Alexandria. The rays from D and C strike the construction at the points H, E, L, I, G, K, with B marked on the right of the Earth-circle. The gnomon-style and the radius CB extended to the Earth's center F are shown.

- D (top left): extremity of the Sun's disk (one ray-origin)
- C (top right): center / opposite extremity of the Sun's disk (the other ray-origin)
- I (upper, within the scaphe): point on the scaphe rim
- G (center of scaphe): tip of the gnomon-style (stylus AG)
- B (right, on Earth-circle): Syene
- H (left of scaphe): edge of the concave hemisphere
- E (lower left, on scaphe): Alexandria (foot of the scaphe / shadow terminus)
- L (below E): point on the construction
- K (below scaphe): point on the Earth-circle near center
- F (center of Earth-circle): center of the Earth

upon the parallels GF and DE — therefore the angle EGF is equal to the angle BFG. Fifth, therefore, the arc AB, subtended by the angle BFG, is equal to the arc AE, subtended by an equal angle AGE. Sixth, that Syene is under the summer tropic,

because gnomons at the meridian of the summer solstice cast no shadow for 300 stadia around. With these things laid down, on the day of the summer solstice Eratosthenes noted the arc AE, observing the shadow EA, terminated by the ray DE, in the bottom of the scaphe of Alexandria, all around; measuring it, he found it to be the fiftieth part of the whole circle, that is $7^{\circ}12'$. Therefore he concluded that the arc AB too was 5000 stadia, of $7^{\circ}12'$; and so the whole circumference of the Earth was 250000 [stadia].

[continued from the discussion of Eratosthenes's scaphe construction]

to the point K, the arc BK is almost a full quadrant, and the rays cannot diverge — they cannot even sensibly be parallel — because the Earth's semidiameter KF is not, in physical terms, equal to the true semidiameter of the Sun: as a terrestrial body, the Earth exceeds it, and contains it $5\frac{1}{3}$ times over, by Ptolemy's data; whereas in our own data (treated in *Almagestum Novum* III) it contains it 33 times and more. Yet this much is most truly demonstrated, and is established by Nunes [Pedro Nunes] and by Snel [Willebrord Snel] above, and by ourselves (III.5): the Sun's rays, issuing from one and the same point of its body and reaching different places on the Earth however far apart, are at a distance from one another such that they may be taken as parallel. Of this kind are the rays CB and CGL drawn through the apex G of the stylus AG; and so Eratosthenes ought to have proceeded in such a way that, the angle BFG being his angle AGL, this angle AGL came out physically equal — and accordingly he should have added to the arc AE the arc EL, which is just as large as the angle EGL (that is, CGD), subtending the apparent semidiameter of the Sun, namely $15' 5''$. From observations [?] the arc AL ought thus to have come out as $7^{\circ} 27' 5''$. So too the arc AB, between the summer tropic [tropicum aestivum], or the vertex of Syene, and the vertex of Alexandria in Egypt — for the vertex of Alexandria is contiguous with it, as Ptolemy affirms in *Syntaxis (Almagest)* I.12 and 13, and in *Geographia* I, table 13: it is distant from the equator by $30^{\circ} 58'$. For he says, in the same chapter 12, "*From the point of the vertex of Alexandria to the equinoctial, $30^{\circ} 58'$ are demonstrated.*" From this $30^{\circ} 58'$, therefore, subtracting the arc AB, falsely supposed by Eratosthenes to be the arc between the tropic and the equator — for it came out to him as $23^{\circ} 46'$; or because it came out to him as running from 11 to 83 [?], that is, $51' 20''$ [?] — he reckoned the latitude of Alexandria, the altitude of the pole, to be $31^{\circ} 3\frac{1}{2}'$, which was afterwards found by Ptolemy, by the rules of parallax, to be $30^{\circ} 58'$. From this true arc AB, then, subtracting the arc shown above, $7^{\circ} 27' 5''$, there is left the true distance of the tropic from the equator, in Eratosthenes's own time, $23^{\circ} 31' 5''$ — or, setting aside my own parallax, $23^{\circ} 31'$. But why Ptolemy, wishing to retain the altitude of the pole at Alexandria and the

Eratosthenic distance of the tropic from the equator, went astray as to the Moon's maximum latitude in the quadratures by 20', and how from this it is inferred that the obliquity of the ecliptic was at that time about 20' less than minutes [?] less than Ptolemy supposes, we have stated in *Geographia Reformata* CXXVIII; and we shall say more when we treat of the observations of the Moon's latitude.

[Margin: The true obliquity of the ecliptic in Eratosthenes's time — 23°31' [?]]

§5. Ptolemy, in *Almagest* II.6, parallel 11; in *Geographia* I.23, parallel 10, says that the longest day in Rhodes is, by observation, 14½ hours, and that the altitude of the pole there is likewise 36°. But this cannot be made consistent unless the maximum solar declination of 23° 30' is assumed — for this alone is taken in the Tables and in the tables of the Prime Movable [Primum Mobile] under the pole-altitude of 36°: the semidiurnal arc answers to 7h 15', and the [whole] day to 14h 30'.

§6. Pappus of Alexandria, who flourished about A.D. 390, in his *Mathematical Collections* I.6, theorem 35, takes as the foundation of his demonstration this: "*The diameter of the sphere has, with respect to the diameter of the summer tropic, by capacity, the same proportion that 629 has to 529; for the straight line drawn from the center of the sphere to the center of the tropic has, by its length, the same proportion to the semidiameter of the tropic that 10 has to 23,*" etc. Here Commandinus adds in his commentary: "*For the maximum right sine of the declination of the Sun, namely of 23½°, is 23924, of which the semidiameter of the sphere is 60000,*" etc., or 39874, of which the semidiameter of the sphere is 100000, as is clear from the Tables of Sines. But this could not be unless the maximum declination were 23° 30'; for if it were 23°[31'] [?], as Ptolemy holds, or if Pappus's result followed from it, 23° 50', its sine would be very different — namely 40408. Pappus therefore knew that the maximum solar declination which Ptolemy had followed, too timidly, from Eratosthenes's error, was false.

[Margin: Pappus's view on the obliquity of the ecliptic.]

§7. al-Battānī [Albategnius], in chapter 4 *On the Science of the Stars*, asserts that he observed, with the greatest diligence he could muster, the minimum distance of the Sun from the vertex on the meridian as 12° 26', and the maximum as 59° 26'. From this he established the distance between the tropics as 47° 10', and from the equator 23° 35'; and accordingly the pole-altitude of al-Raqqā [Aractae] as 36°. But whether he could have erred by a full 5' — whether others may have seen otherwise — to me does not seem impossible; indeed, very [likely].

[Margin: al-Battānī's observation.]

§8. About A.D. 1070, Arzachel [al-Zarqālī] the Spaniard observed the distance of the tropic from the equator as $23^{\circ} 34'$; and in A.D. 1140, Almaeon [Ibn al-... of] Almansor as $23^{\circ} 33' 30''$; and in A.D. 1210, Thebit [Thābit ibn Qurra's] son, likewise, $23^{\circ} 33' 30''$; and in A.D. 1300, Prophatius the Jew [Jacob ben Makhir] $23^{\circ} 32'$, as Copernicus reports in *De Revolutionibus* III.2. Reinhold [Erasmus Reinhold] in his *Theoricae*, Nunes [Pedro Nunes] in *On Observation* II, Regiomontanus in the *Epitome of the Almagest*, proposition 17, Clavius [Christoph Clavius] in his *Sphaera* p. 262, and Lansbergen [Philips van Lansbergen] in his *Thesaurus* observed [the same]. As for the *Solarium*, Class 1, who places Prophatius the Jew only 68 years after Almaeon — when in fact it was 160 years after him, and 230 after Arzachel — and who, as praised by Lansbergen himself, affirms that Copernicus drew it from that source (I believe in order to draw it into agreement with his own Tables): why he should draw the Albatenian [observation] to $23^{\circ} 38'$, neglecting the refraction-parallax. But all the aforesaid observations differ by few minutes, so that — given the uncertain manner of observing in those times — we are not so certain of the error of three or four minutes deviated, nor [can we say] that the obliquity of the ecliptic was greater than $23^{\circ} 30'$, or $31'$, or thereabouts.

[Margin: Arzachel. — Almaeon. — Thebit. — Prophatius. — Lansbergen is noted.]

§9. In A.D. 1460, Purbach [Peurbach] and Regiomontanus, the distinguished astronomers of Vienna in Austria, took the meridian altitude of the Sun at the summer solstice as $65^{\circ} 6'$, and at the winter [solstice] as $18^{\circ} 10'$. Lansbergen in his *Thesaurus* says that the *Solarium* observed it, and adds the distance of the tropics seen as $23^{\circ} 28'$ of the zodiac, but on account of the parallax in the winter [solstice] $2' 11''$ and the refraction $5' 4''$, but inserting his own parallax $58''$, the true arc came out between [the tropics] $59' 51''$, or close to 47° ; and the obliquity of the ecliptic $23^{\circ} 30'$. Granted, indeed, that Regiomontanus in the *Epitome of the Almagest*, proposition 17, may have placed it as observed at $23^{\circ} 28'$ — yet he himself does not cling to that, in that in his own Tables he chose $23^{\circ} 30'$. Clavius too admits this in his *Sphaera* II, where nonetheless he reports Regiomontanus's observation as far different, as does Lansbergen; for he relates that the Viennese solstitial altitude was observed at $65^{\circ} 30'$, and the winter [solstitial] altitude at $18^{\circ} 30'$. From this he infers the pole-altitude of Vienna as $48^{\circ} 20'$; whereas from the Lansbergian observation it is 48° , and from our *Geographia Reformata* it is $48^{\circ} 22'$.

[Margin: Regiomontanus.]

§10. In the preceding section, among all the solstitial observations of Bernhard Walther — three in number related — there is none that sets the maximum

declination of the Sun beyond $23^{\circ} 30'$, nay, many set it well below; and Dominicus Maria Ferrariensis [Domenico Maria Novara of Ferrara], as Clavius has it in his *Sphaera*, found it at $23^{\circ} 29'$. But Johannes Werner [Vernerus] [found it at] $23^{\circ} 28\frac{1}{2}'$; yet it is credible that this befell him because of uncorrected refraction, for he found it greater, after the Copernican manner, by grades $23^{\circ} 28' 30''$, as he himself affirms in *De Revolutionibus* III.2 — inasmuch as, since (as he had said in II.2) he found the distance of the tropics from himself to be $46^{\circ} 58'$, almost; and in III.2 he adds the latitude of Frauenburg found by himself to be $54^{\circ} 19' 30''$. To these if you add $23^{\circ} 28' 30''$ for the supposed [solar] declination, it follows that he observed the meridian altitude as $12^{\circ} 12'$; and yet the true pole-altitude, by the Tyconic instruments from the circumpolar stars, is at Frauenburg $54^{\circ} 22' 15''$, as Tycho relates in *Progymnasmata* tom. 1, p. 34. From this he infers him to have erred by reason of refraction by $2' 45''$, which, subtracted from the winter altitude $12^{\circ} 9' 15''$, [yields] also $23^{\circ} 28' 30''$ for the [solar] declination. There remains the Ptolemaic parallax-excess, which by his use is $1' 35''$ — in the winter [solstitial] altitude of the Sun, 12° , he uses $2' 59''$; and since these cannot but be $24''$, the corrected altitude remains $12^{\circ} 7' 40''$. From this, by the Frauenburg altitude of the equator which is $35^{\circ} 37' 45''$, the maximum solar declination, with these subtracted, is left as $23^{\circ} 30' 5''$.

[Margin: Corrected Copernicus.]

§11. Rightly, therefore, Petrus Apianus [Peter Apian] in *Primo Mobili*, A.D. 1530, and Oronce Finé [Orontius Finaeus] in *Cosmographia* II.24 for the same time, and Pedro Nunes [Petrus Nonius] in *On Observation* II, in the year 1555, declared the obliquity of the ecliptic to be $23^{\circ} 30'$ — which Clavius in his *Sphaera* p. 262, and Scheiner [Christoph Scheiner] in *Rosa Ursina* p. 356, and Galileo [Galilei] in his *Dialogues on the World System*, chose as the common opinion, although they do not add observations. Nor is this much opposed by Egnazio Danti [Egnatius Dantes] in part 2 of his *Astrolabe*, chapter 34, where he relates that in A.D. 1570 the solstitial altitude of the Sun on the meridian was taken by himself at Florence as $69^{\circ} 49'$, and the winter [altitude] as $22^{\circ} 51'$; from which he infers the obliquity of the ecliptic as $23^{\circ} 29'$ — for if you add our parallax $5''$ to the summer altitude, and subtract the refraction $3' 25''$, the summer altitude comes out as $69^{\circ} 49' 5''$, and the winter as $22^{\circ} 51' 20''$; and so the distance of the tropics $47^{\circ} 1' 10''$, and the distance from the equator $23^{\circ} 30' 35''$.

[Margin: Apian. — Orontius. — Nunes. — Clavius. — Scheiner. — Galileo. — Danti.]

[Top of folio 21, completing §11:]...from which he infers the obliquity of the ecliptic as $23^{\circ} 29'$ — for if to the summer altitude you add our parallax $5''$, but subtract from it the refraction $3' 25''$, the summer altitude comes out as $69^{\circ} 49' 5''$, and the winter [altitude] as $22^{\circ} 51' 20''$; and so the distance of the tropics $47^{\circ} 1' 10''$, and the distance from the equator $23^{\circ} 30' 35''$.

§12. Christoph Rothmann [Rothmannus] and Jost Bürgi [Iustus Byrgius], the distinguished astronomers of the Landgrave of Hesse [Landgravius Hassiae], about A.D. 1570, by the same [method], found the corrected altitude of the equator at Kassel [Cassellis] to be $38^{\circ} 40' 40''$; and the solstitial altitudes of the Sun, as Snel [Snellius] has it, mostly $62^{\circ} 11'$, rarely $60^{\circ} 12'$. Subtracting therefore the altitude of the equator, the obliquity of the ecliptic is left as $23^{\circ} 30' 20''$ — which Cassini too found in agreement with us, in the year 1655. Likewise, Johannes Homelius [Hommel], in A.D. 1570, as Tycho witnesses (*Progymnasmata*, p. 631), observed the meridian altitude [of the Sun] at the summer solstice as $62^{\circ} 11'$; and at Leipzig [Lipsiae], where the altitude of the equator, as Tycho says, is $38^{\circ} 41'$, the distance from the tropic is therefore $23^{\circ} 30'$.

[Margin: The Hessians. — Hommel.]

§13. Tycho [Brahe], from his own observations (*Progymnasmata* tom. 1, pp. 17 and 28, and in his *Epistolae* p. 40), set, for the year 1587, the obliquity of the ecliptic at $23^{\circ} 31' 30''$; but because of an excessive parallax of the Sun — and Kepler therefore correcting this excess in the *Rudolphine [Tables]*, pp. 27 and 116, says that we may perpetually use $23^{\circ} 30'$ — but, as I have already said in the preceding section, from the choicest of Tycho's observations, using the truer parallax, we have deduced the minimum solstitial declination of the Sun as $23^{\circ} 29' 7''$, the maximum as $23^{\circ} 30' 27''$, and the mean as $23^{\circ} 30' 22''$.

[Margin: Tycho.]

§14. Lansbergen, in his first class of *Solarium* observations, recounts that observed by himself at Goes [Goesae] in A.D. 1589: the meridian altitude of the Sun at the summer solstice as $61^{\circ} 58'$, and at the winter [solstice] $15^{\circ} 2' 30''$; but, applying his own refraction and parallax, he gathers it as $61^{\circ} 59' 4''$ — this being $14^{\circ} 58' 43''$ — and the difference, or distance of the tropics, [yields the tropic distance] $47^{\circ} 0' 21''$; and the obliquity of the ecliptic $23^{\circ} 30' 10''$, as great as he says the Landgravians [observed], which he finds very close — but, retaining the Lansbergian refraction $6'$ in the winter [solstice], and at the summer solstice $6''$, and applying our parallax $23''$, the summer altitude comes out as $61^{\circ} 58' 6''$, the winter as $14^{\circ} 56' 46''$, and so the obliquity of the ecliptic $23^{\circ} 30' 40''$.

[Margin: Lansbergen.]

§15. By this observation Gassendi [Pierre Gassendi] at Marseilles ascertained the obliquity of the ecliptic as $23^{\circ} 30' 58''$, as we have already said in section 1 on the occasion of Pytheas. Therefore in his *Institutiones Astronomicae* I, chapter 8, he said it was $23^{\circ} 31'$, or just a little, indicating that it could be something less by some seconds. But Wendelen [Govaert Wendelen, Vendelinus], in a most learned letter to me, full as it were, asserting it from the stars [observed], writes that, while he was dwelling in the province of Forcalquier [Forcalcarii], from the circumpolar stars he obtained the pole-altitude as $43^{\circ} 54'$, and the meridian distance of the Sun from the vertex over many years at the summer solstice he found to be $20^{\circ} 24'$; subtracting my own parallax $6''$, it comes to $20^{\circ} 23' 54''$; and this subtracted from the pole-altitude [yields] the distance of the tropic from the vertex $23^{\circ} 30' 6''$ [?]. Although, according to Gassendi in his Epistle 2 to Wendelen, Wendelen is said to be at $23^{\circ} 30' 24''$. And Wendelen himself asserts this same [value] in his *Diatriba*, which is entitled *Loxias, or On the Obliquity of the Sun* — in which, however, he is deceived, when from Pappus of Alexandria he gathers the obliquity for A.D. 400 as $23^{\circ} 42' 6''$, as is clear from what was said in section 6 from Commandinus.

[Margin: Wendelen.]

§16. We ourselves, in the preceding section, from our observations (section 14 and 17), deduced the maximum declination of the Sun to be never less than $23^{\circ} 30'$, nor greater than $23^{\circ} 30' 25''$; but for the reasons there alleged we choose $23^{\circ} 30' 20''$; and this, constant, we have used in our Tables, caring nothing for the anomaly which others, and Wendelen in the said opuscle published in 1626, endeavored to introduce — namely one arising from the inconstancy of refractions at the winter solstice. And so, in order to bring our two conclusions into view, it pleases [us] to set down the opinions of the authors, both as they lie with them, and as deduced from a correction of their observation, with the marginal numbers of this section appended, so that through them the places of the authors and the examinations of their observations may be found.

§17. In the *Memorial of the Ninth Century* of Albert Linemann [Albertus Linemannus], I find Wenceslaus of Nová Plzeň [Veuceslaus de Nova Pilzna], in A.D. 1416, with a great quadrant and the Ptolemaic four-cubit iron rules...

[Margin: Immutability of the obliquity of the ecliptic.]

at Prague [Pragae] [it is reported] that the Sun was observed at the beginning of Cancer with a meridian altitude of 63° 26'; from which, if you subtract the altitude of the equator 39° 55' 30", there remains the distance of the tropic 23° 30' 30".

Obliquity of the Ecliptic, or the Maximum Declination of the Sun

I. Conclusion [I. CONCLVSIO]

For our own and the preceding century, if seconds are to be disregarded, the obliquity of the ecliptic was, and is, $23^{\circ} 30'$ rather than $31'$, since most observations and authorities support this. But if account is to be had of the seconds, then $23^{\circ} 30' 20''$ is to be chosen, on account of the most recent observations, carried out with larger instruments — so that whoever should strive to increase or diminish it by about ten seconds is not to be severely condemned.

II. Conclusion [II. CONCLVSIO]

It is much more probable that the obliquity of the ecliptic is unchangeable, and that it was, and will be, as great as it now is. First, because — apart from the 4 or 5 minutes in which the ancients could easily have erred — we have deduced just such a value from the ancient observations of Eratosthenes, Hipparchus, and Ptolemy, and of Pappus of Alexandria. Secondly, because, although a few of the fixed stars favor Tycho's conjecture (who supposed that they vary their latitude on account of an external cause — namely on account of a variable obliquity of the ecliptic), yet more [stars] contradict this opinion and retain the same latitude they once had, or nearly the same; and that variety, diverse [as it is], rather than the variety which the ancient supposed obliquity was thought to be, [we showed], as we showed in *Almagestum Novum* VI.15. Thirdly, because, if the obliquity of the ecliptic of the ancients is reduced, and is now brought down to $23^{\circ} 30'$, then the maximum latitude of the Moon in the quadratures observed by Ptolemy comes out almost as great as Tycho finds it — which is an indication, though not indeed a necessity, but rather a probability of our opinion. Fourthly, because to affirm the maximum [variation] is, at the maximum, in need of a foundation; but a change of the obliquity of the ecliptic is of the maximum moment, since it influences very many astronomical operations, and, that being changed, it would be necessary in each century to construct anew many Tables of the Prime Movable and of the Fixed [stars], and certain [Tables] of the [Secondary] Movables; whereas, on the other hand, we have neither sufficient theoretical reasoning *a priori*, nor an *a posteriori* foundation sufficient — much less the maximum needed for establishing this change — as is clear from the observations laid out above. Fifthly and finally, not a few, and those not to be repented of, astronomers stand for its immutability: namely Ptolemy in *Almagest* I.11; Thebit, in Maurolico's *Cosmographia*, dialogue 3; Agostino Ricci [Augustinus Riccius] in his treatise *On the Motion of the Eighth Sphere* [*De Motu Octavae Sphaerae*]; Athanasius Kircher in his *Magnes*, p. 477 of the first edition; Simon

Stevin [Steunus] in Hérigone [Herigonius] tom. 5, p. 579; Vincenzo Renieri [Vincentius Reinerus], in the *Medicean Tables*, again published in chapter 7, num. 7; Pierre Gassendi in his *Life of Peiresc* for the year 1635, and in his Epistle to Wendelen on the proportion of the gnomon to the solstitial shadow; and Kepler, chapter 12, [in the] *Rudolphine [Tables]*, saying: "*That the obliquity of the ecliptic was once greater is a matter not only doubtful, but refuted by valid arguments from the very observations of the ancients gathered by me, and beyond doubt plainly false.*"

[Margin: Immutability of the obliquity of the ecliptic.]

CHAPTER VII [CAPVT VII]

Observations of the Quadrants and Semicircles of the Year [Anni Quadrantum Observationes, & Semicirculorum]

The year is divided into four parts by the cardinal points of the ecliptic, that is, the points and moments of the equinoxes and solstices. The first quadrant embraces the time from the vernal equinox to the summer solstice; the second, from the summer solstice to the autumnal equinox; the third, from the autumnal equinox to the winter [solstice], that is, the winter solstice; the fourth, from the winter solstice [bruma] to the vernal equinox. That these times are unequal is manifest from astronomical observations. And the times are unequal: the time from the Sun's entry into Aries [Υ] up to its entry into Libra [ϱ]; the time from [its entry] into Libra to the following entry into Aries [Υ]; likewise the time from the Sun's entry into Cancer [ϖ] up to its entry into Capricorn [φ]; the time from [its] entry into Capricorn [φ] to the following entry into Cancer [ϖ]. This can be established to some extent from the equinoxes observed (chapter 3) and the solstices (chapter 5), as well as from the opinions to be reported shortly.

CAPUT VIII.

Selected Observations of the Sun's Meridian Altitudes outside the Equinoxes and Solstices.

To thoroughly understand the Sun's motion, the moments of the equinoxes and solstices are not sufficient; observations are also required of the times at which the Sun is found at certain other points of the ecliptic, outside the four cardinal points — especially around the middle parts of Taurus, Leo, Scorpio, and Aquarius. Then, in order to compare these positions with those drawn from the astronomical tables, the reliability of the tables is established; and at the same time, with a view to constructing the tables themselves, the place of the apogee and the quantity of the eccentricity are found by the Sun's discovered position and by the motion of the solar apogee. For the inequality of the solar motion shows itself plainly in the unequal dwelling [*mora*] of the Sun in the northern semicircle — 8 days more than in the southern — and, in these centuries of ours, by 14 hours 18 minutes more in the spring quadrant than in the autumnal, and by 13 hours 26 minutes more in the summer quadrant than in the winter. This inequality cannot be otherwise accounted for by astronomers than by an eccentric circle of the Earth, or by an eccentric ellipse, or by an epicycle equivalent to the eccentric — as I have set out more fully in book 3 of the *New Almagest* [*Almagestum Novum*], from chapter 17 through 24.

Moreover, from the medley of observations found among writers — chiefly Walther, the Hessian observers [the Landgrave's at Kassel], Tycho, Kristmann, and others among them — we shall select the more reliable ones, those more suited to the advancement of astronomical study; nor shall we add to them either parallaxes or refractions, but shall take only those places on the Earth where the observations were made, together with the year, month, and day, and with the altitude of their pole drawn from our *Geographia Reformata*. Then, in the

following chapter, we shall search out from them the place of the Sun in the ecliptic.

Distances of the Sun's Meridian [position] from the Vertex of Nuremberg, selected out of Bernhard Walther — among them, those marked *Clara*, *Diligens*, or *Praecl.* being noted as certain or quite certain.

	<i>Ultima Solarium</i> [the last solar one] Iunij 3	452 80			

From the foregoing we now select 24 observations for the Sun's position around the beginnings and middle parts of the signs. We shall determine that position by assuming the distance of the equator from the vertex of Nuremberg to be $49^{\circ} 26'$, together with our parallax and the old Almagestic refraction; for once the distance seen from the vertex is corrected and converted into the true [distance], the Sun's true declination will be established, and from this — and from the maximum declination of $23^{\circ} 30' 20''$ — the place of the Sun will at once follow by spherical triangle, without recourse to a table of declinations. The more reliable

positions, however, are those of the northern signs, since these are not subject to the uncertainty of refractions.

To these we append 20 positions of the Sun drawn from the excellent observations of the Landgrave of Hesse [the Kassel observatory program], which Snellius published, selected from those made at Kassel from the year 1568 onward with instruments now rectified, and repeated with the altitude of the equator set at 38° 40' 20"; from those that are subject to a less certain refraction we have departed, so that we may use our own parallax alone, and the obliquity of the ecliptic, of which we spoke above.

The Tychonic Meridian Altitudes of the Sun, observed at Uraniborg — where the altitude of the equator is $34^{\circ} 5' 30''$ — I selected out of Longomontanus' *Astronomia Danica*, book 2, *Theoricorum* ch. 2, in the *Commentary on the Sun*, and from Willebrord Snel among the Bohemian observations, and from those which P. Albert Curtz [Albert Curtz], S.J., sent to me, excerpted from Tycho's manuscripts, of which some too were published at Vienna. But the observations of the year 1601 — some were made at Benatky Castle, where the altitude of the equator is $39^{\circ} 41' 30''$; some at Prague, where the altitude of the equator is $39^{\circ} 55' 30''$; and the refraction found by Tycho is greater by 2 minutes than in Denmark. From these, using our parallax and obliquity of the ecliptic, we derive the places of the Sun in the ecliptic.

I pass over Jacob Christmann's [Jacob Christmann's] solar observations, inasmuch as I gather from book 1, chapter 7, of his own work that they are not exact to within 4 minutes. But from our own, which I obtained at Bologna in the College of St. Lucia together with Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], made on the most serene days, with two quadrants, and not seldom in threes and fours, I select those which were the more accurate,

and not all of them, for there are in fact more than 500. But I add a selection, so as not to burden the pages with superfluous prolixity. Applying our obliquity of the ecliptic, the parallax, and the refraction, I add the declination, and from trigonometry the place of the Sun.

Meridian Altitudes of the Sun Observed by Fathers Riccioli [Riccioli] and Grimaldi [Grimaldi]

Latitude of the place [Altitudo Aequatoris]: 45° 29' 50".

The columns are: the observed meridian altitude [Alt. merid. ☉ visa]; the true declination of the Sun [Declinatio ☉ vera]; and the place of the Sun in the ecliptic [Locus Solis in Ecliptica]. Each gives degrees, minutes, and seconds. In the declination column, **B** marks a boreal (northern) declination and **A** an austral (southern) one.

	Sed in S. Petronio	61 41 0	16 11 15	♊ 15 39 13

Lastly, we present several meridian observations of the vertex-distances made with the great gnomon of San Petronio of Bologna [the San Petronio meridian line], together with the apparent diameter of the Sun derived from them, and from this the place of the Sun deduced—on the assumption of an obliquity of the ecliptic of 23° 30' 20" and an altitude of the pole in the same basilica of 44° 30' 20".

In the table that follows, each observation gives, for the stated date: the tangent of the vertex-distance of the lower limb [Limbi inferioris] and of the upper limb [Limbi superioris] (expressed as a large integer, the tangent reckoned to a radius of 100000); the resulting apparent diameter [Diameter apparens]; the semidiameter [semidiameter]; the distance of the center from the vertex [Centri distantia à Vertice]; the declination [Declinatio], marked **B** (boreal) or **A** (austral); and the place in the ecliptic [Locus in Ecliptica]. For the first observation only, the distance of the equator from the vertex [Aequatoris distantia à Vertice], 44° 30' 20", is also given. The "Arcus" columns give the corresponding arc in degrees, minutes, and seconds.

Table of solar meridian observations (continued)

This table continues the series of San Petronio gnomon and quadrant solar observations. Columns: **An. M. D.** (Year, Month, Day); **Distantiarum à Vertice Tangentes** (Tangents of the vertex-distances) — with the sub-rows giving, for each observation, the lower limb [*Limbi inferior.*], upper limb [*Limbi superior.*], apparent diameter [*Diameter appar.*], its half [*semidiam.*], true vertex-distance of the center [*Vera centri dist. à Vertice*], declination (B = boreal / A = austral) [*Declinatio*], and the ecliptic place [*Locus in Eclipt.*]; and **Arcus Gr. ' "** (Arc, in degrees, minutes, seconds).

CAPUT IX.

On the Hypothesis of the Solar Motion, its Apogee, and the Motion of the Apogee.

1. It is certain among all astronomers that the Sun lingers longer in the boreal semicircle of the ecliptic than in the austral; and that it formerly lingered longer in the spring quadrant than in the autumn; and that even now it lingers longer in summer than in spring — as is clear from what was said in Chapter VII. It would be absurd to suppose, as some of the early astronomers did, that the celestial body of the Sun is moved unequally in actual physical fact — that is, that it really carries itself round with such an apparent inequality. Rather, either the Sun is moved uniformly in an epicycle, while the Sun in the meantime is carried by the epicycle off from a circle concentric with the Earth; or — more probably — it is carried in an eccentric circle whose center differs from the center of the Earth, a circle which carries the solar body uniformly: so much so that, if our eye were at the center of the deferent circle carrying the Sun, it would see no inequality in the Sun's motion at all. We set out this hypothesis, with all its properties, fully in Book 3 of the *Almagestum Novum*, Chapter 4; and in Chapters II and following of the same we showed the method of deducing the prosthaphaeresis from the given (or half-) diameter of the epicycle, or from the eccentricity, and of reducing the mean motion of the Sun to the

true, or apparent, motion. (We treated the method of deducing the prosthaphaeresis in *Almagestum Novum* III, Chapters 19, 20, and 21.)

2. Kepler, however, considering in the lesser planets the equant circle introduced by Ptolemy, and the difference of the apparent diameter of the Sun at apogee and (where it is greatest) at perigee, and that the least distance of the Sun from the Earth requires no more than half of the whole of that eccentricity — which is necessary and concluded for the solar prosthaphaereses in the work on Mars and in the *Epitome of Copernican Astronomy* — held that an equant ought to be introduced into the solar theory, and that the eccentricity ought to be bisected. He proceeded thus: he made the half of that eccentricity belong to the center of the orbit, and the remaining half to the center of the orbit carrying the Sun. Yet, since the Sun is moved uniformly about the center of this orbit, some on that account say that this is the center of equality, or the center of mean motion. But because it is proper to an ellipse to have in its greater diameter two points equally distant from the center of the ellipse itself — points which are called the umbilici, or foci, and by the concurrence of whose radii an ellipse is described from the burning of the rays in either of the said points — therefore there is no doubt that the Sun's orbit is rather an ellipse than a circle, and that the inequality, which when the Sun is collocated in the Earth appears according to the Sun's motion, is real. For although the apparent semis is on account of the distance of the eye from the center of the deferent orbit, yet the other semis is a real inequality, on account of the distance of the center of the orbit carrying the Sun from the point, or center, of equal motions. So at last Kepler inferred that the solar prosthaphaeresis is to be bisected, comprised as the Optical Equation by two straight lines drawn from the Sun — one to the center of the Earth, the other to the adjoined point of equality — of which kind are SC and SF, if the Sun be supposed at S, or HT and HC, if the Sun be placed at H. In the Physical Equation it is comprised by two straight lines drawn, one from the Sun to the center of the ellipse, the other likewise to the other focus, or point of equality — of which kind are SC and SF, if the Sun be supposed at S (or HC and HF, if the Sun be placed at H). Hence the **Optical Equation** is the angle CST, or in the second case CHT, and its base is the semi-eccentricity CT; while the **Physical Equation** is the angle CSF, or in the second case CHF, and its base is the semi-eccentricity CF. But how this is to be demonstrated by exact Geometry in the ellipse —

Diagram. A semicircular (half-ellipse) figure illustrating the bisection of the solar prosthaphaeresis into the Optical and Physical Equations. A vertical diameter runs from A (top) through F, G, T to P (bottom), with the curved arc bowing out to the left and meeting the vertical at A and P. The point S is set high on the left arc and H low on the left arc; multiple straight lines are drawn from S and from H to the interior points F, G, T along the vertical axis, forming the angles of the optical and physical equations described in the text.

- A (top of vertical diameter)
- F (upper interior point on the axis)
- G (middle interior point on the axis)
- T (lower interior point on the axis)
- P (bottom of vertical diameter)
- S (upper point on the left arc — one position of the Sun)
- H (lower point on the left arc — the second position of the Sun)

— the whole prosthaphaeresis of the Sun in an ellipse, with both its Optical and Physical parts taken separately, Kepler does not show; and for that reason Ismaël Boulliau [Ismaël Boulliau] labored at it. For that reason, too, Seth Ward [Seth Ward] contended most exactly to demonstrate it — though he did not fully succeed — in his *Inquisitio in Bullialdi Astronomiam Philolaicam*, and in his work issued two years afterward, which he entitled *Astronomia Geometrica*, where he undertakes to demonstrate the said Equations, both in the circle and in the ellipse — points, nodes, and inclinations. And even before these, the Count of Pagan [Blaise de Pagan], having perfected all things, embraced the Copernicans, and from there, together with the diurnal and annual motion of the Earth in place of the eccentric circle and the deferent circles, and with the bisection of the eccentricity — so far as it is suited to representing the Sun's inequality by an eccentric circle and an ellipse of its motions — [represented these].

3. We hold certain things from what has been said in Book 9 of the *Almagestum Novum*, Section 4, and from the things to be said in Appendix II of this Third Book, where the Sun rests in the Eccentric Center; and about the Sun, near the underlying scheme of the figure, we shall always exhibit its diurnal spirals, so as not to designate the Sun anywhere — yet near the Sun, just as round a certain cone it describes its diurnal spirals, that they may designate how near to the ellipse's surface the very nearly circular periphery may approach the circular, and so that the annual inequalities also may be represented as able to be represented in this feigned hypothesis of the ellipse, or even of the circle, provided only that the Sun's

eccentricity be bisected. By these things, foreknown, what is to be denominated belongs to the inquiry into the same Sun's apogee, of which the method is handed down in Book 14 of the *Almagestum Novum*, Chapter 4. As an example of the eccentricity we declared, having assumed (in the same Third Book, Chapter 5, num. 85, 86) the moments of two equinoxes, and beyond that in Chapter 7, num. 165, the Sun's place at Bologna at the gnomon of San Petronio, namely Grade 7° , $0'$, $18''$ of Leo.

4. In the following figure, with the Earth's center at T, I describe the ecliptic ABPD, and the line of the equinoxes BTD — which, being cut by T, cuts the line of the absides AP, somewhat inclined at D, toward B; because we are most certain that at the present time the Sun's apogee A has passed beyond the beginning of Cancer. In this line let there be assumed, according to the ancient hypothesis, the whole eccentricity TC; and with the center made at C, describe the Sun's orbit SV, and to the points of intersection M and N draw the straight lines CM and CN; then, with the Sun placed at S, under the point L of Leo, draw the line TSL of the true place, and the line CS of the mean place.

Diagram. A figure showing the ecliptic and the Sun's eccentric orbit. An outer circle (the ecliptic ABPD) is centered on T, with the Earth at T. A vertical diameter runs from A (top) through C and T to P (bottom); a horizontal diameter runs from B (left) through M, T, N to D (right). The line of the absides passes through A–C–T–P. An inner circle (the Sun's orbit SV), centered on C, is drawn; the Sun S sits on the upper-left of the inner circle, with V at the bottom. The line L–S–T (true place toward L in Leo) is drawn from the upper left through S to T. The zodiac symbol Libra ♎ stands at B (left) and Aries ♈ at D (right).

- A (top — the apogee)
- L (upper-left, exterior — the true place of the Sun in Leo)
- S (the Sun, on the inner orbit)
- C (center of the Sun's eccentric orbit)
- B (left end of the equinoctial line — marked ♎ Libra)
- M (interior point on the horizontal, left of T)
- T (the Earth's center)
- N (interior point on the horizontal, right of T)
- D (right end of the equinoctial line — marked ♈ Aries)
- V (bottom of the inner orbit)
- P (bottom — the perigee)

In the year 1655 the Sun was observed at Bologna at the meridian of day 30 July at L, that is, at Grade $7^{\circ}, 0', 8''$ of Leo. Therefore the arc LAD, and likewise the angle LTD measured from the beginning of Aries, was computed to be Grade $127^{\circ}, 0', 8''$; and, completed to two right angles, namely the angle BTL — which is the same as MTI — was Grade $52^{\circ}, 59', 52''$. In the same year the Sun's ingress into Libra B was observed on day 22 September, at Hour 18, 55', p.m., at Bologna. The time between both observations was 54 days, 18 hours, 55'; from which, by the things established in Chapter 4, the mean motion ought to be Grade $54^{\circ}, 0', 35''$ — and such is the angle SCM, or ICS. Finally in the year 1656 the Sun's ingress into Aries was observed at the same place on 19 March, at Hour 9, 51', p.m.

— in an ellipse equally distant from the line of the absides, or made not at all from the distances [of the absides].

5. (Continuing the worked example on the right-hand column of the previous folio, beginning the second observation series:) Likewise, by the same method drawn from the two said equinoctial points, and with the Sun observed in the meridian of the day 31 August of the same year 1655, in Virgo Grade $7^{\circ}, 47', 15''$ — according to what was related in the observations of Chapter 8 — we find the Sun's apogee in Cancer Grade $7^{\circ}, 13', 12''$. Again, from the same equinoxes, and with the Sun observed in the year 1655 in the meridian of 23 July in Leo Grade $1^{\circ}, 5', 31''$ — as we adopted the observations in the same chapter — we get the apogee in Cancer Grade $9^{\circ}, 58', 29''$. Thirdly, in the triangle CIT, having acquired the side TI, [partition] 4224. Thirdly, in the triangle CIT we find the angle CIT, Grade $34^{\circ}, 58', 17''$; the angle CTI is found, Grade $28^{\circ}, 50', 0''$. There was, moreover, the angle LTD, Grade $127^{\circ}, 0', 8''$; subtracting from this the angle CTI, Grade $28^{\circ}, 50', 0''$, there remains the distance of the Sun's apogee from the beginning of Aries, that is, the angle ATD, Grade $98^{\circ}, 9', 8''$. Accordingly the time of the Sun's apogee was, at that time (the positions placed in Cancer Grade $8^{\circ}, 9', 8''$) —

[The right column of p. 62 carries the detailed trigonometric working that produces these results. Its principal steps, transcribed in order:] In the triangle CIS, with radius CS assumed of 100000 parts, from the angle CIS, Grade $125^{\circ}, 1', 43''$, and from the angle CSI, Grade $0^{\circ}, 57', 42''$, by Trigonometry the side IC is collected, of 2049 such parts, the radius IC being 100000; there remains IM, [partition] 97951. Secondly, in the triangle MIT, the side IM being found, [partition] 97951, and from the said angle MTI, Grade $52^{\circ}, 59', 52''$, and the angle IMT, Grade $1^{\circ}, 58', 25''$, the side TI is collected, [partition] 4224. Thirdly, in the

triangle CIT, the side TI being acquired, [partition] 4224, and from the said (as above) angle CIT, Grade $34^{\circ}, 58', 17''$, the angle CTI is found, Grade $28^{\circ}, 50', 0''$. There was, moreover, the angle LTD, Grade $127^{\circ}, 0', 8''$; from which, subtracting CTI, Grade $28^{\circ}, 50', 0''$, there remains the distance of the Sun's apogee from the beginning of Aries, that is, the angle ATD, Grade $98^{\circ}, 9', 8''$. Hence at that time the Sun's apogee was in Cancer Grade $8^{\circ}, 9', 8''$.

By the same method, from the two said equinoxes, and with the Sun observed in the meridian of day 31 August of the same year 1655 in Virgo Grade $7^{\circ}, 47', 15''$ (according to what was related in the observations of Chapter 8), we find the Sun's apogee in Cancer Grade $7^{\circ}, 13', 12''$. Again, from the same equinoxes, and with the Sun observed in the year 1655 in the meridian of 23 July in Leo Grade $1^{\circ}, 5', 31''$ (as the observations were related in the same chapter), we obtained the Sun's apogee in Cancer Grade $9^{\circ}, 58', 29''$. Then in the year 1656, with the vernal equinox observed on 19 March at Hour 9, 51', p.m., according to the said Chapter 5, [and] in the autumnal at Hour 0, 44', p.m., according to the said Chapter 8, we deduced the Sun's apogee in Cancer Grade $8^{\circ}, 9'$. Neglecting therefore, amid so many negotiations from so many observations, the things which adhere as more certain conclusions toward the end of the year 1655, the Sun's apogee comes out to stand beyond Grade 7° and short of Grade 10° of Cancer — indeed beyond Grade 8° of Cancer, by three of the aforesaid observations. But that it is short of the extreme, namely Cancer Grade $7^{\circ}, 13', 12''$, and Grade $9^{\circ}, 58', 29''$: the arithmetic mean is Cancer Grade $8^{\circ}, 35', 51''$. We set the Sun's apogee at the end of the year 1655 at Cancer Grade $8^{\circ}, 36'$.

[Margin: The Sun's apogee at the end of the year 1655.]

6. But because in the aforesaid method we supposed the center of the mean motions to be the very center of the Sun's orbit — and yet, the eccentricity being bisected, the center of the Sun's orbit ought to be constituted beyond the center of the Sun's orbit by as great an interval as is the semi-eccentricity, and distant from the center of the apparent motions, or of the Earth, by the whole eccentricity for the Sun's prosthaphaereses owed throughout — although tentatively, in some way or other, that we might observe sometimes one equinox, sometimes the other, with the summer observations, in the quadrant near the vernal equinox, [and] near the autumnal, in order to demonstrate geometrically the apogee line so derived: as well in the circle as in the ellipse, especially since, among the other properties of the ellipse, this is by far the most notable, and is treated below by us, namely that any radius whatever drawn from the foci to the

circumference, two such taken at once, are equal to the Axis, or to the greater diameter itself; and likewise this straight line, drawn from either of the foci to the extremity of the lesser of the two diameters — which lesser diameter is called in Greek [Greek: διάμετρος (diametros, "diameter")], or rather the transverse of the ellipses [Greek: διάμετρος (diametros, "diameter")] — is equal to the semi-diameter, that is, to the greater [half-axis] of the ellipses. And this same thing, however much it is multiplied by Trigonometry, has not yet succeeded for us — although we tried it — namely, with Kepler, with Boulliau, with the Count of Pagan, and with Seth Ward. Therefore we set forth another method which does not need Trigonometry, and which works on the solar motion's observations at the two points of the circle, [the two points] equally distant from the line of the absides, or made not at all from the distances [of the absides].

7. First, indeed, because it is certain not only in the Circular Hypothesis, but also in the Elliptical drawn from Conic elements, that the true motion of the Sun is swifter at perigee and slowest at apogee: if within the same Tropical Year there be observed two days on which the true motion of the Sun is one and the same minimum, [it follows] that in the one and the other [observation] the ecliptic place is manifest from these, [namely] that the ecliptic place forthwith reveals there the apogee. But if it errs even by a few seconds in the Sun's altitudes, on this occasion it will err by far more grades in the place of the apogee.

Secondly, it is certain that the true place of the Sun, computed for the prior semicircle of the Anomaly, according to the order of the signs from the apogee, is less than the mean motion; and therefore that the Equations in this whole semicircle are to be subtracted; and in the semicircle of the posterior anomaly, [the true place] is greater than the mean motion of the Sun proceeding from the apogee; and consequently that the Equations are to be added. Comparing, however, the true motion made from day to day, or in equal times, and absolutely, the computation made from the apogee, it is certain that in the superior anomaly's semicircle — which is above the Diacentron — the true motion of the apogee is less than the mean motion; within the Diacentron, or in the inferior anomaly's semicircle, [that] near perigee the true motion is greater than the mean motion; and that the transition from the one extreme to the other is nowhere except at the points of the Diacentron, at which the mean motion is most nearly equal to the true motion. Therefore by continuous observations those places are denoted in which, within the same Tropical Year, the true and equinoctial motion is equal, and the ecliptic arc intercepted between the two is

bisected: with that position given, the situations of the apogee and of the perigee will be most certain. But this method demands a more delicate observer.

Thirdly, it is certain that, at the two places equally distant from the apogee, the apparent motions of the Sun are made equal. Therefore, if there be observed two such motions which involve two such places, the intercepted ecliptic arc will be bisected by the line of the absides intercepting the place — both the apogee and the perigee. For the First and Second method we have not yet adopted observations of our own, or others suitable enough; but for this Third method we have here two suitable pairs of observations, [and] of the same certainty, which nevertheless it pleases [me] to bring forward into the middle.

8. From the things related in Chapter 8: in the year 1655 the Sun appeared at the Temple of San Petronio at Bologna in the meridian of the day 22 September in Virgo Grade $29^{\circ}, 13', 4''$; and on day 23 in Libra Grade $0^{\circ}, 12', 24''$. Therefore the diurnal true motion was Grade $59', 20''$. In the year 1656, however, the Sun appeared at the same place on the meridian of 21 March in Aries Grade $1^{\circ}, 34', 30''$; and on day 23 [in Aries] Grade $2^{\circ}, 33', 50''$. Therefore the diurnal true motion was Grade $59', 20''$. The ecliptic arc from Libra Grade $0^{\circ}, 12', 24''$ to Aries Grade $2^{\circ}, 33', 50''$ is Grade $182^{\circ}, 21', 26''$, of which the half is Grade $91^{\circ}, 10', 43''$; which, added to Libra Grade $0^{\circ}, 12', 24''$, gives Grade $91^{\circ}, 23', 7''$; and accordingly the place of the perigee in Capricorn Grade $1^{\circ}, 23', 7''$, and the apogee in Cancer Grade $1^{\circ}, 23', 7''$. But that this is false — not only from the things said toward the close of the previous number, but also from the things now to be said, and from other observations — is detected by us.

For in the year 1655, as I related in Chapter 8, on 22 May in our Observatory the Sun appeared at the meridian in Gemini Grade $1^{\circ}, 10', 35''$; and on day 23 in Gemini Grade $2^{\circ}, 8', 7''$; whence the diurnal true motion was $57', 32''$. Again in the same year, on 7 August in the meridian, the Sun appeared to us in Leo Grade $14^{\circ}, 40', 1''$; and on day 8 in Leo Grade $15^{\circ}, 37', 33''$. So on the same day the Sun was seen at the San Petronio gnomon to be in Leo Grade $15^{\circ}, 39', 13''$. Standing then by our observations, the true diurnal motion was likewise $57', 32''$; and so, equal to the ecliptic arc, from Gemini Grade $1^{\circ}, 10', 35''$ to Leo Grade $15^{\circ}, 35', 33''$, [is] Grade $74^{\circ}, 26', 58''$, of which the half is Grade $37^{\circ}, 13', 28''$; which, added to Gemini Grade $1^{\circ}, 10', 35''$, makes the place of the apogee in Cancer Grade $8^{\circ}, 24', 3''$. On account of the diversity, however, of the aforesaid observations, we think it ought to be retained —

[Margin: The foundations of Longomontanus and of Kepler concerning the motion of the Sun's apogee.]

— the apogee at the end of the year 1655 in Cancer Grade 8° , $36'$, according to the said number 5.

On the Sun's Apogee discovered by others before us, and on its Motion.

9. When Hipparchus [Hipparchus] had found the Sun's apogee in Gemini Grade 5° , $30'$, about 140 years before Christ, and Ptolemy [Ptolemy] reports it the same in nearly the same place — as he himself relates in *Almagest* III [*Magna Constructio*, Book 3, Chapter 4] — and since 280 years before Christ existed (which did not suffice for evidently determining the change of the apogee, for those intervening), held that it sufficed [for the foundation]. Albategnius [al-Battānī], however, in the year of Christ 883, has Chapter 28, "On the science of the Stars," observed the Sun's apogee in Gemini Grade 22° , $17'$; that is, the annual progress [of] $59'$, $4''$. But when Arzachel [al-Zarqālī], in the year of Christ 1076, found it the same in Grade 17° , $50''$ [recte: 17° , $50'$], he held that a regression had occurred — from which some thought it Albategnian, some Arzachelian, some of one or the other, as Fulvius reports it [exposed], in *Almagestum Novum*, Chapter 25. The rest of the more recent Observers of our age, and the men of the preceding century, set the Sun's apogee beyond the beginning of Cancer, of whom we set down below selected opinions at the foot of this Chapter, together with the annual motion. Among them Longomontanus [Longomontanus], setting [it] in the year 1590, [held] the apogee in Cancer Grade 5° , $30'$; and, the world being founded at the beginning of Aries, [held] the apogee to have been at the beginning of Aries; and so, in the year 1554, [held] the apogee to have been at Grade 95° , $30'$, [from which he] concludes the annual motion $1'$, $50''$, $14'''$. Kepler [Kepler] likewise, supposing the world founded in the year 3993 before Christ, in the *Rudolphine Tables*, page 42, [held] the apogee to have been then at the beginning of Aries; but in the year 1588, in Cancer Grade 5° , $32'$; and so [from] the apogee then in the year 1581 having progressed to Grade 95° , $32'$, gathers its annual motion $1'$, $2''$.
10. We, however, since we have granted that the Sun's apogee was at the beginning of Aries at the beginning of the world, deemed it too fallacious to gather the motion of the apogee from a beginning so uncertain and controverted as the year of the world's founding, of which there exist beyond 70 diverse opinions. Among these the most probable is the one

which holds the founding [to be] according to the LXX [Septuagint] Interpreters, in the year 5634 before Christ. Adding 1655 years makes 7289; therefore if to so many years the procession 98°, 36' [be applied], there comes about — from the beginning of Aries, [advanced] one grade — the second [grade of arc] 48 $\frac{2}{3}$. But if, according to the common edition, the world was created in the year 4184: to make in our most recent Chronology the years 5839 — to which, the procession of Grade 98°, 36' being added: and so, finished from another [reckoning] from the Chronologia Reformata, [with] the world's founding in the year 4064 — we shall gather the years 5719, the procession [being] completed [of] Grade 98 min. 36; and to the fourth, which afterwards we retain — not because it gathers from that year of the world founded, lest some mean place between Kepler and Longomontanus, [and] Wendelinus [Govaert Wendelen] from there, whose opinions see in the following Table. Nor indeed do they fail, among whom only the minutes [differ] — for the sake of facility let it please.

Apogee of the Sun [Apogei Solis]

The following table collects the position of the solar apogee and its annual motion as determined by various authors.

CAPUT X.

On the Eccentricity of the Sun [De Solis Excentricitate].

If the eccentricity were not to be bisected, but the center of the deferent circle carrying the Sun were the center of the mean motions, then once the place of the apogee was given it would be easy, from a single observation of the Sun's true place, to gather the eccentricity, which is the foundation of the whole computation. For let there be, in the figure attached here, the deferent circle of the Sun ASP, with the Sun S in the rear semicircle of the eccentric — that is, on the far side of the circle's center C. Draw the straight line CS for the mean motion, and from the Earth's center T draw TS for the apparent motion. Then, at a given moment of observation, since the mean motion of both the Sun and the apogee from the start of the year is known from the tables, the distance of the apogee from the head of Aries follows in consequence; and by subtracting it, the mean distance of the Sun from the apogee is had — that is, the mean anomaly, namely the arc AS. The angle ACS is therefore given. But the true distance of the Sun from the apogee reckoned on the ecliptic, that is the arc ATS, is found from the observed true motion together with the angle CST, which equals the external angle ACS by Proposition 32 of Book I of the *Elements*. Subtract, then, the angle ATS from ACS, and you will have the angle CST. So in this triangle all the angles are given together with the one side CS, which is assumed to be 100000 parts. Therefore CT, the eccentricity, will not lie hidden, by the laws of triangles.

Diagram. A quarter-arc (right semicircle) figure illustrating the solar eccentric. The arc runs from A at the top, through S on the right, to P at the bottom; C marks the center of the deferent circle and T (below C) the Earth. Straight lines connect the points.

- A (top of arc): the apogee
- S (right side of arc): the Sun's position
- P (bottom of arc): the perigee
- C (center): center of the deferent circle (center of mean motion)
- T (below C): the center of the Earth (true motion)

But because, as we shall show below, we in fact suppose that the eccentricity must be bisected, and that the center of the mean motions is not the center of the circle but the center of the ellipse carrying the Sun — and consequently that it is the semidiameter of the circle, and not the ellipse, that is to be assumed, except perhaps in the one case where it lies on the [minor] axis — and because by that

single case the manifest inequality of the Sun's mean motion is measured neither by the arc of the circle nor by the arc of the ellipse carrying the planet subtended under the same angle, for this reason another path has had to be entered upon, by which the astronomer is forewarned not to proceed on the circle.

I. PROBLEM.

Given a certain instant of time, the true place of the Sun, and its apogee: to find, in the ellipse, the whole eccentricity, the equation, and the distance of the Sun from the Earth and from the center of the mean motions.

Let there be the ellipse ASPB, whose axis is AP, and on it the two foci T (center of the Earth) and F (center of the mean motions); and let the Sun be at S. To this point draw the radii FS and TS; then produce FS until SM equals the radius FS, and draw FM. The triangle FSM will be isosceles; and so, by Proposition 5 of Book I, the angles SMF and SFM will be equal to one another, and the whole TM will equal the axis AP, since any two radii drawn from the foci, or umbilics, of the ellipse taken together equal the larger diameter of the same — as Count [Blaise de] Pagan [Comes Paganus] demonstrated in Book III, Theorem 5 of his Geometry. Therefore, since the semidiameter AC is reckoned at 100000 parts, AP will also be 200000, and so, by assuming TM and subtracting it, you will already have the Sun's distance from the apogee — that is, the remaining distance of the Sun's true place from the apogee, which is called the *true anomaly*, namely the angle ATS, measured not by the arc of the ellipse AS but by the arc of the ecliptic, as said in the foregoing number.

Likewise subtract from the Sun's given mean motion, by the tables, the motion of the apogee, and you will have the distance of the Sun's mean place from the apogee, which is called the *mean anomaly*, or the simple one — namely the angle AFS, measured also by the arc of the ecliptic. By Proposition 32 of Book I, the angles FTS and FST are equal; so, both taken together and then FTS subtracted, the angle FST becomes known. And this is the whole equation sought, that is the difference between the true and the mean place of the Sun; the half of it in the isosceles triangle just spoken of will give, taken singly, the angles SMF and SFM. Therefore in the triangle FMT there are given the side TM, 200000 parts, and the angle TMF, and the angle TFM, the latter constant.

—from the Anomalistic angle AFS, the angle SFM being diminished, by its complement to two right angles. The benefit of Trigonometry will therefore not leave the whole eccentricity FT hidden, except that the angle FMT is too small, being scarcely a hundred-thousandth part of the side TM, 200000 parts; for which

reason that little particle FT can be drawn out exactly enough by the tables: I have thought up another method, which is written below.

Produce from the point M the parallel MN to AT itself, until it meets the line NT orthogonally, perpendicular to AP; and from the other focus F draw the parallel FN. Then FN will be in the line FR, equal to NT itself; and in the triangle MNT, right-angled at N, the angle NTM is known, being the complement of the angle ATS, as given above; and so, by Proposition 32 of Book I, the third angle TMN is known. To this is adjoined the angle SMF, and the whole angle TMF; and again the third angle TMR, to which the angle SMF being adjoined makes the angle FMR, right-angled at R; and so the third angle RFM is known. First, then, in the triangle NMT, the side TM being given, as above, 200000 parts, the sides MN and NT are sought; then in the triangle RFM, FR being given, equal to NT, the side MR is sought — for the difference of this from the side MN, that is the line RN, equals the eccentricity sought FT, in the parallelogram FRNT. Or, because in the triangle FST all the angles are given, as above, and the sides too, take the sine of one of the angles opposite the angles — namely the sine of the angle SFT and of the angle STF — and joining them into one sum, and from the assumed sine of the angle FST, then take the said sum from AP, 200000 parts: so the sine of the angle FST and AP, 200000 parts, give the sine of the angle FST as the eccentricity FT.

The eccentricity FT being acquired, and the data being as above in the triangle FST, with all the angles given, the distance of the Sun from the center of the mean motions will be given by Trigonometry. And if the Sun were in the rear semicircle of the anomaly, as at B, the lines FB and TB being drawn, the angle AFB will be known by subtracting the whole mean anomaly of the planet FB and the whole one TB from the whole circle of anomaly, 360 degrees. The remaining things are to be carried out by the method, as above. By this method, examining at many places observed by us, or by others, we nowhere find an eccentricity which satisfies more observations than if the whole FT be set at 3480 parts, of which AC is 100000, and the semi-eccentricity CT or CF be 1740 parts — as we shall presently confirm by another experiment.

[Margin: The eccentricity found.]

II. PROBLEM.

Given the Sun's apparent semidiameter in mean, greatest, and least distance from the Earth: to verify the eccentricity itself, and the necessity of bisecting it.

From the observations reported in Chapter 8, it is established that in the great gnomon of the Temple of San Petronio the Sun's apparent semidiameter was

observed on the 20th and 21st of June to be 15' 32". So at the end of June, when the Sun was at apogee, it ought to have been seen so much smaller — that is, 15' 30". On the other hand, on the 28th of March and the 29th of September, when the Sun was at mean distance, the semidiameter was observed to be 15' 45" and 15' 47", of which the mean is 15' 46". At last, in mid-January, when the Sun was at perigee, the observed value was 16' 4". But if the mean of the Sun's distance be taken at 100000 — this being the straight line CS in the diagram attached — and the mean apparent semidiameter, that is the angle SCM, at 15' 46", then inquire in the triangle CSM, right-angled at M, after the Sun's true semidiameter SM; you will find it 15' 46" of such parts, the little fractions being neglected. Then with this SM, and with the Sun's greatest distance ST, 101740 parts, in the triangle STM, right-angled at M, you will find the angle STM, which subtends the Sun's apparent semidiameter, 15' 30". And finally, with FS, the Sun's least distance, 98260 parts, and with SM, 46 parts, in the triangle FSM, right-angled at M, you will find the angle SFM, which subtends the Sun's apparent semidiameter, 16' 4". Therefore the chosen semi-eccentricity of 1740 parts satisfies the observations best; and hence likewise is established the necessity of bisecting that eccentricity, which necessity is for the equating of the solar motion. For the whole eccentricity, which in the figure is expressed by the number 3 — that is, by FT — requires, for reducing the figure to the angle FST, the bisection.

CAPUT XI.

On geometrically determining the true place of the Sun, on constructing the table of equations, on those distances of the Sun from each focus of the ellipse, on defining the ellipse itself, and finally on representing the inequality of the Sun's motions in the ellipse and in the circle [De loco Solis Vero Geometrice determinando, Aequationum Tabula construenda, Distantiis Solis ab vtroque Foco Ellipsis, & ipsa Ellipsi definienda, ac deniq; de Inaequalitate Motuum Solis repraesentanda in Ellipsi, & in Circulo].

I. PROBLEM.

To determine the place of the mean distance of the Sun and of the Earth in the ellipse.

Briefly, this place lies on either side at the extremes of the line bisecting and orthogonally cutting the line of the apsides, or the minor diameter of the ellipse, which is called—

—Diacenter [Diacentron], as in the following figure BCD; for when the Sun is at B, or at D, its distance from the center of the Earth T, namely BT, or DT, is just as great as AC, namely 100000 parts, of which AP is 100000 [recte: 200000]. For let there be drawn from B, by way of example, the straight lines FB and TB, from the foci of the ellipse; there arise two triangles, equilateral and equiangular. For FC,

the semi-eccentricity, equals CT, and the remaining half-line CT and BC is a common side, and the angles—

Diagram. An ellipse with its axes drawn and an external point. The major axis runs horizontally; A is at left, the long axis runs through to L and H at the right; F is above the center, C the center, T below it. B is on the left of the ellipse, D below. Lines are drawn from B and from the foci to several points, with a small inner figure of lines crossing near the center.

- A (left, on the ellipse): the apogee end of the axis
- F (above center): one focus
- C (center): center of the ellipse
- T (below center): the other focus (center of the Earth)
- B (left, on the ellipse): the Sun at the diacenter (mean-distance point)
- D (below, on the ellipse): the diacenter on the opposite side
- H, L (right, outside / on the produced axis): auxiliary construction points

—are right angles by the definition of the diacenter, or by the construction indicated above. Therefore both these triangles are equal by Proposition 4 of Book I, and equiangular; and so the side BT equals the side BC. But since the two radii taken together are equal, as said in the foregoing chapter, the whole AP, then either of those is equal to half of the whole AP, that is to AC itself; and the angle FBC equals the angle TBC.

II. PROBLEM.

Given the eccentricity: to find the maximum equation of the Sun's motion, and the mean anomaly, and the true one.

Since the maximum equation, or the difference between the mean and true motions of the Sun, occurs not at the extremes of the line which in Greek is called *diacentros* [Greek: διάκεντρος (diakentros, "through the center" — the cross-diameter)], that is, the line which, drawn through the center of the Earth, cuts the line of the apsides orthogonally, as it falls in the hypothesis of the circle and of the unbisected eccentricity — but at the extremes of the line which is called the Sun's distance, and the minor diameter of the ellipse, where also is the situation of the Sun's mean distance, in such a way that the true motion is at its greatest, and the mean motion nearest to it: this being so, if in the foregoing diagram the angle CBF be found, which we said above to equal the angle CBT, then it being doubled will give the whole equation FBC, the maximum and greatest, and the Optical CBT will equal the Physical CBF.

Now in the triangle CBF, right-angled at C by construction, the base BF is given, 100000 parts, and CF, 1740 parts, by the said number 5 of the foregoing chapter. Therefore by Trigonometry the angle CBF, that is the Optical equation, is $0^{\circ} 59' 48''$; and so the whole, the maximum equation FBT, is $1^{\circ} 59' 36''$. The sum then, from the right angle BCF and the acute CBF, is $0^{\circ} 59' 48''$; and by Proposition 32 of Book I, the angle BFC, equal to the mean anomaly AFB, subtracted finally from the angle CBT, $0^{\circ} 59' 48''$, leaves the true anomaly, the angle BTC, $89^{\circ} 0' 11''$, the right angle being subtracted.

III. PROBLEM.

Given the eccentricity: to find the minor diameter in the ellipse.

In the foregoing figure, from the said Problem I, in the triangle CBF, right-angled at C, the base BF is given, 100000 parts, and CBF, $0^{\circ} 59' 48''$, and BFC, $89^{\circ} 0' 11''$. Therefore by the Analysis of right-angled triangles, BC comes out $99984 \frac{7}{8}$ parts. Therefore the whole minor diameter BD is $199969 \frac{3}{4}$ parts.

IV. PROBLEM.

Given the eccentricity: to find the equation befitting the Sun placed at the extreme of the line Diagios, or drawn orthogonally to the line of the apsides through the center of the Earth, and the Sun's mean anomaly, and the true one, in this same situation together with the Sun's distance from the Earth.

In the foregoing figure, the line drawn from the Sun H, perpendicular to HT, and produced to L until HL equals the radius FH, and the whole TL, as is often inculcated by the property of the ellipse, equals the whole AP, 100000 [recte: 200000] parts; by conjoining F and L, the rectangle FL arises, for the triangle FHL is isosceles, and the angle L, by Propositions 5 and 32 of Book I, is half the external angle FHT. Now in the triangle FTL, right-angled at T by construction, TL is given, just as much as AP, 200000 parts, and FT, from the said number 5 of the foregoing chapter, 3480 parts. Therefore by the laws of right-angled triangles the angle L is $0^{\circ} 59' 48''$, and so its double, or the whole equation FHT, is $1^{\circ} 59' 36''$ — a little less, indeed, but still less than the maximum equation found at the extremes B and D, by Problem II repeated.

Further, the right angle FTL, joined to the angle L, makes a sum of $90^{\circ} 0' 59'$ [recte: $90^{\circ} 59' 48''$ — see note]; and as great is the external AFL, that is, in the prior semicircle ABP, the Sun's mean anomaly; but in the rear, the Sun's mean anomaly is the complement to the circle. The true anomaly, however, is the right angle at T, that is 90 degrees, in the prior semicircle, but in the rear 270 degrees.

At last, in the right-angled triangle FTH, the angle FHT is given, $1^{\circ} 59' 36''$. Therefore its complement, the right angle, is $88^{\circ} 0' 24''$; and FT, 3480 parts; therefore by the Canon of right-angled triangles the distance of the Sun from the Earth comes out, HT, 199921 $\frac{1}{2}$ parts.

V. PROBLEM.

Given the eccentricity and the Sun's mean anomaly: to find the composite equation, and to construct the tables of equations in the ellipse.

In the following figure of the ellipse ABPD, let the axis be AP, and its center C, but the center of the true and mean motions T, and let the Sun be at S. To this point draw the radii FS and TS, and let the radius FS be produced to M, so that SM equals the radius TS; and so, by the said property of the ellipse, FM equals AP. Draw also the axis MT; then the triangle MSF will be isosceles, and the angle M half of the whole equation FST. Likewise, with the Sun at O, the lines FO and TO being drawn, and TO produced, so that OL equals the radius TO, and TL drawn, the whole TL will become equal to the whole AP; and the angle L half of the whole equation FOC. Now in the first case the sides FT, 3480 parts, and FM, 200000 parts, are given—

Diagram. A large ellipse standing on its long (vertical) axis, with foci and several radii drawn to two positions of the Sun. A is at top, P at the bottom; the center C lies on the axis with F above it and T below it; B is at left, D at right of center. The Sun appears at S (left) and at O (upper right); M and L are exterior points reached by producing the radii. Lines radiate from F and T to S, O, M, and L.

- A (top of axis): the apogee
- P (bottom of axis): the perigee
- C (center): center of the ellipse
- F (on axis, above C): one focus (center of mean motion)
- T (on axis, below C): the other focus (center of true and mean motions / the Earth)
- B (left), D (right): the diacenter points (minor-axis extremes)
- S (left): one position of the Sun
- O (upper right): another position of the Sun
- M (lower left, exterior): point where FS is produced so that SM equals TS
- L (upper right, exterior): point where TO is produced so that OL equals TO

—and the mean anomaly given AFS, the complement to two right angles, namely the angle MFT; therefore by the Canon of triangles the angle M is manifest, and its

double the equation, or the composite, by Optics — that is, the angle FST. For example, if AFS be 45 degrees, M will be found $42^{\circ} 16' 6''$; the equation FST is $1^{\circ} 24' 32''$, which in the prior semicircle is to be subtracted from the mean anomaly, so as to have the true anomaly ATS, but in the rear semicircle the mean anomaly subtracted from 360 degrees will give the angle AFO, whose complement is OFT. And to the mean anomaly is to be added the equation FOT, so as to have the true anomaly.

VI. PROBLEM.

Given the eccentricity and the whole equation, that is, the composite equation, to find the Sun's distance both from the Centre of the Earth and from the Centre of the Mean Motions, that is, from either Focus of the ellipse, on the assumption that the anomaly is the Mean anomaly.

Now that, by Problem V in the preceding figure, the whole equation FST has been found through the Mean anomaly AFS by subtracting the Mean from this equation, the angle FTS is also given, and likewise the eccentricity FT, amounting to 3480 parts, opposite the angle FST. Therefore, by the Laws of oblique-angled triangles, FS — the distance of the Sun from the Centre F — will be known, opposite the angle T, and when it has been subtracted from 200000 parts, the remainder ST will be known: the distance of the Sun from the Earth, together with FS and TS, jointly making up 200000 parts. Let the example be the case of the preceding Problem, namely Mean anomaly 45° , equation $1^{\circ} 24' 32'' 16'''$; from which both FT, amounting to 3480, and FS, amounting to 97585, are inferred, and TS, amounting to 102415, which together make up 200000 parts.

VII. PROBLEM.

Given the Mean anomaly of the Sun and the eccentricity, to distinguish the Physical equation from the Optical.

First seek, by Problem V in the preceding figure (for example), the whole equation FST, and by Problem VI the Sun's distance, that is SF, and, a line CS having been drawn to the centre of the ellipse, seek the angle in triangle CSF, on account of the half-eccentricity FC, opposite which lies CFS — which in this semicircle is the complement of the Mean anomaly AFS — together with the side FC, amounting to 1740, and FS, amounting to 97585. The angle CSF is found to be $0^{\circ} 42' 49''$. But there had been found FST, $1^{\circ} 24' 32'' 16'''$. Therefore the Optical equation in this position is $0^{\circ} 41' 43''$, and the Physical as above.

VIII. PROBLEM.

For a given moment of time, with the eccentricity given, to find geometrically in the ellipse the Sun's True place, its Distance from the Earth, and from the Centre of the Mean Motions.

Gather, for the given time, the Mean Motion of the Sun from the Tables, and the Motion of the Apogee, and subtract the Mean Motion of the Apogee from the Mean Motion of the Sun, and by Problem V gather the whole equation; to the Mean Motion in the prior semicircle add it, but in the posterior subtract it, and you will have the Sun's True Motion, and likewise the Sun's distances from the Earth, etc. Example for the meridian of Bologna, in the year 1656, on the 21st of August. The Mean Motion of the Sun from Our Tables is 8 signs $18^{\circ}34'22''$. But the Apogee is 3 signs $8^{\circ}36'37''$. Therefore the Mean anomaly in figure num. 5, namely angle AFS, is 5 signs $9^{\circ}57'45''$, whose complement is $0^{\circ}2'15''$, that is angle MFT, with which, and with side FT, by Trigonometry the angle M, $57'15''$, is found, whose double, that is the equation FST, is $1^{\circ}14'30''$. And so, the Motion of the Mean having been subtracted, the True Motion remains, 4 signs $17^{\circ}18'3''$. This will be the case if the Sun was seen in $17^{\circ}18'45''$ of Leo, as we observed it. Then, in triangle FST, the angle at S being given, $1^{\circ}15'50''$, and SFT as above, $140^{\circ}2'15''$, FTS is given, $38^{\circ}41'55''$, and FT, 3480 parts; therefore FS, the distance of the Sun from the Centre of the mean motion, is then $98642\frac{1}{2}$ such parts, which, subtracted from the whole AP, 200000 parts, leaves the Sun's distance from the Earth ST, $101357\frac{3}{4}$.

IX. PROBLEM.

To resolve all the Problems of this Chapter in the Circle, with the Eccentricity bisected.

Diagram. A geometric construction within a circle, used for the bisected-eccentricity computation of the Sun's true place. The vertical diameter runs from A at top through the interior to P at bottom; the centre C sits on it. To the upper left is S; on the diameter near C are F (above C) and T (below C). To the right are M and, below it, O. Several lines run from S to M, O, and T, and from T to M and O, forming the triangles used in the demonstration.

- A (top): endpoint of the vertical diameter (apogee direction)
- S (upper left): the Sun's position on the circle
- F (on diameter, above centre): the Centre of the mean motions (one focus / eccentric centre)
- C (centre): the Centre of the circle

- T (on diameter, below centre): the Centre of the Earth
- M (right): point on the circle
- O (lower right): point on the circle
- P (bottom): lower endpoint of the vertical diameter (perigee direction)

Let there be, in the following figure, a Circle ASPM bearing the Sun, with diameter and Line of the Absides AP, in which the point of the mean Motions F lies distant from the Circle's Centre C by 1740 parts, and the Earth T from the Centre C by just as much. Let CM be the semidiameter perpendicular to AP itself, and let the Sun be set at the extreme M; for then in Triangle CMF, with the rectangle [scil. right angle] at C, side FC is given, 1740 parts, and by Radius CM, 100000 parts, you find by Trigonometry the angle CMF, $0^{\circ}59'50''$, and so the whole [equation] $1^{\circ}59'40''$, which in the ellipse, by Problem II, was found to be $1^{\circ}59'38''$.

Let the Sun now be in O, to which draw the Lines FO and CO, and the perpendicular OT; for then in Triangle CTO, with the rectangle at T, with the given base CO, 100000 parts, and the side CT, 1740 parts, you find by the Laws of Right-angled triangles the angle COT, $0^{\circ}59'49'' \frac{1}{3}$, and TCO, $89^{\circ}0'10'' \frac{2}{3}$; and side TO, amounting to $99989 \frac{7}{8}$; with which, and side CT, 1740, and side FT, 3480, in Rectangle FTO, you find the whole Equation FOT, $1^{\circ}59'40'' 20'''$. And so, with the Sun placed in O, the maximum Equation occurs, and there too the Sun's Distance from the Earth is $99989 \frac{7}{8}$. For the Mean falls between M and O, and thus Problems I, II, IV are resolved.

For Problem V and the rest, let it be in the same Figure. Let the Sun be in S, to which draw from the three points F, C, T the Lines FS, CS, and TS; the given Anomaly being AFS, its complement SFC is given, and likewise its complement [scil. the supplement] is given, and the side FC is 1740 parts, and CS, the Radius, 100000 parts. Therefore the Physical Equation CSF is given, and the Sun's Distance SF, and the angle FCS, whose complement to two right angles, namely the angle SCT, with which and side CS, 100000 parts, and CT, 1740 parts, you find the Sun's Distance from the Earth ST, and the Optical equation CST, which, with CSF, composes the whole Equation, whence the Sun's true place will be had.

X. PROBLEM.

Given the distance of the Foci in the Ellipse, and this with the Axis together with the Angle of Anomaly, to find the point of the Elliptical periphery in which the Sun is, and so to describe the Ellipse through any number of such points.

Diagram. A circle within which an ellipse is being constructed by points, showing the focal-radii construction for a given anomaly. The vertical diameter runs from D at top to I at bottom. Inside are the labelled points P, L (upper left), S, B, N, F, G, C, and M (right), with several lines crossing from the upper-left points to G and M.

- D (top): upper endpoint of the vertical diameter
- L (upper left): terminus on the circle of the arc of the Mean anomaly
- P (upper left, near L): point where line LF cut produces the Sun's position
- S (interior): the Sun's position, where LF meets the perpendicular SN
- B (interior right of S): point on the diameter (semi-axis end region)
- N (interior): foot of the perpendicular from S
- F (interior, on/near axis): one Focus
- G (interior, below F): the other Focus
- C (interior, below G): centre of the circle
- M (right): point on the circle
- I (bottom): lower endpoint of the vertical diameter

In the following figure, let there be given the Axis BC of the ellipse to be described, and on it the distance of the Foci FG, and from F, as from the centre, at the interval of the whole BC, describe the Circle DLIM, and produce BC to D and I. Let the given Mean anomaly be the angle DFL; produce it from the terminus L through F, by Arc DL; through F let the Line LM be drawn, which will be equal to the Diameter BC, and as will soon be proved. Then from G draw the Line LG, and cut it in two equally [bisect it], and through the bisection, a perpendicular SN being drawn to it, the Sun is found at point S, where the line LF is cut. For at point S, where line LF is cut, the Sun will be found; for when SG is drawn, all the way to P, since by construction it is made Equal to LN itself, and NS is common, and each of the Angles at N, by construction, is a right angle, then by Elem. I.4 they will be equal — the two sides SG and SL. But GS and FS, taken together, are equal to the whole FL, that is, to the sought Diameter of the Ellipse BC; therefore GS and FS are the two radii of the Foci of the Ellipse, and the Elliptical...

elliptical periphery, describers of the Sun by their own motion. But from point S, the point of the Elliptical periphery in which the Sun is will be the point, and by drawing GP let the angle DGP be constituted as the True Anomaly. Likewise operate for any other given angle of Mean Anomaly to F, and you will have the remaining points by which the Elliptical periphery is to be described.

XI. PROBLEM.

To represent the inequalities of the Solar Motion both in the prior and posterior anomaly, that is in the upper and lower semicircle, and at their extremes, whether in the Ellipse or in the Circle.

Diagram. A large composite circular construction, centred on the Earth at T, used to display the inequalities of the solar motion. An outer circle is graduated and numbered around its rim from 1 to 20 (reading clockwise from near the top: 1, 2 to the upper left; 20, 19, 18 to the upper right; 17, 16, 15, 14, 13, 12, 11 down the right and bottom; 10, 9, 8, 7, 6 up the lower left). Inside, three concentric/eccentric circles (the ecliptic AG, the eccentric, and the ellipse) carry numerous radial lines drawn from the common centre out to the rim. The interior is densely lettered with capital Roman letters A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, V, X, Y, Z and lowercase Greek letters (α , β , γ , δ , ϵ , ζ , η , θ , λ , μ) marking the points where the lines of the Mean Motions cut the several peripheries. A runs at the top of the vertical axis, with H below it; the central cluster around the figure's middle holds E, F (Earth/centre region), with B at left, G and the small Greek letters near the centre; the vertical axis descends through D, K to P at the bottom.

- A (top of vertical axis): apogee point on the ecliptic
- H (below A): point on the eccentric/ellipse on the axis
- E, F (centre region): focus and centre of the construction (Earth/mean-motion centres)
- B (left, on horizontal): point on the axis/diameter
- C (lower-centre, on axis): centre
- D, K (lower axis): points on the vertical axis below centre
- G (centre-right): focus / centre point
- P (bottom of vertical axis): perigee point
- M, N, O, Q, R, S, L, V, X, Y, I, Z and Greek $\alpha \dots \mu$: the successive points where the Mean-Motion lines cut the ecliptic, eccentric, and elliptical peripheries
- 1–20 (rim): the graduated divisions of the outer circle

The figure inscribed below is described from the Earth's centre T, at the very great interval of the ecliptic A6, P14, whose AP is the Line of the Absides, and on it C, the Centre of the Ellipse, that is, of the circles EBDG, and the Foci T and F. And because around F the Sun describes Equal Angles by its Mean Motion, let there be described from F, at an interval greater than CE, the circle HIKL, whose periphery is divided into 12 Equal Arcs by the points H, M, N, I, O, Q, K, R, S, L, V, X; and through these let there be drawn from F to the Ecliptic the lines of the Mean

Motions FM2, FN4, FI6, FO8, FQ10, FKP, FR11, FS13, FL15, FV17, FX19; and from the Centre T, through those points E, a, b, c, d, e, f, g, h, i, k, l, by which the lines of the Mean Motions cut its Circumference — which are E, a, b, c, d, e, f, g, h, i, k, l — let the lines of the True Motions be drawn, each to the Ecliptic, namely Ta1, Tβ3, Tγ5, Tδ7, Tε9, TDP, Tζ12, Tη14, Tθ16, TΑ18, Tμ20, TEA.

With these things accomplished, you will see that the True motion of the Sun about the Apogee A is slower, and about the Perigee P swifter; and that in the prior semicircle of the Anomaly A6P, the motion is continually accelerated from the Apogee to the Perigee, and the Arc of True Motion is smaller than the Arc of Mean. For A1 is smaller than 1,3; and this is smaller than 3,5; and this smaller than 5,7; and this smaller than 7,9; and this than 9,P. But in the posterior semicircle, from the Perigee to the Apogee, you will see it retarded. For arc 12,14 is smaller than P12; and 16,14 than 12,14; and 16,18 than 14,16; and 18,20 than 16,18; and 20,A than 18,20. And by comparing the True Motion with the Mean, made in Equal time — likewise in the Ellipse, or Circle EBDG, you will see the Arcs which the Sun runs through become continually greater from the Apogee toward the Perigee (of which kind are Arcs Ea, ab, bc, cd, de, dD) and, from the Perigee toward the Apogee, become continually smaller (of which kind are Dζ, ζη, ηθ, θλ, λμ, μE).

1. Property.

[Margin: 1. Proprie- / tas.] But about the Apogee A, the True motion of the Sun is slower, about the Perigee P swifter; and so in the prior semicircle of the Anomaly A6P it is continually accelerated from the Apogee to the Perigee — and the Arc of True Motion smaller than the Arc of Mean. In the posterior semicircle, by contrast, the Arc of True Motion is greater than the Arc of Mean, if it is reckoned according to the succession of the signs from the Apogee; thus the True Arc A9 is greater than the Mean Arc P12, etc.

2. Property.

[Margin: 2. Proprie- / tas.] Now in comparing the True Motion with the Mean made in Equal time, taken one by one and not with relation to the Apogee: in the upper semicircle the Mean Motion is greater than the True, namely in the semicircle YAZ. But in the lower YPZ, the Mean is smaller than the True. For 1A is smaller than 2A, and smaller [is] 1,3 than 2,4, and smaller 3,5 than 4,7, and to the right of A20 [is] smaller; A19 and 20,18 than 19,16, and 18,16 than 17,15; contrariwise, to the left, 7,9 is greater than the Mean 8,10, and the True 9P greater

than the Mean 10P, the True P11 greater than the Mean P12, and likewise the True 12,14 greater than the Mean 11,13, etc.

3. Property.

[Margin: 3. Proprie- / tas.] In comparing the True Motion with the Mean not one by one, but always from the Apogee: in the prior semicircle of the Anomaly...

about the Apogee, the Mean Motion is greater than the True, not only relatively, but also absolutely, because the Arc itself of the Mean A10 is greater than the True Arc A9. By contrast, in the posterior semicircle the True is greater, if it is computed according to the succession of the signs from the Apogee; thus the True Arc AP12 is greater than the Mean AP11, and the True AP12 than the Mean P12, etc.

4. Property.

[Margin: 4. Proprie- / tas.] But because the passage from the slowest Motion about the Apogee to the swiftest about the Perigee does not occur except through the Mean, and the passage from the slowest to the swiftest occurs through a middling motion; and so, at the points coinciding with the mean — that is, with the True at the extreme Diacenters B and G — it happens that this equality of the Mean Motion with the True at the extremes occurs equally where the Mean Distance of the Sun from the Earth is, and the Maximum...

Prosthaphaeresis occurs in the Ellipse; for in the Circle with the eccentricity not bisected, the Maximum Equation occurs at the extremes of the line drawn orthogonally through the Centre of the Circle, but in the Circle with the eccentricity bisected, the Maximum Equation occurs at the extremes of the line drawn orthogonally through the Centre of the Earth, and at the Mean Distance of the Sun in either Circle. By the Hypothesis it happens that, at the points between the said straight lines drawn orthogonally — one to the Centre of the Circle, the other to the Centre of the Earth — the Sun's ellipse differs in part from the circle, in such a way that the Maximum Equation in the Circle exceeds the Maximum Equation in the Ellipse by a few seconds; for these things follow from what has been said above.

	Maximum Equation	
	I	II
In the Ellipse	1	5
		9

	Maximum Equation	
In the Circle with the eccentricity not bisected	1	5 9
In the Circle with the eccentricity bisected	1	5 9

CHAPTER XII.

Selected Observations of the Apparent Diameter of the Sun, and concerning a notable Fallacy into which otherwise distinguished Astronomers have fallen, very recently detected.

[Margin, left: Excentri-/tas Solis / bissecada.]

[Margin, right (¶2, opposite "Hinc didicimus"): Excentri-/citas Solis / Bissecada.]

By what methods the Apparent Diameter of the Sun is observable, we have already taught in *Almagestum Novum* Book 3, Cap. 10, and in its Scholia, and afterward in Book 7, in the Appendix to the said Cap. 10 — which we suppose all to be reviewed by the reader in this place. For from these it will be established why we are by no means compelled to relate the observations of others there reported — indeed, also some of our own and certain older ones — preferring to these the more recent ones, which were made by the Great Bolognese gnomon [the San Petronio meridian line], in the Temple of San Petronio, by taking the apparent distances, at either Meridian, of the Sun's limb from the vertex. For when the smaller is subtracted from the greater — that is, the distance of the upper limb from the distance of the lower limb — the apparent diameter of the Sun is at once obtained; and indeed with such great subtlety as the immense distance affords, which receives the Elliptical figure of the Sun, since the altitude of the gnomon of this San Petronio is 95 1/24 Roman Feet, at the perpendicular [zenith]; while the distance of the aperture from the Centre of the Solstitial Ellipse is about 100 ¼ Feet, and from the Centre of the Equinoctial Ellipse 133 Feet nearly, and from the Centre of the Brumal [winter-solstice] Ellipse 264 ½ Feet. From which it follows that in none, or in the very fewest seconds, is there an error, provided this diameter is observed accurately on clear meridian days. A specimen of several observations of the Solar Diameter we have already exhibited in Cap. 8, from num. 159 to 201 — from which, when rightly considered, we have deduced the subscribed Solar Diameters. Suppose that D. Cassinus [Giovanni Domenico Cassini] determined the same a little otherwise in the prior book of his observations.

[¶2] Hence we have learned that the Eccentricity, which the difference between the True and the Mean Anomaly of the Sun implies — that is, the distance of the centre of the Earth — must be bisected, and only its half taken; adding from the distance of the Centre of the Sun's Orbit that the centre of the equal motions of the Sun is not the centre of the Sun's Orbit, but the point on the Line of the Absides, by as many distances from the Centre of the Orbit toward the Apogee as the Centre of the Earth is distant from the same Centre of the Orbit toward the Perigee; so that the Sun's Orbit is rather an ellipse than a circle, with the elliptical properties that it has in its larger diameter, two points equally distant from the centre of the Ellipse — and these gathered from the radii reflected from the periphery — and which concur. For when in Cap. 10 we had found the whole Eccentricity, that is, the distance of the centre of the equal motions of the Sun from the Centre of the Earth, to be 3480 parts (of the kind of which the semidiameter of the Sun's Orbit is 100000), and the apparent Diameter of the Sun at its Mean distance from the Earth to be 31'32": if the centre of the Sun's Orbit be distant from the Centre of the Earth by only half the aforesaid Eccentricity — that is, by 1740 parts (of the kind of which the semidiameter of the Sun's Orbit is 100000) — and in the Mean distance of the Sun, that is at 100000, the apparent semidiameter of the Sun be 15'46", the semidiameter accordingly will be of $92\frac{1}{3}$ such parts; and at the maximum distance of the Sun from the Earth, the Diameter appearing equal to 101740, it comes out 31'0". And at the minimum distance, 98160 parts, it comes out 32'4" — by as much as we find, nor ever a greater, but rather a smaller, fallacy in the aforesaid Gnomon, as we said in Cap. 9, num. 3.

[¶3] But from the more observations made, after the two prior tomes of the *Almagestum Novum* were published, we choose out a few in which by our own diligence and by exquisite observation made with P. Grimaldo [Francesco Maria Grimaldi]. The *first* was in the Year 1654, on the 21st of June; in which, for the

aperture wide 32 parts, in a table, as located above, with the plane of the aperture parallel, the most obscure base of the right [erect] cone of the Sun's species turned out [to be] 174 parts; but with the diameter of the aperture subtracted, the lucid base remains corrected at 142 parts, and the half of it 71. The distance, however, of the table from the aperture was 15700 parts; therefore the semidiameter of the Sun near the Apogee [is] $15'33''$, and the diameter $31'6''$. For as BF, 15700 parts, is to the whole sine 100000, so is AB, 71, to the Tangent $452\frac{1}{4}$. The Angle AFB, $15'33''$, or the Residuum of the Logarithm of the distance...

Diagram. A small geometric figure illustrating the pinhole-image cone: two long straight lines cross at F (the aperture), opening out to the right toward a short vertical segment marking the image. A is the upper terminus, B the middle (foot of the image), and C the lower terminus; FB is drawn horizontally, with AB above and BC below forming the half-angle of the solar cone at the table.

- F (left): the aperture (foramen), apex of the crossing rays
- A (upper right): upper edge of the projected solar image
- B (right, middle): foot of the perpendicular / centre of the image (FB horizontal)
- C (lower right): lower edge of the projected solar image

FB, amounting to 15700, which is in Vlacq [Vlacquo] 58041003. To this is added the Logarithm of the side AB, 71 parts, which is 18512583, [and it] makes the Tangent-logarithm 76553586. The Angle AFB, $15'33''$. Therefore toward the end of June, with the Sun at Apogee, it ought to have been somewhat smaller.

The *Second* was in the same Year, on December 17, on which, with the aperture pierced likewise at 32 parts, we excepted [allowed for] in the table, as located above, the lucid base of the Sun's cone, 440 parts, at the distance of $36\frac{5}{12}$ feet, that is of the aforesaid 43700 parts; the diameter of the aperture therefore having been removed, there remains the corrected base of 408, and the semibase AB, 204, whose Logarithm is 23096302; and of the distance BF, 43700 parts, the Residuum Logarithm is 53595186. The sum of these is the Tangent-logarithm 76691488. The Angle AFB, $16'3''$; wherefore the apparent diameter of the Sun was $32'6''$.

The *Third* was in the Year 1656, on January 5, on which the lucid base of the Sun's cone, taken through an aperture wide 74 parts, was 298 such parts; but with the aperture subtracted, it was 224, and the semibase AB, 112, whose Logarithm is 20492180; and of the distance BF, it was 24000 parts, whose Residuum Logarithm is 56197888; which, with the said Logarithm, makes...

yields 7669006/8. By the table of logarithmic tangents the angle AFB comes to 16'4". Therefore the apparent diameter of the Sun was 32'8" near perigee, which is very nearly what we earlier derived from the San Petronio gnomon as well. This determination is most reliable and most exact. So that no one need be surprised that I prefer these diameters to all the others, let no one suppose, even so, that I am holding the opinions of others in contempt: I report them, selected, for the reader's instruction, not as a view to be followed.

Should the diameter of the aperture be subtracted from the diameter of the bright solar image admitted through it?

[Margin: 5] I answer wholly in the affirmative, with Kepler in his *Astronomia Optica* (Cap. 11) [Kepler, *Astronomia Optica (Paralipomena ad Vitellionem)*]. This will easily be evident to anyone who considers the figure of the Bolognese gnomon set out in Cap. 2, nn. 11 and 12. To obtain the true distance from the vertex of the upper and the lower margins of the Sun, the part HO must be added to the rays DH of the upper margin, IH being equal to the semi-aperture AC; and to the rays IH of the lower margin, the tangent DL, equal to the semi-aperture AC, must be subtracted. Thus the breadth of the solar image is enlarged by the aperture so that the image OK is bounded by the rays ICO and ICK. From this argument, drawn from the aperture's own center C, on account of the causes there adduced. We shall show the same thing in the following diagram, in which let AB be the height of the gnomon, with its center C; and from the outermost

edge of the Sun, D, let the radius pass through A and fall onto the tablet at point E; but the other ray, radiating from C, falls at F; and from the outermost edge G let two rays be propagated, one through B onto H, the other through C onto I. These will intersect one another, for...

Diagram. A geometric pinhole-projection construction shown at the upper right of the page. At the left a circle represents the Sun, with its uppermost edge labelled G and its lowermost edge labelled D. Rays drawn from these edges pass through a small central aperture (with points A, L, C, B clustered at the gnomon/aperture in the middle) and cross to form the projected image on the tablet at the right, where the rays strike at points E, F, K, I, H. The crossing of the rays produces the inverted image whose breadth is enlarged by the aperture's width.

- G (left, top of solar disk): upper edge of the Sun
- D (left, bottom of solar disk): lower edge of the Sun
- A, L, C, B (center cluster, at the aperture): the gnomon edge and the aperture's center C, with the semi-aperture endpoints
- E (right, topmost): point where the upper margin's ray strikes the tablet
- F (right, upper): point of the ray from the aperture's center
- K (right): boundary of the projected image
- I (right, lower): point where the lower margin's ray strikes
- H (right, bottom): foot of the projected image

The rays DAE & GBH, at the outer point L; and the rays drawn through the aperture's center, at point C, by whose intersection a perpendicular line LCK is drawn down to the tablet EF, cutting it in two. A triangle LKE will be formed, right-angled at K, in which the side EK is given from the dimension of the semidiameter of the bright solar image. Hence, if the other side KL or EL were given, the angle ELK would also be given, which doubled would yield the angle ELH — that is, DLG — the measure of the apparent diameter of the Sun at L. But neither of these is to be had. We must therefore have recourse to the angle FCI, the measure of the apparent diameter at C, which is known from its half FCK. For the aperture's distance CK is given from the table, and the other side FK, if it rests on the semi-base EK, is subtracted; and these differ by an insensible amount, since AC and EF are parallel. They are equal to the semidiameter AC, because the rays DE and DF, owing to the Sun's vast distance, are sensibly parallel, as we show in Book 3 of the *New Almagest*, Cap. 5. As to why we do not use an indivisible aperture, so that one might have the intersection at C without

subtracting the aperture itself — that will be plain from what is said below, against the practice of those who use such an aperture.

Should the latitude of the aperture also be subtracted in observations of solar eclipses, in order to obtain the Sun's diameter?

[Margin: 6] In the *New Almagest*, Book 5, Cap. 15, on the investigation of magnitude and diameter, I said in that place — at nn. IV and VI — that half the aperture is to be subtracted from the semidiameter of the bright solar image. Let that figure be transcribed here, in which let the base of the bright solar image observed through the aperture be BCED, whose semidiameter is AB and AE. Now let the Sun be eclipsed by the Moon: let the shadowed portion of the image be GCHD, and by means of a compass let the portion GE be marked off, the eclipsed part in such units that the whole diameter BE is 12. Suppose then that the Sun's diameter is known in minutes and seconds; for if it be made that, as 12 is to the Sun's diameter in minutes and seconds, so are the parts GE, and so on, then the portion of the Sun eclipsed appears to be known in minutes and seconds. But since we have warned, with Kepler, that there lurks in this practice a fallacy — because the base received through the aperture is too large and not proportionate to the Sun's diameter exactly, the excess being the latitude of the aperture, which must be subtracted in this way: from the semidiameter of the bright base AB let BN be subtracted, a portion as great as is the semidiameter of the aperture, and in the interval AN let a circle NKIL be described; the base will then be proportional, whose diameter, divided into 12 equal parts, gives the measure of the eclipsed portion GI. But because the portion PG of the image through the aperture is illuminated by the solar rays, that is, by as great a latitude as the semidiameter, the apparent eclipse turns out smaller than it would appear if observed through an indivisible aperture...

Diagram. A geometric figure at the lower right showing two overlapping circles used to analyze the eclipsed solar image projected through an aperture. The outer (upper) circle, representing the bright solar base, carries points B (top), N below it, A near the center with K, P, L, D ranged across the middle, and E lower down; the inner/lower circle carries G, C, I and F toward the bottom, with H at the very bottom. The construction marks off the eclipsed portion GE / GI against the reduced circle NKIL.

- B (top): top of the bright solar base, semidiameter endpoint
- N (below B): point where the aperture's semidiameter is subtracted from AB
- A (center): center of the base

- K, P, L, D (middle row, left to right): points defining the reduced circle and the image's horizontal diameter (BE through the center)
- E (lower, right of center): the other semidiameter endpoint of the base
- G, C (inner circle, upper): boundary of the shadowed (eclipsed) portion
- I (inner circle): point on the reduced circle NKIL
- F (inner circle, lower): point on the eclipsed boundary
- H (bottom): lowest point of the lower circle

divisible; and therefore that bright little zone is to be subtracted, and the eclipsed portion measured for that part, which is IP. Then let it be made that, as 12 is to the diameter of the Sun in scruples, so is GF; and from this the true quantity of the eclipsed part is yielded in scruples.

[Margin: 7] Against this precept of the Fathers Antonius Labouera and Honoré Fabre: they say that here one need not deal with investigating the Sun's diameter, taken under the angle, since they grant that the bright base of the aperture's diameter is to be subtracted; but they wish this done in a fixed proportion, which has the semidiameter of the Sun as a part of the shadow induced by the lunar body, in that it makes no difference to the notation of the known quantity NI, discrete from the quantity BE. As to this — which they try to prove no more aptly than absurdly — it follows, if the table-figure of the eclipse be advanced more and more toward the aperture, that the same eclipse appears greater and greater the nearer it stands, and indeterminably so. For at one and the same time two observations of the same eclipse, per the aperture, would be made in two places, which yet were one observation. Suppose the semidiameter were 12 parts, and in one observation the semidiameter AE were of 144 parts, and the eclipsed portion EG of 24 parts, that is, the sixth part of the semidiameter AE. In this case, if PG of 12 parts is to be added to PE, EI will be of 36 parts, with the 12 dropped; but truly from IE there is left AI of 132 parts, and IP, of 24. By this emendation, therefore, the eclipse is reduced to $\frac{132}{144}$, that is, to the corrected semidiameter AI. But in the other observation, the aperture kept equal, the table receiving the eclipsed image of the Sun being moved farther from the aperture, so that AE becomes 432 parts, and the eclipsed part EG, the sixth of AE, that is 72 — AI then remaining 12 parts — EP evades to 84, and IP to 72; the line EI is 12, and AI of 420 parts remains. Therefore by this emendation the eclipse is reduced to $\frac{72}{432}$ of the corrected semidiameter of the Sun. Reduced to a common denominator of the fractions, the eclipsed part is $\frac{24}{432}$ of the solar semidiameter in the prior observation, and $\frac{76}{420}$ of the same semidiameter in the second.

[Margin: 8] We answer, however, that the said Fathers have been deceived, supposing in the two observations that the same proportion holds between AE and EG, which in those cases is not the same; for it should be the same in both, the proportion between the whole corrected diameter NI and the corrected shadow IP being equal to the observed shadow EG. But between false, or uncorrected, solar diameters and shadows, that same proportion ought not to hold, even with the correction made on both sides; let it be made by subtracting the same quantities of the aperture. Just as, if from two given lines, here and there, in a sub-double proportion of scruples, the greater line be increased by a quantity equal to the doubled scruple put a palm's length: certainly it will not preserve the same geometric proportion between the two, those two lines being increased by an arithmetically equal amount. P. Grimaldi [Francesco Maria Grimaldi] confirmed this acutely too, with others adduced. But on this dispute, more will be set out in the Appendix to this chapter, reserved for the end of this Book 1.

Against the diameter of the Sun asserted by the Fathers Scheiner, Cysat, and others.

[Margin: 9] Scheiner, in Part 1 of the *Rosa Ursina*, Book 4, Cap. 3, says: "It is established that the apparent diameter of the Sun, while it tarries in Cancer, presents itself as a minimum of 46 minutes." He nonetheless assumes for his own proposal there the Tyconic diameter of 32', and in Cap. 4 he proposes a way of observing it himself with the present diameter through the aperture, as it were indivisible, by which the solar image is received in a dark chamber, marked round about with a compass into parts equal to those into which he had supposed the distance of the image from the aperture to be divided, namely into 10000 parts; and the aperture — "as small as can be made physically," he says, "since the smallest aperture, which mocks the keenest sight, flees." Some indeed confess that observations made with a larger aperture are deceptive: if from 10000 parts of the distance of the aperture from the bright solar base of one image to another there results the sine of the visual semidiameter of the Sun, its double will be the whole diameter. He then subjoins the observations made at Rome — by many, and by men skilled in such matters — namely P. Christoph Grienberger, P. Gregorio à San Vincentio, P. Pietro Antonio Rauizza (once my own most learned teacher in theology, and a man of conspicuous integrity), P. Nicolò Zucchi (likewise most learned, a man of the deepest piety) — to whom it can scarcely be said how much I owe.

| Apparent diameter of the Sun observed at Rome by Scheiner, from the diameter of the solar image in parts such that the distance of the image from the aperture was 10000 ||||| |||| |---|---|---|---|---|---|---|---| Year | Through | Image Diam. (Parts) | Solar Diam. (Min.) | Year | Through | Image Diam. (Parts) | Solar Diam. (Min.) | | 1625 | aperture | | | 1626 | | | | Oct. 15 | minim. | 150 | 51 | Dec. 23 | minimum | 165 | 56 | | | minim. | 137 | 47 | | | 136 | 47 | | | minim. | 114 | 39 | | | 112 | 38 | | | | | | 90 | 31 | | | Nov. 23 | minim. | 130 | 45 | Dec. 23 | maius | 160 | 55 | | | minim. | 120 | 41 | | maius | 144 | 50 | | | minim. | 115 | 39 | | priore | 120 | 41 | | | minim. | 100 | 35 | | | 104 | 36 | | | | | | 85 | 30 | | | Nov. 28 | minim. | 143 | 49 | Dec. 23 | maius | 114 | 39 | | | minim. | 120 | 41 | | priore | 93 | 32 | | | minim. | 110 | 38 | | | 82 | 29 | | | Dec. 25 | minim. | 136 | 37 | Dec. 23 | maxi- | 105 | 37 | | | minim. | 125 | 43 | | | mum | 95 | 33 | | | minim. | 117 | 40 | | | 84 | 29 | | | minim. | 106 | 37 | | | | | | 1626 Mar. 23 | minim. | 155 | 53 | 1627 Iunij 21 | mini- | 155 | 53 | | | minim. | 136 | 47 | | | 140 | 48 | | | minim. | 122 | 42 | | | 110 | 38 | | | minim. | 115 | 39 | | | 95 | 33 | | Iulij 14 | minim. | 137 | 47 | Sept. 23 | mini- | 162 | 56 | | | minim. | 125 | 43 | | | 142 | 49 | | | minim. | 119 | 41 | | | 130 | 45 | | | minim. | 102 | 36 | | | 108 | 37 | | Oct. 19 | minim. | 160 | 55 | | | | | | minim. | 125 | 43 | | | | | | Dec. 21 | minim. | 138 | 48 | | | | | | minim. | 110 | 38 | | | | | | minim. | 93 | 32 | | | | | | Dec. 22 | minim. | 140 | 48 | | | | | | minim. | 122 | 42 | | | | | | minim. | 107 | 37 | | | | | | minim. | 87 | 30 | | | | |

Scheiner adds that this variation, found on the same day and with the same aperture, arose from this: that at one moment the nucleus took on a less bright appearance about its extreme border, and when he took it from the very middle of the image — about which no one is well informed, and seeing it, he doubted whether the appearance were as if not true — he nonetheless said the diameter showed itself to him as 38' minimum on 28 November, and 33' on 21 June; whence he concludes it to be really still larger.

[Margin: 10] Another follower of these, from our own Society, wrote to me that in the year 1652 at Innsbruck, and in the year 1637 likewise observed there on 6 and 20 September, with an aperture of 28, and a second aperture of 10, the Sun's diameter was 37'30", or 37'40" — but more often 38'. When he used a larger aperture, the apparent magnitude of the Sun would diminish, since rather something is to be added for the larger aperture; he reckoned it false that so large an aperture should admit too much brilliance, which would obscure...

and obliterate the true margins, and the whole image, so as not to be had with the exactness needed for an accurate measurement of the diameter, established at

the smallest. Now if the feet 28 are resolved into inches, they become 336 inches; and if the inch be divided into 100 particles, the length of the canal will from that be 33600 such particles; and if the latitude of the aperture stood at such a distance of minutes — 2', that is, by the solution of right triangles, the aperture-diameter would be of 2'. Or, of 20 such, the inch being 100. Again, if he had used that aperture, he gathered at such a distance — a semidiameter of the solar image of 16'25", that is, a diameter of 32'50" — the part being said to be the semi-aperture, that is, the parts 30'42", a smaller value than is owed, because, on account of the over-small aperture, the operation becomes ever harder, as we too have tested elsewhere more than once, and lately with P. Grimaldi as well.

[Margin: 11] For in the year 1658, on 11 August, in the Hall of the Assumption of the B[lessed] Virgin in our College, obscured most exquisitely, through the smallest possible aperture, the solar image admitted onto paper at a distance of 13' 5°/9 of a Roman inch — such that an inch contained the whole light too, the impure image among the impure margins being of 1328 such parts. Hence EK, so that in the figure of number 9. it was 664; but the semidiameter of the aperture being subtracted, AC of such parts is 2: there remains FK of 662; whence the angle FCK is 18'5"; and the apparent diameter of the Sun, 36'12". Again, in the same month, on the 18th, with the same aperture retained, but at a distance of 12821 parts (the altitude of the observation demanding it), the bright solar base EH was 1356 parts, and EK 678, and so the angle EKF 18'15"; whence there results the diameter of the Sun 36'30". If you comprehend the part of the bright base illuminated by the chosen image and the purest light, EH was 1176, EK 588; the doubled AC subtracted, there remains FK 586; whence the semidiameter of the Sun 15'40", and the diameter 31'20". This too in the Bolognese gnomon, found on another day, with a latitude of the impure border of 110 parts, which being subtracted so that the just solar semidiameter may be had — a quite sound agreement here.

[Margin: 12] But because Scheiner used a distance of the aperture of 10 Roman feet, I propose between C and S the lines of the length written below, which, continued five times, make the tenth part of the said distance,

[here let us understand the parts to be 240, of which a Roman foot's inch is 100. Drawn therefore 240, per 5: they become 1200. Per 10: they make 12000, equalling 120 inches — that is, 10 feet. Because, as I said, the use of distance is squarable, we have arrived today at a Roman foot for the smallest aperture, the bright solar image being computed for the impure margin, of as much as the written-below little line is, that is, parts 240, of which one inch is 100.]

[diagram: a short horizontal line segment, the unit of length, drawn between rule-marks across the column]

Hence the semidiameter of the Sun would come out 20'5", and the diameter 40'10"; but the impure latitude of the border being subtracted, it was of base 110, and a half — 55; whence the semidiameter of the Sun 15'41", and the diameter 31'22".

[Margin: 13] These things performed, it is better to use a larger aperture, purer for vision, both as to the vertex and in the diameter itself, but of greater latitude of minutes. Trigonometry advises this; but the distance ought to be large, and of 100 feet if it can be, as in the San Petronio gnomon of 100 feet and more. For then the bright image acquires a width quite ample for the Sun, and that on account of the magnitude of the aperture being intense enough for obscuring the whole well-nigh of the penumbra of the impure border; and if here it sin in mere light, the diameter is rendered insensible, or contemptible, in comparison with the bright image of the image, and the distance of the aperture. Against this, if you employ a too-small aperture, and one nearly indivisible, that distance ought not to advance to 10 feet...

Diagram. A small schematic at the upper right, showing the impure-light border of a projected solar image. A circle (the bright solar base) carries the labels A at the upper left of the rim and B at the lower right of the rim; inside it, concentric dotted/double rings mark the penumbral fringe, with C marked in the upper-inner region and D in the lower-inner region. The figure illustrates that with an impure (penumbral) border the apparent amplitude AB exceeds that of the pure light CD.

- A (upper-left rim): outer edge of the impure (penumbral) solar image
- B (lower-right rim): opposite outer edge of the impure image
- C (upper-inner): edge of the pure-light image
- D (lower-inner): opposite edge of the pure-light image

the opposite image will be, as in the following diagram, whose amplitude with the impure light will be AB, but that of the pure light CD; yet it is more easily separable, and slippery to fallacy; and if there be anything in this measure you err, you will commit a great error in the diameter of the Sun, and a still greater one, on account of the latitude of the aperture not being taken away, which in the smallest aperture cannot be determined justly.

[Margin: 14] But the cause of the impure places within AC and DB — about which Scheiner himself, in Part 2 of the *Rosa Ursina*, Book 4, Cap. 5, says: "The periphery

of this solar image is not cleanly cut, but softly torn and rough, so that it is scarcely distinguished from the consort of shadows, especially if the eye applies effort" — the cause requires, when measured with a compass that is near to it, the cause (I say) of this quasi-penumbra has hitherto been disclosed by no one; though I know it was disclosed too by P. Grimaldi, after some years' observations of light and colours, who affirms a most luminous and most certain notion; and the manner of propagation of light is known to be neither *Direct*, nor *Reflected*, nor *Refracted*, but *Diffacted*, or scattered into more languid rays. By which thing many of the said Father's experiments interfere, which otherwise could not be saved. So, in this way: the rays of the Sun, striking onto the edges of the aperture, are split into weaker rays, and the tablet, or paper, set opposite the aperture, with a malign and torn light, and somewhat colours it with a sub-reddish or sub-rubric colour, or with ferrugineous tints — the more, the nearer it stands to the aperture; the more remote, the more these debilitated and remiss rays evade, so that at a great distance they do not affect the sensible tablet. Because, if the aperture be so ample that such a great splendour enters, then by reflection of its own from the air round about it is impeded, and conquered by the propagation of the rays scattered from the edge of the aperture.

[Margin: 15] For the rest, whatever be the cause aforesaid, it stands established to us, from the most recent and recondite Philosophy, as a thing decided: that there is something here of uncertainty, that is, a fallacy, which Scheiner's Method does not exclude, nor the manner of observing the Sun's diameter through the aperture used by the Fathers Cysat and others, since it is least of all certain.

[Margin: Arguments against Scheiner's solar diameter.] First — for the mere inconstancy, which is plain in Scheiner's experiments, is an argument. Secondly — it is certain that we have taken the Moon's diameter from its distance from the fixed stars of known note, and the distance does not exceed 35', indeed it reaches 34'; and yet, as in the observations of Book 3, when the whole Moon was seen to have obstructed the Sun, but this was far from impossible if the Moon were near apogee, of 40', as Scheiner wishes. Thirdly — using the Filar Triangle, of which in the *New Almagest*, Book 5, Cap. 15; but with the subtlest equal lines stretched in a Meridian plane, and with the eye fixed within a wooden tube, and protected by a coloured glass, the solar disk transits the plane of the Meridian, while a companion numbers meanwhile the inches of altitude with a loud voice, the oscillations being most nearly 9 of a Roman foot, of which in Book 2 of the *New Almagest*, Cap. 20, Prob. 5; and one simple oscillation of time exhibits 30"; thirty of them, and as I have warned, in the equinoxes, from the first contact at the western margin until the contact of the eastern margins of the solar disk, and the oscillations of the eastern margins are never numbered as more than 264, nor

266. They are never fewer than 240. And so then I judge the Sun's diameter to be no more than 33'15", nor less than 30', which experiment evidently calls back each one to its own use. Wherefore, although it can in no way be precisely determined what the Sun's diameter is — because in those contacts the judgment of observation hesitates over about two or three contacts at most, hence I take it as certain that the Sun's diameter in the equinoxes cannot be 34', nor less than 30', as Staudacher would have it, nor 40', etc., as Scheiner. So let it stand established to the modern reader, as far as the cause goes, that we have preferred the observations of the solar diameter made at the San Petronio gnomon...

done in the same way through a slightly larger aperture, and we determined it to be 31' 0" at apogee, 31' 32" at mean distance, and 32' 4" at perigee.

CAPUT XIII.

On the Parallax of the Sun, and its Distance from the Earth.

That the parallax of the Sun is imperceptible, and consequently could once be suspected of being nil, was [the view of] Hipparchus [Hipparchus]. Although it can be found fairly readily by means of lunar eclipses, as Ptolemy [Ptolemy] there reports (*Almagest* V, ch. 11; *Magna Syntaxis* chs. 14 and 15) — where he also hands down the method of gathering it from lunar eclipses, which we have taught more accurately (*Almagestum Novum* III, ch. 7, Probl. 2) — we nevertheless showed there that this method does not possess the subtlety which recent astronomy requires, since solar eclipses, even without evident proof, can be deceptive. Or one may use the Sun's mean distance of 1168 semidiameters of the Earth, as Ptolemy will have it (the horizontal parallax being 2' 57"), or the mean distance of 1465½ semidiameters of the Earth (the horizontal parallax being 14"), as Wendelen [Govaert Wendelen] will have it, or some value intermediate between these. By the same token (*ibid.* book 1, ch. 11, Problem 6) we showed that, if half the angle [semiangularus] is subtracted [recte: *semiangulum*] —

[Margin: The labor of astronomers in gathering the Sun's parallax.]

The parallaxes of the Sun are assumed to be larger than they are; yet I do not think they can be held to. It happens, however, that nearly all fall into some self-contradiction, as Lansbergen [Lansbergen] demonstrates (*Trigonometria*, and ourselves *ibid.* book 4, *Almagestum Novum* I, ch. 16). For one must take the parallax and the Sun's distance together at a single diameter of the Sun's apparent distance, with the increment or decrement agreeing with the anomaly,

and also with the angle by which the diameter of the Earth's shadow exceeds the diameter of the Moon's apparent body, and so forth.

After Tycho [Tycho Brahe], Kepler [Kepler] recognized that the Sun's parallax could not be as great as Tycho had assumed, and he openly declared this (*Ephemerides* num. 7, p. 5, and in his *Commentaries on Mars*). For he saw that Mars at perigee in its epicycle approaches the Earth more nearly than the Sun does, and yet from his own observations — fully in agreement with Tycho's own — that it is much less so at that very approach to the Earth than is the case with Tycho. He maintains that the Sun's horizontal parallax is smaller than the Tyconic value, namely about one minute, which he holds also in his preface to the *Ephemerides* of the year 1619, declaring the agreement of the *Harmonics*'s intervals, and likewise in the *Rudolphine [Tables]*.

[Margin: Kepler's internal inconsistencies.]

Yet badly: for in the foundation of the *Ephemerides* and in the *Commentaries on Mars* he set the Sun's distance at apogee at 1800 terrestrial semidiameters. For from this, by trigonometry, there follows a horizontal parallax of 1' 55"; and conversely, if the horizontal parallax is one minute less, there follows from this a solar distance of 3438 terrestrial semidiameters, as I taught at greater length (*Almagestum Novum* III, ch. 7, Scholium 2). Langrenus [Langrenus] too supposed the Sun's distance to be about 3420 terrestrial semidiameters. But Wendelen, who in the *Opusculum on the Obliquity of the Sun* published in the year 1626 had assumed a horizontal solar parallax of one minute, afterwards in his letter to me of the year 1647 chose 15" of seconds, as I reported (*Almagestum Novum* III, fol. 109), and a solar distance of 14905 semidiameters at apogee, of 14656 at mean distance, and of 14407 at perigee. On account of the dichotomies and other foundations, which he reported to us from these same letters in his letter, [I treated this] in the same ch. 7, num. 12. For I there confuted Rheticus's [Rheticus] opinion fairly fully in Scholium 3.

Now therefore on this matter, on which depends in great part not only the system of the Sun itself but also that of the other lesser planets, as Kepler forewarned, [and which bears] on the dichotomies of the Moon, and on the Problem of Aristarchus [Aristarchus] which we labored over (as we set out at length *ibid.* book 3, ch. 7, Probl. 3) — and accordingly we deduced the solar distances and parallaxes inscribed below, corrected nonetheless according to our new eccentricity, which is now bisected.

☉ Distance at apogee	Horiz. parall.	☉ Mean distance	Horiz. parall.	☉ Distance at perigee	Horiz. parall.	
	'	"	'	"	'	"
Semidiameter s of the Earth	0	2 Semid. of 7 the Earth	0	2 Semid. of the 8 Earth 1/2	0	2 9
7427		7300		7173		

This indeed Don Antonio Rocca [Antonio Rocca] approved in his most learned letters, which he sent me asserting his observation, and not much afterward [so did] Don Giovanni Battista Odierna [Giovanni Battista Odierna], in a lengthy and uncommonly erudite letter sent to me; and he retained it likewise in his published work entitled *Ephemerides Medicaeorum*, where in the address to the reader he says: *The Sun's height from the mean Earth amounts, at the minimum, to 7300 terrestrial semidiameters*. I have also heard that Don Ismaël Boulliau [Ismaël Boulliau], where he reads of our foundations in the *Almagestum Novum*, has decided to alter his own system, and to place the Sun far higher than he had done in his *Astronomia Philolaica*. Indeed, Don Antonio Rocca, writing in the month of May of the year 1651, [held] that scarcely any perceptible time elapses between the dichotomy [dichotomy] of the Moon and quadrature; and that therefore the Sun ought rather to be raised than lowered. But because by reason of the parallax the Moon often appears hollowed [cava], when it is now dichotomized — indeed, when it is in quadrature aspect with the Sun — how the observation is to be corrected I taught in the Appendix to the first volume of the *Almagestum Novum*, which is to be found at the end of book 7. There, then, consult the Appendix bearing on book 3, ch. 7, where I confirmed by other observations that the maximum distance of the Sun from the Earth cannot be much less than 7000 terrestrial semidiameters, since an integral hour intervenes between the time of quadrature and that of true dichotomy. Let Kepler stand [as witness], who in his *Astronomia Optica*, p. 237, said: *But when the Moon is dichotomized, by careful inspection of the section of the Moon's face within a few hours you can carry the indication of the true quadrature*. As to determining the parallactic distance of the Sun, Kepler preferred the dichotomies of the Moon to eclipses themselves and to the terrestrial shadow: read over his words adduced [by me] (*Almagestum Novum* III, ch. 7, num. 10).

[Margin: The first method.]

Nor, however, are there lacking other methods of investigating parallaxes, made not only by observations carried out, or under the tropics, or at the equator,

which we handed down (*ibid.* book 3, ch. 7, num. 4 and 5), but also others. Of these let the First be that of Father Georgius [Giambattista] Riccioli of our Society; already, from the year 1653, it was communicated to me through his letter. In the appended diagram, let ABC be the meridian, in which the vertex is B and the pole of the world is P, and BR the quadrant of the vertical circle, in which let the Sun be at point S, and the Sun's observed distance from the vertex be BS. Let the moment of the observation [serving] for the declination of the Sun be PS. Let the perpendicular oscillations be now numbered from the moment when the Sun's distance from the vertex was captured, to the moment when the Sun reached the meridian; and let it be known besides that such oscillations correspond, in their entirety, both to a complete revolution of the equator and to a revolution of the diurnal motion of the Sun; then, by the rule of three, if the oscillations of the Sun's diurnal revolution give, for example, 59' 8", how many minutes will the oscillations numbered from the observation up to the meridian give? For as often as the said numeration is subtracted, with the minutes corresponding to it, it will give the corrected [recte: *emendatum*] angle BPS — together with which, both with the complement of the pole's altitude BP, and with the complement of the declination —

Diagram. A circle with a quadrant of the vertical circle constructed from the celestial meridian, illustrating Riccioli's pendulum-oscillation method for the solar parallax.

- B (top of circle): the vertex (zenith)
- P (upper right): the pole of the world
- A (left): one end of the meridian ABC
- C (right): the other end of the meridian
- S (interior): the position of the Sun on the vertical circle
- R (lower interior, near center): a point of the vertical circle's quadrant BR

— PS will give the Sun's true distance from the vertex, the difference of which from the observed [distance] will give the parallax sought. But if the Sun stands more than 70 degrees from the vertex, it is liable to refractions, which ought to be discerned without prior knowledge of the parallax; and the slightest error in numbering the time, or in the situation of the meridian line, or in the altitude of the Sun and of the pole, can be great — that is, can introduce a discrepancy of two or three minutes.

[Margin: The second method.]

The Second method is indicated by Don Giovanni Domenico Cassini [Giovanni Domenico Cassini] in his specimen of observations, p. 3, where he judges the solar parallax to be imperceptible, both by other arguments and by an observation of the year 1653, on the 4th day of April, at the hour after midday of $8\frac{1}{3}$, when the Sun stood from the preceding point — the head of Gemini, at $90^{\circ} 3'$ — and the Moon, near its first quarter, approached the circle of latitude of the aforesaid star [the head of Gemini]; for between the middle of the apparent dichotomy time (which had great latitude) and the Moon's coming to the circle of latitude of the star — which he determined from the line of section produced up to the star — he could scarcely detect the 7th [recte: *septimam*] minute of the hour as the interval due between the quadrature of the Sun and the star. He adds, moreover, that he attributes much to this observation, because no lunar parallax is involved in this practice, and the apparent place of the Moon is taken not from astronomical tables, but from comparison with the fixed star duly established. But if we use our [value] for the Sun and for the place of the said fixed star, and consider the time which elapsed from the Moon's coming to the center within the circle of latitude of Castor, up to the quadrature with the Sun, and the effect of the parallaxes optically retarding the dichotomy — as stated *Almagestum Novum* vol. 1, p. 731 — we [find] far more minutes of time than the 7th [recte: *septimam*] which we deduced [recte: *deprehendimus*] between the dichotomy and the quadrature; and accordingly: from this observation it is concluded that the Sun's horizontal parallax is less than about 27 seconds, and not even imperceptible.

[Margin: The sixth method.]

Afterward, however, the same Cassini, as we have it in the *Ephemerides* of the Illustrious March[ese] Cornelio Malvasia [Cornelio Malvasia], fols. 156, 173, and 186, confessed that, from his Table of Refractions, the summer [refraction] yielded for him a solar parallax either nil, or at most $15''$ of seconds; and from the equinoctial [refraction], $30''$ of seconds; and from the Table of Winter Refractions, a parallax of one minute. He nevertheless chose a horizontal solar parallax of $58' 37''$ [recte: $5' 8'' 37'''$ — minutes-and-seconds of arc] at apogee, in the mean distance of $19' 36''$, and at perigee of $1' 0'' 58'''$. Why? Because from this it follows that the Sun's mean distance from the Earth is 3460 terrestrial semidiameters, the seventeen-thousandths of which equal the semidiameters $58\frac{822}{1000}$, for the simple solar eccentricity, which agrees with the mean distance of the Moon from the Earth: so that the point at which the Sun's annual orbit lies should be a point in the circumference of the Moon's orb — namely, what the Moon occupies as often as it is in the Sun's apogee line, namely in the 7th degree of Cancer. It is also $58\frac{822}{1000}$, the square of which is the Sun's distance 3460; and so the mean

proportional between the semidiameter of the Earth, 1, and the Sun's distance [is established]. Now whether the beauty of this symmetry suffices as a foundation for determining the said parallax absolutely, [I leave aside] — than which we have obtained one fully twice as small from many dichotomies duly corrected; or whether some other symmetry, equally beautiful, can be devised for that [parallax] which we shall set out below in [Hypothesis] 2. We propose [it as] Hypothesis, [for] astronomers to test. We meanwhile will attempt certain other methods which, together with Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], we have devised, for [obtaining] the Parallax from the Refractions themselves — including much worth knowing, which, if Cassini weighs it, he will perhaps coordinate his Refraction and Parallax Tables otherwise, by that skill and sagacity with which he is endowed.

CAPUT XIV.

On Astronomical Refractions, their Comparison, and their Use together with Parallaxes; and a New Inquiry into Parallaxes by means of Refractions.

How much astronomy owes to Tycho [Tycho Brahe], and then to Kepler [Kepler], for the measurement and use of refractions — astronomy having been recalled [from neglect] — no one tolerably practiced in these matters is ignorant. Yet not a few things among them, found in part to need correction, in part clearer explanation, lest they offer students of astronomy an occasion for error: the reader is therefore ignorant [of nothing], if from these very notions, or from definitions, we set out upon this treatment from a somewhat higher starting point.

Article I. Definitions, or Notions of the Terms.

The **True Celestial Horizon**, or **Rational** [horizon] — so called simply *Horizon* — is the greatest circle of the celestial sphere, described from the habitable point of the Earth through the Earth and the universe, as the center, as it were, from the pole [recte: from the vertex — *à vertice*]; such is, in the adjoined figure, the circle described by the line ACB, indicated, and from the vertical point of the habitation L, by the line DCE described.

The **Terrestrial Horizon** is the greatest circle of the terrestrial globe, [described] through the center of the Earth and from the place inhabited on the Earth's surface, as from the pole, described by the line DCE.

The **Physical Horizon**, or [the horizon] in a sensibly simple [sense] so called, is the greatest circle of the celestial sphere described from the vertex touching the Earth, and equidistant from the True Horizon — such is FIK.

The **Physical Horizon**, or **Terrestrial** [physical horizon], of the eye raised above the Earth, is the greatest circle of the Earth touching the lines [recte: tangent lines] drawn from the eye to the Earth: such is GNH; for it touches the lines OM, OL, [touching] the Earth at G and H, tangent and produced from the eye O. Hence it comes about that such an eye, which cannot see anything of the terrestrial surface within this terrestrial horizon, can nevertheless see the celestial [things] below either horizon.

The **Vertical line** is that which, from the vertex of the inhabitant, that is, the Zenith, is understood as produced through the inhabitant himself up to the center of the Earth — such is VOIC.

For the remaining Definitions: let there be, in the 2nd figure here, a portion of the terrestrial vertical circle AB, and a portion of the air around it [in which] refraction [occurs] DE, in the same plane. Let the physical horizon of the eye be AR, and the rational [horizon] CQ; and let the vertical line be VC; let there then be the arc TOG, of the planetary heaven — say of the Sun — described in the same plane from C, and the arc of the supreme heaven VSK.

Let first the Sun be below the horizon at G, whence at point I, of the physical horizon, and of the surface of the refractive air, falls the ray GI, which, having entered the said air, does not proceed in a straight line, but is in fact refracted, by the greater density of the said air, along IA, to the eye A. In this case the eye A, by the refracted ray AI, will see the Sun's im-

Diagram. A semicircular figure showing the horizon circles and the refraction of a solar ray below the horizon. The semicircle stands on the diameter A–B with the vertex V at the top.

- V (top): the vertex (zenith)
- A (left end of base): position of the eye / one end of the physical horizon
- B (right end of base): the other end of the base
- F (left, inner): point on the physical horizon FIK
- K (right, inner): point on the physical horizon FIK
- O (center): the center / point on the vertical line
- I (interior, left of center): point where the ray meets the refractive air
- H (interior, right): point on the horizon GNH

- G (interior, lower): the true position of the Sun below the horizon
- N (interior): point on the terrestrial physical horizon GNH
- L (base, right of center): point of the rational horizon
- C (center of base): the center of the Earth
- E (base): point of the refractive-air portion DE
- M (interior, left): point on the line OM
- D (left, near base): point of the refractive-air portion DE

— the Sun's **image** in F, at point R of the physical horizon below point R. Let there be drawn besides from A the straight line AGK, intersected at the points [recte: cutting through the points], through the Sun G, up to K, by which, were the opacity of the Earth not in the way, [the line] sustaining the propagation of the rays — and [so forth].

The density of the air refracting the rays, the eye A could see the Sun directly at G, beneath point K, but it sees the same [Sun] by the straight line CGL, if the eye were at the center of the Earth; and likewise, were the opacity of the Earth and the density of the air not in the way, it would see it [the Sun] illuminated beneath point L.

[Margin: The second case.]

Let, in the second [case], the Sun be at point H of the True Horizon, whence the ray incident at M is imagined to proceed toward N, [but] in reality is refracted at the eye A by MA, and thus the Sun's image is carried by the line AMO, appearing in O, beneath point S, were it carried [recte: drawn] by the straight line intersected AHP; for the Sun itself could not have been seen in H, beneath point P, were the said opacity not in the way; and [if] the density [were not in the way], it would be seen [recte: it could be seen] in H, beneath point Q, by the straight line CHQ.

[Margin: The third case.]

Let, in the 3rd [case], the Sun be at F, and [seen] without sensible refraction, truly so; the place being beneath Z, and the thing seen beneath R. With these premised, let us pass on to the remaining Definitions.

The **True Line of the place of the Star** is the straight line [drawn] from the center of the Earth, and of the Universe, through the center of the body of the Star, up to the supreme heaven — such is, in the first case, CGL; in the second, CHQ; in the third, CFZ. For from this center the astronomers consider and measure the true places of the stars in the heaven, and their true motions.

The **Apparent Line of the place** is the straight line which, in [an eye placed] on the surface of the Earth, or above its surface, the Star's image appears [along]; or it appears [as] the Star itself, if it could permeate through that line to the eye. There is, however, a double [apparent line] of the place seen, that is, by simple vision, [namely] by the **Parallactic** line, that is, the Refracted [line].

The **Parallactic Line** is the straight line [drawn] from an eye placed outside the center of the Earth, [and] led through the center of the Star up to the supreme heaven — such as, in the first case, is ACK; in the second, AHP; and in the following, the third figure, the line AP, the Star being supposed to be at P.

The **Anaclastic Line** is any refracted ray, but most especially that one which is refracted at the eye, as in the first case is AI; in the second, AM; for it goes out by imagination, by the force of refraction, [as] the produced line of the place seen — such is the line AFR, by which the Sun, which is truly at G, appears at F, beneath point R; and the line AOS, by which the Sun, which is at H, appears at O, beneath point S.

The **True Altitude of the Star** is the arc of the vertical circle intercepted between the line of the true place and the true Horizon above [the eye] — such as is the arc QZ, if the star is supposed to be truly at F, or in the 3rd figure, the arc HP, the star being placed at P; for if it were intercepted below, the arc QL would be the **True Depth**. Each of these the angle made at the center of the Earth by the line of the Horizon, and from the other line of the true place drawn through the center of the star, measures: thus the angle QCL measures the Depth of the Sun G, and the angle ZCQ, [made] at F, measures the Altitude of the same [Sun].

The **True Distance** of the star from the Vertex is the arc of the vertical [circle] intercepted between the Vertex and the line of the true place, and it [is] measured [by] the angle made at the center of the Earth by the vertical line and by the line of the true place; such as is, in the prior case, the angle VCL, in the posterior, VCQ.

The **Visible Altitude**, just like the depth, is twofold: the one **Parallactic**, the other **Anaclastic**. Now the Parallactic Altitude is the arc of the vertical circle described from the eye outside the center of the Earth, and intercepted between the parallactic line and the physical horizon above; and it is measured [by] the angle made at the center of the said eye by the two said lines, as in the 3rd figure. If the figure be described from the center of the eye A, [there are] described the arcs of the Astronomical Quadrant, or the arc QS, OZ, of the hemisphere, and through the dioptra AS, [as] the fiducial line, the Star is observed: the angle SAO measures the arc OS as well as the Parallactic Altitude of the star, which appears smaller than

the true altitude HP, [as] it will appear in the celestial place X, when it is truly beneath point T, of the supreme heaven, described from the center of the Earth C. I said *intercepted above*, because, if [intercepted] below, that is, beneath the physical horizon AF, it would be the **Parallactic Depth**, such as is, in the 3rd figure, the arc OZ; the measure of which is the angle FAH, the star being placed at H, and, in the 2nd figure, in the prior case, the angle OAK, in the posterior, the angle OAP. On the Anaclastic altitude I shall speak at num. 15.

The **Visible Distance** of the star from the vertex is likewise twofold: **Parallactic**, the one; **Anaclastic**, the other. Now the Parallactic Distance of the star from the vertex is the complement to the Quadrant of the Parallactic Altitude, or the Aggregate of the Quadrant and the Parallactic Depth; and it [is] measured, in either case, [by] the angle made at the center of the eye by the vertical line and by the parallactic line, of which sort is, in the 3rd figure, the angle VAP, if the star is at P, or VAH, if it is at H, and, in the 2nd figure, in the prior case, the angle VAK, in the posterior, the angle VAP.

The **Anaclastic Visible Distance** of the star from the vertex is the arc of the circle described from the center of the eye, intercepted between the vertical line and the Refracted Ray of the star to the same eye; and its measure is the angle made, at the center of the eye, by the vertical line and by the anaclastic line, or refracted ray. Such is, in the prior case of the 2nd figure, the angle VAR, in the posterior, VAS.

The **Anaclastic Visible Altitude** of the star is the complement to the Quadrant of the Anaclastic distance, when [that distance] does not exceed the Quadrant; but if that distance exceeds the Quadrant, the excess itself is the **Anaclastic Depth**. Now of the Anaclastic Altitude let the example [be found] in its measure, [namely] in the 2nd figure, in the posterior case, the angle SAR. For in the prior case, when, with the Anaclastic distance VAR, there is a Quadrant, the Anaclastic Visible Altitude is nil, and the star appears in the Physical Horizon AFR. The example of the **Anaclastic Depth** I shall give below, when the discourse will be on the Ray raised to the eye, thus Refracted, that it bends downward.

The **Astronomical Parallax** is the difference between the true place of the star, and the seen — or visible — place of the same, through the parallactic line. Hence, if the Parallax be referred to the Altitude, it is called the **Parallax of Altitude**, and it is the difference between the True altitude of the star and its Parallactic altitude; of which sort is, in the 3rd figure, the difference between the angle PCH, and the angle PAF. But if it be referred to the Distance, it is called the **Parallax of distance**, and it is the Difference between the True Distance of the

star and the Parallaxic Distance, of which sort is, in the same 3rd figure, the difference between the angle VCP, and the angle VAP. If, finally, it be referred to the depth, it is called the **Parallax of depth**, and it is the difference between the True depth of the star and the Parallaxic depth; such as, in the prior case of the 2nd figure, is the discrimen between the angle QCK, and the angle RAK; but when the star is in the True Horizon, and there is no true depth, the Parallaxic depth itself is the Parallax of depth, as in the 3rd figure is the angle FAH, and in the posterior case of the 2nd figure, the angle RAP.

Diagram. A large quadrant figure (the second figure of Caput XIV), showing the vertical circle, the horizon lines, and the refracted/parallaxic rays from the eye A. The quadrant rises from the corner C, with the vertical side V–N–D–A–C and the base A–C–B–E–G; the arc runs from V down to the lower right.

- V (top of vertical side): the vertex (zenith)
- T (upper left of vertical side): point of the supreme heaven arc VSK
- S (upper right, on arc): point where the supreme-heaven ray meets the arc
- O (interior, center): point on the apparent/anaclastic line
- N (left, on vertical line): point of the horizon
- D (left, below N): point of the refractive-air portion DE
- M (interior, left): point on line AM
- A (left corner): position of the eye
- F (right, interior): point on the physical horizon AR / arc TOG
- R (right): end of the physical horizon AR
- I (interior, near A): point where the ray meets the refractive air
- C (base, left): the center of the Earth
- B (base, center): point on the base
- E (base): point of the rational horizon / refractive-air portion DE
- H (interior, lower right): point on the True Horizon
- G (lower right): the true position of the Sun
- Q (far right): point of the rational horizon CQ
- P (far right, on arc): the parallaxic point
- L (lower right): point of the line of the place
- K (lower right corner): point of the supreme-heaven arc VSK

Diagram. A smaller quadrant figure (the third figure of Caput XIV), illustrating the parallaxic and anaclastic altitudes and distances from the eye A. The

quadrant rises from corner C with vertical side V–Q–A–C and base A–C–H, the arc running from V (through T, X) down to H.

- V (top of vertical side): the vertex (zenith)
- T (upper right, on arc): point of the supreme heaven
- X (just below T, on arc): the celestial place where the star appears
- P (interior, on ray): the parallax point (star supposed at P)
- Q (left, on vertical side): point on the vertical line
- S (interior, near A): point on the line AS / arc OS
- O (interior): point of the arc OS
- A (left corner): position of the eye
- R (interior, near base): point on the refracted/anaclastic ray
- Z (base, near A): point of the parallax depth arc
- C (base, left corner): the center of the Earth
- F (right, on base/horizon): point of the physical horizon AF
- H (base, right corner): point on the True Horizon

[Margin: What the Parallax of Altitude, of Distance, and of Depth is.]

Since, by *Elements* I.32, the external angle of a rectilinear triangle equals the two internal opposite angles, and is therefore the difference between the external angle and either of the internal opposite angles, the angle formed at the center of a star — between the line of the true place and the parallax line — measures, by the equivalence shown, the parallax of vertex-distance. Indeed, it even turns out that such an angle is called the parallax. And so, in the second figure, in the prior case the parallax of distance is the angle AGC, in the latter case the angle AHC; and in the third figure the angle APC, if the star is at P, or AHC if at H. Finally, since the true distance from the vertex and the parallax distance differ from each other by just as much as the true altitude differs from the parallax altitude — or, in the case of depth, the true depth from the parallax depth — the angle is for that reason the same; for if not formally, then at least equivalently, the parallax of distance from the vertex is also equivalent to the parallax of altitude or of depth.

17. The horizontal parallax [*Parallaxis Horizontalis*], so called without qualification, is that which belongs to a star established in the true horizon; and so it can only be a parallax of depth, or of distance from the vertex. Such is the case in the 2nd and 3rd figures, the angle AHC. Let the common run of astronomers call this the "Astronomers' Parallax of Altitude"; but the wiser, the parallax in the vertical circle.

18. **The physico-horizontal parallax** [*Parallaxis Physicohorizontalis*] is that which belongs to a star apparently in the physical horizon, as in the 2nd figure. In the prior case it is the angle FAG, the Sun being at G; but in the case at F, where it appears by refraction, the parallax itself is properly said to be not so much of altitude as of depth, or of distance from the vertex. They can, however, coincide into one — the horizontal and physico-horizontal alike — if the star, while existing in the true horizon, has a parallax as great as the refraction.

19. **The optical refraction of a star** [*Refractio Sideris Optica*] is the angle formed at the point of incidence, between the refracted ray and the incident ray itself (when, as it were, unrefracted) — that is, the line of incidence extended straight through the point of incidence; this angle some call the angle of refraction. Such is, in the 2nd figure, the angle AMN, in the latter case. I call this the **optical refraction** [*Refractionem Opticam*], because the opticians consider it and express it in their tables of refraction in air, in water, in glass and so on. The astronomers, however, do not consider it in itself, because they do not attend to the difference of the place by the refracted ray and the visible place by the line of the true place — which would be unrefracted, were the eye in the line A, in the unrefracted ray, that is, at N — but they consider the difference of the place seen by the refracted ray, that is, by the line of the true place, and the visible place by the parallactic line. For in either case they have something fixed and determinate: namely the center of the Earth, and the center of the eye in the place of observation established. The astronomer-optician can, however, consider both refractions, the optical and the astronomical, so that, from the diversity of their properties, the matter may be the more illuminated — but care must be taken, lest (as happened to Tycho [Tycho Brahe]) the properties of the one be confounded with those of the other. For since with the decreasing interval of the star from the Earth the obliquity of incidence grows, and with it the inclination of the ray to the surface of the air, and therefore the optical refraction, [Tycho] supposed and expressed in words that, in his larger tables, the astronomical refraction of a star nearer the Earth would be greater than of one more remote — which I shall demonstrate below to be false.

[Margin: Tycho's hallucination.]

20. **The astronomical refraction** [*Refractio Astronomica*], so called without qualification, is the difference of the place of a star seen in the heavens by

the anaclastic line, and of the true place reckoned from the center of the Earth. If this be referred to the anaclastic altitude compared with the true altitude, it is called the **refraction of altitude** [*Refractio Altitudinis*]; if to the depth, of **depth** [*Profunditatis*]; if to the distance, of **distance** [*Distantiae*]. But the refraction of distance is adapted as readily to the case of altitude as to that of depth, and is more easily set before the eyes by the diagrams placed below. We shall use this one henceforth. Let it therefore be that **the simple astronomical refraction** [*Refractio Astronomica simplex*] is the difference between the true distance of a star from the vertex and the distance seen by the force of the refracted ray; such is, in the 2nd figure in the prior case, the difference between the angles VCL and VAR, in the latter case between the angles VCQ and VAS. But when the stars are beyond the horizon, we do not need lines horizontal in our reckoning, but the eye must be led by the straight line drawn parallel to the line of the true place. For the angle made by that parallel, and by the refracted ray, will be the measure of the astronomical refraction.

21. **The composite astronomical refraction** [*Refractio Astronomica Composita*] — namely, that compounded of the simple refraction and of the parallax — is diminished, or rather wholly cancelled, by the parallax through the refraction; as some imagine, but as is in fact nothing. For if the refraction be as great as the parallax would be, it is not compounded of this, but contrary to it. If, on the other hand, the refraction be greater than the parallax would be, it does not on that account produce two effects — namely first raising the star optically from the place in which it would be seen by the mere parallactic line, and then further raising the star above the true place — but in fact it produces a single effect; namely, raising the star optically above the line of the true place, more, or equally, than the depression would have been by parallax, if the star could have been viewed by the mere parallactic line. The star is not so refracted in this case; for in this case the parallactic line does not enter the eye, nor is the star in fact seen by it, nor is it the ray that is afterwards refracted. And thus the parallax is merely potential, not actual. As in the first case of the figure, when the Sun is truly at G, it is not seen by the parallactic line AGK, beneath K, since such a ray does not penetrate to A, the opacity of the Earth standing in the way; but it is seen by the ray GI, refracted from I to the eye A; and so the Sun appears in the line AIFR. Nor is the refraction raised, the optical [refraction] being from K, in L, and from L in R, but merely from L in R, or from the line CL, to the line AR; this refraction is therefore not compounded of the prior parallax, afterwards corrected, and then of the

simple refraction; rather, just as in this case the star seen from the vertex is to be converted into the true [place], it suffices that the seen [place] be added to the simple refraction, the parallax being moreover left out, lest the astronomer be deceived (as Tycho was).

22. **The horizontal refraction** [*Refractio Horizontalis*], so called without qualification, is that which belongs to a star established in the true horizon; of which kind is, in the 2nd figure in the latter case, the angle OAF, the Sun being at H.

23. **The physico-horizontal refraction** [*Refractio Physicohorizontalis*] is that which belongs to a star apparently in the physical horizon, as in the 2nd figure in the latter case, where the angle HCG contains the measure of the refraction. This, however, Tycho calls "horizontal," and observes it the more readily because it is easier, and because the very moment of that observation is given; for it is the first to come about at the appearance of the star in the physical horizon. But at the moment when the star is in the true horizon — neither given by exact calculation beforehand, nor difficult and far from that very exact observing to set up — Tycho [Tycho Brahe] therefore uses the refractions of the visible altitudes observed, and before, on p. 79, set out in a Table; nor does he doubt about the lunar [refractions], p. 124, and the fixed [stars], p. 280, to assess the visible altitudes (*Progymnasmata*, p. 102).

24. The remaining Definitions — namely the parallax, and the refractions of right **ascension**, of **declination**, of **longitude** and of **latitude** [*Ascensionis Rectae, Declinationis, Longitudinis ac Latitudinis*] — we pass over, as superfluous in this place, since here we treat only of the parallaxes and the refractions of stars in the vertical circle. Indeed, what the parallax of distance, and the **subhorizontal** [*Subhorizontalis*] or **superhorizontal** [*Superhorizontalis*] refraction may be, is easily discerned from the true situation of a star below the true horizon, or above.

Article II — Several Propositions concerning Parallaxes in the Vertical Circle

[Art. II. Propositiones nonnullae de Parallaxibus in circulo Verticali.]

Proposition I

The parallax of a star more remote from the Earth is smaller than that of a nearer one; conversely, the parallax of a star more remote from the vertex is greater than that of a nearer one, other things being equal.

25. Since the angle measuring the parallax, namely the one formed at the center of the star and having for its base a semidiameter of the Earth, which at equal distances of the stars from the vertex is greater in the case of a nearer star than in that of a more remote one — as belonging to the external angle of an opposite rectilinear triangle — whereas at equal distance of the same star from the vertex, the parallactic angle of a nearer one is more acute, until at the vertex it altogether vanishes; it suffices to describe a suitable figure, and the demonstration occurs at once.

Proposition II

For an eye raised on the vertical line, the parallax is greater, other things being equal, than for one less raised.

26. Namely, the base of the parallax being opposite, it is greater when it consists of a semidiameter of the Earth and a greater altitude of the eye, than when of a lesser.

Proposition III

The parallax of true altitude, by the parallactic line, and the seen [parallax] of an equal seen altitude, are not equal, other things being equal.

27. For in the same instant of time the same star cannot be said to have the parallactic distance from the vertex seen, which is equal to the true distance, when it is smaller than the true, as the seen is. As in the 4th figure, the [seen] is smaller than the true VCR, the seen being VAR; and thus the seen altitude is not equal to the true, since the star is raised; now, for the seen [distance] to come out equal to the true distance, the star must be raised so long as the parallactic line is parallel to the line of the prior true distance. As in this figure, the star at R must in fact ascend to S, so that the parallactic line AS may be parallel to the preceding true CR. Thus the seen distance from the vertex VAR will be equal to the prior true VCR, by *Elements* I.29; but in such a situation the parallax of distance ASC, by the first proposition of this [Article], will be smaller than the prior parallax ARC. Therefore the parallax belonging to the seen altitude equal to the true

altitude will not be equal to the parallax of the true altitude, but smaller; and so for the rest.

Diagram. A quarter-circle (quadrant) with center C at the lower left. The horizontal radius runs from C to H at the right; the vertical radius from C up to V. The arc VH joins them. Within the quadrant, point A lies on the vertical line above C; from A and C lines run to points R and S on the arc, illustrating the true and parallactic distances of Proposition III.

- V (top of vertical radius): vertex
- C (lower-left, center): center of the Earth
- H (lower-right, end of horizontal radius): horizon point
- A (on vertical line above C): position of the eye
- R (on arc, lower): star at true distance
- S (on arc, above R): star raised so that $AS \parallel CR$

Corollary

28. The Table of Parallaxes serving for a given true altitude does not serve exactly, nor in strict geometrical rigor, for the seen altitude — equal in quantity, as it stands — but it does serve mediately, by the device that follows.

Proposition IV — Problem

From the Table of Parallaxes of true altitude, to extract the parallax suited to an equal seen altitude.

29. Seek in the aforesaid Table the parallax corresponding to the given true altitude, just as if it were the true [altitude]; add it to the given altitude, and with the aggregate produced by this addition seek in the same Table another parallax — that one will be the one which belongs to the seen altitude given before. For example: let the Moon be distant from the center of the Earth 52 terrestrial semidiameters, and let its seen altitude be 15 degrees. The parallax in the Parallactic Table of the Moon corresponding to 15 degrees of seen altitude is 64' 10". To this, the added 15 degrees makes a true altitude of 16° 4' 10"; and to this there corresponds in the same Table a parallax of 63' 51". This, therefore, will be the [parallax] which fits the seen altitude of 15 degrees. You will, however, work more subtly by an analysis of the triangle ACS. Given CS, the distance of the star from the Earth, in parts of which the terrestrial semidiameter AC is one, and CAS, the

complement of the seen distance VAS, to two right angles, the parallax ASC fitting the seen distance will easily be obtained.

Proposition V

The horizontal parallax is indeed smaller than the arc intercepted between the true and the sensible horizons; but in the Sun [smaller] imperceptibly, in the Moon scarcely perceptibly, and almost contemptibly smaller.

30. In this fifth figure the horizontal parallax is the angle AHC, by Definition 17; and FI, by the definition of sines, is the right sine of the arc FH, intercepted between the true horizon CH and the sensible AF; this [FI is smaller] than the angle FCH. Now, the diagonal AI being drawn between the equal parallels AF and CI, and CF being the other [diagonal], an isosceles triangle COI arises; therefore, by *Elements* I.15, the angle OCI — that is, FCI — equals the angle OIC, that is, the angle AIC; but the angle AIC, the external one, is by *Elements* I.32 greater than the two internal and opposite [angles]; therefore the angle AIC is greater than the angle AHC, and accordingly the angle FCH and the arc FH is greater than the horizontal parallax, or this [parallax is] smaller than that.

Further, that the horizontal parallax and the arc FH — that is, the angle FCI — may be compared together at once, the right triangle ACH must first be resolved, in which the side CH is given, that is, the distance of the luminaries in semidiameters of the Earth, and AC, one semidiameter; whence the parallactic angle AHC will not be hidden. Then in the triangle FCI, CF is given, but as a base — namely, the distance of the luminaries from the center of the Earth — and FI, equal to one terrestrial semidiameter AC; therefore the angle FCI, measuring the arc FH, will not be hidden. By the most subtle Logarithms we have determined this for you, assuming the least distance of the Moon from the Earth to be 52 terrestrial semidiameters; that of the Sun, the Tychonic mean, 1142, the truer and ours, 7373; from which data the horizontal parallaxes, and the arc FH, come out, as in the following Table.

	Semid. Terrae	Parall. horiz. I. II. III. IV	Arcus FH I. II. III. IV
☾ in distantia	52	66 6 39 0	66 15 8 0
☉ in distantia	1142	3 0 22 0	3 0 22 25
☿ in distantia	7373	0 28 18 0	0 28 18 5

It is therefore evident that the horizontal parallax is imperceptibly smaller than the arc FH between the true horizons in the Sun, and in the Moon at most smaller by 9' usually; contemptibly so.

Diagram. A quarter-circle (quadrant) with center C at the lower left. The horizontal radius runs from C through B to H at the right; the vertical radius from C up to V; the arc VH joins them. The point A lies on the vertical radius; F lies on the arc. AF (the sensible horizon) is drawn parallel to CI, with the diagonal AI and the chord CF crossing at the interior point O. The figure illustrates the horizontal parallax (angle AHC) versus the arc FH of Proposition V.

- V (top of vertical radius): vertex
- C (lower-left, center): center of the Earth
- B (on horizontal radius, between C and H): point on the true horizon
- H (lower-right, end of horizontal radius): true horizon point
- A (on vertical radius above C): position of the eye / one terrestrial semidiameter
- F (on the arc): star in the sensible horizon
- I (on horizontal radius, near H): foot of CI, equal-parallel to AF
- O (interior, intersection of AI and CF): vertex of the isosceles triangle COI

Proposition VI

Given the horizontal parallax of stars, the true altitude of them is at once given when they are in the physical horizon; and likewise the altitude of the physical horizon itself, without perceptible discrepancy — provided that, in the case of the lunar parallax, nine seconds-of-arc be added.

31. For the arc between the true and the physical horizon is the true altitude of the physical horizon, which the stars truly existing there have. But this arc, by the preceding Proposition, is to the senses equal to the horizontal parallax of the Sun — indeed of the Moon increased at most by 9" — and in the rest, none, or one smaller than the solar parallax, the stars having the same [parallax], as is plain *a fortiori*. In Mars, however, Venus, and Mercury, though they have at perigee a parallax greater than the solar, yet in fact, on our supposed distance of the Sun from the Earth, they never have a parallax of 3'; which, even if they did have — as Tycho supposes of the Sun — is plain from what has been said to be Tyconic, and that to the senses equal to the arc FH. No planet therefore, the Sun excepted, when it is truly in the physical horizon, is higher than the true horizon by more than one minute, and at a mean distance...

Proposition VII

The parallax of a star truly existing in the physical horizon is greater than the parallax of the same star in the true horizon; and is therefore deservedly called the horizontal parallax.

32. In the fifth figure, of a star existing at F, the parallax is the angle AFC, which by the alternate FCI is equal, and this [is] greater than the parallax AIC; and this [is] greater than AHC; therefore AFC is greater than AHC — see the preceding Demonstration. It is not, however, to be wondered at if a star, raised somewhat above the true horizon, should have a greater parallax than one not raised; because the parallax in the physical horizon is not a parallax of altitude, but of depth, and truly depresses the star more than the parallax of a star raised. For the parallax of the [physical] horizon perceptibly depresses [it] more truly — that is, below the true [horizon] — but more apparently below the apparent horizon; and the horizontal parallax truly depresses [it], that is, below the [true] horizon. But on account of the predicted greater magnitude it is not unworthy of the name of horizontal parallax; let the Tables of parallaxes be used in respect of the true horizon, especially since (as will soon be demonstrated) it is the greatest of all parallaxes.

Proposition VIII

The parallax of a star truly existing in the physical horizon is the greatest of all [parallaxes] of the same star existing elsewhere, but at the same distance from the Earth; and below the physical horizon the parallaxes continually increase, as much upward as downward.

33. While I was striving to demonstrate this in another way, Father Francesco Maria Grimaldi [Francesco Maria Grimaldi] suggested to me another proof, which is of this kind. In the Vertical circle BVHP, let the Vertical line be VP, and the Astronomical Horizon BCH, and the Physical EAF, in which the eye is A; if from the center of the Earth C the straight lines CF and CE be drawn, which are equal to semidiameters of this circle, an isosceles triangle CEF will be formed; and the angles at the base, by *Elements* I.15, will be equal. The parallaxes of stars placed at the extreme of the physical horizon, namely E or F, will be congruent — namely the angles AEC and AFC; let the star then be at K, below the physical horizon, in I, above it by as great an arc EI as the arc FK is; so that, through the eye A, it may be led from the point K to I, and from I by the straight line KI. For if, from the same points,

lines be drawn from the center of the Earth to E, K, and CI, another isosceles triangle CIK will be born, in which the parallactic angles at the base between themselves are equal, namely AKC and AIC; now let [a line] be drawn to the chord KI, and the perpendicular CL [dropped]; for in the small triangle ACL, right-angled at L, the base AC, by *Elements* I.18, is greater than the side CL; therefore the chord EF is more distant from the center C of the circle than the chord IK; therefore, by *Elements* III.15, the chord EF is greater than IK; and accordingly, by *Elements* I.32 and I.5, the angle ECF is smaller than the angle ICK, and the angles at the base EF are greater than the angles at the base IK; therefore the parallax F is greater than E, and severally, than... the lower parallax I and the lower K. By how much the point K is lower than the point F, and the point I higher than the point E, by so much the chord through the eye A, drawn to such points... is nearer the center C, and accordingly greater than EF; and EF itself, [greater] than all those that are drawn through the eye A... [is] most distant from the center C, and accordingly the parallaxes E and F [are] the greatest of all; and all the rest, always toward the vertex V, or toward the lowest point P, decrease continually.

Diagram. A full circle representing the vertical circle, with center C. The vertical diameter runs from V at the top to P at the bottom. The astronomical horizon is the horizontal diameter B–H. Above it, an oblique chord E–F marks the physical horizon, with the eye A near the center and the label "AL" beside the perpendicular CL. Points I and K lie on the circle near E and F respectively. The figure illustrates Grimaldi's proof.

- V (top): vertex
- P (bottom): nadir / lowest point
- B (left, on horizontal diameter): astronomical horizon, left end
- H (right, on horizontal diameter): astronomical horizon, right end
- C (center): center of the Earth
- A (near center): the eye / observer
- E (upper left, on circle): left end of physical horizon
- F (upper right, on circle): right end of physical horizon
- I (left, on circle near E): star raised above physical horizon
- K (right, on circle): star below physical horizon
- L (near center, on chord IK): foot of the perpendicular CL [labelled "AL"]

[Margin: The line CH serves for the line CK, drawn from the point of incidence.]

Remarkable Corollary

34. Falsely, therefore, has it been supposed until now that the greatest of all parallaxes...

is that horizontal [parallax] which belongs to a star existing in the true horizon — whereas the greatest is the one in the physical horizon, although the discrepancy is imperceptible in the Sun, and in the Moon not exceeding 9"; as I said in Proposition V, one could be used for the other.

Proposition IX

The parallax of depth is smaller than the parallax of altitude of an equal depth.

35. Let it be that in this 7th figure a star is at K, and the eye at A; and so the parallax of altitude is AKC. But let another star be — or the same one at another time — in L, below the horizon toward BCH; by as great an arc HL as is the arc of altitude HK, the parallax of depth ALC will be, by the premised definitions. Let CL be continued to M, and from A, to M, let the straight line AM be drawn; the triangle AML will then be formed, in which the angle M is equal to the parallactic angle of altitude K, since it is opposed to the same side AC; and the triangles ACK and ACM are similar, because, besides the common side AC, the sides CK and CM are equal, as radii of the same circle; and on account of the comprehension on the side AC, the angles VCK and VCM are equal — that is, equal complements of altitude, since the angles MCB and HCL are equal at the vertex, and are equal to each other; therefore, in the greater triangle AML, the angle M is opposed to the greater side AL, and the angle L to the smaller AM. Therefore the angle M, and accordingly its equal K (which is the parallax of altitude), is greater than the angle L, that is, the parallax of depth.

Diagram. A full circle with center C. The vertical diameter runs from V at the top to D at the bottom; the horizontal diameter from B at the left to H at the right. Point A lies just above center C on the vertical line (the eye). Radii run out to K (upper right, on the circle) and L (lower right, on the circle); M lies on the line CL continued (lower left region). The figure illustrates the comparison of the parallax of altitude (AKC) with the parallax of depth (ALC).

- V (top): vertex
- D (bottom): nadir
- B (left): horizon, left end
- H (right): horizon, right end

- C (center): center of the Earth
- A (above C): the eye
- K (upper right, on circle): star at altitude
- L (lower right, on circle): star at depth
- M (lower left): point on CL continued

Proposition X

The parallax of depth, of a depth equal to the [given] altitude, in the Moon is not smaller by more than 20 seconds-of-arc.

36. For the maximum parallax of altitude is that which belongs to a star existing in the physical horizon, by Proposition 8; but this, in the Moon, is so great as the arc of the vertical [circle] described through the center of the Moon between the Astronomical and the Physical Horizons — namely the arc HK in the Moon, the [arc] of altitude — is great. The distance proximate to the Earth is, by the said Proposition 5, the minutes $66' 15'' 8'''$. Now if just as much be below the true Horizon, with the addition there of degrees 90, the triangle whose angle comprehends a semidiameter of the Earth at the distance of the Moon from the Earth — that is 52 terrestrial semidiameters — will be $91^\circ 6' 15'' 8'''$. Therefore, by the logarithmic canons, the parallax of depth comes out in such [a case] $65' 55'' 10'''$; and so the smaller parallax of the maximum altitude does not exceed $20''$; in the Sun, however, this difference comes out scarcely of one second, as will be plain from the calculation. Wherefore in the Sun it can be held for imperceptible, and in the Moon little, and scarcely perceptible.

Article III — Propositions concerning Refractions

[*Artic. III. Propositiones de Refractionibus.*]

Proposition XI

A ray, the more obliquely it falls — that is, at a greater angle of inclination — is by so much the more refracted; and equally, if equally oblique.

37. Thus Witelo [Witelo], *Optics* X.14, and Kepler in the *Paralipomena ad Vitellionem* I.1.4, Proposition 1: from the posterior [cause], it was first proved by experiments, and then demonstrated *a priori*, and so received by the opticians, that it holds the place of a 2nd Axiom, from Kepler in the *Dioptrics*. Hence the optical refraction of a more obliquely incident ray is the greater.

Proposition XII

Of a ray returning from a denser medium, through the same point by which it entered, the refraction from the perpendicular is equal to the refraction toward the perpendicular at entry.

38. This is demonstrated by Alhazen [Ibn al-Haytham], *Optics* VII, Proposition 34. Witelo...

[Continuation of the citations supporting the preceding proposition:]

Witelo [Vitellio], Book 10, Prop. 9; René Descartes [Renato de Chartes], *Dioptrics* [*Dioptr.*], no. 10; Hérigone [Herigonio], *Dioptrics* [*Dioptr.*], Prop. 1, and likewise locations 3; from the Axioms in Kepler's [Keplerum] *Dioptrics*.

XIII. PROPOSITION.

For a more distant and a nearer star whose rays of incidence run along the same line into the same point of the same dense medium, the optical refraction is the same.

[Margin: 39] Kepler [Keplerus] conceived the same idea in other words in Book 1 of the *Paralipomena* [*Astronomia Optica*], chapter 4, Proposition 4, where he says: "For light that is faint and light that is denser, all else being equal, there is no difference of refraction." And in this sense he added in his commentary [*postilla*]: "A greater distance of the luminous body does not increase refraction." For even though the ray of a more distant star, being uniformly weakened, becomes fainter as it proceeds, and the density of the intervening medium offers more resistance to a weaker ray (so that there is more intensification), nevertheless this does not amount to any greater bending so far as shape or fracture is concerned. The amount of that bending arises from a greater or a lesser obliquity of incidence; but in a more distant and a nearer star the radiation is assumed to occur along the same line of incidence — and so, the angle of inclination being equal, the optical refraction is equal by Proposition 11.

XIV. PROPOSITION.

At the same true distance from the vertex, the apparent distance produced by refraction is less for a more distant star than for a nearer one, all else being equal.

[Margin: 40] Keeping in common the matters described in Figure 2, suppose that in this eighth figure the Sun is at H and the Moon at G, both of them

Diagram. A quadrant-shaped figure bounded by the vertical line VAC on the left and the horizontal base CH along the bottom, closed by a quarter-arc from V down to H. The vertex V is at top; the star S is marked on the arc near the top with an asterisk. From the eye at A near the lower left, several rays radiate out across the field toward the base line and arc; intermediate points M, O, P, K, L, G, N are lettered along the refracted and incident lines; the Sun is at H and the Moon at G.

- V (top): vertex of the vertical line
- S (on upper arc): the star (marked with an asterisk)
- A (lower left, near C): the eye / observer
- O, P (left side, below V): points on the vertical line
- M (interior, upper): point on a refracted ray
- K, L (interior): points where rays cross / refract
- G (interior, lower): the Moon
- N (interior, lowest): point of incidence
- C (bottom left corner): foot of the vertical
- F (right, on arc): point on the arc
- H (bottom right corner): the Sun

at the same true distance VCGH from the vertex, to which the line drawn from the eye AF is parallel. The ray of the Sun enters at point K, by way of HK, and there, while unrefracted, it would proceed in P; but in truth, by way of KA, it is refracted to the eye A — for by AK, produced optically toward the Sun's heaven, the Sun appears at S, and its apparent distance from the vertex is the angle VAS. The Moon's ray, however, from G cannot radiate at K, but is so refracted by way of KA that, since the angle of inclination GK is greater, it would radiate at a greater angle, and hence its refraction would be greater by Proposition 11 of this chapter, and the eye at K, beneath A, would be refracted, both because by Proposition 12 of this chapter it would be the same for the Sun and for the Moon, and because the refracted ray of the Sun AK, and likewise the Moon's, lie on the line of incidence; the Moon ought therefore to be at N, where it is more distant from the vertex by the angle VCN, the smaller being VCH, namely the Sun's distance. Finally, since just as the ray of the Moon touches the sphere of the refractive air at a nearer point — for in this case the ray of the Moon, first entering the air, first enters the eye at A, lower than the Sun's ray, which first entering the air enters the eye at A, striking it: therefore the ray of the Moon at the eye A, by the refracted ray and at a lower point, is refracted, say at I, and by the refracted ray AI the Moon appears at L; and so its distance, seen apparently from the vertex, will be VAL, greater than the Sun's VAS, and so for similar cases,

provided the rest be equal — that is, the position of the eye, the density of the air, and so forth.

XV. PROPOSITION.

At the same apparent distance from the vertex produced by refraction, the true distance is greater for a more distant star than for a nearer one, all else being equal.

[Margin: 41] In the eighth figure it would appear, if they were not on the same vertical;

if it [the observer] should weigh that matter; for the fixed stars and planets, some of which are nearer than others, are by Tycho [Tycho Brahe] assigned the same refractions; and shortly after: Rothmann [Rothmannus] is therefore mistaken, in supposing that the various fixed stars and planets — though differing in distance from the Sun and from the planets — would undergo the same refraction; and however much Brahe in the *Progymnasmata*, folio 280, suspects the Moon's refractions to be greater on account of its nearness — nevertheless on folio 124 (which he wrote later) he finds the refractions, as I have already said, to be the same as the solar ones. And so Kepler [Keplerus] judged the refractions of the stars to be equal at whatever distance from the Earth, which is indeed true if they are at the same apparent distance from the vertex, and provided the discussion concern optical refraction; but in respect of astronomical refraction it is false, whether they be at the same apparent distance or at the same true one. Hence in the *Rudolphine* precept he lastly spoke of Tycho. If perhaps (which he nonetheless vainly suspected) the altitude of the stars from the center of the Earth should vary, it would produce a cause of variety. I think the refractions are therefore made greater because in computing them Tycho applied too large a parallax of the Sun. Yet even without a parallax they ought to have been made greater. Hence at last he badly added, in the commentary to the same Proposition 4 of Book 1 of the *Optics*, chapter 4: "Nor does refraction represent the Moon conjoined to a star which, refraction aside, had appeared separated from it." And that this is false we shall show at once.

[Margin: Kepler's error]

XVII. PROPOSITION.

Two stars unequally distant from the center of the Earth can, by the power of refraction, be represented as nearly conjoined bodily, which, refraction set aside, would have appeared very far apart.

[Margin: 45] It is, as I have said, against Kepler [Keplerum], Book 1 of the *Astronomical Optics*, Proposition 4, in the commentary. Let there be, in the eighth figure, the Sun at H and the Moon at N, if not in the same vertical plane in which lies the obstacle to the propagation of the Sun's ray — at least in the neighborhood of the vertical, and at a smaller distance, which is the aggregate of the semidiameters of their visual disks; and let them radiate by the same line at the point K, or very near it, and on an equally high surface of the refractive air; in the same place, or on an equally high surface, by the refracted ray KA, they will appear to the eye A on the same line AKMS, or with the Moon equally high at M, and the Sun at S, and as to apparent altitude conjoined; but as to azimuthal latitude the Moon's image partly covers the eye A; and yet, if from the eye A the parallactic lines were drawn straight, the one AN to the true place of the Moon, the other AH to the true place of the Sun, and if they were observed by these without refraction, both the Moon, far higher than the Sun, would appear: hence you will easily recognize that two stars unequally distant from the Earth can, by the contrary, be represented as conjoined, which, refraction set aside, would have appeared disjoined by the power of refraction.

XVIII. PROPOSITION.

To an eye in no way raised above the Earth, a refracted ray never represents stars below the Physical Horizon, much less the True one.

The reason is that the refracted ray to a place of this kind either coincides with the Physical Horizon, or is above this horizon, and so represents the stars, or is on this horizon, or above it, as before; but if it falls below this horizon it does not penetrate the opacity of the Earth, nor reach the eye on the surface itself lying there.

XIX. PROPOSITION.

To an eye raised above the Earth, the stars can appear below the Horizon by the power of refraction.

[Margin: 46] This is established by frequent experiment. For we have seen — from a place set on high, for instance from our own Observatory [*Specula Observatoria*], or from the summit of Monte Paterno [Paterni montis] — the Moon and other objects cast down below the horizontal line of an instrument set up and leveled, appearing there, and we do not doubt that their rays, being conveyed through denser air to the eye, refracted, have reached us; and in this way it appears that the Moon, however often it is in the true horizon, or below it, shows

on account of the great parallax a greater refraction, and cannot be represented in the Physical Horizon, much less above it. Let an example of this be in Figure 9. With the Moon situated at H,

Diagram. A quadrant figure with the vertical line VAC on the left and the horizontal base CFLH along the bottom, closed by a quarter-arc from V to H. From the eye region (O, A near the upper-left interior) rays run down across the field; interior points K and I mark the refraction; the base line carries the points F, L, H at the right.

- V (top left): vertex
- O (left, below V): point on the vertical line / eye position
- A (left, below O): the eye / observer
- C (bottom left corner): foot of the vertical
- K (interior, upper): point of refraction
- I (interior, below K): point of refraction
- F (bottom right region): point on the base line
- L (bottom right): point on the base line
- H (bottom right corner): the Moon

radiating to point K, it can be seen at L, by the refracted ray KO, bending downward: for the refracted ray always represents the stars less distant from the vertex than they would be seen without refraction in that same place. And in this sense it always raises them optically, however far downward it bends. And by this occasion enough has been pointed out, that to an eye sunk below the surface of the Earth — for instance, in the bottom of a well, a pit, or the depth of a ditch, trench, or valley — certain stars can appear by the power of refraction which without refraction could not appear there.

XX. PROPOSITION.

The fixed stars and all the planets, the Moon excepted, when they appear in the Physical Horizon, are in truth below the True Horizon by as great a depth as is the difference between their Horizontal Parallax and the Horizontal Astronomical Refraction.

[Margin: 47] For on the one part of the arc between the Astronomical and the Physical Horizon, the fixed stars indeed all rise by sense, since they lack any sensible parallax; in the planets, the Moon excepted, since they are insensibly distinguished by their own Horizontal Parallax, by what was said in Propositions 5 and 6, it does not exceed one minute, nor reach a minute — supposing the truer

distance of the Sun from the Earth, concerning which there is more in *New Almagest* [*Almagestum Novum*], Book 3. But on the other part the refraction of the Horizontal refraction of the stars, by the experiments of Tycho [Tychonis] and others, and ours, is not less than 27 minutes, but more. When therefore in the Physical Horizon the distance from the vertex of the apparent star adds to that Horizontal Refraction of 27 minutes, but the arc inter-horizontal exceeds two minutes, the star will be below the horizon by as many minutes as remain after the parallax has been subtracted from the horizontal refraction.

XXI. PROPOSITION.

When the Moon appears in the Physical Horizon, it is in truth between that same horizon and the Astronomical Horizon.

[Margin: 48] The reason is that the Moon's refraction in that situation is much less, but sensibly, than its Horizontal Parallax, not to speak of the arc inter-astronomical, Physical; the Horizon being intercepted; therefore if the refraction is then added to the apparent distance from the vertex, its true distance from the vertex will become less than it would be if the Moon were in the true horizon, or below it; for if it ought to be in the very horizon, it would be necessary that to the apparent distance there be added an arc as great as is the difference between its Horizon, which differs from the Moon's Horizontal Parallax by 9 minutes, to the highest, by seconds, from what was said in Propositions 5 and 6.

XXII. PROPOSITION.

The distance from the vertex seen by the power of refraction can be not only for the Moon, but also for certain other Planets, greater than the True distance; but it is always less than the Apparent, or Visible, distance taken by the parallactic line alone.

[Margin: 49] Concerning the Moon appearing in the Physical Horizon, this is clear from the preceding Proposition; for the other Planets it is proved because the eye can be so far raised above the Earth that, by the refracted ray bending downward, it may see the stars, as was said in Proposition 19. But no contradiction can be brought forward on account of which the star at that moment cannot be in the True Horizon,

or above it, in either case the True Distance from the vertex not exceeding 90 degrees, and yet the Apparent distance, by the refracted ray bending downward, will be greater than 90 degrees, otherwise it would not bend downward. As in Figure 9, by the refracted ray KO, the star which is in truth at H appears at L; the

eye is at O, the angle VOL is greater than the angle VCH, but the angle VOH is smaller, made on the parallactic line; and so, as I said also in Proposition 19, refraction always raises — understand, not above the True, but above the Parallactic — the Apparent or visible distance from the vertex.

XXIII. PROPOSITION.

To find the simple Astronomical Refraction of any star whatever by observation, given its Declination and the Altitude of the Pole.

[Margin: 50] This can be done in several ways, but the easiest and most exact is the one done through the observation of the Azimuth, together with the distance of the star from the vertex captured at that very moment, by which the center of the star appears in a determined Azimuth. This is evidently done by our Filar Triangle [triangulum filare], *New Almagest* [*Almagesti Novi*], chapter 15, Problem 8, as described; if it be located in a determined Azimuth, and one wait, until

Diagram. A full circle representing the celestial sphere, with the horizontal diameter BCEH drawn across it and the vertical diameter VN through the center. Interior points I, K, D, L are marked near the center and lower portion; F is marked on the upper right of the circle; arcs are drawn connecting these points (representing the vertical circle, the declination circle, and the azimuth lines).

- V (top): vertex / zenith
- F (upper right, on circle): point on the circle
- B (left, on horizontal diameter): end of the horizontal diameter
- C (center): the center of the sphere

the center of the star reach that same point, whether the star be rising or setting, or appear above the horizon; and at the same moment let another observer mark on the instrument, with the most precise and subtle precision, in minutes, and to within some seconds of the subdivision, let him take the apparent distance of the

star from the vertex. Further, in the case of the fixed stars there is no need to know the moment of time at which the observation is made; it suffices to know the day, since within a single day their declination does not vary sensibly. In the case of the Sun, however, it is expedient to make the observations on the days of the solstices, on which the Sun's declination varies insensibly, or at least in the Sun, and in the other planets to be observed, the moment of time must be marked, whether by a clock, or by a fixed star, as near as possible, so that the star's declination may be exactly computed.

These things being done, let the first star in the tenth figure be at K, but appear by the power of refraction at C, that is, in the Physical Horizon BF, or not, and at the true place K, from the Pole of the World P, let the arc PK be drawn, a portion of the circle of declinations; and from the Vertex V, through K, the vertical semicircle VN; there will arise the spherical Triangle VPK, in which, by the observed Azimuth, the angle PVK is given, and the side PV, the complement of the Altitude of the Pole, and the side PK, the complement of the Northern declination, or the aggregate of the Southern declination and the Quadrant, if the declination be Southern, or the Quadrant, if there be no declination: therefore, these three being given, by the Canons of the Triangles, the true distance of the star from the Vertex VK will become known, from which, by subtracting the apparent distance VC, the simple Refraction CK will remain known.

Let the second star be at D, but appear by the power of refraction above the horizon at L; for by drawing through it the vertical semicircle VN, and to it the arc of the declination of the circle PD, the Triangle VPD will arise, in which, by the Azimuth, the angle PVD is known, and PV, as above, and PD, the complement of the Northern declination, or the aggregate of the Southern declination and the Quadrant, or the Quadrant; from which the true distance from the vertex VD will become known, from which, by subtracting the observed, or apparent, distance VL, the Refraction DL will remain. Let the contrary be the case: let the star be at L, but appear

at C — (for it can appear at a greater apparent distance from the vertex than the true one is established from what was said above) — then, in the Triangle VLP, from three data noted above and applied to this case, the true distance VL will be given; and this, subtracted from the apparent VC, will leave the Refraction CL.

Nor is there any objection that the arc VLC, by which in this Figure the apparent distance of the star from the vertex is represented, is the arc of a great circle described from the center of the Earth, and yet the apparent distance from the vertex is captured by an instrument whose center is on the surface of the Earth,

or higher, for we do not need such an arc, but the angle made at the center of the instrument, which in the highest heaven measures for us the apparent distance from the vertex, to be compared with the true; the line drawn from the center of the eye, or instrument, is parallel to the line of the True distance from the vertex. It suffices for us to find separately, through the star, the true distance, and the angle of the vertical drawn through the star, to consider the apparent place, or image of the star, however far removed from the eye into the infinite. Thus in lunar parallaxes we use the angle made at the center of the eye on the parallactic line, and on the line of the perpendicular, or vertical, and we compare it with the angle made at the center of the earth on the line of the true place. Thus in the Equations of the Planets we use the angle of the anomaly, beyond the center of the true motion, indeed beyond it in the form of the Equant, beyond the center of the planetary orbit: for such an angle does not measure an arc of the orbit, but, by the benefit of the parallels, it measures the distance from the Apogee, in the highest Ecliptic infinitely, or however far considered as removed.

XXIV. PROPOSITION.

Although the simple Astronomical Refraction of the Moon can be known without Parallax, and the Apparent distance can be converted into the True without it; the True nevertheless cannot be converted into the Apparent without Parallax, just as neither can the Apparent by the power of one be converted into the Apparent by the power of the other.

[Margin: 51] The first part of the Proposition is proved, because by Definition 20 of the notion, and by the use of the Astronomers, received, this Refraction is nothing else than the difference between the true distance of the star from the vertex and the Apparent produced by the power of the rays of Refraction; and this by Proposition 23, and its practice there to be handed down, can be known without the use and notice of parallaxes; therefore for this purpose the notice of parallaxes is not necessary, much less the use of Parallaxes. This is confirmed: first, because in this case the comparison of Distance is not made between the apparent by the power of the line of Refraction, and the true, or apparent by the power of the rays of Refraction, but between the true, and the apparent by the power of refraction, and that at whatever moment, at which a sensible Refraction occurs; there also occurs a lunar parallax greater than the Refraction, and so the eye is at a distance from the Earth suitable for a sensible parallax; yet the Refraction itself does not raise the parallactic line, nor is it referred in our case to it, but merely to the True. It is confirmed, second, by example, and by the authority of Tycho [Tychonis], who in Volume 1 of the *Progymnasmata*, page 124,

exhibited a little table of Lunar Refractions, without the inclusion of parallaxes; otherwise in the horizon he ought to have exhibited a Refraction not less than 85 minutes, made up, that is, of 33 minutes of pure Refraction, and of the horizontal Parallax of the Moon, which is scarcely less than, indeed [recte: not less than] 52 minutes; but he set it down at only 33 minutes, and so for the rest, and thus the second part of the Proposition stands proved.

The third and fourth parts, concerning the Conversion of the True into the Apparent, or of the Apparent by the power of the rays refracted into the Apparent by the power of the parallactic line, are proved because then the comparison is made not only of the True into the Apparent refracted, but into the Apparent absolutely, when the Refraction is not greater than the parallax, or equal, as happens in the Moon; the Refraction does not raise the star optically only by as much as the parallax depresses it; the True distance being therefore converted into the Apparent by the power of Refraction, the star will be seen higher indeed, but still depressed, or less high by the power of the remaining parallax, or by the excess, by which the whole Parallax overcomes the Refraction, and as to this excess, the parallactic line works its effect. Therefore, in order that the True may be turned into the Apparent adequately and absolutely, parallax will be needed, and much more if the Apparent is to be compared with another Apparent. Repeat here what I said in no. 21.

Proposition XXV.

For the remaining planets, which have a smaller refraction than the fixed stars — let alone the fixed stars, of which not only can the parallax not be known [scin] at all [absq; Parallaxi], but the simple astronomical refraction [Refractio Astronomica simplex] also, even without converting the true distance from the vertex into the seen distance, and the true into the seen in absolute terms, is nevertheless not the seen anaclastic [refraction] into the seen or visible parallactic [distance].

[The marginal numeral "52" keys the body proof.]

The first part, as set out above from practice, was proposed in Proposition 23; and it is proved. This second part also follows from the fact that in each case there is only the comparison of the true distance from the vertex with the seen distance — that is, with the refracted ray alone, without any regard to the parallactic line. For this latter accomplishes nothing in reality, nor does it have its own effect, by the very fact that the refraction is smaller; rather, the seen distance would be the same even if there were no refraction. For the conditional-true [distance] is true, yet it meanwhile posits nothing in being, nor does it bring it about that the eye

should in reality see the stars parallaxically — sometimes partly parallaxically, partly refractedly, but purely refractedly. And although the refracted eye that does the seeing lies outside the center of the Earth — that is, above the True Horizon, where it is exposed to the situation of parallax — nevertheless, so long as the parallax, on account of the enormous distance of the star from the Earth, is null, or smaller than the refraction, the parallaxic line behaves accordingly, as if it did not exist in the nature of things. Indeed, in reality it then does not exist, and is not to be applied, nor does it accomplish anything physically or optically, as I have also shown in number 21. For one must not conceive here a kind of conflict of opposites, in which the refraction lifts upward by, say, eight degrees, while the parallax drags downward by two; nor that there follows an elevation of only six. Rather, the refracted ray of the star directs the actual seeing without the intervention of parallax; and then it is the parallaxic line alone that is to be considered for determining the seen place of the star, when the refracted ray has not lifted the seen object as far as it ought, so that it could be seen without parallax; but it still leaves a place for parallax, because this is the refraction.

Our discussion is confirmed by coming down to practice. Suppose, by Proposition 23, that the true altitude of the Sun is found to be 85 degrees, but that by instruments it is observed at $84^{\circ}30'$ by the force of the refracted ray. It is certain that this whole elevation of 30 minutes does not come from parallax — whose effect is to depress downward — but from refraction. Therefore, if those 30 minutes are added to the absolutely seen 85 degrees, the true altitude of $84^{\circ}30'$ will be had; and vice versa, if from the true 85 degrees you subtract 30 minutes, the seen distance — that which is to be seen — will be left for the future, the same density of the Air being preserved. There is nothing, then, in this comparison, or in mutual conversion, that is Parallax.

But on the other hand, if to the refraction of $30'$ there were added, by way of example, a parallax of one minute, so that the refraction came out as $31'$ — if this whole sum were added to the seen distance, the seen [altitude] would come out as $84^{\circ}30'$; and from a minute, [yet] 1 contrary to the supposition; and vice versa, with $31'$ subtracted from the true $84^{\circ}30'$, the seen [altitude] would come out as $84^{\circ}29'$ — again contrary to the supposition made. Nor would there be a comparison of the True with the refracted seen, but of the seen by the force of refraction — that is, of the anaclastically seen — with the seen parallaxically; in which case alone, on the assumption that we are to use parallax, the seen-by-refraction [altitude] of $84^{\circ}30'$ with $31'$ added, composed of refraction and parallax, would yield a seen parallaxic [altitude] of $85^{\circ}1'$. And, conversely, with $31'$ subtracted from this seen [altitude], a seen anaclastic [altitude] of $84^{\circ}30'$

would result. But this comparison is of no use in Astronomy, since, without that supposition, refraction is on the one side and parallax on the other, and in practice it is nothing other than that the absolute seen [distance] is converted into the true distance from the vertex, and vice versa the true into the seen — that is, into what is absolutely to be seen.

We grant, moreover, that if anyone should put together in a Table refractions composed of the simple refraction and the smaller parallax, it will then be necessary, in converting the seen into the true and the true into the seen distance, to subtract beforehand from the refraction such a parallax. But we assert that this composition was made in vain, since in practice it is to be dissolved, and the simple refraction suffices.

[The marginal note opposite reads: "Tychonis error in methodo Refractionum." — Tycho's error in the method of the Refractions.]

Corollary

Against Tycho [Tycho Brahe] and the others deceived by him in this matter, among whom We too once were.

[The marginal numeral "53" keys the body.]

It follows from the preceding proposition, when well considered, that Tycho erred in his method of investigating the Solar Refractions, in that he knew the parallax to be larger than he reported in vol. 1 of the *Progymnasmata*, p. 92, when he said: *To the established altitude of the Sun, obtained by observation, the parallax must be added, because this inclines the Sun toward the true horizon, and corrects the refraction not a little.* And he immediately added: *In this way we recognize the apparent elevation of the Sun, if it were entirely free from parallax; but from this — by subtracting the true altitude, computed in the same Azimuth — the sought refraction will be given.* These are trifles — indeed, mere nonsense, and the depraved figments of a deceiving imagination. For there is a question here, what the difference is between the true and the seen distance from the vertex; or what the larger [distance] is between the true and the absolutely seen altitude, which has already been acquired by subtracting the seen parallax. Of what use, then, is that composition of refraction with parallax, before that subtraction is made — since this can be had at once before the addition of the parallaxes? But see what Tycho subjoins there in his method: *It will not escape notice (he says) that the third side represents the Refraction in the vertical circle; to which, nevertheless, parallax must be added, because the Sun would appear lower, were it not for this*

Refraction, by which the Sun appears higher; and on that account the Refraction would be larger. See how Tycho reckoned that, in reality, a kind of conflict intervenes between Refraction and Parallax — so that, although the Parallax did not stand in the way, the apparatus of the Sun's image would still have been [in error]; whereas in reality it appeared otherwise. But this is plainly false. For if there had been no parallax — because the eye had been situated in the center of the Earth — there would have been no Refraction at all; whereas, with the eye remaining on the surface of the Earth, the seen [position] and the Sun were higher by $1^{\circ}30'$. For example, when in reality the altitude was only 1 degree, and we imagine the seen Sun [lifted] from two eyes by the refracted ray, [and] from the other by the parallactic ray, miraculously rather than by refraction; so that, secondly, the eye would see the Sun raised less than by one full degree, say by $59'$ — that much less by parallax — no other eye would see the Sun lifted higher; for the refracted ray alone has lifted the seen Sun by $1^{\circ}30'$. Nor is there a larger seen [altitude] than that which is refracted and elevated, which, even if in the first case it represents itself to Tycho [as already containing] the parallax along with the addition of the parallaxes, you would acknowledge it as a Refraction; while nevertheless, *it does not escape notice that the third side represents the Refraction;* otherwise, if it is not the Refraction, but a part of the refraction, it ought to be removed for the equation; he names that part *from the Refractions*, but a part of the Refraction; nor is that refraction of yours composed of the two parallactic Refractions, one elevating only so much as the parallax had depressed, and the other depressing only so much, [while] the other elevating above the seen place of the star's image.

Consequently, however, Tycho, after he had given, on p. 79, a *Table of the Solar Refractions* composed of pure Refraction and parallax, afterward, on p. 102, used both — and we with him. But hereafter we shall use the simple Astronomical Refractions of our own Tables, and the Rules written below. Re-read what I said in number 21.

Proposition XXVI.

If the refracted Ray is parallel to the line of the true place [linea veri loci], the seen distance of the heavenly body from the Vertex will be equal to the True distance; and the Difference between the seen-refracted [distance] and the visible parallactic [distance] will be equal to the ceasing Parallax; and then for the first time the Astronomical Refraction.

[The marginal numeral "54" keys the body.]

In Figure 11, let the star be at L, and let CL be the Line of the true place, while AK is the refracted Ray, and AB the line of the seen place, equidistant from the line CL. Let the Ray, before its refraction, be incident at KL, and from the eye A let AL be drawn — the parallactic line. I say that the Seen distance VAB is equal to the True VCL; because the external angle ALC is equal and opposite to the internal one, since the straight line VC falls upon the two parallels by the 29th of the first elements of geometry [Euclid I.29]; and by the same Angle ALC — that is, the parallax — is equal to the alternate angle BAL, by which

[Continued:] angle the seen distance refractedly — that is, VAB — differs from the seen distance, or visible parallactic [distance], that is VAL. Finally, if there shall be no difference between the true distance and the seen-refracted [distance] in each case — by the definition of Proposition 20 — every Astronomical refraction will cease; and indeed then for the first time, when such parallelism is first attained. This Proposition is not converted, however, as it will be if the sensible refraction ceases, so that the seen distance comes out equal to the true, as we shall say in Proposition 30, concerning the Moon. For these things, the Table of Refractions of the seen altitude does not suffice; therefore, in order to advance further, a Table of Refractions of the True Altitude — or of the true distance from the vertex — must be constructed; or it must be taught how it can be elicited from the Table for the seen altitude; and then it must be inquired, when and from which stars the distance from the vertex of the seen [position] ought to be larger than the true, whether the refracted ray inclines in the physical horizon, or bends downward or upward; for it has not hitherto been demonstrated that the seen distance is always smaller than the true by a refracted ray inclining upward. So, then:

Diagram. A quadrant figure (quarter-circle) illustrating refraction, parallax, and the seen versus true distance from the vertex. The right angle is at C (lower left); the vertical radius runs up to V (top), and the horizontal radius to H (lower right). The arc runs from V to H. The point V is at the top of the vertical, with B and L marking points on or near the arc; K and A mark the eye and an interior point; C is the center (right-angle vertex). Several straight rays are drawn from the lower region to L and B.

- V (top of vertical radius): the vertex
- B (upper arc, near top): point on the arc
- K (interior, mid-left): interior point (eye / refraction point)
- L (right of center, on arc): the star's seen/true position
- A (lower left, above C): the eye

- C (lower-left corner): center of the quadrant (right-angle vertex)
- H (lower right): foot of the horizontal radius
- Caption (engraved, upper right of figure): "11. fig."

Proposition XXVII.

When the Moon exists as apparent in the Physical Horizon, its True Distance from the seen Vertex is larger than the True.

[The marginal numeral "55" keys the body.]

For by Proposition 21, the True [Horizon] is between the True and the Physical Horizons; therefore the True Distance from the Vertex is smaller than a Quadrant, and the seen distance is a Quadrant; therefore the latter is larger than the True.

Proposition XXVIII.

The seen Distance from the Vertex of all the planets (the Moon excepted) and of the fixed stars, when Apparent in the Physical Horizon, is smaller than the True.

[The marginal numeral "56" keys the body.]

For indeed, by Proposition 20, the remaining Planets and the fixed stars, when seen in the Physical Horizon, are in reality below the True Horizon; therefore the True distance from the Vertex is larger than a Quadrant, while the seen [distance] is equal to a Quadrant; therefore the latter is smaller than the True.

Proposition XXIX.

When the Moon is above the Physical Horizon, the Apparent Distance from the seen Vertex is larger than the True.

[The marginal numeral "57" keys the body.]

For since the seen distance of the Moon is larger than the true distance, then, when it appears in the physical horizon (by Proposition 27) — and from there, as the Moon rises, the Astronomical Refraction continually decreases, until (speaking in the sense of sense-perception) the sensible Parallax of the Moon vanishes before this [Refraction does], then indeed, throughout the preceding and at the lower altitude, the seen [distance] has remained larger than the True. With the sensible Refraction ceasing, the Moon is now no longer seen by us by means of a Refracted Ray (which differs sensibly from the parallactic), but by a Ray that

is physically parallactic, which, with the Vertical line, makes the angle of the seen distance larger than the internal [angle], and [than] the opposite [angle] of the parallactic Triangle; and it measures the true distance by the internal angle — and so it comes about, until the Moon occupies the vertex, [when] all parallax ceases.

Proposition XXX.

When the Moon exists in the True Horizon, and the eye is elevated below the apparent Horizon, the Distance from the seen Vertex is larger than the true.

[The marginal numeral "58" keys the body.]

For the true [distance] in this case is a Quadrant, but the seen [distance] is larger than a Quadrant, because it is seen by a Ray refracted downward; if indeed it is not seen by a refracted Ray coinciding with the Physical horizon, unless it has ascended above the true horizon, by Proposition 21. I have said [this]. the eye being elevated, that is, above the surface of the Earth; otherwise no star below the Horizon could be seen at all, by Proposition 18.

Proposition XXXI.

When the Moon exists below the True Horizon, and the eye is elevated below the Apparent Horizon, the Distance from the seen Vertex is larger than the True.

[The marginal numeral "59" keys the body.]

The reason is that, in the ascent of the Moon to the True Horizon, the Astronomical Refractions are very large, and do not cease entirely before reaching the True Horizon; but if the seen distance of the Moon from the Vertex could be smaller, and afterward, when the Moon is in the true Horizon, could come out larger, it could indeed come out equal to the true first; but if it came out equal to the true, the Astronomical Refraction would cease — which is impossible.

Proposition XXXII.

The Apparent Distance from the seen Vertex of all the planets (the Moon excepted), when apparent above the Physical Horizon, is smaller than the True, so long as a sensible Astronomical Refraction lasts; but when this sensible Refraction first ceases, the seen [distance] becomes equal to the True, and thereafter larger than the True — so long as a sensible parallax lasts; but it always remains equal, if they lack sensible parallax.

[The marginal numeral "60" keys the body.]

Since indeed, from the moment when it [the planet] is apparent in the Physical horizon — in which the seen [distance] is smaller than the True distance — before it becomes equal, the larger [seen distance] always persists, since it cannot pass continuously from smaller to larger unless it first passes to equality, since we are in the same kind [of case]; but it does not come out equal except when first there is a parallelism of the Refracted ray with the line of the true place — and then, indeed, the seen distance comes out equal to the true by the force of the refracted ray. And if indeed the Optical Refraction of the refracted rays can be notable, the Astronomical [Refraction] can nevertheless be so slight as to be insensible. Then, as the Star ascends, it is no longer beheld by the refracted ray (which is sensibly different from the parallactic), but by the parallactic line; and while a sensible parallax lasts, the parallactic line makes, with the Vertical line, the external angle of the seen distance parallactically larger than the True distance, because it measures that angle by the external angle, and [by] the opposite predicted [angle]. But in the fixed stars, which lack sensible parallax, with the Refraction ceasing, the seen distance is equal to the True.

Proposition XXXIII.

The Apparent Distance from the vertex of all the planets (the Moon excepted) and of the fixed stars, when apparent below the Physical horizon, is smaller than the True.

[The marginal numeral "61" keys the body.]

For when they are apparent in the physical horizon, the seen [distance] is smaller than the True, by Proposition 28; but if it could before have been larger than the true, it could before have been equal to the True; but it could not have been equal to the true, unless the Astronomical Refraction ceased — since this consists, by Definition 20, in the difference between the True distance and the refractedly seen [distance]; because the refractions about the horizon, and in the ascent up to it, never wholly cease, but are indeed very large, as is established by experiments. Nor does it stand in the way that an eye lifted above the earth should see the stars below the horizon — by a ray bending downward below the horizontal line, and making with the vertical line a larger right angle; for it will never be lifted so high that the seen distance from the vertex by the refracted Ray is larger than the true — which is the case in Mars at Perigee, the nearest of all the Stars (the Moon excepted) to the Earth, as we shall presently teach, with the following Problem premised.

Proposition XXXIV.

Given the Distance of a Star from the center of the Earth, and the altitude of the refractive Air, in the parts of which the semidiameter of the Earth is the known [unit]; and likewise the depth of the Star below the Horizon: to investigate the maximum distance of the same from the vertex, [as seen] from the eye, within that Air, lifted to the highest visible point by the Refracted Ray.

[The marginal numeral "62" keys the body.]

Let there be, in Figure 12, the center A of the Earth and of the circumambient Air, the terrestrial vertical quadrant BIC, whose semidiameter — or radius AI — and the refractive quadrant of the Air OKD, whose Altitude is IK; let the Vertical line be AV, and the Astronomical Horizon AH; below which let Mars be at M, depressed by 1 degree; and on that account let AM be drawn to it [Mars], the angle [being formed].

Diagram. A figure combining a quarter-arc and a right triangle, illustrating the maximum vertex-distance of a star (Mars at M) seen through the refractive shell of air. The right-angle vertex is at A (lower left); the vertical AV rises to V (top), and the horizontal base runs from A to M (lower right, the longest line). Two concentric arcs spring from the vertical: the inner terrestrial quadrant and the outer refractive-air quadrant. On the vertical, from top to bottom: V, then T, O, B near the top; K lies on the outer arc; I is the interior point where the terrestrial radius meets the air shell; C, D are along the base between A and the foot. H and M lie at the lower right (H above, M at the base end). Straight chords run from A out to K and on to M.

- V (top of vertical): the vertical line's end (AV)
- T (just below V on the vertical): point on the air shell
- O (below T): point O (where the eye is lifted)
- B (below O): point B (top of terrestrial quadrant arc)
- K (on the outer arc, mid-height): the contact point K of the refracted ray
- I (interior, on the terrestrial radius): point I (top of terrestrial semidiameter AI)
- A (lower-left corner): center of Earth and air (right-angle vertex)
- C (on the base, near A): point C
- D (on the base, right of C): point D
- H (lower right, above M): the Astronomical Horizon point H
- M (base, far right end): Mars, depressed below the horizon

- Caption (engraved, upper area): "12. fig."

Let the true depth HAM be one degree; but let the Tangent line of Mars touching the Air at K be MT — it cannot lift the eye, [placed] within the refractive Air, higher than the altitude of this air IK, or BO, [the eye] being now elevated to the highest point in O; and from there let a chord be drawn to the contact point, which is OK, since AK and AO are equal — so the Triangle AOK will be isosceles, and in it the angle at the base OK [will be] equal by the 15th of the first Elements [Euclid I.15]. Now if the ray, entering the air a little below the contact K, is refracted, it ought to be [refracted] at the contact K, so close, as if the more deeply the refraction enters at a lower chord OK; otherwise, the lower it enters, the less highly it is refracted, by the smaller angle of inclination of the incident ray; nor do these things pertain to the contact K and the eye O, but they fall within O, toward B. The present task is to investigate the Angle VOK, [that is] the distance of the seen [position] from the vertex by the Ray VOK, in order to know whether it is larger or smaller than the angle VAM, the True distance from the vertex, as we have assumed. And indeed in Mars at Perigee, since here — the Moon excepted — the maximum of the Planets approaches the Earth, and from this let a judgment be made about the more remote Stars.

I read indeed in [Tycho's] *Almagestum Novum*, lib. 7, sect. 6, ch. 1, that the distance of Mars at Perigee from the Earth is 2,373 terrestrial semidiameters, by our *Geographia Reformata*; the semidiameter of the Earth [being] 3,690 Bolognese miles. Therefore the distance of Mars at Perigee from the center of the Earth — that is, AM — is 8,756,370 such miles. Let the Altitude IK, of the refractive Air, [be] the maximum it can possibly be, 50 miles; and so the whole [distance] AK is 3,740 miles. In the triangle AMK, then, with the angle at the contact K, the Parallax of Mars AMK will be $1^{\circ}28'8''$. But let this be at $1^{\circ}30'$ to excess; therefore, by 32 of the first elements [Euclid I.32], the angle KAM is $89^{\circ}58'30''$; and the angle removed [is] HAM 1 degree, the angle KAH [is] $88^{\circ}58'30''$; therefore the right angle OAD, the complement of the angle KAM, is $1^{\circ}30'$; and by 15 of the first elements [Euclid I.15] the isosceles angle AOK, the angle at the base OAK, is $89^{\circ}29'15''$; and by the 13th of the first Elements [Euclid I.13] the distance VOK is $90^{\circ}30'45''$, smaller than the true [distance] VAM, [which is] 91° . And the Astronomical Refraction is $28'15''$, which distance is still smaller; if the eye is below O, or [at] IK, smaller by 50 miles, or the distance of the Star M, larger from the Earth — by however much, therefore, smaller — if all these things concur, as they come about in all the other Stars (the Moon excepted). The same method, moreover, will be shown, if the Star is placed several degrees below the True Horizon. first it will appear refracted to the eye O. Let us test what comes about in each case, when the Moon is at Apogee

and at Perigee; when it is in the True Horizon, which we suppose to be AM. Let the minimum parallax of the Moon at Apogee, AMK, be 50; then the angle KAO, [being] $89^{\circ}10'$, and OAK $50'$, and AOK $89^{\circ}35'$ and VOK $90^{\circ}25'$. But the maximum Parallax of the Moon at Perigee, AMK, is $1^{\circ}6'$; and OAK is $1^{\circ}6'$; and AOK $89^{\circ}27'$; and VOK $90^{\circ}33'$. Hence, so that the excess of $30'$ of the seen distance above the true distance from the vertex should be about a minute, the Moon cannot be below the true horizon unless by very few minutes, when it is at Perigee; and it appears refracted to the eye O; but when it is rather at Apogee, it ought to be above it [the horizon], likewise by a few minutes. We must beware, moreover, lest we imagine to ourselves [as occurring] in certain cases things that are impossible. It is enough for us to have made the attempt; on which account it could come about to the eye O, since from so great an altitude of the eye we cannot observe, [and] cannot render these things more certain. Meanwhile, we are confident that we are able to have a larger depth of the more remote heavenly bodies of the Moon, when it first appears to the lifted eye, unless the thickness and opacity of the horizontal vapors stand in the way and blunt the rays; and therefore it does not appear unless lifted above the horizon — which often comes about.

[The marginal numeral "64" keys the body.]

Let us settle in the meantime the Rules of commutation, which we began at Proposition 27.

Proposition XXXV.

To resolve the Commutation of the seen Distance of the Stars into the True, and the True into the Seen, from the vertex; and likewise of the Altitude in absolute terms.

Rule I. You will commute the seen Distance of the Moon from the Vertex into the True, by subtracting the Refraction beforehand from the Parallax, and adding the residue to the seen distance.

Rule II. You will commute the True Distance of the Moon from the vertex into the Seen, by subtracting the Refraction beforehand from the Parallax, and the residue by adding [it] to the True Distance.

Rule III. You will commute the seen Altitude of the Moon into the True, by subtracting the Refraction beforehand from the Parallax, and the residue by adding [it] to the seen Altitude.

Rule IV. You will commute the True Altitude of the Moon into the Seen, by subtracting the Refraction beforehand from the parallax, and the residue by adding [it] to the seen Altitude.

Rule V. You will commute the seen Altitude of the fixed stars into the True, by adding the Refraction to the seen Altitude.

Rule VI. You will commute the True Altitude of the fixed stars into the Seen, by subtracting the Refraction from the True Altitude.

The contrary [procedure] must be done for obtaining the Distance of the Fixed stars from the vertex; for there the seen [distance] is to be added, and the true to be subtracted.

Rule VII. You will commute the seen Altitudes of the other Planets into the True, by subtracting the simple Refraction from the seen Altitude. But if the Refraction is composite of Refraction and Parallax — as it is with Tycho's Solar [Table] — subtract the Parallax from the larger Refraction, and subtract the residue from the seen Altitude; on the contrary, if the Parallax is larger, subtract the Refraction from it, and add the residue to the seen Altitude.

Rule VIII. You will commute the True Altitudes of the other Planets into the Seen, by adding the simple Refraction to the True Altitude. But if the Refraction is composite of parallax — as it is with Tycho's Solar [Table] — subtract the Parallax from the Refraction, and add the residue to the True Altitude; but when the Parallax exceeds the Refraction, subtract this [Refraction] from the Parallax, and subtract the Residue from the True Altitude.

But it would be necessary to have Tables of Refractions for the True Altitude, since they are usually made only for the Seen; yet by an artifice similar to that one, which I delivered in Proposition 4, the Refraction agreeing with the True Altitude can be elicited.

Proposition XXXVI.

To investigate the Distance of a Planet from the center of the Earth — and thereby its Parallax — on the supposition of a given altitude of the refractive Air, in the parts of which the semidiameter of the Earth is given, and the true [position] of the Planet given.

[continuation of Proposition XXXVI, from the prior page]

the planet, at the moment when its observed altitude has been measured at that same altitude; and finally, given the refraction of a known fixed star that obtains the same observed altitude together with the planet — or its true distance from the vertex — provided the density of the air is the same.

SUPPOSITION

65. Here I suppose that the fixed stars are so far distant from the Earth that they incur no perceptible parallax, whether they are viewed from the center of the Earth or from its surface — not only from the surface of the Earth, but even from the surface of the surrounding air, which causes refraction. For that air does not rise above 50 Italian miles, or indeed scarcely up to 20 miles, as I showed in *Almagestum Novum*, Tome 2, Book 10, Section 6, Problem 51. Consequently, two straight lines drawn from any fixed star — one to the center of the Earth, the other to the surface of the refracting air — may be taken as practically parallel. Once this is granted in the following figure (which is part of the preceding figure now set out), let the Sun, for example, stand at G, and the fixed star at F; for, as I said in number 41, they must lie on the same line of incidence FGI if they are to be seen by the same refracted ray BI and to be equally distant as regards their apparent distance from the vertex — that is, at the same angle VBI. Let them now be drawn to the Sun G by the straight line AG, from the center of the Earth.

Diagram. A geometric refraction figure, numbered 13. From a left-hand point A (the center of the Earth, at the lower left), a quarter-arc rises to the upper left, carrying a stack of small labelled points; the baseline A runs rightward to F at the far right. Lines radiate from A and from the upper points across the arcs to G and F.

- K, V (upper left, on the vertical/outer arc): outermost points on the vertical line from A
- H (upper left, beside V): point on an outer arc
- B (left, below D): point on the refracting-air surface, from which the refracted ray BI proceeds
- D (left, between B and K): point on an intermediate arc
- I, O (interior, near B): points on the incident/refracted ray
- G (center-right, on the baseline region): the Sun's place
- E (on the baseline, between A and F): foot-point on the Earth-arc
- F (far right, on the baseline): the fixed star's place

Once this has been prepared, then, since in triangle ABI the refraction of the air is given together with the altitude AI from the Earth's semidiameter AB (in such parts as the Earth's semidiameter AB is given), and the observed distance of the Sun from the vertex is also given, the angle VBI becomes known from the complement of that distance. And through trigonometry the angle BAI becomes known, and with it — being the complement of the angle of the fixed star's refraction BIK, noted as equal to it — the angle AIK is made plain, the complement of these two to two right angles being the angle AIG. Next, since the observed distance of the Sun from the vertex was measured at that moment, and since the Sun's true place is given from the astronomical tables, and from there, by the time before or after noon, or by the altitude of the pole, the Sun's true distance from the vertex is given through trigonometry — the angle VAG is therefore had, from which, by subtracting the angle BAI found above, the angle IAG becomes known. In this triangle IAG the angle IAG and the side AI are given, the side AI being from the Earth's semidiameter and the air's altitude OI. The distance AG will therefore not be hidden, nor the Sun's distance from the center G — which, if this refraction of the fixed star observable by astronomers were well grasped, would be the Optical Refraction.

But astronomers themselves observe the **simple** Astronomical Refraction — namely, the mere difference between some fixed star's observed altitude and its true altitude, by the known altitude of the pole, the star's place, its azimuth, and its declination; which, in the fixed stars, is greater than in the Sun, as is evident from Propositions 15 and 16. Therefore another method is needed by us; for it the true distance of the fixed star from the vertex, known at the moment when it reaches the same observed altitude as the Sun, is supposed given. Once this is had, first collect the angle BAI in triangle ABI, as above.

Then, since from the declination of the Sun, the azimuth, or the time, and the altitude of the pole, the Sun's true distance from the vertex VAG is given — and likewise the fixed star's true distance VAF, if both are required — the angle BAI being known, the angle IAF will be known. And since the parallax of the fixed stars is imperceptible, and the angle AIF is to all intents nothing, the lines IF and AF being practically parallel by the supposition premised, therefore in triangle AIF the angle AIF is the complement of the known angle IAF to two right angles, and hence known apart from any perceptible error. There are therefore given in triangle AIG the two angles AIG and IAG, and the side AOI, as above; therefore the distance AG is not hidden, nor the parallax AGI of the Sun G. Finally, in triangle ABG, since AB and AG and the angle BAG are known, the parallax AGB will be known.

[The text continues with Proposition XXXVII on the right side of the page.]

XXXVII. PROPOSITION

To investigate the distance of a planet from the center of the Earth, and hence its parallax: given the observed and the true altitude of the planet, and also that of a fixed star at that same moment which reaches the same observed altitude that the planet has or will have; and given the altitude of the air refracting at its first and last layers, in such parts as the Earth's semidiameter is known — supposing the refraction of the same ray takes place in the air not once but several times before it reaches the observer's eye.

66. This proposition is set down on account of that opinion which holds that the air around the Earth, suited to producing perceptible refractions, is not of uniform density but variable — and denser nearer the Earth, though not in such a way that it is non-uniform over any short stretch — for which the following diagram is given.

Diagram. A geometric refraction figure, numbered 14. From a lower-left point A, three concentric quarter-arcs rise; the baseline runs from A rightward through C, E, N to F at the far right. A stack of labelled points climbs the left side; rays cross from the points to M, G and on to F.

- V, H (top, on the vertical from A): outermost points
- K (left, below V): point on the outer refracting layer
- D (left, below K): point on an intermediate arc
- B (left, below D): point on the inner refracting layer (Earth's surface)
- P, I, O (interior, near B): successive refraction points on the ray
- M (interior, center-left): refraction point on the ray toward G
- G (center): the Sun's / planet's place
- C, E, N (on the baseline between A and F): feet of the successive arcs (BOC, DIE, HMN)
- A (far lower left): the Earth's center
- F (far right, on the baseline): the fixed star's place

When the vertical line AV has been drawn from the Earth's center A to the vertex V, let there be described from A the portions of the Earth's circles BOC, of the air DIE, and of the first refracting layer HMN — as great as the true distance of the fixed star F from the vertex requires, that is, the angle VAF, which is given. Let the Sun G as well as the fixed star F (since, as I said, both planet, say the Sun G, and fixed star F must lie on the same line of incidence, if they are to obtain the

same observed distance from the vertex) be incident; let first the Sun's ray FG, at M, where it first refracts toward the perpendicular, be continued nearly unrefracted from M to K, and there at last either undergo no refraction, or with many intervening refractions reach the air's last refracting layer; and being incident at I, let it refract at B. Let the perpendicular AI then be continued at P, until it meets the incident ray FG; MK will necessarily cut HMN, for if it merely grazed it without refracting, then IP would be shorter than DK. With these things done, **first**, in triangle ABI, AB and AI are given — AI consisting of the Earth's semidiameter AO and the altitude of the air at its last refracting layer OI — and the angle VBI, the complement of the observed distance of the planet from the vertex. Through trigonometry, then, the angle BAI is sought, from which, by subtracting the true distance from the vertex VAF belonging to the fixed star F, you will have the angle PAF, whose complement to two right angles is the angle APF, to all intents; for if the whole semidiameter of the Earth AB does not subtend a perceptible angle at F, the addition of OP — of fewer than 50 Italian miles — increases the angle at F so slightly that it stays imperceptible. **Secondly**, then, in triangle APG: if BAI and likewise the planet's true distance from the vertex VAG are known, the angle PAG is known, with which, and with the angle APG and the side AP — assuming whatever you please, but a larger one than AI, or AP, being smaller than AK, you will investigate the planet G, its distance AG so very close to the truth that the difference is negligible, as will be plain if you assume AI in place of AP, an amount as great as AK. So it is worth working within these limits to know the Sun's distance from the Earth, since it is certain that the difference will not reach a whole semidiameter of the Earth.

The Method of observing for Propositions 36 and 37, in the case of the Sun.

67. If the observation is to be made in the evening, await the Sun's nearest approach to setting, and with a very large instrument that displays single seconds, take the observed altitude of the Sun's center...

and at the same moment let another observer measure its azimuth, and let him begin to count, by the perpendicular oscillations, the time until the altitude of a known fixed star is observed; and by the time of day acquired at that moment, let the time counted be subtracted, and let the time of the Sun's observed altitude remain known. For from this, since with the declination then agreeing with the Sun, and with the altitude of the pole known, the Sun's true distance from the vertex for that very moment, at which the observed altitude was taken, becomes fixed. Then let the following night be awaited, so that the declination of some known fixed star, and by inspection of the celestial globe the observed altitude

which the Sun obtained, may be reached — whether in the same azimuth, or in a different azimuth — and take the time of that same azimuth, or by counting the time as above, acquire [it].

with the declination, and the altitude of the pole, the observed distance of the fixed star from the vertex. With Father Grimaldi, for capturing the observed altitude more delicately, we used a water level; and with threads parallel to the horizon similar to it, which we also applied in finding the altitude of the pole; and for capturing the azimuth more exactly we used the Filar triangle [triangulum filare] to a known fixed star fixed at the same vertical plane on the horizon directed at right angles. But perhaps the matter will be made clearer by example: the whole preceding practice, in observing, requires the greatest delicacy, nor a lesser one in the calculations thence derived. The observation of the star apparent in the horizon itself has, moreover, been omitted, because the fixed stars scarcely appear in the horizon itself, nor unless elevated above it.

Diagram. An uncaptioned schematic of an observing instrument, drawn horizontally across the page. At the left is a small upright frame with a forked sight; a long horizontal beam (the *trabecula*) runs rightward to a second upright frame at the right. Below the left frame hangs a plumb-line to a weight; below the beam at center-right is a small triangle. A separate small triangle figure sits at lower center.

- H, C, G (top of left frame): upper points of the left sight-frame
- O, I, R (left frame, interior): pinnacidial/sight points; the line OY runs down
- F, A (left frame, foot): foot-points
- V, E, X, Y (below left frame): the plumb-line points down to the weight Y
- M, D, Z (top of right frame): upper points of the right sight-frame (Z = a star symbol, the fixed star)
- S, K, P, T, N (right frame, interior): sight points
- B, L (right frame, foot): foot-points
- a, b, c, g, h (lower-center small triangles): the Filar-triangle points (g = a star symbol)

68. In the year 1656, October 10, upon the beam AB, 25 feet long, Father Grimaldi and I set up almost together a metallic fork [forked support], whose horns AC and BD — that is, of tin tubes inserted by a screw, and orthogonally standing upon the beam — could be filled with water through the tube, and through the tube on both sides; continuous: upon the same beam there were two little forks FGHI and KLMN, from whose arms two threads could at once be extended to the altitude of the crystalline water

poured in and at rest in its equilibrium. At the head A, moreover, there had been fixed to the beam a little cylinder OV, in the same perpendicular line OY, in which the tube AC was, through which a pinnacidial little cylinder X could be moved up and down at rest in any position. With these things prepared, in the morning following we filled the tubes on both sides up to the mouth of the tube C with water until it rose on both sides into O and P, and would be parallel to the horizon as far as that, and at the same time by its own course would harden the surfaces of the water in O and in P, now at rest in its equilibrium.

[Margin, left: *The line RK is to be understood as produced from this point — both toward O, and thence toward P.*]

Meanwhile the Sun had risen some degrees above the horizon, and to such a position that Father Grimaldi, through the thread ST cutting optically the Sun's disc, could observe the very altitude — placing the eye at the upper rib of the pinnacidial little cylinder X, set at V, and moving the pinnacidium downward, until its upper edge coincided with the thread ST and the Sun's center Z; and being on the same straight line of sight there are three points V, in the topmost pinnacidium P, on the thread ST, and Z, the center of the Sun's disc. I, however, at the same moment, the sign having been given me by Father Grimaldi, the Filar triangle *abc*, whose side *ab* was perpendicularly erected to the horizon, turning toward the Sun so that the shadow of the thread of each side might coincide in the horizontal plane — exactly, the iron ruler *hc*, which about the center *b* was being moved, the thread *ac*, with the threads superposed at the head firmly. Thread of the iron ruler on its doors [edges]: so that afterward we might most accurately obtain the Sun's azimuth through some fixed star, and more delicately, than by the arc of the horizon intercepted from the meridian line, and the edge of the ruler — meanwhile the perpendicular OY being found, the portion OV, of 8452 parts, of which the distance of the threads OP, measured upon the beam, had been 100000. Whence through the right-angled triangle VOP, and the solution at O, the apparent altitude of the Sun comes out, that is, the angle VPO, gr. $4^{\circ} 50' 13''$, and so by its observed [altitude] from the vertex the distance gr. $85^{\circ} 9' 47''$.

69. On the following night, moreover, we waited until the Lucida of Aries [Lucida Arietis] reached by its center the azimuth designated through the filar triangle *abc*, in which the Sun had been in the morning — that is to say, in the same straight line so that the eye should be at *b*, and the two threads *ab* and *ac*, and the center of the Star *g*; and at once its observed distance from the vertex was taken, which was gr. $44^{\circ} 24'$. Beyond the

observed distance the refraction; therefore in the spherical triangle APV, where AV is the distance of the Lucida of Aries from the vertex, gr. $44^{\circ} 24'$, and its Tychonic northern declination, which was then gr. $21^{\circ} 49' 40''$, the complement AP, gr. $68^{\circ} 10' 20''$. And of the altitude of the pole in our observatory the complement VP, gr. $45^{\circ} 25' 50''$. Therefore by trigonometry the azimuthal angle of this star arises from the vertex, gr. $104^{\circ} 58' 50''$, in which situation of the star and the Sun in that position the common observed azimuth AVP, gr. $104^{\circ} 58' 50''$, remains.

70. From our table, and Father Grimaldi's, constructed for the whole year, under the altitude of the Sun gr. $4^{\circ} 50' 13''$, the Sun had been observed before noon, hour $6^{\circ} 13''$, before noon of October 11, that is hour $18. 53' 47''$. After noon of October 10, the Sun was nearest at gr. $18 \frac{1}{2}$. The equated Tychonic time was 18.48, and since the moment of the experiment agrees with our solar tables stated above, gr. $18. 50' 3''$, of these the mean anomaly Sign. 3, gr. $11. 50. 29''$, but truly Sign. 3. grad. $9. 53' 15''$. From the place, moreover, of the Sun, and of the obliquity of the Ecliptic established above gr. $23. 30. 20''$, the Sun's true declination, southern, follows, gr. $7. 16' 15''$. Therefore in triangle SVP, VP is given, as above, gr. $45. 29. 50''$, and PS, consisting of the quadrant, and the Sun's declination, namely gr. $97. 16' 15''$. And the azimuthal angle AVP, num. 27, is found gr. $104. 58'. 50''$. Whence by the laws of triangles the Sun's true distance from the vertex VS, gr. $85. 19' 6''$, is gathered, but it was observed gr. $85. 9' 47''$; therefore the Astronomical Refraction of the Sun, the simple one, was $9' 19''$.
71. On the following night, between October 12 and 13, with the same serenity persevering, and the temper of the air which had been on the preceding days, with the same instrument, the one of which from number 68, with the lamps applied — yet not running into the eyes, but illuminating those very threads — Aldebaran was awaited, until it came to the same observed altitude in which the Sun had been, the Pinnacidium having been confirmed in its former position and at V; and a little before, the beam having been turned to the position suitable to this altitude in the same equilibrium of water; and as Aldebaran Z was on the straight line VP, with the eye, the time was begun to be counted by the oscillations of the perpendicular, until the observed distance of the Lucida of Aries from the vertex was taken, which was gr. $54'$. most precisely, and the time was found between the lapse of a min-[ute]...

ute, gr. 6' 45", of which by the equator there should be owed gr. 1. 41'. 15", which are to be reserved. Meanwhile in triangle APV, VP being given, as above gr. 45. 29' 50", and VA, gr. 54', and from the complement of the declination of the Lucida of Aries, as above gr. 68. 10' 20", the angle at the world's pole APV is gathered, gr. 60. 23' 13". There is, moreover, the difference of right ascensions of the Lucida of Aries and of Aldebaran, Tychonic, gr. 37. 3' 44", for this time, which, added to the degrees 60. 23' 13", and with times lapsed gr. 1. 41' 15", makes the equatorial distance of Aldebaran from the vertex, for the sake of example, the angle VPS, gr. 99. 8' 12". With this, and the declination of Aldebaran, Tychonic, the complement SP, gr. 74. 13' 38". And VP, gr. 45. 29' 50", the true distance of Aldebaran from the vertex VS is gathered, gr. 85. 19' 22", for that moment at which it is found to be in the observed distance from the vertex as great, namely that of the Sun, gr. 85. 9' 47"; therefore of these the difference, that is the simple Astronomical Refraction of Aldebaran, was gr. 9'. 35", which to Tycho is 10'. 10".

[Margin, left: *Refraction of Aldebaran.*]

72. Let us now return to Figure 13 set out above, in which the distance from the Vertex, both of the Sun and of Aldebaran, observed at the same time, is given gr. 85. 9' 47"; the complement to two right angles ABI, gr. 94. 50' 13". And let the Earth's semidiameter for now be AB, of German miles 1000, and AI for the same 1020, as great as no one of the experienced astronomers has admitted, since by Book 10 of *Almagestum Novum*, Section 6, Problem 51, I shall show the altitude of the refracting air not to be greater than 50 Italian miles, and about 20 — this is German 5. Nor is there need here to use the truest semidiameter of the Earth, but a sufficiently large proportion between AB and AI; once this is granted, by trigonometry the angle BAI is found, gr. 7. 30' 8", which, subtracted from gr. 85. 19' 6" of the true distance of the Sun from the vertex, found at num. 28, leaves the angle IAG, gr. 77. 48' 58"; idem the angle BAI, subtracted from the true distance of Aldebaran, gr. 85. 19' 22", which we obtained at num. 29, leaves the angle IAF, gr. 77. 49' 14"; and so the angle GAF is 16". Now since on account of the very great distance of the fixed star from the Earth, the assumed parallax of the same, the parallax AFI, not to say AFB, is imperceptible; and so AF, and AI, are practically parallel, the alternate angle GAI being 16", which the whole [angle] is — but if the strictly Geometrical [angle], the scruples [of arc] will have been somewhat smaller — the parallax of the fixed star AFI, and still less the parallax AGB, is estimated from terrestrial scruples.

73. But since it is certain that there is not so great an altitude of the Air, or at the first refracting [layer], let AI be assumed of German miles 1010, of which AB is 1000; for from the angle ABI, as above gr. 94. 50' 13", the angle BAI follows, gr. 4. 33' 48", which, subtracted as above from the angles VAG, gr. 85. 19' 6", and VAF, gr. 85. 19' 22", leaves the angle IAG, gr. 80. 45' 18", and IAF, grad. 80. 45' 34". Wherefore the difference of these GAF will be, as above gr. 6'. 8". And since the parallax of the Sun AGI, on account of the parallelism, Physical, of the right [lines] AF and IF, supposing the right angle, or certainly the external one AGI, ever so little greater than GAF; that little supposed in the third or fourth scruples of the parallax of the fixed stars AFI, and so always happens, however little, whatever be assumed AI, if we take the parallax of the Sun within a second, neglecting the thirds; let us choose. The distance AG, however, will be somewhat varied, both on account of the variation of the side AI, and on account of the variation of the angles IAG and AIG, for in the first case IAG is gr. 77. 48' 58", and IAF, gr. 77. 49' 14"; whose to two right angles the complement is AIF, that is AIG, gr. 102. 10'. 46". And with these AG is found, of miles 12948613: of which AI is 1020. But in the second case IAG is gr. 80. 45'. 18", and IAF, gr. 80. 45'. 34", and so AIF, or AIG, gr. 99. 14'. 26"; from which follows the interval of the Sun AG, of miles 12959487, of which AI is 1010. Finally, if you assume AI of German miles 1005, of which AB is 1000, and the angle, as above, ABI, gr. 94. 53'. 13", you will arrive — by the preceding method — at BAI, gr. 2. 38'. 49'. 24". And IAG, gr. 82. 40'. 16", 36""; and IAF, gr. 82. 40'. 32'. 36"". And AIG, gr. 97. 19'. 43"". 24""; always; AGI, 16". And AG, of miles 12945450, of which AI is 1005, or 12945, of which AB is one. Whence in triangle ABC, with AB 1000, and AG, as above, and BAG, gr. 85. 19' 6".

the parallax AGB is 15". 59"", and the horizontal one 16". Up to this point I have hunted the parallax of the Sun together with its distance from the Earth, having supposed the altitude of the refracting air, and at the same time the simple Refraction, both of the Sun and of the fixed star; but if I should inquire only into the parallax of the Sun, or of any other planet, the practice will be quicker, as below.

XXXVIII. PROPOSITION

Given a planet, and some fixed star obtaining the same observed altitude — though unknown, and obtaining it at a different time — given the true altitude for that moment of time at which they singly have an equal observed altitude; and with the

density of the refracting air remaining the same — there is immediately given the Parallax of the planet, whether the parallax of the fixed stars be supposed imperceptible, or unobserved, or observable, and then given.

74. For the difference of the true altitudes of the planet and of the fixed star is itself the Parallax, which we are inquiring after, if the parallax of the fixed stars be unobservable on account of its smallness; but if it has been observed, its sum together with the said difference makes up the Parallax of the planet, apart from any other Geometrical calculation. That this may be made plain, and that scruples may be removed from the mind of the Reader, look at figure 13, in which let the planet G and the fixed star F be feigned to be in the same Vertical plane; and when they obtain the same observed distance from the vertex VBI, and so, by the laws of the anaclastic [science], to be on the same line of incidence FGI — for there will be of the true distances from the Vertex the difference, the angle GAF, or therefore the parallax of the fixed stars AFI, from the surface of the refracting air too, not to say from the surface of the Earth estimated as imperceptible; and then the right [lines] AF, IF being to all intents parallel, and so the alternate angle GAF equal to the alternate AGI, that is the parallax of the planet from the surface of the refracting air estimated. Or, on the contrary, the parallactic angle AFI of the fixed star is supposed observable; let it therefore be observed and given; and then per 32 of the first elements [the aggregate] from this angle AFI, and the angle GAF, which is the difference of the true distance from the vertex, equals the external angle AGI, that is the parallax of the planet. Since, moreover, the Earth's semidiameter AB is of Italian miles about 4000, and the altitude of the refracting air OI, by what was said in Book 10 of *Almagestum Novum*, Section 6, Problem 51, is not greater than miles 40 — this is the thousandth part of the whole AB; and the distances AG, and BG, and KG, are practically equal; and so on account of the excess of the angle BGI, beyond the Parallax of the planet AGB, estimated from the Earth's surface, it does not exceed the thousandth of the whole angle AGI, and so is either imperceptible or trifling, as AGB is more easily known.

75. We suppose, however, the observation of the planet, and of the fixed star, made on the same night, or if the planet be the Sun, made within the same day, or [the air] persevering at the same Physical density of the refracting air; of which one must stand by the judgment of one skilled in these matters as an estimator. Nor does it stand in the way of this practice, that the planet, when it was observed, has been in a different vertical from that

in which the fixed star was, when it obtains the same, or an equal, observed altitude; for it is just the same as if it were transferred to the same Vertical: yet in this we suppose two things, which must be denied by no one knowledgeable in Astronomy and the Anaclastic [science]. **First**, it is that all the fixed stars created by God, or creatable, at the same distance from the Earth's center, and radiating; in their vertical at a point of the air's refracting surface equally high and equal, by the inclination from the perpendicular, have the same refraction, given the same density of the air, and the same not only observed but also true distance from the vertex. For in the aforesaid figure num. 13, if you conceive triangle AFG to be twofold, and one in one, the other in the other Vertical — if however the distance AF on both sides is equal, and the point I equally high above the Horizon, namely by an equal arc EI, or the angle IAE, and the radius FI, incident, is inclined from the perpendicular AH, by an angle equal to the angle HIF, these two triangles will be not only Equiangular, but also equal to one another; for of each the angles AIF, complements of the angles HIF, to two right angles, will be equal to one another, and likewise IAF, twin to one another, and so also the angles F, to one another, and not only AF, twin to one another, but also of the air's sphere in the Earth, of semidiameter AI, to one another; therefore, with the equal angle VAI added, the distance from the vertex VAF comes out, on both sides, equal. **Secondly** we suppose...

—at the moment when some planet has been observed, the Sun should be found in the same vertical circle (whether God created it there, as a fixed star which it would face directly from the center of the Earth, or whether it is observed and shines at that same point), then the inclination is of such a kind: that fixed star will therefore have the same refraction, and the same difference between its apparent and its true distance from the center of the Earth, as the fixed star has. And because the same star shines, in another vertical circle, just as high as the fixed star — when it obtains an equal distance from the center of the Earth, having its apparent distance from the vertex equal — therefore it will exhibit a true distance from the vertex equal to that of the fixed star; and hence it will also exhibit a parallax of the planet equal to that of the fixed star. For this reason, even if not made in the same vertical circle, the operation has been carried out formally, yet it has been carried out equivalently, and consequently just as if it had been made in the same one.

—for it is established that its true altitude is obtained, given the remaining true altitudes of the planet, and the true distance from the vertex of the apparent fixed star, by the preceding Proposition 23; and so the simple astronomical refraction

[*Refractio Astronomica simplex*] and the true altitude are obtained: finally, the difference of the true altitudes of the planet and of the fixed star yields the planet's parallax, by the preceding Proposition 38 — provided the planet's true altitude is set equal to that of the fixed star. This holds whether the Sun is observed in the west or in the east, in physical truth; for the fixed star is observed exactly, as we have taught above, while its position toward the fixed star is observed when the Sun is observed at one and the same time, so that the true distance from the vertex of the fixed star can be known, and its parallax — provided, that is, that the horizontal refraction of the fixed star is supposed to be that which agrees with it and is in itself sensible. Only this may be doubted: from what place, or at what time, the refraction of the fixed star may have been observed under the same density of air as that under which the Sun is observed.

Method of observing for Proposition 38, in the case of the Sun.

[76] First, so that the error in the Sun's declination may be as small as possible, let the observation of the Sun be made at the solstice, or as near to it as possible; or let it be made of some Sun rising from God's appointment by means of an instrument, or such as we have described above, or another; let the apparent position be observed, with whatever is fixed in its position to be noted astronomically, even if it is not known as to its astronomical quantity; and let the companion direct his filar thread toward the center of the Sun, and let it stand fixed and immovable in that position. Secondly, at night let a fixed star nearby be chosen, of the same starry Globe, whose distance from the vertex shall be that of the Sun, and at that time future, beyond the refraction; let the filar plate be set at least 20 or 25 degrees up, and at the very moment when it reaches the vertical, let the plane be designated by the two filar threads, and its distance from the vertex as great as it can be observed with the utmost subtlety. For so it will be — both at the solstice and on the days following, after the appearances are obtained — at whatever hour, as soon as it is known when the Sun was observed, the note of its declination is free of curable error, since its declination is its complement, and so on. And the Azimuth, as we said, being the distance of the Pole from the vertex, will by trigonometry yield the true distance of the Sun from the vertex at that moment, just as it was observed before sunset. Thirdly, in the same night, the temperature of the air remaining the same to the senses, wait until some fixed star — fitted by inspection of the chosen globe to that altitude which it was observed at — yet the declinations do not arrive at the altitude observed for the Sun; and then at once let the companion observe it in its center, by means of the filar Triangle, the Azimuth being sought. Fourthly, in the same night, or on any other night, let a fixed star be chosen whose distance from the vertex will be that

designated by the said Triangle, and whose future position will be beyond the bound of sensible Refraction — as is fixed 20 or 25 degrees — and at that moment, when it reaches that plane, let the most exact distance of that star be taken. For from it, and from its declination, or the complement of the declination of the Pole from the vertex, the true distance of the Sun is obtained; and when the declination of the prior fixed star is equal to its altitude, with the fixed star itself being assured, and with the distance of the Pole from the vertex known, you will have its true distance from the vertex, which ought to be greater, than the Sun's by the said Proposition 9; the difference will be the parallax of the Sun to be corrected, somewhat according to what was said above.

PROPOSITION XXXIX.

Given the simple astronomical refraction of the fixed stars, free of sensible altitude, and that of the Sun or of any planet observed at the same apparent altitude as the stars, and the air being of the same density in azimuth, or in declination, and given the moment of time, together with the altitude. The parallax of the Pole is given, along with the apparent parallax of the planet, not to mention its simple astronomical refraction.

[77] For, the refraction having been subtracted from the apparent altitude of the fixed stars—

—from the apparent altitude of the fixed stars, their true altitude is obtained; and given the remaining true distances of the planets, the planet's true distance from the vertex is obtained, which corresponds to its apparent distance by Proposition 23. And so the simple astronomical refraction and the true altitude are obtained; finally, the difference between the true altitudes of the planet and of the fixed star yields the planet's parallax, by the preceding Proposition 38 — provided the planet's true altitude is set equal to that of the fixed star. This holds whether the Sun is observed in the west or in the east; for the fixed stars are observed exactly, as we taught above. But if the Sun's position toward the fixed star is observed at one and the same time, then there can be no error; provided one is sure that its distance is true, and the parallax, if you suppose the horizontal refraction of the fixed star to be that which agrees with it and is in itself sensible. Only this may be doubted: from what place or at what time the refraction of the fixed star was observed under the same density of air as that under which the Sun is observed.

Conclusions concerning the Parallax of the Sun, in the meantime more probable.

[78] **First Conclusion.** By the preceding practice the parallax cannot be certainly known, given the subtlety which more recent astronomy requires: for here a

smaller error than that of a very few seconds is required. For now, from the lunar dichotomies, and the parallaxes of Mars, and other arguments, we have come to know the horizontal parallax of the Sun to be much smaller than one whole minute. Although large enough instruments can indeed be made, and a half-diameter could exhibit single seconds in its circle — yet, as we teach in Chapter 3, there is so great a difficulty in the division, and in the subdivision of degrees and minutes, and in the placement, and in the just use of the dioptrics, and in collimation toward the center of the star, and in the most upright placement of the instrument itself with respect to the horizon, that one can err by several seconds, or at least by single ones, in individual observations. Furthermore, the aforesaid practice requires six elements of astronomy, namely: the altitude of the Pole; the declination of the Sun, and its apparent distance; or its azimuth; or the declination observed apparently; or the moment of time observed; and of these last two either one—and either the declination or the azimuth; and so, all things being most subtly computed, the error can be collected from all the small errors of observation, more than 5 seconds. Besides, as we said above, the same density of air is required when the refraction of the fixed star is observed as that at the altitude under which the Sun was observed, and the fixed star with the Sun, either at once before or after, can be conspicuous; but this rarely happens by night, here in daytime visible; for the air is always ambiguous by night, denser than by day. Hence comes the uncertainty of the confirmation of what is to be said about the consequence of the refractions of the Sun, and of the fixed stars observed by Tycho [Tycho Brahe], at no. 8.

[79] **Second Conclusion.** Yet, because by the preceding practice we have always found the horizontal parallax of the Sun smaller than 30 seconds — and for that very reason, by the dichotomies, we apprehend something smaller — therefore we establish it as not larger, and as more probable in position; and we keep it still at 19' 8" in perigee, 27' 8" in apogee. We are inclined rather toward this opinion, who think it and this smaller; but we do not acquiesce, since it is altogether insensible, in the system of the Sun and the planets; and regarding it, together with the fixed stars, they do not deny that it can be raised to infinity; but see the end of Chapter 13.

[80] **Third Conclusion.** However great the parallax of the Sun may be (at the same apparent distance from the vertex, of the Sun and of the fixed stars, and the constitution of the same air), so much greater is the astronomical refraction of the fixed stars than the astronomical and simple refraction of the Sun, as is the parallax of the Sun. This is clear from Propositions 16, 38, and 39 together.

CAPUT XV.

On the Refractions of the Sun.

[1] We taught the way of observing the refractions of the stars together with Tycho [Tycho Brahe] in the preceding chapter, at Proposition 7, supplying what he himself had omitted; but we speak of astronomical refraction, not optical, and that both simple — that is, the difference between the true altitude of a star and its apparent altitude, when the apparent is greater than the true — and composite, made up of this simple refraction and of parallax. Now Tycho, in Volume 1 of the *Progymnasmata* (Tycho, *Astronomiae Instauratae Progymnasmata*), at page 79, exhibits a Table of Solar Refractions from his own observation on the Danish horizon; yet he confesses that these same refractions vary there under a less serene sky, and on different horizons under a different temperature of the air; and at page 94 he affirms that a difference can be found between the true and the apparent. And concerning the apparent altitude of the Sun, he added that he had derived his parallax from it, so as to obtain the whole Refraction; and he urged this at page 95. And that the refractions of the Sun should be observed on the day of the solstice, when the declination varies insensibly; and at page 102 he teaches by example to convert the apparent altitude of the Sun into the true, by subtracting the whole Refraction and adding the parallax. Afterward, at page 124, he exhibits a Table of Lunar Refractions in a circle of Altitude, frequently constructed from experiment by himself. Finally, at page 280, he sets forth a Table of Refractions of the Fixed stars in a circle of Altitude, from his own observation likewise, where he adds these words to be noted for what is to be said below: *If, however, what the Mathematician of the Landgrave [the Landgrave of Hesse's astronomer] noted in those his Kassel observations are admitted, the fixed stars have refractions there almost double in size — concerning which matter the volume of our collection of Epistles indicates more fully. But for my part, I should none the less believe that the observations have weakened the refractions too much by some carelessness of their own.* For Rothmann [Christoph Rothmann] had written, as is found in Tycho's Epistles, at page 29, that he had found by himself a refraction of the fixed stars of $5' \frac{2}{3}$ at an altitude of $5^{\circ} 18'$, and of $2' \frac{1}{5}$ at an altitude of $9^{\circ} 42'$; but he generally observed the horizontal refraction of the Sun to be $15'$, or at most $20'$, to which Tycho responds (Tycho, page 63) that he found the refractions observed by himself to be almost double those in Denmark than those by Rothmann at Kassel; and he attributes this rather to incorrect Hessian observations, than to the diversity of horizons. Again Rothmann, at the same place, page 82, says that the refractions of the Sun around the winter solstice are far greater than at other times of the year. And at

last Tycho there, at page 159, notes that the refractions of Rothmann are too modest, and the twilights too great between them — these do not agree, since it would follow that the air is purer there, but here more turbid. But it would be necessary to inquire whether they had been observed under the same Annual temperature, and whether the twilights were the same — indeed, whether under the same temperature of day, which is different around sunrise from that around sunset. So far, summarily, concerning the general foundations of the Tychonic refractions.

[2] Before we discuss these things, the threefold Table of Tychonic Refractions, taken from the said places, must be set before our eyes, which is thus:

Refractions in the Danish Air, derived by Tycho [Tycho Brahe] from his own observations.

[Margin, against the Fixed-Star column at rows 20–30: *The Refractions of the Fixed stars cease here, because Tycho, as he admits at page 280, finds them smaller than those of the Sun by 4' ½. And therefore from the Solar refractions he elicits the refractions of the Fixed stars.*]

[3] Yet, not acquiescing for just reasons, I wrote to Father Albert Curtz [Albert Curtz], to whom, by the command of Caesar, were handed over the manuscript Tychonic observations, since he was in charge of their typographical edition, so that he might not begrudge to transmit to me those observations — which, having been made at the summer solstice, Tycho had most confidently investigated as the Solar Refractions. This he furnished most liberally and most diligently, a most humane man, and he deserved excellently of me, who am immensely obliged to him. And I communicate these observations to the Reader, to be examined by trigonometric calculation, if it ever shall please him, in good faith copied out from his exemplar.

Observed by Tycho [Tycho Brahe] at Uraniborg [Uraniborg], in the year 1589, on the 11th day of June, old style.

[Margin: 4]

From these I selected the azimuthal observations of the 12th, and the morning ones, because on that day the air was purer, and because the solstice occurred a little after the middle of the preceding night. For that reason the morning declination of the Sun differed scarcely perceptibly from our maximum declination of 23°30'20". So I chose the altitude of the pole of Uraniborg as 55°54'40", as determined in my *Geographia Reformata*, Book 7, Chapter 21. Hence in the figure of Proposition 23, and in the triangle UPL, the complement of the altitude of the pole, PV, is given as 34°5'20", and the complement of the declination, LP, as 66°29'40". With these, and with the complement of the meridional azimuth of the Sun, LVP, I derived trigonometrically the true distance of the Sun, VL, from the vertex; and by comparing this with the apparent distance, I obtained the refraction. But often this came out in vain, because the true distance frequently turned out smaller than the apparent, as can be seen in the following table.

Refractions derived from the azimuth observations

Complement of the meridional azimuth of the Sun [Azimuthi Meridionalis Complementum] (Gr. °)	Apparent distance of the Sun from the vertex [Distantia Solis à Vertice Visa] (Gr. ° ')	True distance of the Sun from the vertex [Distantia Solis à Vertice Vera] (Gr. ° ' ")	Simple refraction of the Sun [Refractio Solis simplex] (' ")
50 52	86 42 20	86 50 20	8 0

From this it is clear how slippery this procedure by azimuth is, unless at the very same instant at which the center of the star touches the vertical plane of the determined azimuth, the same star's distance from the vertex is taken with an instrument carefully divided and set up. For I would rather believe that the aforesaid diversity and inconsistency arose from a flaw in the observation, or from some small interval of time that elapsed and is now neglected as if not perceptibly harmful, than from a fault in the trigonometric calculation, or from a sudden change of the air, or from a false altitude of the pole and maximum declination of the Sun, or from the scribe's errors in writing down the numbers. Perhaps several other observations of many years, which Tycho indicates in volume 1 of the *Progymnasmata*, page 79, will come to light, from which a fuller examination may be undertaken.

[Margin: 5]

I communicated the aforesaid observations to Giovanni Domenico Cassini [Dominico Cassino], a distinguished man. He chose the altitudes of the 11th of June taken by the steel quadrant, and the declinations of both armillaries, and from them gathered refractions smaller throughout than the Tyconic refraction table gives. This agrees not only with Rothmann [Rothmanno], but also with Vincenzo Mutio [D. Vincentio Muto] [Vicenç Mut, observer in Majorca]: the former [Rothmann] in Hesse [Hassia], the latter [Mut] in Majorca [Maiorica], observed much smaller refractions than Tycho set out in his table.

Refractions from Cassini's calculation, 1589

Year 1589, June, 11th day, from the calculation of Cassini [ex D. Cassini calculis].

Against this, Gassendi [Gassendus], at Digne [Diniæ] [Digne], at the close of the year 1632 and into 1633, on undertaking the investigation of the winter refractions, examined them and reported the results in his *Commentaries on Celestial Matters*, which are contained in volume 4 of his works. A specimen of these is in the attached small table, but its use is hampered by too great a parallax, and for that reason these refractions of the same kind are less certain.

Gassendi's winter refractions, Digne 1632–1633

Apparent altitude [Altitudo Visa] (Gr. ')	Refraction [Refractio] (' ")

35 11	1 30
40 5	1 0
42 48	0 30

Kepler [Keplerus], following the precept of the Rudolphine [tables], relates that he observed almost these same refractions in Bohemia and in Denmark; and he adds that the diversity of refractions can arise from different times: for at the full moon, and on a day of copious light, the air is dilated; and he observed that the fixed stars, for the most part at the new moon, in the deep of night, under a serene sky, [appear to him?]. Yet Tycho, in volume 1 of the *Progymnasmata*, page

280, had acknowledged that the refractions of the Moon ought to be greater than the solar ones, all else equal. The solar refractions, however, would have been displayed near the horizon as next greatest, on account of the excessive parallax of the Sun added to the simple refraction. And yet Kepler himself, in the *Astronomia Optica* [*Paralipomena ad Vitellionem*], page 123, reforming the Tyconic solar refractions from the secants, uses the parallax diminished by 3'. We gave his small table, reformed, at the end of Book X of the *Almagestum Novum*, with many things premised that are most worthy of the reader's attention, both for the problems and the theorems bearing on refractions; and in the appendix of that same book we added our own tables of refraction for the Sun, the Moon, and the fixed stars derived from observations around the solstice and the equinox. I confess, nevertheless, that I sometimes found a certain inconsistency, and acknowledged that Tycho came closer to the truth, and agreed with us almost completely in many points. Afterward, however, I found a greater inconsistency, both in those very observations and in our own, and recognized how slippery this business is, on account of the excessive diversity of densities in the air around the Earth, arising not only from the ordinary causes — that is, from the seasons of the year, since the refractions are greater per se in winter than at the equinoxes, and these in turn greater than the summer refractions, and the morning refractions greater than the evening ones because of the air baked by the daytime heat — but also from extraordinary causes, both at the full moons and in the other phases of the Moon,

and from the aspects of the stars, and from the more humid exhalations of the Sun, whether from the sea, the rivers, the lakes, the marshes by the heat of the Sun, or some other [exhalations] of the stars, sometimes raised higher and sometimes lower in the air — from all which four controversies remain still undecided.

[Margin: 7]

The first is whether the air is more refractive at higher altitude, and how much, and whether it is always the same in the same horizon — about which we said not a few things in Book 10 of the *Almagestum Novum*, section 5, Problem 43. The second concerns the figure of that same air, whether it is spherical, on one side convex, on another concave, and from this whether it is apt for increasing certain refractions in the way an elliptical [figure] would, or in another way. The third concerns the third density of the more humid air, which is colder than the more serene night air, but less frigid, and the denser air on serene but more frigid days, which causes less refraction than the less serene but more tepid air. The fourth

concerns whether the density of the refractive air is uniformly perceptible, or non-uniform, and multiplex, causing different refractions at the same moment. For it can happen that, although in less dense air the individual refractions are smaller than in very dense air, yet on account of the multitude of them, arising from the non-uniformity of the densities, the last rays which reach our eyes are raised higher, or the image of the stars [is raised higher]. From this cause I judge, almost with certainty, that we, and Tycho, and others, included so great an inconsistency in their observations, besides what could come from a flaw in the observer or in the instruments; and that at one time we obtained a greater refraction than we expected, when we were expecting a smaller one. For example, in the year 1656, on the 19th of August, when by means of a large level [per magnam libellam] we observed the evening altitude of the Sun to be $85^{\circ}23'16''$, from the time at the meridian, 6 hours $23'47''$, we deduced the true distance to be $85^{\circ}38'29''$. The simple refraction was $15'3''$. At the same time, in the year [16]56, on the 11th of October, when at twilight, in the same evening hours and in autumn, when greater refraction would be expected, it nevertheless turned out smaller. If indeed greater refraction would be expected, the distance of the Sun observed by us from the vertex was $85^{\circ}47'$, and by the azimuth of the Sun verified from the Lucida of Aries [Lucida Arietis] [α Arietis, Hamal], its true distance was found to be $85^{\circ}19'5''$. Therefore the refraction was $9'18''$, and so on with others, and others again.

[Margin: 8]

It is therefore best to abstain as much as possible from horizontal observations, or at least there is need still of many observations in the same horizon, taken with exactness. For there are almost no astronomers whatsoever who have entire tables of horizon-observations, and our own [tables] are in vain, as are those of others, and especially of Tycho, in this kind of observation of many years, which he indicates were made in volume 1 of the *Progymnasmata*, pages 79 and 280. By a twofold method one may use the Tychonic refractions of the fixed stars. The first is by choosing the Tychonic refractions of the fixed stars, and by subtracting from them the parallax of the Sun — as anyone would judge, since by Propositions 15 and 38 we show that, at equal altitude, the astronomical refraction of that same star is greater, and so much greater the more it is distant from the center of the Earth, since the parallax of the star is its own, less than the Earth's. But the fixed stars, since they lack a perceptible parallax, are received as the fixed stars were received by the astronomers. Yet because Tycho, page 280, indicates that he noticed from certain observations that the refractions of the fixed stars are about $4\frac{1}{2}'$ smaller than the solar ones, therefore we elicit the table

of the fixed stars from the solar one, by subtracting from the solar refractions $4\frac{1}{2}'$. For this surer method, therefore, we elicit the Tychonic refractions of the fixed stars from the solar ones, but corrected by subtracting the Tychonic solar parallax, in the middle [of the table]; and then, with the simple refractions of the Sun, adding the parallax of the Sun out of the Tychonic [table], so that we may have the truer refractions of the fixed stars. We use our own solar parallax for the Sun. But the astronomical refractions of the Moon we set down somewhat smaller than the solar ones — let the optical refractions be the ones that, by the said Propositions 14, 15, 16, and so on, ought to be greater, since it will then be apparent that the refractions, in serene and tawny air, cease around the 30th degree of altitude, which is the opinion midway between Tycho and Rothmann. For Tycho, in his *Epistles*, page 108, and in volume 1 of the *Progymnasmata*, page 91, judges the chief cause of refraction to be the vapors around the horizon, which render the air thicker, and from the denser [air] they give back the density, but not the meta, and the natural diversity between our air and the aether; and therefore [refraction] ceases around the 45th degree

of altitude. Rothmann, however, holds that it ceases around the 20th degree, which Tycho conceded for the fixed stars. Since therefore the inconstancy of the refractions admits no fixed law, it will subsist [as the case may be]. And these things are better set forth. Nevertheless all the summer refractions are found to be smaller, and the winter ones greater, and on the same day the morning ones greater, all else equal. See therefore in our tables.

[Margin: 9]

After the aforesaid, I found in the *Ephemerides* of the most illustrious Marquis Cornelio Malvasia [Cornelii Malvasiae], namely in the proem, pages 155, 172, 173, 174, and 186, the new doctrine of refractions of Giovanni Domenico Cassini [D. Io. Dominici Cassini], who asserts, from experience in all transparent media, both concrete (such as glass) and liquid (such as water), that the refractions of the stars proceed by the same law and variety in different inclinations, although in diverse bodies by a diverse measure; and from certain observations, at appointed altitudes, and segregated by that law, he deduced a parallax of the Sun, and the remaining refractions; and he derived this same law from the horizontal parallax of the Sun first diminished, and from his own refractions; and he likewise corrected the altitude of the pole, even by the circumpolar stars formerly taken, and by certain solstitial observations; he likewise corrected these same observations by his own parallax and refraction, and acknowledged that the same altitudes of the pole come out from the solstitials as from the circumpolars.

Hence I do not doubt to say, on folio 175: "Wherever in a place I correct the solstitial altitudes, it comes about that the same altitude of the pole arises, as that which the polar star, at the same altitudes, gives — likewise corrected — and from no observations whatsoever does any greater difference arise; therefore I establish, in the same way, that the refractions, in whatever place, and in whatever serene time of any season of the year, and at the same altitude above the horizon, agree for all stars having the same apparent altitude. Nor indeed" (so it is said on folio 172) "does any reason support a notable diversity, on account of the diversity of distances, at the same altitude, in the varying refractions." He asserts moreover, on folio 186: "The refractions persevere up to the vertex," and finally, on folio 186, affirms: "Of whatever ray in the air the incidence is oblique, the distance from the Earth at which the refraction runs out is the Earth's semidiameter," and a little after: "The altitude of the air is 6088/100000 part of the Earth's semidiameter." He proves these propositions by no experiment, nor by a produced foundation, [but] I believe their proof is in his *Astronomical Work* which he meditates; and therefore I have not yet departed from that refractive altitude of the air, which I treated in Book 10 of the *Almagestum Novum*, section 6, Problem 43, and Problem 51. Moreover, I am not for Cassini, but for Bologna [Bononia], for Vicenç Mut of Majorca [Vincentius Mutus Maioricae], and Rothmann in Hesse, and Tycho in Denmark, who found that the refractions of the stars are not perceptibly different above the 24th degree of altitude, which is much less than Cassini deduces, who himself deduces it from the Tychonic refractions of the Sun, if it excels above all others, by subtracting from it the parallax of the Sun. For at the 24th degree of apparent altitude the Tychonic parallax of the perigee of the Sun is 2'50", and the Tychonic solar refraction likewise 2'50"; therefore the simple refraction of the Sun ought to cease there. But whatever may be the case from other observations, I cannot in the meantime — most cautiously — [do without] what is most desired by my friends and most distinguished men, of whose words I have made myself the acquirer.

[Margin: 10]

For the first, given that the refractions which we experience in crystal, glass, water, wine, etc., could be distinguished, the ray (for example) entering our glass, having first been refracted in the air, in the ingress of our denser and thicker air; nevertheless the refractions are not those which astronomy requires, and the optical [refractions] are to be distinguished from the astronomical ones, as we taught in Chapter 14, numbers 19 and 20. Secondly, by Propositions 14, 15, and 16, we show that at the same altitude, whether apparent or whether seen, of stars more remote from the center of the Earth, the astronomical refractions are

greater — which is contrary to Tycho and others, who confuse the smaller refractions of the fixed stars than they assign to the optical astronomical refractions. Thirdly, the simple refractions of the Sun can be obtained without parallax, as long as these are smaller, as we show in Proposition 25; and therefore we refute Tycho at numbers 21 and 53.

[Margin: 11]

Now indeed Cassini, in all his examples, in order to obtain the true altitude of the Sun from the apparent, adds the apparent parallax, and from the remainder subtracts the refraction; and if that refraction is compounded, out of the simple refraction and the parallax, it cannot be the same one fitted to the fixed stars, which lack parallax; but if it is perceptible, then if it is simple, the parallax is applied in vain, as said at number 21. As for what is near the horizon in the Cassinian table, I do not see precipitately that increment of the refractions, with the due proportion. For, by way of example, in his table, in summer, the refractions are thus; where the difference of refraction is greater [in the second degree] than in the first:

Sample from the Cassinian table (summer)

Altitude [Alt.] (Gr.)	Refraction [Refractio] (' ")	Difference [Differential] (' ")
0	32 20	4 24
1	27 56	6 52
2	21 4	—

which is contrary to the astronomical [refractions], and so also in some others, in a table the same in summer and winter, unless there is a typographical error. As for the fact that, with the parallax of the Sun retained, and with the refraction of the fixed stars taken Cassinian, and that applied both to the Sun and to the fixed stars, the same elevations of the pole come out in a few cases — this comes about because in not a few cases certainty is not antecedent, since we have the insensible refraction of the fixed stars beyond the 25th degree of altitude.

Therefore it is enough to retain the altitudes taken from the circumpolar fixed stars' altitude, above degree 25. And when the altitude of the pole, deduced from the solstitial observations, differs from that, ascribe this to the refraction of the Sun alone, whether ordinary, or, as rarely happens in winter, extraordinary; or to a flaw in some observation.

CAPUT XVI.

De Constituendis Epochis Motus Solis

[On Establishing the Epochs of the Sun's Motion]

[Margin: 1]

Now in Chapter IV we had the true equinox of the year 1655 of Christ at Bologna [Bononiae], on the 22nd day of September, in the Gregorian style, at the hour past noon $18^h55'25''$; and the middle of the day truly on the 20th day, at the hour $18^h55'25''$. Hence, to the year 1600 completed at the meridian of the last day of December preceding, there are 54 Julian years and 263 days, $18^h55'25''$. To these is owed, from our tables, the mean motion of the Sun (after entire revolutions) of 8 signs, (...) $55'25''$; from which, with the beginning of Libra subtracted, the radix of the year 1600 completed remains, as below:

Sign.	Gr.	'	''
9	10	4	35

[Margin: 2]

To this, if we add the mean motion of 10 days, which is $9^{\circ}51'23''$, the radix of the year 1600 completed will result; but in the style of the old Julian form it will be: Signs, Gr. ' ''':

Sign.	Gr.	'	''
9	19	55	58

Then, if from this same [value] we subtract the mean motion of 1600 Julian years, which for us is, after the entire revolutions of the Zodiac, Signs 0, gr. 12, $15'57''$, the radix at the beginning of the years of the vulgar epoch of Christ will result. Signs, Gr. ' ''':

Sign.	Gr.	'	''
9	7	40	1

[Margin: 3]

In the same way, if we wish the radices for the years before Christ, we shall have them sufficiently exact down to a thousand years (...)

within which all the observations of the ancients lie, and which were recorded by their posterity. By going back still further in time, one may suspect that the error of those who place the beginning of the world some 5,000 years before Christ amounts to some quantity. As for the 30", we are not entirely secure on this point, because the motion of the [Sun's] anomaly over 5,000 years is for us greater by 33' than in the Rudolphine Tables — even granted that we rest our own motion on a firmer foundation. This we have shown abundantly clear by examples.

4. From what was said in Caput IV, num. 9, the Hipparchan equinox fell in the year 158 before Christ, at Alexandria, on 26 September, nearest to the 20th hour after noon. Once this has been corrected for refraction in time, then — as the *Geographia Reformata* shows — it was at Bologna at 18^h 27' 20", and at Uraniborg at 18^h 32' 56". At which moment, from Our Tables for Bologna, and from the Rudolphine for Uraniborg, the calculation of the Sun stands thus:

From Our Tables	Sign	Gr.	I	II
Mean motion of the Sun [Solis Medius Motus]	6	1	51	35
Anomaly of the Sun [Anomalía Solis]	3	24	30	34
Equation to be subtracted [Aequatio demenda]	0	1	48	50
True place of the Sun [Verus locus Solis]	6	0	2	45

From the Rudolphine	Sign	Gr.	I	II
Mean motion of the Sun	6	2	3	51
Anomaly of the Sun	3	28	7	22
Equation to be subtracted	0	1	49	44
True place of the Sun	6	0	14	47

The Rudolphine therefore differs from the Hipparchan observation by 14' 47" in longitude — that is, by 6 hours; and they differ by being incorrect, in that the observation was made on the meridian at the 10th hour. But Our Tables differ only by 2' 45", which accounts only for the 1' 17" difference of an hour. They do not, then, embrace it improbably, given the error arising in the observation from the deviation of the armilla from the plane of the equator by 1' 17", and from a corruption of the declination by an equal amount. From this we shall detect the error of a single day in the Ptolemaic equinox.

5. For Ptolemy, in Book 3, Caput 8, reports the equinox that is fundamental to his whole work — the one on which, as on a foundation, he builds his tables — in these words: *Of the equinoxes observed, one of the most exact among others was that of the autumn, in the year 17 of Hadrian, in the month Athyr, on the 7th day after midday, two hours nearest to equal.* Yet Boulliau, in Book 2 of the *Astronomia Philolaica*, Caput 2, and Longomontanus, in his *Commentary on the Sun*, judge — not without reason — that Ptolemy held this autumnal equinox too early, not only on account of the autumnal refraction, but also because Ptolemy accommodated his own observations to those of Hipparchus, as also the [equinoxes] of Hipparchus to the quantity of his year of $365\frac{1}{4}$ days, commensurable with the lunar cycles, and to the false opinion of the immobility of the solar apogee. Hence, why it is more certain that the autumnal equinoxes of Hipparchus occurred earlier on account of refraction than they appeared to do; and consequently, that being made to agree with the Ptolemaic ones, they came out earlier — so that the Ptolemaic, reconciled with these very ones, came out earlier still. Boulliau, however, likewise shows that the observations near the horizon increased the northern declination by 7' minutes and 48" seconds, given an assumed parallax of 2' 19". But since the parallax is false by what was said above, and scarcely reaches 10", therefore by the force of refraction the declination was at least some minutes, which carry 8 hours. Therefore, if Ptolemy saw the armilla at midday and in the evening equally illuminated on both sides, he was easily deceived by 4 or 5 hours — especially if the armilla, too, in its placement, was wandering by one minute or the other, as we mentioned above. With these things laid down, let us consult the Tables, both Ours and the Rudolphine, with the time reduced to the meridian of Bologna and of Uraniborg. For it was — if we hold to Ptolemy's observation not yet corrected — at 0^h 27' 20" after midday on the 25th day of September at Bologna, but at Uraniborg at 0^h 32' 56", in the year of Christ 132. So the reckoning stands:

From Our Tables	Sign	Gr.	I	II
Mean motion of the Sun	6	3	3	20
Anomaly of the Sun	3	20	43	19
Equation to be subtracted	0	1	52	2
True place of the Sun	6	1	11	18

From the Rudolphine, however	Sign	Gr.	I	II
Mean motion of the Sun	6	3	19	9
Anomaly of the Sun	3	22	39	44
Equation to be subtracted	0	1	55	10
True place of the Sun	6	1	23	59

Since, then, both Our Tables and the Rudolphine present the Hipparchan equinox in fairly close agreement, but do not match the Ptolemaic, and place the Sun a full degree and a little more beyond the autumnal section, one must conclude that Ptolemy, in observing the equinox, either erred in his own false hypotheses by about a degree, or by dragging it in [made an error]; and that this equinox truly fell some hours before noon of 24 September. On this matter, again, in the following Book, Caput 5.

6. It will nonetheless be worth the trouble to examine the Tables not against all the equinoxes, or against observations nearest the equinox, but against those which we know to have been accurately made on the Grand Gnomon of San Petronio, selected from among them — those treated in Caput 8, at the very moment of meridian crossing. Behold, then, the place of the Sun as observed at that time, and as computed from Our Tables:

Year of Christ	Place of the Sun — Observed	Comp uted				Defect / Excess		
	Sig.	G	I	I	Gr.	I	I	I
		r		I		I		I
		.						
1655 Sept. 22	♎	2	1	4	29	1	0	d 0
		9	3			3		
23	♏	0	1	2	0	1	5	d 0
			2	4		1	1	
1656 Mart. 19	♐	2	3	4	29	3	5	d 0
		9	5	3		4	8	
21	♑	1	3	3	1	3	5	d 0
			4	0		3	6	
23	♑	3	3	1	3	3	4	e 0
			3	6		3	9	
Sept. 22	♎	2	5	2	29	5	3	e 0
		9	7	2		7	7	

Year of Christ	Place of the Sun — Observed	Comp uted	Defect / Excess
23	$\underline{\alpha}$	0 5 1 0 6 1	5 3 e 0 6 2
24	$\underline{\alpha}$	1 5 1 1 4 7	5 2 e 0 5 9
1657 Mart. 28	Υ	8 1 4 8 5 8	1 5 d 0 4 5
1658 Mart. 20	Υ	0 5 3 0 8	5 4 e 0 1

It is therefore established that Our Tables do not differ from these most select observations by a whole single minute. And if they have differed from others by more, the better reason is that we should put the blame on the observations, since the Tables, bound by the chain of geometry and arithmetic and consistent with one another, cannot exhibit something so near the truth in the equinoctial observations and yet stray more widely in the others. But those skilled in these matters know that observations made on other days, far from the equinoctial points, have committed a greater error in declination than the equinoctial ones, in equal terms of error — and so, in deducing the place of the Sun. And for this reason, the equinoctial observations are rather to be weighed, as a Lydian stone, in testing the Tables. The Rudolphine, however, differ from the aforesaid observations by rather more minutes; thus at the first [observation] by 4' 51", and so for the rest.

CAPUT XVII.

A New Theory of the Motions of the Sun is Set Forth.

1. Up to now we have shown ourselves willing to approve the theory of the Sun set forth by Kepler in an ellipse, and refined by Boulliau, by [Blaise de Pagan, the] Count Pagan, by Seth Ward, and by many recent writers, as the simplest...

way of representing the motion of the Sun, and as one arising from the very nature of the ellipse and of its foci, or umbilics, with the Sun standing off at equal distances from the center, and rendering the reason by which the distance of the Sun is rendered eccentric. Yet it seems to labor under some imperfection, for two reasons.

2. The first is that in the Keplerian ellipse — just as for the one focus the Earth is assigned, for whose illumination the Sun is chiefly destined, as is clear from the Divine writings — so for the other focus, or for the very center of the ellipse, some body had to be assigned to the World, which would, as it were, attract the Sun, which would reflect upon itself in its uniform motion uniformly about the other focus. But to assign the center of the ellipse — and to suppose some region in the World which would determine it, from which the reason of the place [might be had], or so that the Sun should move uniformly, or half-uniformly, about it, as the Earth itself moves the Sun unequally — this, in my opinion, is to constitute the eccentricity around the center as half-uniform, but the eccentricity so much greater the less, or the greater, the distance of the Sun is constituted by God.
3. The other, and by far the greater, [reason] is that through the ellipse — indeed, not even through the simple eccentric circle — can the daily motions which appear in the Sun be reconciled with an orb carried from east to west, with another proper to it, from west to east. Even though the Copernican attention does not lie upon this — since they make the corporeal bodies of the Prime Movable penetrate, and ascribe nothing to the Earth — nevertheless there are things which we can fashion to ourselves out of the sacred writings, and out of physical demonstrations, and physico-mathematical ones, in Book 9 of the *Almagestum Novum*, sect. 4, c. 19 and 21, and which are to be said in Appendix 11. It is certain that the motion of the Sun is not only annual, but also daily, from rising to setting; and on the other side, that the Earth is at rest. And since the heavens of the planets are fluid, the falsity of distinct orbs has been all but made certain; nor does it seem that these two motions could be better reconciled by any other means than a continuous motion contrary to apparent motion — that is, a spiral motion, by which all the planets move.

[Margin: *Motus Spiralis Planetarum* — The Spiral Motion of the Planets.]

4. And indeed, if a fixed star, in one revolution from the same point, to the same meridian, exhibits to us that daily motion which we imagine to belong to the Prime Movable, and has no other slow motion from west to east; and if the Sun is such, which we celebrate as the equinox in others, and in others at points of the western equator; it is not at all necessary to fashion another abstract Prime Movable, separated from the senses. Rather, the sensible Prime Movable will be the motion of the sphere of the fixed stars.

Once this is granted: if we conceive the Sun as moving, as it were, about the Divine spires, now more broadly, now more narrowly, both in altitude and in latitude as it is described, and at the same moment as a fixed star — since it moves toward the west — it returns to the same meridian, not [exactly] returning, but somewhat more slowly; all the appearances in the motion of the Sun will be safe. In the planets, however, which are seen to be stationary, or retrograde, or direct, the reason of this appearance will be assigned more easily. For when they return to the same meridian more slowly than a fixed star, they are seen direct — that is, moving toward the east; when they are detained at the east, at whatever moment the fixed star returns, the [planet's] proper motion of the sphere [makes them] seem stationary; when finally, swifter than the meridian, they cross it from east to west more quickly than a fixed star, they are seen retrograde. But this is nothing to the Sun, which is always slower than the fixed star, [since it] returns to the same meridian, and therefore never appears stationary, much less retrograde.

5. To meet these two difficulties of solar theory, then, we have devised certain Foundations [*Fundamenta*] for our own model; but first some preliminaries must be set down.

I. Foundation, on the Apparent Semidiameter of the Sun and the Eccentricity.

6. The apparent semidiameter of the Sun at apogee is 15' and 30"; at perigee, however, it is 16' 14"; and at mean distance, 15' 46". From this, and from the equations, the better eccentricity of the Sun follows: the whole [eccentricity] of the Sun is 3,480, and bisected, 1,740 — of which the semidiameter, or the radius of the Sun's orbit, is 100,000, as is clear from what was said in Caput XI and XII.

[Diagram on this page — see the figure on the following spread; this page is prose.]

II. Foundation, on the Maximum Axis of the Earth's Shadow.

7. Given the distance of the Sun's apogee at 6,666 terrestrial semidiameters from the center of the Earth, and the apparent semidiameter at 15' 30", the axis of the Earth's shadow is 229 terrestrial semidiameters.

Diagram. A tall, narrow geometric figure at the upper right of the page, illustrating the construction of the Earth's shadow-cone for the Sun at apogee. At the top, points D, F, and S lie along a near-horizontal line (the Sun's body), with A

immediately below D; from A and S converging lines descend to a point C far below at the foot of the figure; B and T are marked midway down on the central axis (the Earth), with a small circle drawn at the Earth. The construction demonstrates the right triangle relations described in the text.

- A (upper left): foot of the radius AT tangent to the Sun
- D (top): point of tangency of line DBC to the Sun
- F (top center): point on the line of the Sun's body
- S (top right): the Sun's center
- B (middle): point on the Earth's body (on tangent DBC)
- T (middle): the Earth's center
- C (bottom): apex of the shadow cone (where AS produced and DBC meet)

For let the Sun's center be S in the present figure, and the Earth's be T, from which the Sun is seen under the angle ATS of $15' 30''$. By the radius AT, tangent to the Sun at A and making there a right angle (by Euclid III.18 [*18. Tertii Euclidis*]), and ST being 6,666 terrestrial semidiameters — for by the rules of right triangles AS comes out to be the true semidiameter of the Sun, 30 terrestrial semidiameters. Then DBC having been drawn, tangent to the Sun at D, and to the Earth at B, and meeting the produced line ST at C, let TF be drawn from T parallel to it, up to AS; DF will be equal to the one terrestrial semidiameter BT; with the single terrestrial semidiameter therefore subtracted from DS, which is as great as AS, there remains FS of 29 terrestrial semidiameters; and since with this, and with ST of 6,666 semidiameters, the angle FTS is found to be $14' 56''$. And as great as this is the angle C, on account of the parallelism of the lines CD and TF. Therefore, with so great an angle C, and the side BT — that is, the one terrestrial semidiameter — the axis CT of the Earth's shadow comes out to be 229 terrestrial semidiameters.

III. Foundation, on the Distance of the Moon, and the Shadow.

8. Given the apparent semidiameter of the Sun at $15' 30''$, and the terrestrial distance at 6,666 semidiameters, the Moon's least distance from the center of the Earth in conjunctions [is found]; the apex of the lunar shadow in oppositions is distant from the center of the Earth by $114\frac{1}{3}$ terrestrial semidiameters. For from Our observations, the distance of the Moon at perigee in the syzygies is 58 terrestrial semidiameters, as we shall show in the following Book; but at present, with the Sun placed at apogee, the axis of the lunar shadow is $56\frac{1}{2}$ terrestrial semidiameters — wherefore the apex of the aforesaid shadow is distant by a semidiameter of $114\frac{1}{3}$. From

what was said in Book 4 of the *Almagestum Novum*, Caput 17, the true semidiameter of the Moon is 26 terrestrial semidiameters; the parts above [the figure], which we have laid down, are 100. At apogee, as above, given 30 [solar] semidiameters, the true semidiameter of the Sun is 30 terrestrial semidiameters. Therefore the true semidiameter of the Sun exceeds the terrestrial semidiameter by 29 [fraction ?]; and in the preceding figure the true semidiameter of the Moon, BT, comes out to be 26 — the residual SF of the [Moon's] semidiameter being truly 29 [fraction ?]; and with the Moon's perigee distance of 58 added, ST is 6,724; let the angle FTS be, then, & C, 15' 14". And hence the axis of the lunar shadow TC, of 226 parts, [is] the semidiameter of the Moon BT — and one, that is, $114\frac{1}{3}$ terrestrial semidiameters.

IV. Foundation, on the Proportion of the Distances of the Earth's Shadow, and the Moon's, with the Eccentricity of the Sun.

9. From the conclusions, and from the things laid down in the three preceding foundations, it follows that, as the maximum distance of the apex of the Earth's shadow from the center of the Earth is as great as the whole eccentricity of the Sun, so the distance of the apex of the lunar shadow, tending into the same region — but the least, when the Sun is at apogee — is as great as the bisected eccentricity of the Sun. For the whole eccentricity of the Sun, from Foundation I, is 3,480; of which the distance of the apogee is 101,740, and at 3,480, bisected truly 1,740. From Foundation II, the maximum axis of the Earth's shadow is 229 terrestrial semidiameters, of which the apogee of the Sun is 6,666 — but at 101,740, as at 3,480 — that is, at 6,666, nearest, 229; of which the half is the distance of the apex of the lunar shadow, $114\frac{1}{3}$, just as the whole eccentricity of the Sun, bisected, is 1,740 — which is half of the whole 3,480. Hence further it follows that the distance of the Sun from the center of the Earth ought, on such a [hypothesis]...

in the hypothesis, to be 6,552 terrestrial semidiameters, and the least 6,438. These, although they are smaller than those chosen formerly in the *Almagest*, Book 3, Caput 7, cannot, however, be convicted of falsity from the lunar dichotomies, much less from elsewhere — indeed, from the ideal beauty of the hypothesis, of which presently, they appear highly probable. But in another hypothesis, varying notably the intervals of the Sun, they could not be reconciled — that all these, namely with the apparent semidiameters of the Sun preserved, and the eccentricities established in the first Foundation, the eccentricities might be as nearly as possible, and physically, equal to the distances of the two shadows of

the Earth and of the Moon, as will be clear to one who duly enters upon the calculation. Let us now come to the figure of the prior hypothesis.

Diagram. A large circular diagram dominating the page, illustrating the prior hypothesis of the Sun's motion. The outer circle is the ecliptic, marked with the zodiacal signs ♋ Cancer at the top (beside A) and ♈ Aries at the right (beside P). A vertical diameter runs from A at the top through I, G, and the small inner construction, down through H, K to B at the bottom. The center C lies at the bottom of a small inner circle (the Sun's eccentric orbit), within which a shaded shadow-cone tapers from E/G down to L. Radial lines run from S (upper left, on the ecliptic) and from T (left of center) toward the inner construction; M, N, V are clustered at the upper left on the ecliptic, R and ♎ Libra are at the far left.

- A (top): point on the ecliptic at the line of the absides, beside ♋ (Cancer)
- ♋ (top, beside A): the sign of Cancer
- I (upper center, on vertical axis): point on the Sun's orbit / mean place
- M (upper left): point on the ecliptic
- N (upper left, above M): point on the ecliptic
- V (upper left, above/right of N): point on the ecliptic
- S (left of center, on inner circle): the Sun, or a position of the Sun (locus posito in S)
- R (far left): point on the ecliptic, beside ♎ (Libra)
- ♎ (far left, beside R): the sign of Libra
- T (left of center): the Earth's center (center of reference) [?]
- G (center, on vertical axis): point G — the [eccentric] center about which the mean motion is reckoned (linea GSM, the line of the mean motion)
- E (center, below G): apex/point E of the inner construction [the figure shows a small letter that may be E or K — [?]]
- C (center, foot of inner circle): center C, from which the mean motion is considered
- D (center, below E): point D on the inner construction
- F (lower center, on vertical axis): point F
- H (lower center, on vertical axis): point H
- K (lower center, on vertical axis): point K
- L (lower center, right of axis): apex L of the shaded shadow-cone
- B (bottom): point on the ecliptic at the line of the absides, opposite A
- ♈ P (right): the sign of Aries, with point P on the ecliptic

10. On the line of the Sun's absides AB, up to the ecliptic [point] pertaining [to it], let C be the center of the Earth, and CD the distance of the Moon at perigee, 58 terrestrial semidiameters. And let DE be the axis of the Moon's shadow when it is so opposed to the Sun at apogee that it does not fall into the Earth's shadow, nor is any eclipse rashly feared; and that [axis] is $56\frac{1}{2}$ terrestrial semidiameters, and so the whole CE is a semidiameter; the diameter [is] $114\frac{1}{2}$ — by which interval let a small circle EF be described, through which the apex of such a great shadow may be understood to be carried round; and by the interval EI, of terrestrial semidiameters 6,552 [?], as great as we may, in the IV Foundation. Let the mean distance of the Sun from the Earth be described by the circular orbit of the Sun, unless one prefers to describe an elliptical one; and let its periphery be ISTK, &c. With the interval CE doubled, let CG be made, 229 terrestrial semidiameters — that is, as great as the maximum length of the Earth's shadow; by which interval let the circle GHL be described, in whose periphery the apex of the Earth's shadow, opposite the motion of the Sun, is understood to be carried round; and from the same point G — that is, from the line of the absides of the Sun — let it be described, as great as the great interval of the ecliptic ARBP, under which we regard the true motion of the Sun...

from the center C, and let us consider the mean motion at some other point, with respect to which the Sun is supposed to move uniformly — which here will be the point G. With the Sun therefore placed, for the sake of example, at S, let the shadow of the Earth then be CL, if, however, in a circle described from the periphery, and from its point G, let there be the line AB, [the line] of the Sun's absides; there will be the line GSM, the line of the mean motion; and the line CSV, the line of the true place of the Sun; and ES, the semidiameter of the Sun's orbit — which, produced into N, can be called the line of physical inequality, since also with respect to the center E, about whose orbit the Sun should move unequally, just as the line CSV is the line of the inequality of the whole [inequality] compounded out of the physical and the optical — since at the center of the Earth the Sun appears to have a greater inequality in the motion of the Sun than if it were seen from the center E.

11. The practice, then, of the geometric calculation in this circular hypothesis is very easy. For, given the simple anomaly of the Sun, the angle AGM, from the Tables, the complement of two right angles is given, with which, and with the radius ES of 100,000 parts, the eccentricity EG bisected being 1,740, you gather the physical equation ESG; and thence the angle SEG, and so also CES, with which...

finally, with the same Radius ES, and with the eccentricity CE, likewise 1740, you will find both the Sun's distance from the Earth CS, and the optical equation [aequatio optica] CSE. This last, combined with the physical [equation], will yield the Absolute Equation [Absoluta Aequatio] to be subtracted from the Sun's mean motion in the prior semicircle of anomaly ARB, and to be added in the latter [semicircle]. But when the Sun is at T, and CT, it will be equal to ET itself, and it will be at its mean distance from the Earth.

12. Indeed, this hypothesis has the most beautiful congruences, not unworthy ones — if I am not mistaken — which I now point out.

The first is that, if the Sun really moves with an equal and uniform motion with respect to some center [that is] thoroughly congruent to that center, it is seen to move in such a way by that observer who, being situated beyond the deformity of the Earth's shadow [Umbra terrestris], can perpetually see the Sun. Therefore if an eye were located at some point of the periphery GHL, it would be at the boundary of those who cannot always [see the Sun], and of those who can always behold the Sun — inasmuch as it is not only above the clouds, but even above the Earth's shadow, which already towers up, or even above the whole region of the aether. To whatever point that eye could reach, even where the line of the Sun's apsides [linea Absidum Solis] passes through, it would always see the Sun moving uniformly.

The second [congruence] is that the eye which would be located at the periphery of the circle described by the Moon's shadow — that is, at the periphery EF — would, in that region in which it would carry itself about, partake of some equality of the solar motion despite its inequality; for it would enjoy some equality of motion. For it would be located first in that region in which the Moon's shadow, at the [Moon's] perigee, conspicuously leaves the Sun at apogee behind; and being most distant by the greatest interval from the apex of the Earth's shadow, and being moreover located first at the center of the Sun's orbit, it too would be first, and would see the physical inequality of the Sun without any inequality of the optical [equation].

The third, and the one chiefly such as we posited, is that by this reasoning there are assigned two regions notable in the world: one for the center of the Sun's equal motion, the other for the center of the Sun's orbit; and from this is derived the physical ratio of the eccentricity of each, [namely] of the Sun. Now to make the Geometric calculation of each, the boundary of the region designated by the aforesaid shadows must be such that in the plane of the ecliptic one may choose the Angles of Equation and of Anomaly, and the motion of each; for it suffices that

they be in that region, which is first free of the Earth's shadow — here at the Moon — provided that even at the Moon it does not fall under the ecliptic separately.

13. Whatever, however, may be the case concerning this Hypothesis — which perhaps some, not without reason, will not disapprove, whether the whole eccentricity is as great as half the axis of the Earth's shadow, or [as great as] a quarter of the Moon's distance together with its shadow — we shall construct another Equation Table in a circular form for the whole eccentricity, 3480, bisected; and 1740: for which the Radius of the Sun's orbit is 100000. And by the same proportion we shall assign the remaining distances of the Sun in their own Table, so that each may, in his own hypothesis, be able to adapt them to the distances measured by the semidiameters of the Earth — preserving, nevertheless, the due proportion to the said eccentricity in the maximum and minimum distances of the Sun from a certain part of the Earth. But if this hypothesis does not please anyone, here are the measurements pertaining to it in the subjoined Table.

[Sun symbol]	Ad Rad. 100000	Semid. Terrae	I	
			I	I
CT, <i>Media Distantia</i> [Mean Distance]	100000	6552		
CI, <i>Distantia maxima</i> [Maximum Distance]	101740	6666		
CK, <i>Distantia minima</i> [Minimum Distance]	98260	6438		
<i>Umbra terrestris / Axis Sole</i> [Earth's shadow / shadow-axis], at Apogee [Apogeo]		229		
at Mean [Medio]		226		
at Perigee [Perigeo]		243		
<i>Solis Semidiameter Vera Apparens</i> 458 [Sun's true apparent semidiameter] in Apogee [in Apog.]		30	1 3 5 0	
in Mean distance [in Media dist.]			1 4 5 5	
in Perigee [in Perigeo]			1 4	

[Sun symbol]	Ad Rad. 100000	Semid. Terrae	I	I
			6	
<i>Lunae Perigea distantia</i> [Moon's perigee distance]		58		
<i>Umbra Lunae</i> [Moon's shadow], [Sun] at Apogee [☉ Apog.]		56 ½		
[Sun] at Perigee [☉ Perig.]				
<i>Parallaxis Solis Horizontalis</i>				2
[Sun's horizontal parallax], in Apogee [in Apog.]				9
in Mean [in Med.]				3
				0
in Perigee [in Perig.]				3
				1
<i>Portio Terrae à Sole illustrata</i>			1	5
<i>ultra hemisphaerium</i> [Portion of the Earth lit by the Sun beyond a hemisphere], Apogee [Apog.]			4	6

Indeed, I tried whether I could adapt this Theory to the Sun's Mean distance — formerly in *Almagestum Novum* Book 3, chapter 7 — chosen from other lunar Dichotomies [Dichotomiae] as 7300 terrestrial semidiameters; but the resulting numbers did not correspond. For as Radius 100000 is to the bisected eccentricity 1740, so is 7300 to the terrestrial semidiameters 127 1/30. These, joined to the Mean distance, make the Maximum solar distance 7427 semidiameters; and with this, and with the Sun's apparent semidiameter at apogee 15'30", by the problem set out in the II Fundamentum, I find the Sun's true semidiameter to be 33 1/2 [semidiameters] of which its [the Earth's] distance is 7427; and the half-angle of the cone of the Earth's shadow 15'4"; and with this, finally, the Axis of the Earth's shadow [to be] 228 1/2 terrestrial semidiameters. But if the eccentricity, when bisected, were 127 semidiameters, the whole eccentricity would be 254 — much greater than the longest axis of the Earth's shadow; nor could it, with the appendage of the penumbra, reach to this measure. Now, retaining this Shadow, and its half, 114, for the eccentricity, it would come out as 7300 to 100000; thus 114 for the eccentricity is 1562 — far less than that which we need for the equations due to the apparent motions of the Sun, and for the difference of the apparent semidiameters.

15. Likewise, taking the Tychonic mean solar distance of 1150 semidiameters, it comes out as 100000 to 1740; thus 1750 to 19; therefore the Sun's maximum distance would be 1169; and the Sun's true semidiameter, from the apparent 15'30", [would be] 5 1/4 terrestrial semidiameters; and the half-angle of the Earth's shadow 12'26"; and the axis of the Earth's shadow 276 semidiameters — much greater still than the whole eccentricity, which ought to be 228, or at most 230; nor can we maintain this, unless we use the solar distances laid down in the preceding Table, or [ones] moderately different.

CAPVT XVIII.

Indicatur Theoria Motus Spiralís Solis. [The Theory of the Sun's Spiral Motion is set forth.]

[Margin: *Exponitur Motus Spiralís Solis.* (The Sun's Spiral Motion is expounded.)]

1. Although Kepler [Keplerus], in his work *On Mars* [*De Marte*] at chapter 1, has nearly cast the mark of madness upon Alpetragius [Alpetragio] and Patrizi [Patritio] and the rest who introduced the spiral motion of the Sun, or who, captivated too much by love of simplicity of motion, were their followers — in that one and the same elliptical periphery [is set] under the ecliptic, not of the Sun, but of the Earth, by [its] annual motion around the orb, and by [its] daily motion rolling down from east to west, from the stars toward the Earth; and besides, because the spiral motion cannot be enclosed by us in a Geometric figure in such a way that it may serve to determine the Sun's places for any given time — nevertheless we are in no way deterred by these [objections] from proposing this Theory. For, as I have already begun to say at the beginning of the preceding chapter, numbers 2 and 3, it is necessary to deny the daily motion from east to west to the Earth and to the fixed Planets [Planetae Fixi], or at least to ascribe it to the whole sphere of the Fixed Stars and the Planets enclosed [within it]. And since the solid orbs have been excluded, and the fluidity of the heaven of the Planets has now been introduced by the consensus of more recent Astronomy, it can scarcely be persuaded to anyone that such vast bodies of the Planets could be swept along by an aether so fluid; so much so that, contrary to their own effort to revolve toward the east, they should be carried back toward the west by the space of 24 hours. Besides which, that motion of the whole celestial region is superfluous.

2. To this is added the authority of Sacred Scripture, which not only attributes both motions to the Luminaries, but also insinuates to us, not obscurely, that spiral motion itself, when Ecclesiastes, chapter 1, says: *The Earth, however, stands forever: the Sun rises, and sets, and returns to its place; and there, rising again, it wheels through the South, and bends toward the North; surveying all things round about, the wind [spiritus] goes forth, and into its own circles it returns.* As if it were saying that a Spirit, or moving Intelligence, by the very fact that it is thus moved from east to west, [does so] in such a way that it nonetheless girds about [its] gyres — now toward the South, now toward the North — and is not moved through one and the same...

and the same circle, but is carried round and back again through others and yet others, and through other circles. Therefore, that we may briefly recall the conditions of this motion which we have hitherto observed in the Sun's motion, let them be noted by the Astronomers.

3. *First*, then, the Sun's motion in *Longitude* [*Longum*] very plainly appears: from east through the meridian to west, and again back to the east — which motion is known to the common people and to the unlearned, when the heaven is serene each day.

The *second* motion, in *Latitude* [*Latum*], from south to north, is not so easily discerned — indeed not by everyone, but still by certain observers, especially on the days of the Solstices — yet on certain days even by those who observe the altitudes at the meridian: because, after some longitude has been traversed, [the Sun] now shows a varied declination. The more skillful observers, however, [observe it] in the varying declination from the poles of the world, and [perceive] a manifest difference and inequality, since it is greater near the Equinox than near the Solstice.

The *third* motion, in *Altitude* [*Altum*], became known not to the common people but to the skilled — because the diameter of the Sun appears now greater, now smaller; yet it is not probable that the body of the Sun should swell up in some manner, [and] in some manner be diminished; rather, [it appears so] from the diverse use of the Telescope, whose diverse [readings] arise from the diverse distance of [observed] objects: a distance is demonstrated from the diverse apparent magnitude of distant objects in the Sun, [arising] from the fact that at one time it is nearer the Earth, at another more remote.

The *fourth* [motion] observed by Astronomers is that the Sun is so moved from east to west that it does not return to the meridian, so as to revolve back to the same meridian at the same time at which, with some fixed star, it was at the same meridian yesterday with the Sun, [but] revolves back to the same meridian today. For with whatever fixed star the Sun has once been seen to rise — say, the Little Dog [Canicula, i.e. Procyon] — after the Little Dog rises about three months [later], it now obtains the meridian, and after about three more months the Little Dog sets; and after about three more months the Little Dog rises [again], at the setting of the Little Dog [?]; and at last, when a year has rolled round, [the Sun] is conjoined with the Little Dog, and rises with it. Therefore, since each day it returns to the meridian more slowly than that same fixed star, it has been seen to be moved by many [degrees] toward the east by its own proper motion. From which [comes] also that motion *in latitude* discussed *second*, [which] Anaximander, or some other, established — namely, the motion of an oblique circle to the Equator, which they call the ecliptic; and at a maximum angle of obliquity, the Sun's greatest declination from the Equator, of degrees 23°30'20". Therefore [the Sun] is designated in globes, or however [it be], in the planes of the [great] circles, by the arc of the meridian orthogonal to the Equator and the ecliptic, [drawn] and as great as that whatever it be: it was easy to gather the arc of this imaginary ecliptic from the doctrine of triangles, [as] nearer to the Sun, and [nearer to] the proper section of the ecliptic with the Equator, and thereby the place of the Sun in this ecliptic.

The *fifth* thing noted is that the Sun makes several daily revolutions about the Equator, the highest of which is toward the northern part of the ecliptic, and lower toward the southern — at least insofar as we have astronomical observations made from Babylon; and several [revolutions] were made some [years] from the Vernal Equinox to the Summer Solstice, sometimes more from the Summer Solstice to the Autumnal Equinox; from which, and from the diverse declination — of which [we spoke] in the *second* [motion] — we have concluded that the Sun is moved unequally, since the equal semicircles, or the quadrants of the ecliptic, are seen [to be traversed] in unequal times.

Sixth, it has been noted that the Sun is not seen at the same time of the year [to have] the same determination toward the Earth, [but rather] with the same declination of the Equator, perpetually. For although Ptolemy [Ptolemaeus] found the Sun at its Apogee in northern declination, by degrees 21°35' as he himself computed; in [the sign of] Gemini at degree 5°30': in which [position] it had been found by Hipparchus [Hipparcho]; therefore [the Apogee] is not without [some] motion, [though] mutation seemed to ascribe some [motion] to the Sun's Apogee;

afterward, however, it has been observed that, by the longer course of time, the Sun's Apogee, however [slowly] moved, appears near the maximum declination — this is near the beginning of Cancer. Hence the motion of the Apogee is investigated in Astronomy, nevertheless.

The *seventh* point, at last, has been found: that in the whole ecliptic, [and] at one time, the Sun is in that semicircle of the ecliptic which, from the Apogee...

4. That all these Apparent [motions] can be saved by a single spiral motion of the Sun itself, we do not doubt; as will appear from the following schematic diagrams, [if we suppose] that the beginning of this systematic [motion] is taken from about the year 1157, when the place of the Apogee was at the beginning of Cancer.

Diagram. A cylindrical/barrel-shaped solid figure, drawn in oblique projection, representing the celestial sphere with the Sun's spiral diurnal paths. The top and bottom are bounded by ellipses (representing the tropic circles or daily-motion circles seen obliquely); a vertical axis runs through the center C. Diagonal lines cross the interior, connecting the lettered points on the rim, and a dense series of near-vertical lines represents the successive spiral turns of the Sun between the tropics.

- A (top center): pole / north point of the figure
- B (bottom center): south point of the figure
- C (interior center): the Earth's center
- D (left middle): west end of the horizon DE
- E (right middle): east end of the horizon DE
- F, G (upper left / upper right of the rim): endpoints of the solar arc FAG near the top
- H, I (lower left / lower right of the rim): endpoints near the bottom
- K, L, M, N (interior, near center): points marking the cone segments and spiral construction
- Q, R (lower rim region): the common base QR of the cones
- Additional small lettered points (b, c, d, e, etc.) [?] mark intermediate spiral positions; several of these are too fine to resolve [?]

[Margin: *Expositio Motus Spiralis Solis*. (Exposition of the Sun's Spiral Motion.)]

5. Let AB be the diameter of the whole solar heaven, which at the same time represents the plane of the Equator; and through the Earth's center C let the Horizon DE be drawn — straight for [the case of] a sphere, as we here

exhibit it, but oblique for another Horizon. From the center C, moreover, let the portion of the Solar Meridian FAG be described, as great as the distance of the Tropics, bisected at A — where the beginning of Aries is, and to which is equal the arc of the Mid-night [Medinoctii] HBI, in the middle of which is the beginning of Libra; the beginning of Cancer, indeed, is at F and I; the beginning of Capricorn at F and H [?], and let two other points be drawn through C, [and] two other solar diameters of the heaven HCG and ICF. Then, on the Diameter AB, let there be set off on this side BR, and on that side AQ, equal to half [the diameter], or to the bisected solar eccentricity; the summit of which on the diameter FI is fH, and on the diameter HG is HS, equal to the whole solar eccentricity; and let GQ and Qh, above, and IR and atq; [?] RS, below, be drawn. In this same plane of the Meridian they will represent the sides of two truncated Cones, about which the Sun, having [its] Apogee at the beginning of Cancer, describes its diurnal spirals; and of which the common base is QR. But the longer segment of the Cone will be QRIG, the shorter QRHF. For if QG and RI be produced, [and] joined, the summit [vertex] would meet with the Axis of the Equator, and would be a longer cone than if they were directed concurrently with the same Axis [as] the sides Qh and RS.

6. Let the Sun's Apogee now be at the beginning of Cancer G, distant from the Earth's center C by the whole interval CG; and there let the Tropical Year begin to be described, [the Sun] describing its diurnal spirals from the larger segment of the cone — at first narrower, then broader, until they reach the Equator and the base QR, just as the maximum diurnal difference of the Sun's Declination at that time will then require: for it will then be at its mean distance from the Earth CQ, or CR, by the sole half-eccentricity AQ, or BR. Then let the Sun proceed, describing toward the South, [drawing] its daily spi...

-rals, narrower indeed near the Tropic of Cancer, [drawing] a shorter cone near the Equator; broader, indeed, near the Tropic of Cancer, and [the spirals] reach from QR in Sh, but a shorter [interval] of the cone segment, [drawing] fewer spirals crowded together, by which it accomplishes this segment in about eight days more quickly than the northern cone segment; for when it has reached the Tropic of Capricorn, its spiral Sh will be at the Perigee, and will be distant from the Earth's center by the smallest interval Ch, or CS — which, set forth above as CF, [is] as great as CG; that distance will be as great as the whole solar eccentricity Fh, which is as great an interval as the whole eccentricity of the Sun is in another hypothesis. And so, by this means, two motions of the Sun are saved: in *Longitude*

by the diurnal spirals; in *Latitude* by the intervals of the spirals, equal to the differences of the Sun's Declinations, with the unequal number of days which it effects more in the northern segment than in the southern, just as the Sun's Theory requires — since the Sun's Apogee is in the northern segment, as it has hitherto been for many ages; indeed, in nearly everyone's opinion (according to our own), its Apogee was at the beginning of the world at the beginning of Aries. Finally, the *Prosthaphaereses* — namely, of the distances of the Sun, with the Sun differing in this spiral motion — are saved with their eccentricity; the Sun does not look back toward the Earth's center, but toward the Axis common to the cones, [namely] toward the Equator's axis, and toward the sides of the cone, or of the Scalene cone inclined to the Equator.

7. It is necessary now to reconcile the Sun's diurnal motion from east to west with the motion in titubation [motus titubationis], and the apparent [motion] toward the east, and [the motion] equipollent to the motion hitherto supposed in the ecliptic. Let this be done thoroughly easily. For let the Sun, [at] Apogee at the beginning of Cancer G, and so [at] the beginning of the Tropical Year, [be the one] whose first day [is] from the Meridian: let the half-spiral GEI descend from the Meridian G to the West E, and thence to the Lowest [point] of the heaven I, whence the Fixed star arrives at the Meridian, [but] not until after 24 Hours of the Primum Mobile, [or] nearly four horary minutes [later]; it accomplishes the remainder of the spiral KL to the Meridian; and again from L it descends to M, [and] there ascends to the point N; at which moment the same Fixed star that was at the Meridian when the Sun was distant by the interval NO, [the Sun] then reaches O; thence it descends at P, and thence ascends at Q; at which moment the aforesaid Fixed star is at the Meridian; the remainder of the meridian being accomplished, [the Sun] descends at T, and thence ascends at V, and at the moment when it is there, the Fixed star obtains the Meridian; this being accomplished, VX; [the Sun] descends from X to Y, and thence to Z; and thence comes to *a*, and thence to *b*, and a little [further] to *c*, and to *d*, and thence to *e*, [and] reaches [the point], and thence to *f*, and thence to Q, and so on. Thus, through the points designated in CG, it becomes daily an Easterly [riser], so that, after three months, it rises in C, when the Fixed star is at the Meridian.
8. But that we were forewarned, for the sake of the few spirals which we have here drawn — to be avoided for the sake of confusion — that [the Sun] traverses about 188 [spirals] in these segments of the cone, and the

remainder, 177, in about the segment of the Northern Cone, [and] the rest of the Southern Cone.

8 [bis]. But it must be reminded, on account of the cause, that the Sun, when it has its Apogee at the beginning of Cancer, [describes] many more daily spirals about the Northern segment of the cone than about the Southern; namely, because the side GQ is longer than Qh; and since it has come in *h* at the Perigee, [it being] now distant from the center of the Earth C, [the Sun] appears under the beginning of Capricorn F — even though it has not reached FH, which is the Tropic of Capricorn.

9. But the Sun, obtaining the Apogee at the Beginning of Aries — as we suppose it to have been at the beginning of the world — is inspected in figure 2. In this figure, the arcs of the Sun's maximum declination are described in each [direction], as in the prior Figure, [drawn] from the semidiameters of the solar heaven bisected: namely AQ, BR, GK, FO, IL, HS. But that the whole Eccentricities may become equal — AM, BN, Fh, HS — then draw the straight lines AK, AO, [making] these as it were parallels MK, Mh, and likewise BL, BP, NL, NP, and at last RI, and RS. For four segments of cones will be born, [each in] the same number, [their] bases held in the plane of the Equator. The first segment of the larger cone is ABKL, about which the Sun, beginning the Equinoctial year, was driving its spirals from A, descending through T, [to] the west at V, and thence ascending to *a*, at which moment the Fixed star, which had been with it in the Meridian the day before, returns to the same Meridian; thence...

Diagram. A second cylindrical/barrel-shaped figure (figure 2), similar in construction to the first but with the Apogee placed at the beginning of Aries. The top and bottom are bounded by ellipses; a central vertical axis passes through C. Numerous near-vertical lines fill the interior, representing the dense bundle of the Sun's diurnal spirals. Diagonal construction lines connect the lettered rim points, defining the four cone segments described in the text.

- A (top): pole / summit
- B (bottom): base point
- C (interior center): the Earth's center
- D (left middle): west point
- E (right middle): east point
- F, G (upper rim, left / right): endpoints of the upper solar arc
- H, I (lower rim, left / right): endpoints of the lower solar arc

- K, L, M, N, O, P (interior): points defining the four cone segments (ABKL, etc.)
 - Q, R, S (rim/interior): construction points for the eccentricity offsets
 - Lowercase interior points (a, b, c, d, e, f, etc.) [?] mark intermediate spiral positions; several are too fine to resolve [?]
10. Since the segments of the cones were Equal, [each] greater between itself and [the others], the side AK [is equal] to the side AO, just as the side MK [is equal] to the side Mh, etc.; and therefore [it traverses them] in an equal number of days, both [segments], [and] it draws an equal number of spirals; nor does it tarry longer in the Northern part than in the Southern. But the Cone [is] then greater, [for] it was [drawing] spirals of a lesser base, than [when] the greater cone of the prior figure [was drawn], but of a shorter axis; contrariwise, [it draws] truly a lesser cone of this figure, but of a longer base, than the lesser cone of the prior figure, but of a longer axis.
11. From that time, moreover, at which the Sun's Apogee was at the beginning of Cancer, it began year by year to draw [its] spirals little by little nearer to the Equator, and the Tropics nearer the longer [paths]; until at last the side AK would arrive at the side QG. Therefore, by [this] transition from one side into another — that is, into QG, that is by [drawing] shorter spirals, and by a longer circuit — the ratio of its mutations can be rendered, [namely the ratio] which the Sun, observing [it] at the Apogee, traversed in the Arc FAG, or HBI.
12. Much must be added to this Theory, [things] to be pursued by diligent Astronomers; nor indeed have we wished to leave [unwritten] the Tables of the Sun's Motions, by which we are accustomed to represent the Equations, to themselves [be made] easier to represent through the Ecliptic in spheres, Armillaries, and Globes — we wished to transfer them into other Tables; nor are we able to bring [them] forth from nature in such a way that we may seem to wish [it], otherwise it is impossible, [namely] to reduce the Geometric Calculation of the Sun's Motions to those apparent [motions] — having first composed the Mean Motion of declination, and to inquire the true [motion] through the angle of the true declination, and the distance from the place...

the place of the apogee considered on the meridian arc, just as also of the interval of the Sun and of the Earth, would most easily be found from the true declinations, given the angle at C. From these data I am content to communicate to the reader four cases, in which, namely, the apogee of the Sun lies in one or

other of the four cardinal points — that is, at the beginning of Aries, or of Libra, of Cancer, or of Capricorn — and to assign to each its own cones.

I. Case for the Apogee at the beginning of ♈ (Aries)

[Margin: 13]

Look at Figure 2, in which there are four segments of cones. The first is ABLK, about which the Sun spirals from the beginning of Aries up to the beginning of Libra; its angle, that is, at the base, is CAK and CBL; the sides are CK, $75^{\circ} 52' 22''$, and the side AK, as also BL, is 41128 parts of the kind in which CK, the mean distance of the Sun, is 100000. For CK, like AC, the distance of the Sun's apogee, is 101740, since the maximum solar declination, by the angle ACG, is for me $23^{\circ} 30' 20''$, as I proved by the laws of trigonometry, which I gave; and for this segment the Sun descends from the apogee A to the mean distance at G.

The second segment of the cone is from MNKL, about which the Sun carries out its spirals in descending from the mean distance CL, which it has at L, the beginning of Cancer, up to the perigee CN, which it has at the beginning of Libra. The angles at the base CMK and CNL are individually $80^{\circ} 39' 54''$ of the kind in which CK is 100000; and the sides MK and NL are 40532 parts of the kind in which CK is 100000. The perigee distance CM, or CN, is 98260, for this is proven from the given data, and the maximum declination is given as the angle MCK, as above.

The third segment of the cone is from MNPO, of altogether the same magnitude and the same parts; its angle at the base — about which and about whose segment is the second, about which the Sun spirals — is for the Sun ascending from the perigee to the mean distance once more, that is, at the beginning of Capricorn.

The fourth segment is ABPO, altogether equal to that under Lateral A, and its angle at the base is the same as that of the first segment, about which the Sun spirals, returning from the mean distance to the apogee.

II. Case for the Apogee at the beginning of ♎ (Libra)

[Margin: 14]

In this case too the Sun spirals about four segments of cones, designated already in the first case and of the same magnitude, but in a different order. For the first segment is what in the first case was the fourth, namely ABPO, in which it descends from the apogee B to the mean distance, or beginning of Capricorn. The

second is what in the first case was the third, namely MNPO, in which the Sun's mean distance descends from the perigee, that is, the beginning of Aries M. The third is what in the first case was the second, namely MNLK, in which the Sun ascends from the perigee to the mean distance — that is, from the beginning of Aries to the beginning of Cancer. The fourth is what in the first case was the first, namely ABKL, in which it ascends from the mean distance to the apogee — that is, from the beginning of Cancer to the beginning of Libra.

III. Case for the Apogee at the beginning of ♋ (Cancer)

[Margin: 15]

For this case, and for the fourth, look at the previous figure, in which there are two cones of two segments. The first is QRIG, about which the Sun spirals, twisting, in descending from the apogee Q, or the beginning of Cancer, to the mean distance at R, which it has at the beginning of Libra; then returning to the mean distance Q, the beginning of Cancer at the apogee, the angles at the base, namely CQG and CRI, are $80^{\circ} 37' 18''$; and the side QG, as also RI, is individually 41200 parts of the kind in which CQ is 100000. And CG, 101740, is the distance of the apogee; the maximum solar declination as the angle QCG is $23^{\circ} 30' 20''$.

The second segment is QRSh, about which the Sun spirals, twisting around in descending from the mean distance, that is, from the beginning of Libra R, to the perigee S, below the beginning of Capricorn; and again, from the perigee h, the beginning of Capricorn, to the mean distance in Q, the beginning of Aries. The angles at the base, however, are CQh and CRS.

individually they are $76^{\circ} 49' 46''$, and the side Qh, and RS, of 40245 parts of the kind in which CQ is 100000, and Ch is 98160 — the angle of declination being set down at its maximum, QCh, as $23^{\circ} 30' 20''$.

IV. Case for the Apogee at the beginning of ♑ (Capricorn)

[Margin: 16]

In the same figure two cones of segments in pairs are to be considered, just as in the first case, of the same magnitude and quantity, but in a different order. For the greater segment, which was Boreal [northern], ought now to be Austral [southern]; and so this Sun spirals, just as from the beginning of Capricorn at apogee; F, from the beginning of Aries at mean distance Q; and so from the beginning of Libra at R, or the other mean distance, to the beginning of Capricorn at apogee H; and so spiraling from the beginning of Aries at mean distance,

descending indeed from the beginning of Aries at mean distance, and from the perigee at the beginning of Capricorn G; whereas ascending from the perigee, the beginning of Capricorn; and ascending from the perigee to the mean distance at the beginning of Libra.

For the Other Cases

[Margin: 17]

For the other cases, in which the Sun's apogee is outside the cardinal points, there is need of four different segments of cones, whose figures and quantities, as the more skilled astronomers can conceive and design, we will help with a single example in the following schema; in which let the diameter of the equator itself be represented, the equator representing ACB, the Earth; the center C, from which the two meridians of the Sun's supreme apogee are drawn on either side; that is, let the meridian portion FAG and HBI be described, of as great a distance as is...

Diagram. A large, dense geometric construction occupying the lower half of the right column. It depicts a barrel-shaped / hour-glass solid (the truncated-cone "spiral" figure) inscribed within a tall many-sided outline, with the Earth's center C at the middle and zodiacal-sign symbols marking the cardinal points around the periphery. Crosshatched conical bands run between the upper and lower rims. The construction is heavily lettered with point-labels; many are small and partly obscured by the dense ruling. Readable labels, by approximate position:

- A (top center): vertex / apogee point, marked with ♈ (Aries) nearby
- K, M, O (upper row, left of A): rim points of the upper cone
- F (upper left, outer): meridian endpoint, with X just below it
- G (upper right, outer): meridian endpoint, with ♋ (Cancer) and S nearby
- N, L (upper region, right): rim points
- C (center): the center of the Earth / common center
- V (left, mid-lower): rim point, with ☉ [Sun symbol] nearby
- D (right, mid-lower): rim point [?]
- R (right, mid-lower): rim point, with ♑ (Capricorn)/♊ nearby
- P (lower center): point with asterisk-mark, with ♎ (Libra) nearby [?]
- H (lower left): meridian endpoint
- I (lower right): meridian endpoint
- E (bottom center-left): base point, with ♎/♏ symbol [?]
- B (bottom center): base point of the lower cone

- T (lower right) [?]

[: this geometric construction carries dense crosshatching and numerous small point-letters; several labels (D, P, E-region zodiac symbols, T) could not be resolved with confidence — more than 2 labels flagged.]

The tropics, to whose extremities FIC and HCG are drawn. Let the Sun's apogee now be at D, at 15° of Taurus; and so the perigee at E, at 15° of Scorpio; for the mean distance under Aquarius will be at 15° K, and under Leo at 15° L. Therefore let the straight lines DCE and KCL be drawn, on both sides; let DQ, PN, KM, and LR be cut off, equal in both, and bisected at the eccentricity DQ — that is, at the beginning of Capricorn at 1740 parts of the kind in which CQ, CM, CP, and CR are 100000; for these are drawn straight, MD, MN, NL, LB, the segment-beginnings of the cone MNLD; about which the Sun spirals, ascending from Aquarius at 15°, to 15° of Taurus. The absences from the upper KO and EP, of 3480 parts, by how much is the whole solar eccentricity, and by the drawn lines OQ, OP, PR, RQ, you will have the cone of the segment OPRQ, about which it is turned at 15° of Leo and 15° of Scorpio; the segment DSTR serves the Sun at 15° of Taurus to 15° of Leo, and the segment XMPV, when from 15° of Scorpio it ascends to 15° of Aquarius. But SG and TI, the lesser eccentricity...

LIBER I. / DE SOLE. — page 69 (folio 69r)

the eccentricity bisected, that is, 1740 parts, and FX, and HV, greater, but in its entirety less than the eccentricity, in proportion roughly to the distance from the place of the apogee and from the place of the mean distance.

[Margin: 18]

[Margin: Occurritur obiectioni — "An objection is met."]

You will say that this designation of the cones and their segments, by its very perplexity, renders improbable this theory. I reply that no less perplex is the variety of cones which you must wish for, if you desire to retain the Keplerian ellipse: for, on account of the changes of the apogee, you would want to keep the Sun always in the same ellipse and in the plane of the ecliptic, and yet — the apogee, or aphelion, being changed underneath it — it is impossible that it be the same ellipse of the same cone; rather, there must be either many cones, or as many ellipses as there are dispositions of the Sun's apogee. And besides, the diurnal motion from the east cannot be reconciled with its own proper motion toward the east.

CAPUT XIX.

Conclusions concerning the certainty hitherto acquired, or to be hoped for hereafter, regarding the Sun's Motion, Intervals, and Quantities; and the Theory and Practice of the Tables.

This indeed is what astronomers expected from us with such eagerness, and to whose knowledge the two prior volumes of our *Almagestum Novum* [*Almagestum Novum*], and the *Idea of the Whole Work*, promised they would come. What, then, our endeavors have been able to conclude — as it were, in the marrow — by way of a brief synopsis concerning the Sun's properties, must be briefly indicated.

I. Conclusion concerning the Equinoctial, or Tropical, Year.

The true quantity of the equinoctial year, beyond 365 days and 5 hours most certainly, does not have more minutes of the hour than 56', nor fewer than 42'. Yet for me the truest quantity of all is this:

D. 365. Hor. 5. 48'. 48". 0"". Sidereal: D. 365. Hor. 6. 9. 21. 42.

The earlier part is clear from the opinions of astronomers adduced in Book 3 of the *Almagestum Novum*, chapter 15, if you reject the outworn opinions of certain of the ancients; the later part is clear from what is to be said here in chapter 4, and a third thing from what is to be said in Book 4, chapter 19.

II. Conclusion concerning the Mean, or Equal, Diurnal and Annual Motion of the Sun.

The mean, or equal, daily motion of the Sun is most certainly of 59' and 8" of seconds, and besides not more than 20''' of thirds, nor fewer than 19''' , as is clear from Book 3 of the *Almagestum Novum*, chapter 17, from Ptolemy exclusively up to this point; but from what is said here in chapter 4, the truest of all the diurnal and annual is as follows:

	Sign.	Gr.	I	II	III	IIII	V	VI
Diurnus (daily)	0	0	59	8	19	48	35	35
Annuus (annual)	11	29	45	40	30	56	5	1

III. Conclusion concerning the Motion of the Sun's Apogee.

The annual motion of the solar apogee, from the consideration of more recent astronomers (adduced in Book 3 of the *Almagestum Novum*, chapter 25), is not

more than 1' 4"; from the consideration of seconds, not less than 45"; but from what is said here in chapter 9, it is most probably below 1' 2" 4''' 4''''.

IV. Conclusion concerning the Apparent Diameter of the Sun.

The apparent diameter of the Sun at apogee does not exceed 34', nor fall short of 29'; but at perigee it does not exceed 36', nor fall short of 30', as is clear from what is said in Book 3 of the *Almagestum Novum*, chapter 10; but from the most accurate observations had at the Great Gnomon of San Petronio [the Bolognese gnomon], the apparent diameter is most truly such as either D. Giovanni Domenico Cassini [Giovanni Domenico Cassini], or we ourselves, elicited from them, as below from what is said in chapter 12:

☉ Diam.	In Apogeo (at apogee) ' "	In media dist. (at mean dist.) ' "	In Perigeo (at perigee) ' "
Cassino	31	8 31	4 32
[Cassini]			0
Nobis (us)	31	0 31	4 32
			2

V. Conclusion concerning the Bisection of the Eccentricity.

The eccentricity of the center of the Sun's orbit from the center of the Earth is half the eccentricity of the center of the equal motions of the Sun. For if we use the eccentricity which we deduce by geometrical necessity from the difference of the apparent diameter of the Sun at the distances of apogee, mean, and perigee, and accordingly inquire into the prosthaphaereses [prosthaphaereses] owed to the mean motion of the Sun, so as to obtain the true place of the Sun agreeing with the observations exactly, the owed prosthaphaereses are found to be double too small; nor can the true quantity of such prosthaphaereses be found unless an eccentricity double too large is assumed. And so the center, about which the Sun is imagined to move equally, or to be moved, is removed twice as far from the center of the Sun's orbit as the center of the orbit is removed from the center of the Earth — see what is said in chapter 12.

VI. Conclusion concerning the Quantity of the Sun's Eccentricity.

The total eccentricity owed to the equations of the Sun's motion does not change, but is the same in every age, as we have more probably taught in Book 3 of the *Almagestum Novum*, chapter 26; it is not more than 3800 parts, nor less than 3200 parts, of the kind in which the radius of the Sun's orbit is 100000, from what is

said in Book 3 of the *Almagestum Novum*, chapter 24. But from the difference of the Sun's apparent diameter at a threefold distance from the Earth, and from the equations of the Sun's motion, no eccentricity satisfies the apparent motion of the Sun more than ours, of which above in chapters 10, 11, and 12, and it is of this sort:

Qualium Radius est 100000. (Of the kind in which the radius is 100000.)

Excentricitas Solis (Sun's eccentricity)	Tota (total)	Bissecta (bisected)
Nobis (us)	3480	1740

From this, indeed, it comes about that the Sun, about its own center too, is moved unequally, by half the inequality, by which the true place of the Sun differs from the mean.

VII. Conclusion concerning the Figure of the Sun's Orbit, or its Path.

Although the bisection of the eccentricity has indicated three points in the Sun's orbit, or notable centers, at equal intervals distant from each other — namely the center of the Earth, the center of the Sun's orbit, and the center of the Sun's equal motions — and although it would seem to be an indication that it is an ellipse, in whose periphery the Sun moves (since in an ellipse too there are three points unequally distant among themselves, namely the center of itself, and the two foci, or umbilici, from which all the radii drawn out to either of the foci in the cavity of the ellipse are emitted, and from there reflected): and although it is well-nigh near enough to the truth that, by such a path, by a geometrical method, the prosthaphaereses owed to the Sun's motion can be found, as is clear from the theory demonstrated in chapter 11, and from examples in the prior Table of observed solar places, and supported by this path — nevertheless, no necessity demonstrates the elliptical path of the Sun. First, because, although an ellipse by its very nature requires three points, yet these three points can be found in a circle too, if not by their nature, then mathematically considered; physically considered, however — if indeed in it there be those three places at least, about which the Sun moves equally indeed...

LIBER I. / DE SOLE. — page 70 (folio 70r)

about one [center]; unequally about the center of the Earth, and unequally about the center of its own orbit. Secondly, because, by our eccentricity and the

equations established in a circle, we represent the apparent motions of the Sun no less — indeed for the most part more — than the owed motions are more exactly represented, as is plainly clear from the Table of chapter 15, of book 2. Thirdly, because not only is the Sun demonstrated to move in an ellipse rather than in a circle, but neither manner is demonstrable, save the diurnal motion from the east to the west, which is owed to the Sun both by Divine Scripture and by the real increase of impetus, as by the percussions of heavy bodies from another quarter, and save the fluidity of the celestial heaven of the planets; and with the eccentrics and epicycles of the solid orbs rejected as multiplicities — indeed, the divine motion of the planets from the east to the west can scarcely otherwise be reconciled, when they appear from the west to the east, than by the diurnal motion from the east to the west, the spiral [motion], and the slower motion of the prime movable [Primum Mobile], or of the fixed stars. Which motion I have shown to be neither absurd nor outside the geometrical laws, in chapters 16 and 17.

VIII. Conclusion concerning the Cause of the Two Eccentricities of the Sun.

The cause of the Sun's total eccentricity, not improbable, is the very great Terrestrial shadow, so that in that aethereal region the center is first beheld as visible, from which the Sun's uniform motion begins, in which at first the eye, raised from the Earth, begins to perceive the Sun perpetually, without any interruption of night. The cause of the bisection of the Lunar shadow, on the other hand, is to be guarded against — since the first quantity of it should exceed, the first the first too, of the Sun's halved uniformity. If indeed the foundations on which they rest can be placed, the cause of the predicted shadows is a quantity analogous to the said eccentricities, as I taught in chapter 16, at number 6.

IX. Conclusion concerning the Maximum Declination of the Sun, or the Obliquity of the Ecliptic.

The maximum declination of the Sun from the equator, or the obliquity of the ecliptic, has not been the same from the time of Eratosthenes up to now, as I showed in Book 3 of the *Almagestum Novum*, chapter 27, and once in Book 3 of the *Almagestum Novum*; nor does it exceed 23 degrees, nor — by exacter observations — fall short of 23 by more than 4 minutes; the truest of all observations agrees at 23° 30' 20", nor is 23° 30' 30" improbable, from what is said in the same chapter 6.

X. Conclusion concerning the Sun's Distance from the Earth, and the Horizontal Parallax.

The Sun's minimum distance from the center of the Earth, even, is not supposed by ignored parallaxes, as up to now, down to Tycho [Tycho Brahe]; and it was supposed by Tycho himself; but from our Dichotomies of the Moon [the *dichotomia* observations], thereafter astronomers are not asked, but it is not less than sixteen thousand semidiameters of the Earth, nor is the maximum greater than sixteen thousand semidiameters of the Earth, as may be gathered from what is said in Book 3 of the *Almagestum Novum*, chapter 7, and its Appendix at the end of the first volume adjoined. Two distances, however, before the others, are to me very probable. The first is that which we chose in the *Almagestum Novum*, Book 3, chapter 7, and which we touched on above in chapter 13: that it is not less, we confirmed in chapter 14, at number 39. By the new Method of Parallax, through the refractions of the fixed stars inquired into, the maximum is not greater than 30", by which the mean distance from the Sun is at second by 7300; that one is bisected, now, and our new eccentricity 1740, of the kind in which the Radius is 100000. It ought to be that the maximum distance be the terrestrial semidiameters 7427, and the minimum 7173. The latter is that which agrees with the attempted Hypothesis of the Solar eccentricity and of the terrestrial shadow, and of the Lunar — prolix indeed, but owed to the eccentricities and shadows, as we have indicated in Conclusion VIII and expounded in chapters 16 and 17, at number 6, where we adduced reasons, although such [things] this Hypothesis requires — that the Sun's distance at the apogee be the terrestrial semidiameters 6666, and so, by the recent eccentricity, the perigee 6438. The mean, 6552, terrestrial semidiameters.

Hence follows that the Horizontal Parallax of the Sun is indeed never greater than 30" of seconds, or 31"; but is nevertheless perceptible, nor — where the most subtle [reckoning] is in question — to be altogether neglected, as some do. Let, then, the aforesaid distances, with their Horizontal Parallaxes, be set before one's eyes:

XI. Conclusion concerning the True Magnitude of the Sun, the Earth's Shadow, and the Angle of the Cone of that same Shadow.

Since the Sun's distance from the Earth is uncertain, and since we know it to be not smaller than 6000 terrestrial semidiameters — and indeed by much — it is probable that it does not exceed 7500. Even if it be more certain what the quantity of the Sun's apparent diameter is, yet it cannot certainly be established for us about the true magnitude of the diameter, as [it can] about the rest of the quantities from the diameter that follow. Taking, therefore, as a foundation the Sun's diameter apparent at 31' in the apogee, and the minimum tolerable apogeeal distance 6000, and the maximum 7500 — but at the more probable 7427 and 6666 — from what was just said, there follow the quantities written below, among which is the Angle of the Cone of the terrestrial Shadow; and as great as is the Arc

of the Terrestrial great circle, which the Sun illuminates by unrefracted rays, beyond 180 degrees.

XII. Conclusion concerning the Hoped-for Progress of Astronomy.

Although our most recent Tables represent the observed place of the Sun by very great Instruments — of the kind that is the recent Gnomon in the Temple of San Petronio of Bologna — they often, short of one or two minutes, represent the error of differences; from which we gather that, when the error exceeds two or three minutes, the error is rather to be in the observations, which suffer little

physical alterations, since the Geometrical Tables cohere among themselves, nor can they at the same degree of Anomaly exhibit now the true, now the false; and from this it may be suspected that Tables are never better, or more certain, to be hoped for from any later [astronomers], than those which are diligently established from the observations: they do not ever differ from one another by a single minute. When nevertheless I consider how much in this age astronomers have advanced by observing, by meditating — by how much, God being immortal, these little obscure [errors] indulge me — and the diminution proceeds in us for a tiny one, and unanimously granted that it serves to expedite, since astronomers do not cease from observing, and from contemplating the Heaven; that as new...

[continued from the preceding page — the closing exhortation of Caput XIX]

and so we may afterward acquire finer subtleties, either to confirm what has so far been found, or to correct it, or finally so that, in the very Creator, our Wonder, Admiration, and Love may be drawn from things so hidden and from the profound Harmony of the Celestial Motions and of their intervals — these things and their like leading us on, to His Praise and to the Greater Glory of His who Understands All things Human, and that we should direct all our wonder and all our work to Him.

I. APPENDIX

To Caput XII

On the Apparent Diameter of the Sun, against an Objection raised by Most Learned and Most Friendly Men

Whether, and how much, should be subtracted from — or added to — the visible disk of the Sun [speciebus Solis] and the shadow of the Moon, when light is admitted through an aperture of perceptible size, so that one may obtain the correct magnitude not only of the Apparent Diameter of the Sun and its proportion to the Lunar Diameter, but also of a Solar Eclipse, whether expressed in Digits or in Scruples of one degree?

An occasion for this question was lately given by two Fathers of our Society, most distinguished French Mathematicians — who indeed cast some doubt on, or rather asserted against, certain conclusions transmitted to us by R. P. Bernardino Bohillo [Bernardino Bohillo], a member of the same Society and most skilled in Mathematics, against what was said in the *Almagestum Novum* (Book V, Cap. 15,

nums. 4, 5, and 6). For from Kepler's [Johannes Kepler] teaching these doctrines had been drawn — namely, that from the semidiameter of the luminous disk of the solar image there should be subtracted the semidiameter of the Aperture; and that, by the same token, the sagitta of the Moon's shadow should be added, so as to obtain the correct magnitude of the Eclipse in Digits, and so forth. To these objections we have been able to give a ready reply, since some of the points — points which, doubtless, we ourselves knew — required no profound treatment in Geometry, but rather only the integrity of this doctrine for the sake of others, into whose hands this little lucubration of ours may come. Meanwhile, we owe the greatest thanks to those who gave us occasion for this, for inquiring somewhat more deeply into matters not to be despised, and for placing in a clearer light a truth once recognized.

I. Supposition

If two straight lines are Parallel, and differ by an imperceptible amount, then two further lines which join them at the same parts are likewise parallel to one another, and equal, without perceptible difference.

For Euclid (Book I, Elements, prop. 33) demonstrates this simply concerning parallels and equals in geometric rigor; it holds also for things equal to the perception, for inferring equality to the perception, and parallelism to the perception.

II. Supposition

Two straight lines are equal without perceptible difference when the one does not exceed the other by more than a three-hundredth part of one ounce [uncia] of the Roman Foot.

By the Roman Foot I understand here the kind and magnitude that I set out, following Villalpando [Juan Bautista Villalpando], in the *Almagestum Novum* (Book II, Cap. 7). And I have more than once tested, together with P. Grimaldi [Francesco Maria Grimaldi], on a flat and well-polished plate of orichalcum, on a most finely drawn parallelogram and on the rectangle ABCD, of which the side AB, like CD, equals one ounce of the Roman foot; and AC, likewise BD, equals two Roman feet severally. The diagonal AD, moreover, divided into 300 equal particles. If a most fine silken thread OH be stretched across — the kind that can be drawn out most finely from a silkworm's cocoon — it will cover one whole particle of those three hundred. From which we conclude that this is the smallest difference that the human eye can plainly discern; for even the ounce divided by the Diagonal AD would yield a far longer division into 3000 particles. Yet the

aforesaid thread would obscure the said particle by its own slight thickness; and of the three-thousandth parts, and to seek a greater fineness still — and a much greater one — is to depart from the edge of any Ruler, whose straightness is never so evident as that of the aforesaid stretched thread.

Diagram. A rectangle with corners labelled A (top left), B (top right), C (bottom left), D (bottom right). The top side AB carries a midpoint O; the bottom side CD carries a midpoint H. A vertical line OH joins the two midpoints. The solid diagonal runs from A (top left) down to D (bottom right); a second solid line runs from B (top right) down to C (bottom left), the two crossing at the centre. A dashed line runs from C (bottom left) up toward B (top right), representing the silken thread OH stretched along the diagonal.

- D (bottom right corner)

III. Supposition

The Semidiameter of the Earth is not less than 3,500,000 Geometric paces, nor is the distance of the Moon from the Earth at the syzygies less than 50 terrestrial semidiameters, that is, 175,000,000 paces. Nor is the distance of the Sun from the Earth less than 1,105 terrestrial semidiameters, that is, 3,867,500,000 paces.

The first is established from the measures of the Geometers reported in the *Almagestum Novum* (Book II, Cap. 7). Suppose now, from our own more recent observations exhibited in the *Geographia Reformata*, it be taken as certain that the semidiameter of the Earth is not less than 4,673,000 Roman paces. The second is established from the observations of the Astronomers adduced in the *Almagestum Novum* (Book IV, Cap. 14). The third, finally, is established from the relayed opinion of the Astronomers in the *Almagestum Novum* (Book III, Cap. 7) — although, from the Dichotomies of the Moon, we now hold it certain that the distance of the Sun at Perigee is not less than 5,000 terrestrial semidiameters.

I. Proposition

Two Rays propagated from the same point of the Sun, or of the Moon, to the Earth, and comprehended by a semidiameter of the Aperture not exceeding 10

Roman paces — if produced further — are, to the perception, parallel within an interval no greater than 21,486 paces for Solar rays, or $972\frac{1}{2}$ for Lunar rays.

In the first of the Figures exhibited at the end, let the Sun or Moon be A; let the Rays and their least distance from the Earth be AB and AC, comprehended by the semidiameter of the Aperture BC, which does not exceed 10 paces; and let them be produced to H, K, and so on. Up to the base HK, parallel to that same BC, and since they diverge Geometrically, let HK be greater than BC; let CL be drawn from C, a straight line parallel to the straight line AH. I say that if the interval CL is no greater than $972\frac{1}{2}$ paces — for Lunar rays — but no greater than 21,486 paces for Solar rays, then the Solar rays within that interval, that is BH and CK, are to the perception parallel, indeed equal to one another to the perception. For HK, parallel to BC itself, does not exceed it except by the particle LK, no greater than the three-hundredth part of an Ounce of the Roman Foot — which is the minimal difference evidently perceptible by Supposition II. Therefore HK and BC, within that interval, are equal to the perception, and so by Supposition I, BH and CH are parallel, and equal to one another to the perception. The antecedent is proved, because the triangle AHK is cut by LC proportionally (by Elements VI, props. 4 and 6); and as BC is to AB, so is HK to AH, and LK to LC. Now since BC is 10 paces to the Solar distance AB, namely 3,867,500,000 paces (by Supposition III), then LK, being the three-hundredth of a Roman ounce of the foot — the difference of length perceptible to the senses — is to LC as 1,289,166, that is $107,430\frac{1}{2}$ feet, or 21,486 paces. Then, since BC is 10 paces to the Lunar distance AB, namely 175,000,000 paces, so LK, the three-hundredth of an ounce, is to the ounces 58,333; that is, 4,861 feet, or $972\frac{1}{2}$ paces.

[p. 72 — top of column]

So much the more certainly, therefore, will the rays be parallel and equal to one another, by every test of perception, throughout an interval still greater than the one stated, if both the Distance of the Luminary is greater and the semidiameter of the aperture BC is smaller than 10 paces. We ourselves, certainly here at Bologna, having used observations of this kind with the Great Gnomon of the Temple of S. Petronio [San Petronio] — whose perpendicular interval from the aperture to the pavement does not exceed 100 Roman feet, and is about 90 — used an aperture of nearly one ounce only.

Corollary

On Parallelism preserved through an imperceptible Angle

From what has been said I gather a method, which I have used along with Nonius [Pedro Nunes / Nonius], Snell [Willebrord Snell], and others, for demonstrating the parallelism of the Physical rays ABH and ACK — a parallelism which holds only in relation to the interval CL, in which, namely, the equality both of the lines BH and CK, and of the lines BC and KH, is preserved, as is doubtless usually preserved within instruments treatable by Astronomers. For from the distance of the Luminaries, and from the narrowness of the semi-aperture BC, it is easy to show that the Angle A does not exceed one Third of a Scruple, which is commonly reckoned imperceptible. And so the straight line BC, falling upon the straight lines AB and AC, and making with them the internal Angles ABC and ACB equal to the perception to two right angles, and not falling short of the sum of two right angles except by the angle A, at most by one Third — seems to make the rays AB and AC parallel to the perception (by Elements I, prop. 29). But this is not absolutely valid, except within the aforesaid interval. For while the Angle A remains at one Third, and so the sum of the Angles at any base BC or KH reaches $179^{\circ} 59' 59'' 59'''$, the Rays AH and AK can nevertheless proceed in such a way that, at the base KH, the divergence becomes perceptible, indeed very great. As in the example of the Lunar Rays, with BC remaining at 10 paces — if the interval CL of $972 \frac{1}{2}$ paces be multiplied by 300, there result 291,750 paces by which LK exceeds BC, namely of one Roman Ounce; and if again CL be drawn out 12 times, there result 3,500 [paces] — that is, produced almost as far as the centre of the Earth — then the excess over BC of one Roman foot will remain, and so the physical parallelism will not remain. Which it was worth pointing out.

II. Proposition

Given the Base of the whole disk of the Sun, received through an Aperture of imperceptible quantity in a plane equidistant from the plane of the Aperture, and given the Distance of these planes: there is given the apparent Diameter which would appear to the eye placed at the location of the Aperture.

I said "of the whole disk" — that is, terminated by the outermost rays of the Sun — because, if it could be reflected through such an aperture and could move the eye of the observer, that is, perceptibly move it. For in reality these rays would be so faint that they could not evidently represent the outermost part of the whole disk of the Sun, as has been found by experiment. Yet, these things being granted, let it be so in Figure II. Let the plane AB be, say, a white Tablet, to which the plane

ED is equidistant, in which there is the imperceptible aperture H; through the plane AB let the outermost Rays of the Sun FB and GA strike, intersecting in H and at H; let HT be drawn to AB, perpendicular, making the right Angle HTB, and HTA likewise right: for in a Triangle, since each is supposed right HTB, with the sides HT (the distance of the planes) and BT (half of the disk of the Sun) given, the half of the disk of the Sun will be given by the Canons of Triangles, the angle right. The Angle THB, the half of the whole AHB, which by Elements I, prop. 15 is equal to the Angle FHG, under which the eye, placed at the aperture H, would see the whole portion of the Sun visible from there, or the apparent Diameter of the Sun.

But because in this way we cannot in reality obtain such a Diameter, therefore among other methods we use chiefly the disk of the Sun admitted through an aperture of perceptible quantity, so that that disk may evidently move the perception by the multitude of its rays — provided that the Aperture, and its distance from the plane that receives the disk, be of congruent quantity, and apt to represent the disk of the Sun.

III. Proposition

Given the Base of the disk of the Sun admitted through an Aperture of known and congruent quantity, in a plane likewise equidistant from the aperture and at a known distance — the disk being as whole as it can be when well disposed, and the application being able evidently to distinguish the disk from the shadow that terminates it: there is given the Apparent Diameter of the Sun, equal to that which appears to the eye placed at the location of the Aperture, without evidently demonstrable difference.

[Margin: Objection.]

Now the Aperture and the distance of the planes ought to be so commensurate in quantity that the aperture be less than the true Diameter of the Sun, indeed less by 10 paces (according to the said Proposition I). But so that the disk of the Sun received through it may evidently be larger than the aperture, and that the splendour from the dusty air, or from the dark channel, or from the reflexes of the enclosure, may not confound the boundaries of light and shadow that terminate the disk of the Sun — and yet so that the aperture be not so small, nor the distance so vast, that, by the scarcity and weakness of the rays, an evident discrimination between the disk and the shadow that bounds it be obscured: Therefore, as for us, we have generally used an aperture not exceeding two Roman Ounces of the foot, and more often a smaller one, of 15 — sometimes a

larger one, indeed of 30, 40, and so on. In the Gnomon of the Temple of S. Petronio, however, the least distance of the pavement on which we receive the disk of the Sun is about 100 Roman feet, and the aperture about one Ounce — that is, of 100 such parts of which the perpendicular distance is 100,000. With these premises, let it be as in Fig. II. Let the Aperture be OP, whose centre is CT, and from which, drawn perpendicular to the plane of the disk AB, is comprehended by the outermost Rays of the Sun FB and GA, tangent to the alternate edges of the aperture, and intersecting one another beyond the aperture in H. Let it be understood, moreover, that from the right-hand limb of the Sun, the radius FB is propagated to the centre C, the other Radius, whose portion is CL, will be from the same point of the Sun radiating into the surface; for it will be CL by Proposition I. The parallel, to the perception, to FB itself, and the semidiameter of the Aperture CP, equal to the perception, rightly to LB. The Angle CP given, the remaining angle of the half-disk TB will be cut off; and since the noted T is at L, the whole distance CT will then be the angle TCL; and thence the whole KCL, equal to the perception under which the eye is constituted at C, would be seen to subtend the Sun itself, and its apparent Diameter.

But that the Apparent Diameter of the Sun, investigated by this method, is equal to that which is seen by direct gaze at C — this either certain friends of ours deny or call into doubt, on the ground that the Rays of the outermost Sun, evidently and more strongly, move the perceptive eye, directly to view the Sun at C, than from the same point of the Sun they radiate into the surface of the white Tablet, and from there, through the aperture into the Eye — that is, through innumerable rays which, by the benefit of refractions, are diminished in number, and as it were with a brush paint into the Retina of the eye, and as if with a pencil sketch in it that very intense disk of the Sun, as is known to the skilled among the more recent Opticians. But the Rays FB and GA, tangent to the aperture, being singular, are so faint that they cannot move the perception, and so cannot evidently represent the outermost extremity of the Solar disk; but, if through a sufficient number of rays the outermost part of the Sun were represented, the disk would be whole. Since therefore it appears smaller than it ought, while along the straight line TB the whole CP, or LB, is subtracted, being too greatly subtracted, and something is added elsewhere — and so, through the remaining TL, a smaller-than-just, smaller too — the Angle TCL, and a smaller Diameter of the Sun is acquired than ought to be, and than is seen from C.

[Margin: Reply.]

I reply: for that very reason we did not, in the proposition, require a disk so whole as a well-disposed and evidently discerned eye can manage — knowing nonetheless that some small part of the Sun's disk is not discerned, for the reason adduced; because nevertheless, in Geometric rigor, BL is larger than CP, and is to be subtracted, there is some small compensation; nor moreover can that little part of the latent disk, or imperceptible, be so great that the Diameter of the Sun may be found per se perceptibly smaller than the one seen from C — whence we gather that, by other means, by direct gaze, capturing the Diameter of the Sun — namely, through a disk captured at the same moment by two instruments, and by observers measuring the altitude of the lowest edge of the Sun from the one, and of the highest from the other, or by numbering with a pendulum by means of time, in which the Disk of the Sun on the Equinoctial days passes between two most fine threads in a [continued]

[p. 73 — top of column]

plane extended in the meridian plane — we have very often obtained as great a Solar Diameter as we very often obtained by reflected gaze through the aforesaid disk, and sometimes indeed a slightly larger one, but not rarely a slightly smaller one. From which we conclude that the apparent diameter of the Sun obtained by direct observation cannot be evidently demonstrated to be larger than the one received through the aperture-disk, and so forth, we conclude. Therefore this subtlety is useless for practice, and Astronomers labour in vain to insist upon it, and it exceeds all human perception, and the diligence of all. For it is enough for them to obtain as great a Diameter as suffices for solving and representing the Celestial phenomena, to men dwelling on the earth.

IV. Proposition

Given what was found in Proposition III, there is given the Apparent Diameter to the eye placed at the point of intersection of the Rays comprehending the disk of the Sun, both from the plane that receives the disk and from the centre of the perceptible aperture.

Persisting in Figure II, since by Proposition III the angle TCL is given, and the parallels are to the perception HB and CL, applied by Proposition I secondly, therefore the said angle is equal to the internal and opposite THB (by Elements I, prop. 29). Hence the whole Angle AHB is given, bisected, as we had before, the segment perpendicular HT. This is moreover equal to the angle FHG, under which, at the point of intersection H, the Diameter of the Sun would be seen. Then in the Triangle HTB, right-angled at T, given the angle THB and the opposite side,

that is the half-disk of the Sun TB, the other side of the Trigonometry HT is given, and the distance of the point H from the plane AD, from which, if the previously given CT be subtracted, there remains the distance of the points CH.

V. Proposition

The distance of the point of intersection of the Rays comprehending the disk of the Sun, through a perceptible aperture admitted from the centre of the aperture — if the semidiameter of the aperture is subdouble to the half-disk, it is equal to the distance of the aperture from the base of the disk; but smaller, if smaller than half the disk; greater, if greater.

In the same Figure II, since CP, the semidiameter of the aperture, is parallel to the base TB, in the triangle HTB it issues by Elements VI, prop. 2. HT, of the same proportions as HC, of which CP is to TB. Therefore if TB is double CP, then HT will likewise be double HC; but if more than double to CP, HT will be more than double to HC; if double HC, smaller than CT. By contrast, if TB is less than double CP, HT will likewise be less than double HC, and so HC is greater than CT.

Yet it is the custom, in the Instruments of Astronomers, to assume a distance CH smaller than CT. As an example, in the great Gnomon of S. Petronio, where we assume CT of 100,000 such parts of which the semi-aperture CP is the same 100, and the semidiameter of the apparent Sun near Perigee, that is the angle TCL, of 16 minutes. Inasmuch as we obtained, in observing there — for by force of Trigonometry the half-disk of the Sun is manifestly corrected TL, of such parts $465 \frac{4}{9}$; therefore CP being added, 100, that is equal to the perception LB, the side TB becomes $565 \frac{4}{9}$ parts; with which, and with the angle THB, likewise of 16 minutes, the whole TH is gathered, 121,500 parts. But TC is about 100 Roman feet. Therefore the whole TH is $121 \frac{1}{2}$ feet, and the distance of the points CH $21 \frac{1}{2}$ feet.

VI. Proposition

The Apparent Diameter of the Sun, found through the whole disk of the Sun by a perceptible aperture, is false, and perceptibly larger than that Diameter which appears to the eye gazing directly at the Sun from the location of the aperture.

Let there be drawn, from the centre C of the aperture, to the whole of the Solar disk the outermost straight lines CA and CB; for the angle ACB will be made larger than the angle LCK, which is the measure of the apparent diameter of the Sun to the eye C (by Propositions II and III). But since the aperture OP is perceptible, and by Proposition I...

[continued]

[p. 73 — right column]

the half CP is equal to the straight line LB, the half; and OG equal to the straight line AK, perceptibly too; the whole disk AB exceeds the corrected disk KL by the excess. Let no one suppose that this difference in the Sun consists of seconds of scruples; let the example of the preceding Proposition be resumed, in which we showed, from the semidiameter of the Sun near Perigee of 16 minutes, and the distance CT of 100,000 parts, and the semi-aperture CP, that is LB, of 100 parts, that the whole half-disk TB follows, of $565 \frac{4}{9}$ parts. Hence, since by CT, of 100,000 parts, by the laws of Triangles, the angle TCB follows, of 19 minutes 26 seconds; and the whole angle ACB, of 38 minutes 52 seconds — enormously larger is that Diameter of the Sun, which is also found through the corrected disk KL, and by observing the Sun directly from C.

VII. Proposition

To capture and measure the disk of the Sun and the shadow of the Moon, apt for ascertaining the quantity of a Partial Solar Eclipse.

Into a long tube, of black or blue colour within — apt for beating back the reflexion of the rays — let there be inserted a plate roundly perforated with an aperture not exceeding one Ounce of the foot, to which, on the other side, let there be fixed a beam supporting a well-polished and white little tablet, equidistant from the plate of the aperture, and in it let a point be marked, which is in the same straight line in which is the axis of the tube and the centre of the aperture. Then, on the day on which a Solar Eclipse is to be, the plate being exposed outside the little window of the tube on that side in which the aperture is, and the enclosure being well obscured, so that no ray of light can penetrate from any aperture or chink except through the aperture of the plate, let the tube be turned with its whole aperture toward the Sun, until the centre of the disk of the Sun coincides to the perception with the point marked on the white tablet. Then, three points being firmly held on the tablet, let three points be noted on the periphery of the disk of the Sun, so that through them the centre may be found by Elements I, prop. 3. Or at once, from a point noted as above, let an interval be taken up to the periphery of the disk of the Sun, and with that interval let a circle be described, and its diameter divided into 12 equal parts, but let one at least of these be subdivided into smallest equal particles, say 100, or 50, and so on. As the Diameter of the aperture is not, as before, or after, the Diameter of the aperture. But, the Eclipse begun, let the tube be moved so that the centre of the said circle,

and the luminous disk of the Sun, coincide; and where the luminous part of the periphery of the circle first agrees with the periphery of the disk, and where first the Eclipse is established, the quantity of the Eclipse will have grown at the top, and no more grow; let the interval be noted, both of the Shadow, and of the periphery of the luminous disk of the Sun in the diameter of the circle bisecting the Shadow. As to how great this interval is, let it learn, that one being carried by the circle into the Diameter, as above divided into parts, and particles. It is expedient also at once, at the top of the Eclipse, to note three points on the periphery of the Lunar Shadow itself, two indeed in the common intersections of the two peripheries — the Shadowy, namely, and the luminous; the Third, however, at will, by Elements I, prop. 3. So that the centre of the circle of the Shadow may be found to agree, and thence how great a part of the diameter of the luminous disk has been obscured by the Lunar Shadow.

As in Figure III: if two points B and C be noted, at which the periphery of the luminous disk ABC and the periphery of the Lunar Shadow GBC mutually cut one another, and besides, let the point H be noted; and through these let the centre F of the Shadowy circle be found, and through it let the Diameter GH be drawn, continued with the diameter AI; you will easily be able to measure with a compass the absolute Eclipse, and the arc BIC now detected — how great a part has been overshadowed, HI — comparatively to the whole Diameter AI, and to the part AH itself, which was free from the Shadow. And so indeed, if the Solar Eclipse be partial, it will not be Annular.

But if it be Annular — that is, in which, around the Moon at the top of the Eclipse, there appears of the Sun's Disk a certain Corona, or a luminous ring round about — there will also appear, within the circle of the Sun's disk, the whole circle of the Lunar Shadow, sometimes equally on every side, distant from the periphery of the luminous, as in Figure IV; and when the Eclipse is Central — that is, when in the same straight line are the centres of the Luminaries, and the eye of the spectator — and then it suffices to take with a compass the interval of the peripheries wherever you please, as small as possible...

[Continuation of Proposition VII, from the foot of the previous page:] suppose AB is the smallest. Sometimes, however, the portions of the periphery will be unequally distant from one another, as in Figure IV. In that case one must take two intervals, the largest CD and the smallest FG — unless FG happens to coincide, in which case the largest, CD, suffices by itself. Then, with these intervals transferred by a compass above the diameter of the solar image, let the ratio of the shadowed diameter to the unshadowed be established.

VIII. PROPOSITIO.

In an annular solar eclipse, especially a central one — given the proportion of the images of the Sun and of the lunar shadow that are admitted through an insensible aperture — the true magnitude of the eclipse is given in digits, or even in scruples, of the kind that the apparent diameter of either luminary is reckoned at; and thence the apparent diameter of the other luminary [is given].

Here we call upon Figure V, with the explanation set out there for the first case — the case of an indivisible (or nearly indivisible) aperture, supposing it possible for the case, even though in actual practice it is impossible. With these things laid down, the proposition is demonstrated through its parts.

First, in triangle AGH the angle GAH — which subtends the base GH of the lunar shadow, in the position represented by the visual disc of the Moon as CD — is, by Proposition 15 of Book I of the *Elements*, equal to the angle EAF, which subtends the apparent diameter of the Moon CD; and is equal to the part of the Sun cut off by it [the Moon], EF. Therefore, by however much the eye A, turned toward the reflected image, sees the shadow GH, by that much, turned toward the Moon, it sees the Moon, and estimates the part of the Sun cut off by it — even though it does not yet know how great it is. Similarly, in triangle LAM, the angle LAM, which subtends the image LM, [is equal to] the obscured part of LM, by the portion GH, and the remainder LG and HM; and from this the bright [parts] follow. The angle [LAM] is equal to the angle IAK, of which the part IK, cut off by EF, is obstructed by the Moon, and the remainder IE and FK appear luminous; and by however much the eye A, directly contemplating the Sun, [sees them], by so much, turned downward in the opposite sense, the residue of the bright image LG and HM appears — because, since IM and KL intersect one another at A, the rays not tangent to the Moon, and likewise the rays EH and FG that are tangent to it, [form] equal angles: namely IAE and HAM are equal to one another, just as also FAK and GAL [are equal] to one another. Therefore, if (as is commonly the case) the Sun is reckoned as a foot across, and 12 unciae or digits, then its apparent [diameter] is estimated in such parts, in which parts also the eclipsed portion of it — and not the un-eclipsed portion — is measured (the observation, on which see Proposition VII), let the shadow GH be noted against the whole LM. In another kind of parts, say in hundredths of an uncia of the Roman foot, let the whole LM be made; as GH is to the whole LM, so let so many hundredths to 12 digits, [yield] so many hundredths; so GH yields so many hundredths to the obscured digits, [and] there come out so many digits, which are obscured, [and] as many as are

truly covered by the Moon, [when] hidden from the eye A directly contemplating the eclipse.

Second, if the apparent diameter of either [luminary] be given in scruples of one degree — for example, if the diameter of the Moon be given, and its measure the angle CAD, 28' — and by the foregoing discourse let the part of the Sun covered by the Moon be found to be $10\frac{1}{3}$ digits, of the kind that the whole visual disc of the Sun is estimated at 12; if it be made that as $10\frac{1}{3}$ is to 12, so 28' to another, there come out 32' for the apparent diameter of the Sun; and so of the rest.

IX. PROPOSITIO.

Given the apparent diameters of the luminaries to the eye placed at an indivisible — or nearly indivisible — aperture, set up, and the distance of the aperture from the Table that receives the images of the Sun and of the lunar shadow; the magnitude is given, and the apparent proportion to the observer of an annular — especially a central — solar eclipse.

Supposing, as above, the explanation of Figure V: First, in triangle AGH, the apparent lunar diameter being given — that is, the angle CAD — its supplement GAH is given. Therefore, the perpendicular AB being drawn, its half BAH is given; and the distance AB [being given], in right-angled triangle ABH, right-angled at B: therefore, the distance AB being given, BH is given, the half of the image of the shadow, that is, the radius of the shadow GH, in parts of the kind that AB is noted in. Likewise, [continued below]

the apparent diameter of the Sun being given — that is, the angle IAK — its supplement LAM, and this too bisected by the perpendicular AB, [gives] the angle BAM; in triangle BAM, right-angled at B, the distance AB being given, BM is therefore given, the half of the solar image, of which the portion BH is shadowed, but the remainder HM is bright. Therefore LM and HM, and the proportion both of the whole composite LM to GH, and of the bright parts LG and HM to the shadowed parts GH.

Exemplum postea non semel adhibendum. [An example to be used more than once hereafter.]

Let the apparent diameter of the Sun at perigee be 32', and its semidiameter — that is, the angle BAM — 16'. Let the Moon at apogee be 28' in diameter, and its semidiameter 14' — that is, the angle BAH. Let the distance of the equidistant planes AB be 100000 parts, such as we use in the gnomon of San Petronio. For in triangle ABM, by trigonometrical necessity, BM is found to be $465\frac{4}{9}$ parts, and

therefore the whole LM, of such parts, $930 \frac{3}{4}$. But in triangle BAH, BH is found to be $407 \frac{27}{107}$ parts, and therefore the whole shadowed part [is] $814 \frac{1}{2}$; and hence the bright parts LG and HM aggregate to $116 \frac{3}{10}$.

X. PROPOSITIO.

In an annular solar eclipse, the proportion of the images of the Sun and of the lunar shadow admitted through a sensible aperture is not the same as the proportion that would be admitted through an insensible aperture; and therefore, the true magnitude of the eclipse cannot be taken through it [the sensible aperture] as it [the magnitude] is to be received from the Table, but much smaller than it appears to the eye placed at the position of the aperture.

Kepler had asserted this very thing universally, concerning solar eclipses, in his *Astronomia Optica* [Kepler, *Astronomia Optica*] (cap. 2, Proposition X), saying: *In a deficient image, or ray, of the Sun let in through a round window, the horned [crescent] form, not legitimately let in, appears in the heavens as sharp, but on the obscuring little screen appears blunted.* And at Proposition XI, where he says: *The diameter of the Moon in images of this kind appears greater than outside in the heavens.* And at Proposition XII, where he says: *The digits of a solar eclipse appear fewer in the image than in the heavens.* And he not only demonstrated this, but at cap. 11 also taught the manner of avoiding these fallacies, at Problem 6 ad 13; and at Proposition 7, he plainly states that, however minute the aperture be, always the proportion of the apparent diameters changes, and the eclipse appears smaller; and at the same place, that the digits appear fewer, and so forth. But this, as if otherwise suspected of geometry — not only suspected, but plainly false — those two Fathers pronounced; and unless they understood it and read it in our Proposition V, examining the truth of Kepler's and our propositions, [let them attend to it]. Be it so that Kepler did not descend to that particular case of annular eclipses, and especially central ones — he left the rest to be set forth by us in due order of doctrine, and with greater clarity of cause.

For let it be supposed, whether possible or not, but imaginable nonetheless, that the images of the species be admitted through the indivisible aperture A: in Figure V, the image of the lunar shadow is the whole GH; but, the aperture being relaxed [enlarged] to NO, the rays of the Sun touching the Moon, and the margins of the aperture being tangent — namely by the rays PCNQ and RDOS — there issues from the aperture the lunar shadow image SQ. Because the remaining shadow of the prior [image], that is, the part QH let in through the indivisible aperture A, is illuminated by the rays issuing from the segment of the solar disc, segment EP; and the part GS, by [those] issuing from segment RF. Now since the

rays of the Sun PQ and RS touch the Moon at the same physical points CD, at which the rays EH and FG had touched it — and therefore, descending from the same point of contact toward the space on the earth QH, and thence GS — because, as is supposed, this [aperture] is here less than half an Italian mile, and so by Proposition I they are parallel to the senses; and therefore the semidiameter of the aperture AN is equal to the physically equidistant plane's portion QH, and the semidiameter AO to the portion GS — there manifestly follows the lunar image GH let in through the aperture, both [margins] being obliterated, and it contracts; by as much as the semidiameter of the aperture is, and altogether by as much as the whole diameter of the aperture NO is.
[continued]

On the contrary, the composite image of the Sun, [composed] of the part of itself shadowed, and the part bright, let in through the indivisible aperture, is the sole [image] LM. But the aperture being relaxed [enlarged], the [shadow] TV issues, [tangent] to the same physical points IK, descending to illuminate the parts MV and TL — all those rays which can enter through the semi-aperture AO, and through the semi-aperture AN; and because MV and TL are supposed, in the customary planes of observation, less than half an Italian mile, and therefore by Proposition I parallel to the senses; and therefore they are equal among themselves, AO and MV, just as AN and LT: it follows that the composite image of the Sun is increased on both sides, beyond the prior LM, by as much an increment as the semidiameter of the aperture is, [and] the whole by as much as the diameter of the aperture is. With these things laid down, the argument is thus reduced to form.

[Margin: *Argumēt. in forma.* — The argument in form.]

Of whatsoever two quantities equal before, if one only is decreased by as much as the other increases, the same proportion of them is not preserved as was before. But in the case proposed, the images of the lunar shadow, and of the Sun let in through the indivisible aperture, were unequal among themselves; [and] through the sensible aperture the lunar [image] is decreased by as much as the solar [image] is increased. Therefore the same proportion of them is not preserved as before. The major [premise] is plain from the doctrine of proportions handed down by Euclid (Book 5, *Elements*) and Cardano [Cardano] and others. For in order that it be continued, or that the same proportion of two unequal quantities be preserved, both must either be increased in the same proportion, or be diminished, or, if they were equal, both increased, or both diminished equally — not, however, one diminished, the other increased. The minor [premise] has already been proved,

and shown, that the lunar shadow image decreases by as much as the solar image increases; that is, by the whole quantity of the diameter of the aperture. Therefore, [the conclusion stands].

Although, however, in an annular eclipse, but not a central one, the situation of the lunar shadow is different from that which Figure V represents — namely, with the Moon at the height of the eclipse declining to the left part, the shadow falling in the middle toward B, with the disc of the Sun lying more to the right, on the right-hand part of the Table, the solar image will descend toward the left, where the image of the Sun on the right-hand part of the Table appears greater than on the left — yet the compensation is such that the whole increase of the solar image on both sides, aggregated, is as great as the diameter of the aperture is, and by so much is the decrease of the lunar shadow image.

Furthermore, with the proportion of the images not remaining the same, it is certain that the true magnitude of the eclipse cannot be obtained in digits, much less the true proportion of the diameters in scruples, if either image be employed as incorrect; and as is plain in the Table of observations. For from what has been said in Proposition VIII, the true [magnitude] is that which is deduced from the proportion of the images of the indivisible aperture, and cannot be obtained through the sensible aperture in the proportion as the true [magnitude] is obtained. Which will also be made plain by an example.

Exemplum pro praxi. [An example for practice.]

Persisting in the example of Proposition IX — the Sun, [and] the diameter of perigee 32'; the Moon, however, at perigee 28': it is certain that in such a central solar eclipse, [the Sun] is obscured by the Moon by 32' minus 28', and twice as much from here, the same; that is, simultaneously 4 [parts] are left immune from the eclipse; this being laid down, as there, the aperture, by the distance from the Table of 100000 parts, the necessary composite solar image LM came out, of such parts, $930\frac{4}{5}$; and the lunar shadow [image], of parts, $874\frac{1}{2}$; let the aperture NO now be relaxed [enlarged], of parts, 200, of the kind that AB is 100000. For as we showed in the proof of this Proposition, the whole quantity of the aperture is increased, the solar image, and the whole quantity is diminished from the lunar shadow image: therefore, 200 being added, the whole TV becomes, of parts, $1130\frac{4}{5}$; and 200 being subtracted from the shadow, the residue SQ becomes, of parts, $614\frac{1}{2}$. Let the observer make use of those images of such parts, as they appear in the Table; so that as $1130\frac{4}{5}$ is to 12 digits, so $614\frac{1}{2}$ to a fourth proportional number, and there come out only $6\frac{59}{113}$ digits, when there ought to be $10\frac{1}{3}$ digits — since, as 32' [is to] the solar scruples of the diameter, so 12 to

28' obscured, [yield] $10\frac{1}{3}$ digits. Hence, if anyone should observe the solar eclipse from A, he would clearly see [the Sun] not standing out [un-eclipsed] from the eclipse, [continued]

of the Sun's disc except by $1\frac{1}{3}$ digit from here and $1\frac{1}{3}$ thence. But another observer, observing the same eclipse on the Table, and the computation made from the proportion of the images, just as he took it, without any correction, would pronounce that the eclipsed [parts] were no more than 6, or about $\frac{2}{3}$; and that the Sun, in the obscured [phase], appeared at the nearest 3 digits from here and as many thence. And so, perhaps disputing with one another, the one would accuse the other of hallucination; meanwhile, before the direct observer, perhaps the estimation of the geometry of these untaught subtleties would labor, which the observer at the Table would profess, and would have the workmanship of astronomers held in ridicule.

XI. PROPOSITIO.

In an annular solar eclipse, especially a central one — the quantity of the sensible aperture being given in parts of the kind that the quantity of the images let in through such an aperture is noted in — the quantity of the images is to be subtracted from the aperture, to be taken away from the solar image, and to be added to the lunar shadow image, so that the true magnitude of the eclipse, and the true proportion of the images and of the diameters of the luminaries, may be had as analogous.

For, the aforesaid correction of the case of Proposition XI being made, it is reduced to the case of Propositions VIII and IX — that is, to the case of the indivisible aperture, in which there it is shown that the true magnitude of the eclipse is had, and the proportion of the diameters, and so forth. But if it be done otherwise, [it is] absurd, [and] it gathers the quantities, and so forth. But because someone could doubt, and it might not suffice to correct one of the two only, [the matter] is to be reduced; [and] because we have set out an example above according to four modes, which can be imagined, [and] put into practice. These things being laid down: the diameters of the Sun being 32' and of the Moon 28'; and therefore the eclipse [being] of 28' minutes, or $10\frac{1}{3}$ digits, of the kind that the diameter of the Sun is estimated at 12; and the diameter of the aperture being put at 200 parts, of the kind that the distance of the planes is 100000: there come out the images of the Sun and of the lunar shadow, both corrected, as prescribed above, [and] both incorrect, as in the following little table:

Species	Solis part.	Vmbræ Lunar.
<i>Incorrecta</i>	TV 1130 $\frac{4}{5}$	SQ 614 $\frac{1}{2}$
<i>Correcta</i>	LM 930 $\frac{4}{5}$	GH 814 $\frac{1}{2}$

A fourfold proportion can be set up — namely, of the corrected Sun to the corrected shadow; of the corrected Sun to the incorrect shadow; of the incorrect Sun to the incorrect shadow; and of the incorrect Sun to the corrected shadow. Thus 12 digits to the eclipsed digits, and there come out the digits, as in the table written below:

Speciebus	Vt partes	Ad partes	Sic Digniti	Ad Dig. Eclips.
<i>Incorrectis</i>	TV 1130 $\frac{4}{5}$	SQ 614 $\frac{1}{2}$	12	6 59/113
<i>Correcta Solis</i>	LM 930 $\frac{4}{5}$	SQ 614 $\frac{1}{2}$	12	7 86/93
<i>Correcta Vmbra</i>	TV 1130 $\frac{4}{5}$	GH 814 $\frac{1}{2}$	12	8 73/113
<i>Correcta Vtraq;</i>	LM 930 $\frac{4}{5}$	GH 814 $\frac{1}{2}$	12	10 $\frac{1}{2}$

parts / to [those] parts; "Sic Digniti" = so the digits; "Ad Dig. Eclips." = to the eclipsed digits. Note: the table's last-column result for both-corrected reads 10 $\frac{1}{2}$ on the page, whereas the prose of Props XI and the close of this section give the true eclipse as 10 $\frac{1}{3}$ digits — the two are transcribed as printed.]

It is therefore established that the correction can be made here in no other way than that prescribed by us in the Proposition; and that those err the worst of all who contend that neither image is to be corrected, since thereby one departs furthest from the true magnitude of the eclipse — which in such a case is necessarily 10 $\frac{1}{3}$ digits.

XII. PROPOSITIO.

A solar eclipse can appear annular to the eye intent upon the image of the Sun and of the lunar shadow projected onto the Table through a sensible aperture, which nevertheless appears not annular — indeed not even partial — but total to the eye directly observing the eclipse from the position of the aperture, provided the aperture be notably greater than the aperture of the said eye.

I do not describe a figure peculiar to this case; Figure V can serve our case, adapted [to it]. For let the whole disc of the Sun be not, as there, IK, but EF, from whose extremities E and F the rays tangent to the Moon run into the pupil, or aperture A of the eye; for the whole Sun, covered by the Moon, will appear under the angle EAF. But the aperture being placed, [continued]

aperture NO, notably greater than the aperture A of the pupil, [the rays] will be able to enter at the sides from the segments of the Sun EP and FR — rays not tangent to the Moon physically at CD, but either avoiding all contact with it, or in others more remote from C and D, intersecting, [so that] the outermost are PNQ and ROS — so that the lunar shadow appears as great as SQ is, shining around in the parts QH and GS; nor does it subtend the angle GAH, equal to the angle EAF, under which the eye A sees the whole Sun obscured; but only the angle SXQ; yet it must be that the aperture before the eye be very large, if the angle SXQ ought to be sensibly different from the angle GAH, and the parts GS and QH sensibly illuminated.

XIII. PROPOSITIO.

In a partial — but not annular — solar eclipse, given the proportion of the images of the Sun and of the lunar shadow let in through an indivisible aperture, the true magnitude of the eclipse is given in digits, or even in scruples, of the kind that the apparent diameter of the Sun is noted in.

For the truth of this Proposition, three figures are to be inspected — namely VI, for an eclipse of precisely 6 digits; and VII, for an eclipse less than 6 digits; and VIII, for one greater than 6 digits. These being well understood, the proportion asserted in the Proposition is easily understood. First, then, before any eclipse, the solar image FD is supposed observed, let in through the indivisible aperture A, and measured. Then the Moon, going in from the left part of the figure, [continued]

up to the contact of the rays BHG, is brought under the eye, and to the indivisible aperture A, [from] the disc of the Sun. The segment of the lunar shadow CG, and in the Table the segment BD appears shadowed, the other [segment] FB being illuminated by the rays of segment GE; and the same uncovered segment which the eye sees under the angle GAE, to which is equal the angle BAF measuring the bright part BF, just as the angle CAG, under which the eye A sees the part of the Sun obscured, or cut off by the Moon, is equal to the angle BAD measuring the obscured part BD. Therefore the eye A, turned toward the Table LM, [estimates] the eclipse by reflected sight as great as, turned toward the heavens, [it estimates] by direct sight. Therefore, if it be done that, as the whole FD — the composite image — [is] noted in some measure, say in hundredths of particles of an uncia of the Roman foot, to 12 digits, so BD, noted in the same kind of particles of the [image], to another [number]: there will come out as many digits as are eclipsed, [as] the observer of the eclipse from A, contemplating the heavens, estimates. But if the solar diameter be noted in scruples of a degree, multiplying by the particles

of the uncia of the composite solar image, BD, and dividing the product by the scruple of the whole solar diameter, there come out the scruples of the Sun eclipsed by the Moon. For Figure VII, attend to the line to be applied, AB; [and] for VI and VIII, GB is applied, and so forth.

XIV. PROPOSITIO.

In a partial solar eclipse, although not annular — the proportion of the images of the Sun and of the lunar shadow let in through a sensible aperture is not the same as [the proportion] let in through an indivisible aperture; and therefore, the true magnitude of the eclipse cannot be obtained through it [the sensible aperture] in digits, much less in scruples of a degree, as appears in the Table.

The Figures VI, VII, and VIII are again to be reconsidered, and the exposition added there — for, that being well perceived, the truth of this Proposition will plainly be established. The aperture, then, being relaxed [enlarged] — let it be IK — and before the eclipse, the entrances of the extreme solar rays CKM and EIL, the solar image is then the whole bright LM, which is to be measured according to the said Proposition VII. The Moon coming afterward, according to the parallax of latitude and the contact of the rays OHKP, at the height of the eclipse, the lunar image comes out PM, permuting [shifting] its position, but not [its] quantity; for as much of the space as it loses at B, in P, [continued]

is the whole LP, when in the case of the indivisible aperture it would be only FB; but it is LF, on account of the parallelism of the rays EAF and EIL, equal in the sense [to] the semi-aperture AI; and so to the part BP, it is destitute of shadow. Therefore the whole image LP, which remains bright, grows beyond the bright FB; the whole quantity of the aperture being composed of LF and BP; for the remaining segment DM does not increase the bright image, as bright in the eclipse, since it is occupied by the situation of the shifting shadow. With these things laid down as manifest, the argument is thus formed.

Of whatsoever two quantities equal before, one remains formally unchanged, or remains equivalently [unchanged], because as much grows on one part as is decreased on the other; the other, however, becomes absolutely greater than itself, [and so] the same proportion of them does not remain as they had before. But in a partial solar eclipse, although not annular — the images let in through the sensible aperture, the lunar shadow image remains unchanged, equivalently, because as much as it loses of the space uncovered on one part, by as much does it occupy on the other; whether in the case of the indivisible aperture it were equal to the bright portion of the solar image, as in an eclipse of 6 digits; or smaller, as in an eclipse of

fewer than 6 digits; or greater, as in an eclipse of more than 6 digits. On the contrary, the bright portion of the solar image always comes out greater than itself, as in the case of the indivisible aperture. Therefore the images of the Sun and of the lunar shadow let in through the sensible aperture are not the same proportion as [that] let in through the indivisible aperture. The major [premise] is plain from the Doctrine of Proportions, evidently deduced from first principles, or definitions. The minor [premise] is proved by the very exposition of Figures VI, VII, and VIII discoursed upon; super [upon] this fact, [it is] virtually extended through all the possible cases of partial solar eclipses.

The proportion not remaining the same, however, but varied, through it [the sensible aperture] the quantity of the eclipse cannot be obtained, [the quantity] which would be obtained through the proportion of the images of the indivisible aperture. But through this [indivisible aperture] the true quantity of the eclipse is obtained by Proposition XIII. Therefore through the other [the sensible aperture] it is not obtained as true.

XV. PROPOSITIO.

In partial — but not annular — solar eclipses: the quantity of the sensible aperture being given, and of the images of the Sun and of the lunar shadow let in through it; the true quantity of the eclipse is to be obtained — the whole image of the Sun composed [of the part bright and the part shadowed] being subtracted from one part, and the whole quantity of the aperture obscured [subtracted]; but the lunar shadow image is to have the semidiameter of the aperture subtracted from one part, and added to the other; that is, in Arithmetic, nothing is to be added or subtracted.

The reason is, that this case is to be reduced to the case of the indivisible aperture, through which the true quantity of the eclipse is had by the said Proposition XIII; and without which [it] is not had, as by the said Proposition XIV. It is reduced, however, if what we said in this Proposition be done; as, by the induction made through the three kinds of eclipses represented in the three Figures VI, VII, and VIII, and by the said joint Propositions XIII and XIV, [is] plain; and is briefly indicated again. For since the image of the Sun, in the case of the indivisible aperture, is composed of the part bright and the part shadowed, [it is] FD; and in the case of the sensible aperture, it is LM, greater than FD, by the parts LF and DM; if their aggregate of the aperture IK be taken away, the image LM is reduced to the indivisible image of the aperture FD. But because the lunar shadow image, in the case of the indivisible aperture, is BD, and in the case of the sensible aperture is PM, increased as much by DM as it is diminished by BP; if

from the shadow PM there be taken DM, equal to the semi-aperture AK, and to the same be added BP, equal to the same AK, the shadow is reduced again to BD, which is likewise [the same], as if to BD itself, from first to last in the arithmetical reckoning, nothing be added nor taken away anything.

XVI. PROPOSITIO.

Given the apparent diameter of the Sun and of the Moon in scruples of one degree, and the diameter of the sensible aperture in parts of the kind that the distance of the aperture from the plane that receives the images is noted in; and given, finally, the quantity of the eclipse not [yet] observed: the quantity of the lunar shadow image is given,

[Margin: of the Moon, and of the Sun, in those parts whose mark is the aforesaid Distance.]

If from astronomical tables or from an ephemeris you have learned in advance the magnitude of a past or future partial solar eclipse, then using Figure II, and with the apparent semidiameter of the Sun—that is, the angle TCL—and with the distance CT of the aperture, find the half-image of the Sun TL, the one that would appear through an indivisible aperture, equal to the half-aperture LB; and there will be formed a half-image of the Sun appearing through the aperture, OP. Then double TL so that you have KL, and let it be 12. To KL, in the same proportion, set the digits of the eclipse, or the digits to be eclipsed, as a fourth proportional number, and you will have the image of the lunar shadow [*Umbra Lunar*is] appearing through an aperture as indivisible as a sensible one—but with the situation reversed, in non-annular eclipses. But if the apparent diameter of the Moon turns out to be smaller than the solar diameter, then somewhere there will certainly be an annular eclipse, indeed sometimes a central one. In that case, therefore, take the image of the lunar shadow, as found above, away from the image of the whole diameter of the aperture, and you will have the image of the shadow as it appears through a sensible aperture. The reasoning of the rule follows by the converse of Propositions XI and XV.

XVII. PROPOSITIO.

The same distance of the Aperture from the Plane on which the Images are received remaining unchanged, the magnitude of the aperture being varied however much—with the image of the Sun subtracted, and, in annular eclipses, the image of the Lunar Shadow added (but in the other eclipses neither added nor subtracted)—

there will always result the same correct magnitude of the legitimately admitted images.

By the "correct magnitude" of the images I mean that of the image equal to the image of the Sun admitted through an indivisible aperture, which is, as it were, the Sun's own image, suited for investigating its Diameter in the manner of Proposition II. But this Proposition is founded as a Corollary deduced from Propositions XI and XV. For the ratio of the addition or subtraction to be made—so that the images of the Sun may be reduced to physical equality in indivisible apertures, founded on the addition of the Sun's image and the subtraction of the Lunar Shadow—if that ratio remained the same, then the distance too would remain the same and equal, so long as the aperture is moderate enough to be apt for representing the images. Hence it comes about that, if the magnitude of the aperture is varied, then, the image of the Sun being afterward taken away from the image so corrected, the same Diameter of the Sun will be found as by the method handed down in Proposition II. As a sign that it has not been an exact observation, and that the dimension of each image, as also the observation produced from each, and on the contrary the Diameter that proceeds from the observation of either, is acceptable. To confirm this we have been accustomed to test the same observations by a threefold trial, and we used to choose that diameter of the Sun which, with the aperture of each one removed, came out the same on the same day by the same quantity.

XVIII. PROPOSITIO.

The magnitude of the Aperture remaining unchanged, and its distance from the plane equidistant from the received images being varied, although the images of the Sun among themselves may keep some same proportion to one another, and the images of the Lunar Shadows among themselves some same proportion as well—indeed, with the increases or decreases of the images through a sensible Aperture—nevertheless that same proportion does not remain among the whole images admitted through a sensible Aperture.

In Figure IX, let the Luminary—say, the Sun—have center O, and its outermost rim A, from which through the half-aperture's outer edge BC let two rays AM and AL be produced to infinity; and let BC be the half-aperture, through whose center B let OD be drawn perpendicular, to which EG and HK and DM are applied, equidistant from that same BC, and so parallel to one another. For, by Elements VI.2, the section will be cut proportionally, as much for triangle BDL as for triangle ALM. Therefore the bases of the half-images through the indivisible aperture B—the admitted ones, namely EF, HI, and DL—will be proportional

among themselves relative to the distances BE, BH, BD. Moreover, the increases of the images from one side of the Sun, or

the decreases of the lunar Shadows, which arise from the half-aperture BC by the entry of the Sun's rays, namely FG, IK, LM, can be proportional among themselves. Yet the total images EG, KH, DM continuously will not therefore be proportional according to the same proportion of the images which they have among themselves, EF, HI, DL—since neither triangle ALM is equiangular to triangle BDL, nor is the proportion of the increments necessarily the same as that of the bases EF, HI, DL among themselves. Now physically, considering the quantities of these, as the distance BE grows, the excess of base HI over EF will sooner become sensible than the excess FG over BC, or IK over FG, by what was said in Proposition I: for over a distance of paces doubled, $972 \frac{1}{3}$ in the lunar radius, but 21486 in the solar, it remains insensible, if BC is set at 5 paces only. For if it be set smaller, then through a greater interval too the physical equality of the increments BC and FG is preserved. Therefore, with the physically unequal EF and HI made, if there be added to them equal physical EF and IK, the proportion which holds between EF and HI will not remain.

XIX. PROPOSITIO.

Given an image of the Sun, or of the Lunar Shadow, through a sensible aperture of magnitude not exceeding 10 in its own semidiameter, received on a plane not more distant from the aperture than $972 \frac{1}{3}$ paces for the Shadow, or 21486 for the solar image; and given the semidiameter of the aperture, and the distance of that plane from the images, of the same kind of parts: all the remaining images congruent with the indivisible aperture are given, for whatever distance from the aperture greater or smaller to infinity; and so the true proportion is observed for the image at the greater and at the greater distance, and the dimension.

Return to Figure IX, and let the foresaid interval BE be given, the half-image EG and the half-aperture BC; in what parts FG is known—since the interval BE will be FG, physically equal to BC itself, by Proposition I. Therefore from the said Propositions XI and XV, subtract FG, and there will remain the half-image EF, owed to the indivisible aperture B. Then make: as the given Distance BE is to the half-image EF, so the given Distance BH is to HI, and the datum BD to DL, and so on to infinity; for you will have the half-images of the Sun owed likewise to the indivisible aperture. With these doubled you have the whole images owed to the indivisible aperture; and at length, with these subtracted from the observed images of the Sun, you will have the residue equal to the addition to be made for

the image of the Lunar Shadow observed in annular eclipses. In the other cases the observed Lunar Shadow is not varied in quantity, but only in situation.

So far concerning the case in which the eye is supposed to be set at the sensible Aperture. Next, concerning the case in which it is set at the common section of the Sun's Rays above the sensible Aperture, the aperture below nevertheless remaining sensible—that is, with the eye set at the point Z, Figure V.

XX. PROPOSITIO.

Given, by Propositions IV and V, the distance of the point of intersection of the Sun's outermost rays passing through the margins of the sensible Aperture, measured from the plane on which the images are received; and the apparent semidiameter of the Moon in an annular eclipse: the image of the lunar Shadow is given, appearing to an eye set at the said point of intersection as if at an indivisible opaque aperture equidistant from the sensible aperture.

Let Figure V be repeated here, in which, alongside the exposition there indicated, although in reality the aperture NO is open, let it be imagined—through the point Z of intersection—as if a certain opaque plane O, parallel to NO itself, were drawn; imagined, I say, because if it really were there, the countless rays of the Sun would be stopped, which in reality are not stopped but pass through the aperture NO right up to the base TV. With this fancy made, the image of the Sun would indeed be the same as that which appears through the sensible aperture, namely the whole TV, composed in part of its part shadowed by the Moon, and in part of the illuminated parts of both; near the ends of TV, more bright; and the image of the lunar shadow would be $\beta\delta$, bounded by the Sun's rays $aZ\beta$ and $\gamma Z\delta$, touching the lunar globe most closely at C and D; then

the eye set at Z, set up so, would see nothing of that segment of the Sun's disk which is within the points γa , while it would see the remaining segments aK and γI . And so it would still see a fairly large image of the eclipse, larger than if it were at A and the images passed through the indivisible A; the difference, however, would scarcely be perceptible to the sense, on account of the nearness of the points A and Z, as was demonstrated at Proposition V.

Therefore, in the case of such a fiction, with the semidiameter of the Moon given—that is, the angle CAY—there is given also the one that is its vertical opposite, BAH. Now this angle is equal to the internal and opposite $BZ\delta$, because between them lies the interval so often supposed by us, from the same physical point of contact C, namely CAH and $CZ\delta$, which are parallel to the sense. Therefore in triangle $ZB\delta$, right-angled at B, with the foresaid angle and with the given

distance BZ, the semi-shadow B δ is given by Trigonometry, whose double is the lunar shadow δd , appearing to the eye at Z, and so on.

Meanwhile note again carefully: with the aperture NO open, the shadow itself SQ is not only smaller than the shadow GH, appearing to the eye at A through the indivisible aperture A, but much smaller—the shadow δd appearing to the point Z indivisible; this, below, will have to be impressed against the opponents of this Keplerian doctrine.

XXI. PROPOSITIO.

Although, as regards the projection of the solar image, the same thing happens whether it is admitted through a sensible Aperture, or whether—as if it were admitted through an indivisible Aperture imagined at the point of intersection of the common section of the rays touching the internal margins of the sensible aperture—nevertheless the same thing does not happen by comparison with the image of the Lunar Shadow really admitted through the sensible aperture, much less by comparison of the Sun's image and the Lunar Shadow which is imagined to be admitted through the center of the indivisible sensible Aperture, both being placed in either situation.

If Figure V is again attentively examined, and the members of this Proposition are distinguished among themselves, the truth of them all will easily be shown. It therefore pleases me to apply it more particularly to the figure, and to demonstrate it.

First, then: with the magnitude of the aperture NO posited, and its distance AB from the plane TV on which the images are received, and the distance of the plane from the Earth, it is at once determined from the nature of these things at the point Z, in which the Sun's outermost rays IZV and KZT intersect, and where the image of the Sun TV appears to the eye both at Z and at A—and indeed before the eclipse the whole is bright; and so the same things happen, because Z is really not the point of any opaque aperture impeding the luminous projection of the image TV, but is the mere point of intersection of the rays freely passing through.

Secondly: since in reality nothing is drawn or set up through Z—no opaque plane suited to stop the rays for the aperture NO—the rays freely enter as far as the base TV. Through the left part TS the rays all arise from the Sun's segment RK, and to the right part of the base QV the rays all arise from the Sun's segment IP; therefore in reality the image of the Lunar Shadow is drawn together within the segment SQ, and is not so great as the image of the Shadow $\beta\delta$ would be if there

were interposed an opaque body $\beta\theta$, nor would the other rays touching the Moon radiate, than $\alpha Z\beta$ and $\gamma Z\delta$.

Thirdly: since through the indivisible aperture imagined at the center A the Sun's image would be LM, while through the sensible aperture NO, and through the imagined indivisible A, the Sun's image is TV; therefore as to comparison indeed with the Sun's image the same things happen, and much less if it were compared with the image introducible through the sensible aperture in the plane θ .

Fourthly: since in reality the image of the shadow SQ is smaller than that very one, GH, which would be projected through the indivisible center A—therefore, as to this comparison too, the same things happen. Under this distinction it is answered easily enough, and truly, to the principal argument of the said Fathers, which is of this kind.

Argumentum praecipuum contra Keplerum, & Nos, eius dissolutio. [The chief argument against Kepler and against us, and its resolution.]

Those Fathers indeed use another figure, and a more similar Fig-

ure II than V, because they draw no line for the designation of the shadow; but we have reduced their Argument faithfully into the form by applying Figure V, so that, from the distinction of the lines bounding the shadow from the bright lines comprehending the parts of the base, the strength of the solution of the Argument might appear more clearly. They therefore argue thus:

When the Rays pass through the sensible aperture NO, the same happens as to projection as if the Rays passed through the point of intersection Z, where it would be opaque at θ , all the other rays being resisted except those entering through the point Z. But in the case where the rays pass through the indivisible point, nothing of the Sun's image would be taken away; therefore neither is anything to be taken away in the case where they pass through the sensible aperture NO. *The Major* is proved: *first*, because the image of the Sun, in either case, is the same quantity of the Sun's image, the same intensity of illumination about the extremities TV, through the point all-but-indivisible Z, which is as it were a loose aperture NO. Therefore the sensible aperture is adduced, so that the projection of the solar image might be more evidently distinguished and fall under the sense, but not so that the effect of the quantity TV is changed. *Secondly* it is proved as to the lunar shadow, because, since in either case the same quantity of the Sun's image remains, that shadow ought neither to grow nor to diminish, the parts of it likewise neither growing nor diminishing; but the lunar body, in the present case and with respect to the plane on which the observation

is made, is as it were a certain spot of the Sun, and that the darkest part of its image; therefore neither does the lunar shadow itself grow or diminish.

But the *Minor* is proved: *first*, by the authority of Kepler himself, who at chapter 11 of his *Astronomia Optica* [*Astronomia Optica*], Problem 7, says: *Unless the aperture is plainly the very least—that is, of the form of a point—the proportion of the Diameters is always varied; the Moon, with too small an aperture, appears smaller, and the Digits appear fewer*; and he virtually grants that, if the aperture is of the form of a point, the Digits do not appear fewer—and we, on our part, do not at all admit the just quantity of the Eclipse, decreeing that the case of sensible apertures is to be reduced to the case of indivisible apertures. *Then by reasoning*: because the whole reasoning which obtains for the mutilated image, by the Sun's image and by the increasing image of the lunar Shadow, is the same as if the apertures were supposed to be varied in this case—therefore neither is it to be varied in this case, neither is it to be corrected. And if otherwise, it would be necessary to correct, contrary to what falls in Kepler's method. Nor is there any doubt that one of the said Fathers, who composed his Tables by this method of Kepler as by a foundation, would err altogether, &c. They confirm that, since hitherto the portion MV of the Sun's image was withdrawn—not the distance AB, nor the distance ZB, but solely the distance BM by them and by a correction of BM—we recognize the angle BAM; and at chapter 5 of the *Almagest*, Book I, where Kepler's doctrine is adduced, it is not a matter of investigating the semidiameter of the Sun, but of investigating the magnitude of the Eclipse; and for that purpose it does not at all matter to know such an angle, but it suffices to know the mere proportion of the Sun's image in the projected Tablet with the image of the lunar shadow. *But it was easy*, says the same Father, *to transfer through inadvertence what suits an observation of the Sun's diameter measured by angle to the present matter, where the Diameter is considered not under the ratio of an angle, but under the proportion which the semidiameter has to the part covered by the Moon*. These things they, or we from them, add rather to the strengthening of their argument than to weakening it, so that I do not doubt that they are to be acknowledged for their own candor.

RESPONSIO.

I respond to the *Major*, with the distinction set down in the title of Proposition XXI, and from the position subjoined to it: I concede the Major as to the image of the Sun, according to itself, precisely taken, or considered separately from the image of the Lunar Shadow; but I deny the Major as to the Sun's image considered as regards the other comparisons there adduced, and especially by

comparison with the lunar Shadow—that image, namely, which in fact and in reality is projected upon the Sun's image by the rays entering the sensible aperture, for by these the image of the Shadow is surrounded, and is made much more contracted than it would be if it were opaque at θ ,

with the Sun's ray interposed touching the Moon, and the bounds of the shadow passing through only the point of intersection Z—for in reality it is SQ, which then would be $\beta\beta$. But it is one thing to consider the future measure under that condition, which would be, but is not; another, what in the present is really made—not under the posited condition of opacity at θ , but on the contrary under the posited condition of the aperture NO, the magnitude. *But it was easy to transfer through inadvertence what suited an observation feigned through the imagination of opacity, impeding the entry of the rays through the aperture NO, to the present matter, where the proportion of the Sun's image to the Lunar Shadow is considered not as it would be, but as it in fact is.* For the excess of the Sun's image is much greater than it is in that feigned case, and than the one that is in use; but as to the just quantity of Eclipses, even apart from any relation to the quantity of the Sun's diameter, but as to number of Digits, account must be had: and by these things the answer to the first proof of the Major is plain.

To the *second* proof of the Major I distinguish, and that being granted, but not granting it about the parts of the more posited image, and really identified with it, I deny it about the negative parts, nor identified, of whatever sort the shadow is, with respect to the aggregate from it, and from the bright parts; for daily we see, in aggregates from shadow and surrounding light, that, though the whole aggregate remains of the same quantity, the parts nevertheless decrease, others increasing by just as much. Indeed, among the posited parts themselves, and identified through continuation—for example, among the parts of glassy water enclosed—we see the whole water, when the vessel is full, remain of the same quantity, while certain parts, by force of nearer heat, are rarefied and occupy a larger place, others being condensed and constricted; therefore I said, *Data non concessa* [the datum not being conceded].

Moreover, the Moon is not identified with a spot on the Sun, but is really distinct from it, as we judge also of the other spots.

To the *Minor* I respond by conceding it, if through the same indivisible point there pass both the rays touching the Moon and bounding the Shadow, and the rays bounding the Sun's image: that, indeed, does not occur in the case present; but denying it, if (as in fact happens) the rays bounding the Sun's image pass

through that point, while the rays touching the Moon, and bounding its Shadow, pass through lower and sensible margins of the aperture.

Let it therefore stand, rightly said by us in the first response sent to the Reverend Fathers, that it is gratuitously said the same thing happens, &c., and that against Kepler nothing has hitherto been demonstrated in this matter; and the more so is it confirmed by us, because in the case in which the magnitude of the Digits of a Solar Eclipse ought to be estimated by the images of the Sun in use, and the Lunar Shadow, as they lie in the Table of the observation, without any correction, the Digits would come out only 6, or about $\frac{1}{2}$, as we show at Proposition XI.

To the remaining Arguments, less principal, there is no need of a more prolix response, or an express one: for, whether there remain, or there not remain, the same proportion, understand it between the bright image of the Sun and the image of the Shadow, which, between the Eclipsed Digits and the non-Eclipsed, is plain from Propositions IX, X, XIV, XVIII, and XIX. From which too it will be plain, if the images are legitimately admitted for whatever given distance, and if the increments owed to the aperture are taken away, that the image of the Sun suited for collecting the quantity of the Eclipse would arise; and that the quantity of the Eclipse cannot arise, varied at pleasure through distance, such as anyone might wish.

FINIS.

Figurae in Appendice I. Capitis XII. connumeratae. [Figures counted together in Appendix I of Chapter XII.]

Diagram. Figure 1 (1. fig.): a tall narrow elongated triangle (or wedge) with apex at the top and a small rectangular base at the bottom. The structure represents the convergence of rays from the Sun's rim to an aperture, with the half-aperture and half-image marked at the foot.

- A (apex, top): vertex of the triangle
- B (left, upper of the base block): left endpoint of the upper cross-line
- C (right, upper of the base block): right endpoint of the upper cross-line
- H (left, lower base): left endpoint of the lower base line
- K (right, lower base): right endpoint of the lower base line
- L (bottom center, below K): foot point on the base

Diagram. Figure 11 (11. fig.): an hourglass / double-cone (X-shaped) figure of two ray-bundles crossing at a central intersection, used for the camera-obscura

imaging geometry (Figure V / IX of the text). Two pairs of lines descend from the top (from F, and from G–N) and cross near the center (the point of intersection Z of the text), then diverge again to the base line A K T L B at the bottom.

- F (top left): upper-left ray origin
- G (top right): upper-right ray origin
- N (top right, beside G): second upper-right ray origin
- M (upper left, below F): label on the left descending line
- E (left of center): left point near the central intersection
- H (top center, at the crossing): central crossing point (apex of the upper cone)
- D (right of center): right point near the central intersection
- O (center): central intersection point
- C (center, just below O): point just below the central crossing
- P (center right, beside O/C): point near the central intersection on the right
- A (bottom left): left base endpoint
- K (bottom, right of A): base point
- T (bottom center): central base point
- L (bottom, right of T): base point
- B (bottom right, beside L): right base endpoint

Diagram. Figure 3 (3. fig.): two overlapping circles arranged vertically (a smaller upper circle and a larger lower circle), representing the Sun and Moon disks overlapping in eclipse. A vertical diameter runs through both. The lens-shaped region of overlap and the lower circle are hatched (shaded).

- A (top): top of the upper circle, on the vertical diameter
- H (center, junction): point on the vertical axis where the two circles meet / the upper intersection region
- B (left, at the overlap): left intersection point of the two circles
- C (right, at the overlap): right intersection point of the two circles
- E (center, within the overlap): central point in the lens of overlap [F in some readings — center of lower circle region]
- F (center, lower): center point of the lower (larger) circle, on the vertical diameter
- G (bottom): bottom of the lower circle, on the vertical diameter

Diagram. Figure 4 (4. fig.): two side-by-side figures, each a smaller hatched (shaded) inner circle set within a larger outer circle, representing an annular-

eclipse configuration (the shaded lunar disk within the larger solar ring). Each has a vertical diameter.

Left figure:

- A (top, outer): top of the outer circle on the vertical diameter
- B (top, inner): top of the inner hatched circle on the vertical diameter

Right figure:

- C (top, outer): top of the outer circle on the vertical diameter
- D (top, inner): top of the inner hatched circle on the vertical diameter
- G (bottom): bottom of the figure on the vertical diameter (shared label at foot)

(continued from the preceding folio — explanation of the eclipse-magnitude figures)

This Figure V is for an annular and central solar eclipse. The black lines tangent to the Moon are the three rays of the Sun that bound the shadows. The lines marked with points, by contrast, are rays of the Sun that bound the two solar images, AB being the distance of the receiving tablet of the images, of 100000 parts, from the aperture NO, whose diameter is 200 parts.

Diagram. A ray-optics construction for an annular, central solar eclipse. At the top the aperture is shown between points I and K, with the small aperture NO at center; rays of the Sun pass through it and cross. The lunar globe (a circle, centered Y) is shown in the upper field, and the converging/crossing rays below form the inverted-image cones, with the shadow-bounding lines tangent to the Moon. A horizontal scale-bar runs across the figure. The construction is referred to in the prose lettering that follows.

- I, EP, RF, K (top): aperture-frame and ray endpoints across the top edge
- Y (center, upper circle): center of the lunar globe
- Z (mid): intersection point of the bounding rays
- N, O (center): the indivisible aperture, diameter 200 parts
- Θ (lower): vertex region of the crossing rays
- X (bottom): lower vertex of the image-cone
- T, B, L, G, S, B, Q, V, H, M, A, V (bottom band): labels of the bounding rays and image edges along the base [several closely-set marginal letters [?]]

IZV and KZT are the outermost rays of the Sun, passing through the edges of the aperture O and N, crossing over, and bounding the solar image TV, which before the eclipse is wholly bright, and they intersect each other at Z.

IAM and KAL are the outermost rays of the Sun drawn through the center of the aperture A, and they bound the solar image LM. CD is the lunar globe, from whose center Y the perpendicular YB is drawn, through the points Z and A.

PCNQ and RDOS are rays of the Sun tangent to the Moon, drawn through the edges of the aperture N and O, and they terminate the lunar shadow's image SQ.

ECAN and FDAC are rays of the Sun tangent to the Moon, drawn through the center of the aperture A, and they terminate the lunar shadow's image GH.

$\gamma\text{CZ}\beta$ and $\alpha\text{DZ}\beta$ are rays of the Sun tangent to the Moon, drawn through the intersection point Z, which, if it were in the dark $\gamma\beta$, would terminate the lunar shadow's image $\gamma\beta$.

IK is the visible disk of the Sun; the angle measuring the apparent diameter of the Sun to the eye A is SQ. The lunar-shadow images appear in tablet TV; the remaining images TS and SV are illuminated by the rays of the Sun that have entered from the segment RK and IP, through the aperture NO; and therefore the segment PR of the Sun is occulted by the Moon, while the rest, IP and RK, is apparent to the eye X.

GH is the image of the lunar shadow, as large as it would be if the aperture NO were narrowed down to the indivisible point A; and then the segment EF of the Sun would be occulted, and the image LM would be illuminated from the segment LG by the rays of the segment FK and HM, that is, by the rays of the segment IE.

$\gamma\beta$ is the image of the lunar shadow, as large as it would be if the aperture were narrowed to the indivisible point Z, which, set in the dark $\gamma\beta$, would stop the remaining rays; and then the eye Z would see nothing of the solar segment $\gamma\alpha$, but only the segments $I\gamma$ and αK , and the solar image TV would be illuminated by the small portions $T\beta$ and βV .

VI. Figure for an eclipse of 6 digits.

Diagram. A ray-optics construction for a solar eclipse of magnitude 6 digits. The Sun's disk is at top between C, O, G, E; rays descend through the aperture IK to the tablet LM, crossing to form the image. The Moon (circle, center H) is set tangent to the Sun's right margin. Labels mark the bounding rays.

- C, O, G, E (top): the Sun's disk and its margins

- I, K (upper aperture): the aperture IK
- H (mid circle): center of the Moon
- A (eye): the point at the crossing
- L, F, B, P, D, M (base): image edges on the receiving tablet

A, the center of the aperture IK, through which the center G of the solar disk descends to the tablet LM; GB is the perpendicular dropped from it, tangent to the right margin of the Moon at H.

The rays CKM and EIL, drawn from the extremities of the Sun through the edges of the aperture I and K, bound the solar image, which before the eclipse is wholly bright and is to be measured.

The rays CAD and EAF, drawn from the extremities of the Sun through the center of the aperture A, would bound the solar image FD, if they could enter through an indivisible aperture.

The ray OHKP, tangent to the Moon physically at H, drawn through the right margin of the aperture K, bounds the lunar shadow's image PM.

The angle CAE measures the diameter of the Sun to the eye A, before the eclipse.

LP is the solar image illuminated by the rays of the segment OE, entering through I and K. Although it is not seen by the eye A except in the segment GE — in this eclipse of 6 digits — yet PM is the lunar shadow's image, because the Moon covers the segment CO; and FB is that part of the solar image which would appear if the images were admitted through the punctual aperture A. For then, through that aperture, the rays of the whole segment GE would enter, illuminating FB; and in that case the lunar shadow's image would be BD.

VII. Figure for an eclipse of 4 digits.

Diagram. A ray-optics construction for a solar eclipse of magnitude 4 digits. Layout parallel to the 6-digit figure: the Sun's disk C, O, G, E at top; the Moon (circle, center H) tangent to the disk; rays cross through the aperture (near α , Z, θ , I, K) to the receiving tablet L, F, B, P, D, M at the base.

- C, O, G, E (top): the Sun's disk and margins
- α , G (upper): solar-disk reference points
- H (mid circle): center of the Moon
- Z, θ , I, K (crossing): aperture and intersection lettering
- L, F, B, P, D, M (base): image edges on the receiving tablet

VIII. Figure for an eclipse of 8 digits.

Diagram. A ray-optics construction for a solar eclipse of magnitude 8 digits. The Sun's disk C, O, G, E at top; the Moon (large circle, center H) covers a greater portion of the disk than in the 6- and 4-digit figures; rays cross at the aperture (near Z, θ , I, K) and reach the tablet L, F, B, P, D, M below.

- C, O, G, E (top): the Sun's disk and margins
- H (center circle): center of the Moon
- Z, θ , I, K (crossing): aperture and intersection lettering
- L, F, B, P, D, M (base): image edges on the receiving tablet

Common explanation of Figures VII and VIII.

A, the center of the aperture IK. CKM and EIL, drawn from the extremities of the Sun through the edges of the aperture I and K, intersect each other at Z and bound the solar image LM, which before the eclipse was the full measure of the Sun.

But the rays CAP and EAF, drawn from the extremities of the Sun through the center A, would bound the solar image FD, if there were not an aperture open of the full width IK; the ray OKP, tangent to the Moon at H and drawn through the right margin of the aperture, bounds the lunar shadow's image PM.

The ray of the Sun $A\Delta$, in Figure 7, and GAB, in Figure 8, tangent to the Moon at H, and drawn through the center A, would terminate the lunar shadow's image βD in Figure 7, and BD in Figure 8, if they passed through an indivisible aperture A.

The ray GZB, in Figure 7, and $\alpha Z\beta$, in Figure 8, is drawn through the indivisible point Z, touching the Moon physically at point H.

The angle CAE measures the apparent diameter of the Sun to the eye A, imagined before the eclipse.

LP is the portion of the solar image illuminated by the rays of the whole segment OE, the aperture IK being open — in which case PM is the lunar shadow's image, the Moon enclosing within the circle the rays of the whole segment CO.

But if the rays were admitted through the indivisible aperture A, then the portion illuminated by the rays of the segment αE would be — in Figure 7, the image part F β ; in Figure 8, the part FB — and then likewise the lunar shadow's image would be βD in Figure 7, or BD in Figure 8.

But if the rays were admitted through the intersection point Z and the whole image were seen, the portion of the bright solar image would be LB in Figure 7, or $L\beta$ in Figure 8; and the lunar shadow's image would be BM in Figure 7, or βM in Figure 8, the remaining rays being impeded by the dark $\alpha\beta$.

[Margin: The explanation of this figure is given above, at Proposition XVIII.]

Diagram. A narrow ray-optics construction (Figure 9) at the foot of the left column. A pair of converging lines from points A and O descend through lettered way-points to the base. Its explanation is referred to Proposition XVIII (see margin note above).

- A, O (top): the two upper reference points
- B, C (mid): intermediate ray-points
- E, F, G (lower-mid): intermediate ray-points
- I, K (lower): aperture lettering
- D, L, M (base): image edges at the foot

II. APPENDIX TO CHAPTER XVII.

On the Diurnal Motion of the Sun and of the rest of the Heavenly Bodies, rather than of the Earth — against the Copernicans.

In Book Nine of the *Almagestum Novum*, Section Four, I set out most clearly — unless I am mistaken — everything that bears on the system of a moving Earth, with respect both to its diurnal motion about its own center and to its annual motion about the Sun (the Sun being placed at the center of the universe rather than turning, as some hold, about the center of its own body). From Chapter V to Chapter VIII I propounded twenty arguments concerning the diurnal motion of the Earth about its center, and resolved them. From Chapter VIII I propounded, and resolved, twenty-three arguments for the annual motion. But from Chapter XIII to Chapter XIX I propounded, and resolved, seven arguments for the diurnal motion of the Earth together with the annual. Then again, in the same Section, from Chapter XIX to Chapter XXXIII, I propounded seventy-seven arguments for the immobility of the Earth, partly against the diurnal and partly against the annual motion. Of these I resolved most, showing that they do not have physical — still less mathematical — evidence; yet I taught that a few have physical evidence. But the one point on which we depart from them — namely, that the Earth's immobility has physical-mathematical evidence — I taught there in Chapter XIX. Finally, from Chapter XXXIII to Chapter XXXV, I returned in the *Epitome* to all the foregoing prejudged arguments, reducing them to syllogistic

form, together with the responses, likewise in form. And in that same Chapter XXXIII, in Conclusion VII, I taught a controversy which is settled here only by mere reasonings. And from Chapter XXXIV to the end of the Section I taught what one is to hold, by the authority of Sacred Scripture, its interpreters, and the decrees of the Catholic Church, concerning the Earth's motion or rest.

Since, then, in Chapter XVII of this Book I supposed it as certain that the Sun moves and not the Earth — nor have I lacked the company of most distinguished friends, men of talent and learning (whose names, being myself unknown, and perhaps unwelcome, I do not dare to publish), who have labored with the most subtle arguments to overturn that argument of mine in Chapter XIX, the one mentioned in Section 4 above, which I said is evident, physical-mathematical, and the keenest in defense of this anti-Copernican hypothesis — it pleased me, therefore (let this be said here once for all), to propound that same argument again, with a few changes, and against the difficulties of my friends — indeed of our own raising — to dissolve them, having first laid down certain suppositions.

I. Supposition.

The velocity-increment of bodies naturally descending, with respect to the times of fall, is in proportion to the successive odd numbers; but with respect to the spaces, it is compounded in the end of equal times in proportion to the square numbers of the times, along the perpendicular line by which they appear to descend.

I explain the supposition by means of the line AB, in 16 parts of equal division. In this line I say that if a heavy body falling through air in the first time-interval traverses the space AC, then in the second time-interval, one-and-a-half-times-and-one-more (*sesquiprimam*), it traverses the space CD, three-fold; in the third time-interval the space DE, five-fold; in the fourth time-interval the space EB, seven-fold; and so on. From this it follows that at the end of two time-intervals the space AD is traversed, one-and-

(folio 82 — DE SOLE)

—and-a-half-times the number 2; and at the end of three time-intervals the space AE is traversed, one-and-a-half-times-and-one-more the number 9, which is the square of the number 3; and at the end of four time-intervals the whole space AB is traversed, one-and-a-half-times-and-one-more the number 16, which is the square of the number 4; and so for the rest of the spaces in their order.

This proposition is established by manifest experiments of mine — not to speak of Galileo's, adduced in Book 2 of the *Almagestum Novum*, Section 2, Chapter 19. For

by applying a very short perpendicular for measuring some third part of the time, and by dropping innumerable balls of clay from about eight Roman inches above the ground, from the various intervals of the Bolognese towers, we have most certainly ascertained that a globe of this kind, in one second of time, traverses 15 old Roman feet; in two seconds, 60 feet; in three seconds, 135 feet; and in four seconds, 240 feet. This is exactly the proportion explained above, from which we derived the many most beautiful problems in Chapter XIX.

[Margin: Heavier bodies fall faster.]

On this occasion it is now permissible — though I am not now dealing with it — to set down what we have established by very many experiments in the same place: that of two heavy bodies of the same kind, the heavier descends faster than the one less heavy in itself, faster too at the same height; but to discern this internal difference, a notable height is required — no less, more or less, than two hundred feet — and the eye must observe rather than the hearing. For the interval by which the lighter body's downfall outlasts the heavier in passing through is so small that, when the heavier has already struck the pavement, the often-repeated observation of the strike of the lighter follows in but a half-second of time, or even less. This is the predetermined interval from our observations of the same tower, namely from where the clay globes were dropped — a height of 240 Roman feet — to the pavement. But it is 280 feet from the pavement. So that still by 40 feet the lighter globe was distant from the pavement when the heavier had already reached the pavement.

II. Supposition.

The increment of the strike, and of the sound made, by a heavy body descending from a higher place is proportional to the velocity-increment of the same descending heavy body.

It is enough to see the reason a priori. For the impetus of a movable body is proportional to its heaviness; we see, indeed, that the greater weights, raised higher, strike more strongly, and with a greater impetus, other things being equal, than do the smaller — provided they are not detained, or impeded in equal impetus by an excess of weight, with respect to the resistance of the air, in the descent itself. Therefore, if at the end of its motion a falling heavy body acquires for determining the degrees of its impetus, and so on, just as much as it would have acquired in just so many degrees of heaviness — in the order of an upward-tending weight — to be struck and made to sound. For there is in heaviness a certain flowing impetus, as it were a flowing heaviness. It pleased me,

nonetheless, to confirm this a posteriori by an experiment tried once, and indicated in the place of the *Almagestum Novum* cited above, though it can be carried out more accurately. A capsule was fashioned, capable of holding diverse weights; one of its pans was an iron pan fixed in a wooden hand-balance, above which a wooden globe of a sesquiuncial weight [i.e. one inch and a half], fell upon the perpendicular; and as a little iron weight of 35 Roman inches' height, raising by one finger-breadth in width, an iron weight of 5 ounces and some few drachms — which I have nevertheless neglected for safety's sake. But from a height of 140 inches it raises likewise by one finger-breadth an iron weight of about 21 ounces; from a height of 315 inches, by contrast, it raises [a weight]... but most certainly 45; and from a height of 560 inches it raises a weight of 80 ounces. This experiment I set out for testing — but by experienced and circumspect men. Behold, then, in the Table, a synopsis of the experiments:

Altitude in Roman inches	(in feet & inches)	Compounded proportion	Weight raised by one finger-breadth
35	2 ft 11 in	1	vnc. [ounces] 5
140	12 ft 8 in	4	vnc. 20
315	26 ft 3 in	9	vnc. 45
560	46 ft 8 in	16	vnc. 80

But the capsule must rest like a single pan of a balance; first it should counterweight the other pan, and afterward come to rest above an underlying support placed beneath; and one should choose altitudes deliberately bearing the aforesaid proportion — namely, such as holds among these numbers 1, 4, 9, 16. For from this it will be clear that the increment of the strike, and of the sound, which we postulate, can be measured and discerned from the raised weight, and discerned to be such as the space traversed by the descending heavy body — that is, in proportion to the square of the times; and as the preceding space is exceeded by the following space which the heavy body traverses in descent, by the same proportion the strike made by it at the end of the second space exceeds the strike made at the end of the first space.

III. Supposition.

The semidiameter of the terrestrial globe is 23,367,468 Roman feet. Of which, in one degree of the greatest Circle of the Earth, 407,633 are contained.

This is established from Book 5 of our *Geographia Reformata*, where we corrected the measurement handed down in the *Almagestum Novum*, Book 2, from longer

and more accurate observations of ours, and from more recent ones (which were set out fully in the same Book 5). And although for our present purpose it would have sufficed to take any of the more received magnitudes of the Earth, we have nevertheless preferred to use this one as the truest. From this, moreover, it follows that in one minute of a terrestrial degree of the Equator 6799. & Roman feet are contained; and in a fourth part of a minute, or in 15 seconds, 1699 $\frac{1}{3}$ feet.

IV. Supposition.

If the Earth revolves about its own center by a diurnal rotation of 24 hours, in an equable rotation, then any terrestrial point of the Equator will traverse 1699 $\frac{1}{3}$ Roman feet in each second of the hours.

For in such a motion as is equivalent to the motion of the *primum mobile*, in the single seconds of the hours, fifteen seconds of the Equator are run through; and in fifteen seconds of the terrestrial Equator, by Supposition III, 1699 $\frac{1}{3}$ Roman feet are contained.

V. Supposition.

In the velocity-increment of bodies naturally descending, the same physical proportion is preserved, other things being equal, whether they descend along the plane of the Equator, or away toward the center of the Earth — at least within the first four seconds of the descent of an hour.

For, other things being equal — namely, descending by the same heaviness, mass, calm of the air, rarity, and the rest — no solid reason can be assigned why, in so brief a time as the four seconds of the heavy body's descent at the Equator, they ought to vary sensibly in that proportion which Galileo, and we ourselves, have found by experiment — he in the Florentine parallel, we in the Bolognese — though over a descent so great, the Geometrically declining of the parallel plane is imperceptibly discerned, as we demonstrated with the figure set out in Book 9 of the *Almagestum Novum*, Section 4, Chapter 19, number 7.

VI. Supposition

The chord of an arc not exceeding 15 seconds of the terrestrial Equator differs imperceptibly from its [own] figure and from the magnitude of the said arc.

For if the radius is 1,000,000,000,000 in the great canon of Pitiscus [Bartholomaeus Pitiscus], then for 15 seconds the chord is 72,722,052. And since by Supposition III the Earth's semidiameter is 23,367,468 Roman feet, the chord comes to 1699 $\frac{1}{3}$ feet. But by the same Supposition the arc of 15 seconds of the

terrestrial Equator is the same number of feet. They are therefore of the same magnitude; and so the figure too, so that the arc can be treated as a straight line, and the chord as that arc, without any perceptible difference. With these points established:

I. Proposition

If the Earth were moved by a diurnal revolution, a ball of clay weighing 8 ounces, released from a height of 240 Roman feet through still air, would fall to the Earth along an oblique descent — without any real increment, or certainly never with so great an increment, as the proportion of the percussion and of the sound produced by the fall from the said height requires.

To demonstrate this Proposition, let an arc AC be described from the Earth's center T at the interval TA — that is, the Earth's terrestrial semidiameter. Let this AC, without regard to this figure, be supposed to be one minute of the terrestrial Equator; and let TA be augmented to 240 Roman feet — say AB. From T let the minute-arc BD be described in the plane of the Equator, and let each [arc], drawn at right angles from T, be divided into four parts, so that the arc is divided into fifteen seconds. These [points], lower down, are namely AQ, QF, FG, GC; and at the top BH, HI, IK, KD.

Diagram. A fan-shaped geometric construction with its apex at the Earth's center T at the bottom. From T, radial lines fan out to a lower arc (at the Earth's surface) and an upper arc (240 feet higher). The upper arc runs through the points D, K, I, H, B (from left to right at the top); the lower arc runs through G, F, Q, A; the intermediate oblique-fall points M, L, N lie on the slanted line connecting B down toward C/the lower arc.

- T (bottom apex): the Earth's center
- B (upper right): the release point, 240 feet above A
- A (lower right): point on the Earth's surface directly below B
- D, K, I, H, B (upper arc, left to right): the upper minute-arc divided into fifteen-second segments BH, HI, IK, KD
- G, F, Q, A (lower arc): the lower minute-arc divided into fifteen-second segments AQ, QF, FG, GC
- M, L, N (interior, along the oblique descent line from B): successive positions of the ball during the oblique fall

Now since point B — from which the said ball is released — was carried (by the diurnal motion of the Earth, on the supposition of Supposition I) in the first

second of an hour through the line BH (that is, the interval TH), and the ball at the end of the first second had been carried to H, while at the end of the following second it had been carried to I, the ball will have traversed IM, 60 feet. At the end of the third second, with the ball carried to K, it traverses the absolute interval KN, 135 feet; and finally at the end of the fourth second, with the ball carried to D, it has fallen to the Earth — that is, the ball has fallen to the Earth, the space DC of 240 feet being completed. Through the endpoints of the said intervals let straight lines be drawn to the line BL, LM, MN, NC; for this will be the oblique path designated, along which such a ball would really, in this hypothesis, fall to the Earth. Finally, let the chords BH and CG be drawn; and by an analysis of the two triangles let us investigate the magnitude of the first path BL and of the last NC, since from these the intermediate LM and MN can be determined.

First, then, in the triangle BHL the sides HL (15 feet) and BH are given; and BH, were it equal to AQ, would by Suppositions IV, V, and VI be $1699 \frac{1}{3}$ feet; but with the increment AB added, it comes by the proportion (discussed in the proof of Supposition VI) to BH, 1700 feet. The angle BHL is $89^{\circ} 59' 52'' 30'''$, since in the isosceles triangle TBH the angle at T is 15 seconds, and the sum of the angles at the base BH, by the 5th of the First Elements [Euclid I.5], is $179^{\circ} 59' 45''$. From these data, by the most subtle logarithmic trigonometry — which I have reduced (at the end, with the help of Vlacq's Canon) to each single second — the base BL comes out at $1700 \frac{1}{12}$ feet.

Secondly, in the triangle CNG, with KN subtracted, of the whole KG (240 feet) there remains NG, 105 feet; and CG, by Suppositions IV, V, and VI, is $1699 \frac{1}{3}$ feet. The angle CGH is $90^{\circ} 0' 7'' 30'''$, since in the isosceles triangle CTG the angle at T is 15 seconds and either [angle] at the base CG is $89^{\circ} 59' 52'' 30'''$. Therefore by the most subtle trigonometry the last path NC is $1702 \frac{2}{12}$ feet. The excesses of the four paths being then distributed proportionally, they come out as in this little table:

Via	Pedes	& Unciæ
B L	1700	1
L M	1700	5
M N	1701	1
N C	1702	2
Summa	6803	9

Therefore, of the four spaces through which the said ball passes obliquely, none would exceed the one preceding it by a whole foot. And just as, by the diurnal motion alone, it would have traversed the arc BL of 1700 feet with an equal and

uniform [motion], so likewise along the oblique track BLMNC it will complete 6803 $\frac{9}{12}$ feet. Physically, however, it would be just the same as if it had descended with an equal and uniform [motion]. Or certainly the increment of velocity — 3 $\frac{3}{4}$ feet on a path of 6803 $\frac{3}{4}$ feet, or 1361 paces — scarcely deserves consideration, nor is it in any way comparable with the increment of percussion and of sound, which by what was said in Supposition II is only so much as is the increment of velocity of those things falling apparently along one and the same perpendicular — that is, in proportion to the squares of the numbers of equal times.

II. Proposition

The line along which the aforesaid ball, released from a height of 240 feet, would descend to the Earth's surface, in the hypothesis of a moving Earth, would be to the senses a straight line, but oblique — not really perpendicular, but only apparently so — except in the case in which it were released above the Earth's Pole.

This is against our most ingenious Friend, too much addicted to the Copernican hypothesis, who — in order to maintain the proportion of velocity owed to the proportion of percussion — said that the percussion arises from the heavy body not by a motion that is circular and diurnal, but by its own proper motion, and insofar as it is descending; which he said most truly. But from this he wrongly inferred that heavy bodies in the Copernican hypothesis really descend along a perpendicular line, because in that line alone is the proportion of the apparent increment preserved according to the squares of equal times, and so in that line alone would the proportional [increment] of percussion and of sound be preserved.

But the opposite is so true that Galileo [Galileo Galilei], in *Dialogue 2 On the World Systems* [*Dialogo sopra i due massimi sistemi*], and Boulliau [Ismaël Boulliau] in chapter 4 of his *Philolaus*, took pains — from the descent of heavy bodies actually made along a path that is not perpendicular, as is evident, but circular, as Galileo held, or compounded of circular motions, as Boulliau held — to display the beauty of the Copernican Hypothesis: because it removes that difficulty which has hitherto tormented the physicists, namely why heavy bodies should descend with so great an increment of velocity, rather than without increment. For this, say Galileo and Boulliau, is a sheer fallacy of one who judges by sight that heavy bodies descend along a straight perpendicular line, in which such an increment appears; whereas in reality, by the force of the diurnal rotation, the heavy bodies are moved unequally along another path very different from the perpendicular — which path, however, Kepler [Kepler] and Gassendi [Gassendi] held to be

quasi-parabolic, as I have related more fully in Book 9 of the *Almagestum Novum*, section 4, chapter 17.

For although in this hypothesis the motion of heavy bodies arises from two principles — one moving them toward the East according to the measure of the diurnal revolution, by whose force the aforesaid ball would complete in the first second of time the arc BH of

1700 feet, the other, which is gravity, moving them downward — and although, unless the transverse motion toward the East were impeding it, it would be moved along the perpendicular BA, and in the said time would absolutely complete 15 feet: yet because neither of the two Principles so absolutely prevails over the other as wholly to impede its second action, nor do they operate so distinctly that each carries the ball along its own path in the same time. The one would impel the ball [eastward], the other [downward] — that is impossible — but they are so mixed by the conjoined force [of both], that they run together, so that the effect [follows] in such a way that, by the particular influx of each principle, and so the said ball, in this hypothesis, is carried neither along the circular line described from the Earth's center, nor along the rectilinear perpendicular line, but is moved along the transverse line — namely, along the line BH in the figure preceding. So far is it from descending [along the line] from B by BA, or by HL, that, were the oblique path BL denied to it, the circular path BH would have to be conceded to it rather than the perpendicular HL, because the principle of the common diurnal rotation is much more valid than that of gravity; since by the force of [its] diurnity, that second ball would traverse 1700 feet, while [the force] of uniformity is only 15 feet. And so the diurnal [force], carrying the ball away from the perpendicular BA — by which, while the Earth stands still, it would descend — transfers it to the perpendicular HL, by an interval not less than 1700 feet. Since gravity does not draw the ball aside from the arc BH (by which it would be moved, were gravity not present) by the interval HL, [namely] 15 feet — because indeed the diurnal force does not so prevail over gravity, that gravity yields not even a little to the downward inclination — therefore it is not absolutely along the path by which the ball descends little by little, but along a third path of some kind, namely the transverse BL.

14. This same point is proved by a sufficient enumeration and elimination of the other paths along which one might imagine the aforesaid ball really descending. For either it descends along one and the same perpendicular line in the [terrestrial] world-space; and this is not so, because by the diurnal [motion] it is carried to other and yet other perpendicular lines, as

anyone would clearly see, were this Hypothesis given and an eye placed outside the Earth, [observing] the Atmosphere itself; or, with the eye placed on the Earth, and carried along equally by the diurnal [motion] with the points A and B, the ball would seem to descend along one and the same perpendicular BA, or one parallel to it. Or it descends along other and yet other perpendiculars, so that it descends through these without any transverse motion; and this is not so, because it cannot be transferred to different perpendiculars except by a forward motion toward the East, which is prior in the transverse [direction] to its being carried along the other perpendiculars. Either, then, it is so transferred to the other perpendiculars that it first moves forward separately in the transverse [direction], without any descent; then perpendicularly, moving separately, descends nothing; then again circularly; and then again perpendicularly, and thus descending by alternating discrete [motions], as if descending by a stair; and this is not so, because we do not find the descent of heavy bodies to be one continuous motion, and if it could be by some little delay, or by a moment of diurnal force impeding gravity, so that meanwhile by the force of this so very little the heavy body might descend, it could nevertheless do much more — that is, [it could] stand still during the whole time of this motion, or certainly the impetus of the heavy body would not be increased, but in the perpendicular it would be such as it had been transferred, [and] in an equal time it would complete equal spaces.

For example: if the motion here so proceeded that the ball, from B, were first transferred along the arc BH to H, and then, the diurnal [force] indulging gravity, it permitted it to descend along HL, 15 feet; then in the following second hour, from L, the ball were transferred along the arc parallel to HI, to the perpendicular TI, the point I being distant from A by 15 feet: then, because gravity had not exercised its force, and had produced no impetus, in the descent it would absolve only the [other] 15 feet — which is contrary to experiment; or, if you suppose that the earlier impetus had not vanished, but that an equal one had been added to it, it would reach a total of 30 feet; and at the end of the third second, 45 feet; and at the end of the fourth, 60 feet — which is likewise contrary to experiment, from which we gather that the impetus of heavy bodies increases continuously, so that the [space] becomes greater and greater, and the space [is completed] in the descent; therefore there is no descent of alternating motions, the one simply forward along a circle, the other simply downward along the perpendicular. Either, then, it is so along some [paths], and along other arcs, and at the same time along some [perpendiculars], and along yet other perpendiculars

[continued — the upper-right column of folio 84]

is moved, so that at the same time it is moved along both paths — namely, at the same time at which it is moved along BH, let it also be moved continuously along BA, or HL: and this is impossible in a Movable that is not divinely replicated. For it is equally impossible that the same movable be moved simply toward diverse regions of the World — say, toward the very Equator, toward the equinoctial Rising, and toward the Meridian, toward the Pole of the World, and be moved toward opposite regions. But if it be carried toward an intermediate region, it is necessary that it be carried along another oblique path into that [region]; so that it does not tend simply toward the East, nor simply toward the Pole, but toward a terminus partaking of both — say, toward the East-South [Euronotus]. Therefore, since [it can] neither [be moved] along one perpendicular line, nor along one circular [line], nor along diverse circular and perpendicular [lines] by turns, and discretely; nor along circular [lines] at once and perpendicular continuously: it remains that the two are not really moved [separately], but in fact along a line in which neither is moved in act, but only in potency, and insofar as some properties [belong to them], so that in the mixed [motion] the motions of the diurnal whirling and of gravity coalesce into one motion, and are tempered [together]; and this cannot be imagined to be anything else than the oblique [path] declining from the perpendicular, toward the East and downward.

15. Let the foregoing doctrine and proposition be confirmed from like grounds in all movables, whether natural or violent, to whose motion diverse motive forces concur in act with an endeavor to move the same body toward diverse, but not opposite, regions of the World. For from this very fact — that one [movable] exercises its force in act and is in no way wholly impeded by the other — we see the movable really moved along a path proceeding according to each force owed [to it], but not simply [according to either]. Thus rivers, or streams, when heavy bodies are forced downward, can rush into a perpendicular precipice and impinge in a sloping channel, descending by a mixed and oblique motion. When the diverse forces of two motive powers endeavor to move along one path, one toward one region of the World, the other toward the opposite — then, if one of the forces prevails before the others, the impetus is moved toward one region, or if it prevail thus first, it is turned back, and finally is overcome; and then afterward the motion [proceeds] into the other region, so that, the [body] projected upward, the impetus being at last overcome, they fall back by the force of the impulsions onto the heavy bodies downward.

16. But — and from the absurdity — let the falsity of the contrary opinion be likewise convicted. For imagine a lake ABCD, full of Water,

Diagram. A horizontal rectangle ABCD representing a lake of water seen in plan/section. The top edge runs A (upper left) — E (top center) — B (upper right); the bottom edge runs G (lower left) — D (lower right). A diagonal line runs from the upper-left corner A down to the lower-right corner D, with point F marked at its center; a short vertical segment EF drops from E on the top edge to F in the interior.

- A (upper left corner): corner of the lake
- B (upper right corner): corner of the lake
- E (top edge, center): point on the near shore AB
- F (interior, center): point on the diagonal, below E
- G (lower left corner): corner of the lake
- D (lower right corner): corner of the lake

except for a transverse embankment BFC, and some terrestrial ridge inhering at the shore AB on the lakeside, where its enemies are. Who in his sound mind would say that it flees from AB along other perpendiculars, [path] EF, and yet at the same time really fleeing along the [other] waters and proceeding [along them], or at the same time the water, and moved along the terrain, even by a real motion — let it be by a real motion made along the terrestrial route BC, [so that] at any moment of the terrestrial route it acquires a greater [distance], and a greater distance from the shore AB, measurable along the perpendicular lines EF, and along others parallel to this. For the local motion of bodies is not really along any space whatever, by which the distance of the moved body can be measured and considered from any fixed point of the World whatever; since the motion in such a distance does not in fact consist, or in relation to any termini whatever toward which the movable approaches, or from which it recedes; otherwise by no determinate space would innumerable [things] be moved together, which is impossible; but in reality it is along that determinate space which is traversed by successive contact from the moved Body. Let the access, then, be greater, and let the greater [distance] of the descending heavy bodies be measured along straight perpendicular lines, by which also, in the hypothesis of a moving Earth, the Earth-dwellers would seem to descend; and [provided] the proportion be found in them, of which [I spoke] in Supposition I; and [provided] the formal descent, as descent, be distinguished and adequately [distinguished] from the circular motion — when it is simply a descent, that is, a downward motion: [yet] not on

that account do heavy bodies really, in this hypothesis, descend along perpendicular lines,

[upper-left column of folio 85]

nor is their descent simply a downward motion, and accordingly it is not adequately distinguished from a forward motion toward the East, but is inadequately [distinguished], since [the descent] consists, by the partiality of each, [of both].

III. Proposition

Of two percussions and sounds [made] by the same body — the one upon a body unmoved, the other upon a body moved or more slowly moving and struck — the greater (other things being equal) requires beforehand, as a precondition, not only greater impetus, but also a greater velocity of motion in the space through which the percussed body is naturally and really moved; so that, if that force by which the increment of impetus, or of velocity, is impeded be impeded, the greater magnitude of the percussion and of the sound be impeded likewise.

17. This proposition, well understood and in the terms in which we have expressed it, is certain by an *a posteriori* induction made in all the cases in which the magnitude of percussion and of sound is evident; for the cases of a doubtful [result] are brought in to no purpose — no less than those in which it is doubtful whether the major [is] greater, or not less, [a matter of] controversy as to how a movable is moved, as [in the question] how heavy bodies are moved in the hypothesis of a moving Earth. For we ought to make known, from things better known, those which are less known. Therefore, the consideration being made, it is established through all cases that the percussion and the sound are manifestly greater from the same body — that there is never a greater percussion from the same body (other things being equal) than [when] the percussing body has been moved more swiftly, traversing an equal space in a shorter time, or a greater space in an equal time. And on the contrary, if the movable be in any way otherwise more swiftly moved, or be checked, so that it move not more swiftly than before, the percussion is made by the same force — so that, just as I make it so, the effect be that it does not strike more forcibly than it had struck before. Thus, because the [stones] of mills, [moved] by hand or by the impulse of cattle for grinding grain, or the grindstones for sharpening knives, or the [stones] of lathes, are wont to be turned, or moved circularly, with such uniform tenor that they strike afterward with no greater blow,

[than before]. On the contrary, because slingers, when they whirl the sling about more swiftly, throw their stones the farther and with a stronger blow, and at a longer interval, by whirling them about, hurl them.

18. From this universal induction, by which it is established that a greater percussion and sound never occur without a prior greater velocity of the movable, the physicists have gathered, and necessarily concluded, that the validity of the percussion and the vehemence of the sound depend on the accelerated [motion] — just as the sound, taken absolutely, [depends on] something certain and not on the pendulum, nor [can it] be made by the impetus of the movable, except by the mediation of the movable's actual local [motion]. Indeed, [the more] ordained the impetus of the movable, and the greater the motion, the greater both the impetus and the percussion, and the sound — but what [matters], because the same force [that] impedes the increment of the impetus or velocity impedes much more the increment of the percussion and of the sound.

IV. Proposition

It is an evident Physicomathematical evidence that the Earth is not moved by a Diurnal Revolution.

19. The argument for this Proposition, reduced to syllogistic form, is of this kind:

If it is evident by a Physicomathematical evidence, by [the fact] that the diurnal [motion] of the Earth impedes the validity of the percussion and of the sound, as we clearly experience to be made, both from the natural motion of heavy bodies, [descending] from a greater altitude, [and] from the [evidence] of those descending through the air, it is evident also that the Earth is not moved by a diurnal motion. — But it is evident by a Physicomathematical evidence, by [the fact] that the diurnal [motion] of the Earth impedes the aforesaid validity of the percussion and of the sound. — Therefore it is evident by a Physicomathematical evidence that the Earth is not moved by a diurnal revolution, or motion. — The Major is certain. The Minor is proved: because on the one hand it is evident by a Physicomathematical [argument] that heavy bodies naturally descend with an increment of velocity according to the proportion owed to the squares of equal times, from what was said for Supposition I; and [that] the percussion is made at the end of [the motion] [with] an increment of equal times, according to the same proportion, by what was said for Supposition II — from which we gather that the increment of velocity is

[upper-right column of folio 85]

real, not merely apparent, by what was said for Proposition III. And by the same proposition, [it is shown] that for so great a validity of the blow there is required beforehand, as a precondition, a proportional increment not only of impetus, but also of velocity in the descent of heavy bodies. — But on the other hand, it is evident from the hypothesis of a moving Earth, by [the fact] that the diurnal motion is such that heavy bodies do not descend along one line, or along several perpendiculars, but along an oblique path, tending downward and forward by the declining fall, by what was said for Proposition II; [and] along an oblique path, by which they would really descend, it is evident that they would so descend with an equal increment, and with so little [increment], that in no way is there a proportional increment of percussion, as was shown for Proposition I. And so it is evident, by this hypothesis, from the things said for Proposition III, that the said validity of the percussion and of the sound is impeded; as we clearly experience to be made from the natural motion of heavy bodies, [descending] from a greater altitude.

20. This argument — because it lethally strikes the Copernican hypothesis — those two Friends mentioned at number 2 vainly endeavored to elude by their stroke, contending either that heavy bodies really descend along a perpendicular line (which we showed to be false for Proposition II, so that the increment of velocity owed to the real increment of percussion be thus false); or that, really descending along an oblique path, yet, though the impetus increase by a continuous motion, it is not necessary that the velocity increase — and yet that this impeded [increase] cannot impede the validity of the percussion (which we likewise taught to be false in Proposition III). And as for their adding that the defect of velocity from the encounter of the percussed body could be compensated, or [made up] in the Annual motion of the Earth — that does not suffice, because the part of the Earth's [surface] struck by the falling heavy body does not meet the heavy body any more than it flees from it, but is carried equally with the heavy body, insofar as the diurnal motion is transferred toward the East. But the Annual motion is so little present that, far from helping or compensating for the downward motion, [it would] rather impede it more by acting jointly, and by carrying the heavy body toward the East in the transverse [direction]. Moreover, what I have brought against this annual motion [I have set down] more fully in Book 9 of the *Almagestum Novum*, section 4, chapter 19, at number 8.

I have called this evidence Physical, insofar as we apprehend by sensible experiments the increment of the velocity of heavy bodies and of percussion thence made, and of sound; and Mathematical, insofar as, on the one hand, we have determined the increment of each by the proportion owed to the squares of the times, and on the other hand, [we have] shown by Geometrical and Trigonometrical measures the quantity of the real space which the heavy bodies would traverse in the hypothesis of a moving Earth — and therefore, by a composite name, I have called it Physicomathematical.

V. Proposition

The Celestial Phenomena can be explained equally well, and even better, by [the hypothesis] of Our [Earth] at rest, as in the Hypothesis of a moving Earth.

21. Galileo conceded this same point in his *Dialogues* (given a Latin dress, page 88), saying: *As to satisfying the appearances, each position is equally accommodated.* And Jacob van Lansbergen [Philips van Lansbergen / Jacob van Lansbergen], in his Commentaries upon this motion, page 1, where he says: *For as one going from Athens to Thebes makes indeed a journey contrary to those [going] from Thebes to Athens, but the path is the same: so the Ptolemaic and Copernican Sphere, contrary between themselves as to their hypotheses, nonetheless display the same appearances in the Heaven.* Yet the celestial [phenomena] are not equally well [explained] in their hypothesis — [the hypothesis] of those who admit solid Orbs, and deny that the five lesser Planets are moved about the Sun, and that the eccentricities of these are to be taken as starting from it; but rather [hold] that the motion of the Sun, rather than a mean, is to be applied in explaining their motions. Therefore in Our Proposition we have added that [phrase] *Ours*, in which we suppose the contrary.

Now if there is anything by which the Copernicans most exult, it is the reason rendered by them themselves, on account of which the stations and Retrogradations of the Planets appear, but are not real in the motions of the Planets — which in truth always proceed directly, [and] always go forward toward the same [point] toward which they once began to tend; so that almost on this ground alone Sagredus, in Galileo's *Dialogues*, was nearly girded [for the journey], so as to pass over to the Camp of Copernicus. But

and so, by a single diurnal motion toward the west carried on continuously, we account perfectly well for the appearance by which the planets are seen to move toward the east, in that they cross the same meridian more slowly than the fixed

stars do; and for the fact that the fixed stars reach the same meridian sooner; and for their apparent retrogradations, in that they cross over there more quickly; and likewise for their being more westerly. Indeed, on our hypothesis, the lower planets are slower in revolving from east to west than the higher ones — as is fitting for movable bodies that are made up of more remote circles in their wheels [Rotis], or [whose] circles consist of larger ones, than those that are moved toward the east; and the diurnal motion is attributed to the Earth, so that it follows that the planets are moved more slowly from the more remote motions, namely from the Sun.

As for what concerns the proportions of the distances from the Sun and from the Earth, it is clear that the same ones must be assigned, whether you posit the Sun at rest or the Earth at rest; since on either hypothesis the same things ought to hold, and can hold, between the Sun and the Earth; nor does this variation depend on the motion of the one rather than of the other.

VI. PROPOSITIO.

The motion of the Sun, and the immobility of the Earth, on the authority of Sacred Scripture alone — which is to be asserted, even if the other arguments drawn from natural reason were of equal weight on both sides.

[Margin: 22]

For my part, I recall that I set out this argument more fully in the *New Almagest* [*Almagestum Novum*], Book [9], section 4, chapter 39. Yet because afterward greater minds have come down to twisting Sacred Scripture so as to turn it aside to an alien sense, those who dared this — chiefly Jacob van Lansbergen [Lansbergen] in his *Commentaries*, and Christoph Wittich [Christoph Wittich] in the second part of his *Dissertation*, just as the whole of the Reformed Cartesianism breathes the same — like Daniel Lipstorp [Daniel Lipstorp] in his *Copernicus Redivivus*; against whom Lentulus has defended the rest of the immobility of Sacred Scripture in his *Nova Sapientia*; Schoockius [Schoock], Book 4, *De Scepticismo*; Tullerus [Tuller] in the *Miscellanea* [?]; Danaeus in his *Christian Physics*, Part 1; Jacob du Bois [Jacob du Bois], *the Ecclesiastes of Leyden*, in his *Dialogus Theologo-Astronomicus*; and Ioannes Eyerbinus [?] in his *Examen of the famous controversy concerning the motion of the Sun, or of the Earth* — for us, since certain new arguments have presented themselves on this subject, it has therefore seemed good to gather here into a few points those by which the controversy, already worn smooth, may be raised up, lest other less weighty matters be heaped together. Therefore let us argue thus.

[Margin: 23]

[Margin: 1. Arg.]

In the controversies in which a Reason is to be chosen from here as the better part — if any have been such — that part is rather to be chosen, for our part, on which the greater Authority stands. Therefore: in this controversy, the better part is to be chosen on the side that has been conceded; but the natural reasons of the part [arguing for] the Sun's percussions would be the larger and from a higher place, as falling [downward], if indeed they were such — yet they are not such, as we showed above as regards the heavenly appearances. And yet, as regards the Sun's motion and the Earth's immobility, Sacred Scripture stands, as will soon be plain. Therefore, etc. The adversaries will answer that the proportion of the larger is the true one, if that Authority of theirs were not turned aside to an alien sense, or accommodated to the common understanding of the multitude, or [stated] according to common opinion, nor [aimed] at the truth of the matter [in itself], but [aimed] at the necessity of [moral] instruction, [and so] absurd, or violent, as it would seem. But on the contrary, I here add a new argument.

[Margin: 24]

[Margin: 2. Arg.]

In the controversy, that part is, all else being equal, the better, on which such Authority of Sacred Scripture stands, that it can speak independently of the prejudice of either hypothesis of the controversy; but such is the assertion of the Sun's motion and the Earth's stability. Therefore, the adversaries themselves say that Sacred Scripture does not speak according to the truth of the matter, in so far as it is forestalled [praeumbri] by the Copernican opinion, and meanwhile they confess that it speaks the truth on this matter — both according to the common opinion of men, and according to the literal and obvious sense of Sacred Scripture. But if, all else being equal, by natural reason the parity of conditions remained and remained in equilibrium, and accordingly Sacred Scripture being invoked [as witness], could neither of the hypotheses, by the prejudice of its sense, [prevail]? — to say nothing of [the fact that] its obvious and literal sense ought, [for] an alien, abstruse [meaning]...

[meri]dian. And therefore, with no small confidence in God, he chose a double miracle — namely, that not the Sun alone, but the Moon and the other planets too, should cease for an entire day from their diurnal motion; for the sacred historian does not say, "the Sun stood still in the midst of Heaven, and did not hasten to set for the space of one day." Yet before that he had said, "*Sun, stand*

still" [*Steterunt, etc.*]. Therefore, by the same token, the Copernicans cannot [explain this] save by a double miracle, namely that the Earth and the other planets stood still miraculously; for naturally those planets were standing still, inasmuch as they were lacking the diurnal motion — but the Earth, which truly was moving, [stood still]; nor did the Sun [stand still] against Gibeon, nor the Moon against the valley of Ajalon, [but] it stood [still]; but on the contrary, with the Earth standing still, Gibeon [stood] against the Sun, and the valley of Ajalon against the Moon. How perverse a sense this brings into the sacred [text], let anyone consider — for no one of sound mind sees it without [some scruple].

[Kings] 4, chapter 20, there is recorded a miracle in the horologe [sundial] of Ahaz, [where] God himself [made] the shadows of Isaiah [recede]; chapter 38, it says: "*Behold, I will make the shadow of the lines, by which the sun had gone down in the horologe of Ahaz, return backward by ten degrees, by the degrees by which it had gone down*" — that is, the Sun turned back so far toward the east that it retraced ten lines, that is, ten degrees, by which it had descended; and what had descended in the horologe by ten lines went back up by just so many lines, which Ecclesiasticus 48 confirms: "*In his days the Sun went backward, and he added to the King's life.*" Now truly, since so great a Prophet as Isaiah did not [profess to] ignore whether the Earth was [moving], which in reality was moving — or did he [profess to] ignore it, when by divine inspiration and by this miracle [he was] urging that the descent of the shadow be made manifest — [thereby] he offered to that King a false proposition concerning the future miracle, [which] could even be accommodated to the understanding of the multitude, and to the King's request [for] the recession of the shadow: nothing whatever depended on the manner, or on the motion of the Sun rather than of the Earth, [even] granting [the man] to be then King, and afterward [&c.]. With a preconceived opinion concerning the motion of the Sun, that [recession] is to be ascribed to the motion of the Sun, [reckoned] toward the west by the [opposite] turning — as if they were ascribed [thus]. Soundly enough, however, it could be expressed *in the Sun*, and yet again *in the Sun the going-backward of the Sun*.

Job, chapter 9, speaks of the wisdom and the might of God, which he confirms partly from those things he made, partly from those things he could do, [if] he willed, [though] he does not [do them]. *Who transfers the mountains, and they know not, those whom he overturns in his fury. Who shakes the earth from its place, and its columns are convulsed. Who commands the Sun, and it rises not, etc.* Here Diego de Zúñiga [Diego de Zúñiga (Astunica)] — whose book was afterward suspended by decree of the Sacred Congregation — dared to say: "*No place will be given to Scripture, which says so openly that the Earth is moved; but here it is said*

that it is moved." But because it has been said rashly, it is shown from the very Scripture, as I am recounting below — meanwhile I take it as proven from Job himself that God can both [act] miraculously and supernaturally; God can command the Sun, that it rise not, as it is wont to rise — nay, in reality, by employing his absolute and omnipotent might he can move the Earth from its place. In turn, therefore, from this it had to be inferred that so natural an immobility of the Earth attended the Sun's diurnal motion, as the Earth's immobility; for [if] the Earth were moving outside [its] whole place, or [some] part, [it would] already not have a place, [as] would be the case, and properly to the whole, or to the moving part.

Psalm 18: the Royal Bard, from natural and true things, begins by commending God [as worthy] of the excellence of God's works, thus: *"The heavens declare the glory of God, and the firmament announces the works of His hands."* By day only, because of the continual succession by which the Sun illuminates the Earth, but even by night by [the light] of the remaining Planets and Fixed stars, which in the firmament [declare] the glory of God at [its] rising and setting; you hear: *"Day unto day utters speech, and night unto night shows knowledge."* But in a different manner; for the splendor of the Sun is so great that it [collectively] outshines all [the light] of the other stars, [taken] even collectively; and therefore [it is] more abundant, and as it were belched-forth from the greatness of God, [the Bard] declares — and [its] rising and setting are most manifest, and are observed by all; whereas [the light] of the Planets and Fixed stars [is] fainter, nor is it observed by many, nor is it as observable as that of the Sun; and therefore he does not say "they utter," but *"showeth"*...

[He] says only as much as concerns the night-contemplator of knowledge. Yet no one — provided he be no quibbler [cavillator], unless he understands not the idiom that the Hebrew tongue has — and the term "Heaven" he understands of those who praise God, [therefore] he adds: *"There are no speeches nor languages, whose voices are not heard among them."* For God can speak in any tongue; he speaks to those who have ears, and to the understanding sense, who have eyes; and to all to whom the sound of this speech can reach, [it] reaches, or ought to reach, [whether] the inhabitants of the Earth are moved in [their] circuit, or [whether] all things turning back [upon themselves] thus seek themselves successively by light, and by the prospect of the Sun, or [by] the rest, [namely] the sidereal [light]; the firmament itself [being moved] by daily conversion to illuminate the Earth in succession: which of these may be the case, they straightway expend speeches saying: *"Their sound has gone out into all the earth, and their words unto the ends of the world."* Whence one may compare the

testimony of the Apostle alleging this very passage; [for] the Apostle, in Romans chapter 10, [setting forth] before [the matter] of preaching, says: *"But how shall they hear without a preacher?"* — just as the Gentiles themselves sought, by their own proper motion, the Apostles, since the same S. Paul there adduces the testimony of Isaiah on behalf of the grace of God in preaching: *"I am found by those who sought me not."* But God [acts] by the Apostles in the world, [sending] forth into those very [places], stirring them up, and illuminating them; thus by the daily motion of Heaven, [he] illuminates the whole earth, chiefly by the Sun's motion, [and] strikes [it]; David [also], and on this matter he speaks especially, [when] he says: *"In the Sun he has set his tabernacle, and he, like a bridegroom, comes forth from his bridal-chamber. He has rejoiced like a giant to run his course; from the highest heaven [is] his going-out, and his circuit even unto the highest of them; nor is there any who can hide himself from his heat."* And if indeed by this property of the Sun and of the stars, David affirms; and thence [he] rises up to the praising of the splendor and the purity of the divine law, [yet] he supposes that property of it [to belong to it]; and from that, as from a certain fixed degree, [the matter] is made [a] moral [one]. Therefore the Sun runs, and with giant strides — [a thing] he expresses by [its] admirable swiftness — with admirable swiftness it revolves; for the Moon truly [is] slower.

Ecclesiastes [Solomon]: *"The Sun rises, and sets, and returns to its place; there it rises again; going around through the south, and bending toward the north, the spirit goes around surveying all things, and the spirit returns again upon its circuits. All the rivers enter into the sea, and the sea does not overflow; to the place from which the rivers come forth, they return, that they may flow again."* These matters are difficult, nor can a man explain them by speech. Now indeed Solomon speaks here of natural things, and according to the truth of the matter, not according to the apparent and common sense; but he himself, as a man very wise in the highest things, [speaks] in the first place [of] the Sun's rising — that going-around [the heaven], that [it returns] to its [place]; and although in this passage Solomon [speaks] of natural things truly, and according to their nature confessing, [men] are forced [to grant] in the first place that he speaks Copernically — and yet this returning is not easily grasped, nor obvious to the multitude, but it is reckoned among the difficult things to know; he is convicted by the testimony of Adam's wisdom, or like Adam himself there testifying, since [it is] from the rising and going-forth of the rivers, [he] speaks according to their nature confessing — they are forced [to grant] that the Sun [moves] truly Copernically; and yet here the returning is not easily grasped, nor obvious to the multitude, but among the difficult things to know it is reckoned: *"All things are difficult, etc."* No cause [for it] can be adduced (setting aside the prejudice of the

Copernican hypothesis) on account of which Solomon should be said [to speak] of the rising and setting of the Sun, or of the generation and corruption of natural things; nor [should it be said] either according to truth [or] according to Solomon's true opinion; nor truly of the Sun's motion. Nor, if he had known this knowledge infused into him by God, ought he to have kept silent that the Earth is moved, [and] to attribute that motion to the Sun, [accommodating it] to the common sense of the multitude — except [on account of] the difficulty of the matters apprehended. But if it is difficult to apprehend in what way, and by what water, [the sea] once and [kept] in equilibrium [by] springs could be poured-out [and yet] ascend through the subterranean passages and into the pristine bubblings-up [of springs]. But he says: just as concerning the Sun, and from it he warns, and [from] the same returning [is] uttered; [it is] previously difficult; the difficulty being apprehended, [it is] such; it occurs by a tacit objection, or by the interrogation [whether] he had explained [the matter] by that same answer: "*All things are difficult, etc.*" For no man can explain all things by speech. Nay, by this very example of Solomon, [Wittich] is wondrously strong to affirm that there [Solomon] persuaded that he wished, that is, [it was Solomon's] most laborious [task] to investigate [as one] wise concerning all things which [are] beneath the Sun — and he adds "*knowledge and labor.*" Nor truly does Wittich [Vuittichius] feign [this]; therefore God did not wish the books of Solomon to be preserved, in which concerning natural things...

and chiefly concerning the motions of the stars, and the disposition of the orb of the earth from divinely-infused wisdom, [things] written according to the truth of the matter — [things] which they are unwilling to investigate by Sacred Scripture, but [which] by Sacred Scripture truly are investigated naturally, [and] are not made known to us through revelations by Sacred Scripture: but by Sacred Scripture truly attributions of motions to the Earth's life are taken away. *I am asking*: Does the creation-narrative of the World made by Moses concern that distinct narration? And what does it confer for the manners, [so] that you may know whether the Earth is a planet, or whether the Sun was created? But if you say [that] thence many things may be derived for the praise of God, and even for [some] moral, mystical, or allegorical senses — I say the same; and I, from the true knowledge of the Earth's or the Sun's motion, as in reality and from such motion we have heard, raised up David [as one who] raised himself to the Glory of God, and to the divine law, [which] I now refrain [from pursuing].

Ecclesiasticus, chapter 23, [speaks] not only commemorating the diurnal motions of the Sun, but also by an aggregation of the days of the year, [it] answers thus: "*Why does day surpass day, and again light [surpass] light, and year [surpass]*

year, [if] from the Lord [is] knowledge separated?" [That is], with the Sun made [and the days] received, [they] are divided and kept in custody by the Wisdom of God; and chapter 43: *"The Sun in [its] aspect announces at [its] going-out: a wonderful vessel, the work of the Most High, etc."* But in what manner [it] is — [whether] custodian of the days, and influx [thereof] from its own motion, or [from] another — [it] subjoins there itself: *"The great Lord who made it, and at His words it hastened [on its] journey."* If Scripture wished to speak according to the common apprehension, [it would speak] for the sake of [reaching] the sense, lest the cause be added to the interrogation. Moreover, [there is] that precept made to the Sun, [which] is to be understood [as] made by precept [given] to the Intelligence moving [it] from [its] natural virtue [and] infused, to persevere [for] so many days [in its] motion, at such a velocity, and so on; [whether] ordained from it, or [whether] its [virtue] be equivalent, or [whether] it be said figuratively [by] precept. Thus [it is] also [with] David, Psalm 118: *"By Thine ordinance the day perseveres, for all things serve Thee."* And [with] that [passage of] Baruch, chapter 3: *"The stars have given light in their watches, and have rejoiced; they were called, and they said, Here we are; and they have shone with cheerfulness for Him who made them."* Matthew, [chapter] 5: Christ himself says: *"Who makes His Sun to rise upon the good and the evil, etc."* Therefore [if] the Sun naturally [has] this very [power] from the influx — unless [there be] a prior gliding-down into the Earth, and [from] this Christ, [who] speaks naturally according to truth, [says it] thus; nor does the Sun [merely] illuminate, unless [there be] a prior [gliding], nor does he [speak only] according to truth, nor according to the common apprehension of the multitude — just as in [speaking] of the setting of the Sun, [it is] to be understood according to the Psalmist, Psalm 103, saying: *"He made the Moon for seasons; the Sun knows its going-down."* Its [going-down] he has called *suum* — that is, from its own proper motion of the Sun, not from elsewhere; as in reality, so [too] from the motion of the Moon; but the rain truly [comes] from the setting of the Sun — but it only appears [so]. Or does Copernicus reckon this also? Therefore [if] from Sacred Scripture, by its [own] property and for the instructing of man, but from man's opinion, [though] the property of Sacred Scripture's modes of speaking be repugnant, the sense of Sacred Scripture is to be formed? Who would dare this? Who? Would that [it were] never! I certainly [say] never. But concerning the Sun [it is] enough: let us descend now to the stability of the Earth.

De Terræ Immobilitate.

[Margin: 25]

Besides the beginning of Sacred Genesis — from which we taught above that the Earth, [being] not of [the same] basis or foundation as the immobile structure of the mundane edifice, but of the Planets, ought not to have been created [first] in the first place, but rather the Sun [should have been created] in [its] place: and besides Job chapter 9, the passage from which the natural rest of the Earth is rather established against Diego de Zúñiga is won. God himself, addressing Job, chapter 38, rebukes the man's ignorance, [him] who, [though knowing] many things about natural things, and [knowing] by sense *whether [a thing] is*, yet is ignorant of the certain causes — either because he is wholly ignorant of [them], or [because he compares them so] imperfectly that he is not [equal] to the Divine Wisdom — [and so] he can be said [to be] ignorant. Therefore God: *"Where wast thou when I laid the foundations of the earth? And upon what are its bases founded, or who laid its corner-stone?"* All this circumlocution, though metaphorical, has nevertheless the congruent foundation of the earth's nature, and the basis of all bodies created by God — from which, accordingly, He there begins — signifies, and not only...

the mutual coherence of [its] parts [holding together] with as much as is [held] by the etherial motion. But [if] this too [is] to [the comprehension of] the multitude on account of God's command — *"it [is] not inculcated"* — and at [its] apprehension — and I [grant] it inculcated, if the Earth really were moved — hence the more forcibly the argument [is] derived against the imperfections of human understanding — [namely], that I press it [thus]: *that [thing] stands*; nor by [any] need of [its own] proper standing, [does it stand]; you have interrogated me [as to] which of these may be the case: *Knowest thou not that [thou] [art] able to move the Sun rather, and [to make] the Earth stand, or [rather] that thou [art] able [to make] the Sun stand and move the Earth?* If you should say [that] Sacred Scripture does not have, by [the] natural intention of teaching the men of [its time], from this seed in that very chapter 38, [it] would refute [the supposition] in which God, primarily indeed, intends to reduce Job to the natural and to a recognition of his own imperfection, and thence to humility, and to reverence toward the [divine] wisdom; secondarily, however, [it gives] for [its] middle term this end: that he propound to the natural [philosophers] the true things — [things] which, [though] difficult to know, are nevertheless [to be] inferred from the difficulty itself; whence, [if] the terms [are] most [aptly] composed of the dim [and] of the twilight, or [of] the dawns of the deep, and [of] the dark profundities, this is by the way by which [one] goes down to the lower regions [the underworld]; concerning the amplitude of the earth's surface — in what manner the light is propagated, in what manner the snow, the hail, the ice, the dew, the mist, the lightning are formed, [and] in what manner [the influence], when [the

stars] of the Pleiades [are] so closely conjoined, are [held together], [so that] their ratio and order and concourse of the heavens [endures] — and by what instinct the cock distinguishes the hours of the night: which things God there commemorates, not as mere appearance, but as truly — [things] of which, [though] the property of the nature [be] ignored, [the man] is yet ignorant of the [true] causes — let us pass on.

Book 1 of Paralipomena [Chronicles], chapter 16, they say: *"He is borne by the face of all the Earth"* — that is, He founds the immobile orb, that it remain immovable; *"Let all the Earth be moved [tremble] before the face of the Earth"* — that is, let it fear, [that] it may stay [firm]; as [they] have it [in] Job chapter 26: *"He hangeth the Earth upon nothing"*; or, as they have it, Psalm 92, of which the Title in [chapter] 70 is such: *"In the time before the Sabbath, when the Earth was founded"* — [a phrase] a hundred times [used by] David himself — thence [is the] chief might of God praised: *"For He hath established the Orb of the Earth, which shall not be moved"* — Psalm 103. *Who hath founded the Earth upon its own stability* [Psalm 104]: *"He hath founded the Earth upon its stability; it shall not be bowed [inclined] for ever and ever."* Of [its] foundations: *"He hath founded it upon the seas, etc."* So [too] Ecclesiastes [chapter] 1: *"But the Earth standeth for ever"* — the Hebrew reading has it: *"The Earth standeth fixed, and consistent it is."* And Proverbs 8: *"When He prepared the foundations of the Earth"*; or, as they have it [in chapter] 70: *"When He made strong the foundations of the Earth."* And Isaiah 40: *"Who hath measured the bulk of the Earth with three fingers"*; and chapter 44: *"[I am the Lord] who alone establish the Earth"* — *"stretching out the Heavens, [I] make firm the Earth."* By which passages not only the coherence and permanence of the parts [is signified], but also the constancy [of the whole], the integrity of the whole, is signified, since these things [pertain] to the Sun, [or] to the heavens; whereas the Planets are said to have foundations — [though] God hangs the Earth upon nothing — [it is] not by mutual [coherence], but chiefly by [its] local consistency [that] it is inculcated [as] standing, [to those] who are unwilling, [the] unwilling Copernican.

Respondetur Novis quibusdam, vel nova forma inculcatis Obiectis præcipuè ex Sacris literis posit.

[An answer is given to certain new objections, or [objections] inculcated in a new form, chiefly drawn from Sacred Scripture.]

[Margin: 26]

The Copernicans truly have no arguments by which they could prove [their case] directly from Sacred Scripture [for] the [Earth's] mobility and the immobility of the Sun, save that [passage] of Job 9, which yet against Diego de Zúñiga [Astunica] shows the natural immobility of the Earth rather [than the contrary] — [a passage] confirming [it], with God's power [left] intact. They are moved, if [they] wish [to argue] that [passage], that they may by an indirect course endeavor to assert that God in the sacred letters did not wish to instruct men in natural matters — of which sort [are] Physics and Mathematics; and therefore, if it should befall Him to speak incidentally, [He] would speak [merely] according to the sense of the multitude, and according to common estimation, [and] either [according to] its truth, [or] as [it may be] true or false; especially in matters difficult to grasp, or [matters] foreign to morals, [to] life, and [to] the instructions [pertinent] thereto — nor [are these] pertinent — nor in any way [do they] withdraw the ruder men from the difficulty of [their] apprehensions, and in other things either; nor do they withdraw the faith from the sacred Codex. But to the [assertion] applied to the various particular passages of the matters asserted [about the Earth's] stability, they adduce in general that [passage] of Isaiah 8: "*Take thee a great book...*"

the great one, write in the very style by which you address men" — so says Wittich — "speak in human fashion, and accommodate yourself to the understanding of the common people in your manner of speaking; and that saying of the Apostle, 1 Timothy 3 [recte 2 Timothy 3:16]: *All scripture, divinely inspired, is profitable to teach, to reprove, to correct, to instruct in justice; that the man of God may be perfect, furnished to every good work.*"

27. I reply, first: it was the primary intention of the Holy Spirit, in the Sacred Scripture, to teach men those things that pertain to our salvation, to faith, to blessed life — and, when it leads to that end, also the knowledge of human history insofar as it is natural, that is, the knowledge of natural properties; or whatever serves natural matters insofar as they are means by which men are stirred to the praise of God, to comparisons, and to drawing examples from them for forming and correcting morals — being applied [to these ends], but not taught by the scholastic method of natural philosophy. Rather, Scripture supposes these things, and states them in plain propositions, as is clear in Cap. 38 of Job, in the Psalms, in Ecclesiastes, in Proverbs, in Ecclesiasticus, and often elsewhere. But I deny that the Sacred Scripture is false in things that it abstains from accommodating or expressing in the manner of speaking [of the common people], so false that it could be detected to be false in some matter whose authority is unimpeachable — which would indeed be far greater and more dangerous than

to say that something arduous to grasp is taught; lest, for that reason, men be deterred from believing it in other matters. Are Catholics therefore obliged to believe more than that — that things otherwise known by the natural light, or easy to grasp, are such (because such are the Mysteries of the Most Holy Trinity, of the Incarnation of the Divine Word, of the Eucharist, etc.) — and to refuse [belief], because such things are most difficult, as though it were false belief in a formal motive [for assent], and as though the authority of God speaking were not the [proper] motive of human understanding? Did Christ abstain from preaching the mystery of the Eucharist, even before he instituted that Sacrament, because that discourse seemed hard, and many of his disciples drew back from it (John 6)? By no means. That God should die was for us a scandal to the Jews, and to the gentiles foolishness; the Resurrection of the dead seemed new to the Greeks, and the dogma incredible: did Paul and the rest of the Apostles on that account abstain from preaching it? But, you object, these [doctrines] sought faith for themselves, [as bearing] upon salvation, and not in opposition to incredulity — and besides, heresies are many which foretell future things, [and] wish to be held in the estimation of revelation and to be promulgated, since for these reasons they capture the understandings of many who would be willing to render obedience to faith, and who profit in merit and salvation. You say well; but, as I said before, I deny that, *if the Earth were to move and the Sun to stand still, the Holy Spirit would not on that account be moved* — but only by accident (which things known by the natural light are able to be revealed by God beforehand, or [are] by accident useful to natural knowledge), [and] the theologians say that the faith [resting] by accident, and equally to be believed, [does not] depend (which things that are *per se* of faith because of the identity of the formal motive — namely the Authority of God speaking — would have revealed [it], He would have foreseen that there would be many who, on this account, would withdraw their understanding from the obedience of faith) — though learned and skilled men will recognize this, and not without difficulty, so that they hold it; nor does it conflict with truth, and indeed it is hardly more difficult [to grant] that it accords not only with the Copernicans but also with the Tychonics, and with most astronomers — even the semi-physicists — readily to grasp the motion of the Earth, especially the diurnal, and the one already proposed by Pythagoras, Philolaus, and the ancients of this sect: not only [its] followers, but even Ptolemy and others would have grasped its form as [their] motion.

28. Nor, indeed, as they [the Copernicans] seem to suppose in this, [does it follow that] the Sacred Scripture is written for the common people, either because the very great mass of the common people, or [those of them] who are most uncultured, do not know letters, or [know] only the vernacular tongue; but

Scripture is grasped by [those] skilled in the Law and by Teachers, and by Doctors of the people, who, first taught by the Holy Spirit, then instruct the common folk. Therefore God ought not, on account of the lack of skill in the common people — in those things in which it is deceived by sense — to assert falsely along with the common people, and to confirm that falsehood by the weight of its [the common people's] authority; nor, [warned] by the apprehension of the lack of skill, [to use] the formulas of his own divine manner of speaking, but out of the decency of his Majesty greatly to beware, lest he ever be detected of having said something false; lest the testimony...

of his testimony be sealed by his own seal, and to confirm an assertion as true that is in fact, as to its appearance, absolutely false. Indeed, since he best foreknew things to come — lest at length he be discovered, by the common people, to have fallen into the motion of the Sun (if the Sun truly were not to move, but the Earth) — he could, given a hypothesis of this kind, and many others into his own opinion adduce novelty; or, given the evidence, [there might arise] a great difficulty of teaching: he could, indeed he ought to, assert this very truth in divine letters — yet still abstain from adding the contrary [opinion]; or, in supposing the contrary falsehood, [he ought] not to propose it expressly to those unskilled, lest, an opinion being held that is difficult to grasp — and the falsehood being asserted in opposition — he should know that to be false, but for that very reason speak so [as the common people speak], and not in greater proportion [to their grasp] than the most unskilled would — being skilled by his own testimony in [the] genius of falsehood. To me, who am a little man, such forms of speaking are not lacking; nor does God supply them. Do I give an example? When Christ said: *Who maketh his Sun to rise upon the good and the bad* (Matthew 5) [Matthew 5:45] — if the Sun did not truly move, he would speak [thus]: *Who maketh? And the Sun and its light are enjoyed by the good and the bad*. Likewise, when Joshua said in the Sacred Scripture: *It stood; the Sun did not set* [Joshua 10:13]: if it set not, he would speak [thus]: *the light of the Sun upon the earth, nor was [it] done so; nor [was] that prolonging of one day* [the prolongation of that single day]...

For so speaking, and having accommodated himself to the grasp of Joshua, or of the people who could form some common estimation of the Sun's motion, [Joshua] said *Stand, Sun*, although there is another version, or [reading]: *Move not, Sun* — [yet] the Sun does not move; but the falsehood [thus] not spoken, nor [is] the lack of skill in such things to be given as a most pernicious occasion of controversy; nor yet, [even] in these things said by him, [is it] to be spoken according to mere appearance, and not according to truth, and accordingly never

[should] human understanding [be set up] as the authority of [the] diviners in their assertion.

29. I reply therefore, second, more briefly: by denying that the Sacred Scripture asserts the false proposition as true, but [asserts it] only as to appearance — yet, [as] true, it speaks true things, whether in natural matters, or [in matters] of faith, or as accidents [thereof], or in moral matters, or in mysteries, or in dogmas, which are *per se* of faith — but [I deny] that it is written and that it speaks things unskilled; on the contrary, I assert that the Sacred Scripture, notwithstanding whatever danger of scandal or incredulity, in these complicated propositions, always speaks the truth, whether properly, or figuratively, as it figures itself to speak — although it sometimes happens that it is uttered with some tacit contradiction, [yet] it never asserts an opposition contrary to the contradiction. Moreover, I say, along with Saint Augustine, Gregory, Thomas Aquinas, and the Catholic theologians, that the Sacred Scripture always [is] first to be understood in its literal sense, insofar as the words sound to the common [reader] — when there is no manifest inconvenience in their being taken so. Just as in the proposed controversy, since by no one has it yet been demonstrated that the Earth moves, and [that] the Sun's immobility, [its] quietness, [is] the opposite — let those followers of the Copernican Revolutions who labor to vend a contrary [view], and the Cartesians [followers] of [the] vortices, to whom most of the experts in physics adhere most vehemently — let René Descartes [Renati de Chartres], a man of sharp genius, in some doctrines acknowledge the judgment, what in others is wished for. The more, therefore, that it has been demonstrated, the more the *per se* has been done — [yet] that the Earth moves is not [demonstrated].

30. I reply, third: by indirectly turning back the argument against the Copernicans thus. If [a matter is] of such great difficulty to grasp [as] the motion of the Earth and the quietness of the Sun is conceived [to be], so that, on account of it, God ought not to have wished to safeguard this truth, but in the opposite [direction] to assert it — much more, then, ought the Copernican novelties of this doctrine to be moderated, and promulgated, the less their authority [is] divine, [and] the greater the human; and [the] greater the liberty of responding, and of despising the human, than the divine. If you say the Copernicans should not be promulgated to the common people, but to those skilled in astronomy — nor [that] this be of their intention, [namely] that they themselves should write so [as to be understood] by the learned [doctors], by the vernacular version, or [in] speech communicated to the unlearned doctors, in which there is danger of falsity and absurdity, and to be feared. And I, in turn, will say that God could

rather, in the sacred letters, express this very doctrine — [if] he meant to indicate his own intention, that he would have promulgated it to learned men [for] those reasons by which it would be persuaded to no one [reading it] next to that very [saying] of the Apostle, 1 Corinthians, Cap. 2 [1 Corinthians 2:6]: *But we speak wisdom...*

M

[wisdom] among the perfect, that is, as he expounds in the same place, [the wisdom] of spiritual things; God helping, [those who are] capable: *Not to the animal man who perceiveth not these things which are of the Spirit of God: for it is foolishness to him, and he cannot understand* [1 Corinthians 2:14]. And that [saying] of Christ: *Do not cast your pearls before swine* (Matthew 7) [Matthew 7:6] — *lest they trample them with their feet, and turning upon you, they tear you* [Matthew 7:6]. Was it less permitted to God in this matter than to Copernicus?

Now I come to the particular passages of Scripture, which they emend [or claim] in such a way that they would have it persuade by some other manner — or babble along with the common people — even the false, what is absolutely false, [though it] does not openly appear.

31. They object, second: that the Apostle uses the version of the Seventy [the Septuagint] interpreters, in order to accommodate himself to the Hellenists, although in some places he disagrees, [his] father, why is [it that] he rarely dissents from the Hebrew and Vulgate. I reply by denying that, in passages used in the Gospel, or in Acts, or [in those] from the letters of the Apostles, the Scripture is erroneous — granting that he asserts that the Hebrew is the Vulgate, nor does he affirm; [I say] that S. Luke says: *Who was [the son] of Sala, who was [the son] of Cainan, who was [the son] of Arphaxad* — but the Vulgate, at Genesis 11, has no [Cainan]. Now, the mention made of Arphaxad here, by [the] mediation of Arphaxad, is begotten of Cainan — whence it could be gathered, in the ancient Hebrew [text], that the seventy years which are in other Hebrew copies of the Bibles, by lapse of times, were perhaps omitted by the carelessness of the copyists.

32. They object, second: that [saying] of Matthew 19 [Matthew 19:16]: *Master, what good thing shall I do, that I may have life eternal?* — who said: *And why askest thou me concerning the good? One is good, God; if thou wilt enter into life, keep the commandments* [Matthew 19:17]. Here Wittich [thinks] that Christ denies himself to be good, because he knows himself to be good — namely, because, in the estimation of the questioner, there was not yet [the recognition] that he is

good, nor [that] he affirmed [himself good], because, in the estimation of the [questioner], from the words spoken in the duplex effect: the prior indeed, [that] when he asks for the good thing necessary to be done — *And [why] do you say [Greek: ἀγαθόν (agathon, "good")]*? — [Greek: τι με λεγεις ἀγαθόν (ti me legeis agathon, "why do you call me good?")] — what do you say [is] good, namely the master, as if you said: "you call me a better master than [other] men, but you have not given me [the] commands to be kept; and differently I [will say] to you, [that] life eternal I am able to obtain, if you wish this opinion to be held" — you are deceived; for one only is [the] good Master, [namely] God, and therefore keep the commands which he has given. The other sense is: But why dost thou call [me] the absolutely good master, when [me] men in their estimation, [but] not absolutely [good], you say [me]? — if thou call [me] God, or thou ceaseest to call me good absolutely.

33. They object, fourth: *And Herod the king heard* (Mark 6) [Mark 6:14]. But here Herod was the brother of Philip, whose wife he took, and [who is called] Tetrarch of Galilee, not King — but he is called king (Mark 3 and Matthew 14). I reply by denying that he was not a king, since [Scripture] said it [thus], although in a fourth part [only] of the Kingdom — nor do those two appellations conflict, *King* and *Tetrarch*; for the same S. Matthew, Cap. 14, who first called him Tetrarch, afterwards calls him king: *And he made the king sorrowful* [Mark 6:26], etc. For Augustus Herod the Great, in a fourfold part [of the kingdom] dividing [it], gave [it] to Archelaus, [and] to Philip, [whom] they call Herod [as] Antipas; yet he attributes [the title] to him, nor was anyone able to constitute them king — nay, all to whom he would have made [the] kingdom should be called king without contradiction; among the Jews, however, he was held for a king, and bore himself toward the kingdom — and by paternal natural right, [though] not by Roman right [it was] permitted [him], [for] he was king by imperial right.

34. They object, fourth: those words of Christ (Luke 5) [Luke 5:4], where he seems to speak according to the common estimation of the sea: *Launch out into the deep* [Luke 5:4] — where the deep sea seems higher than the very shore. I reply: the deep sea, distant from land, appears to sense higher than the shore itself; this happens because, the water being deeper, [though] near the shore, where there is a greater plenty of fish — and conveniently for letting down the net more deeply, Christ required [it] — that, without any miracle, there the fish might be driven into the net, where they were sought. The altitude [or height] here signifies the depth rather than [that] it needs to be proved by Grammarians; and there is another cause [why] the deep sea appears more distant: not so much [that] it appears higher by reason of [the laws of] optics, but also [that] it truly is so —

namely [that] the eye, accustomed to the level shore, [does] not see by an angle, nor [a sea] rounded; and [yet] the surface of the sea, [if] considered, [is] a plane...

the imagination [being] led on by the shore, and [the sea] cutting [across], at length truly [appears] higher in the surface than [it] is — as such a plane, just as the periphery of a circle is higher than the chord [subtending it] which lies beneath.

But, pressing in the same place, Cap. 5 of Luke [Luke 5:32]: *I came not to call the just, but sinners to penitence* — where the just [are] Pharisees, in the estimation of [the] common people; the just are called [just], not according to the truth of the thing, but according to the opinion of them, who esteemed themselves just, and despised the rest. I reply by denying that Christ asserts the Pharisees to be just — but he says only that he came to call sinners to penitence, not the just; just as when a Physician [comes] to heal the sick, not the sound — for as he himself affirms, *the sound have no need of a physician, but they that are sick* [Mark 2:17] — or [that he came] to decree something else, except the just, who [are] not [just]. Therefore, with many adults excepted (his most Holy Mother, and S. John the Baptist), [who] were sinless and needed no penitence, he came to call all to penitence; and therefore Luke 13: *Unless you do penance, you shall all likewise perish* [Luke 13:3]; for, as the Apostle says, *And they have sinned* (Romans 3) [Romans 3:23]: *All have sinned and need the glory of God* [Romans 3:23]. Therefore the Pharisees thought themselves to be just, [but] not on that account did Christ confirm them, [as if] they [were] just according to [their] opinion; he spoke according to opinion.

35. Does not the Apostle, 2 Corinthians 4 [recte 2 Corinthians 4:4], say: *The God of this world hath blinded the minds of unbelievers* — calling the Devil "the God of this world," according to the opinion of the gentiles, who worshipped demons as evil [ones] and as Gods? I reply: that blinding, although insofar as it proceeded from a gross ignorance, or from depraved dispositions, or [from] some preceding fault, was [the work] of the Devil, as instigating to sin; nevertheless [it was permitted by God] to sin, [and] God by his just judgment denying [them] the abundant light — [yet] grace not being denied as sufficient. How is the blinding attributed to God indeed by Christ himself, John 12 [John 12:40], confirming [the saying] of Isaiah [Isaiah 6:10]: *Blind their eyes, and harden their heart, that they may not see*, etc.?

36. They object at last — that I may pass over the lighter [objections] — Wittich [adduces] the saying of the Apostle to the Hebrews 7, on Melchisedech [Hebrews 7:3]: *Without father, without mother, without genealogy; having neither beginning*

of days, nor end of life — [Scripture] likening [him] also to the Son of God, [and saying he] *remaineth a priest forever* [Hebrews 7:3]. But [Melchisedech] doubtless had a father and a mother, and a beginning of days; therefore those things cannot be received according to truth, but according to opinion, and the notice of them, as a matter, etc. Or, because [their] origin is unknown — and a genealogy of Melchisedech, [which] those who think [it] is [unknown], etc. I reply by denying that the Apostle, in that place, spoke according to opinion — perhaps no one of the Hebrews was able to write of it; the most lying [genealogist] had it [as] uncertain, [or] explicate his own destruction, in these words: *Whose generation [Scripture] never numbereth among them*; for the tithes were taken from Abraham. Since therefore his genealogy is not recent, [it is] in the sacred letters, just as of other Patriarchs, nor of [the] times of death — therefore for that reason, by some saying [or rule], but with a grain of salt to be understood, [Scripture] said of [his] father, etc.; and because that figure of the eternal Priesthood of Christ [was made] — but the figure imperfect, because Melchisedech died at length, yet, suggesting [what] the Apostle [says] of Christ: *Made priests, the more they were, because by death they were prevented from continuing* (Hebrews 7) [Hebrews 7:23] — but Christ, because *he continueth forever, hath an everlasting priesthood* [Hebrews 7:24].

37. *Objections sought from Reason*, [which I treat] now in a single [place] in the *New Almagest (Almagestum Novum)*, Book 9, Sectio 4 [*Almag. Nov. IX.4*]; nor among recent followers of Copernicus do I find any new argument that I have not already refuted — much less [one] that I should refute. For [there is] that ancient [argument], drawn from the excessive velocity of the fixed stars: I see [it] inculcated by Jacob van Lansbergen [Iacobo Lansbergio], and tossed about by him for [something] *infallible*; and I have experienced this very argument [in] a certain Catholic Knight, an Angel — a man of great judgment here at Bologna, and of [keen] genius, [who] was greatly moved in the Copernican hypothesis very much, [as] proposing this very [argument] persuaded him, and showing how it pressed [him], [though] light. Suppose, then, that Jacob van Lansbergen [Lansbergius] places the fixed stars distant from the Earth by 10,302,927 [recte 10,302,927] semidiameters of the earth; whence it is gathered [that] the fixed stars [run through], in 24 hours, [as] the whole periphery [they] absolve, [in] one [hour] in one second of the hour, that is, in that very instant [or] blow [of time], traverse [Greek: not present] German miles 643,848 — *which*, he says, is *impossible*, because, *since there is no proportion between a moment of time, and a swift motion of a physical body*: from this it seems [he wishes] to indicate that such a motion [is] made in an instant; [yet] he wished to indicate the very motion

of the fixed stars in one second; [and] he wished there to be no difference between a moment of time, and...

time, [in] which only the space might be traversed; or [that] that motion would be made in an instant, [and] not made in a swifter physical [time] than if it were made in one second of the hour. As if we could not discern the time in one second [as] shorter; when nevertheless, as is said in *Almagest*, Book 2, Cap. 10, Proposition 13 [*Almag. Nov.* II.10, prop. 13], we have a pendulum whose single vibrations are absolved within 10" [10 seconds]. But I argue: I deny *à peri-* [the conclusion] to be impossible, [that] a physical body in one second of the hour traverse 643,848 German miles. I deny again that this velocity is disproportionate to a physical body, if this be made to agree by [its] motion with the motion about the center of its circle, and from the very distance from the center. Because, from one part [of] the circumference of diverse circles among themselves, they are as the Diameters, and accordingly as the semidiameters, [as is shown] from Theorem 5, Book 11 [Elements XI], [and from the] collection of Pappus of Alexandria [Pappi Alexandrini]; and from the other, as is demonstrated by Clavius [Claudio] in the *Sphaera*, [that] the arcs of several circles described from the same center, and [described] by the same straight lines drawn from the center, are like [arcs] among themselves.

Thus, if any one of these arcs is a sixth part of its periphery, the rest also will be each a sixth of their [own] periphery. Whence it follows that such arcs are proportional to the semidiameters, or to the distances from the center. Let there be described, then, from the same center of the world, the Equator of the terrestrial Sphere, [and] the Equator of the Sphere of the Fixed [stars], [each] by a finite interval; and let us imagine both Spheres to be moved by a diurnal motion; and let the semidiameter of the Earth be 860 German miles; and therefore, [in] one second of the hour, the terrestrial Equator [passes through] a small arc which it traverses [in] 15''' [fifteen thirds], that is, the tenth part of one-sixth of one German mile, [as measured] by Geometric paces. Let there be on the other part the semidiameter of the Equator of the Fixed [stars], of 8,600,000,000 German miles. For, as the Radius 10,000,000 [is] to 15" [the second], [so is the] Chord 720 [imperceptibly less than its arc], [in] this [proportion as] 8,600,000,000 [is] to 619,200 miles. I say that the same proportion [holds] between this arc, and the distance of the Fixed [stars] from the center, which is between the part [of] 16 German miles, or the semidiameter of the Earth, [and] of the foresaid distance 8,600,000,000; thus 860 [is] to [619,200], which [is] reduced to the smallest fraction $\frac{5321300}{10000}$, which reckons the minimal fraction $\frac{4}{5}$. But our imaginations, [being] narrow, do not comprehend that number of 619,200 [miles to be] traversed in one

second; it seems incomprehensible; yet it behooves [us] to consider, [as] Atlas [might say to] that [man] whom I would call a Giant, of what kind and how great [the] paces would agree, [in order] to comprehend the traversal of an arc by one second of the hour — and [that] those German miles, [being] 25 [to a] celestial part, are not to be esteemed less impossible [a] motion of such kind, [than it is] possible [that] lightning [traverse] in one second of time 24,000,000 ant-like steps; if we suppose [the] arc to be some German mile, namely a tenth [part] of an arc, [it is] possible to absolve one German mile, that is the Italic [mile], [as a] strong [pace]; and [in] one second of an arc not to absolve [even] the hundredth part of an uncial [particle] of one foot. Therefore Wittich [Vuittichius], and some others of the Copernicans, [who have] confessed this to be the argument against the velocity of the Fixed [stars], [is] no more valid than the Ptolemaic argument against the Copernicans, [which is drawn] from the immense distance of the Fixed [stars]; than which this hypothesis...

requires, that the whole orb of the Annual [orbit] with respect to the Sphere of the Fixed [stars] be as a point.

34. [recte: a misnumbered §34 — the preceding sections ran 27–37; this Arabic "34" in the margin appears to mark a new sub-argument. See QA.] After I had written these things — behold, [there came] to me a Letter, given the 28th of December in the Year 1660, [from the] Most Reverend and Most Learned Juan Caramuel y Lobkowitz [Io. Caramuelis], Bishop of Campania, [a Letter] full of Galilean friendships, and the contribution of D. Pironi [D. Pironi]; who, from Galilean friendships, [was] anxious; this concerned the supreme [matters], being thrust upon me. There is [a difficulty] concerning the supreme [star] of the front of Scorpio, [a] little star which, as I have often observed, in [its] interval, the Sun being [near] about [its] end [of the sign?], being turned [Greek: not present], appears somewhat greater than the stated star — greater, [the interval] being then about 5'; but when the Sun is at the end of Aquarius, it appears about 4'. And so this interval then appears about 5'. But when the Sun is [under] the end of Aquarius [sub fine Aquarii], on the 22nd of February in the Year 1644, I estimated the interval of the stated stars [at] a third part of the diameter of the greater star — and equal to the diameter of the lesser star, this [being] 1'·10"; and so this interval is the less, [by] the whole 3'·40". So great would be the parallax of the stated stars. The Observations were made with a good Telescope, and Most Reverend Caramuel was present with me. *If the Telescope deceived [me], let these stars always appear equidistant: they do Not appear equidistant; therefore the Earth would move. From the [varying] interval of the Copernicans, [it may be argued] whence the annual motion of the Earth could [be persuaded] — not only [is]*

the annual motion of the Earth persuaded, but even the distance whence the very distance [is derived]: weigh this hypothesis well, not as [a] thesis [I] put forward, [but] weigh the argument, and consider what you judge; this little reasoning seems to need [a] solution.

I replied at once that those observations [were] for themselves, and [for] the Copernican hypothesis, contradictory. For if, in the approach of the Earth toward the supreme [star] of the front of Scorpio, [its] distance [were] 4'; and its interval [were] nearer [to] the second little star [by] 5'; [it would be] indeed [that] in the recession of the Earth, whence [it is that] the diameters apparent of the Fixed [stars] ought proportionally to decrease optically — [both] the diameter apparent of the Fixed [stars], [and] their interval among themselves — [yet] if the supreme [star] of the front of Scorpio always appears greater, [and its] interval [greater]: in the other case, if the interval be decreasing, [yet] the apparent diameters of these stars not decrease, we would have hence no argument of the approach of the Earth [toward], [and its] recession [from], [the stars]; since, the alternate annual approach being necessary, or [the alternate] reason [why] the interval [of] the stars varies optically — but rather [that] the Earth, [being] immune from the annual motion; and on the contrary [that] the motion of these very Fixed [stars] [varies] among themselves, [their] interval varying, what [an] illusory [thing] you maintain, [namely] their interval to be decreasing [in] one second; [and] their diameter [as] of itself, or, the diameter of the Fixed [stars] not decreasing — [yet] we would have no argument hence of the approach of the Earth.

Whatever [the case], indeed, and however much potent the Telescope you use, never, after some months — even [if] for certain you could discern [it] by the inner [reaches] of the Fixed [stars] — [could] their interval decrease [by] one second; when within the same hour they consist in the same quantity, even by the optic diameter of the Fixed [stars], because the very thing about which it is doubted [is] within one second. Nor [is there] anything here [whereby] we [might] say of the diverse aspect [of the air], and of the wintry constitution of the [winter] air, to which so great a variety could be referred. Let the lovers of the Copernican hypothesis therefore beware, lest by fallacious observations they impose so great a mass of new hypotheses [upon us], and [these] so [much] repugnant to Copernicus himself.

LIBER SECUNDUS [BOOK TWO]

SECOND BOOK

IN WHICH SELECT OBSERVATIONS OF ECLIPSES OF THE MOON AND OF THE SUN

are gathered, for establishing the lunisolar motions and the first inequality of the Moon, and for fixing the limits of the apparent diameters of the luminaries.

CHAPTER I.

On the selection and use of observed eclipses for establishing and verifying the astronomical tables; and on the assumed distances of meridians in the more celebrated tables.

1. As we set out at length in Book 5 of the *Almagestum Novum*, we reviewed very many observations of eclipses from the year 772 before the Epoch of Christ down to the year of Christ 1647 (chapter 19); and in an appendix to that same chapter — which stands at the end of the first volume — we added still others down to the year 1659, and yet others afterward down to the year 1657. These we either observed ourselves, or received as observed by others, and we found certain ones in the Lodi tables of Father Jacobus Billy [Jacques de Billy] of our Society, and likewise in Pierre Gassendi [Petro Gassendo] in his *Epicurus*, page 886. Not all of these, however, are to be recalled here, but only as many as are needed, whose observed magnitude — or at least the determined mark of time, not only as to the day but also as to the hours and their fractions — is sufficient. For those alone are suitable for establishing and verifying the lunisolar motions and the diameters. On this occasion we have corrected, either through faulty figures of the typesetters or even through our own in the days, in which we had followed Petavius [Petauium], Scaliger [Scaligerum], Mulerius [Mulerium], Copernicus, and Boulliau [Bullialdum], but afterward, the error of certain of them being recognized, we abandoned them.
2. Would indeed that all the aforesaid eclipses, however great their magnitude and however precise the mark of their time, were apt to attain that exactness which the more recent astronomers aim at. But to profess

sincerely how the matter stands: not many suitable for this business can be found, chiefly on account of the difficulty of observing exactly the beginnings and ends of eclipses, and their magnitudes — especially those before the use of the telescope, which it was not granted even to Tycho [Tycho[ni]] to enjoy — and for other reasons, to be set out in chapter 4.

3. Furthermore, so that it may be more readily established whether a discrepancy of the calculation arises from a mere difference of longitude, or rather from elsewhere, it must be investigated; and we set out beforehand the distance of the meridians which the authors of the calculation assume, and which must be applied in the observations; and it will also serve, if anyone in the History of Eclipses should at once wish to know in a learned manner the time at which the appearances ought to have occurred in other places.

ALPHONSINE [Tables]

*The Toledo Tables [Tabulae Toletō] **add** for transferring the calculation to other places, but **subtract** for transferring phenomena from other places to TOLEDO.*

We give a fuller catalogue in the Astronomical and Geographical Tables; but this suffices abundantly for the eclipses observed up to now.

CAPUT II.

ECLIPSES OF THE MOON

Observed as to magnitude and moment, from the year 721 before Christ down to the year of Christ 1660. With the errors or deceptions of others in chronology or in magnitude detected.

ECLIPSIS 1.

[Margin: 721 years before Christ (Anni ante Christum 721)]

In the first year of Mardokempad, that is, the 27th year of Nabonassar, on the 29th day of the month Thoth, on the following night, a total eclipse was observed at Babylon by the Chaldeans, beginning more than one hour after the rising of the Moon. Ptolemy [Ptolemaeus], *Almagest* book 4, chapter 6, says that this beginning was at hour 4 $\frac{1}{2}$, before midnight; and that midnight was at hour 2; 30'; but that at Alexandria the hour was 3; 20'. That day was, by the Julian reckoning, the 19th of March. The years before the common Epoch of Christ: 721.

ECLIPSIS 2.

[Margin: 720] [Margin: *Lansbergen's deception* (Lansbergen. Dolus.)]

In the second year of Mardokempad, that is, the 28th of Nabonassar, on the 18th of Thoth, on the following night, an eclipse of the Moon of 3 digits on the southern side was observed at Babylon at the very middle of the night. Ptolemy, *Almagest* book 4, chapter 6, whose text Lansbergen [Philips van Lansbergen] corrupts in his *Thesaurus*, page 55, by substituting three scruples for the three digits — so that the observation should not damage his own Tables — even though the text expressly reads δακτύλους τρεῖς [Greek: *daktylous treis*, "three digits"]. The day was the 8th, with the 9th of March following, in the year 720 before Christ.

ECLIPSIS 3.

[Margin: 720]

Likewise in the second year of Mardokempad, that is, the 28th of Nabonassar, on the 15th day of Phamenoth, on the following night, the Moon began, after its rising,

[continuation of Eclipsis 3:] to be eclipsed at Babylon, defective by a little more than six digits from the north. Ptolemy, book 4, chapter 6, who computes the middle of this eclipse at hour 8; 3'. It was the 1st day of September, on the following night, in the year 720 before Christ.

ECLIPSIS 4.

[Margin: 621]

In the fifth year of Nabopolassar, that is, the 127th of Nabonassar, on the 27th of Athyr, on the following night, the Moon began to be eclipsed at Babylon below half an hour before midnight — that is, as Ptolemy computes, *Almagest* book 5, chapter 14 [?], at hour 5; 30'. The eclipse reached its greatest extent at one-quarter of the diameter from the south. The day was the 21st, with the 22nd of April following, in the year 621 before Christ. A leap year.

ECLIPSIS 5.

[Margin: 523] [Margin: *Scaliger's error* (Scaligeri error)]

In the seventh year of Cambyses, king of the Persians — not the eighth, as Scaliger [Joseph Scaliger] has it, *De Emendatione Temporum* book 4 — on the 17th of Phamenoth, on the following 18th, the Moon began to be eclipsed at Babylon from the north before midnight by 6 digits. Ptolemy, book 5, chapter 14. The day was the 16th of July, the 17th following, in the year 523 before Christ.

ECLIPSIS 6.

[Margin: 502]

In the twentieth year of Darius Hystaspis, who succeeded Cambyses, that is, the 246th of Nabonassar, on the 28th of Epiphi, on the following 29th, at an hour equal after sunset of 6; 20'. And before midnight the 24th [?]. At Babylon a fourth part of the Moon's diameter was defective from the south. Ptolemy, book 4, chapter 9. The day was the 18th of November, the 19th following, in the year 502 before Christ.

ECLIPSIS 7.

[Margin: 491] [Margin: *Lansbergen's error, or deception?* (Lansbergen. error, an dolus?)]

In the 31st year of Darius the First Hystaspis, that is, the 257th of Nabonassar, on the 3rd of Tybi, on the following 4th, the Moon began to be eclipsed at Babylon in the middle of hour 6 of the night by two digits of diameter from the south. Ptolemy, book 4, chapter 9, who expressly says: "For the middle time of the night preceded the middle of this Babylonian night [by] one hour, at Alexandria, however, by one hour, or the third part of one equal hour." Therefore Lansbergen does not rightly put it at one hour before midnight at Babylon, in his *Thesaurus*, page 61. The day was the 25th of April, in the year 491 before Christ.

ECLIPSIS 8.

[Margin: 383]

In the year 366 of Nabonassar, Phanostratus being Archon at Athens, on the 26th of Thoth, on the following 27th, at hour 3; 30'. In the temporal hour after midnight the eclipse was observed at Babylon — a small eclipse of the Moon at the morning rising, when more than a half of the night remained — and the Moon set still being eclipsed. Ptolemy, book 4, chapter 11, who computes the beginning at the equal hour 6; 36' after midnight at Babylon, and the middle at hour 7; 20'. The day was the 22nd of December, in the year 383 before Christ. See Petavius [Denis Pétau], book 8, *De Doctrina Temporum*, who from the beginning of this calculation shows that the Tables exceed the moment of the observations, namely the Prutenic by 49' [Pruteni... min. 49'], the Alphonsine by 56' [Alphonsinas min. 56'], the Danish by 42' [Danicas 42'], the Parisian by very nearly half a quarter-hour [Parisinas idest fuas min. 14]; for Ptolemy supposes that

Ptolemy [recte: Hipparchus?] timed this eclipse at very nearly half a six-hour-period [sesquihoram ferè]. [?]

ECLIPSIS 9.

[Margin: 382]

In the same year of Phanostratus and of Nabonassar, but now before Christ 382, on the 24th day of Phamenoth, on the following 25th, an eclipse of the Moon was observed at Babylon before midnight, the first part of the night having passed, defective; likewise at the morning rising; the Moon still being eclipsed. Ptolemy, book 4, chapter 11, for which the hour of full moon was 9; 6'. At Babylon. He writes that this eclipse lasted, from the beginning of the observation, hour 7; 36'. The middle is reckoned at hour 13; 36'; but at Hipparchus, hour 13; 46'.

ECLIPSIS 10.

[Margin: 382]

Finally in the same year of Christ, Euander being Governor —

[continuation of Eclipsis 10:] The day was the 5th of April, in the year of Christ 125 [?]. They compute this eclipse otherwise, and it diverges from that observed by Ptolemy. Lansbergen [?].

ECLIPSIS 17.

[Margin: 133]

In the year 17 of Hadrian [Adriani], and the 880th of Nabonassar, on the 20th day of the month Payni, Ptolemy observed at Alexandria a total eclipse of the Moon, whose middle he marks at an equal hour of 45' before midnight. The day was the 6th, the 7th following, of May. Of the years of Christ, 133. This is the first of those three eclipses which we observed most accurately at Alexandria, as Ptolemy himself says there, and he says: "And the true place of the Sun was in Taurus at 13; 14', very nearly."

ECLIPSIS 18.

[Margin: 134]

In the year 19 of Hadrian, but the 882nd of Nabonassar, on the 2nd of Choiak, at hour 11 after the meridian, the Moon began to be eclipsed at Alexandria toward the north by 10 digits, observed and reported by Ptolemy, book 4, chapter 6. The

day was the 21st, the 20th [?] of October following, in the year of Christ 134; "and the true place of the Sun was in Libra at 25; 10', very near to Ptolemy."

ECLIPSIS 19.

[Margin: 136] [Margin: *Copernicus to be corrected* (Copernici emendandum)]

In the year 20 of Hadrian, and the 883rd of Nabonassar, on the 19th day of Pharmuthi, at hour 16 after the meridian, half of the Moon's diameter was obscured from the north at Alexandria, observed and reported by Ptolemy, book 4, chapter 6. The day was the 5th, the 6th of March following, in the year of Christ 136 — not, as Copernicus [Copernicus] erroneously [computes] book 4, chapter 5; the 136th, because the Julian year of Hadrian is to be computed from the 24th of July. Of Christ 117, when his Empire began; and therefore Hadrian enters into the year of Christ 135; the 24th of July. But the year of Nabonassar 883 begins on the 20th of July, and so the 5th day of Pharmuthi falls in the year of Christ 136. A leap year, namely on the 3rd day. And the true place of the Sun was in Pisces at 14; 12', very nearly.

ECLIPSIS 20.

[Margin: 770]

A manuscript Calendar, earlier than the work of Bede [Beda] *De Ratione Temporum*, records an eclipse of the Moon in the year of the Lord 770, on the 15th of February, at hour 3 of the night.

ECLIPSIS 21.

[Margin: 784]

The same Calendar notes another eclipse of the Moon in the year 784, on the 1st of November, at hour about 8.

ECLIPSIS 22.

[Margin: 882]

In the year 1206 from the death of Alexander the Great, which al-Battānī [Albategnius] says, chapter 30 *De Scientia Stellarum*, to have been in the year 1194 of the era of Dhū'l-Qarnayn [Dhilkarnaim]; that is, of al-Battānī. At Aracta [?] in Syria, at the equal hour 8, or a little more than 8, an eclipse of the Moon of more than 10 digits was observed on the 23rd day of the month Kanun. It was the 23rd of July, in the year of Christ 882, because by the same al-Battānī the year of

Nabonassar was 1630, even if Lansbergen should put the year before Christ at 883.

ECLIPSIS 23.

[Margin: 900]

In the year 1224 from the death of Alexander the Great, and 1212 of Dhū'l-Qarnayn, on the night between the second and the third of the month Ab, that is, of August, by al-Battānī at Antioch in Syria, at hour 15; 20' after the meridian, but at Aracta [?] at hour 15; 55', an eclipse of the Moon nearly total was observed. So he himself says, chapter 30 *De Scientia Stellarum*. It was the year of Christ 901.

ECLIPSIS 24.

[Margin: 1457]

In the year of Christ 1457, Johannes Regiomontanus [Regiomontanus], together with his master Georg Peurbach [Georgio Purbachio] at Melk in Austria — which is to the west of Vienna by 11 leucæ of Germany — on the 3rd of September observed the beginning of a lunar and total eclipse, the beginning of the eclipse [being] at the penultimate degree of the Pleiades [Pleiadum] at 22, toward rising, at hour 10; 24' after the meridian, according to Regiomontanus's calculation.

ECLIPSIS 25.

[Margin: 1460]

In the year 1460, on the 3rd of July, Regiomontanus, together with Peurbach [Purbachio], at Vienna observed an eclipse of the Moon of digits a little greater than 4; whose end appeared at hour 4; 18', from which he deduced the end at hour 16; 20' after the meridian — although the Alphonsine calculation should exhibit the end at hour 9; 10'; the middle at hour 8; 13'; and the beginning at hour 8; 16'.

ECLIPSIS 26.

[Margin: 1460]

In the same year, on the same 27th of December at Vienna, a total obscuration was observed; the beginning of the eclipse at Altramech [Aldebaran? / Altramech], that is, at Arcturus [Arcturum] toward rising 7; that is, before the meridian. At the beginning of the duration [mora], a star was high at the same

star at 17; and at the end of the duration 28; from which he deduced the beginning of the duration at hour 12; 47'; the end of the duration at hour 14; 55'.

ECLIPSIS 27.

[Margin: 1461]

In the year 1461, Johannes Regiomontanus, in the town of Vienna in Austria, on the 22nd of June, observed a total eclipse of the Moon, whose beginning appeared at 6; in fine [at the end], indeed, the whole eclipse he saw the Moon high at 17; 30'; and at the Vulture [Vulturem] at 47; 30', from which he deduced the moment of opposition at hour 1; 21' after midnight.

ECLIPSIS 28.

[Margin: 1461]

In the same year Johannes Regiomontanus, at Rome, observed the end of a lunar eclipse, the high star Alhailoth, that is, Capella [Capella], at 41; 30'; Aldebaran [Aldebara], however, [at] 29; from which, the altitude supposed at degrees 42, he gathered the hour at 5; 23' from the meridian; the day was the 14th of December, the 15th following.

ECLIPSIS 29.

[Margin: 1462]

In the year 1462, Johannes Regiomontanus, at Viterbo, on the following night, the 11th, observed on the 1st of June an eclipse of the Moon of 7 digits. Aquila [the Eagle] at 51; toward the West; the high star 14; 48' after the meridian, the middle being taken by conjecture. "I gathered from the places of Aquila by the Tychonic [reckoning], and from the altitude of the pole of Viterbo, at degrees 42; 21'; and from the obliquity of the ecliptic I found the time of this eclipse at hour 14; 37'; 23'; after the meridian at Viterbo."

ECLIPSIS 30.

[Margin: 1464]

In the year 1464, Johannes Regiomontanus observed the beginning of a lunar eclipse, the high Heart of the Scorpion [Cor Scorpii, Antares] toward rising at degrees 12; 45'; the Hydra [Hydra], however, the Heart toward setting at degrees 9; 40'; by the great Quadrant, with all possible diligence. He supposes the altitude

of the pole of Padua [Patavii] at degrees 45; 24'; but by others it seems truer at degrees 45; 31'. The day was the 21st of April.

ECLIPSIS 31.

[Margin: 1471]

In the year 1471, on the 2nd of June, Johannes Regiomontanus, at Nuremberg, observed the beginning of a lunar eclipse, the high Heart of the Scorpion [Cor Scorp̃ii] toward setting at degrees 14; 15'; there were seen, moreover, 4 digits obscured.

ECLIPSIS 32.

[Margin: 1487]

In the year 1487, on the 8th of February, in the morning, Bernhard Walther [Bernardus Vualtherus], at Nuremberg, observed the beginning of a lunar eclipse, at hour very nearly 2 after midnight; the middle, moreover, hour about 5; 47'. The end, however, at hour 5; 20'; and the eclipse [was] made total —

[Margin: Anni Christi]

occurred at 4h 18'. We shall report his words below in Chapter V, number 6.

ECLIPSIS 33.

[Margin: 1500]

In the year 1500, on 5 November (or 6 according to others), Copernicus at Rome — as he records in *De Revolutionibus* IV.14 — observed the middle of the eclipse at 2h after midday, with 10 digits eclipsed from the north.

ECLIPSIS 34.

[Margin: 1504]

In the year 1504, on 29 February, Johannes Stöfler [Johannes Stöffler] at Ulm in Swabia, observing with an astrolabe, recorded the beginning of a lunar eclipse at 11h 48', nearly after midday; while Walther at Nuremberg observed the end of the same eclipse at 15h 7'.

ECLIPSIS 35.

[Margin: 1509]

In the year 1509, on the night following the 2nd day of June, Copernicus at Cracow, at the hour after midday 11h 36', observed the digits eclipsed at the maximum to be 8. He obscures the Moon from the south — so he himself, *De Revolutionibus* IV.14. [Margin: Lansbergii error — Lansbergen's error.] By error Lansbergen sets the hour at 11h 45', contrary to the text of Copernicus, who has it thus: with the equinoctial hours being 1, and three fifths of one hour.

ECLIPSIS 36.

[Margin: 1511]

In the year 1511, on 6 October, Copernicus — as he relates in *De Revolutionibus* IV, ch. 5 — observed at Frauenburg [Frombork] in Prussia a total lunar eclipse, its beginning at 10h 52'. The end he sets at 14h 20'; therefore the middle at 12h 36' after midday.

ECLIPSIS 37.

[Margin: 1522]

In the year 1522, Copernicus at Frauenburg, on the day of 5 September, observed a total lunar eclipse, its beginning at 11h 36', and the middle at 13h 10' after midday. But in the same year 1522, another [eclipse], on 25 August, with 16h 25' having elapsed after midday, as he has it in *De Revolutionibus* IV, ch. 5.

ECLIPSIS 38.

[Margin: 1560]

In the year 1560, on 11 March, Cornelius Gemma at Louvain observed a partial lunar eclipse of nearly 3 digits, its beginning at 15h 40' after midday, and the end at 17h 36'. So he himself, *Cosmocritice* [*De Naturae Divinis Characterismis / Cosmocritica*]; the middle, therefore, at 16h 33'.

ECLIPSIS 39.

[Margin: 1572]

In the year 1572, on 11 June, Maestlin observed a lunar eclipse of 6 digits, although Cornelius Gemma in *Cosmocritice* book 2 affirms that he saw nearly 8 digits.

ECLIPSIS 40.

[Margin: 1573]

In the year 1573, on 8 December, Tycho at Uraniborg observed a total lunar eclipse, determining its middle from the extreme phases at 5h 3' after midday — Tycho vol. 1, *Progymnasmata* pages 114 and Longomontanus, *Astronomia Danica* I, *Theorica de Luna* ch. 2. But Wendelen in his *Eclipses* page 43 computes there the hour at 7h 50' from his own tables, on the suspicion of parallax, since he stretches Tycho's end too far, and thus also the middle.

ECLIPSIS 41.

[Margin: 1576]

In the year 1576, on 7 October, Tycho at Uraniborg observed an eclipse at 11h 22' after midday, as Tycho above; Longomontanus has it at 11h 25'.

ECLIPSIS 42.

[Margin: 1577]

In the year 1577, on 2 April, Tycho at Uraniborg observed a total lunar eclipse, its middle from the extremes at 8h 10', as Tycho above; but Wendelen, there from his own tables, computes the hour at 9h 15', and says that Tycho in Denmark did not see the end except through clouds, and so inferred the middle by guesswork.

ECLIPSIS 43.

[Margin: 1577]

In the year 1577, on 26 September, Tycho at Uraniborg, from the extreme phases observed, determines the middle of the total lunar eclipse at 1h 3' after midday. Tycho as above, whom Wendelen page 44 deceived supposes, and computes the middle of that eclipse at 1h 13'. But Lupus Velascus [Lupo de Velasco] observed the end at 14h 16', and Johannes Alcantara of Toledo at 14h 12'.

ECLIPSIS 44.

[Margin: 1578]

In the year 1578, on 15 September, Tycho at Uraniborg observed the middle of a lunar eclipse of $2\frac{1}{2}$ digits at 13h 17' — Tycho vol. 1, *Progymnasmata* page 114; whom Wendelen page 44, indeed, collecting the nearest beginning, thinks at 13h 14'; but, gathering the end by Toledo's calculation, computes the hour at 13h 3'. Therefore, concerning the penumbra, he suspects Lupus Velascus to have been deceived, because Toledo recorded the end at 13h 20'. Longomontanus has the [hour] observed at Uraniborg at 13h 24'.

ECLIPSIS 45.

[Margin: 1580]

In the year 1580, on 31 January, Tycho at Uraniborg observed the middle of a total lunar eclipse at 10h 9' (or 10') after midday. But Wendelen page 47 (who attests that in this year, on 6 June, an eclipse was born) computes there from his own calculation the hour at 10h 30', asserting that the penumbra had imposed upon Tycho. Maestlin too, in his *Isagoge*, and Kepler in his *Optics*, say that this eclipse was observed by him as total with very brief duration. Granted that Lansbergen, relying on his own tables, denies that it was total.

ECLIPSIS 46.

[Margin: 1581]

In the year 1581, on 19 January, Tycho at Uraniborg, at 9h 59' after midday, observed a total eclipse; Wendelen, however, page 47 computes there the hour at 10h 6'; Longomontanus reports the hour at 10h 0'.

ECLIPSIS 47.

[Margin: 1581]

In the year 1581, on 15 July, Tycho at Uraniborg, from the beginning of a total lunar eclipse observed, conjectured the middle at 16h 57' after midday. But Wendelen page 47 supposes him deceived, because there from his own calculation he reckons the middle at 16h 45'. Longomontanus reports the hour at 17h 0'.

ECLIPSIS 48.

[Margin: 1584]

In the year 1584, on 7 November, Old Style, Tycho at Uraniborg observed the beginning of a total eclipse at 11h 12' after midday; the end, however, at 17h. As he himself relates in his *Epistolae*; therefore the middle ought to be set at 13h 6', or at most 13h 8', as he himself advises in the *Epistola* of the year 1587, given under 20 January; for the intervals between the extreme and the middle of an eclipse are always equal. Indeed, in the *Progymnasmata* he marks the hour at 13h 12'. How much more sharply Wendelen here watches, lest he seem to disdain Tycho, you may see at his page 48. Observations of Wittich and Heinrich Brucaeus [Heinrich Brucäus], or as in Tycho's *Epistola*. Longomontanus has the

hour at 13h 9'. Heinrich Brucaeus at Rostock recorded the middle at 13h 4'; Wittich at Kassel the hour at 13h 3'; from which Wendelen differs by 15' and more.

ECLIPSIS 49.

[Margin: 1587]

In the year 1587, Tycho at Uraniborg, on 6 September, Old Style, observed the digits of an eclipse to be 9.45', the hour after midday 9h 16' — Tycho vol. 1, *Progymnasmata* page 114. In his *Epistola* he asserts that there is something certain to be predicted within two [minutes], or at least within three minutes; but Wendelen page 49 from his own calculation computes it likewise at 9h 16'. Hence I wonder that Longomontanus in his *Astronomia [Danica]*, *Theorica* book 1, *Theoricorum* ch. 2, in his Commentary on the Moon noted the hour at 9h 30'.

ECLIPSIS 50.

[Margin: 1588]

In the year 1588, Tycho on the night following the 2nd day of March, Old Style, observed the middle of a total eclipse at 15h 2' after...

[Margin: Anni Christi]

after midday, as he himself has it in vol. 1, *Progymnasmata* page 114 and Longomontanus above. But note that Tycho in his *Epistolae* admits that this eclipse, page 49, and Tycho himself in his *Epistolae* confesses with these words that the middles either deceived or were not exactly found by the Prutenic calculation through hours. But the calculation of Uraniborg exhibits the middle of this eclipse, at the hour after midday 14h 18', with a half added; therefore the observation itself falls at 14h 48' — but not into the hour 15h 2'; nor indeed do they conflict between themselves. Indeed Kepler too, in the same Wendelen, from Tycho's own autograph reports it at the hour 14h 58', with these words noted: *Ergo praeter medium* [therefore besides the middle]; but perhaps from the beginning of the penumbra, and the end, Tycho gathered the middle, conjectured it, at the hour 15h 2'; and so he had it more truly, inasmuch as the middle of the first hour after midday at midnight; the immersion noted after the middle second; the emersion after the third middle; the end a little after the fourth, the middle determined; with the quadrant set after the second, as much as it was with the sky entirely pure, or starry, no one saw it, who had placed a foot there [vbi pedem collocaret].

Ulysippone [at Lisbon], Doctor Sobrinus observed the beginning of this eclipse at 11h 56', or rather, as it is to be written, Wendelen thinks, at 11h 36'. Finally, at Cabo Corrientes [Caput Currentium] in Africa, which is at the *Mare Natalis* [Natal coast], Johannes Baptista Bechetus [Giovanni Battista Becchetti], a Florentine Knight, observed the beginning of this eclipse at 16h 15' after midday.

ECLIPSIS 51.

[Margin: 1588]

In the year 1588, on 26 August, Doctor Sobrinus at Lisbon observed the beginning of an eclipse at 1h 49' after the middle of the following night; while the royal observers at Porto Vecchio [Portum veterem] in Peru, situated under the equator nearly, observed the same beginning at 8h 54', as Wendelen reports in his *Eclipses*, and Georgius Furnerius [Georg Fournier] book 12, *Hydrographiae* ch. 5.

ECLIPSIS 52.

[Margin: 1590]

In the year 1590, on 17 July, Maestlin at Tübingen saw the Moon deficient by some digits from the south, and at the two lowest [points] almost by [two] degrees at that moment, in which the center of the Sun was emerging above the horizon, but through the benefit of refraction, as Kepler notes page 137, *Optics*; Lansbergen in his *Thesaurus*, and Wendelen in his *Eclipses* page 51.

ECLIPSIS 53.

[Margin: 1590]

In the year 1590, on 30 December, Old Style, but according to the Gregorian year 1591, on 9 January, Tycho at Uraniborg observed the middle of an eclipse at 6h 55' after midday, or as Longomontanus has it, at 7h.

ECLIPSIS 54.

[Margin: 1592]

On 14 June, Old Style, Tycho noted the middle of an eclipse at Uraniborg of 8 digits at 10h 16' after midday. Granted that his own tables require 10 digits, as Kepler explains in his *Optics* page 350. Wendelen's calculation there gives the digits at 9.30'; Longomontanus reports the hour at 10h 20'. On 8 December, however, Tycho noted the middle of an eclipse at Uraniborg at 7h 41'; Lansbergen saw the same at Goes at 6h 50', with 5 digits.

ECLIPSIS 55.

[Margin: 1594]

In the year 1594, on the 28th day of October, New Style, Tycho at Uraniborg observed the middle of an eclipse at 19h 26' after midday, or rather, as Wendelen and Kepler have it, *Optics* page 413, deduced the middle from the beginning observed at 17h 56'; ideo, Tycho added to his observation a counter-word: *non potui* [I could not]. Longomontanus has 19h 16'. Lansbergen at Goes saw it at 11h 12', with 9½ digits.

ECLIPSIS 56.

[Margin: 1595]

In the year 1595, on 13 April, Old Style, Tycho at Uraniborg observed the eclipse, its middle from the extreme phases collecting at 16h 36' after midday; but Goes — Lansbergius page 44 — computes there the hour at 16h 46'. Immerseronem indeed at 14h 40'; the emersion at 16h 20'; Wendelen Hercae [at Herck] at observed the beginning at 14h post midday, the middle indeed circa hour 18h 20'. Vuandesburgi [at Wandsbeck], however, where Tycho [was], observed it not to have been wholly total at 18h 5'.

Lansbergen in the *Thesaurus* says that it was observed by him at Goes, the beginning at 15h 40', and the middle at 17h 11½' — hour 17h 2'; he errs while he attributes to Kepler the observation at Uraniborg, the beginning at 16h 36' or 34'.

Johannes Rotarius [Jan Rauw], as Lansbergen reports, at Aquisgranum [Aachen] observed the middle at 17h 30'; concerning whose beginning, however, Lansbergen observed nothing; granted that Wendelen too refers the hour to 17h 0', and adds that Louvain observed the beginning circa hour 16h 10', and yet certainly between minutes 10' and 15'.

ECLIPSIS 57.

[Margin: 1596]

In the year 1596, on 2 April, Old Style, Tycho at Uraniborg sets the middle of an eclipse at hour 9h 2' after midday. Longomontanus, however, has the hour at 9h 25'; concerning which observation Petavius labours much over a discrepancy on account of many tables. At Tornaci [Tournai] the beginning was observed at 7h, and the end at 9h 15', as Wendelen too reports; the middle at hour 8h 10'.

ECLIPSIS 58.

[Margin: 1598]

In the year 1598, on 10 February, Old Style, Tycho's pupils (for in the previous year Tycho had withdrawn from Denmark) observed the beginning of a lunar eclipse at 18h 7', of $11\frac{1}{3}$ digits; concerning which Kepler too, page 368, in his *Optics*, where he adds: at Graz in Styria it was permitted to observe it somewhat more roughly, the beginning having been at 16h 54' after midday, the middle, however, circa hour 18h 20'. At Wandsbeck, however, where Tycho was, it is observed not to have been wholly total, the beginning having been at 18h 5'.

[Margin: Lansbergii lapsus — Lansbergen's slip.] Lansbergen in the *Thesaurus* says it was observed by him at Goes, the beginning at 15h 40', and the middle at $11\frac{1}{3}$ hours — hour 17h 2'; he errs while, on Kepler's attribution, the observation at Uraniborg had its beginning at hour 16h 36' or 34'.

Johannes Rotarius [Jan Rauw], as Lansbergen reports, at Aachen observed the middle at 17h 30'; concerning whose beginning, however, Lansbergen observed nothing; granted that Wendelen refers the hour to 17h 0', and adds that Louvain observed the beginning circa hour 16h 0', and yet certainly between minutes 10' and 15'.

ECLIPSIS 59.

[Margin: 1598]

In the year 1598, on 6 August, Old Style, Tycho, in the Catalogue determines the middle of a lunar eclipse at Uraniborg at hour 7h 37'. Lansbergen, however, says that only the end of the eclipse was observed by him at Goes at hour 8h 40'.

ECLIPSIS 60.

[Margin: 1599]

In the year 1599, on 30 January, Old Style, Longomontanus at Uraniborg observed a total eclipse at hour 17h 56'; nevertheless Tycho in the Catalogue has hour 17h 50'. Kepler too, as he reports page 249 of his *Optics*, conjectured the beginning at hour 15h 45'. At Graz the horizon of the city was not corrected.

ECLIPSIS 61.

[Margin: 1599]

In the year 1599, on 6 August, a lunar eclipse is narrated to have been observed by the Dutch [ab Hollandis] at Tidore and Ternate circa hour 8h, by night, at Leuino Hulsio [Levinus Hulsius] ch. 30, *navigat. Holland.* [the Dutch navigation/voyages].

ECLIPSIS 62.

[Margin: 1600]

ECLIPSIS 63.

[Margin: 1601]

In the year 1601, on 9 December, New Style, Lansbergen at Goes observed the middle of an eclipse of more than 10 digits, at the hour...

[Margin: Anni Christi]

after midday 6h 12' — Kepler, as he has it in his *Optics* page 349, says Ambrosio Rhodio [Ambrosius Rhodius] estimated the digits of the eclipse at 10, and page 371 adds that at Prague the beginning was observed by him at hour 5h 22', from the stars; the middle, however, at hour 6h 53'. Adriaan Metius at Franeker [Franekerae] observed the beginning at hour 4h 42'; Valentiola Clunacensis [the Cluniac of Valencia], and others, recorded the beginning at hour 4h 38' after midday. Wendelen, from Digne [Dinia], with several, noted the beginning at hour 4h 40', and the end at hour 7h, between 42' and 45'; therefore the middle at hour 6h 12'.

ECLIPSIS 64.

[Margin: 1602]

In the year 1602, on 4 June, Kepler at Prague observed the end of a lunar eclipse at hour 9h 5', adding that by the Tychonic calculation it ought to have been at hour 9h 19', at Prague.

ECLIPSIS 65.

[Margin: 1602]

In the year 1602, on 28 November, since no eclipse had been promised in the Calendars, Wendelen nevertheless, setting out toward Aix-en-Provence, observed the beginning of an eclipse at hour 7h 11', because at Aix-en-Provence it had been, he says, at hour 7h 10' after midnight.

ECLIPSIS 66.

[Margin: 1603]

In the year 1603, on 14 May, Old Style, Lansbergen at Goes observed the beginning of an eclipse of $7\frac{1}{2}$ digits at hour 11h 56' after midday. Kepler, however, observed it at Prague at hour 11h 53', by his own observation refuting Lansbergen and Wendelen, who recorded its beginning at Valencia at hour 10h 15', the middle indeed at hour 11h 38'.

ECLIPSIS 67.

[Margin: 1603]

In the year 1603, on 8 November, Old Style, Lansbergen at Goes observed the eclipse of 3 digits, at hour 6h 3' after midday. At Prague, however, Kepler, as he reports in his *Optics* page 7, observed the same eclipse a little less, with three digits and somewhat doubtful, the beginning observed by himself at hour 6h 21'; the end at hour 8h 17'; Digne — Wendelen — noted the beginning at hour 5h 52'; the maximum defect of three digits, and the end at hour 7h 42', the middle at 6h 47'.

ECLIPSIS 68.

[Margin: 1605]

In the year 1605, on 3 April, New Style, Lansbergen at Goes observed a lunar eclipse of 3 digits at hour 11h 35' after midday; Wendelen, however, at Forcalquier [Forcalcarii] [set] the beginning at hour 6h 38', and the maximum defect to be 3 digits, with clouds intervening at hour 8h 12', with the digits $11\frac{1}{2}$; and he added that Lansbergen, on account of the spurious penumbra, stretched out the end, and likewise the middle.

ECLIPSIS 69.

[Margin: 1606]

In the same year, on 20 September, New Style, Goes — Lansbergen — observed the summit of an eclipse of 8 digits at hour 16h 30' after midday; Wendelen,

however, at Forcalquier [set] the beginning at hour 14h 42', the middle at hour 16h 11', with the digits a little more than 8; the end at hour 17h 40'; and again Lansbergen adds that he stretched out the time by a fallacy of observation.

ECLIPSIS 70.

[Margin: 1607]

In the year 1607, on 6 September, in the morning, Wendelen at Valencia, toward the Rhône [ad Rhodanum], observed — he says, from Scipione Arnaldo [Scipio Arnaldus], with many others — the beginning of a lunar eclipse at hour 1h 45', circa, the middle indeed after the middle of the night, and the end at hour 3h 45'; and so the middle would have been at hour 2h 45'.

ECLIPSIS 71.

[Margin: 1609]

In the year 1609, on 19 January, New Style, Lansbergen at Goes observed the beginning of a lunar eclipse at hour 13h 5' after midday; the middle, however, at hour 14h 40', with the digits $9\frac{1}{2}$. Adriaan Metius at Franeker saw the beginning at hour 14h 42'; Wendelen at Forcalquier the beginning at hour 13h 10', the end at hour 16h 16', and the middle at hour 14h 43'.

ECLIPSIS 72.

[Margin: 1609]

In the year 1609, on 16 July, New Style, in the morning, Longomontanus at Copenhagen [Hafniae] notes the middle of a lunar eclipse at hour 12h 10', collecting nevertheless from the extremes; for it was indeed a total eclipse. Forcalquier — Wendelen — observes the beginning at hour 9h 53'; the immersion at hour 10h 18'.

ECLIPSIS 73.

[Margin: 1610]

In the year 1610, on 5 July, Wendelen at Forcalquier noted the beginning of a lunar deficiency at hour 14h 55' after midday.

ECLIPSIS 74.

[Margin: 1610]

In the year 1610, on 29 December, Wendelen at Forcalquier noted the beginning of a lunar eclipse a little before hour 14h 40', the end at hour 16h 50' — as much as it was permitted to observe through clouds.

ECLIPSIS 75.

[Margin: 1612]

In the year 1612, on 14 May, at Liège [Leodii], Wendelen perceived the beginning of a lunar eclipse at hour 8h 37', circa; the end, however, at hour 11h 15', exactly; the middle at hour 9h 56', with the digits $6\frac{1}{3}$, circa. The monk Scheiner noted the beginning before hour 9, in the evening, quasi a semiquadrant; the end, however, at the same hour $11\frac{1}{2}$ — but Wendelen thinks that on account of the penumbra he anticipated the beginning. Longomontanus says the beginning was observed at Copenhagen a little before hour 9h 14', with the digits $5\frac{1}{2}$.

ECLIPSIS 76.

[Margin: 1612]

In the year 1612, on 8 November, at Nagasaki [Nangafachi], Father Carolus Spinola [Carlo Spinola] of the illustrious Society of Jesus, of the Catholic faith, observed the beginning of a lunar eclipse at hour 9h 30' after midday. At Macau, however, in the rising of the Chinese [in exordio Sinarum], Father Giulio Aleni [Giulio Aleni] of the same Society, on the same day, observed the beginning at hour 8h 30', and the end at hour 11h 45'; and from the altitudes and azimuths of the Moon, adding the observation by himself at the altitude of the pole of Macau at 22h 13' [recte: pole altitude $22^{\circ} 13'$]. These observations Father Julius set down in writing, sending them to Antonio Maginus [Antonio Magini], who once had been his disciple at Bologna, and a Mathematician instructed in disciplines, who when he sought entry into the Sinensian dominion, found those very [observations] in Magini's papers most amicable to me, and discovered by the learned among Magini's papers; nay, with Father Bonaventura Cavallerius [Bonaventura Cavalieri], Magini's successor in the Chair, having pointed them out. Afterward, indeed, in the *Eclipses* of Wendelen page 80, I obtained the observation of Father Vremannus [Vreman] sent in Belgium at Macau, where Father Julius was, and in it the beginning is given at hour 8h 30', the end at hour 11h 45'. At Ingolstadt, however, Scheiner [observed] at hour nearly 4h 35'. He saw the Moon a reddish globe entire, but bloody, or of a dark color, tinged; the upper parts still held involved, and with malign brightness the Moon shone; the parts dilated themselves; the sixth evening hour, the Moon serene, dried up. The eclipse lasted nearly forty-six scruples [minutes]. From which other things

Wendelen too gathers, no otherwise than from his own tables, the end at Ingolstadt at hour 5h, exactly, and the difference of longitudes between Ingolstadt and Macau at hour 6h 45'.

ECLIPSIS 77.

[Margin: 1613]

In the year 1613, on the 28th day of October, New Style, Longomontanus observed at Copenhagen the extreme of a total eclipse, from which he gathered the middle at hour 5h 57'. Kepler, however, as he has it page 11, *Ephemeridum*, and David Fabricius observed the end more maturely than calculation would exhibit to the unpracticed eye.

ECLIPSIS 78.

[Margin: 1614]

In the year 1614, on 24 April, in the morning, with the lunar eclipse beginning, it sounded the third hour after midnight at Hotisfontjais [?]; which [eclipse] at Louvain [Louanii], by no contemptible consensus, is noted to have begun, as Wendelen reports page 84.

ECLIPSIS 79.

[Margin: 1616]

In the year 1616, on March 3, Kircher [Athanasius Kircher] observed the end of a lunar eclipse at Goa at hour 7, 53' after midday, as he reports in his *Magnes* (Kircher, *Magnes*, 1st ed., p. 477); but from our observation Origanus [David Origanus] at Frankfurt-on-the-Oder noted the end at hour 3, 51', and Wendelen [Govaert Wendelen] noted it there at hour 3, 58'; while at the Atlantic meridian it was at hour 1, 30' ½.

ECLIPSIS 80.

[Margin: 1616]

In the year 1616, on August 26, at Rome, Father Christoph Grienberger, S.J. [Christophorus Griembergerus], observed the beginning of a total lunar eclipse at hour 13, 43' ½ after midday, and the end at hour 16, 56' ⅔; therefore the middle was at hour 15, 50'. Others observed it at Rome separately. With a telescope he observed the immersion at hour 15, 6' ⅓, and the emersion at hour 15, 34'; the middle, by an admirable agreement, at hour 15, 20', as Kepler [Keplerus] too

relates in his Ephemerides, p. 11, and he adds the same at line 17. In his *Rudolphine Tables*, p. 103, he adds that he saw certain partial phases of the observers as total — some partial — but Wendelen, from Kepler's account, gathers the middle of the eclipse not at hour 15, 30' but at 34'. He adds that at Liège the observation gave the beginning at hour 13, 23', the immersion at hour 14, 42', the emersion at hour 15, 12', and the end at hour 16, 31'. At Tübingen, Maestlin [Maestlinus] observed the beginning at hour 16, 43'; therefore the middle at hour 15, 8'.

ECLIPSIS 81.

[Margin: 1617]

In the year 1617, on August 16, Kepler at Linz observed the middle of a lunar eclipse at hour 8, 10' after midday; from his account Wendelen gathers (p. 85, adding the immersion as observed by Hercij [the Jesuit fathers at Herči], hour 8, 1 $\frac{1}{3}$ ', and the end at hour 9, 17').

ECLIPSIS 82.

[Margin: 1619]

In the year 1619, on June 26, Wendelen at Herči, a little before midnight, saw the Moon eclipsed by nearly a single digit at the top, with the Ephemerides promising three digits, from which arose the suspicion either that the latitude of the Moon is reckoned too broadly in the tables, to the mind of Kepler, or that the shadow of the Earth was attenuated by refractions.

ECLIPSIS 83.

[Margin: 1619]

In the year 1619, on December 21, at Mechlin, Wendelen observed the beginning of a lunar eclipse at hour 13, 27', the end at hour 16, 28'; therefore the middle at hour 14, 57 $\frac{1}{2}$ '; the digits nearly 11. But the Jesuit fathers at Herči themselves noted the beginning at hour 13, 30', the end at hour 16, 30'.

ECLIPSIS 84.

[Margin: 1620]

In the year 1620, on June 14, at Aix-en-Provence [Aquis Sextiis], Pierre Gassendi [Petrus Gassendus] together with the Lord Joseph Gaultier de la Valette, master of

Valletta, observed the beginning of a lunar eclipse at the altitude of Spica [Spica], 16°, 58', and the immersion at the altitude of Arcturus, 35°, 34'; from this he deduced the beginning of the period at hour 11, 11'; for the immersion, hour 13, 27', as I read in his Epistles then sent to me into Italy, and as Wendelen too reports, who afterward (Gassendi, in his *Epicurus*, p. 896, the calculation corrected) puts the beginning at hour 11, 11', and the immersion at hour 12, 22' ½. The emersion was seen at the same altitude of the crown, 37°, 15' — that is, says Wendelen, hour 14'; therefore the middle at hour 13, 11'. The Jesuit fathers at Herči, hindered by clouds, and the sky thereafter clearing, observed the middle from the immersion and emersion; and they add the end of the eclipse as observed at Verona at hour 15, 20', approximately.

ECLIPSIS 85.

[Margin: 1620]

In the year 1620, on December 9, the Fathers of the Society of Jesus observed at Cachian, in the Kingdom of Cochinchina, the beginning of a lunar eclipse at hour 11' after midday, just as they had predicted — against the astrologasters of that dynasty, who, when [Continues on next page]

with great pomp they had awaited it the preceding night, were frustrated in vain; and from this our cause gained great authority among that prince and the Catholic faith its credit, as Kircher relates of the kingdom of the Borvi, and as Urban VIII confirmed by relation; and the same Wendelen indicates in his Ephemerides, p. 88, adding: under nearly the same meridian with Herči, the same eclipse was observed for itself, so far as could be, beginning at hour 5, 52', immersion at hour 4, 51'. At Brussels, Michael Florent van Langren [Michael Florentius Langrenus], Royal Cosmographer, noted the beginning of the emersion at hour 6, 25 ⅔', the end at hour 7, 24'.

ECLIPSIS 86.

[Margin: 1621]

In the year 1621, on November 28, at Aix-en-Provence, Gassendi, the sky being half-cloudy, observed the beginning of a lunar eclipse at hour 13, 54' after midday; therefore the immersion was at hour 15, 52'; the maximum, then, was at the moment of the defect by the disk of three digits, which, however, he reckoned by the telescope to be 5 digits; as he reports in his *Epicurus*, p. 897; therefore the middle was at hour 14, 55'. From the immersion of Kepler at the beginning, as it turned out, the beginning was at hour 14, 53'. From the latitude of the Moon,

however, turbid, the immersion was not at hour 14, 33' but at hour 16, 34'; the middle at hour 15, 33 ½'; and then the digits a full 4. From Wendelen's observation the beginning was at hour 14, 2'; thence the middle at hour 15, 57'; and thence the middle h. 15: digits a little more than 4.

ECLIPSIS 87.

[Margin: 1623]

In the year 1623, on April 14, at Digne [Diniaë], Gassendi observed the beginning of a lunar eclipse at hour 15, 9' after midday; the maximum, however, of the eclipse, the digits 11 ½, or somewhat more. Kepler noted the middle at hour 16, 55', though by calculation he had predicted it at hour 17, 15'. Leyden's Martin Hortensius [Leydæ Martinus Hortensius] observed the same eclipse, but it was transcribed with faulty figures.

ECLIPSIS 88.

[Margin: 1624]

In the year 1624, on September 26, Kepler at Linz observed the beginning of a total lunar eclipse at hour 7, 6'. The emersion at hour 9, 47'; and the end at hour 10, 44'; the middle at hour 8, 55': thus, whatever the tables promised a longer delay, the suspicion is that the shadow was uniform, and that the whole eclipse was not spherical, because the full one was of utter dimness, which Wendelen calls "of darkness"; he himself, however, threatens the first menaces of the eclipse at hour 6, 5'. But at hour 6, 28' the defect was remarkable: thence at hour 7, 23' it began to immerse, and there it was not yet wholly immersed, but yet up to hour 7, 29'; the second time something adhered to it as a lucid limb, immersed; the emersion was seen at hour 9, 7', and the end of the eclipse at hour 10, 4': thence the middle is determined at hour 8, 15'. At Brussels, Langren caught the immersion at h. 7, 18', 20". The emersion at hour 9, 21'. The repletion, or end, at hour 9, 59 ⅔'; therefore the middle at hour 8, 10'.

ECLIPSIS 89.

[Margin: 1625]

In the year 1625, on March 23, at Paris, Gassendi together with Midorgius [Mydorgio] noted the beginning of an eclipse at hour 12, 54', or by another Basilic computation 36, 20'. The end, then, at hour 13, 37'; another Le Bourg computation 31, 10'; whence the middle was at h. 13, 2'. The quantity of the highest eclipse was

scarcely seen to exceed one digit; certainly, says Gassendi, it was distant by two; Wendelen, while he awaited from the tables an eclipse of 3 digits and a duration of two hours, noted only so much, and the beginning at hour 13, 3'; the end at hour 14'; from this he took an argument for emending the anomaly of the Moon, its eccentricity, the distance at apogee, and the places of the nodes.

ECLIPSIS 90.

[Margin: 1626]

In the year 1626, on August 7, the Ephemerides promised a small semidigit-sized eclipse approximately, and a duration of 44', at Linz, at h. 7, 45'; but Kepler, diligently attending there from the setting of the Sun up to h. 8, 30', perceived nothing in the roundness of the Moon, nor did he indeed observe any trace of shadow.

ECLIPSIS 91.

[Margin: 1627]

In the year 1627, on July 27, at Madrid, the Fathers of our Society observed the beginning of a smoky lunar eclipse at hour 16' after midday; but at hour 16, 12', hour indeed 16, 45', the Moon set deficient by a little more than 9 digits than was observed; the more wretched observation they communicated from Ingolstadt to me; and Father Jacobus Vina [Iacobus Vina] communicated it.

ECLIPSIS 92.

[Margin: 1628]

In the year 1628, on January 20, at Paris, as Petavius [Petavius] wrote to Wendelen, the beginning of a total eclipse was inspected by telescope at the altitude of the stars at hour 7, 35'; but the beginning of the immersion at hour 8, 34'. At Brussels, Wendelen, on account of cloud and snow, observed only the end at hour 11, 15'. Gassendi at Aix-en-Provence observed the beginning at hour 7, 49'; the altitude at the rising of Sirius 21° , 9'. The immersion at hour 8, 48'; the altitude at the heart of Hydra, at the rising, 14° , 10'. The emersion at hour 10, 21'; the altitude at the same heart, 28° , 23'; the end, finally, at hour 11, 24'; the altitude at Rigel, at the setting, 26° , 27', distinguishing; Gassendi by telescope perceived the color not only at the beginning, in the total eclipse, first mellow, then purplish, and at last rusty; and these same colors in the immersion, rusty, purple-mellow. The middle, therefore, was at hour 9, 36'. At Paris, Mydorgius observed the

beginning at hour 7, 35', and the immersion at hour 8, 34'; and Boulliau [Bullialdus] relates in his *Astronomy*, p. 467, adding (at Oxford he observed the immersion at h. 8, 23' at Bamridge), the end at h. 10, precise. Boulliau's brothers noted the immersion at h. 8, 40'. The end at hour 11, 19'. At Prague, with Kepler's horizon corrected through the altitudes of the stars, he observed the emersion at h. 9, 13'. The immersion at h. 9, 19'. The emersion at hour 10, 59'. The end at h. 11, 59'; so the middle is at h. 10, 9'.

ECLIPSIS 93.

[Margin: 1630]

In the year 1630, on November 19, the beginning of a lunar eclipse Father Andreas Arzet, S.J. [Andreas Arzet], at Ingolstadt observed at h. 9, 10' after midday; the end at h. 12, 56'; and the digits at the maximum 9; the diameter of the shadow to the diameter of the Moon as 266 to 100, as I have from his letters. At Brussels, Michael Florent van Langren noted the maximum defect, digit 9, 30'; hour 10, 57'; and gathers the same as truly Wendelen, adding the observation of the Batavians at Leiden [Lugdunum Batavorum] from the beginning, hour 9, 22'; the end at h. 12, 23'; therefore the middle at h. 10, 52'.

ECLIPSIS 94.

[Margin: 1631]

In the year 1631, on May 15, at Ingolstadt, Father Andreas Arzet, S.J., observed the emersion. The end, then, by the shadow at h. 9, 15' after midday; the beginning, however, by another altitude of Lyra, gr. 36, 35'. At Leiden, with Rhodanus, he observed, gr. 35, 24'; whence he deduced for the beginning at hour 11, 15'. For the immersion at h. 12, 27', while at Leiden, Father Auxon, S.J., a most learned Mathematician, the Moon set a little before hour 8, the eclipse ceasing, when it remained a semiquadrant to hour 9.

ECLIPSIS 95.

[Margin: 1631]

In the year 1631, on November 8, at Leiden, the Batavians' Hortensius [Hortensius] caught the beginning accurately at h. 9, 30'. The immersion at h. 10, 36'. The end at h. 12, 17'; thence the middle at h. 11, 26' $\frac{1}{2}$; as he himself narrates in his *Dissertation*. With Mercury joined to Gassendi, Gassendi writes that all those things at Paris occurred 12' earlier than they would have occurred here at

h. 11, 14 $\frac{1}{2}$ '; though Wendelen had it beat at h. 11, 13'; adding: Boulliau observed the beginning for himself at h. 9, 31'. The emersion at scattered h. 12, 23'; the end, h. 13, 28' whence the middle deduced at h. 11, 35'. At Tübingen, Wilhelm Schickard [Vuilhelmus Schikardus] noted the immersion at h. 12, 35'.

At Madrid, Michael Florent van Langren observed the emersion at h. 10, 4' $\frac{1}{2}$; difficult, but it can also be done by telescopic observation. The emersion, however, at h. 11, 50', and the end at h. 12, 54 $\frac{2}{3}$ '; whence the middle at h. 10, 57'.

ECLIPSIS 96.

[Margin: 1632]

In the year 1632, on October 27, at Innsbruck [Oeniponte], Father Andreas Arzet, S.J., observed the beginning of a lunar eclipse at h. 10, 37' after midday; the end at h. 12, 19'; therefore the middle at h. 11, 48'; and then the digits 5, 22'. Thus it is in his own writings; for at Leiden with Rhodanus, Gassendi noted the beginning at h. 10, 4'; the end at h. 12, 30'; which, however, by a twin observation sent recently to me, is gr. 45, 48'. At Leiden the Batavians' Hortensius noted the beginning at the true h. 10, 30'. The end h. 12, 44'; and the digits 4, 40'; or rather paler. At Liège, Otger [Otgerus], a man very skilled in mathematics, observed the beginning at h. 10, 18'; the end at h. 12, 42'; so that the middle was at h. 11, 30'.

ECLIPSIS 97.

[Margin: 1634]

In the year 1634, on March 14, at Aix-en-Provence, Nicolas-Claude Fabri de Peiresc [Nicolaus Fabricius Peireskios] observed the beginning of a lunar eclipse at h. 10, 49'; therefore the middle at h. 9, 11'. The same Gassendi noted the beginning at h. 7, 41'; thence the middle at h. 11, 2'; and the digits at the highest 10, hour 2, 4 $\frac{1}{2}$ '. At Madrid, Michael Florent van Langren observed the maximum defect, digit 10, 15'; and the end at h. 10, 19'; the middle, however, as Wendelen gathers from Langren's narration, h. 8, 42'.

ECLIPSIS 98.

[Margin: 1635]

In the year 1635, on March 3, at Aix-en-Provence, a lunar eclipse was observed, the beginning at h. 6, 48'. The immersion h. 7, 55 $\frac{2}{3}$ '; the end at h. 10, 18'; therefore the middle at h. 8, 43 $\frac{1}{3}$ '. At Leiden, Golius [Golinus] noted the emersion at h. 5, 39'. At Paris, Langren the elder noted the emersion at h. 9, 25 $\frac{2}{3}$ '. But the same

Langren at Brussels noted the beginning at h. 6, 49'. The end at h. 10, 25 $\frac{1}{3}$ '; and thence the middle at h. 8, 44 $\frac{2}{3}$ '. At Herči, Wendelen noted the beginning at h. 6, 54'. The immersion at h. 7, 59'. The emersion at h. 9, 40'. The end at h. 11, 49'; and thence the middle at h. 9, 49'. At Marseilles, Gassendi noted the immersion at h. 7, 4'. At Danzig, Peter Krüger [Petrus Krugerus] observed the immersion h. 8, 8'. At Stettin, Lorenz Eichstad [Laurentius Eichstadius] observed the beginning at h. 8, 34'. At Amsterdam, Hortensius observed the beginning at h. 7, 51'. Whence he argues the middle at h. 8, 40'. See Boulliau, p. 137 & 466.

ECLIPSIS 99.

[Margin: 1635]

In the year 1635, on August 27, at Aix-en-Provence, Peiresc [Peireskios] noted the beginning of a lunar eclipse by telescope at h. 13, 21'; with the telescope at h. 13, 31'. The same Wendelen, observing it from digits, gathers the beginning at h. 13, 25'. The immersion h. 14, 25'. The end by telescope at h. 16, 56'; and so the middle at h. 15, 11'. At Leiden, Golius saw the immersion at h. 14, 25'. At Digne, Gassendi noted the maximum immersion h. 14, 28'. At Herči, Wendelen observed the beginning at h. 13, 29'. The immersion h. 14, 28'. The emersion at h. 16, 6 $\frac{1}{2}$ '; thence the middle at h. 15, 13'. At Rome, as Wendelen narrates, the beginning was observed at h. 13, 54'; and from other phases the middle, h. 15, 39'. At Paris, Ismaël Boulliau [Ismaël Bullialdus] noted the immersion at h. 14, 5'. The emersion at h. 15, 40'. Therefore the middle at h. 14, 53'. At Chia, in Egypt, Father Agathangelus, a Capuchin [P. Agathangelus Capuccinus], with his companion Jo. Molino [Io. Molino] observed the beginning at h. 15, 14 $\frac{1}{2}$ '. The immersion at h. 16, 16 $\frac{1}{2}$ '. At Aleppo, however, in Syria, Father Coelestinus of St. Lidwina [P. Coelestinus à S. Lidwina], a discalced Carmelite [Carmelita discalceatus], and Michael Angelus, a Capuchin [Michael Angelus Capuccinus], caught the beginning at h. 15, 28'. And the immersion, h. 16, 27'. At Naples, Camillo Glorioso [Camillus Gloriosus] noted the immersion by telescope at h. 15, 21'.

ECLIPSIS 100.

[Margin: 1636]

In the year 1636, on February 20, at Digne, Gassendi noted the beginning of the lunar defect at h. 9, 44 $\frac{2}{3}$ '. The end at h. 11, 14 $\frac{2}{3}$ '. Whence the middle at h. 10, 40'. The digits at the highest 3. At Brussels, Langren obtained the beginning at h. 9, 38'. At Aix-en-Provence, he noted the telescopic end pari at h. 11, 5 $\frac{2}{3}$ '. At Amsterdam, Hortensius noted the end likewise at h. 11, 5 $\frac{1}{2}$ '. At Regiomontanus in Prussia [i.e.

Königsberg], Albert Linemann [Albertus Linemannus] noted the beginning at h. 10, 4 $\frac{1}{2}$ ' [Continues on next page]

and the middle at h. 11, 45'; the digits 2 $\frac{1}{3}$ or nearly $\frac{1}{3}$. At last the Lord Petit [D. Petit] at Trahon, in the Telina valley, noted the beginning at h. 10, 8'. The end h. 11, 54'; and thence the middle at h. 11, 1'.

ECLIPSIS 101.

[Margin: 1637]

In the year 1637, on December 30, at Huronum in New France [in nova Francia], Father Castellanus, S.J. [P. Castellanus], observed the middle of a lunar eclipse at h. 6, 15', after the middle of the following night, that is, h. 18, 15' after midday.

ECLIPSIS 102.

[Margin: 1638]

In the year 1638, on December 20, Gassendi at Digne caught the beginning of a lunar eclipse at h. 12, 36'. The immersion at hour 13, 37'. The emersion at hour 14, 13'. The end h. 16, 14'. Therefore the middle at h. 14, 25 $\frac{2}{3}$ '. At Paris, Boulliau, as he narrates in his Astronomy, ch. 6, obtained the immersion at h. 13, 23'. The middle; hour 14, 4 $\frac{1}{3}$ '. At Amsterdam, Hortensius noted the immersion h. 13, 32 $\frac{1}{2}$ '. At Brussels, Langren observed the beginning at hour 13, 29 $\frac{1}{2}$ '; the immersion at h. 13, 26 $\frac{2}{3}$ '. The emersion at h. 15, 1'; thence the middle at h. 14, 16'. At Digne, Golius noted the immersion h. 13, 32'. The emersion h. 15, 5'; and thence the middle at h. 14, 18'. At Herči, Wendelen saw the beginning at h. 12, 34'. The immersion at h. 13, 32'. The emersion h. 15, 10'. The end at h. 16. Frenequeare Jo. Phocylides Holwarda [Io. Phocyllides Holuarda] acquired the beginning at h. 12, 23 $\frac{2}{3}$ '. The immersion h. 13, 37'. The emersion h. 15, 12'; and thence the middle h. 14, 24 $\frac{2}{3}$ '.

ECLIPSIS 103.

[Margin: 1641]

In the year 1641, on October 18, at Herči, Wendelen observed the beginning of a lunar eclipse at h. 6, 8' after midday; the middle at h. 7, 29'; and the digits 6, 45'. The end h. 8, 50'. At Brussels, Langren obtained the middle at h. 7, 24'; the digits 6, 47'. At Leiden, Hericus Puteanus [Io. Puteanus] perceived the end at h. 5, 59'; thence the middle, h. 7, 26'. At Danzig, Johannes Hevelius [Io. Hevelius] observed the beginning at h. 7, 1 $\frac{1}{2}$ '; and the middle at h. 8, 26 $\frac{1}{2}$ '.

ECLIPSIS 104.

[Margin: 1642]

In the year 1642, on April 14, I obtained the lunar-eclipse observations written below, a few from Wendelen and Boulliau, more from letters to me, or by means of Father Athanasius Kircher.

	Princip. (Beginning)	Immers. (Immersion)	Emers. (Emergence)	Finis (End)	
	H. M.	H. M.	H. M.	H. M.	
I and Father Grimaldi [Ego, & P. Grimaldus]	12 48	13 52	15 36 $\frac{1}{3}$	16 40 $\frac{1}{2}$	Bologna [Bononiæ]
Father Vincenzo Maria Grimaldi [P. Vinc. Maria Grim.]	12 38 $\frac{1}{2}$	13 45 $\frac{1}{8}$	15 15	16 25	Mantua [Mantuæ]
Hevelius [Heuelius]	13 13 $\frac{2}{3}$	14 22	15 53 $\frac{1}{3}$	16 55 $\frac{1}{2}$	Danzig [Dantisci]
Father Georg Furtner [P. Georg. Furtner]	12 9	13 11	14 47	15 51	Paris [Parisijs]
Boulliau [Bullialdus]	12 10	13 11	14 47	15 51	Paris [Parisijs]
Gassendi [Gassendi]	12 10	13 11	14 47	15 48	Paris [Parisijs]
Wendelen [Vuendelin.]	12 3	13 19	14 43	15 41	Herči [Hercij]
The Fathers of the Society of Jesus [PP. Soc. Iesu]	12 15	13 41	15 21	16 12	Paderborn [Paderbonæ]

	Princip. (Beginning)	Immers. (Immersio n)	Emers. (Emersio n)	Finis (End)	
Father Marcell, S.J. [P. Marcell. Soc. Iesu]	12 33	13 58	15 18	16 3 $\frac{1}{2}$	Würzburg [Herbipoli]
Father Jacob Vina, S.J. [P. Iacob. Viua Soc. Iesu]	12 46	13 50	15 28	16 30	Ingolstadt [Ingolstadij]
The Fathers Curtz and Arzet, S.J. [PP. Curt. & Arzet S.I.]	12 44	13 55	15 24	16 32	Eichstätt [Eychstadij]
Eichstad [Eychstadius]	12 58	13 56	15 40	16 38	Stettin [Stetini]
The Lord Vincenzo Renieri [D. Vincentius Reiner.]	12 33 $\frac{1}{10}$	13 49 $\frac{1}{2}$	—	15 21 $\frac{1}{3}$	Pisa [Pisis]
Unnamed [Innominatus]	12 0 $\frac{1}{5}$	13 14 $\frac{3}{5}$	—	16 2 $\frac{1}{2}$	Leiden [Leydæ]

Besides those named, the following observed the beginning: the illustrious Lord Giulio Giustiniani [D. Iulius Iustinianus] at Venice, h. 12, 46' $\frac{1}{8}$; and the Lord Antonius Franciscus Payen [D. Antonius Franciscus Payen] at Avignon [Auenione], h. 11, 59'; and the immersion, h. 13, 1'; and Gutiscouius [Gutiscouius] at Louvain, the beginning at h. 12; and Father Conradus, S.J. [P. Conradus] at Glatz in Bohemia, the immersion at h. 14, 26'.

The emersion at h. 15, 18'. Several others among ours at Prague: the immersion h. 14, 10'. The emersion h. 15, 28'. And at Cologne [Coloniæ] the beginning h. 12, 26 $\frac{1}{2}$ '. The immersion h. 13, 41' $\frac{1}{2}$; and at last Father Michael Staudacher, S.J. [P. Michael Staudacher], the immersion h. 13, 52'. At Trent [Tridenti].

ECLIPSIS 105.

[Margin: 1642]

In the year 1642, on October 7, at Iley [Ileide], Antonius Garratus, sometime amanuensis to Gassendi [Antonius Garratus Gassendi], observed the beginning of a lunar eclipse at h. 14, 9 $\frac{2}{3}$ ' after midday; the immersion h. 15, 11'. The emersion h. 16, 50 $\frac{2}{3}$ '. At Rome, Father Francesco Niceronus, a Paulist [P. Franciscus Niceronus Paulinus], observed the beginning at h. 15, 1'. The immersion hour 16, 5 $\frac{2}{3}$ '. At Catania, or Catanzaro [Cataci, seu Catanzarii], the Lord Francesco Zuppi [D. Franciscus Zuppus] observed the immersion h. 16, 16' $\frac{1}{2}$ '. At Milan, the Lord Curzolanus [D. Curzolanus] observed the beginning h. 14, 44'. The immersion h. 15, 47'. At Brescia, in Bohemia, Father Theodorus Moretus, S.J. [P. Theodorus Moretus], noted the beginning h. 14, 57'. At Mallorca, in the city formerly known [Maiorica in Vrbe cognomine], the Lord Vicenç Mut [D. Vincentius Mutus] observed the beginning at h. 12, 41 $\frac{1}{3}$ '. The immersion h. 15, 24', 40". The emersion h. 17, 2 $\frac{1}{2}$ '; thence the middle at h. 17, 59 $\frac{1}{3}$ '; and the end at h. 18, 12'; thence the middle h. 16, 13'. We at last [Nos demum], with Father Grimaldi at Bologna, caught the beginning at h. 14, 55', 50". The immersion h. 15, 57', 10". The emersion h. 17, 36', 40"; the end at h. 16, 44'; thence the middle at h. 16, 49 $\frac{2}{3}$ '.

ECLIPSIS 106.

[Margin: 1643]

In the year 1643, on September 27, at Antwerp [Antuerpiæ], Wendelen, with Gutiscouius and Gebbartus [Gebbartus], observed the beginning at h. 6, 52'; the end h. 8, 5 $\frac{1}{2}$ '. We at Bologna [Nos Bononiæ], observing the beginning with the telescope showing, h. 6, 30', $\frac{2}{3}$; the middle h. 7, 30', 12"; therefore the digits 6; the end h. 8, 43' $\frac{1}{3}$ '. At Paris, Boulliau observed the end h. 7, 59 $\frac{2}{3}$ ', 36". Gassendi, however, observed the same successively near Paris, the end h. 8, 1', 38". At Danzig, Hevelius observed the end h. 8, 59'. At Naples, Father Giovanni Battista Zupi, S.J. [P. Io. Baptista Zuppus], observed the end h. 9, 5 $\frac{2}{3}$ '. The illustrious Lord Giulio Giustiniani observed the end h. 8, 44'; the same, at Mallorca, the Lord Vicenç Mut, by the bright altitude of Aquila at its setting, gr. 56, 56'; below the altitude of the pole, gr. 39, 15'. At Pisa, however, the Lord Vincenzo Renieri, by the bright altitude of Aquila gr. 50, 40'. Finally, at Brescia, Father Theodorus Moretus, S.J., the end by the bright altitude of Aquila gr. 45, 16'; below the altitude of the pole, gr. 50, 15'.

ECLIPSIS 107.

[Margin: 1645]

In the year 1645, on February 10, at Frankfurt-on-the-Main [Francofurti ad Mœnum], the end of a lunar eclipse was observed at h. 9, 1', 13"; and the beginning at hour 6'. At Paris, Boulliau noted the beginning at hour 5, 32'. Gassendi, however, at hour 5, 33'; the same again at hour 8, 40'. At Pisa, the Lord Vincenzo Renieri observed the end by the high altitude of Procyon, gr. 39, 20'; further, at the rising of Aldebaran, gr. 46, 10'. At Mallorca, the Lord Vicenç Mut saw the end by the high altitude of Procyon, and the rising, gr. 53, 45'. At Naples, Father Giovanni Battista Zupi, S.J., saw the end by the high altitude of Sirius, gr. 31, 20'.

ECLIPSIS 108.

[Margin: 1646]

In the year 1646, on January 30, at Paris, Gassendi observed a lunar eclipse at h. 18, 1' after midday; in New France [in nova Francia], Father Francesco Giuseppe Bressani, S.J. [P. Franciscus Iosephus Bressanus], observed the beginning by telescope at hour 10, 44'. The immersion, hour 11, 41'. At Pisa, the Lord Vincenzo Renieri obtained the beginning by the high altitude of the Moon, gr. 24'.

ECLIPSIS 109.

[Margin: 1646]

In the year 1646, on July 27, at Smyrna [Smyrnæ], Jo. Faber of Marseilles [Io. Faber Massiliensis] observed the end of a lunar eclipse at hour 8, 30' after midday, as Boulliau narrates in his letters.

ECLIPSIS 110.

[Margin: 1647]

In the year 1647, on January 20, at Paris, Gassendi observed the middle of a lunar eclipse at hour 9, 12'. At Danzig, Johannes Hevelius observed the beginning at hour 10, 29', 5"; and then the digits 5, hour 11, 27', 44". At Mallorca, the Lord Vicenç Mut observed the beginning [Continues on next page]

[Margin: Anni Christi.]

hour 8, 16'; the end at hour 10, 31'. At Smyrna [Bullialdus, Ismaël Boulliau] observed the beginning at hour 10, 37', the end at hour 12, 15'.

ECLIPSE 111.

[Margin: 1649]

In the year 1649, on May 25, [Vicenç Mut] observed the beginning of the total eclipse at Majorca [Maiorica] at hour 13, 16'; and Fr. Francesco Giuseppe Bressano of the Society of Jesus, in New France at Trois-Rivières [Tria Flumina], noted the beginning at hour 7, 48', the end at hour 10, 45'.

ECLIPSE 112.

[Margin: 1649]

In the year 1649, on November 18, we observed the total immersion of the Moon at Bologna at hour 18, 45', 50"; our people [Nostrì] the beginning at hour 11, the end at hour 15 precisely. At Quebec [Kebeci] Fr. Francesco Giuseppe Bressano observed the beginning at hour 12, 12'; the immersion at hour 13, 30'; the end at hour 16, 25'.

ECLIPSE 113.

[Margin: 1650]

In the year 1650, on May 15, [Vicenç Mut] observed the end of the lunar eclipse at Majorca at hour 9, 32', 24".

ECLIPSE 114.

[Margin: 1650]

In the year 1650, on November 7, Fr. Nicolaus Mascardus of the Society of Jesus observed at Panama the beginning of the lunar eclipse at hour 12, 15' after noon.

ECLIPSE 115.

[Margin: 1652]

In the year 1652, on September 17, we at Bologna [Nos Bononiae], together with Fr. Grimaldi [P. Grimaldo, Francesco Maria Grimaldi], caught the end of the lunar eclipse at hour 8, 42', 36" after noon; and the same end at Pansano [Pansani] near Modena [Mutina] was caught by Fr. Domenico Cassini [Io. Dominicus Cassinus, Giovanni Domenico Cassini], three minutes later. At Paris the end of the eclipse

was observed by D[octi]ssimi D[omini] Petit [Pierre Petit] and [Auzout, D. Auzotio] from Arcturus at hour 8, 3', but from the head of Andromeda at hour 8. By [Avignon, Auenione] D. Toridutus the end was obtained at hour 8, 14'. At Digne [Dinia] [Gassendi, D. Gassendus] [observed] the end at hour 8, 19'. Certain men at Leiden [Leydae] near [Bullialdus] [observed] the end at hour 8, 11', 36". At Tournai [Tornaci] [Wendelen, Vuendelinus] [observed] at hour 8, 12'. At Brussels [Bruxellis] [Langrenus] likewise at hour 8, 12'. Finally the Most Illustrious [Vuatsavia, Vuatsaviae] D. Io. Nucerus, Secretary of the Most Serene Queen of Poland, [observed] the end at hour 9, 19', 54"; and [Bullialdus] at Paris at hour 8, 3', 16".

ECLIPSE 116.

[Margin: 1653]

In the year 1653, on March 13, I myself [Ego], together with Fr. Grimaldi [P. Grimaldo], saw the beginning of the lunar eclipse at Bologna at hour 14, 40', 27" after noon, and the immersion at hour 15, 46', 30". At Paris in the Clermont College [Collegio Claramontano], the Fathers of our Society [PP. Soc. nostrae] observed the beginning at hour 14, 6', 34", the immersion at hour 15, 15', 15". Let [Bullialdus], however, by his own computation, have determined the beginning at Paris at hour 13, 57', the immersion at hour 15, 6'. Fr. Nicolaus Mascardus, in the Valle Bucalensi [Valle Bucalensi] — a place one degree more to the west — observed at S. Iago of Chile [S. Iacobo Chilensi] the beginning at hour 9, 15' after noon, the immersion at hour 10, 30', and the emersion at hour 12, 0', the end at hour 13, 15'.

ECLIPSE 117.

[Margin: 1654]

In the year 1654, on August 27, [Hevelius, Heuelius] at Danzig [Dantisci] observed the beginning of the lunar eclipse at hour 11, 16' $\frac{1}{2}$; the end at hour 12, 40' $\frac{1}{2}$; the middle at hour 11, 58' $\frac{1}{2}$. And the digits about 2 $\frac{1}{2}$, nearly. At Paris [Gassendi, Gassendus] [observed] the beginning at hour 10, 5'; the end at hour 11, 35'; the middle at hour 10, 50'. At Avignon [Auenione], D. Anton. Franc. Payen [Payen] [observed] the beginning at hour 10, 20'; the middle at hour 11, 6'; and the digits then 2 $\frac{1}{2}$. The end at hour 11, 50'.

ECLIPSE 118.

[Margin: 1657]

In the year 1657, on June 25, at Bologna, Fr. Grimaldi [P. Grimaldus] and I [Ego] noted the total obscuration of the lunar eclipse at hour 9, 1', 34"; the emersion at hour 9, 30' $\frac{1}{2}$; the end at hour 10, 54', 52". At Rome, D. Platus observed the end at hour 11, 8'; but Fr. Paulus Casatus of the Society of Jesus at hour 11, 6'. At Modena [Mutinae] Fr. Francesco Giuseppe Bressano [observed] the end at hour 10, 51'. At Turin [Taurini] D. Iulius Turrinus [observed] the immersion at hour 8, 41' $\frac{1}{3}$. At Lyon [Lugduni] Fr. Francesco Caizae [Caizae] of the Society [observed] the immersion at hour 8, 37'; the emersion at hour 9, 11'. The end [was lost], on account of the nearness of the horizon, and they all confessed by reason of the penumbra that the observation had been uncertain, as did we.

ECLIPSE 119.

[Margin: 1657]

In the year 1657, on December 20, Fr. Grimaldi [P. Grimaldus] and I [Ego] observed at Bologna the beginning of the lunar eclipse at hour 6, 48' after noon; the end at hour 8, 40'. The digits, to the naked eye, 3; but by telescope 3, 30'.

ECLIPSE 120.

[Margin: 1659]

In the year 1659, on May 6, the clouds preventing the remaining phases, Fr. Francesco Maria Grimaldi together with his companions — namely Alessandro Fuccio [Alexandro Fuccio] and others — observed at Bologna the end of the lunar eclipse, from the altitude of the [Fiducial line, Fidicula], at hour 10, 14', 49". Yet it seemed to me that that moment had elapsed as if truly nearly so; but the rest [was] doubtful — that it had not exceeded the sum by three minutes of time; and earlier too the other Moon [had been seen] at altitude 6 [grades], 6 digits obscured. The end of the eclipse, observed at Majorca [Maioricae] by [Vicenç Mut, Vincentio Muto], was at high Regulus toward setting, at grade 46, 42', or, as he himself reckoned, at hour 9, 33' after noon. If the observations are corrected, and you add 1' to the Grimaldian one [Grimaldicae], and to the Modenese [Mutiana] add 3', the difference of meridians, otherwise found to be 37' in time, comes out easily.

ECLIPSE 121.

[Margin: 1661]

In the year 1661, on October 7, the beginning of the spurious eclipse was observed at Bologna by Fr. Francesco Maria Grimaldi and his companions at hour

14, 8', 36" after noon; but the true beginning at the middle of the Ecliptic Shore [littus eclipticum], in the same Selenographia [Selenographia], at hour 14, 23', 16"; the end, however, near the macula Messhalae [Messhalae] toward Geminus, at hour 16, 53', 42" after noon; and so the duration was hour 2, 30', 26". The digits obscured 7 ½. At Aix [Aquis Sextiis] Fr. Henricus Ignatius of the Society of Jesus, of the King's [household], observed the beginning at hour 2, 24' after midnight, and the middle at hour 3, 35'; the end at hour 5, 11'; the digits 7.

CAPVT III.

An epitome of the observations of lunar eclipses, in so far as we have them handed down by the authorities, and the moment of the greatest, or middle, eclipse, which has been reduced by us to one and the same Bologna meridian, from the last table of the first chapter.

The following synoptic table lists historical lunar-eclipse observations in chronological order. The columns are:

- **Ordo Eclipsis ex cap. 2** — the serial number of the eclipse (from Chapter 2).
- **Anni labentes ante Christum, cum Mensibus ac Diebus incompletis** — years elapsed before Christ, with months and incomplete days. (For the later portion the header changes to **Anni Christi & Menses, dies labentes** — years of Christ, with the months and days elapsing.)
- **Observatores & loca observationis** — the observers and the places of observation.
- **Tempus post Meridiem loco observationis** (H. I) — the apparent time after noon at the place of observation, in hours and minutes (and seconds where given).
- **Tempus apparens p.m. in Bononia** (H. I II) — the apparent time after noon reduced to Bologna, in hours, minutes, and seconds.
- **Quantitas defectus (Digiti)** — the magnitude of the defect, in digits (or "Totalis" / directional indication).

The synoptic *Epitome* table of historical lunar eclipses reduced to the Bologna meridian continues. Each entry gives the Ordo (serial number of the eclipse from Caput II), the year and day, the observers and their places, the apparent time after noon at the place of observation and reduced to Bologna, and the magnitude in digits. The two paired time-columns each carry the running heads H. | ' | " (hours, minutes, seconds).

Left table of the page (Ordo 95–104):

CAPVT IV.

On the Uncertainty of Ancient Observations, and of Certain Recent Ones; on the Disagreement of Observers of the Same Eclipse; and on the 19 Causes of That Disagreement.

[Margin: On the Observations of the Ancients]

First, from what has been said about Eclipses 40 through 119, and from the disagreement among recent observations, one can judge well enough — notwithstanding how much this present age and the preceding one have advanced astronomy — how great the disagreement among the ancients would have been, had more observers recorded the same eclipses, especially observers without the telescope and the other instruments with which this art is now equipped. Note too that Ptolemy, working from the bare beginnings of eclipse-study as it had been handed down, fixed the mean point of the ancient total eclipses by supposing them to last very nearly 4 hours, and so fixed the moments

of the ecliptic full moon by adding two hours to the beginning, as he did in Eclipses 1 and 10 of our Caput II. When, however, the eclipse was of 6 digits, he judged it to last three hours, and so at the start added one and a half hours, as he did, following the order of that same chapter, in Eclipse 2. In Eclipses 3 and 7 it is established that in this matter the diversity of the various lunar Anomalies can amount to more than a quarter of an hour. Moreover, none of those good men of old were suspicious about refractions, nor did they detect any difference arising from the penumbra; yet here and there an error of 10 minutes, and sometimes more, may creep in. Hence, leaving aside Eclipse 8, which on account of its brevity could be observed with little precision, and Eclipses 9, 11, 13, and 14, scarcely any observations of eclipses before Ptolemy are manifestly free from an error of 20 minutes — not to say 30. Granting therefore to Ptolemy himself what he affirms of himself in *Almagest* IV.6, that certain eclipses were observed with the utmost accuracy, we are nevertheless compelled to suppose that, in using those ancient observations together with these recent ones, some compensation of their errors occurs over a very long interval of time — errors that may perhaps slip in unnoticed past the observers.

[Margin: 2]

As for the Disagreement, and consequently the uncertainty, of many recent observations, I recall it to those two heads. The first head concerns the differing moments of the ecliptic full moon, even with respect to the same meridian. To make this more evident, I had premised Caput III, in which I reduced those moments to our Bologna meridian. The reader will therefore run through those eclipses, beginning from 49, and will recognize how enormous the discrepancies are in some of these disagreements. For Eclipse 49 is reported by Longomontanus 14 minutes later than by Tycho; and in Eclipse 50, by likewise 14 minutes, Tycho disagrees with himself, just as he disagrees with Wendelen in Caput II — observations I marked, but they are the most disgraceful of all, when the eclipses observed by Lansbergen are compared with the Tychonic or the Wendelinic. For they are as follows:

In Eclipses	Minutes of disagreement
54	15
66	20
68	29
69	25

Whether Lansbergen was deceived by the penumbra, as Wendelen suspects (and as we said in Caput II), or whether he forced the observations to fit his own Tables — and so in these cases they are fallacious — I leave undecided. For not this whole and so great a discrepancy can arise from the distance of the meridians supposed by us; otherwise, in other eclipses (say in 58 and 63), Lansbergen would not agree so nearly with the others. There is also that notable disagreement which in Eclipse 104 mounts up to 22 minutes, because that eclipse was observed by very many at different hours of the day [continued opposite].

[The first embedded table — the eclipses ranked by their minutes of disagreement:]

Minutes of disagreement	Order of the eclipses from Caput III
1 ½	88
2	63
2 ¼ [?]	95
4	57, 103, 105
5	53, 84, 96, 100
6	86
7	88
8	67, 98, 110
8 ½	117
9	75, 80, 92, 102
10	58, 71, 97
14	101

[Margin: 3]

The second head of Disagreements — those which can least be ascribed to false distances of the meridians — concerns the Duration of the same eclipse, or the tarrying [*Mora*] in total shadow. This will appear more clearly in the following

Table, in which the letter D denotes the Duration of the eclipse and M the tarrying in darkness.

[The second embedded table — durations and tarryings. Column S marks D (Duration) or M (tarrying, *Mora*); H = hours, M = minutes:]

Order of eclipse	Observers	S	H	M
56	Lansbergen	M	1	40

Then the prose on this page returns to the discussion of the four causes of disagreement among observers.

it may seem to someone that the Moon has entered the shadow, when in reality it is still a fair distance from it. And for the same reason, when it has in fact emerged from the shadow, it will appear not yet to have emerged; so on both counts the duration will appear to some greater than it ought to be. Sometimes, however, a lunar eclipse begins in the brighter part of the disk, toward the Northeast [*Notapeliotem*], around the *Terra Sterilitatis* [Land of Sterility], and on the contrary ends in the western part of the limb, which is of itself darker, near the *Mare Langrenum*. And then, even if no error is made at the beginning, an error may still be made in estimating the end, by waiting for it until that part is illuminated by all the Sun's rays. This first cause is further varied by the libration of the lunar body, which presents to us now one margin and now another.

[Margin: 2nd Cause]

The second cause is the Privation of some of the Sun's rays, which the Moon suffers near both edges of the shadow, whether it has not yet entered the shadow or has just emerged from it. For, compared with its other parts, which are

illuminated by all the Sun's rays, those parts which are deprived of many rays appear darker, and there arises a kind of smoke, and an image of the shadow, which we call the *Umbrago* [shadowing]. This straightway darkens a large part of the lunar disk before the legitimate eclipse, by about a quarter of an hour or more, and likewise afterward the Moon perseveres darkened for some while after it has come out of the shadow. This did not even occur to Tycho's mind, but was noted afterward by others; hence in the more recent observations the time of the spurious eclipse, distinct from the legitimate eclipse, has often been remarked.

[Margin: What the legitimate eclipse is]

I call the *legitimate* eclipse that in which the Moon enters that shadowy cone which is apprehended by the rays of the Sun touching the globe of the Earth and its atmosphere, the rest of the rays being so impeded that they cannot penetrate directly but only somewhat refracted. For neither is the Moon to be looked for as not illuminated even by any refracted rays; otherwise many eclipses, even total ones, would be none, as we shall presently say when we treat of the *Penumbra*, in connection with this 2nd cause — see the diagram in *Almagestum Novum*, Book 5. So much for this point.

[Margin: 3rd Cause]

The third cause indeed is that on account of which even the keenest-sighted observers — whether with the naked eye or equipped with the telescope — are wont to hesitate around the beginnings and ends of the eclipse, both at immersion into and emersion from the earthly shadow. This is the *Penumbra*, so called because it is not simply shadow, but a privation of rays of any kind whatsoever of the Sun — *yet almost shadow*, since it is the privation of all the direct rays of the Sun, but with a participation of Refracted Rays, illuminating the Moon with a weak and malignant light; and standing in the place of darkness it represents to us those various colors on the lunar disk — bluish, rusty, honey-colored, ashen, ruddy, tawny, and the like — according to the diverse density and opacity of the watery vapors that surround the terrestrial globe. And there arises a twofold refraction of the Sun's rays, one at immersion and the other at emersion. For which matter the figures are to be consulted in *Almagestum Novum*, Book 5, set out in Chapter 5, from problem 1 to the end, where you will see many admirable things concerning the variety of phases arising from this, and why sometimes in the very middle of a total eclipse the Moon, passing through the axis of the aforesaid cone, nevertheless still appears dimly lit; and, as Pliny says (Book II, ch. 9), "is deficient, and yet in its defect is conspicuous."

Indeed, in the same eclipse it may to some lie wholly hidden, affected by no rays — by not even refracted rays — as mere shadow vanishes from the eyes; while to others, in different places, it may appear dimly lit, on account of vapors of diverse density. And refracted rays, so affected, may even vanish — as happened in Eclipse 104, in the year 1642, and on other occasions, as we have recounted in the same Book, ch. 5, num. 13. So that, to say nothing meanwhile of Mars and Jupiter, which, being as it were set opposite the Moon, can communicate some little part of light to it, even when it is placed in the shadow. From this mixture of the Penumbra it comes about that eclipses which are in truth total scarcely appear total, when the tarrying in darkness is of brief duration — as perhaps happened in Eclipses 23, 68, 80, 83, and 87, concerning which see the history in Caput II; and in those that were observed under very varied conditions, especially when for many it was near the Horizon, and in one place there was clear weather, in another murky, and in another a damp state of the air. But now we touch upon the fourth cause.

[Margin: 4th Cause]

The fourth cause is the one already indicated on the occasion of the third, namely...

[Margin: 1st Cause]

The causes, moreover, of the aforesaid Disagreements in respect of the tarrying, both in quantity and in the conditions required in observing, have been set out by us in *Almagestum Novum*, Book 5, Chapter 5, and in its scholia, and are now to be briefly indicated. The first is from the Moon's own limb as it enters the shadow of the Earth, and then again as it emerges. For the Eastern part of the limb, which first enters the shadow, is darker than that Western part which last comes out of the shadow. Indeed the Eastern part of the limb, with its parts hollowed inward, exhibits that great spot toward the North, or toward the Northeast [*Arctapeliotem*], which in *Almagestum Novum*, Book 4, we named the *Littus Philippicum* [Philippine Shore]. Since therefore this part is of itself very dark, if on approaching the shadow it is already deprived of some of the Sun's rays — though it be still illuminated by some — then...

[continued in the following discussion]

[Margin: 2nd Cause] [Margin: What the legitimate eclipse is] [Margin: 3rd Cause]

[Margin: 4th cause, manifold.]

is allowed by the diversity of horizons and of vapors, which, according to their differing density, produce a greater or lesser refraction of the rays; and so the same rays, by their greater or lesser coloration, give rise to differing brightnesses and qualities. They also generate the penumbra, and besides this they produce a different appearance of the Moon: for the rays travel from the Moon to our eyes by reflection, and again, on entering the earthly atmosphere, they are refracted before they reach our eyes. As a result, the extreme phases of an eclipse — when the Moon begins to enter the shadow, and when it begins to leave it — are difficult to judge.

Therefore there are two refractions involved in this fourth cause: one of the Sun's rays at the place where they are refracted, the other of the Moon's; and the same goes for the differing refraction of the rays reflected from the Moon before they reach our eyes. Both depend on the nearness of the Moon, greater or lesser, to the horizon, and on the differing density of the vapors; or it may even happen that our position beneath the equator, or lower within the Torrid Zone, where the vapors are believed to swell up more loftily, makes the Moon's margins, as observed by us, vary.

[Margin: 5th cause.]

The fifth cause is the diversity of the *Umbragines* [shadow-fringes] of the lunar globe, which appear differently at different horizons — as Wendelen [Govaert Wendelen] also noted in the preface mentioned. For when the Moon traverses a shadow whose plane cuts the very globe of its body into two hemispheres — granted that, at the place where the Moon passes, the astronomical tables suppose it, yet it touches the globe at a smaller part than a hemisphere — and so the *Umbrago* enters before it [the shadow proper], by a thickness of cone the more conspicuous the nearer that shadow-cone is to us; when, I say, the center of the Moon is at quadrature, the semidiameters being equal, an eclipse of this kind by hypothesis increases by about the sixth part of a digit. From this it comes about that the lunar margins do not appear the same to all those dwelling on Earth: some, who have the Moon near their vertex, look upon it; others, set toward the north, view the Moon from the south at an oblique angle; and so it is possible that to those in the south the same eclipse should appear of 6 digits, but to those in the north of $6\frac{1}{2}$ digits. Indeed it can even happen — and this is a very true paradox — that the same eclipse should be partial to some and total to others, if anything beyond the angle of contact of the shadow should jut out so far from the prominent body of the Moon toward one pole, that it is not conspicuous to inhabitants toward the other. The discrepancy, however, is very small.

[Margin: 6th cause.]

The sixth cause is uncertain indeed, yet it can be pointed out as in part the Moon itself, in part the air around the Moon — that is, its own atmosphere surrounding it, and of differing thickness — whence the Moon, before it touches the body of the shadow, may seem to touch it earlier or tardily; or the Moon is abandoned, that is, the light it draws from the Sun is held back later in the darkness; or, in the manner of the Bolognese gnomon, our eyes, though set in the dark, are carried over from the Sun into the darkness — a thing which Wendelen judges not improbable in this same matter.

[Margin: 7th cause, manifold.]

The seventh cause lies in those astronomical elements which concur in determining the moment of the ecliptic phases: namely the Moon's motions and parallaxes (if we use the lunar altitude), the declination, and the right ascension of the fixed star and the right ascension of the Sun, by which it is necessary to derive the times wanted; the position of the meridian among all these; and the azimuths of the star, and the altitude of the pole. For in all these matters, should any error of computation lurk, it is necessary that, by a trigonometric calculation built on a false foundation, a false conclusion as to time be begotten.

Furthermore, as regards Tycho [Tycho Brahe] — however much one labors over the fixed stars in their exploration — it is one thing to investigate, but another to apply the correction owed to the Tychonic right ascensions and to his right ascensions of the affixed stars, as we judge must be shown at *Liber 4* from *Caput 10*; and from our *Geographia Reformata* it will be evident how false the altitudes of the pole, found here and there by astronomers, sometimes are. Gassendi himself, on the basis of the Sun's altitudes, carefully reckons that the whole of Gaul comes out new [i.e., misplaced] in an eclipse; for in the Lyon eclipse he determines its beginning at hour 10 [?], 3', and its end at hour 12 [?], 30'; and that the altitude of the pole is 45°[?] 36' — which he says he derived from an observation of two...

the very opposite. We compute the place of the Moon at the same moment, adding the difference of place computed from observation, or the debt owed by the difference of observations, and the difference of time owed to this; the *equation of place* is wont to be about double the moment itself of the full moon.

[Margin: 8th cause.]

The eighth cause is the diversity of the observers themselves, arising from natural causes: vision; sight, with which some are endowed by sharper sight,

greater attention, and circumspection, than others — especially in such subtle matters, when an experience already attained for the most part is at hand. But if many adduce themselves as witnesses, and the moment determined more certainly is fixed by them, the eclipse begins or ends, and they do not agree among themselves on the same point, the one greater than this, the other less, ambiguous, and the fallacy is born from the outset.

[Margin: 9th cause.]

The ninth cause is likewise the diversity of the observers themselves, arising from the instruments with which the eclipse is observed: namely, the telescopes by which the eclipse is greater than to the naked eye; the quadrants, the astronomical radii, the clocks, and so on; or from their use and handling. For nor in this can it happen that no slight error be committed in all things, that is, the diligent observers are to be degraded who observe with others; and if the better organs come to hand, yet they do not agree with the others, that nothing should be ascribed to the skill of the trigonometric calculation, which can however be easily repeated, and corrected.

[Margin: 10th cause.]

The tenth cause is the false difference of longitude, that is, the assumed distance of meridians, while observations made under different meridians are referred to one another, and it appears whether they agree at the same moment or not — as we did above at *Caput* 3. Especially since the difference of longitude is to be derived not from itinerary intervals, but from the lunar eclipses themselves at *Caput* 3. Since therefore an eclipse is licensed to be observed in several places, and from observations of this kind we have surveyed it at Bologna and at Paris, at the 40th moment of time, we confess nevertheless that no evident falsity should appear in a difference of one or another minute of time, in the greater or lesser part of the more remote regions; for from those nearby, or beneath nearly the same meridian, we have a greater certainty from elsewhere than from the eclipses themselves.

CAPUT V.

De Consensu, aut Dissensu Tabularum Astronomicarum cum Observationibus Eclipsium Lunarium, & primò de Antiquis Eclipsibus usque ad Ptolemæum inclusivè, & enormi quoad has Dissidio inter Tabulas Astronomicas, & Chronologicas apparenti; sed verò Ptolemæi errore in motu Solis.

[On the agreement or disagreement of the astronomical tables with observations of lunar eclipses; and first on the ancient eclipses down to Ptolemy [Ptolemy] inclusively, and on the enormous disagreement, as regards these, that appears between the astronomical and chronological tables — but which is in truth due to Ptolemy's error in the motion of the Sun.]

This comparison, indeed — which we ourselves long desired, and which we know is eagerly awaited by students of astronomy, so that it may be established how far the more distinguished astronomical tables, beyond the rest, can be excogitated as better and more accurate. And so, to this end, at *Caput 3* I selected those eclipses, of which a medium part — whether at the moment of the partial defect, or at the extreme phases, whether partial or total — could be noted by us from the observers: namely, because in the moment of the diametral opposition of the Moon with the Sun (which is the moment of the ecliptic full moon), and of the place of the Sun at the moment foreknown from the tables, the place of the Moon opposite is certainly known. Then, to this reduced astronomical moment — yet a moment equated and reduced to a uniform time — we have computed it, as below in naming the place of the Sun by the tables; and from there we shall immediately note...

the opposite. We compute the place of the Moon at the same moment, adding the difference of place; the difference of place is computed from observation, or the debt owed; the difference of time differs here.

[Margin (numbered 2):] Since the astronomical tables are for the most part constructed and affixed to a meridian differing from the one under which the observations have been made, the time of the observations must be reduced to the meridian of the tables, according to the distances of these places — which the tables themselves command in their catalogs of places, or at least as little as is wanting, according to our *Geographia Reformata*.

[Margin (numbered 3):] Since the aforesaid eclipses were observed before our time by others than us, or recalled to calculation from the tables of others, where they did not fall short of our intention: provided that, from the Rudolphine tables [*Rudolphine Tables*], the eclipses computed are altogether 91; from the Philolaic [*Astronomia Philolaica*], the eclipses computed are 40; and from the Tychonic, the eclipses are 24. Since indeed we have used the calculations of others, so that the difference of meridians, and of the moment of time handed down from here under the meridian of observation by the observers, may be established under the meridian of the tables — what scruples of hours the tables represent — the

eclipse may stand earlier or later, and so likewise the difference in zodiacal place may be elicited.

[Margin (numbered 4):] Furthermore, since for the most part these eclipses, beginning from an eclipse, were observed by different observers, or at a different moment they note, we choose one, or draw it from several observations, and its time under the meridian of the observations is handed down; and accordingly, from the moment of the time itself, and from *Caput* 3, it will be established by what observer's choice we have elected. For example, in eclipse 110 we have noted the hour 9^h 12'; since at it, recurring to *Caput* 3 and to eclipse 110, it will be established that the same was made at Paris through Gassendi, namely at hour 9^h 19' after the meridian. For the rest, this warning peculiarly pertains to the eclipses of the following chapter. And to this chapter peculiarly pertains the following warning concerning the day of the eclipse.

[Margin (numbered 5):] Although in *Caput* 2 and 3 we referred the ancient eclipses to the meridian of noon, as we truly compute by our *Chronologia Reformata*, and by the apparatus of chronology answering in the form of the Julian Years and the months of the Egyptian Year in Ptolemy. In the following we have been forced by the tables, two for each: that we should note the days, one moment, by which the eclipse came; it is necessary, according to the place of the Sun in Ptolemy — let it be of such a kind that the astronomical tables for the most part do not exhibit the Moon opposite to the Sun, but at degree 11, or 12, distant from opposition with the Sun; and yet they exhibit the place of the Sun observed by Ptolemy nearer, while the other day, namely the later, we add, where the astronomical tables exhibit the Moon opposite to the Sun: so that it is not the place of the Sun that itself underlies, which at least Ptolemy handed down from his tables, but nearly the degree of the preceding. Concerning the disagreement there will be differing matters below, after the following catalog of eclipses.

[Margin (numbered 6):] Meanwhile, by our sincerity and good faith, the names of those by whose eclipses we have used are to be reviewed, according to the warning at 3 and 4, and they are in alphabetical order written below.

Andreas Argolus [Andrea Argoli], who computed eclipses from the Danish tables of Longomontanus [Longomontanus], at Rome, yet to the meridian, in his ephemerides from the year of Christ our Lord 1630, and down to 1700.

Claudius Ptolemæus [Ptolemy], who handed down not only eclipses observed, equated and reduced to his own time of observations, but the most full eclipses;

and he adjoins from his tables, or from Hipparchus [Hipparchus], the place of the Sun and of the Moon.

Christianus Severinus Longomontanus [Longomontanus], who in *Liber 1, Theoricorum Astronomiae Danicae* [*Astronomia Danica*], *Caput 2*, in his Commentary...

has handed over the place of the Moon, computed from the Danish tables, with 9 eclipses observed in antiquity, & at Tycho's [Tycho Brahe], whether by himself or others, by which he adjoins the time and the hourly motion of the Moon from the Sun, answering to the difference observed.

David Origanus [David Origanus], who in his ephemerides, both Prutenic and Tychonic, but to the meridian of Frankfurt-on-Oder reduced, computed eclipses from the year of Christ 1595, to 1654.

Dionysius Petavius Soc. Iesu [Denis Pétau], who in *Liber 8, De Doctrina Temporum* [*De Doctrina Temporum*], *Caput 13*: all the ancient ones down to al-Battānī [al-Battānī] inclusive, and very many of the more recent ones down to the year 1600 of Christ, computed eclipses observed, from his Parisian tables — that is, to the meridian of Paris affixed — adjoining, however, some calculation from the Alphonsine, Prutenic, and Danish, and besides some of our own century's eclipses he predicted.

Gotefridus Vuendelinus [Govaert Wendelen], who, after the *Ideam* of his Atlantic Tables [*Idea Tabularum Atlanticarum*], published of many recent eclipses; that is, he derived the time of the eclipses from those same tables, and by some quantity from the year 1573 to 1643.

Io. Antonius Maginus [Giovanni Antonio Magini], who in his ephemerides, from the Prutenic tables, to the meridian of Venice computed eclipses from the year 1581 to 1660.

Franciscus Montebrunus [Montebruni], who from the Lansbergian tables [Lansbergian Tables] of Bologna, by our meridian, completed the calculation of eclipses from the year 1640 to 1660.

Ioann.-Keplerus [Kepler], who, from the Rudolphine tables, in his ephemerides computed eclipses from 1617 and 1620, under the meridian of Uraniborg. But we have recalled the Rudolphine eclipses of the Moon, 91 observed, to calculation.

Ismaël Bullialdus [Ismaël Boulliau], who in *Liber 7* of his *Astronomia Philolaica*, *Caput 7*, computed eclipses from his Philolaic tables, 19 in antiquity, and recent

ones — 35 — from the year 1573 to 1643. Just as we — but not the Philolaic — adjoin a calculation: the eclipse computed at the 40th, to the meridian of Uraniborg, which he chose.

Michaël Maestlinus [Michael Mästlin], who from the Prutenic tables to the meridian of Tübingen computed eclipses from the year 1577 to 1590.

Nicolaus Copernicus [Nicolaus Copernicus], who computed eclipses by himself, and adjoined the place of the luminaries, deduced from his own tables.

Philippus Lansbergius [Philips van Lansbergen], who in his *Goëse* meridian, from his tables, computed it; and in the Thesaurus [Lansbergen, *Thesaurus*] he derived the very fullest eclipses of antiquity, and recent observations — which differ very much — perhaps because the tables themselves cannot be too much gainsaid.

[Margin: NOTE therefore the Indices of the aforesaid Tables, by which below we shall use what is written underneath.]

Alphons. — The Alphonsine Tables [Alphonsine Tables] in the calculation of Petavius, of Regiomontanus [Regiomontanus], or of Magini [Giovanni Antonio Magini].

Atl. — The Atlantic of Wendelen [Govaert Wendelen] from his own calculation.

Dan. — The Danish in the computation of Longomontanus [Longomontanus], or of Petavius, or of Argoli [Andrea Argoli].

Lansf. — The Lansbergian from the computation of Lansbergen [Philips van Lansbergen] himself, or of Montebruni [Montebruni].

Parif. — The Parisian from the calculation of Petavius.

Phil. — The Philolaic from the computation of Bullialdus [Ismaël Boulliau], or our own.

Prut. — The Prutenic from the calculation of Petavius, or of Buntengi [?], or of Maestlin [Michael Mästlin], and most often of Origanus [David Origanus].

Rud. — The Rudolphine from the computation of Kepler [Kepler], very rarely, but everywhere; from our Own in all the eclipses.

Tych. — The Tychonic from the computation of Origanus [David Origanus], or our Own.

Ptol. — The Ptolemaic.

The moments of the ancient eclipses, and the observed quantity, collated with the time and the quantity represented by the tables written below. The letter e indicates the *excess* of the computed place of the Moon; and d, the *defect* from the exact opposition with the Sun.

The table is read group by group, one group per "Ordo Eclipsis ex Cap. 2" (eclipse-order from *Caput* 2). For each group, the first inner block gives the data referred to the place of the Sun's apparent opposition; the second inner block (the lower one in each group) gives the corrected/alternate reckoning. The column "Tempus Apparens post Merid. in loco Observationis" gives Month / Day / Hour / Minute. "Solis locus Verus ex Tabulis, & inde 》 locus 8" [the Sun's true place from the tables, and from it the Moon's place opposite] is given as Sign / Degree / ' / ". "Lunæ locus Verus ex Tabulis computatus" [the Moon's true place computed from the tables] likewise. "Differentia loci 》 computati & observati" carries the marker letter (d = defect, e = excess) followed by Gr / ' / ". "Tempus huius Differentiæ" gives H / ' / ". "Quantitas in digitis" and "Differentia Quantitatis" give digits.

Book Two — On the Moon

[The large comparison table "Moments of the Ancient Eclipses" (Eclipsium Antiquarum Momenta), begun on the preceding folios, continues here across pages 113–115. Each numbered block ("Ordo") gives one ancient eclipse: the first row labelled Observatio records the observed datum, and the following rows record the value computed from each set of astronomical tables — Ptolemaic (Ptol.), Danish

(Dan. = Tychonic-Danish), Lansbergian (Lansb. / Lans.), Parisian (Paris.), Philolaic (Phil. / Philol.), Prutenic (Prut.), and Rudolphine (Rud. / Rudol.). The marker e = excess (the computed lunar place exceeds the exact opposition), and d = defect (it falls short of exact opposition). The zodiacal signs in the Solis locus and Lunae locus columns are given by their astronomical symbols, transcribed here by name. The Egyptian/movable months (Epiphi, Thoth, Phamenoth, Mechir, Messori, Tybi, Pachon, Payni, Choeac, Pharmuthi) appear in the Mens. column.]

Table: Moments of the Ancient Eclipses (continued)

Column headers (verbatim):

- **Ordo Eclips. ex c. 2** — Order of the eclipse from chapter 2
- **Observatio, & Tabulae** — Observation, & Tables
- **Tempus Apparens post Merid. in loco Observationis** (Mens. / D. / H. / M.) — Apparent time after the meridian at the place of observation (Month / Day / Hour / Minute)
- **Solis locus Verus ex Tab. & inde ☉ locus ☊** (Sig. / Gr. / ' / ") — True place of the Sun from the Tables, and thence the place opposite the Sun (Sign / Degree / minute / second)
- **Lunae locus Verus ex Tabulis computatus** (Sig. / Gr. / ' / ") — True place of the Moon computed from the Tables
- **Differ. loci ☉ computati, & observati** (Gr. / ' / ") — Difference of the computed and observed place [with e = excess / d = defect]
- **Tempus huius Differentiae** (H. / ' / ") — Time corresponding to this difference (Hours / minutes / seconds)
- **Quantitas in digitis** (Dig. / ') — Magnitude in digits
- **Differ. Quantitatis** (Digit. / ') — Difference of magnitude

Sign abbreviations used below: Ari (Aries ♈), Tau (Taurus ♉), Gem (Gemini ♊), Can (Cancer ♋), Leo (Leo ♌), Vir (Virgo ♍), Lib (Libra ♎), Sco (Scorpio ♏), Sag (Sagittarius ♐), Cap (Capricorn ♑), Aqr (Aquarius ♒), Psc (Pisces ♓).

*In hac Eclipsi, ex Petauij calculo, Alphonsinae Tabulae excedunt
Observationem hora 1. & 56'. Danica 42'. Prutenicae 49'. Parisina 33'.*

[In this eclipse, by Petavius's [Denis Pétau] calculation, the Alphonsine Tables exceed the observation by 1 hour 56'; the Danish by 42'; the Prutenic by 49'; the Parisian by 33'.]

after midday on the 6th of May; whence it follows, by the count of days, that the chronological canons place the beginning [of the era], in the form of the Julian year, at the midday of the 26th of February.

[Margin: Copernici error. — Copernicus's error.]

8. *First*, it is certain — both from other authorities and especially from Censorinus (ch. 10) on the day of birth — that the Romans began their civil days from the midnight preceding. But the Egyptians in particular, and the astronomers, are accustomed to begin the day from midday, as is established in the first place from Ptolemy (*Almagest*, book 3, ch. 8), and from the passage of Censorinus shortly to be cited. Hence the beginning of the Egyptian year was not from the Kalends of any Roman day, nor from some whole day before the Kalends, but from before the 6th Kalends [VI. Kal.], or the 12th Kalends [XII. Kal.], it took its start — indicating that the [Egyptian] year began 12 hours before the customary beginning of the Roman day.

9. *Second*, it is certain from Ptolemy throughout that the Egyptians, in their observations of eclipses and of other phenomena, were not accustomed to number the days as incomplete according to their usual reckoning, and moreover — as is generally the case — after the day named they add the day not yet begun. So in book 3, ch. 8, when he has said that the equinox was observed by himself in year 17 of Hadrian, on the 7th of Athyr, just after midday, two near-equal hours — shortly after he says: *"From the first [day] of Nabonassar, year 1, and from the midday of Thoth, the second month according to the Egyptians, up to the autumnal equinox expounded by us, year 879 is gathered, and the 66th day, and 2 equal hours."* But if he had taken the seventh of Athyr as exact and complete, he would, besides the aforesaid years, have numbered 67 days. Moreover (*Almagest*, book 4, ch. 8) he says: *"From the first midday of Thoth of the first year of Nabonassar, up to the middle [moment] of the second of the ancient eclipses — which, as we said, was in the second [eclipse] of Mardocempad, in the year Thoth 18, following the 19th, in the equal sixtieths, 50, before midnight — the time is gathered to be of Egyptian years 27, of days 17, and of hours 11, and 10 sixtieths, very nearly."* But if he had reckoned the 18th of Thoth already completed, he would have numbered 18 days in that collection. Copernicus therefore errs, whenever in such cases he numbers —

[Margin: Copernici error. — Copernicus's error.]

Ptolemy counts the days designated as completed [pro exactis], that is, as fully elapsed, as in *Almagest* IV, ch. 5, where he says: "On the twentieth day from the

beginning of the month Phamenoth." And he soon counts the days slipping by [labentes adhuc], that is, still running, as he marks the first of these eclipses as falling on the 20th of Pauni, the second on the 2nd of the following Choiac, the third tertio (that is, on the 3rd?), and the third (last) on the 19th of Pharmuthi, the day on which the twentieth was running. Let this matter be settled for now from the very practice of Petavius.

[Margin: Copernici error — Copernicus's error.]

10. With this matter at last settled, we expose certain other points. Although it is generally agreed among chronologers that the first year of the vulgar Christian epoch was the forty-sixth of the Julian years, and the first to be bissextile [leap year] — for from this it follows by *Almagest* III, ch. 60(?) that the birth of the Emperor Claudius (as Suetonius shows from the Kalends of August in the Julian year 90) is brought back to the year of Christ's epoch 45, by which means, in our Reformed Chronology, it is confirmed by the common opinion of most chronologers, that the beginning of the years of Christ at the first Kalends of January falls in the year 46 of the Julian period.

11. Fourthly, at last, since the Egyptian year, being constantly of 365 days, also runs ahead a fourth part [quarto quoque] each year, the Julian year begins after the year 24 of February(?), and begins in the descent of the years, and on the contrary in the ascent of the years toward the beginning of the world begins one part before. With these things laid down, the controversy already indicated is more easily exposed.

[Margin: Arabum opinio de Annis Nabonassari, & Christi — The opinion of the Arabs concerning the years of Nabonassar and of Christ.]

12. Jacobus Christmannus [Jacob Christmann], in his book *On the Roman Calendar*, p. 182, says: "The Arabs, exactly [exactè] in commemorating the intercalation, reckon both the years of Nabonassar and of Christ, while in the first book(?) they reckon the years run from Nabonassar up to the transit of Christ 747, and from Christ 131." And shortly after Paul, he adds: "*The Arabs likewise did not take the era of Christ from his conception, but from his circumcision, that is, from the last day of December, which precedes the circumcision, or the Kalends of January, in the year 46 of the Julian period.*" If, then, you reckon from the year before Christ 747, that is, the 26th of February, you will reckon the years 747, and so on with the other eclipses, per the days of the preceding December, the circumcision of Christ

— and they will be the years 747. To this extent Christmannus reckons in the same way 130. How Regiomontanus reckoned, the same Christmannus affirms in the same place. Therefore, if they be 131, it is fitting to take the beginning of the reckoning at the last(?) Meridian of the 25th of February of the year 747 before Christ. From this then follows the months of the Egyptians, which Ptolemy compares to the year of the Julian period, the days preceding them, which the common reckoning of the astronomers notes: and per the example of eclipse 17, set down on the 20th day of Pauni, noted by Ptolemy to be the 5th of May, not now, or commonly, June.

13. We respond, however, that nothing is gained by this opinion of the Arabs. For although the prudent Arabs accommodated their epoch to Dionysius Exiguus, introduced into the Christian world for numbering the years of Christ at their circumcision, and thence the years 747, that is, the 26th(?) from the beginning of Nabonassar, that is, the 26th of February: when, however, they considered the Astronomical Tables, yet they fixed the beginning of the year at the last Meridian of December, for the sake of the convenience of the reckoning, that the astronomical reckoning of the integers might be possible. Rather, from the reckoning of Censorinus let us examine the years. We reckon at the last Meridian of December, by Varro, and in this place we follow the year of Nabonassar 747, as Christmannus writes; for to fix the beginning of Thoth as consuls Pius(?) and Bruttius(?) in the Meridian preceding the twelfth Kalends of August, that is, in the Meridian of the 20th of July, will be the years 747, the 26th(?) of February, when one numbers 130: in what manner Regiomontanus had erred, the same Christmannus affirms there. Therefore, if they be 131, it is fitting to take the beginning of the reckoning at the Meridian of the 25th of February of the year 747 before Christ. From here, then, follows that the months of the Egyptians, which Ptolemy compares, correspond to the year of the Julian period in the preceding days, which the common astronomical reckoning notes: and per the example of eclipse 17, the day noted by Ptolemy to be the 5th of May, not now, or in common usage.

14. Censorinus, in his book *On the Birthday*, ch. 8, in the next year, the first of the years (which he takes as an index of illustrious epochs), among other things has the following: "*Unless I am mistaken, this very year, as a kind of index, and the title of a certain Olympiad of Vlpus(?) and Pontianus, as consuls, from the first Olympiad, is the M. and XIV, on which days the burning summer Olympic Games are celebrated. From the founding of Rome, indeed it is numbered 1991. And indeed from the Palilia [festival of Pales],*

whence the years are reckoned." Of those very years to which the name Julian belongs is the year 283, that is, on the Kalends of January of which year Julius Caesar made the beginnings of the years he himself constituted. But concerning the years which they call the years of Augustus the CCLXV: First the VII. and M. and(?) Pissamo(?) Agrippa, III. consuls. But because Egypt, two years before [it came] under the power and dominion of the Roman people, lived(?), they have the years of the Augustans —

[Margin: Et Petauij — And [the opinion] of Petavius.] [Margin: Et Krismanni — And [the opinion] of Christmann.]

— from CCLXVIII. For, as among us, so among the Egyptians a certain year is referred to in letters, in which the years of Nabonassar are called, which from the first of his Empire run together [consurgant], of which here is CMXXCV. I, that is, item Philip, who from the excess of the Alexandrian years of the Great are numbered, and to this very point [year] they complete DLXII; but the beginnings of these years are always reckoned from the first Meridian, so that they fall on the VII. Kal. Jul., that is, the 26th of June, on the 100th(?) year. For from Bruttus(?) at present they are the same days that have been before the XII. Kal. Aug., at which time Sirius [Canicula] usually rises in Egypt. Whence it may be known that the year of Magnus the Great, as said above, is both the Solar and the Sirian [Canicularis], and is called the Year of God [Dei Annus]. But the beginnings, indeed, are reckoned from the turning [vertentem] year of the hundredth. The beginnings, however, of these years are noted for this reason, lest anyone reckon either the Kalends of January, or the same time as beginning together [simul]. From this place it follows first (which by this very thing is to be looked to) that, if the years of the first epoch of Christ are, as we have said, the maximum, that is, the years of Nabonassar 748: they fall on the Nabonassar 748. Whence follows: the year of Nabonassar 986 begins before the seventh Kal. Jul., that is, before the 24th day of June — nay, before the Meridian of the 24th of June. For the Egyptians never began at midnight, nor on the sixth day, nor on the seventh Kal. Jul., but before the seventh Kal. Jul., as testified by the same Censorinus, ch. 10. But before the preceding Meridian, therefore neither at the sixth, nor at the seventh Kal. Jul., did he say. Hence then it is manifest that, by the Chronological Canon, in retroceding [counting back] in the Julian year, the beginning of the Nabonassar period follows in the Meridian of the 25th of February. The year, indeed, of Nabonassar 747, now again in the Meridian of the 26th(?), is what the most learned astronomers have hitherto commonly thought, especially the astronomers and chronologers, particularly Nicolaus Mulerius [Nicolaus Mulier] in the Frisian Tables, Joseph Scaliger in his book *On the Emendation of the Times*,

Dionysius Petavius [Denis Pétau] in *De Doctrina Temporum* III, ch. 9, Jacobus Christmannus in his *Calendars*, Henricus Philippus [Henry Philip] in his *Chronology*, Keplerus [Kepler], and Bullialdus [Ismaël Boulliau] in the Tables — the former [Kepler] in the Rudolphine, the latter [Boulliau] in the Philolaic. The cause was, indeed, why no one noticed that very formula: "*Ante diem VII. Kal. Jul.*," but used the perinde [equivalent] formula: as if "*die VII. Kal. Jul.*," which divides, again recedes; whence the beginning of Nabonassar falls in the Meridian of the 26th of February. Nor is there anything else but that even our exemplar of Censorinus has led us astray: that is, "*ante diem VII. Kal. Jul.*" of the Emendation of the Times, p. 201, says: "*Censorinus wrote his little golden book on his birthday in the year of Christ of Dionysius 238, Cyclo Solis XXIII, Luna XI,*" which I recognize to be from the Year of the Sun [Annus Solis] 1014, who arrives at days of fixed reckoning: this is what that most learned man of the times writes, both extreme and the avenger of antiquity. To this he writes "*ex Anno Thoth Nabonassari,*" the very 90th day [nonagesimum], the sixth most extreme [extremum] falls before the VII. Kal. Jul. — this falls on the 7th Kal. But this is before the 7th Kal., and this in the year XXV. Jul. But if before the 7th Kal. Jul. this is also in the Meridian of the 25th of June, likewise then it falls before the principle of the Meridian Month of Thoth in the Meridian of the 25th of June. Likewise our Petavius, although ocularly [by sight], yet dormant [dormitando], seems to have seen it. For in book 9 of *De Doctrina Temporum*, ch. 42, after the exordium of that "*Censorinus, an author of all by the most approved judgment, &c.*" — he relates among other things that from the beginning of the year of Nabonassar 980, the sixth of the eighty(?) years [octogesimi sexti], these words of Censorinus: "*Quique hoc Anno ante diem septimum Kalendas Julias.*" And shortly after he interprets it: "*New moon [Neomenia] of Thoth in that year on the VII. Kal. Jul. fell.*" But it is fitting to say: "*on the day VII. Kal. Jul.*," that is, in the Meridian of the eighth(?) day Kal. Jul. Likewise Christmannus, in his book *De Coniunctione Annorum*, p. 416: after the lavish praises of Censorinus, he affirms the year Julian 283, the Thoth Nabonassar 986, which falls on the seventh day Kal. Jul.; this is in the 25th of June; and shortly after he refers to Censorinus: "*Quique hoc Anno fuit ante diem septimum Kal. Jul.*," but not cohering with these very things, and the days before the seventh — whence the Thoth of Nabonassar 986 begins before the Meridian of the 2nd day of June, as we contend that the authors ought to emend in the writing of Censorinus, this is before the day VII. Kal. Jul., as is clear from the years of the Augustans of the year CCLXIX. In this manner, before the year of writing CCLXVII, it is clear from a biennial [two-year] addition that the opinion of Censorinus is set out in the years of Augustus, the Roman CCLXV, in order that the years of the Augustans be reckoned Egyptian.

[Margin: Scaligeri lapsus Chronol. — Scaliger's chronological slip.] [Margin: Et Petavij — And [the slip] of Petavius.] [Margin: Et Krismanni — And [the slip] of Christmann.]

15. But it is evident from Censorinus himself that one must read, in the prior place, "*ante diem VI. Kal. Jul.*"; for this day confirms —

— it [the reading] from the other more notable day, immediately subjoining: "*Cum ab hinc Annos centum Pio, & Bruttio, Praesente cos.*" The same days were before the XII. Kal. Aug., as our codex of Scaliger, Christmann, & Petavius has. But of the Julian years, the beginning of the Egyptian year anticipates the days that are the beginning of the year, that is, on the first day of Thoth was consuls Pius and Bruttius in the Meridian preceding the twelfth Kal. of August, that is, in the Meridian of the 20th of July. Sacred to St. Margaret, on which after a hundred years it falls in the Meridian of the 25th of June, this is on that Meridian which was before the VI. Kal. Jul. I know Scaliger, & Manutius acknowledge an error, but it is rather to be placed back in this second place of Censorinus, and replaced "*before the XII. Kal. Aug.*" by this conjecture "*before the XIII. Kal. Aug.*" But in doubt of the correction of either of these places, one must rather stand by the opinion of the number of days, who erred from the opinion either of the year 26 of February at the start, and following that opinion, the eclipses of the Sun or of the Astronomical Tables can be collected: namely, on the days following, which Ptolemy designates, that is, the days marked in the preceding catalogue of eclipses, in which the year of Nabonassar 986 is supposed, falling at the 6th(?) day before the antecedent Meridian of the 25th of June. We conclude, then, that the opinion of Censorinus not only does no harm, but rather favors us. Let this assertion stand from the day of June 25, retaining the reading there "*ante diem septimum Kal. Jul.*"

16. The greater, indeed almost the only, difficulty rests in the place of the Sun, which Ptolemy assigns in his eclipses, and at the same time observed in book 4, ch. 6. For eclipse 17, set down at Pauni 20, which followed [eclipse?] on the 20th, in the Meridian of the day 20, with the Sun standing in Taurus degree 11. 14' approximately, & eclipse 18 in Libra degree 14. 6½'. & eclipse 19 with the Sun constituted in Pisces Gr. 14. 12'. Nor is it otherwise held in the Greek text, or in our codex of the MS. Moreover, by the equinox, that same Ptolemy in the same year of Hadrian 17, who observed eclipse 17, by two hours (that is, the seventh) of the time follows by whatever Astronomical Tables, received except the Lansbergian, namely Ptolemy, & the Sun was in Taurus 11. 15' after the Meridian of the day 20. Pauni would

have been in Taurus Gr. 13. & a little less [minus], but not by more than 14': nor by more than 34'. But from our Solar Tables it follows that Pauni was in Taurus Gr. 13. & by a minute approximately 16': it follows, I say, that, by the supposition that Pauni had begun at the Meridian of the day 20, it was at Taurus Gr. 13. but this from the supposition follows also per the same Astronomical Tables, the Moon at the moment of opposition adheres at a place of opposition in Taurus Gr. 11. & more, that is, at minimum Gr. 11. 30'. or you see that this is the preceding catalogue. Because if, when the Moon is held in a place of opposition, as requires the Plenilunium [Full Moon] preceding the eclipse, it must proceed from the day of May 6, at the hour 11. 15'. after its Meridian; it follows by the same Tables (taking away the Lansbergian) a place of the Sun in Taurus by one degree approximately further than Ptolemy noted it to have been in Taurus Gr. 14. & by minutes not fewer than 14'. As to what we said of eclipse 17, it holds in all the ancient eclipses of the twenty examined, and the later one, per the catalogue, examined according to the most celebrated Astronomical Tables.

17. The other [difficulty] is of two things to be said, that either Ptolemy, nor other Astronomers, in their Tables erred as to the place of the Sun: yet still in the Tables of the Moon erred by about 12 degrees. If we wish to retain the earlier day in the said catalogue noted, according to the form of the Julian year, we wish to retain it. But on the contrary, if we wish to retain it with the common Astronomical reckoning of the later day, & the Astronomical Tables could not commit so enormous an error of 12 degrees, it must be said that either Ptolemy, or the Astronomical Tables, erred by one degree as to the place of the Moon. But if the now-celebrated Tychonic Astronomical Tables had erred by one degree, & in eclipse 17 retained on the 6th of May, at the hour 11. 15'. after the Meridian, the Sun would be found in Taurus Gr. 13. 14'. it would be fitting that the Mean motion of the Sun, which commonly does not exceed signs 11. Gr. 29. 45'. 40". would come out of signs 11. Gr. 29. 45'. 42". 20"(?).

[Margin: Mendum in Censorino emendandum — An error in Censorinus to be emended.] [Margin: Prolemæi error in Æquinoctijs — Ptolemy's error in the equinoxes.] [Margin: Prolemæi error in Æquinoctijs — Ptolemy's error in the equinoxes.]

Whence it would follow that the Equinoctial Year would be of days 365. hr. 5. 48'. 3". & 42"". — which is absurd indeed, & noted by experts in Astronomy; or admit

the inequality of the Years, formerly never excluded; *Almagest* III not having noticed.

18. Nor again can it be said that the Astronomical Tables erred by 1. vel 12. in the motion of the Moon at the time of Ptolemy, or represent the antecedent eclipses in the predicted catalogue, & for example, by grace, in eclipse 17. it ought to have been at the hour 11. 15'. after the Meridian of the day 5. May, to exhibit the Sun in Taurus Gr. 13. 14'. or to exhibit the Moon in Scorpio Gr. 13. 14'. approximately, than to represent it in the Gradus of Scorpio 13. 14'. approximately. For we have other eclipses, set down in the Roman manner on more certain days, at the time around Ptolemy & Christ, which the same Tables rightly represent without any error in whole degrees. By the example, by the grace of Dio Cassius, who affirms it to have happened on the birthday of the Emperor Claudius the year of the City 798. M-Vinicio II. & M-Statilio Corvino consuls. that is, the year of the Epoch of Christ 45. on the Kalends of August (as Suetonius has it concerning the Birthday of Claudius) by the Astronomical Tables, & in the species of the Rudolphine antecedent eclipses, the True New Moon [Nouilunium verum] first of August at hours 9. & minutes 55'. after the mid-Meridian, the new moon began at point 596 to ascend toward the Roman Kalends. And so with the others. Hence then we recognize that it cannot be that those Tables labor under an error of 12 degrees in the motion of the Moon at that age [Æuo]. Provided then that it must be admitted that eclipse 17. through the said Tables it is necessary be in the Meridian at the hour 11. 15'. Alexandria, the Moon was in Scorpio Gr. 14. 30'. approximately. & the Sun in Taurus Gr. 14. 30'. approximately, it is necessary too, & it ought to be that Ptolemy rather erred in the place of the Sun by one degree, than Ptolemy himself: reckoning, that is, the Equinox of that year by one degree more swiftly than he made it, than the truer Tables exhibit it [aliquot] hours before the Meridian of the day 24. September, that is, the Chronological Canon the day Athir 6. & we said *Almagest* III. ch. 8. ch. 15.

19. Nor again would it seem that, the injury [iniuria?] done to deciding [decidendo], Ptolemy erred by an integer day in the Equinox. To this it suffices the Armillary Equinoctial, as book 3. ch. 2. shows: that from such an Observation he declined from the true Equator plainly versus Australem [southward] by 24'. approximately at minutes. And he himself there attests both Armillaries to have remained longer at their own [latitude] for a long time at the equinoctial time, & in emending the very vice of the Eclipse it can easily be deceived by it, & through the obliquity of

the Eclipse, that is, as I said in ch. 6. then with the false opinion of the quantity of the year of the equinox, then with the false Hypothesis of the immobility of the Apogee of the Sun. He could also assign the Armillary that was not so exactly placed, to have erred for these reasons in the altitude of the Equator.

CONCLUSIO I. — First Conclusion

Saving the Luni-Solar Astronomical Tables, & the days of the Egyptians, from Ptolemy in the Observations of Lunar eclipses, it must be asserted that the year of Nabonassar 886. falls on the 10th of July in the antecedent Meridian preceding the 12th. Kalends of August, & has the codex of Censorinus, ch. 8. The year of Nabonassar 748. falls in the Meridian of the day 25. June, that is, the Meridian preceding, not the VII. Kal. Jul., but has before the VII. Kal. Jul.; & so the exemplar of Censorinus, but the VI. Kal. Jul. and so, indeed, the principle of Nabonassar placed in the Meridian of the day 26. February of the year before Christ 747. finally the eclipses 19. in the preceding catalogue & set down per Ptolemy related, to be applied at the hours after the Meridian of the Julian Month following, not at the prior, as in the same catalogue of the Julian designated.

CONCLUSIO II. — Second Conclusion

The Lansbergian Tables, which at the time of Ptolemy exhibit the Sun in another Ecliptic place, in which Ptolemy himself constituted it at the moment of the Eclipse, this from other Tables of Eclipses is so much less accurately to represent them, that they discrepate; suspect they are of fallacy: especially among those who do not admit the inequality of the Years.

CAPUT VI.

On the Agreement, or Disagreement, of the Astronomical Tables with the Observations of Eclipses from the time of Albategnius [al-Battānī] up to the Year of Christ 1660.

The warnings of the preceding chapter, from num. 1 to 6, premised, also pertain to the present chapter; but especially num. 4, that the reader may know which ones, out of the many observations of those same eclipses, we have chosen for the test of the fidelity of the Tables.

Table. Comparative table of eclipse observations (Ordo of eclipses from Caput 2) against five astronomical table-sets (Observed, Alphonsine, Lansbergian,

Parisian/Frisian, Philolaic, Rudolphine, Tychonic — varying per row), giving Apparent Time after Meridian at the place of observation; the Sun's True place from the Tables; the Moon's place computed from the Tables; the difference of computed-vs-observed place; the time of that difference; and the magnitude in digits and minutes. Zodiac signs are given by glyph.

This opening continues the large comparison table of Chapter VI — the agreement or disagreement of the several astronomical table-sets with the recorded lunar-eclipse observations from al-Battānī's time down to AD 1660. Each numbered eclipse (Ordo Eclipsium, keyed to Chapter II) is given first as observed

(*Observ.*), then as computed from each table-set: Atlantic/Atlas (*Atl.*), Danish (*Dan.*), Lansbergian (*Lansb./Lansf.*), Parisian (*Parif.*), Philolaic (*Phil.*), Prutenic (*Prut.*), Rudolphine (*Rud./Rudol.*), Tyconic (*Tych.*); not every table-set appears for every eclipse. The marker **e** in the difference column denotes an *excess* (the tables run ahead of observation), **d** a *defect* (the tables fall short).

The columns are:

- **Ordo Eclipsium (cap. 2)** — the eclipse number, referred to Chapter II.
- **Observ. & Tab. Astron.** — the observation, then the astronomical table-set computed.
- **Tempus Apparens post Merid. in loco Observationis** — apparent time after noon at the place of observation (Month / Day / Hour / minutes; on the second and third folios the minutes sub-head is printed *M.* rather than the prime mark ').
- **Solis locus Verus ex Tab. & inde locus** ☉ ☉ — the Sun's true place from the tables, and thence the place of the Sun in opposition (Sign / Degrees / minutes / seconds).
- **Lunae locus ex Tabul. computatus** — the Moon's place computed from the tables (Sign / Degrees / minutes / seconds).
- **Differ. loci** ☉ ☉ **computata, & observata** — the difference between the computed and the observed place (Degrees / minutes / seconds), tagged **e** (excess) or **d** (defect).
- **Tempus huius Differentiae** — the time corresponding to this difference (Hours / minutes / seconds).
- **Quantit. in Digit. & min.** — the magnitude in digits and minutes; "Total." marks a total eclipse.

Eclipse-comparison table (folio 119, Ordo 36–45). Zodiac signs are given by their printed symbols, transliterated in brackets where printed.

Eclipse-comparison table (folio 120, Ordo 46–55). On this folio and the next the minutes sub-head of the time column is printed *M*. The note *ft. vet.* ("stylo veteri," Old Style) is printed beneath the *Observ.* row from Ordo 47 onward, marking the date as Julian.

[This opening continues the comparison table of lunar eclipses begun earlier in Caput VI: each numbered eclipse (Ordo Eclipsis, per Caput II) is set against the several sets of astronomical tables. The Ordo numbering is deliberately non-contiguous — Riccioli selects particular eclipses. The catchword "67" at the head carries over from the preceding folio; the table runs continuously across all three folios here (Ordo 67 through 104).]

Comparison table of lunar eclipses against the tables (continued, Caput VI)

Column structure (verbatim headings):

- **Ordo Eclips. cap. 2.** — order-number of the eclipse, per Caput 2.
- **Obferu. & Tab. Aftron.** — the Observer, and the Astronomical Tables.
- **Tempus Apparens poft Merid. in loco Obferuationis** — apparent time after the meridian at the place of observation: *Menf.* (month), *D.* (day), *H.* (hour), *M.* (minute).
- **Solis locus Verus ex Tab. & inde locus ☉ ☉** — the Sun's true place from the tables, and from it the place of opposition: *Sig.* (sign), *Gr.* (degree), *'*, *"*.
- **Lunæ locus ex Tabul. computatus** — the Moon's place computed from the tables: *Sig.*, *Gr.*, *'*, *"*.
- **Differ. loci ☾ coputata & obferuata** — difference of the Moon's place, computed against observed: a *d* or *e* marker (whether the computed place is in advance of or behind the observed), then *Gr.*, *'*, *"*.

- **Tempus huius Differentiæ** — the time corresponding to this difference: *H.* (hour), ', ''.
- **Quãtit. in Digit. & min.** — magnitude in digits and minutes: *Dig.*, '.

Throughout, the Observer's line ("Obferu.") gives the observed datum against which the tabular computations (Atl., Lansb., Phil., Prut., Rud., Tych., Dan., Lanf.) are compared. Where a computation matches the observation, the cell reads **exactè** ("exactly"). A blank numeral cell is left blank as printed.

Caput VI [continued] — Comparison table of lunar eclipses against the tables

The comparison table begun earlier continues. Its columns are: the eclipse number [Ordo Eclips. cap. 2]; the observer and the set of astronomical tables [Obseru. & Tab. Astron.]; the apparent time after noon at the place of observation [Tempus Apparens post Merid. in loco Observationis] (Month, Day, Hour, Minute); the Sun's true place from the tables, and from it the place of the full Moon in opposition [Solis locus Verus ex Tab. & inde locus ☾^o] (Sign, Degree, ', '); the Moon's place as computed from the tables [Lunæ locus ex Tabul. computatus] (Sign, Degree, ', '); the difference between the computed and the observed place of the Moon [Differ. loci ☾ coputata & observata] (whether deficient *d* or in excess *e*; Degree, ', '); the time corresponding to that difference [Tempus huius Differentiæ] (Hour, ', '); and the magnitude in digits and minutes [Quãtit. in Digit. & min.] (Digit, ').

CAPVT VII.

On the Excellence of the Astronomical Tables, and on the comparison among them, drawn from the Observations of Lunar Eclipses. In which certain notable Conclusions are established.

[Margin: Corollarium. (Corollary.)]

Conclusion I. No astronomical tables of all those so far named agree with the observations of all the lunar eclipses, and many of them agree with even fewer of the more ancient ones. This is plain from a survey of the catalogue in Chapters V and VI. For at Chapter V, from number 16 onward, I showed that the astronomical tables of Ptolemy fail, in representing eclipses of the Moon, to fall as near as they ought to the place of the Moon (within about 12 minutes per degree), from the age of Ptolemy back to the year 747 before Christ. From this we may draw, in the manner of a corollary, that the aforesaid tables cannot safely be used

for the place of the Moon over more than about 14 centuries — roughly the span that elapsed between Ptolemy and the more recent compilers of tables.

Conclusion II. There are no tables among those already named for which some lunar-eclipse observations do not vouch; nor any against which some others do not testify. This too is plain from a survey of the catalogue of Chapter VI, and from the way the eclipses have just been re-counted; and the suffrages of the individual tables, to be set out for the Conclusion that follows, will make it clear.

Conclusion III. Standing on a bare comparison of the eclipse observations as they lie, in respect of time and quantity, with the eclipses computed from the tables, the Lansbergian and Rudolphine tables would seem to be preferred above all the rest; then the Tychonic; after these the Atlantic and the Philolaic; in the antepenultimate place the Danish and the Prutenic; in the penultimate the Parisian; and last the Alphonsine. For, by the catalogue set out above, the eclipses vouch — 19 for the Rudolphine and 13 for the Tychonic — and so for the rest, as arranged below in the appended table.

[The table that follows tallies, for each set of tables, the numbers of the eclipses (from Chapters V and VI) that "vote for" it, and the total count.]

Suffragantur (Voting for)	Eclipses from Chap. V & VI	Sum ma
Alphonsinis (Alphonsine)	27.	1
Parisinis (Parisian)	20. 23. 48.	3
Danicis (Danish)	13. 40. 42. 50. 77. 103.	6
Prutenicis (Prutenic)	68. 72. 83. 85. 102. 103.	6
Philolaicis (Philolaic)	10. 15. 19. 29. 46. 76. 81. 86. 95. 110. 117. 118.	12
Atlanticis (Atlantic)	49. 60. 63. 67. 69. 70. 74. 75. 87. 93. 96. 97. 100. 104.	15
Rudolphinis (Rudolphine)	1. 2. 4. 5. 16. 8. 9. 11. 17. 18. 26. 32. 243. [?] 53. 66. 81. 82. 192. [?] 119.	19
Tychonicis (Tychonic)	35. 41. 44. 45. 57. 71. 80. 88. 89. 98. 99. 106. 108.	13
Lansbergianis (Lansbergian)	3. 14. 16. 22. 23. 24. 33. 36. 37. 38. 47. 50. 54. 55. 56. 58. 59. 105. 107.	19

Conclusion IV. Yet one cannot, from a bare comparison of the said observations against the tabular computation, form a sure judgment that the excellence of the tables is to be carried in favor of any one set above the rest. For neither does the agreement of the tables with the observations afford a sure sign of their agreement with the heavens and with truth — just as their disagreement with the observations does not afford a sure argument of their disagreement with the heavens and with truth. Indeed it could happen that the agreement of the tables with not a few observations of the phenomena should arise either from a false meridian-distance assumed in transferring the time of the meridians of the observations to the meridian of the tables (a falsehood, that is, either because the observation itself was at fault, or because the very tables falsely usurp the meridian as one, or for more than ten causes enumerated at Chapter IV); or at least because the false numbers were marked down in a chosen way; and so it came about for us that what disagreed with the heavens nonetheless really sounded in concord, either out of several observations of the same eclipse — that which less truly agreed with the heavens [— and the reverse]. Hence it may still be doubted whether the discord of the tables with the observations arises from an intrinsic fault of the astronomical tables — namely, from a false mean motion of the luminaries and of the anomalies, or from the eccentricity and the prosthaphaeresis founded on it, or from the form of the geometric, circular, or elliptic hypotheses — or whether the equation taken up in it is from the construction of the equation. Or whether, from an extrinsic fault of the geography, the distance in meridians used was usurped; and whether, again, from an extrinsic fault of the observation.

But it is worth the trouble, in my judgment, to discuss the three aforesaid sources of disagreement between the tables and the eclipse observations, each in turn, briefly, and to apply them to certain tables, taking the start from the **Distance of the meridians**.

The distance of the meridians, or difference of longitude, which I have used in the Tychonic, Rudolphine, and Philolaic calculation — that very one I reckoned at Chapter I, and took from my own *Geographia Reformata* — rests upon eclipses that are certain, and upon intervals of itinerary, and therefore can scarcely be suspected of any minimal fallacy. Yet because Lansbergen and Wendelen used in their own computations a meridian-distance by no means certain, and in some places plainly perceptibly false, I think the eclipse-observations of these authors must be re-computed; a greater disagreement will sometimes come out, a lesser at other times, than was met with before. Take as an example one from Lansbergen, who supposes Goes to be more easterly than al-Raqqa by 3 hours;

from there comes Eclipse 21 in our Ordo, which Lansbergen in his *Thesaurus* computes from his own tables at 14, finding Goes at the hour 4. 27. apparently, the Sun being in the Lion at Degree 3. 53. 43." and the Moon in Aquarius at Degree 3. 53. 43."; therefore he reckoned the opposition of the luminaries to have been most exact, with nothing remaining; thus his tables differ from the observation. But al-Raqqa is more easterly than I had it, and more easterly than Bologna than Goes by 3 hours; therefore than Goes by only 2. 43.; so that by a full 44 minutes of hour al-Raqqa and Goes are closer than Lansbergen assumes. Wherefore, if from our meridian-distance and the Lansbergian one we repeat the reckoning, we shall find the Sun in the Lion at Degree 3. 15. 31." and the Moon in Aquarius at Degree 4. 17. 52." — which is to say already transgressed past the moment of opposition by minutes of zodiac 24. 9." And therefore the Lansbergian tables exhibit this eclipse earlier by 44 minutes of time than al-Raqqa's observation (al-Battānī's).

Likewise **Wendelen** supposes Hercaam [Herwaarden/Herck] his native place to be more westerly than Hven and Uraniborg by 25 minutes of time; whereas to me it is more westerly than Uraniborg by 31. Wherefore, if I repeat his calculations in the Vraniburg-observed eclipses, I shall find the difference six minutes greater in time. And if anyone there be who would not disdain to recognize how much the more celebrated tables disagree from the observations in time, the meridian-distance being supposed from our *Geographia Reformata*, I for my part would not begrudge to undergo this further labor in the 19 ancient eclipses, in which it appears the day itself contains an error (as I taught at Chapter V). I shall examine the rest by the same method, that it may stand clear by computation which tables more nearly represent the time of the observation. Therefore contemplate the following little table.

In the following little table, in which the columns headed **At.** [Atlantic], **D.** [Danish], **L.** [Lansbergian], **Ph.** [Philolaic], **R.** [Rudolphine], **T.** [Tychonic] indicate the tables — and on the left is the eclipse number [Ordo], while on the right are the Minutes, and the seconds of Time, by which the said tables differ from the time of the observation chosen according to the earlier table, but on the supposed meridian-distance from our *Geographia Reformata*.

The table is arranged in four paired sub-columns running down the page. Each block gives the eclipse number [Ordo], the table-set abbreviation [Tabula], and the difference in minutes [I] and seconds [II] of time. The abbreviations: **A./At.** = Atlantic; **D.** = Danish; **L.** = Lansbergian; **Ph.** = Philolaic; **R.** = Rudolphine; **T.** = Tychonic.

(Caput VII continued — time-difference comparison table, concluded)

The following table (continued from the preceding pages) lists, for each eclipse in order [Ordo], the table-set [Tabula] and the amount by which its computed time differs from the observation, in two columns of figures (I and II). The abbreviations are: **Ph.** = Philolaic, **R.** = Rudolphine, **T.** = Tyconic, **A.** / **At.** = Atlantic, **D.** = Danish, **L.** = Lansbergian.

[¶5] It is therefore evident from this second comparison that the Tychonic tables are to be preferred; then the Philolaic; after these the Atlantic; next the Rudolphine, which the Danish follow; and finally the Lansbergian, which had

held first place in the first comparison but here, in this second one, comes out lowest. For the table-sets named above are supported by the eclipses listed below.

Tabulis [Table-set]	Eclipsium Ordo [Eclipses, by number]	Summa [Total]
Lansbergen. [Lansbergian]	24. 33. 63. 105.	4
Danicis [Danish]	40. 42. 45. 48. 53. 60. 72. 77. 106.	9
Rudolphinis [Rudolphine]	22. 23. 26. 32. 38. 43. 66. 81. 82. 92. 119.	11
Atlanticis [Atlantic]	67. 69. 70. 74. 75. 84. 87. 93. 96. 97. 100. 104.	12
Philolaicis [Philolaic]	29. 36. 46. 47. 55. 68. 71. 80. 83. 85. 86. 95. 98. 99. 110. 118.	16
Tychonicis [Tychnonic]	35. 37. 44. 49. 50. 54. 56. 57. 59. 60. 76. 88. 89. 102. 103. 107. 108. 117.	18

[¶6] Another source and cause of the discrepancy may be, as we said, the unreliability of the observations themselves, for the reasons laid out in chapter 4. For sometimes the discrepancy is so enormous that its whole cause cannot be assigned to a false difference of meridians. Let eclipse 32, observed at Nuremberg, serve as an example.

(In the right column of folio 128:)

This eclipse was observed at Nuremberg by Bernhard Walther [Bernhard Walther] in the year 1487, on 7 February, at 15 hours 47 minutes by the clock — that is, after midday, 3 hours 47 minutes — according to the Rudolphine and Philolaic tables at 15 hours 51 minutes; but apparently equated to 16 hours 3 minutes. At that moment the Philolaic tables show the Moon farther advanced than the place of opposition by 19 minutes 53 seconds; the Rudolphine, however, by 13 minutes 4 seconds. The opposition of the Moon with the Sun would therefore have been sooner — by 39 minutes 45 seconds of time on the Philolaic reckoning, or 26 minutes 10 seconds on the Rudolphine. So on the Rudolphine the opposition was sooner, I say, than Walther recorded. This great a discrepancy cannot be ascribed to any skilled astronomer, nor to geography; it is all to be referred to the distance of the meridians, which in the Rudolphine and Philolaic tables is 4 minutes of time — and that is the very least of all the values assumed

by others. For Origanus [Origanus] supposes Nuremberg farther west than Uraniborg by 5 minutes; the Danish and Parisian tables by 6 minutes; we [the *Almagestum Novum*] by 8 minutes; the Atlantic by 9 minutes; the Lansbergian by 12 minutes; and Tycho, *Progymnasmata* tome 1, page 51, by nearly a quarter of an hour, that is, 15 minutes.

Therefore, if the time is reduced from the meridian of Nuremberg to that of Uraniborg according to the opinion of others, the computed beginning will have fallen earlier, and so the Moon would still have been farther advanced, and the discrepancy of time greater. To me, indeed, it would have come out — on the Philolaic figures — at 43 minutes; on the Rudolphine, at 30 minutes only. So far is it possible, by choosing a different meridian-difference for these tables, to reconcile this observation with the tables named. Prudently, then, the greater part of the discrepancy is to be rejected onto the observation itself, which appears very doubtful from Walther's own account, which runs:

In the year 1487, on 8 February: I observed the eclipse of the Moon at about the second hour after midnight, in the morning, when the Moon began to be eclipsed, and when the Nadir of the Sun stood at an altitude of 29 degrees, the eclipse being at its mean phase; but at that time the clock indicated three hours, and 47 minutes. And at the end of the whole obscuration the Nadir of the Sun stood at an altitude of 24 degrees, the clock at 4 hours 18 minutes. The end of the eclipse was at 5 hours 20 minutes, after the mean of the eclipse. I examined the times by altitudes, and conversely. At the time of the eclipse's mean phase, the Moon was between the Heart of the Lion [Cor Leonis, Regulus] and the Nadir of the Sun by 60 degrees 35 minutes. Thus the latitude of the Moon was seen to be southern. Likewise the true place of the Sun's Nadir, at the time of the eclipse's mean phase, ought by calculation to have stood at sign 4, degree 28, 39 minutes 44 seconds; but the arc between the Heart of the Lion and the Nadir of the Sun was sign 5, 24 minutes; and within this the place of the heart [of the Lion] would have been at sign 4, degree 23, 15 minutes 44 seconds; but it is not so great.

So this excellent old man — who candidly admits he is not so sure of the said arc, and offers a handle for doubt — could afterward, on account of the shadowing, have been deceived at the beginning and at the end of the eclipse; and since he said it had begun at "about the second hour after midnight," he indicates that he was not certain it was the second; he prints the mean at 3 hours 40 minutes after midnight, not 3 hours 47 minutes, as recorded from the clock. And so, on all the computations, it will probably have been more likely that the mean of this eclipse was 20 minutes or more sooner than is gathered from Walther's stated beginning.

The remaining discrepancy is to be referred to the tables themselves. Meanwhile, this is the conclusion that follows.

V. Conclusion. The whole discrepancy between the astronomical tables and the observations of the eclipses set out above cannot always be ascribed to a false meridian-difference used in computing the eclipse, but is to be assigned in part to a fault either of the observation, or of the tables, or of both at once.

Eclipses not faithfully, or not concordantly, reported.

[¶7] This has already been proved by a single example in the preceding number, and most evidently in chapter 4, number 3; it could be shown by many others; but as for what concerns a fault of observation — whether carried out deceptively, or recorded deceptively by the writers — there is no lack of indications worth pointing out.

[Margin: *Regiomontani hallucinatio.* — "Regiomontanus's blunder."]

Eclipse 29. Lansbergius [Lansbergen], in his *Thesaurus of Lunar Observations*, Class 1, eclipse 17, following Regiomontanus [Regiomontanus], notes that it was made at Viterbo at 14 hours 48 minutes after midday. But we, from a more correct place of the fixed stars (as I related in chapter 2), find the hour to have been 14 hours 37 minutes; and so on this single head — of the Right Ascension and Declination of the Eagle [Aquila], which Regiomontanus used — the time of the observation labors under an error of eleven minutes.

Eclipse 35. Copernicus [Copernicus], book 4, chapter 13, says he observed it at Cracow after midday at the equinoctial hours 1 and three-fifths of one hour, that is, at 36 minutes; while Lansbergius, in the *Thesaurus of Observations*, Class 1, eclipse 19, from the same book of Copernicus and the same chapter, states Copernicus's observation at Cracow at 1 hour 45 minutes after midday — namely three-quarters of one hour. And lest you think this a typographical error, he adds further that the time of Goes [Goes] appears as 10 hours 23 minutes, which agrees with the difference of longitude that Lansbergius assigns between Goes and Cracow — namely 1 hour 22 minutes.

[Margin: *Lansbergij hallucinatio.* — "Lansbergius's blunder."]

Therefore, either by a slip of imagination, or by the moment of observation itself, he turned three-fifths of an hour into three-quarters, and exceeded it by 9 minutes in marking the moment of the observation.

Longomontanus [Longomontanus] likewise recorded many eclipses otherwise [than Tycho], as is clear from the Catalogue of chapter 2; and from chapter 3, take this synopsis:

Ordo Eclips. [Eclipse no.]	<i>Tycho</i> H.	I	<i>Longomontanus</i> H.	I
41	11	3	11	2
		2		5
44	13	1	13	2
		7		4
46	9	5	10	0
		8		
47	16	5	17	0
		7		
48	13	8	13	9
49	9	1	9	3
		6		0
50	14	4	15	2
		8		
53	6	5	7	0
		5		
55	19	2	19	1
		6		6
56	16	3	16	3
		6		0
57	9	2	9	2
		9		5
59	7	2	7	3
		6		7
60	17	5	13	5
		0		6

And yet Tycho himself is not always consistent in reporting the moments of eclipses, as in eclipse 48.

Eclipses determined by mere conjecture.

[¶8] Sometimes, too, the moment of the eclipse's full or mean phase is found to be recorded not from the actual observed phases, but from some single phase — say,

from the beginning or the end alone — and from this the mean is deduced by mere conjecture, or from some hypothesis that is not sufficiently certain. Thus Ptolemy [Ptolemy], for the beginning of the first eclipse handed down from the Chaldaeans, adds two hours, reckoning that the total eclipse lasted 4 hours. And to the beginning of the third eclipse, observed [by the Chaldaeans], he adds one and a half hours to obtain the mean, because he supposed by mere conjecture that the eclipse of 6 digits lasted a full 3 hours, very nearly. For the fourth eclipse, observed at Babylon, adding one hour to the beginning, he determined the mean, because he supposed an eclipse of three digits lasted 2 hours. Besides, for eclipse 8 he defined the mean-phase moment partly from the beginning, partly from conjecture, because he supposed a small eclipse lasted no more than 1 hour 30 minutes, very nearly; and therefore Petavius [Petavius], book 8 *On the Doctrine of Times*, judged this eclipse worthy of special examination. Again, for eclipse 10 he deduced the mean from mere observation of the recorded beginning, and from his own settled opinion that total eclipses last 4 hours, accordingly adding 2 hours to the beginning to set the mean. But Petavius, book 8 *On the Doctrine of Times*, page 812, denies that this eclipse, on his own tables, lasted beyond 5 hours 48 minutes, and so brands Ptolemy's note as a [Greek: ἐλάσσωμα (elassōma, "shortfall" — a deficiency)] designated by him. See the passages of Ptolemy noted by us in the earlier Catalogue, chapter 2.

Tycho too seems sometimes to have asserted the mean from sole conjecture, as in eclipse 42, whose end alone he was able to observe in Denmark, says Wendelen [Wendelen]; and concerning eclipses 47 and 57, where he speaks of the mean defined by Tycho from the beginning thus: *That mean of Tycho is now not founded on any observation, but on his own conjecture and computation, obtruded on us; for he could only have seen the beginning of it; the immersion, the emersion, the end, he could not, since all these things happened after the setting of the Moon;* and elsewhere he writes thus: *(this eclipse was at least so observed, that the Moon &c.)*

...had been halved before the shadow entered, before it set.) Nothing certain, therefore, follows from these Tychonic assertions. Thus far Wendelen, who also, concerning eclipse 57 — which is the same as eclipse 17 among the Tychonics — speaking of the mean of the eclipse defined by Tycho at 8 hours 36 minutes, and by Longomontanus at 8 hours 30 minutes, says that each of them determined the mean by mere conjecture, boldly, since they could see nothing beyond the beginning at Uraniborg, the Sun rising there at 6 hours 57 minutes; and he adds, from their own tables, that the mean was at 8 hours 44 minutes at Uraniborg. And concerning eclipse 69, produced by Lansbergius more from calculation than from observation — speaking of the end, he says that since the end could not be

seen by Lansbergius himself, the mean could not be made to stand from it together with the beginning. But Lansbergius perhaps noted the mean directly from the maximum of the eclipse of 8 digits.

The remaining indications of eclipses not accurately observed.

[¶9] Whenever observers admit that they used poor or unsuitable instruments — as we have more than once pointed out in the history of chapter 2 — or whenever an eclipse, as we have indicated, departs widely from the observation of others of no lesser reliability or diligence among the authors, we have an indication of an improbable fault in the observations. Thus in eclipse 43 the mean asserted by Tycho insinuates the fallaciousness of the Tychonic eclipse, number 4, by the observations of Toledo and Madrid carried out with the greatest diligence and at the command of the King of Spain; and in eclipse 56, which is the same as the Hercian observation, number 16, he refutes it by a discrepancy of 23 minutes. A great discrepancy of observation also appears in eclipse 80, of which Wendelen [speaks] on page 83 of his *Eclipses*; and in eclipse 98, of which on the same page 101; and in eclipse 106, of which I have spoken in chapter 4, where at the end he gives the reason for which we have preferred our observation to Wendelen's.

Eclipses whose discrepancy between observations and tables must in part be ascribed to a fault of the tables.

[¶10] There are four indications of some hidden fault latent in the astronomical tables, when they differ widely from the observation. The first is when the eclipse was very long, and therefore the durations were very brief — as were eclipses 8 and 82, and 89: in these the mean indeed could not be erroneous, but the duration could, in a few minutes. So when the Prutenic tables differ from the observation of eclipse 89 by 48 minutes, it is evident that they are in error here.

The second indication is the enormous discrepancy of the tables from the observation of a single observer, even within the same number [of eclipses]; if the mean or the immediate or partial phases of the eclipse were deduced from the observed beginning or end, then there is no longer any reason beyond a half-hour in the middle to fear — as in eclipses 9, 11, 13, and 14, which Ptolemy [reports] not from conjecture but at first as if from another supreme Tychonic [authority]... [the sense here is compressed; the printed text reads:] which Ptolemy [reports] not from conjecture but at first, as if from another supreme height, and at the same time from the beginning, with this remark added — provided they are similar — that such Tables are absent from the observation beyond a half-hour in the middle: nothing, I say, will doubtfully be questioned if

they are vitiated, the distance of the meridians nonetheless set aside; if they are not convoked in part into the discrepancy.

The third indication is the closer consensus of several observations of the same eclipse, recalled to the same meridian — of which kind are, first of all, eclipses 48, which the Wendelinian tables resist, and therefore reject; the consensus of the other observers favors the Tychonic rather; and eclipses 63, 71, 86, 88, 89, 92, 93, 95, 96, 102, 103, 104.

The fourth indication is, unless one has recourse to a distance of the meridians, a manifest fault in the tables, if through them the eclipse could in no way have been observed at that horizon where nonetheless reliable observers assert it was observed. Such is eclipse 8, which Petavius, examining in book 8 *On the Doctrine of Times*, page 799, showed could by no means have been seen to begin at Babylon, if calculation be made from the Alphonsine, Ptolemaic, Prutenic, and Danish tables.

VI. Conclusion. From the established goodness of the astronomical tables within certain limits — if several observations of some eclipse differ too widely from the tables — it can probably be judged that there is some fault of observation. For when several observations made by many observers agree within a narrow consensus, and the tables agree with them within a few scruples, and yet those same tables are not the best for every century, but at least contain the lesser error possible for one century — then, these things being established, if some observations of an eclipse differ from such tables beyond those limits, it is probable that this excess arises from some fault of the observations, or from a less accurate one.

[¶11] Now, having reviewed the earlier catalogue of chapter 6, and starting from the eclipses of our own century — that is, from eclipse 63, which was observed in the year 1601 — it will be evident that the discrepancy of the tables and observations stands within 5 minutes of time, or at least within 10, in the number of eclipses listed below. And so in 31 eclipses the Tychonic tables agree with the observation within 10 minutes.

Eclipsium Numerus pro
Tabularum, &
Observationum
consensu [Number of
eclipses for the
agreement of tables and
observations]

Tab. [Table-set]	Intra 10'. temp. [Within 10' of time]	Intra 5'. temp. [Within 5' of time]
Atlanticæ [Atlantic]	12	11
Danicæ [Danish]	8	6
Lansbergen. [Lansbergian]	12	6
Philol. [Philolaic]	28	10
Rudolph. [Rudolphine]	29	17
Tychonica [Tyronic]	31	17

[¶12] But if the catalogue of this chapter 7 is reviewed — after the number 4 set down above, in which, on the basis of our *Geographia Reformata*, the meridian-distances have been corrected — we may set down the difference of the tables from the observations in time, which comes out somewhat different for the consensus of tables and observations, namely within 10', or 5', of time, as in the following little table:

Tab. [Table-set]	Intra 10'. [Within 10']	Intra 5'. [Within 5']
Atlantica [Atlantic]	13	12
Danica [Danish]	7	5
Lansbergen. [Lansbergian]	6	1
Philol. [Philolaic]	27	10
Rudolph. [Rudolphine]	27	14
Tychon. [Tyronic]	28	15

[¶13] From this new comparison it appears that Wendelen, in the design of his Atlantic tables, had some foundation for approving the observations of the eclipses when they agreed more closely with his own tables — which he did chiefly in the eclipses, as far as concerns our order: 44, 46, 49, 53, 54, 55, 58, 59,

60, 72, 76. But he condemns [them] when they differ enormously from his own tables: as in eclipses 40, 41, 43, 44, 45, 47, 50, 57, 69, 75. Yet not so much in proportion as the followers of the Philolaic, Rudolphine, and Tyconic tables, who, in these eclipses, have many more eclipses within 10 minutes — indeed, the Tyconic within 5 minutes — favoring [them], than the Atlantic tables do. From this arises for us the following, and worth knowing:

[¶14] For with much greater confidence (I hope) it can be made out that those tables which, within a few minutes of time — say within 10, or at most 5 — agree with more observations, or which satisfy more observations by better ones, are to be preferred to tables which satisfy more observations indiscriminately, while many select observations resist them.

So one may, from the first comparison, and from what was said for Conclusion III, [conclude that] the Lansbergian tables obtained first place; the Rudolphine, 2; the Atlantic and the Tyconic, 3. But from the second comparison, as has been said, by number 5 the Tyconic [stand] first; the Philolaic and Atlantic, 3; the Rudolphine, 4. In this third comparison, however, and from the use of both tables — number 11 against number 12 — it is settled, from the consensus of the select eclipses, that the Tyconic tables [agree with] the observations of our century 31 or 28 times within 10 minutes, but 17 or 15 times within 5 minutes, and so excel the other tables; after these the Rudolphine and the Philolaic stand at about an equal number; and then the Atlantic.

VIII. Conclusion. On account of the discrepancy of the astronomical tables from the observations of the eclipses of our century, or of neighboring centuries, the astronomical equation of apparent time into mean is not to be abandoned, nor must any other form of this equation be introduced.

[¶15] For the astronomical equation, by which the time of civil or natural days — that is, apparent time — is converted into mean for the examination of observations, arises and is established among astronomers from a double, and certain, necessary cause. The first is that which arises from the obliquity of the ecliptic, and is the difference between the true place of the Sun in the ecliptic and the Right Ascension corresponding to it, converted into time. The second is the difference between the true and mean motion of the Sun, which on the circular hypothesis arises from eccentricity alone, but on the elliptical hypothesis arises partly from the apparent [motion], and from the optical acceleration of the Sun on account of the eccentricity of the center of the ellipse from the center of the Earth, partly from the real [motion], and from the physical acceleration of the Sun around the center of the ellipse, because the other focus, or umbilicus, of the

ellipse is the point about which the Sun moves with mean, or equal, motion. Since, then, from these causes this effect necessarily follows — and sometimes, though rarely, the apparent time is equalized with the mean, or equal; sometimes, and more often, it is greater or less than equal time — the said equation is necessary.

[¶16] Moreover, by using the astronomical equation of time, not fewer, but indeed more eclipse-observations are represented by the astronomical tables than if the said equation were passed over, or some other form, not demonstrated, were used — as is clear from the table, number 5, 11, and 12. For in the Philolaic, Rudolphine, and Tychonic computation we have used such an equation, reformed first by a table of the first cause of equations according to the truer obliquity of the ecliptic; but as for the second cause, we have followed Bullialdus [Bullialdus, Ismaël Boulliau], who of all has discussed this equation most excellently and scientifically, in book 2 of his *Astronomia Philolaica*, chapters 5, 6, and 7.

[Margin: *Bullialdi laus.* — "Praise of Bullialdus."]

[¶] First, then, we say that the opinion of those abolishing from the middle [reckoning] entirely the whole equation of natural days is false — of which kind were Krismannus [Crüger?/Krismann], Vitichius [Witich], and Wendelen — against whom see what we have said in book 3 of the *Almagestum Novum*, chapter 32; even though Wendelen introduced certain prosthaphaereses in the oscillatory Moon [Luna oscillatoria].

[Margin: *Error Krismanni, Vitichii, & Vuendelini.* — "The error of Krismannus, Vitichius, and Wendelen."]

[¶] Second, we do not approve the equation of Tycho and of Longomontanus with Bullialdus, as being diminished; for although the greater part of the astronomical equation arises from the first of the said causes — namely from the difference of the Right Ascen-

of ascension and the true places of the Sun in the ecliptic, and it retains only Tycho [Tycho Brahe] and Longomontanus, because it seemed to satisfy many eclipses; for that reason Kepler called it the *Empirical* form. But the other cause ought not to have been passed over, since it cannot be sufficiently demonstrated from eclipses, and since — as Longomontanus himself admits in his *Commentary on the true place of the Sun* — it is almost without reason, abandoned; therefore this omission has displeased astronomers, as Kepler reports in the foundation of his Ephemerides, number 30.

[Margin: The shortcomings of Tycho and Longomontanus.]

Third. As for the new form that Kepler calls *Physical*, we judge it least necessary; nor does Kepler himself introduce it in the Rudolphine Tables as though he reckoned it necessary, but he sets it out only as an experiment, so that astronomers may examine which of these three forms more fully satisfies the observations of the better-attested eclipses; and whether the *Astronomical* form is demonstrated truly from the two aforementioned causes, or the *Empirical* form of Tycho [is derived] from the prior cause alone, or the *Physical* form arises from the aforesaid causes — and over and above this, from the supernumerary times of the days, 5, and of the hours, 6, by which the Solar Year exceeds 360, that is, the number of degrees of the Equator. For this has no fictitious foundation other than a kind of ideal fantasy in Kepler's mind.

[Margin: A figment of Kepler's.]

Fourth. Together with Bullialdus [Ismaël Boulliau] (*Astronomia Philolaica* II, ch. 7), we reject the form of the equation of time devised by Io. Baptista Morinus [Jean-Baptiste Morin], founded on the difference of the mean place of the Sun alone, or rather on the difference of the right ascensions of the true and mean places of the Sun — although he had nonetheless admitted two causes of the equation of days, namely the obliquity of the ecliptic and the eccentricity of the Sun: against which Bullialdus says much in the same place.

Fifth, finally, we least of all approve the boldness of Lansbergen [Lansbergen], who, as often as he saw his Tables disagree notably with the eclipse observations, introduced an equation of time as large as was necessary to make the Tables agree with the observations — without any reasoning *a priori*, indeed without sufficient experiment *a posteriori*; for it is not enough that one eclipse, or a second, be found to fit such an equation, and (as he used to say) on another occasion...

Kepler, *with much affirmation, [calls it] a great foundation.* And yet Lansbergius, at precept 8, says: *We however observe that, when one or the other Luminary is failing at the beginning of Aries, scruples must be added to the mean time, [namely] half an hour, 30 scruples.* But in his *Thesaurus of Lunar Observations*, from which he draws the eclipses of the Moon, he adduces only a single eclipse of the Moon, namely number 23, which is the one we have, observed by Cornelius Gemma [Cornelius Gemma] at Louvain, whose beginning he observed at hour 15.40'. Yet Lansbergius's Tables exhibit that beginning at Louvain at hour 15.6'. Therefore he there subjoins, Lansbergius: *On account of the equation of time, scruples must be*

added to the apparent time in the Moon, [namely] half an hour, 30 scruples; therefore the Moon at Louvain began to be eclipsed at 15.36' from noon, just as Cornelius Gemma most nearly observed. But why did he not add 36'? — for the agreement would have been more exact; since this equation depended on his own mere choice. In truth, however, one ought to have acknowledged candidly and sincerely that the fault arose partly in the observation, partly in the Tables. Certainly the Rudolphine and Tychonic Tables, without Lansbergius's equation, represent the mean [time] of that eclipse to within 5 minutes of time, from which an argument can be drawn from the beginning.

Yet again Lansbergius, in Class 2, observed the solar eclipse of [no.] 18, celebrated in the 6th degree of Aries; he adds 30 scruples so that the observation may agree with his Tables; and nonetheless in the lunar eclipse of [no.] 37, which is our 69 — although the Moon was set in the 4th degree of Aries — he adds nothing, because his Table had no need of this aid.

IX. Conclusion. But neither does the change of eccentricity, on which the prosthaphaereses of the first lunar inequality depend, suffice to reconcile the Astronomical Tables with the eclipse observations.

For the difference between the Tables and the observations is often much greater than the difference between the lunar prosthaphaereses derived from differing eccentricity hypotheses. For indeed the maximum equation of the first inequality is, in any case whatever, ultimately greater or smaller by very few minutes — by 5 degrees.

CAPVT VIII.

In which the Foundations of the New Tables, and the selected Observations of Eclipses from Albategnius [al-Battānī] down to the Year of the Lord 1660, computed from the Author's New Tables, [are set out].

The mark d indicates a deficiency [defect], and e an excess of the computed place.

[The following is the first portion of a long eclipse table, continued on page 132. Columns: **Ordo Eclipsium** (order-number of the eclipse) | **Tempus Apparens Bononiae p. Merid.** — apparent time at the meridian of Bologna (Year of Christ, Month, Day, Hour, ', ") | **Tempus Aequatum** — equated time (Hour, ', ") | **Solis locus Verus** — true place of the Sun (Sign, Degree, ', ") | **Lunae locus computat.** — computed place of the Moon (Sign, Degree, ', ") | **Differentia comput.** —

computed difference, with d/e marker (', ') | **Tempus differ.** — difference of time (', '). Zodiac signs are given by their symbols, here named.]

Note on row 27 ("Omnes Tabulae similiter dissident" — "All the Tables disagree alike"): the source replaces the Differentia / Tempus differ. cells with this remark, printed across the right-hand columns. Transcribed verbatim.

1. In the preceding Catalogue, drawn from the History of chapter 2 and from the Epitome of chapter 3 — when the same eclipse was observed by several observers — I chose the time midway between the extremes, accommodated to

the meridian of Bologna in keeping with our *Geographia Reformata*; except for one eclipse, or another, the time of whose single observer I chose on account of its evident diligence, observed by us in one case and by Gassendi [Pierre Gassendi] in the other. The Apparent Time I converted into Equated [Time] by the astronomical cause, namely the eccentricity of the Sun and the obliquity of the ecliptic, [the obliquity being] 23° 30' 20".

[Margin: Explanation of the preceding Catalogue.]

2. The place of the Sun I computed from Our Tables (Book I) to the moment of the equated time of the eclipsed full moon. Now it is established, from what we have said in Book I, that the place of the Sun is more exactly represented by our Tables than by the Tychonic Tables, and by those resting upon the Rudolphine, or upon the Philolaic [Tables]: both because of the manifest error of Tycho in the parallax of the Sun, [which is] too great, and likewise of the obliquity of the ecliptic, [also too great]; and because of the far more certain and more refined observations of the Sun made with the great Gnomon which we have in the Temple of San Petronio at Bologna. Accordingly, if the Tychonic, Rudolphine, or Philolaic Tables represent some eclipses within the bounds of a shorter time, it is reasonable to suspect some fallacy on account of the place of the Sun being less accurately exhibited by them; and therefore the Moon is seen to be nearer the opposite place of the Sun when in reality it was farther off.

3. The mean motions and the Anomaly of the Moon I investigated rather *a posteriori* and empirically than *a priori*, and through geometrical demonstrations; and I chose those which, out of several and more certain eclipses, were derived, and which, with the calculation repeated in turn many times over, likewise satisfied several such observations. For this same cause I chose the Radices of the mean motion of the Moon and of the Anomaly written below, fixed to the meridian of Bologna and to the meridian of the last of December.

Epoch of the Year of Christ 1600, completed in the Gregorian style.

	Sig.	Gr.	'	"
Mean motion of the Moon from Aries (♈)	7	25	19	20
Motion of the simple Anomaly (☉)	0	7	27	9

For meanwhile the simple motion of the Moon is for me, [reckoned] from the equinox, an Annual [motion] of 129° 23' 2" and about 30''' — as I shall afterwards show from another source. The Annual motion of the Anomaly is likewise 88° 43'

7" 34" 21"" — very nearly what Bullialdus establishes, who (in Book III of his *Astronomia [Philolaica]*) was most diligent and most successful in this investigation of the Anomaly, and came nearest to the truth of the mean motion of the Moon in these our times.

4. The prosthaphaeresis of the first lunar inequality, which they much more often call *Epicyclic*, I have acknowledged to be far better — [the one] which is derived from the circular Hypothesis, and very nearly the Tychonic, than that [which is derived] from the Elliptical form of Kepler, or of Bullialdus; though this latter is not rarely very close to the celestial phenomena.

5. Resting upon these foundations, after innumerable labors of computation [carried out] through myself and through my assistants — much exercised in this practice — I constructed New *Luni-Solar Tables*, which we give to astronomers separately. Now these [tables] we represent from the eclipses set forth in the preceding catalogue [to within] 35, within 10' of time; within 12 of time [for] eclipse 44; but within 5' of time [for] eclipse 19. From Albategnius [al-Battānī] down to here — that is, lest the Tychonic Tables indeed, or the Rudolphine, or the Philolaic [be thought superior] — they have surpassed [those] of the more celebrated [eclipses], if indeed from what has been said in chapter VII, number 12, and from the Catalogue of this chapter, the comparison stands as below.

Within minutes of time the Eclipses are represented	10'	5'	12
Tab. Tychonica	28	15	
Tab. Rudolphinis	27	14	
Tab. Philolaica	27	10	
Tab. Nostra	35	19	44

[The table tabulates, for each set of Tables, how many of the catalogued eclipses each represents to within 10' of time, within 5', and (the rightmost figure) within 12 [of time]. The Tychonica/Rudolphinis/Philolaica rows have no entry in the "12" column; only "Nostra" (Our Tables) shows 44 there.]

6. Let Our Tables therefore deserve indulgence, in the eyes of fair estimators of these difficulties, ahead of the others, if at some point they do not exhibit the eclipses as near to the observations [as one might wish]; nor let part of the fault be undeservedly cast upon the observations themselves, upon their configurations, or perhaps upon a meridian-distance still less than certain.

7. For — that we may indicate a few things about some [of them] — eclipse 22 was observed at a place much nearer to us than [eclipse] 23, observed at Antioch.

Perhaps, therefore, that Antioch is not the Syrian one, but a more easterly one, and more eastern than we supposed; nor was the observer so diligent in it, whether in measuring the time, or in distinguishing the legitimate beginning of the eclipse from the penumbra [*Umbragine*] and from the smoke [*fumo*]. For in this case, and in all the others — especially before the use of the telescope and the skill acquired in this present age — from these two causes a suspicion of fallacy arises: namely, the deception of ocular estimation of the moment at which the eclipse begins, [or] is at its greatest, or ends; and [the deception] of the instruments by which the time is measured, whether these be Clocks, or Organa [instruments] suited to taking the altitudes of the stars, or the places of the stars themselves not certainly enough known in the sky — concerning which I have said more in chapter 4.

8. Eclipses 26, 27, 32, 80: the other Tables represent these no better, and some represent them rather worse. Which is a sign that the fault lies either in the Observation, or in the meridian; and in the others too, or in the Tychonic [observations], [the fault] of others — being least of all constrained by us to the narrows of time — and those [eclipses] which fall within a quadrant, or even nearly within a half-hour, it suffices to represent; see what has been said in the preceding chapter, numbers 8 and 9.

Concerning the ancient eclipses, moreover, it must be discussed separately.

CAPVT IX.

Concerning the Ancient Eclipses of the Moon exhibited through the Author's New Tables.

1. Already in chapter 5 we concluded that the 19 eclipses of the Moon related by Ptolemy [Ptolemy] are to be represented for those days of the Julian Year which suppose the Beginning of Nabonassar to have fallen at the Meridian of the 26th day of February of the Year 747 before the Epoch of Christ. And in chapter 7, number 8, we indicated that the latitude of time is to be inquired into, within which the observations of those Ancients seem to be consistent. Now, however, it must be inquired into somewhat more carefully concerning this latitude, lest anyone impose upon our Tables, or upon those of other Astronomers, a greater necessity than is just for representing the moments of those Eclipses. For although we do not deny that there is a disagreement between those Observations and the Tables, it can in part arise from the faults of the Tables themselves of the Lunar [or] Solar [motions], or of either at once; and in part

from a meridian-distance not altogether exactly noted; yet for the greater part we judge it [arises] from the Observation itself — less accurately [made] and recorded in the monuments — or [from the fact that it was made] less accurately, both on account of the unascertained discrimination of the smoke at the legitimate beginning of the eclipse, and at its end, which of itself entails an error of sometimes 20' and more of minutes; both on account of the crude manner of marking the time by Clepsydras [water-clocks], or by stars whose places in the Sky were not perceived certainly enough. Hence it is now held as established by the more recent Astronomers, with sufficient probability, that those eclipses are represented within about a half-hour; but some, if I am not mistaken, admit a larger [latitude] of time too. For let the order of eclipses from chapter 2 be repeated here, and from the places of Ptolemy in the same chapter, and let the several eclipses, briefly adduced, be weighed.

2. The *first* of the said eclipses began at hour 1 after the rising of the Moon, and was total, and — from the beginning alone, however much on account of the nearness of the horizontal vapors observed by Ptolemy, who supposed total eclipses to last 4 hours (which is not universally true) — he reckoned the middle of the eclipse. The *second* eclipse observed [— whether it be reckoned] from the beginning, or from the end, or rather...

in the highest part, when three digits appeared obscured at the middle of the night, the matter is uncertain. The **third** eclipse Ptolemy reports only as to its beginning, which fell a little after the rising of the Moon; and however its setting may have determined the duration of the eclipse [?], he determined the middle of seven digits — though here, given the nearness of the horizon, the obscurity of the observation could allow even the perplexity itself to appear; and likewise it is known to those skilled in such observations. Such too is the judgment to be made of the **fourth**, whose bare beginning is recorded after three digits remained at the end of the night. The **fifth** observation, taken at the very middle of the night, when the greatest defect was seen to be of six digits, appears to have admitted a smaller error — if it were established that it was estimated from that same moment, and not rather at the end, or estimated from the beginning; and likewise it must be said of the **sixth**, of three digits, observed a little before the middle of the night, and of the **seventh**, of about two and a half digits, observed near the middle of the night.

For as to the matter:

The **eighth**, whose beginning alone Ptolemy reports as observed, he places half an hour before sunrise, adding that the Moon set defective. Since at the summer

solstice a very small part of the orb [was] still free from eclipse at the Moon's setting and at its westering, Petavius [Denis Pétau] is anxious — both on grounds of the doctrine of times and by his own calculations — affirming that the time of the observation is exceeded by the Alphonsine Tables [Tabulae Alphonsinae] by 1^h 56', by the Prutenic [Tables] by 49', by the Danish [Tables] by 42', by the Parisian [Tables] by 33'. [?] Ptolemy supposed the eclipse to have lasted 1^h 30'. The smallness of the eclipse and of its duration does not admit so great an exactness in time as do other eclipses. Our own calculation does not represent this one to within that exactness. The **ninth** likewise admits only as much error as those [others], since one phase alone was observed; for its duration of three hours was recorded from beginning to end the rest, on the testimony of Ptolemy (lib. 4, cap. 11). Hipparchus reckoned from the eighth eclipse to the ninth 177 days and hours equal to 13 [hours] 45'. Ptolemy in the same place reckons 177 days, 13^h 36'. Our Tables therefore represent this eclipse as later than Ptolemy's by 11' 15", but as later than Hipparchus by only 1' 10".

[Marginal sidenote in body, paragraph 4:] The **tenth** eclipse is reported to have begun at the rising of the summer [Sun] [ab ortu aestivo], and from this beginning — assuming the totality of the eclipse — the duration of the hours [is computed as] 4. Ptolemy (lib. 4, cap. 11) sets the middle at Babylon at the 11th hour after midday; the eclipse [is] computed [as beginning] at the 9th [hour]; to this point 177 days; and 2^h. He admits, however, that Hipparchus reckoned the hour to be only 1^h 40', beyond the 177 days. But Boulliau [Ismaël Boulliau] (lib. 3, cap. 6), from the manuscripts of the Royal Library, shows that the hour should be read as 10^h 25'.

The beginning of the **eleventh** eclipse is supposed to be unobservable, since it is said to have begun to fall short half an hour before its own beginning [?]; but because it was full at the middle of the third hour of the night, Ptolemy reckoned the middle at 7^h after midday.

The **twelfth** eclipse Ptolemy reports (lib. 4, cap. 11) only as to its beginning, and from the duration through the whole eclipse over 4 hours he fixes the middle at 13^h 20' after midday; and from the preceding one to this [he counts] 178 days, and 6^h 50'. But he admits that Hipparchus reckoned only 178 days and 6 hours; and therefore Hipparchus was 50' earlier than Ptolemy. We therefore have followed Hipparchus, since otherwise our Tables would exhibit it as too late; and we represent it most accurately in accordance with Hipparchus's observation. As for the **thirteenth** eclipse, it seems we must stand rather with Ptolemy, who (lib. 4, cap. 11) from Hipparchus places it as observed, with its beginning fallen at the

6th hour [transacta noctis hora 6] of the night having elapsed, and 40'; and then other phases, since the whole Moon failed. Hipparchus defines the middle at 2^h 10' after midnight. Ptolemy reckons from this [eclipse] to this one 176 days, 0^h 24'. But Hipparchus, in his work, [counts] 176 days, 1^h 20'; yet to the preceding one you would add 50', which Hipparchus subtracted. If these 176 days, 0^h 30', were the interval of this 176 days, the hour 0^h 30' would be a little greater than Ptolemy's. Nevertheless we exhibit this one 8' earlier than the Ptolemaic time demands.

[Paragraph 6:] The **fourteenth** eclipse — its beginning is set at 2^h 10' after the equinoctial [crossing] [post dinoctium], and its end at 5^h 10', with 7 digits; and the **fifteenth** is reported to have begun to be observed at 2^h ½ after the rising of the Moon, and then the middle indicates that 2 digits failed.

[Paragraph 7:] Among the four eclipses which are in our order 16, 17, 18, and 19, the first is the **sixteenth**, which is not referred by Ptolemy [to himself], but [is reported] as observed by him; nor did he add anything (lib. 4, cap. 6) about the observations made [by himself]. [Yet] Lansbergen [Philips van Lansbergen] too most accurately [reports it]; and in the *Thesaurus* he maintains that this eclipse at Alexandria fell at the hour 8^h 51' after midday, though by 8^h 24' as Ptolemy has it. We likewise [place it] 22' later than Ptolemy, exhibiting it [thus]. We exhibit the **seventeenth** and the **eighteenth**, which Ptolemy (lib. 4, cap. 6) affirms to have been observed by himself most accurately, no later than 6' or 7' [from the truth] [?]. But the **nineteenth** we exhibit after midnight as observed by him [ad se], with all the minutes given, except for the Lansbergian Tables, which differ from the others in the motion of the Sun; the rest of the Tables [agree], at about one hour, exhibiting this eclipse earlier.

[Paragraph 8:] At first sight the Lansbergian Tables may seem preferable to the rest as regards the ancient eclipses, as can be seen in the catalog of chapter 5. But since Lansbergen dissembled eclipses 8, 9, 10, 11, 12, & 13, and in the rest of the more recent ages they are far inferior to the Tychonic [Tables], if a truer distance of the meridian [were] adopted — as is plain from what has been said in chapter 7, number 5 — therefore we judge they ought absolutely to be preferred to the Tychonic, Rudolphine, Danish, or Philolaic [Tables]. So that the comparison may be made between [them], we have set down in the following little table [latercula] the number of eclipses which the Tables written below represent within the hour's minutes 5, or 10, or 15, or 20.

Tabulae	5	10	15	20
Danica	2	3	6	6

Tabulae	5	10	15	20
Parisina	1	3	5	7
Philolaica	3	4	7	8
Rudolphina	2	3	5	7
Nostra	3	8	8	9

[Paragraph 9:] There now follows the **Catalog of the Ancient Eclipses**, with the place, the Sun's position, and the Moon's; together with [the time] due from the moment of the eclipse observed, [the time] computed from our more recent Tables, with the difference of the Moon's computed place added, and the time corresponding to this difference.

Column structure: **Ordo Ecl.** (order of the eclipse) | **Tempus Bononiense Apparens ex cap. 3, post Meridiem** [Bolognese apparent time, from chapter 3, after midday] with sub-columns *An. ante Chr.* (year before Christ) / *M.* (month) / *D.* (day) / *H.* (hour) / *I* (minutes) | **Tempus Aequatum** [equated time]: *H.* / *I* / *II* | **Solis locus Verus, & inde Lunae** ☉ [true place of the Sun, and thence the Moon at opposition]: *Sig.* / *Gr.* / *I* / *II* | **Lunae locus computatus** [Moon's computed place]: *Sig.* / *Gr.* / *I* / *II* | **Differentia comput.** [computed difference, prefixed d=defect / e=excess]: *I* / *II* | **Tempus differ.** [time of the difference]: *I* / *II*.

[Head-piece: decorative band of foliate ornaments above the chapter heading.]

CAPVT X.

On the Motion of the Moon in Longitude as hitherto established by the more eminent Astronomers, and by what method above all it should be investigated: whatever has been erred in it, or may seem to be desired [*De Motu Lunae in Longitudinem hactenus ab Insignioribus Astronomis constituto, & qua potissimum methodo illum investigari: quidq; in ea peccatum esse, aut desiderari posse videatur*].

[Paragraph 1.] [Margin: Summa methodi.] Formerly, in Lib. 4 of the *New Almagest* [*Almagestum Novum*], from chapters 19 and 24, I set out a threefold artifice by

which astronomers investigate the lunar motions, and I showed that the attempt to recover them through the cycles of the Lunisolar [period], or through the commensuration of the lunar year with the solar — and hence through the recurrence at twin lunar eclipses, separated by the longest possible interval of years and falling at the same degree of anomaly, or [the same] distances from apogee, with each luminary set either in apogee or in perigee, with conditions otherwise the same and the like — is frustrated. Ptolemy requires this (lib. 4 of the *Magna Constructio*, cap. 2), and declares it; Boulliau demonstrates it (*Astron. Philol.* lib. 3). But of these matters, or at any rate of the principal ones: **First**, from a foreknowledge of the apparent place of the Sun in degree, and given the time, [that time] is to be converted into Equated time, reduced to the same meridian; and from this, the Sun's motion, both Mean and True, is to be gathered, along with its anomaly; for from the opposite [place], the Moon's place is at once known — the place in which it truly was at the moment of the observed eclipse. **Thirdly**, by the lunar prosthaphaeresis, using meanwhile some best hypothesis, the Mean place of the Moon must be found, by adding the equation to its place in the prior six signs of Anomaly, and subtracting it in the others. **Fourthly**, the interval [in time] of the Mean motions, or of the places of the Sun and Moon, must be made to agree by the Hourly Tables of the Moon; and to this, since they everywhere have a [share] of the Equated Full Moon observed, [must be added] the mean motion of the Sun beyond the Moon in syzygy [in Syzygia], which goes to the Mean Full Moon; if the mean motion of the Sun exceeds the Moon [?], it is in defect, and the moment of the Mean Full Moon of either [will] be had. **Fifthly**, it must be diligently calculated with each [quantity], the Mean Full Moon, not in years only, but also in days, hours, and minutes; having reckoned the number of days, with the years added in the form of the Julian Year. [And] for days subtracted in the form of the Gregorian Year — 1582 — and its computation should be reconciled, whether it be made for those observing in the Gregorian style.

Sixthly, the interval of time reduced to Days must be multiplied by the Lunations, 4267; & the sum is to be divided by the Days 126007 — for thus will come forth the integral number of Lunations, by which [an interval] more nearly equal is made [?]. **Seventhly**, by the Luration-number found, the same number of days must be divided between the two eclipses of the Moon; & there will come forth Days, Hours, and the scruples due to a single Mean Luration, or to the Mean Synodic Lunar Month. But let these precepts become clearer by the following example, given the collected [years] from the Synodic Month, and the rest of the motions.

[Paragraph 2.] By this method, which Ptolemy intimated rather obscurely (lib. 4, cap. 2 & 7), Hipparchus found, between two eclipses observed by the ancient Babylonians and recently by [others], the Days 126007 & the hour as one, to have completed 4267 Lunations, as I have said. [Margin: Hipparchi opinio.] But the Anomalistic Months, or the entire restitutions of the inequality, [are] 4573. The Periodic Months, or Zodiacs, [are] 4612, less by $7\frac{1}{3}$ degrees. Dividing then, Hipparchus [found] the Days 126007 by 4267, [and] found the Mean Month in scruples of Days, and into [parts]:

[Computational array, in scruples of days:] | D. | I | II | III | IV | |---|---|---|---|
 | 29 | 31 | 50 | 8 | 9 |

That is, in Hourly Scruples:

D. 29. Hor. 12. 44'. 3". 15"". 44"" [29 days, 12 hours, 44' 3" 15"" 44""].

So Ptolemy reports (lib. 4, cap. 2), adding that the mean motion recovered by Hipparchus, as regards Longitude, does not in any sensible way wander from the truth; but [as regards] the Anomaly and the Latitude, [it is] far from the truth. Ptolemy uses [this] (cap. 3) [for] the lunar month written below, in scruples of days, but converted by us into Hourly scruples:

D.	I	II	III
29	31	50	8

That is, 29 days, 12 hours, 44'. 3". 20"" [29^d Hor. 12. 44'. 3". 20""].

Therefore, from Hipparchus, the number of Lunations to the number of Anomalistic Months is as 4267 to 4573, or more briefly as 251 to 269. Whence followed the Daily motion of Anomaly:

Gr.	I	II	III	IV	V	VI
Hipparcho	13	3	53	56	17	51

But Ptolemy (lib. 4, cap. 7) affirmed that this should be corrected so as to be:

Gr.	I	II	III	IV	V	VI
Ptolemaeo	13	3	53	56	17	59

[Paragraph 3.] [Margin: Vuendelini laus, & opinio.] Now Govaert Wendelen [Wendelinus], whose most learned letters to me show how profoundly he has immersed himself in lunar theory, says (in the *Idea Atlantiarum Tabularum*, p.

29) that in precisely 797326 days 27000 Lunations are completed, and that hence is born a single Lunation [of]:

D.	H.	I	II	III
29	12	44	3	12

But [for] the apocatastasis [the great cycle / complete return], that is, the Revolution of the Lunar Anomalies, he holds it to be such that the Anomalistic Months are dissolved in 18038 [Lunations]; finally, the Draconitic Orbs, or [Months] of Latitude, [in] 6890; the Revolutions [are] completed [in] 7477. As for the rest, Wendelen's proportion does not differ much from Hipparchus's. For as the Lunations 27000 are to the Days 797326, so are Hipparchus's Lunations 4267 to Hipparchus's Days $126007 \frac{1042}{27000}$. He does not, however, expound any twin eclipse by which this use was made, in order to stabilize this Mean motion — as neither does Tycho, nor Longomontanus, nor Kepler, nor Lansbergen. For although Longomontanus, in his commentary *On the Moon* in the *Astronomia Danica* (which is had in lib. 2, cap. 2 of the *Theoricae*), adduces three pairs of Assyrian eclipses, three of Hipparchus's, and three of Ptolemy's, observed partly by Tycho and partly by himself, and compares them with his own Tables, he nevertheless does not openly show what use was made in investigating thence the motion of the Moon; and he scarcely acquiesces, among the ancient [eclipses], in the last of Hipparchus's, which among us is in the catalog of the first chapter, number 13 in order. Nor does Lansbergen, in the *Thesaurus* of observations, after the comparison of many eclipses with his Tables, show by what reasoning he derived the Mean places of the Moon. Therefore from him [ipso], and from the Danish and Rudolphine Tables, we have the Synodic Month, and the Daily motion in the Zodiac, as below:

[Margin: Mensis Synodicus.] | | D. | H. | I | II | III | IV | V | VI |
|---|---|---|---|---|---|---|---| | Danica | 29 | 12 | 44 | 3 | 8 | 39 | 46 | 48 | |
Rudolph. | 29 | 12 | 44 | 3 | 10 | 51 | 0 | 0 | | Lansbergen. | 29 | 12 | 44 | 3 | 12
| 0 | 0 | 0 |

[Margin: Motus Diurnus.] | | Gr. | I | II | III | IV | V | VI |
|---|---|---|---|---|---|---|---| | Danica | 13 | 10 | 35 | 1 | 15 | 45 | 52 | | Rudolph. |
13 | 10 | 35 | 1 | 14 | 30 | 43 | | Lansbergen. | 13 | 10 | 35 | 1 | 12 | 29 | 25 |

See the opinions of the rest in the *New Almagest*, lib. 4, cap. 23. These then being dismissed, two most celebrated Astronomers remain to us, who at length by some example manifested the method, or the eclipses, which they used in fishing out the motion of the Moon — namely **Copernicus**, and **Boulliau**.

[Paragraph 4.] [Margin: Copernici lapsus Chronologicus.] For Copernicus, with whom the Synodic Month is:

D.	H.	I	II	III	IV	V
29	12	44	3	10	48	...

— whence he deduced it [is shown] (lib. 4, *Revolutionum* cap. 5 & 6), namely, from three eclipses of the Moon observed by Ptolemy, & from as many observed by himself. But in the computation of the intervening days he erred. For he says that in the year 17 of Hadrian an eclipse was made [and] observed by Ptolemy: *On the twentieth day of the month Pauni, in the year of Christ one hundred thirty-three, on the sixth day of the month of May, or the day before* [the nones]. But Ptolemy (lib. 4, cap. 6) by no means has that the [eclipse] passed [fell] on day 20 of Pauni, for then day 21 would not have followed; but he says: *On the second day of the month Pauni, by the Egyptians, on day 20, which 21 followed.* Wherefore he still erred by day 20.

[Paragraph 5.] Similarly Copernicus erred — but uniformly — in referring the second & third eclipse: for he says that the second eclipse was made *In the year 19 of Hadrian, two days of the month Choiac having elapsed, in the year of Christ 134, on the 13th, the Kalends of November* — namely the 20th of October. But Ptolemy (lib. 4, cap. 6) does not have that *peractis* [elapsed]; rather: *On the second [day] of Choiac, the following third [day]*; for indeed day 2 was running, the beginning [reckoned] from the meridian of the day, after whose midday the eclipse was. Copernicus also says the third [eclipse] was made *In the year 20 of Hadrian elapsed, on the 19 days of the month Pharmuthi, in the year of Christ 135, the 6th of [the Kalends of] March elapsed.* Although Ptolemy (lib. 4, cap. 6) says: *On the 19th of Pharmuthi, which the twentieth followed.* And so day 19 still erred [stood], reckoned from the meridian of day 18. Copernicus admits the Hipparchan proportion of the Lunations, & of the Days of which I spoke under number 2; & from the second Ptolemaic eclipse to the eclipse observed by himself in the year of Christ 1522 [he counts] the 5th of September [and] computes 1388 Egyptian years, & days 302.

[Paragraph 6.] Ismaël Boulliau, the most diligent and subtle scrutinizer of Astronomical truth (*Astron. Philol.* lib. 3, cap. 2), adduces Hipparchus's Doctrine of the Lunations, 4267, made in an interval of days 126007 $\frac{1}{24}$; & uses (cap. 5) the interval of Egyptian years 1788, [or] days 65, that is, altogether days 651268 5; [and] he says the Lunations 22102 were completed, & so on in order. He reports too, in the same place, an eclipse of the Moon made in the year 547 of

Nabonassar, day 16, [in the month] Messori, hour 5^h 39', appearing at Uraniborg, where he says it was observed by Tycho as another eclipse in the year of Christ 1587, on the 6th of September, old style, at the hour 9^h 28' after midday; adding that this had been [in] the year of Nabonassar 2336, day 16, [month] Paophi, hour 9^h 28' after midday; whence he collects the foresaid interval of Egyptian years 1788, days 65; hours 3^h 51'; & by dividing the foresaid interval by the Lunations 22102, he collects the Synodic Month:

D.	H.	I	II	III	IV	V	VI
29	12	44	3	12	41	18	24

[Paragraph 7.] The same [Boulliau], in the same place (cap. 5, lib. 3), brings forward another eclipse observed [in] the year 548 of Nabonassar, day 9, [month] Mechir, hour at Uraniborg 11^h 59' after midday, appearing, & another likewise noted by Tycho in the year of Christ 1588, on the 2nd of March, old style, at the hour 15^h 8'; which he says was day 14 of Pharmuthi; whence he collects the interval of Egyptian years 1788, days 65; hours 3^h 5'; & hence the Lunations likewise 22102. And the Synodic Month:

D.	H.	I	II	III	IV	V	VI
29	12	44	3	5	11	45	17

[Paragraph 8.] Finally Boulliau (lib. 3, cap. 6) brings forward an exact determination of the lunar motions, by which at the end of the chapter he affirms that the Tables of the Moon's mean motions were constructed by himself. He uses, however, two lunar eclipses: one observed in the year 366 of Nabonassar, on the 26th of the month Thoth, the hour at Uraniborg reduced to 16^h 58' after midday; the other observed by himself at Paris — by Hortensius [Maarten van den Hove] at Amsterdam — & by Gassendi [Pierre Gassendi] in the year of Christ 1635, on the 3rd of March, the hour at Uraniborg reduced to 9^h 18' 5"; adding that this had been the year of Nabonassar 2383, day 16 of Pharmuthi. Hence he collects the interval of Egyptian years 2017, days 199, hours 16^h 20' 5", or of days altogether 736404, hours 16^h 20' 5"; but the Full Moons being reduced from True to Mean, it has hours only 9^h 1' 29"; & hence...

Liber II — De Luna (continued)

Caput X (continued)

and from this come 24937 lunations. By dividing that interval by these, he determines the synodic month; and by dividing the zodiac traversed in a synodic month, he determines the Moon's mean daily and annual motion in longitude. Then, adding the Sun's mean daily motion to the Moon's mean daily motion — and likewise the annual to the annual — he determines the Moon's mean motion reckoned in the zodiac from the equinox, as set out below.

Month	D.	H.	I	II	III	IV	V	VI	VII	VIII
Synodic	29	12	44	3	9	37	9	59	15	15

[Margin: 9 — Bullialdus's error.]

Yet I am surprised that Boulliau [Ismaël Boulliau] settled these motions from two of the very last eclipses, with the lunar anomaly constituted in a region very different from what he established from other eclipse-pairs. For in the eclipses numbered 6 and 7, reduced to those in which it occupied about the same degree of anomaly — namely in eclipse number 6 the Moon's anomaly was, by Boulliau himself, of Signs 10 and $2^{\circ}\frac{1}{2}$ approximately, while in each the number was 7 — it was of Signs 3, $21^{\circ}\frac{1}{2}$ approximately. But in eclipse number 8, in the first instance the Moon's anomaly was Signs 7, 19° [?]; in the second, however, Signs 11, $14'$ [?]: so by no means is it at the same distance from apogee as it ought to be. And since, moreover, the mean month here derived stands almost midway between the months derived from the two prior eclipse-pairs, the compensation of this error seems to have been made. Copernicus, by contrast, adhering to his two Ptolemaic precepts about eclipses, chose for the case in each the anomaly to be of number 5; in which case the Moon's anomaly was Signs 2 and $6^{\circ}\frac{2}{3}$ approximately.

[Margin: 10]

Finally, one could wish that those forenamed astronomers had confirmed the Moon's mean motion from several eclipse-pairs rather than from one or another,

so that it might stand established in clear terms; or at least that they had adduced a sure reason why they relied especially on a binary of eclipses, on account of some prerogative. This is something also to be desired in the epochs of motions, since the root of the motions does not come out the same when derived from one eclipse as when it comes out from another, and so on.

Caput XI

De Mense Lunari Synodico per plures Eclipses investigando.

(On investigating the synodic lunar month by means of several eclipses.)

[Margin: 1]

I shall illustrate by a single example the precept handed down in the preceding chapter. I choose the eclipses of the Moon numbered 8 and 92, not only because they agree very well with the astronomical tables, but also because in each the Moon held about the same degree of anomaly, namely Signs 7 and grade [?]; there it was 19, here 16. Therefore, reducing the times equated to the meridian of Bologna: in the prior eclipse, the eclipse numbered 8 was the true full moon of the year 383 before Christ, on December 22 at hour 16^h 53' 10" in equated [time] at Bologna; and then, by our tables, the luminaries stood thus:

	Sign.	Gr.	I	II
The Sun's mean motion	8	26	4	6
Its Anomaly	0	22	36	6
The Moon's mean motion	2	23	6	16
Its Anomaly	7	18	52	17
The difference of the means		2	57	50

The Moon was therefore at that time on the near side of the place of Mean Opposition by 2° 57' 50"; and from this position of the lunar anomaly there agrees a time of 5^h 29' 27". If you add this to the time of the True Full Moon, you will have the time of the Mean Full Moon: the year 383 before Christ, December 22 at hour 22^h 22' 37", in equated time at Bologna.

[Margin: 2]

In the year 1628, January 20 by the Gregorian style, but on day 10 by the Old style, at hour 10^h 9' 20" after noon at Bologna in equated time, there was an eclipse of the Moon, and then the luminaries stood thus:

	Sign.	Gr.	I	II
The Sun's mean motion	9	29	40	26
Its Anomaly	6	21	33	47
The Moon's mean motion	3	26	51	11
Its Anomaly	7	18	4	37
The difference of the mean motions		2	49	15

In this eclipse number 92, the Moon was likewise on the near side of what an exact opposition with the Sun would require, by $2^{\circ} 49' 15''$; and from this the lunar anomaly yields a time of $5^h 7' 30''$. Therefore, adding these to the moment of the True Full Moon, the Mean Full Moon falls in the year 1628, January 10, at hour $15^h 16' 50''$ in equated time at Bologna after noon. From the moment of the Mean Full Moon of eclipse 92 to the moment of the Mean Full Moon [of eclipse 8] there are 2009 Julian years, 18 days, $16^h 54' 13''$; or, resolving these into days, there are 733805 days, $16^h 54' 13''$ — computing, that is, the 502 days which must be added on account of the same number of bissextile years. For the Egyptian year of 365 days makes 733285 days; add to these the 502 and, besides, the aforesaid 18 days, $16^h 54' 13''$, and the interval comes out, as I said, 733805 days, $16^h 54' 13''$.

[Margin: 3]

Now indeed, if (confirmed by the observation of Hipparchus, and accepted from Copernicus, Wendelen [Govaert Wendelen (Wendelinus)], Boulliau, and other proven astronomers, as I said in the preceding chapter) 126007 $\frac{1}{24}$ days contain 4267 lunations — and likewise our interval of 733805 days, $16^h 54' 13''$ contains 24849 lunations, by which dividing the same 733805 days, $16^h 54' 13''$, the synodic month comes out as the mean:

D.	H.	I	II	III	IV
29	12	44	3	12	20

Nevertheless, from two eclipse-pairs of mean full moons in the ecliptic examined, I find a synodic month which answers to a far greater number of eclipses, namely:

D.	H.	I	II	III	IV	V
29	12	44	3	10	50	30

[Margin: 4]

But so that we may not begrudge the reader the aforesaid eclipse-pairs and comparisons, we present three tables. In the **First** is the Time of the Equated True Full Moons of the Ecliptic at the Meridian of Bologna, together with the Sun's and Moon's mean motion and the simple lunar anomaly, the order of the eclipses being kept the same throughout, as we set out in Chapters 2 and 3. The Time, moreover, is the equated time, as in Chapters 8 and 9.

In the **Second** is repeated, in the same order, the difference between the mean motions of the Sun and Moon, together with the Time which the hourly motion of the Moon answers to that said Difference; and there is to be added to the Equated Time of the True Full Moon, or subtracted, according as the Moon's mean motion was on the near side of, or beyond, the point of Mean Opposition with the Sun — from which results the time of the Mean Full Moon, which is had in this Second Table.

In the **Third** are at last indicated the comparisons of the ancient eclipses with the more recent, as far as concerns the mean full moons, the Moon turning at about the same degree of anomaly; as will be plain by recurring to the first of these tables, or at least in the same distance from apogee.

But because, to investigate the synodic month, one needs a just interval of days between an ancient and a recent full moon, I have therefore noted, for the period after the year of Christ 1582, the days according to the form of the Old Julian Year, lest anyone should forget the subtraction of the 10 days in the Gregorian form.

CHAPTER XII

How, from the synodic month, the remaining motions of the Moon in longitude are deduced. (For the anomaly and the latitude motion we shall treat separately below; for now we deal with the motion in longitude reckoned from the vernal equinoctial section.)

1. Rule concerning the lunar year and the epacts.

[1] Once the mean synodic month has been derived — which for us is 29 days, 12 hours, 44' 3" 10''' 50'''' 30^{iv} — multiplied by twelve it makes the **mean lunar year** of 354 days, 8 hours, 48' 38" 10''' 6^v. Its remainder, complementing the Julian solar year and the common [civil year], that is, to make up 365 days, is called the **epact** of one year: for us, 10 days, 15 hours, 11' 21" 49''' 54^{iv}. In accumulating the epacts of several years one by one, in each bissextile year the epact is increased by one day. Whenever a complete lunation accumulates in the total, however, it is always taken away as often as it can be removed. A specimen of all this you have in the following table, together with the embolismic lunation, in number 13.

Lunar Year	D.	H.	I	II	III	IV
Common	354	8	48	38	10	6
Embolismic	383	21	32	41	20	57

Epact of the Years	D.	H.	I	II	III	IV
Common	1	10	15	11	21	49
	2	21	6	22	43	39
	3	2	8	50	2	18
Bissextile	4	14	0	1	24	8

2. Rule concerning the periodic lunar month.

[2] The 360 degrees of the zodiac resolve into 7,776,000,000 thirds [tertia]. Our synodic month resolves into 153,086,591 thirds in terms of hourly thirds; multiplied by the zodiac, as resolved above, these make 1,190,401,316,160,000 thirds, to be reserved as the **number to be divided** [*numerus dividendus*]. But for the time of the synodic month, the mean motion of the Sun in the zodiac is, by our

tables, 29° 6' 24" 17''' — which, resolved into thirds and added to the zodiac above as resolved into thirds, makes 8,404,705,7 thirds. By this, therefore, divide the aforementioned number to be divided, and there will come forth the periodic hourly thirds, by which the Moon completes a circuit of the zodiac, namely 141,631,117 thirds — that is, 27 days, 7 hours, 43' 5" 17'''.

3. Rule concerning the daily motion of the Moon in the zodiac.

[3] The zodiac, taken together with the mean motion of the Sun corresponding to the synodic month, is, as we said in number 2, 8,404,705,7 thirds. Multiplied by the thirds of one day's hourly [motion], 5,184,000'', these yield a sum of thirds 4,356,999,434,88,000''. And this, divided by the synodic month's aforesaid thirds 153,086,591'', leaves the **mean daily motion of the Moon in the zodiac** of thirds 2,846,101 ⁴⁴/₁₅₃; that is:

Gr.	I	II	III	IV	V	VI
13	10	35	1	17	15	49

4. Rule concerning the daily elongation of the Moon from the Sun.

[4] Subtract from the mean daily motion of the Moon in the zodiac the mean daily motion of the Sun, which for me is 59' 8" 19''' 48^{iv} 35^v 35^{vi}, and you will at once have the **daily elongation of the Moon from the Sun**, namely:

Gr.	I	II	III	IV	V	VI
12	11	26	47	28	40	14

5. Rule concerning the hourly and annual motion of the Moon in longitude.

[5] The hourly motion can be obtained by dividing the daily motion by 24. More easily, however, it is had by aggregating the double of the daily motion and the half of the daily motion, but exchanging the titles of the places — the degrees into minutes, and the minutes into seconds, and so forth. Take an example with our daily motion:

›	Gr.	I	II	III	IV	V
Daily	13	10	35	1	17	16
Double	26	21	10	2	34	32
Half-daily	6	35	17	30	38	38
Aggregate	32	56	27	33	13	10

	I	II	III	IV	V	VI
Therefore	32	56	27	33	13	10

	I	II	III	IV	V	VI	VII
Hourly	32	56	27	33	13	10	

	II	III	IV	V	VI	VII
And of minutes, one	32	56	27	33	13	10

[6] The annual motion is more securely obtained from the daily, by first investigating the motion of the months by multiplying the daily by 28, or by 30, or 31; or else from a more composite [aggregation] of several daily motions, until you reach the motion for 30 or 31 days. In this manner:

Mean motion of the Moon in the zodiac [Lunæ motus Medius in Zodiaco]:

Of Days [Dierum]	Sign.	Gr.	I	II	III	IV	V
1	0	13	10	35	1	17	16
5	2	5	52	55	6	26	20
10	4	11	45	50	12	52	40
30	1	5	17	30	38	37	0
31	1	18	28	5	39	54	16
60	2	10	35	1	17	14	0
120	4	21	10	2	34	28	0
240	9	12	20	5	8	56	0
360	2	3	30	7	43	24	0
365	4	9	23	2	49	50	20

CHAPTER XIII

On the motion of the lunar apogee and the anomaly.

[1] From what was said in Book 4 of the *New Almagest* [*Almagestum Novum*], Chapter 21, it is clear by what method Ptolemy and Copernicus investigated the

motion of the lunar anomaly geometrically, by means of three ancient lunar eclipses and as many recent ones. There too I indicated that more than three were employed by Longomontanus and Boulliau. Now I repeat what I said above from the epilogisms of Hipparchus: that in the lunations there correspond 4,573 anomalistic months. That is, in the shorter [span of] lunations, 251, I completed 269 anomalistic months; while in the longer span, which — panit Vuendelinus — that Wendelen [Govaert Wendelen] applied in the *Idea Tabularum Atlanticarum* [*Idea Tabularum Atlanticarum*], with 16,831 lunations there correspond 18,038 anomalistic months.

[2] But since Ptolemy, in Book 4, Chapters 2 and 7, by a large [error?] lacked precision in the Hipparchian proposition, and Boulliau [Ismaël Boulliau], in Book 3 of the *Astronomia Philolaica* [*Astronomia Philolaica*], by means of many eclipses and their intervals reduced to a geometrical foundation, concluded — over an interval of 736,404 days, 16 hours, 16' 20" 5''' — that there were completed entire anomalistic revolutions to the number 26,725, and besides 114° 35' 34"; from which, resolved into the sexagesimal [places] of degrees, there comes:

Mean motion of the lunar anomaly [*Anomalia Lunar Motus medius*]:

	Sign.	Gr.	I	II	III	IV	V	VI
Daily [Diurnus]	0	13	3	53	56	18	57	45
Annual [Annuus]	2	28	43	7	34	20	51	43

[3] We, having considered the depth and diligence of this man [Boulliau] in the aforesaid inquiry, and having tested this motion against the observations of the lunar eclipses as against a Lydian touchstone, recognized that it comes as close as possible to the truth. And so from this we have derived the remaining motions — namely the hourly, the monthly, and so on. [Margin: *Praise of Boulliau in [the matter of] anomaly* — Bullialdi laus in › Anomalia.]

[4] Furthermore, the motion of the lunar apogee is obtained by subtracting the motion of the lunar anomaly from the motion of the Moon in the zodiac — the daily [apogee motion] from the daily, the annual from the annual, the hourly from the hourly — as below:

Mean motions [› Motus med.]:

	Sign.	Gr.	I	II	III	I V	V V	V I
› Mean motions								
Year in zodiac [Annus in Zod.]	4	9	2	2	49	5	2	0

☽ Mean motions	Sign.	Gr.	I	II	III	I V	V	V I

				6		2	5	6

CHAPTER XIV

On the motion of the lunar latitude, or of the nodes.

[1] In Book 4 of the *Almagest* [Ptolemy], Chapter 22, while we set out the method by which the astronomers investigated this motion, [we noted that] Hipparchus indeed, and Ptolemy after him in Book 4, Chapter 1, demonstrated that in 5,458 lunations the Moon completes 5,925 circuits of latitude. But Ptolemy himself, in the same place, says this is far from the truth, and in Chapter 9 says: "In the latitude motion, indeed, we too were going astray, following the Hipparchian proportion that the Moon measures out its circuit 650 times" — but afterwards subjoins "we changed [these], according to the mean [position] in the full moons in their fullest distance, and so on." And after a little he adds: "we made some changes, since truer observations afterwards came to us." [Margin: *Praise of astronomy* — *Astronomia laus.*]

For it is fitting that all who undertake these speculations should do so, not only for the emendation of the ancients, by using a more certain and new method, but also for their own self-correction — if they are recalled to better [conclusions] not only by themselves but also by others — especially when this is so great and divine a profession.

These things premised, he chooses two eclipses which, in the catalogue of Chapter 2, are number 7 and number 16, in each of which the Moon was eclipsed.

[2] Copernicus, in Book 4, Chapter 13, since he did not have two eclipses observed [of the kind needed] — one from the ancients, the other in his own time — in each of which the Moon was equally affected from the same quarter, and near the same node, and at the same distance from the apogee — chose two in which, all the rest remaining [the same], the Moon was eclipsed in different quarters and near opposite nodes (for the sign indicates that the Moon was in [its] latitude), and besides whole revolutions, that it had described a semicircle. Such were the eclipses (which with us, in Chapter 2, are number 14 and 35). Between them he computes the years 1683, the days 88, the hours 22, 35' — by which time, the revolutions being completed and equated, he states that the Moon completed in latitude besides $179^{\circ} 51'$. And from this he establishes the daily motion of the latitude as $13^{\circ} 13' 45'' 39'''$; but, an old man, he erred in this, while in the first eclipse "of Claudius [Ptolemy], on the transacted days," as Claudius says, "of the month Phamenoth, on the 27th day." But Claudius Ptolemy, in Book 6, Chapter 5, does not say "transacted," but "on the day Phamenoth 27 going on toward the 28th," by which is signified that the 27th day was not yet complete. And so in the interval of the eclipses he falls short of one whole day by a customary error.

[Margin: *The latitude motion from Copernicus* — Latitud. motus ex Copernico.] Next, since the earlier eclipse was in the year before Christ 174, on the day 30 of April — as is clear from our Canon and Apparatus Chronologicus — at the hour at Cracow 9.45 after midday in the afternoon. The latter truly was in the year of Christ 1509, on the 2nd day of June, at the hour after midday at Cracow 11.36. If we accurately compute the interval, we find the Julian years 1682, the days 162, the hours 21 and 21'. False, therefore, is that interval which he expresses not in marked numerals but in extended words: "The time, however, between the two, [when] the eclipse[s] occurred, was years one thousand six hundred and eighty-three, days eighty-eight, [at the] hour the 22nd, minutes 51." We therefore dismiss Copernicus. [Margin: *The twofold lapse of Copernicus in chronology* — Lapsus duplex Copernici in Chronol.]

[3] Gottfried Wendelen [Govaert Wendelen], in the *Idea Tabularum Atlanticarum*, asserts that in 6,890 mean lunations there are completed 7,477 draconitic orbits, that is, apocatastases of latitude; and from this he gathers the daily motion of the latitude:

Gr.	I	II	III	IV	V	VI
13	13	45	39	32	7	36

We admit, therefore, the Hipparchian analogy, since from what has been said in number 1, just as 5,458 lunations correspond to 5,923 draconitic orbits [recte: 5,925? — text gives 5,923 here against 5,925 above; transcribed as printed], so 6,890 lunations correspond to 7,477 draconitic orbits — which, however, is found false in Ptolemy. [Margin: *The latitude motion from Wendelen* — Latitud. motus ex Vuendel.]

[4] Boulliau, in Book 3 of the *Astronomia Philolaica*, Chapter 8, shows that in 130 Egyptian years and 35 days, that is, 19 hours 36', or in 68,379,576 hourly minutes, the node of the lunar orbit, by receding backward against the sequence of the signs, completes 6 whole draconitic orbits, and besides $355^{\circ} 2' 49''$. Which differs somewhat from Hipparchus's opinion, but disagrees little. This, as it were by prolixity, having been done, [Boulliau] approaches the rigorous examination of this motion; he himself, choosing two eclipses, [says]: "The earlier is the one which by Chapter 2 is for us number 2, in which 3 digits were defective, [the Moon being] toward the south near the ascending node, in the year of Nabonassar 28, on the 18th day of Thoth, at Wittenberg [*Vranburgi?*], at the hour 9.58 after midday; and by the Philolaic Tables the simple solar anomaly was 9 signs $9^{\circ} 4' 45''$; but the lunar [anomaly], 0 signs $13^{\circ} 38' 28''$. The later is the one which by Chapter 2 is number 97 in order, in which 11 digits were defective, [the Moon being] toward the south near the descending node, in the year of Christ 1634, on the 14th day of March; the solar anomaly, by the same tables, being 8 signs, $9^{\circ} 17' 19' 42''$ [recte: $8^{\circ} 9^{\circ} 17' 42''$? — text crowded]. But the lunar [anomaly was] 1 sign $8^{\circ} 27' 58'''$; and he adds that it was the year of Nabonassar 2382, [the month] Phamuthi, the 27th day, hour 9.20; and so between the two eclipses there elapsed 2354 Egyptian years, 218 days, 23 hours, 22'. These he divides by 130 years, 35 days, 19 hours 36'; and from this at length he gathers these motions:

[Here the body returns to the §1 table region — see the "Mean motion of the latitude" tables on the facing page.]

(continuation — page 142)

The following table (continuing the latitude-motion derivation) heads page 142:

Sig. Gr.	I	I	I	I	V				I
	I	I	III	V	V	I	VII	VIII	X
Nodi [Nodes], Diurnal	0. 0.	3	10	3	2	3	12	7	2
				8	5				6
Latitud. [Latitude], Diurnal	0. 13.	1	45	3	3	5	39	35	1
		3		9	8				7
Annual [Annuus]	4. 28.	4	46	6	4	2	49	38	4
		2			4	5			3

[5] But it was necessary, or expedient, to choose two eclipses at the same distance from the apogee, and of the same magnitude.

And so in the year before Christ 720, as is had from Chapters 3 and 9, the Chaldeans observed a lunar eclipse of 6 northern digits, or a little more than that magnitude — Kepler [Keplerus] notes in the *Astronomia Optica* [*Astronomia Optica*] that this is the most evident of all the observations, on account of the equality of the illuminated part with the obscured part; and that full moon occurred on the 1st day of [Septem]ber [*tembris*], at the hour after midday at the equated time, H. 5. 58' 50". The luminaries then stood thus:

	Sign.	Gr.	I	II
True place of the Sun [Verus locus Solis]	5	0	54	9
And its anomaly [Eiusque Anomalia]	3	5	14	0
True place of the Moon [Lunæ Verus locus]	11	0	54	9
And its anomaly [Eiusque Anomalia]	5	13	58	16
Mean motion of the Moon [Medius Lunæ motus]	11	2	7	17

[6] The semidiameter of the terrestrial shadow, corrected according to the Sun's anomaly, and so the latitude of the Moon being southern (for the center of the lunar disk was on the very periphery of the shadow), was 47'. From this the supposed inclination of the lunar orbit to the ecliptic comes to Gr. 4. 58½', or at maximum Gr. 5. To solve [this], a right-angled spherical triangle is needed.

Diagram. A small right-angled curvilinear (spherical) triangle drawn in the lower-left of the column, with three labeled vertices and a curved hypotenuse

running from the upper vertex E down to the right vertex N, the right angle at the lower-left vertex L.

- E (upper-left vertex): label "E"
- L (lower-left vertex, the right angle): label "L"
- N (right vertex): label "N"

The accompanying text identifies the sides: in the triangle the angle N is given at Gr. 5 (or, by the Tychonic value, 5°), the latitude of the Moon opposite it being $EL = 47'$; therefore the base EN, that is, the lunar [arc] reduced to the ecliptic, [is found], the distance from the nearer of the nodes coming out by the laws of trigonometry at Gr. 9. 3'. 18". Therefore the true place of the node was in Aquarius Gr. 23. 3'. 59", but according to the mean motion the Moon was in Aquarius Gr. 23. 3'. 59" [recte: the node-place $23^\circ 3' 59''$; the two near-identical Aquarius values are as printed].

[7] Likewise, when with P. Grimaldi [Francesco Maria Grimaldi] at Bologna in the year 1643, on the 27th day of September by the Gregorian style — but the 17th by the old style — we observed a lunar eclipse of 6 digits from the north, one hour after midday, but equated [to] 7. 25'. 28". The luminaries then stood thus:

	Sign.	Gr.	I	II
True place of the Sun [Solis Verus locus]	6	4	20	27
Its anomaly [Eius Anomalia]	2	28	56	3
True place of the Moon [Lunæ Verus locus]	0	4	20	27
Its anomaly [Eius Anomalia]	6	16	3	57
Mean motion of the Moon [Lunæ medius motus]	0	3	16	31

[8] The semidiameter of the shadow, corrected, and so the true latitude of the Moon — as in eclipse number 6 of 6 digits — was $48'$. Namely, in the aforesaid triangle, the side EL, with which, and with the angle N at the maximum Gr. 5, the lunar [path] ecliptic [angle] from the node comes out [as] the distance EN, Gr. 9. 13'. 10". Hence the place of the node was in Pisces Gr. 25. 7'. 17"; but according to the mean motion of the Moon, [it was] in Pisces $\propto$ Gr. 24. 3'. 21".

1. Rule concerning the annual motion of the node.

[9] The interval of these eclipses was 862,736 days, 1 hour, 26' 38" — which time resolves into hourly minutes altogether 1,242,341,365'. And in this time, according to the analogy indicated in number 4, the southern node, against the order of the signs, completes 126 zodiacs, and, retrograding from the degree of Aquarius 23.

3'. 59" to the degree of Pisces 24. 3'. 21", traverses Gr. 329. 0'. 38". There are resolved [therefore] 126 zodiacs together with the 329° 0' 38"; in the second [reckoning]: 164,470,931". By these now multiplied per the minutes of one year, 525,600', there is made the number of seconds of the zodiac 86,445,921,333,100"; which number, divided by the aforesaid minutes of the interval, 1,242,341,365', leaves the annual motion of the lunar node, in seconds 69,583" $\frac{82}{1242}$ — that is, Gr. 19. 19'. 43''' 3''' 53''' [recte: 19° 19' 43" 3''' 53'''], not badly [agreeing] with the Tychonic [tables], which have Gr. 19. 19' 43" 4'''. Let this motion be divided per the year's days 365, and there will come forth the daily motion of the node, 3' 10" 38''' 40'''. [Margin: *Annual node motion* — Annuus nodi motus.] [Margin: *Daily node motion* — Diurnus nodi motus.]

2. Rule concerning the motion of the latitude.

[10] Add the daily node motion to the daily motion of the Moon from the beginning of Aries (concerning which, in Chapter 12, number 3), and there will be the **daily mean motion of the latitude**. Add likewise the annual node motion to the annual motion of the Moon (concerning which, in the same place, number 6), and there will be the **annual motion of the latitude**, as below:

Mean motion of the latitude [Latitudinis › Motus Medius]:

	Sign.	Gr.	I	II	III	IV	V
Daily [Diurnus]	0	13	13	45	39	57	16
Annual [Annuus]	4	28	42	45	53	43	20

CHAPTER XV

On establishing the epochs of the lunar motions.

[1] If, out of a single eclipse selected as the most evident among all, the radix of the motions is to be established for the beginning or end of that year, the time of that full moon must be reduced to the equated time, and the true place of the Moon to its place, or mean motion. By adding to this, or subtracting from it, the mean motion corresponding to the interval between the time of the observed full moon and the beginning or end of the year, there will be had the radix of the lunar motion for the end or the beginning of that year.

For example, in the year 1610: a Christmas-eclipse [*Christi Eclipsis*] was observed on December 29; at Bologna the apparent hour was 16. 10', but equated 16. 13'.

20". At which moment the mean motion of the Moon was Sign. 3. Gr. 8. 3'. 47"; the true opposition of the Sun was at sign 3. gr. 8. 22'. 25"; and the anomaly was sign 6. gr. 3. 28'. 15"; and so the equation 18'. 38" was to be subtracted from the true place of the Moon. From that moment to the end of the year there remained 1 day, 7 hours, 46'. 40"; for which there belongs to the mean motion of the Moon Gr. 17. 26'. 47"; but for the anomaly Gr. 17. 17'. 56". Adding these to the mean motion of the [eclipse] moment, there arises for the year 1610 complete:

	Sign.	Gr.	I	II
Radix ☽	3	26	0	34
Anomaly [Anomaliæ]	6	20	46	11

[3] But if a radix of the same years is to be had from several eclipse-observations, sufficiently accurate, it is expedient to inquire after the radix of the same year from several such observations, so that, if a discrepancy be found, one may then choose the one which least of all departs from the observations. For this reason, those who have established their epochs from a single eclipse have never been able to win my approval: namely Ptolemy, Book 4, Chapter 8; Copernicus, Book 4, Chapter 7; Wendelen, in the *Idea Tabularum Atlanticarum*, page 35; and Boulliau, Book 3 of the *Astronomia Philolaica*, Chapter 7. By how many, and which, eclipses Tycho [Tycho Brahe], Longomontanus, Kepler, Lansbergen [Lansbergius], and Petavius established their lunar epochs, [these] do not disclose, but only indicate that, just as their mean motions, so too their epochs of the motions, are derived from several [eclipses]. We, indeed, having brought into the catalogue all the eclipses of Chapters 8 and 9, although [obtaining] differing radices for the years complete by the Gregorian [reckoning], and [for] the epoch of the year 1 of Christ at the beginning, on account of the diversity of the observations—

LIBER II — DE LVNA

and at last, however, after very many labors of calculation, we have noticed that the Radices written below answer more closely and more nearly to most of the eclipse-observations; and therefore we choose them for the meridian of Bologna, at the meridian of the last of December.

[Margin (left): *anno tame.* (i.e. *anni tamen* — abbreviated note, partly cropped) [?]]
 [Margin (left): *us no.* (partly cropped) [?]]

Radix table — Mean Sun [☉] from Aries [♈], and Anomaly:

Radi x	☉ from ♀ Sign.	G r			Anomaly Sign.	G r		
		.	I (')	II (")		.	I (')	II (")
Christ	4	2	3	35	6	2	4	24
1600	7	2	19	20	0	7	27	9
		5						

[The headers "Sign. Gr. I II" denote sign, degrees, first minutes, second minutes (i.e. degrees, minutes, seconds).]

4. Now for the Epochs of the Lunar Node: since, by what was said at Caput XIV, num. 8, in the year 1643, on September 27, at the hour after noon at Bologna equated to 7h 25' 28", the Southern Node was in Pisces at 24° 3' 21" as to the place of the mean Moon — and from there to the end of the year 1644 (which are one bissextile year, and besides 94 days, 16h 44' 32") — by which, for the mean motion of the node, there accrue 24° 23' 48": if these are subtracted from the said place in Pisces, there will remain the Radix of this Northern Node at 10 signs 29° 39' 33". And the Radix of the Northern Node is:

Sign.	Gr.	I (')	II (")
4	29	39	33

Now to this, by adding the motion of 44 Julian Years (which is 4 signs 11° 2' 29"), there results the Radix for the year 1600 in the Gregorian reckoning:

Sign.	Gr.	I (')	II (")
9	10	42	2

5. But from other eclipses, as the Annual motion of the Node is held to be 19° 19' and nearly 3", so the Radix for the year of Christ 1600 in the Gregorian reckoning satisfies more of them:

Sign.	Gr.	I (')	II (")
9	11	22	50

And hence the Radix at the beginning of the Years of Christ:

Sign.	Gr.	I (')	II (")
8	28	51	22

CAPVT XVI.

Eclipses of the Sun Observed, the more suitable however being selected for the Lunisolar motions, and for establishing the diameters of the luminaries: with the calculations of the astronomers added throughout.

Although certain universal notes and characters of the years would suffice for establishing Chronology, and therefore the more numerous Solar eclipses, by whomever observed, would be useful to Chronologers — yet for Astronomers far fewer of them serve the purpose; that is, only those whose magnitude, or more certain mark of time, was observed. Therefore we select only such; and in the computations we will from time to time subjoin those which we shall change as to the distance of the Meridians from those used by the astronomers themselves, since otherwise the Parallaxes of Longitude would have to be recomputed, when the calculation is transferred to different Altitudes of the Pole.

[Margin (left): *Ordo*. ("Order")]

1. [Margin: *Totalis*. ("Total")] In the year before Christ 585, on May 28, there occurred a most celebrated Eclipse of the Sun, inasmuch as it had been predicted long before by Thales [Thales of Miletus] to the Ionians. It was seen around the Hellespont and at Sardis in Lydia, and in both places total, in the sixth year of the war between Cyaxares, king of the Medes, and Halyattes [Alyattes], king of the Lydians, as Eudemus relates in Clemens [Clement of Alexandria], *Stromata* I, and Herodotus, book I — where he adds that, after on that day they had long fought with even fortune, the day was suddenly turned into night.

the same was, but others maintain that the Totality was around the Hellespont, while those of Alexandria in Egypt make it 9 digits and 36 [?], or rather, as Cleomedes maintains, in book 2, cap. 3; and Theon of Alexandria in book 6 of the *Almagest*, cap. 11. Plinius [Pliny], book 2, cap. 12, assigns it to the fourth year of the 48th Olympiad; and so it is accepted by Buntingus, Scaliger, Salianus [in the] Year of the World 1469. Keplerus [Kepler], in the *Optics*, does not contest Lansbergius [Lansbergen], who in the *Thesaurus Observationum* assumes the Third year of Olympiad 48. For from this New-Moon, as being the most nearly preceding the Solstice, the Third year could be reckoned as the fourth of the said Olympiad. Lansbergius adds that it had been the year of Nabonassar 163; and so, as Tycho [Tycho Brahe], and from his own Tables, elicits the Eclipse at 7 digits in the Hellespont, and near Sardis at 4 38' p.m. But at Alexandria at digit 12'. For us, however, by Tycho's New Tables and those of Magini, an Anomaly of the Sun of 1° 8' comes out for the same year, and the day the 28th of May, at the hour at Sardis

of 5h, around p.m., with the Sun in [Gemini] $1\frac{3}{4}^{\circ}$ and the Moon nearly 170° . Calvisius therefore badly advanced this Eclipse into the year 597; and Petavius (whom Iacob Billy follows in the *Tabulae Lodoicaeae*) into the year 597, July 9, since by his own Tables he ends it nearly at highest morning, and the digits at 9 22', near Sardis, because neither [?]; the totality therefore requires that the time of the battle, joined to it, fall out; and they concede that the battle was begun straightway at highest morning — yet it would not last unless after the hour of the Sun, 1 16' after sunrise. Petavius, who computes the Eclipse, supposes 5h 45' p.m. after night, yet that in this year there is sparing... as to the Doctrine of Times c. 1, very many of the opinions about this Eclipse are most learnedly examined; I know that Petavius, book 10, de Doctrina Temporum c. 1; the more common from the year 585, although from the Prutenic Tables [Prutenic Tables] the digits are $11^{\circ} 30'$. From the Parisians, however, the same, that is, the digits $11^{\circ} 20'$; therefore he nevertheless got it most fittingly from those Tables, that it was at 5h 45' p.m. and nearly before sunset, but for the certain outcome on account of the excessive distance of the Meridians, or the fault of the Parisian Tables — since others do not cease, who represent that Eclipse by hours before sunset, by that very year 585, by its totality. Rudolphine, at Sardis, exhibit the totality at 5h 17' 4". Digits 12 1' 36". The Anomaly of the Sun was truer at $359^{\circ} 2'$, and the Moon at 170° .

2. In the year 310 before Christ, when Agathocles, king of Sicily, was carrying his fleet across into Africa against Carthage — namely in the third year of Olympiad 117, as Diodorus Siculus relates, book 20, and Justin, book 22: "So great a darkening of the Sun came about, that it plainly seemed full night, with stars appearing everywhere," says Diodorus. There was very nearly total night. Buntingus, with Salianus, supposes from the Prutenic Tables August 15, and 8 15' p.m. Syracuse, at the digits 11. Petavius from the Parisians [computes] h. 8 2' and digit 11 10'. The Anomaly of the Sun was 74° , around; and the Moon 201° .

3. In the year 217 of Christ, in which Gordian the younger held the imperium [recte: the context refers to the consuls; cf. Iulius Capitolinus] — by the testimony of Iulius Capitolinus — began the Eclipse of the Sun, so that it was believed to be night, nor without lights kindled could anything be done. Keplerus in the *Optics* asserts it total. The Prutenic give less, since the digits are 11. Petavius [places it at] Rome h. 4 51' p. merid., the digit 10. Lansbergen in the *Thesaurus* 12, April 11 h. 5 2' post merid. at Rome collects digits 11 30'; yet he says it was seen Total, because the little particle of the Sun untouched by the Eclipse was near the Horizon. The Anomaly of the Sun was 306° . The Moon 204° .

4. In the year 334 of Christ, with Optatus and Paulinus being consuls, as Firmicus [Firmicus Maternus] says, book 1, cap. 2: "The Sun in mid-day, at the time of the Lunar eclipse, as if by some impediments was deprived of its light, the deadly lights of its [orb] dying" [recte: poetic phrasing] — and that it was added [as recorded] by the Astronomers, and seen as Byzantine too. This Eclipse cannot be drawn out from the Prutenic; and Mulerus [Müller] in the *Isagoge* cap. 11, and Petavius lib. 8, cap. 14, note it. Petavius supposes that one of July 17, h. at Rome 11 12' p. merid., with the digit 10 24'. Lansbergius h. 11 9' and at around the Moon that it appeared somewhere, [a partly] lucid disc with the margin [?], which species of Eclipse we have called Annular in the *Almagest*. The Anomaly of the Sun was at 39°. The Moon 296°.

5. [Margin: *Annular.*] In the year 484 of Christ, on January 13: "The Eclipse of the Sun, [such] that the Day in the night was turned, fell about deep shadows, and the Stars were seen," notes Reinerus in his *Catalogue of Eclipses*; and from the life of Proclus, described by Marinus in Greek, which is asserted... [continues at top of next column on the following folio]

in the library of the most serene M. Duke of Hetruria [Tuscany]. The Anomaly of the Sun was 216°. The Moon 169°.

6. [Margin: *Total.*] In the year 840 of Christ, on May 5, on the Vigil of the Ascension, there was an Eclipse of the Sun: "So great that even the Stars were seen, and the reddish color in the lands changed itself; nor did anything differ in true appearance from night — for the Moon, first receiving its light from a part opposite to the rising Sun, then withdrew its whole [light] as it had received it," as the Anonymous author whom Ludovicus Ph. Hammonius cites, book 3, cap. 19, relates; and the *Chronicon Floriacense*. Petavius assigns the Eclipse at h. 11 22' p.m., and collects digits 9 20', which does not agree with the history. The Anomaly of the Sun was 324°. The Moon 173°.

7. [Margin: *Total.*] In the year 878 of Christ, on October 29 — which was a leap year — of Ludovicus Balbus [Louis the Stammerer], post 9, on the 4th of the Kalends of November: "The Sun obscured itself for half an hour, so that the Stars appeared in the Sky, and all who saw it feared night to be threatening," from Petrus the Librarian, and the *Annales of the Franks*, or those of Fulda. Petavius assigns it the nothing [i.e. none]. The Anomaly of the Sun was at 135°. The Moon 220°. Keplerus in the *Optics* receives it as total.

8. In the year 890 of Christ, but after the death of Alexander [the Great] 1214, and Dhil Karnaim 1202, on the 1st of August, Albateginus [al-Battānī], as Petavius

refers, observed at Aracta an Eclipse of the Sun more than half [the disc], at the eighth hour and one Temporal hour. Petavius supposes at the Parisian [meridian] for Aracta h. 0 46' p.m. and digit 9 22'. The Anomaly of the Sun was at 64°. The Moon 335°. And it has the Year 8.

9. In the year 893 of Christ, on the 23rd of January, or after Alexander, of death 1214, and Dhil-Karnaim 1212, Albateginus, as he refers, observed an Eclipse of the Sun at Syria at h. 1 40', very nearly mid-meridian, and the [Sun] diminished by 9 40'; and h. 2 15' ante merid. it was at Aractae. Lansbergius supposes digits 9 40' and h. 2 15' ante merid. Aractae.

10. [Margin: *Total.*] In the year 1187 of Christ, on September 4: "So great was the Eclipse of the Sun, that the stars per the day appeared as though by night, as the Lycosthenes" — and from the 4th of the Kalends of September. [recte: the date forms here are confused in the source.]

11. [Margin: *Total.*] In the year 1197 of Christ, on the day before the Nones of September: "Gregorius Tholosanus [Gregory of Toulouse], lib. 21, de Republica cap. 27, notes so great an [eclipse] of the Sun, and that the Stars appeared."

12. [Margin: *Total.*] In the year 1239, Gassendus [Gassendi] copies these words out from the *Martyrologium Diniense*, in the *Epicurum* pag. 895: "In the year 1239, on the 3rd of the Nones of June, on the day of Venus [Friday] the Sun obscured itself, so that for that day it was turned to night around mid-day, and the Stars appeared," the same; and being conspicuous and engraved on a stone in a public square.

13. In the year 1415, Gassendus refers from the *Historia Diniensis* as above: "In the Year of the Lord 1415, on the day of Venus [Friday], there was an Eclipse of the Sun, and it endured for nearly one hour; and at its very beginning the Stars were seen most clearly." This Reinholdus, in the *Theoricae*, copies out; Pruteni from the *Polish History* of Matthias Mechouiensis [Maciej of Miechów], as does Origanus in the Preface, Tom. 2, *Ephem.* — relates as contingent at Constantinople in the year 1415, June 7, h. 4 hora 6, in the morning, not only the Stars seen as though by night, but also voices likewise hushed by sudden darkness, the lands obscured. Lansbergius computes 12 11', hour 6 5' post mid-day. The Anomaly of the Sun was at 351, and the Moon 204.

14. [Margin: *Total.*] In the year 1478, July 29, Bernardus Vualtherus [Bernhard Walther] observed at Nuremberg the beginning of the Solar eclipse together with sunrise at 5 14' 30", and its end at 41 30'. In the year 1485, March 16, by the testimony of Lycosthenes: "Fires were lit in the open at midday, and so much

darkness, as even the candles being lit, was diffused." Bernardus Vualtherus observed at Nuremberg an Eclipse of the Sun with the digit nearly 11 ab Austro, h. 4 27' post merid. The Alphonsine [Tables] assign the digits 12 and Kepler in *Opt.* pag. 131. He contends that it was total, although Lansbergius collects by his own Tables h. 4 45'. Norimbergae [at Nuremberg] computes digit 10 56'. Anomaly of the Sun at 170°.

15. [Margin: *Total.*] In the year 1497, on January 18, Bernard Vualther saw at Nuremberg an Eclipse of the Sun, its end at h. 3 24' p.m.

16. In the year 1539, April 18, at Milan was seen the defect of the Sun in the digit 9, as Reinerus refers, and Cardanus.

17. [Margin: *Total.*] In the year 1544, January 24, Gemma Frisius, cap. 18, [says]: "The Radii of the Sun-disc cast obliquely showed a sun-defect at h. 8 53' around p.m., the digit greater than 10 in the lower part," in the Ephemerides supersold.

18. [Margin: *Total.* — second of two paired marks here]

[Margin (right column, top of this folio is given by the previous folio's body): *Total.*]

they had marked. Funccius [Funck] adds, in Keplerus, in the *Optics* pag. 296, that the day began to grow night, and the birds, which first had chirped merrily with full light, fell silent; he estimated that Eclipse at 11 digits. Reinholdus computes it somewhere as total at h. 7 58' p.m.n. at Louvain, digit 1'. The Anomaly of the Sun was at gr. 217. They attribute totality to the Moon by the Eclipse; nevertheless it could be seen as larger, because it was in the morning, and near the Horizon's vapors.

19. In the year 1545, on the 5th of the Ides of June, was observed the defect of the Sun by Gemma Frisius at h. 4 p.m. and digits $4\frac{2}{3}$, from its own Radius [Margin: *Astron.* (i.e. astronomical reference)] cap. 15 and 17.

20. [Margin: *Total.*] In the year 1560, August 21, at Coimbra around midday was seen a horrible Eclipse of the Sun, total, and with delay, as the eyewitness Clavius reports in cap. 4 of the *Sphaera*, where he relates: "The Sun in our time truly hid itself for no brief moment: it showed darkness somewhat greater than nocturnal ones; nor indeed could anyone set a foot anywhere; and most brightly the Stars in the Sky appeared (a thing even marvelous to tell!); and the air from the lands..." [recte: poetic phrasing] ...such foul obscurity fell. P. Emmanuel Vega was present — from whom, or from Scheinerus, in the *Rosa Ursina* lib. 3, cap. 7, [it is] narrated — that it lasted nearly through one and a half hours, with the women

lamenting, and as though the end of the World present, the men clamoring; nor was there ever seen so clear a view of the stars, as the work of the Lucerni [?]; though some men with the lights of those not recognizing, although men knew Ignatius Danes hither; the same at Rome with Ignatius Danes. The instructions, moreover, in his own Preface. The Tables, however, assign it at observation 10' before midday. But from the *Chronicon* of Mercator, Vienna in Austria has it observed at 5 2' p.m., the highest digit 5. From Paulus Fabricius and Tilemannus Stella: Joannes Stadius in the Ephemeris of this year says it was at Brussels its end at h. 1 48' p.m. and Lansbergius in the *Thesaurus* observed the digits 6 31'. At Coimbra, however, he computes the digits 12 4', but adds delay, because the Sun showed long delay, since the Sun contracted [its] Radii, [it was] adduced to view at the digit 12 28', which thing they are accustomed to use for the patronizing of their Hypothesis. Tycho, who admits all total Eclipses, writing for this Eclipse of Clavius as one to be admired and incredible, refers in the *Astronomia Optica* pag. 285. The Anomaly of the Sun was at gr. 64. The Moon, however, at gr. 136.

21. In the year 1567, April 9, Clavius at Rome (as he himself says, in cap. 4 of the *Sphaera*): "The Sun did not entirely defect, but a certain little circle remained shining round about." Tycho, in his letters, against Clavius, who refers from Keplerus on this Optical Eclipse, narrates from sight at Rostock with triple obscured meridian, the digit not plainly 7; but in the *Progymnasmata* computes the digits 8 20'. Maestlinus [Mästlin] at Tübingen observed somewhere from the South, h. 10 25' p.m.n. its beginning, h. 1, ab Austro. Mercator at Duisburg saw the beginning [at] h. 10 25' p.m.n. its end at h. 1. Cornelius Gemma at Louvain saw the beginning h. 10 12', its summit at h. 11 40', its end nearly 9. The Time as though evening, 11 40' end 35' digits nearly 9. Nevertheless Keplerus above, vesp. 35', because this Tables does not exhibit an Annular Eclipse; [in the] surrounding region therefore it refers an Eclipse not differing in contact of the Sun illuminated, [so] that the radii of the Sun refracted at the air, were circumlunar, but [as] Lansbergius collects this Annular Eclipse from his own Tables.

22. [Margin: *Total.*] In the year 1584, April 30, in the old style, Tycho at Uraniborg [observed] h. 5 39' p.m.n. observed an Eclipse of the Sun, the digit 3. Maginus from the Prutenic supposes at Venice the digit 2 25'. Vuendelinus [Wendelen] from the Atlantic Tables collects at Uraniborg h. 5 36'.

23. In the year 1588, February 16, Tycho at Uraniborg [had] the beginning of the Solar eclipse, saw it h. 1 32' p.m. its end h. 2 51'. From the Tyconic schedules Keplerus pag. 414 *Astron. Opt.* expounds the inclinations of the Eclipse.

Maestlinus from the Prutenic computes at Tübingen 57' post merid. and digit 1 10'. But Maginus at Venice [had] h. 1 23' and the digit 1 3'.

24. In the year 1590, July 31, in the new style, Tycho at Uraniborg ob-[served]... [continues at top of next column on the following folio]

observed an Eclipse of the Sun h. 6 51' p.m.n. the digit 4, as in the Epistle to Maginum pag. 81. Directio adding the Prutenic, promised the digit 8. Tycho himself from his own Tables, in the *Progymnasmata*, gives digit 5. Maestlinus at Tübingen observed h. 7 36' ex Prutenicis computavit h. 7 40' and digit 9. Lansbergius at Tübingen supposes h. 7 44' and digit 9. But Maginus from the Prutenic computes at Venice h. 7 57' digit 10 27'.

25. In the year 1591, July 20, in the new style, Tycho at Uraniborg observed an Eclipse of the Sun h. 3 33' p.m. digit 2½; but the Prutenic give h. 4 6' and digit 1.

26. In the year 1595, October 3, in the new style, Tycho at Uraniborg noticed a defect of the Sun at hor. 1 8' p.m. and digit 3 50'. At Tübingen Maestlinus saw the digit 2½. Grati [?] Keplerus the digit 3. Maginus at Venice computes from the Prutenic h. 1 16' and digit 4 14'. But Origanus at Frankfurt and Oderam [Frankfurt-on-Oder] computes Prutenically h. 2 4' and digit 5 18'; but Tychonice h. 1 16' and digit 3.

27. [Margin: *Annular.*] In the year 1598, March 17, in the new style, at Uraniborg, an Alumnus of Tycho's observed an Eclipse of the Sun [at] 44 minutes before midday, and digit 9 minut. 40' alii 40. Tycho himself at Uuandersburg noted the beginning at h. 9 12' p. med. noctem. At Torga, however, in Misnia, Doctor Iessenius observed in the prince's hall this central Eclipse, prominent everywhere, since the Moon was within the margin of the Sun, as Keplerus refers in the *Optics* pag. 299 and 419. Lansbergius computes at Torga h. 10 28' p.m.n. and nearly Annular he found on account of the Anomaly of the Sun [being] 248° in degrees, and of these the diameter [was] 31° 54'; the diameter [of the Sun being] 32'. But he himself at Torga observed the beginning h. 9 12' ante merid., with such darkness that the next was seen to begin. At Frankfurt and Oderam Origanus observed the inter-minute 28' and 46' of the eleventh hour and the digit 9; licet calculo Prutenico collects h. 5 28' and digit 10 55'. Maginus at Venice Prutenically supposes h. 9 45' and digit 11 33' subjoined in the *Tomus Directionum* the same [at] Uraniborg ex Alphonsinis h. 11 44' digit 8 20'. From the Prutenic h. 9 50' digits 11 26' ex Tychonicis h. 11 7' and digit 10 6'.

28. In the year 1600, July 10, in the new style, at Uraniborg is posited Tom. 1, of the *Progymnasmata*, Tycho's Eclipse of the Sun [at] the digits 5 h. 1 44' p.m. But

Benatica in Bohemia, Tythonici cum viderunt l. 1 46' digit 5. At Tübingen Maestlinus [has] the digits more than 5. At Prague Keplerus the digits $7\frac{2}{3}$, h. 1 47', as he has in the *Optics* a pag. 421, and digit 5. Maginus Prutenically computes at Venice hor. 2 14' but at Uraniborg h. 1 47' and the digits hic 4 50' ibi 7 19'. Origanus at Frankfurt Prutenically h. 2 10' digit 5 39' but at Uraniborg h. 1 55' and digit 3 19'.

29. [Margin: *Annular.*] In the year 1601, December 24, in the new style, Lansbergius observed an Eclipse of the Sun [at] h. 1 50' p.m. But there was a distance, now of the Austrine [southern] margin of the Sun from the Boreal [northern] margin of the Moon margins; the Sun, and the Boreal Moon coincided so far, that the whole orb of the Sun was seen [within the orb of the Sun]: thus in the *Thesaurus Observat.* where he computes hor. 1 51'. And the Anomaly of the Sun gr. 176 cum diameter 35' 53". But the Moon gr. 71 with diameter 30' vel optice 28' 30". Keplerus at Prague observed plusquam digit 8, h. 2 53', as in the *Optics* pag. 359 and 413. in the Appendix moreover and the *Progymnasmata* notes the diameter Tythonicam non concordasse with observation. Longomontanus l. 1 *Theoric.* cap. 9, narrates at Piscatorium [Fishery] milliariis 18, ultra Nidrosiam observatam fuisse the Moon to encircle the Sun everywhere, equal, as though three-quarters-digit prominentem, and such an Eclipse type as he himself depicts in the *Andrea Foxio* monstrated to have been at Bergis: from which he contends the diameter of the Moon in the Eclipse to be contracted Optice, the Sun moreover larger, on which is our judgment lib. 3 *Almag. Novi* pag. 376. Lansbergius at Bergis h. 1 52' and the said diameter this phase tueatur. Gassendus in the *Epicurum* pag. 893, since the Moon's diameter could exceed the larger Solar [diameter] by four minutes, refers an excellent appearance of greater view in the *Optics* observed, or by the attenuation of the luminaries; Maginus in the *Directionibus* computes at Uraniborg Alphonsine h. 3 32'. digit 7 36'. Prutenically h. 1 52'. digits 9 19'. Tythonice h. 2. 36'. digitos 9. 33'. Origanus at Frankfurt Prutenically h. 1 57'. digit 9 56'. But Tythonice h. 1 46'. and digit 9 52'.

30. In the year 1605, October 12, at Middelburg the Eclipse of the Sun was observed by Ioanne Rotario [Jan Rotarius] h. 1 15' p.m. digit 10 $\frac{1}{2}$, ab Austro, ut narrat Lansbergen in the *Thesaurus* supputat h. 1 22' and digit 10 38'. At Naples that the total was observed says Keplerus in the *Epitome Astronomicae* pag. 893, and cap. 23, on the new Star. Lansbergius at Naples supposes h. 2 49' and diameter Solis 34' 38". The Moon, however, 34' 52'; and Solem to be contrary [opposite]. *Pueningius* [Wendelen? — *Vuendelinus*] [recte: Vuendelinus] *Foscalarii* [?] in the Province saw the Sun with extreme thinness in the most threaded vestiges Septentrional, except for a thin thread of the Northern part; the

whole Sun obscured, the visible Atmosphere of the disc illustrated tribuit; and adds that at Marseille the whole Sun [was] obscured, the Atmosphere of the disc appearing with dense shadows. Maginus at Venice Prutenically collects hor. 2 55' digits 11 31'. Origanus Prutenically at Frankfurt h. 2 0' digit 10 35' Tychonice h. 2 3 $\frac{2}{3}$ digit 9 25'.

31. In the year 1608, August 10, in the new style, an Eclipse of the Sun [at] Goesa [Goes] was observed by Lansbergius h. 4 7 $\frac{1}{2}$ digit 5 30' ab Austro; ex calculus dat h. 4 8' digit 3 29'. Vultemberg [Wittenberg] Melchior Ioestelius [Melchior Jöstel] observed the digits 2 ab Austro Longomontanus nullam vidit ob aëris crassitiem, ut ipse censet lib. 2 cap. 9. Origanus 1600, [Frankfurt] nullam debuisse esse ex Tychonicis semidiam. sed iis correctis ex Prutenicis computat digitos 1 46', h. 4 40'. Maginus Venetiis Prutenice digits 5 47' and digit 3 14'.

32. In the year 1612, May 30, the Monk Christophorus Scheinerus [Scheiner] observed the defect of the Sun [at] digit 8, h. 11 23' post med. noct. Longomontanus at Hafnia [Copenhagen] cum 7 sociis observed the digits 8, h. 11 7', as Theoricor. c. 9 he has. Maginus Venice deduces Prutenically hor. 11 23' digit 8 38'. Tychonice h. 11 38' digit 7 14'.

33. In the year 1611, May 21, Petrus Gassendus [Gassendi] at Aix [Aquis Sextiis] observed an Eclipse of the Sun h. 8 18' circiter p. med. noct. and digit 9 $\frac{2}{3}$, as he himself narrates in the *Epicurum* pag. 892, and Furnerius lib. 12, *Hydrograph.* cap. 14. Lansbergius at Middelburg computes the same [for] h. 8 18' and digit 11 12'; he himself, however, gives the calculus for h. 8 16' digit 11 11'. The Prutenic calculus Magino [gives] Venice dat h. 8 43' digit 9 20'. But Origanus at Frankfurt h. 8 55' and digit 10 30'. Tychonice ibidem h. 9 6' cum digit 10 44'.

34. In the year 1628, December 16, Baronovae [Baron] P. Io-Baptista Cyssatus [Cysat] observed an Eclipse of the Sun h. 4 19' p.m. digit 8 45'. Keplerus in Austria observed it cum annulo lucido, and vaporoso circa Lunam. Origanus translated the calculus ad Fretum Gaditanum [Strait of Gibraltar] predicted ex Prutenicis h. ibi 2 40' digit [?] 6 34'. But Tychonice minutis 8 ante meridiem, and digits 4 45'.

35. In the year 1629, June 21, P. Rhodes Soc. Iesu in the city of Rum, distance to Tunquin [Tonkin], whichever it is of the kingdom Tunquinici Metropolis milliaribus Italicis 240, sub altitude Poli gr. 18, observed an Eclipse of the Sun semihora circiter ante meridiem the digit 8. Origanus narrates in locis Orientalibus aliquibus the distance from Frankfurt Odera hor. 6 18', and sub latitude Boreali gr. 18, supposes this Prutenically the digit 12, 21' and Tychonice h.

11 26'; quod valde discrepat ab observation in sub latitude majori certainly nor in such a [measure], however, just as he requires here discrepantia [discrepancy].

36. In the same year 1629, December 14, observed by Eclipse of the Sun in America Australis in the Province Mascha sub latitude Poli Australis gr. 10, the beginning saw it h. 1 45' ante meridiem, finis at end post meridiem h. 1 45', et habeo ex litteris nostrorum Patrum ad me. Origanus translated the calculus ad Mediterranea Peruvij sub latitude Australem gradum 27, and the meridian distance from Frankfurt Oderae h. 5 6' collects Prutenically the Eclipse h. 1 ante meridiem digit 11 36' sed Tyconice h. 1 26' quod valde discrepat ab observation, in sub latitude majori, indeed not in so much [a measure], however, just as one requires here discrepantia.

37. In the year 1630, June 10, the Eclipse of the Sun was observed at Dordrecht by Martino Hortensio [Maarten van den Hove] h. 7 15' digit 10, aut paullo plus. But at Middelburg Lansbergius h. 7 10' digit 10. Ex calculus extrahit ipsius Goesae dat quidem digit 10 42' et h. 7 10'. Parisiis Gassendus h. 7 12' observed digit 11 32', as he narrates in the *Epicurum* pag. 885. At Oxonii [Oxford] Baindbrigius [Bainbridge] noted it the beginning h. 5 58' end h. 7 48' p. m. The PP. Andreas Arzet and Io. Baptista Cyssatus at Ingolstadt observed h. 7 54 $\frac{1}{2}$ digit 11 57' p.m. We too at Forum Navij [Forni? / Markt] in the agro Parmensi h. 1 ferè ante occasum Solis vidimus eam digitorum ferè 11 $\frac{1}{3}$. Magi-[nus]... [continues at top of next column on the following folio]

[Bernhard Walther] had computed, by the Prutenic Tables, at 7h 37', with a magnitude of 10 [digits]; at 35' [Origanus] [David Origanus], at Frankfurt, by the Prutenic Tables, 7h 41', magnitude 12 [digits] 8'; by the Tyconic, 7h 47', magnitude 10 [digits] 29'.

38. In the year 1633, on April 8, Fr. Andreas Arzet [Andreas Arzet, S.J.], of the Society of Jesus, observed the solar eclipse at Regensburg at 5h 3', with a magnitude of 6 [digits] 44'. We saw it at Bologna at 5h 15', magnitude 5 [digits]. At Digne [Gassendi] saw it at 4h 42', with 8 [digits] 18'. At Aix-en-Provence [Peiresc] and Gaultier saw it at 5h 41', with 8 [digits] 48'. Fr. Beaugrand [P. Beaugrand] at 4h 20', with more than 6 digits. At Oxford [John Bainbridge], at 5h 19' — concerning which Furnerius treats in Book 12 of his *Hydrographia*, chap. 17. [Origanus] [David Origanus] computes it, at Frankfurt, by the Prutenic Tables, at 4h 37', magnitude 7 [digits]; by the Tyconic, at 4h 30'.

39. In the year 1639, on June 1, [Hevelius] observed a solar eclipse at Danzig at 6h 21 $\frac{1}{2}$ ', with a magnitude of 10 [digits] 48'. In Prussia, Albert Linemann [Albert

Linemann] at 6h, with a magnitude of 20' or 25', [digits] 11 [digits] 30'. At Stettin, [Lorenz Eichstad] at 6h 2', [digits] 10 [digits] 0' — as Linemann reports from memory four centuries later [recte: *quadrennio*, four years later]. [Recte: the source reads 4. *ſæculari* but the sense plainly requires "four years later"; transcribed as printed.] At [Keckermann? — see note] [Keuhelius] [?] (Goes) [recte: *dæ D. Keuhelius*] at 5h 30', [digits] 10 [digits] 20'. At Aix-en-Provence [Gassendi] saw it at [digits] 8 [digits] 10', or 16', and a mid-eclipse of 5h 45', gathered from the phases at 5h 45' — and he refers to it in *Epicurus*, p. 889. At Paris, [Petavius], Roberval, Mydorge, Hardy [?], noted a mid-eclipse at 5h 23', [digits] 9 [digits] 34'. Blaeu [Blesi D. Beaunius — possibly "Blesius" / De Beaune] [?] at 5h 17', [digits] 8 [digits] 30'. At Flexis [Fleche?] [?], the Fathers Deirennes, Battier [Batterus] and Furnerius [?], as he records here in Book 12, chap. 17, observed a maximum eclipse of 5h 18½'. At Rome, [Bertus] [D. Bertus] and Fr. Kircher [Athanasius Kircher] at 6h 10' or 16', [digits] 8 [digits] or 8½ [digits]. In Canada, Fr. [Agathangelus] the Capuchin, at the Residence of the Conception, observed [digits] 4, at 10h 15' in the morning. Fr. Agathangelus the Capuchin, at Cairo, saw no part of the Sun obscured. [Origanus] [David Origanus], at Frankfurt, gathers it by the Prutenic Tables at 5h 54', [digits] 8 [digits] 52'; by the Tychonic, 5h 59', [digits] 10 [digits] 40'.

40. In the year 1645, on August 21, [Gassendi] at Paris observed the beginning...

[The following entries — the bodies of nos. 40, 41, and 42 — are completed in the right-hand column of this folio, beneath the running header *DE LVNA*, and continue around the tabulated observations.]

observed the solar eclipse at 10h 4' p.m., as night fell — as he reports in *Epicurus*, p. 889. At Majorca, [Vicenç Mut] saw its beginning, the Sun being high, at 57° 38' from sunrise, and its end, the Sun also being high, at 62° 20'. At Reims, as Fr. Jacques Billy [P. Jacobus Billy] writes, the mid-eclipse was observed 58' before noon. At Bologna we saw it at 31' p.m., [digits] 4 [digits] 30'. At Rome Fr. Daniel Bartoli [Daniel Bartoli] noted the beginning at 52' before noon. At Prague Fr. Theodorus Moretus, S.J., observed [digits] 6, adding that at Alderbach, on the Danube, [it was] 10' p.m. The mid-eclipse appeared of a saffron color, [digits] 5 [digits] 45'. At Danzig [Hevelius] observed mid-eclipse at 12h 42' after midnight, and, the arc being computed, [digits] 5 [digits] 45'. [Origanus] [David Origanus], at Frankfurt, elicits, by the Prutenic Tables, a mid-eclipse at 1h 2' p.m., [digits] 7 [digits] 23'; by the Tychonic, 30' p.m., [digits] 5 [digits] 24' — but reduced to the Nassau Strait [Fretum Nassovium] by the Prutenic, [digits] 12 [digits] 4'; by the Tychonic, 10 [digits] 38'. [Andrea Argoli], at Rome, gathers from the Danish Tables

a mid-eclipse at 28' after noon, [digits] 4 [digits] 19'. [Montebruno] [Montebrunus], at Bologna, from [Lansbergen], [digits] 35' p.m.

41. In the year 1649, on November 4, [Hevelius], at Danzig, observed the maximum of a solar eclipse at 3h 14½' p.m., [digits] 5 [digits] 45'. Fr. Theodorus Moretus, at Kostelec in Bohemia, noted the beginning at 5h 15', observed mid-eclipse at 2h 3' p.m., [digits] 3 [digits] 33', and [found] the diameter of the Moon to the diameter of the Sun as 4230 to 4150. [Origanus] [David Origanus], at Frankfurt, gives, by the Prutenic Tables, 3h 30', [digits] 5 [digits] 42'; by the Tychonic, 3h 8', [digits] 4 [digits] 44'. [Andrea Argoli], at Rome, from the Danish Tables, 3h 20', [digits] 5 [digits] 19'. [Montebruno] [Montebrunus], at Bologna, from [Lansbergen], 5h 48'.

42. In the year 1652, on April 8, a solar eclipse was observed, in the hours after midnight written below, as is established from the letters [sent] to me, or from the now-published treatises of the observers.

CAPUT XVII.

De Diametris Luminarium Apparentibus idoneis ad repraesentandas Eclipses Solis Totales, & Annulares.

[On the apparent diameters of the luminaries suitable for representing total and annular solar eclipses.]

1. Just as lunar eclipses are eminently serviceable for determining the motions of the luminaries, and at times their diameters, so solar eclipses — total ones, and

especially annular ones — require of the astronomer such a symmetry of the diameters of both luminaries, fitted to the apparent diameter of the Sun and to the anomaly of the Sun and Moon, as the observations of the foresaid eclipses demand. Therefore, to account for annular eclipses, the apparent diameter of the Sun must be greater than the apparent diameter of the Moon at that same moment in each; and that anomaly, which agrees with the motions of both by the tables, [must obtain] at the time of the eclipse. It is not required, however, that the Sun's diameter exceed the Moon's by as much as the doubled width of the little ring, or corona, that appears around the Moon. For part of this phenomenon can arise from the optical enlargement of the Sun's disk, produced by the Sun's rays reflected from the Moon's edge into the air, or into the atmosphere surrounding the Moon.

2. Total solar eclipses, in turn, require, with the anomaly of both luminaries agreeing at the time of the eclipse, that the apparent diameter of the Moon be greater than the Sun's — and the greater, the longer the tarrying of the Sun [mora Solis] in total obscuration shall have been, especially if the eclipse does not occur near the horizon. For that contraction of the Sun — which [Lansbergen] dared to devise to prop up his hypotheses — is supported by no optical foundation. Moreover, although Kepler [Kepler] contends that the stars are seen for a long time [in total eclipse], and that a solar eclipse is not at all total, by contrast a solar eclipse is not seen by everyone, although it be total — for, according to the varying condition of the air, possession of totality is held in doubt, however often observers may assert that the stars were seen by day just as by night. Therefore, if the rest of the necessary safeguards be observed, the diameters of the luminaries can be so commensurate that eclipses of this kind turn out total, and satisfy the observations with greater simplicity and likelihood of truth.

For that reason, as it were to the Lydian touchstone, the diameters of the luminaries are to be tested against the eclipses noted below, by the degrees of anomaly attached in the following little table, or to those nearest them. The *first* column gives the numbers signifying the eclipses, in the same order in which we reported them in the preceding chapter. In the *second* column are the degrees of the Sun's anomaly, which it had at the time of the eclipse. In the *third* column is the apparent [semidiameter] of the Sun, which is most certain for us from what was demonstrated in Book 1, chap. 12. In the *fourth* is the anomaly of the Moon, which it had at the time of the eclipse. In the *fifth* are the limits of the apparent semidiameter of the Moon, necessary for representing the foresaid total and annular solar eclipses. And note that *Ma.* means a *greater*, *Min.* a *smaller*,

semidiameter of the Moon than must be set [for the Sun] — that is, than the solar [semidiameter] expressed in the third column and repeated in the fifth.

15	270	15	4 170 6	Ma. 1 4 5 6
6	324	15	3 173 5	Ma. 1 3 5 5

Use of the preceding table. [*Usus praecedentis Tabellae.*]

3. In the preceding table I have preferred, in the fourth column, the order of the Moon's anomaly to the order of the other quantities, because, the Sun's semidiameter having now been fixed for us, it is necessary to harmonize the Moon's semidiameter so that, in the four annular solar eclipses, it is smaller than the Sun's, while in the remaining total ones it is greater — and yet so that the increment, or decrement, due to the Moon's distance from the Earth is preserved. Thus, for example, with the Moon distant from apogee by 140°, its apparent semidiameter ought to be greater than 15' 55", because at the time of the total solar eclipse no. 7 — indicated in the first column — the Sun, distant from apogee by 135° (as is noted in the second column), had an apparent semidiameter of 15' 55" (as it has in the third column). Otherwise that eclipse could not be represented as total. Hence, if you once posit that the Moon's apparent [semidiameter], at an anomaly of 140°, is greater than 15' 55", then in the remaining greater distances from apogee a still greater semidiameter will result, up to and including degree 173. The Moon's semidiameter, at an anomaly [of that magnitude], will turn out greater than the Sun's.

4. Furthermore, on surveying the tables of other astronomers, you will recognize that not all the foresaid solar eclipses can be represented by them all — for

example, in eclipse 4 the Danish, Rudolphine, and Parisian Tables err, because they make the Moon's semidiameter greater than the Sun's at a Sun-anomaly of 39° ; the Moon at 64° exhibits a Moon-semidiameter greater than the Sun's, when an annular eclipse requires it to be smaller. Similarly the following Tables err in the eclipses written below:

In Eclipse	The Tables that err [Peccant Tabulae]
4	Danish, Parisian, Rudolphine
5	Lansbergian
6	Lansbergian
7	Lansbergian
21	Alphonsine, Copernican, Danish, Parisian, Philolaic, and Rudolphine
27	Alphonsine, Copernican, Danish, Parisian, Philolaic, and Rudolphine
30	Lansbergian

Acutely too, the Marquis Cornelio Malvasia [Cornelio Malvasia, Marquis], at fol. 219 of his *Lansbergian Ephemerides*, frequently noted the excess of the ☉ diameter [in the Lansbergian computation], whatever may be the case as to the method employed by Lansbergen himself, and as indicated at fol. 218.

5. We, therefore, have so ordered the semidiameters of the luminaries that, with the observations of the solar semidiameter being safe — those made and set out in Book 1, chap. 12 — and with solar eclipses, both annular and total, [the proportion] due to them would nonetheless be preserved, [derived] from the distance of the luminaries from the Earth and from the horizontal parallax. Concerning, then, the lunar distance and its parallax in the syzygies, we shall speak in the following chapter.

CAPUT XVIII.

On determining the eccentricity of the Moon's orbit, the lunar interval, the parallaxes, and the apparent semidiameters, both by a circle and by an ellipse.

1. Of all the hypotheses of the *prosthaphaeresis* by which the motion of the Moon is reduced to the truth, none answers more closely to the more frequent observations of eclipses than the one that takes as its foundation an eccentricity

of 8686 parts, the whole eccentric semidiameter being 100000 — and accordingly a maximum equation of the first inequality of $4^{\circ}58'28''$. For the apparent semidiameter of the Moon at apogee in syzygies scarcely exceeds $14'30''$, while at perigee it is $16'22''$. According to more accurate and more recent observers, this same distance of the Moon at perigee in syzygies is 58 terrestrial semidiameters and 20', or at most 21' (as I shall show presently); and the distance at apogee is 64 terrestrial semidiameters, or, as some prefer to work it, 63 semidiameters and 40'. Therefore the difference between the maximum and the minimum distance turns out to be twice as small as the whole eccentricity of 8686 parts — namely, the difference between the center of the apparent motions and the center of the lunar orbit.

2. From this I recognize, with Kepler and Magini [Giovanni Antonio Magini] and most others, that an equipoint [*aequans*] must be introduced into the Moon, and that the eccentricity is to be bisected — so that its half, 4343 parts, falls between the center of the Earth and the center of the lunar orbit, and is the foundation of the *Optical Equation*; while the other half, 4343, lies between the center of the mean motion and the center of the orbit — that is, in the elliptical hypothesis it is the other focus, or navel [*umbilicus*] of the ellipse, and is the foundation of the *Physical Equation*. But before the theory of this equation is set out, the foundation of the distances from the Earth and of the parallaxes must be laid down.

3. Accordingly, in the year 1648, on March 8, when the Moon was at full and nearest to perigee, We, together with Father P. Grimaldi [Francesco Maria Grimaldi] at Bologna, took the distance of the Moon's center from the vertex to be $33^{\circ}55'30''$; and then, from the altitude of Spica at its rising one hour after the meridian at $11^{\text{h}}48'34''$, the Moon appeared (but as equated) at $11^{\text{h}}56'$. And then the luminaries stood as follows:

	Sign.	Gr.	'	"
The Moon's true place [<i>Luna Verus locus</i>]	♍	13	29	17
Its equated anomaly [<i>Anomalia eius Aequata</i>]	5	25	29	37
The Moon's northern latitude [<i>Latitudo Boreal. Lunae</i>]	0	4	48	13
Therefore the northern declination [<i>Ergo declinatio Boreal.</i>]	0	10	58	0
Distance of the equator from the vertex [<i>Distantia Aequatoris à Vertice</i>]	0	44	30	10
Therefore the Moon's true distance from the	0	33	32	10

	Sign.	Gr.	'	"
vertex [<i>Ergo Luna vera distantia à Vertice</i>]				
But it was seen [<i>At Visa fuit</i>]	0	33	55	30
Therefore the parallax [<i>Ergo Parallaxis</i>]	0	0	23	20
And the distance from the center of the Earth in semidiameters T. [<i>Et distantia à centro Terrae semid.T.</i>]	58	20	0	
And the horizontal parallax [<i>Et Parallaxis Horizontalis</i>]		58	50	

From this we deduced that at perigee itself the distance of the Moon is 58 terrestrial semidiameters and 20', or 21' — though at other times, beyond perigee, a somewhat larger value has come out for us. Nor should we trust the numbers we deduced when we were using an uncorrected pole-altitude and incorrect positions of the fixed stars. Likewise, through corrected and limited observations, as is fitting, we find the Moon's apogeal distance in syzygies to be rather 63°40' than 64 terrestrial semidiameters — as we shall show at the end of the chapter.

4. Let the measures written below, then, be ratified for us as the measures of the Moon in conjunction $\odot$ and opposition $\oslash$:

	Semidiam. Terrae [Semidiam. of the Earth]		
Eccentricity in parts [<i>Excentricitas partium</i>]	8686		
Half-part [<i>Dimidia pars</i>]	4343		
Mean distance [<i>Distantia media</i>]	10000	61	
	0		
Apogeal [<i>Apogea</i>]	10434	63	40
	3		
Perigeal [<i>Perigea</i>]	95657	58	21
Horizontal parallax [<i>Parallaxis Horizontalis</i>] — Apog.	54		2'
— Perig.	58		58"
Apparent semidiameter [<i>Semidiameter Apparens</i>] — Apogeal	14'		30"

		Semidiam. Terrae [Semidiam. of the Earth]	
— Perigeal		16	22
Maximum equation in $\circ$ $\circ^o$	Gr. 4	58	28
[<i>Aequatio Maxima in $\circ$ $\circ^o$</i>]			

5. With these laid down, let there be described from the center C a semicircle ALP, or a semi-ellipse, by the device I set out in Book 1, Chapter 11, Problem 4. Let T be the center of the Earth, distant from the center of the orbit C by the half eccentricity CT, 4343 parts. And let the point about which the Moon is supposed to move uniformly be F, distant from C, in like manner by 4343 parts, just as AC is 100000 and AP 200000. And let there be, for example, the Moon in L, to which the lines of mean motion FL are drawn, and so on. The true or apparent angle TL will be the angle AFL, measured not under the arcs of this orbit but under the ecliptic. The Moon's anomaly, or prior distance from apogee A — whose complement to two right angles will be the angle LFT — being thus given, the angle so given is given as data.

Diagram. A geometric construction for the lunar orbit. A vertical line on the right runs from A (top) down through F, C, T to P (bottom); to the upper left the point M lies off the line, with L set between M and the vertical, on the curve of the semicircle/semi-ellipse that bulges leftward from A to P. Lines are drawn from M and from F through L.

- A (top of vertical axis): apogee
- M (upper left): auxiliary point on the line of mean motion produced
- L (on the curve): position of the Moon
- F (on axis, below A): center of uniform (mean) motion
- C (on axis, below F): center of the orbit
- T (on axis, below C): center of the Earth
- P (bottom of axis): perigee

I. Problem: To find the Equation in the Ellipse.

6. If, then, you wish to use the ellipse, produce the line LF to M until LM equals LT itself, and join the extremities M and T by the straight line MT. For then will arise the triangle FMT, of which one part is the isosceles triangle MLT — since ML, being made equal to LT itself, and since by the property of the ellipse any two radii drawn from its foci to the periphery, such as FL and TL, taken together are equal to the whole diameter AP. Therefore in the larger triangle AP, that is, in the

triangle CLF, the data are — there will be two sides FT, 8686 parts, and FM, 200000 parts. And the angle MFT, being the complement of the given anomaly, is therefore given. So through the canons of triangles the third is made known — namely the side CR and FR. And the angle FMT, or the half of it, will be 32 — that is, the [equation of the] first elements of the lunar inequality, the integer equation of the first inequality of the Moon, composed from the Physical CLF and the Optical CLT.

II. Problem: To investigate the Equation in the circle.

7. But if you use a circular orbit, the angle FLT, drawn by the radius CL, must be divided in the triangle CLF; and, the half eccentricity CF, of 4343 parts, being given — such parts as the radius CL is 100000 — the angle CLF, one part of the equation, is given. The complement CFL equals the external angle TCL; since therefore CT, 4343, and CL, 100000, are given, the optical part of the equation CLT is to be sought.

III. Problem: To find the Moon's Distance from the Earth in the syzygies.

8. The first method, whether in the circle or in the ellipse, supposes the given eccentricity, and from the anomaly the angle FLT, and the angle of the integer anomaly's complement, namely TFL. For from these data the line LT, the Moon's distance from the center of the Earth T, is found — but only when the angle FLT is greater than a right angle, the rules of trigonometry bid us use its complement to find...

the sines, or the logarithms; whence comes a smaller radius, and since the distance and the radius must be predicted, the radius is the greater. Accordingly, by however much the distance falls short, by so much must one add to the radius to obtain the required distance — the radius being the greater. But this method itself is hindered by the smallness of the angles near apogee and perigee, so that even given a small error in the equation, the distances err by a few seconds, and elsewhere err enormously. For example, if from the equation of the Moon you use $4^{\circ}53'27''$, the distance of the Moon from the Earth comes out as 97013 parts, of which the whole eccentricity is 8686. But if you use an equation of $4^{\circ}53'30''$, the distance of the Moon would yield 96924 parts, smaller by some 89 parts. It is therefore not expedient to use these angles, but only the angles of the whole anomaly and round numbers, to which the sines or logarithms correspond exactly — nor is it of use to seek the proportional part, since at the beginning and the end of the trigonometric canon it is less exact.

9. But in truth, using only the angle of the anomaly and the eccentricity — although the triangle FLT, being oblique-angled, must be reduced to one, or to two right angles; yet, while we cannot abstract the perpendicular angles, we cannot find the distance TL by sines or logarithms immediately, since these canons of trigonometry have not advanced so far that, given two sides of a right triangle, or given the base of a right-angled triangle and one side, we can by sines or logarithms immediately find the third side. We shall therefore have recourse to the squares of their sides, and the roots, and indeed first in the circular form.

10. Let the Moon be in L, where the three straight lines run to three centers — namely LF to the center of the mean motion, and LC to the center of the circular orbit, and LT to the center of the Earth. Then produce LF, until in R it meets the produced [line] out from C, and let it make with this LF a right angle CRF. Likewise let the same LF be produced further to B, until it meets the [line] produced out from T, and let it make with this LF the right angle FBT. Thus arise two right-angled triangles CRF and TBF.

Now in the prior triangle CRF, besides the right angle R, and the base FC of 4343 parts, the angle AFL is given, since it supposes the integer anomaly; and so also is the angle CFR, the complement of AFL, therefore by sines. And so the other angle, namely CR and FR. The square of the radius CL — which is 10000000000 — is to be taken away from the square of the whole side LR, whose root is the square root of the side LR. From this you subtract the found FR found above, the remaining known side LF, the Moon's distance from the center of the mean motion.

11. With these completed, resolve the triangle TFB, right-angled at B, for in it FT, 8686, is given, and from the anomaly the angle TFB is given in whole degrees; whence the side TB is known, and so the other; the side LB, which when added to LF, will give the whole side LB; therefore the sides LB and TB, squared, will be reduced to a single sum; for they will make a certain square, whose root, when investigated, will give the sought distance of the Moon LT — being the base opposite the right angle LBT, by Element 47 of the first book. Hence it is not difficult to understand how the perpendicular is to be drawn in the inferior part of the semicircle.

12. For the Moon, set in L, and the three straight lines LF, LC, LT being drawn as above, draw out C perpendicular to LF, and in the triangle CFR, right-angled at F, the data being CF of 4343 parts and the angle CFR — the complement of the anomaly — find the other side CR and its square; then subtract from the square of the radius CL, for there will remain the square...

Diagram. A geometric figure for the circular construction. A vertical axis on the right runs from A (top) down through R, B, C, T to P (bottom); the point L lies to the left on the curve of the semicircle. Lines connect L to F, R, B, C, T. The interior point F lies near R and B.

- A (top of axis): apogee
- L (left, on curve): position of the Moon
- R (on axis): foot of the perpendicular from C on LF produced
- F (interior, near R/B): center of mean motion
- B (on axis): foot of the perpendicular from T on LF produced
- C (on axis): center of orbit
- T (on axis): center of the Earth
- P (bottom of axis): perigee

13. Nor indeed does it shame me to illustrate the precept of this latter figure with one example.

	Gr.
Let the Moon's anomaly [<i>Sit Anomalia Lunae</i>]	
That is, the angle AFL [<i>Idest Angulus AFL</i>]	140
Therefore the acute angle F [<i>Ergo Angulus acutus F</i>]	40
And FCR, as FTB [<i>Et FCR, ac FTB</i>]	50
Let FC be of parts [<i>Sit FC partium</i>]	4343
Therefore hence RF [<i>Ergo hinc RF</i>]	3327
And CR [<i>Et CR</i>]	2791 62/100
Square of the side CR [<i>Quadratum lateris CR</i>]	7792142
Radius CL [<i>Radius CL</i>]	100000
Its square [<i>Huius quadratum</i>]	10000000000
From which, subtracting the square [<i>Cui subducto quadrato</i>]	7792142
There remains the square of the side LR [<i>Restat Lateris LR, Quadratum</i>]	9992207858
Whose root is the side LR [<i>Cuius Radix est latus LR</i>]	99961

Add RF, it becomes LF [<i>Adde RF, fit LF</i>]	103288
In the triangle BTF, the angle F, of 40 gr. and T, 50 [<i>In Triangulo BTF, Angulus F, gr. 40. & T, 50</i>]	
And FT [<i>Et FT</i>]	8686
Therefore BT [<i>Ergo BT</i>]	5583 25/100
And BF [<i>Et BF</i>]	6654
Side LF [<i>Lateris LF</i>]	103288
Subtract the side BF [<i>Subduc latus BF</i>]	6654
There remains the side LB [<i>Restat latus LB</i>]	96634
Its square is [<i>Cuius Quadratum est</i>]	9338129956
And the square of the side BT [<i>Et Quadratum lateris BT</i>]	31172681
The sum of these squares [<i>Summa horum Quadratorum</i>]	936932637
Is the square of the side LT [<i>Est quadratum lateris LT</i>]	
Its square root is [<i>Eius Radix Quadrata est</i>]	96795

So great, then, is the Moon's distance LT, namely 96795 parts, such as the eccentric radius is 100000.

14. But in order to fulfill the promise I made at the end of number 4, I select two of our observations made at full Moon with the Moon near apogee. The first was in the year 1645, May 10. The hour, from the altitudes of the fixed stars, appeared 11h53'52" after the meridian; but equated, 11h48'. The conditions of the Moon then were such — the distance of the Moon's center, meridian, from the vertex, with the refraction computed, being 58°53'40":

	Sign.	Gr.	'	"
The Moon's place in the ecliptic [<i>Locus Lunae in Eclipt.</i>]	♌	22	35	40
Equated anomaly [<i>Anomalia Aequata</i>]	11	29	45	0
Northern latitude [<i>Latitudo Boreal.</i>]	0	4	58	22
Therefore southern declination [<i>Ergo Declinatio Austr.</i>]	0	13	37	15

	Sign.	Gr.	'	"
Distance of the equator from the vertex [<i>Distantia Aequatoris à vertice</i>]	0	44	30	10
Therefore the Moon's true distance from the vertex [<i>Ergo » vera dist. à vertice</i>]	0	58	7	25
But it was seen [<i>At visa fuit</i>]	0	58	53	40
Therefore the parallax [<i>Ergo Parallaxis</i>]	0	0	46	15

And hence the distance from the center of the Earth, 63 terrestrial semidiameters and 39' [*Et hinc Distantia à centro Telluris semidiametrorum terrestrium 63.39*].

15. The second was in the year 1646, June 27. For the hour, equated, was 11h55'35" after the meridian. The Moon's center passed through the mid-heaven, and we observed its distance from the vertex, with the refractions removed, as 66°26'40". The remaining conditions of the Moon were as follows:

	Sign.	Gr.	'	"
The Moon's place in the ecliptic [<i>Lunae locus in Eclipt.</i>]	♊	4	52	40
Equated anomaly » [<i>Anomalia » Aequata</i>]	11	25	34	15
Northern latitude [<i>Latitudo Borealis</i>]	0	2	16	55
Therefore southern declination [<i>Ergo declinatio Austr.</i>]	0	21	7	10
Distance of the equator from the vertex [<i>Distantia Aequatoris à vertice</i>]	0	44	30	10
Therefore the Moon's true distance from the vertex [<i>Ergo » vera dist. à vertice</i>]	0	65	37	20
But it was seen [<i>At visa fuit</i>]	0	66	26	40
Therefore the parallax [<i>Ergo Parallaxis</i>]	0	0	49	20

And... [*Et*]

Diagram. A geometric figure for the perpendicular drawn in the lower part of the semicircle. A vertical axis on the right runs from A (top) down through F, C, T to P (bottom); the point L lies to the left, with R and B nearby on the interior. Lines connect L to F, R, C, T.

- A (top of axis): apogee
- L (left): position of the Moon

- R (interior, upper): foot of perpendicular
- B (interior): point on LF
- F (on axis): center of mean motion
- C (on axis): center of orbit
- T (on axis): center of the Earth
- P (bottom of axis): perigee

And hence the distance of the Moon from the center of the Earth is 63 terrestrial semidiameters and 47'. Yet we put more trust in the earlier observation, inasmuch as the Moon was then situated almost at the very apex of apogee; and so we chose the distance of 63 semidiameters 40'.

CAPUT XIX.

On the True Magnitude of the Moon.

1. Since at the Moon's distance of 59 terrestrial semidiameters the apparent semidiameter of the Moon is precisely 16' when the Moon is distant from apogee in syzygies by $14\frac{1}{2}^\circ$, and when it is distant from the Earth by $63\frac{1}{2}$ terrestrial semidiameters, and existing at apogee, it has a semidiameter of $14'48''$, and at perigee $16'12''$ — thus, as observations of solar eclipses, both annular and total, require, after long and elaborate work, we hold that the true semidiameter of the Moon is such as the semidiameter of the Earth is 60. The true semidiameter of the Moon, then, is $16\frac{1}{3}$. But from our *Reformed Geography* the terrestrial semidiameter is $4673495\frac{3}{4}$ paces of the ancient Romans; therefore the semidiameter of the Moon is 1285210 such paces, and the diameter 2570420. But if the diameter of the Earth be taken as 100, the diameter of the Moon will be $27\frac{1}{2}$ of such parts — a little larger than we put it in the *Almagestum Novum*, Book 4, Chapter 27, where we put it at $26\frac{2}{3}$ of such parts. By this proportion, therefore, the remaining measures of the Moon, and of its shadow [*Umbra*], which we set down there, are to be corrected.

CAPUT XX.

On the Latitude of the Moon, the Anomaly of this Motion, and the Reduction of the Moon to the Ecliptic.

1. Besides what we said in Chapter 14 about the motion of the nodes, their mean anomaly, and the equation, we accept the Tychonic, and exhibit it in the tables. We suppose the maximum latitude in syzygies to be 5° , or, as a minimum, $4^\circ58'$ — nearly agreeing with the Tychonic, which in the quadratures is $5^\circ18'$, according to

Book 4 of the *Almagestum Novum*. There too we expound the theory of the latitude in Chapter 12. We expound the maximum latitude of the Moon in Chapter 29, and the reduction of the Moon from its orbit to the ecliptic in Chapter 30. Consult, then, those chapters, lest we be here uselessly prolix in re-treating what has been treated.

BOOK THREE

IN WHICH

LUNAR OBSERVATIONS OUTSIDE OF ECLIPSES

For the Monthly Inequality of the Moon, and for its Variation and Libration.

CAPUT I.

Ancient Lunar Observations outside of Eclipses, from the year 295 before Christ down to the year of Christ 509, with respect to the Places of the Moon in the Heavens.

1. In the year 36 of the first Callippic period, on the 25th day exactly elapsed; or — in Posidonius's reckoning, the month of Nabonassar Phaophi 16, the following day 17 — at the equated hour of 3 hours 24 minutes after midnight, at Alexandria, Timocharis [Timocharis] saw the Moon touching with its northern edge the Northern star of the Front of Scorpius. Ptolemy [Ptolemy], *Almagest* VII.3, says that the Moon was in truth in Scorpius $1^{\circ}41'$, with northern latitude $1^{\circ}20'$, but that it appeared in Scorpius $2^{\circ}0'$, with latitude $1^{\circ}12'$ — which place he assigns to the Moon, and the star to itself.

Lansbergen [Lansbergen], in the *Thesaurus of Lunar Observations*, Class 7, asserts that Ptolemy was deceived: for the culminating degree at Alexandria was $1^{\circ}20'$ of Leo, and the hour from midnight was 2h 30m. He says that the Moon, together with the star, was below the horizon, but seen above it by benefit of Refraction; and that the Moon's true place was in Scorpius $0^{\circ}47'7''$, with northern latitude $1^{\circ}16'49''$, though its seen place was in Scorpius $1^{\circ}38'33''$; and that the latitude of the star Front of Scorpius was $1^{\circ}7'16''$. He further says that the apparent place of the Front of Scorpius was in Scorpius $1^{\circ}26'29''$, with latitude $1^{\circ}15'$. Having therefore computed the Moon's semidiameter as touching the star, [he proceeds]. But Ptolemy says it culminated in the middle of the sign of Leo, and Timocharis says the beginning was at the *tenth* temporal hour, whereas Lansbergen says *Read ninth* [*Lege nona*]. [Margin: *Lansbergen's deceit.*]

This is surely to want to drag the observation to the standard of one's own Tables, and not the Tables to the standard of the Observations. Moreover, that year preceded the vulgar Epoch of Christ by 295 current, and the days [were] 20; on the following 21st of December. [Margin: *Lansbergen's trustworthiness undermined.*] Longomontanus [Longomontanus], however, *On the First Theory* I, chapter 2, says the corrected hour was 3h 30m, and the seen place of the Moon Scorpius $1^{\circ}58'$.

2. In the same year 36 of the first Callippic period, on the 15th of Elaphebolion; or — in the year of Nabonassar 454, Tybi 5, the following 6, beginning at hour 3 — at Alexandria, Timocharis saw the Moon with its extremity, which was toward the eastern rising, reach the Spike; it passed through; Spica separated a third part of the Moon's diameter exactly to the North. Ptolemy, *Almagest* VII.3, says that this was at hour 4 equated before midnight, and that the Moon's true longitude was Virgo $21^{\circ}21'$, with southern latitude $1^{\circ}50'$; but that it was seen in Virgo $22^{\circ}12'$, with latitude $2^{\circ}0'$ — which he likewise attributes to Spica.

Lansbergen, in the *Thesaurus of Observations*, Lunar Class 7, gathering from his own Tables the conjunction of the Moon with Spica after the meridian at hour 8, concludes that the Moon's true place was Virgo $21^{\circ}13'21''$, its seen place Virgo $22^{\circ}3'21''$; and the true latitude $1^{\circ}47'43''$, the seen latitude $1^{\circ}55'15''$. But for a third of the Lunar *diameter* he afterwards employs a third of the *semidiameter* — inconsistent with himself and at odds with Timocharis. That year was before the Epoch of Christ 294, on the following March 9.

3. In the year 47 of the first Callippic period, on the 8th day of Anthesterion; or — in the year of Nabonassar 465, Athyr 29, the following 30, at the end of the third hour — at Alexandria, Timocharis saw the middle of the southern part of the Moon brought to the third part, or to the middle, of the following part of the Virgins. Ptolemy, *Almagest* VII.3, says that this was at the equated hour 3h 30m before midnight, and the true place of the Moon in Taurus $0^{\circ}20'$, with northern latitude $3^{\circ}45'$; but its seen longitude was Moon and star in Aries $29^{\circ}20'$, with latitude $3^{\circ}40'$, very nearly.

Lansbergen, Class 7. He observes that that star is the eastern one of the Pleiades, and the true place of the Moon was in Aries $29^{\circ}55'8''$, but seen in $29^{\circ}8'50''$; and the true latitude $3^{\circ}57'$, the seen $3^{\circ}51'$. That year was before the Epoch of Christ 284, on the following January 29, then 30. Longomontanus, *On the First Theory*, chapter 2, says the hour was 3h 20m, and the seen place of the Moon in Aries $29^{\circ}32'$.

4. In the year 48 of the first Callippic period, on the day of Pyanepsion 6, at hour 9 and a half elapsed, at Alexandria, with Timocharis observing, Spica was seen exactly touching the northern part of the rising side of the Moon above the horizon. Ptolemy, *Almagest* VII.3, says that this was in the year of Nabonassar 466, and the day Thoth 7, the following 8, at the equated hour 2h 30m after midnight; and the true place of the Moon in Virgo $21^{\circ}30'$, with southern latitude $2^{\circ}10'$; but its seen place, and that of Spica, in Virgo $22^{\circ}30'$, with latitude $1^{\circ}15'$; but Spica at $2^{\circ}0'$. Timocharis, however, reported it at hour 4h 7m.

Lansbergen, Class 7. He observes — he gathers from his own Tables the Moon's true place in Virgo $21^{\circ}21'35''$, seen at $22^{\circ}26'47''$; and the true latitude $2^{\circ}20'3''$. But the longitude of Spica he gives as Virgo $22^{\circ}12'21''$, with latitude $2^{\circ}0'$. That year was before the Epoch of Christ 283, on the following November 8, then 9.

Longomontanus, however, *On the First Theory* I, chapter 2, in his Commentary on the Fixed Stars, says the corrected hour was 3h 54m, and the seen place of the Moon in Virgo $22^{\circ}40'$.

5. In the year 50 of the third Callippic period, on the day with the first hour begun and 40 minutes elapsed, Hipparchus [Hipparchus] at Rhodes observed the Moon to be distant from the Sun in the preceding direction by $86^{\circ}15'$. Ptolemy, *Almagest* V.3, says that this was in the year of Nabonassar 620, Epiphi 16, and at the equated hour after the meridian 17h 45m at Rhodes — which is nearly that of Alexandria — and that the Sun was in Leo $9^{\circ}8'20''$; but not in degree $8^{\circ}35'$, as Hipparchus supposed; and that the Moon was in the first quarter. Lansbergen, in the 2nd Class. He observes — he reckons the Sun in Leo $8^{\circ}18'31''$, the Moon in Taurus $12^{\circ}2'52''$, and so the distance $86^{\circ}15'$; but since Ptolemy says the Moon was distant from the maximum longitude of the Epicycle by $257^{\circ}47'$, of which the complement is $102^{\circ}13'$, and that in that situation it is at the maximum of inequality according to the Epicycle — Lansbergen nevertheless says the Moon departed from the eccentric Perigee by 81° , and there occurs nearly the maximum inequality of the Moon. That year was before the Epoch of Christ 128, on August 5, the following 6.

6. In the year 197, at the death of Alexander the Great, on the 11th day of Pharmuthi beginning, at hour 2, Hipparchus at Rhodes observed the Sun in Taurus $7^{\circ}45'$. But the Moon was in Pisces $21^{\circ}40'$ — which truly was in $21^{\circ}43'$ — and so the true distance from the Sun, with respect to longitude, was $314^{\circ}43'$. Ptolemy, *Almagest* V.5, says that this was in the year of Nabonassar 621, at the equated hour 18 after the meridian of day 11 of Pharmuthi, and the middle

distance of the Moon from the Sun $314^{\circ}28'$; and from the maximum of the Epicycle longitude $185^{\circ}30'$.

Lansbergen, in the 3rd Class of Lunar Observations, says the hour was 6h 20m after midnight, and gathers the place of the Sun in Taurus $7^{\circ}40'31''$, and the Moon in Pisces $21^{\circ}23'35''$. That year was before the Epoch of Christ 127, and the days 2 May, the following 3.

7. In the same year 197, at the death of Alexander, on the 17th of Pauni, at hour 3h 20m, at Rhodes, Hipparchus observed the Sun in Leo $29^{\circ}20'$ very closely, but the Moon in Cancer $10^{\circ}54'$. Ptolemy, *Almagest* V.5, says that this was in the year of Nabonassar 621, and at the equated hour 4 after midday, and the distance of the Moon from the Sun $48^{\circ}6'$; but from his own Tables he places the Sun in degree $10^{\circ}40'$ of Cancer. Copernicus [Copernicus] uses this [data], Book IV, chapter 10.

Lansbergen, Class 3. He observes — he gathers the place of the Sun in Cancer $10^{\circ}36'32''$, the Moon in Leo $28^{\circ}42'38''$. That year was before the Epoch of Christ 127, on July 7, the following 8.

8. In the year 12 of Domitian, on the 7th of the month Metroüs beginning, at hour 3 of the night, in Bithynia, Agrippa [Agrippa] saw the Moon with its southern horn occulting the following, Southern part of the Virgins. Ptolemy, *Almagest* VII.3, says that this was in the year of Nabonassar 840, on the day 2, Tybi the following 3, and at the equated hour at Alexandria 5h 20m before midnight; and the Moon by its true motion was in Taurus $3^{\circ}7'$; but in Bithynia $3^{\circ}15'$ apparently, and there too was that star, with northern latitude $3^{\circ}40'$. That year was of Christ 92, on November 30, the following [day].

Lansbergen, Class 7. He observes — he says that this was in the year of Christ 92, and in the months of the leap [bissextile] year 10, and the day 28, and at hour 7h 0m, apparently in Bithynia, the true place of the Moon in Taurus $2^{\circ}25'$; but seen in $2^{\circ}39'31''$, with northern latitude $4^{\circ}21'37''$ — and the star in Taurus $2^{\circ}39'24''$, with northern latitude $3^{\circ}51'$.

9. In the year 1 of Trajan, Menelaus [Menelaus of Alexandria] at Rome, on the day Mechir 15, the following 16, at the exact hour 10, saw Spica of the Virgins entirely covered by the Moon, for it was not visible; but at the end of hour 11 it was seen, in the foregoing manner, distant equally from the centre of the Moon by the horns, but by less than the Moon's diameter. Ptolemy, *Almagest* VII.3, adding that this was in the year of Nabonassar 845, at the equated hour $6\frac{1}{2}$ after midnight at Alexandria, but at Rome 5, and the Moon was in Virgo $25^{\circ}45'$, with southern

latitude $2^{\circ}0'$ — as much as he attributes to Spica also. That year was of Christ 98, on January 10.

Lansbergen, Class 7. He observes — he says that this was in the year of Christ 98, on January 10, the following 11, and at hour 16, apparently at Rome after the meridian. The true place of the Moon was Virgo $25^{\circ}45'29''$, seen $25^{\circ}54'16''$, the true latitude $1^{\circ}22'15''$, seen $1^{\circ}59'49''$; and the longitude of Spica was Virgo $26^{\circ}1'36''$, with latitude $2^{\circ}0'$.

10. In the same year, and on the day 18 of the month, at the eleventh hour of the night ending, Menelaus at Rome saw the southern horn of the Moon in a straight line with the middle, and with the southern part of the Front of Scorpius; but the centre of the Moon truly fell short of that straight line, by as much as the middle was distant from the southern [star], and the Northern of the Front of Scorpius was covered, since it was nowhere to be seen. Ptolemy, *Almagest* VII.3, adding that this was at the equated hour after midnight, the following 6h 10m at Rome, but at Alexandria 7h 30m; and the Moon was in Scorpius $5^{\circ}20'$ apparently, but its true latitude Northern $2^{\circ}10'$; seen at $5^{\circ}55'$; and as the seen places he gives those of the Front of Scorpius, Northern.

Lansbergen, Class 7. He observes — he says that this was in the year of Christ 98, on January 12, the following 13, at the apparent hour at Rome 18; and the Moon's true place was in $5^{\circ}19'52''$, seen $5^{\circ}[?]26''$; and the true northern latitude $2^{\circ}11'22''$, seen $1^{\circ}25'26''$; and that star in Scorpius $5^{\circ}24'36''$, with northern latitude $1^{\circ}15'$.

11. In the year 20 of Hadrian, on the 13th of Athyr, at hour 5h 50m, with the Sun equally setting in Libra $5^{\circ}28'$, Ptolemy at Alexandria, with the Parallactic Rules, observed the meridian distance of the Moon from the vertex to be $50^{\circ}55'$, when it was in Capricorn $5^{\circ}10'$; and from this the true distance was $49^{\circ}48'$; he inferred a *parallax* of latitude $1^{\circ}7'$, *Almagest* V.13, just as in V.12, when the Moon was at the beginning of Cancer he observed the Moon in the Meridian distant from the vertex by $2^{\circ}8'$. Copernicus uses this, Book IV, chapters 15 and 16. The year of Christ was 135, October 1.

12. In the year 2 of the Emperor Antoninus, on the 25th of Phamenoth, in the morning at hour 5h 15m before midday, with the Heaven midway in Sagittarius 4° , Ptolemy at Alexandria, with the Astrolabe, observed the Sun in Aquarius $18^{\circ}50'$, and the Moon in Scorpius $9^{\circ}40'$; and so it was distant from the Sun in longitude $99^{\circ}10'$. Ptolemy, *Almagest* V.3, adds that the Moon lacked a perceptible parallax. The year was of Christ 139, of Nabonassar 886, on the day 9, then 9.

Lansbergen, Class 2. He observes — he places the year of Nabonassar 886, and the Sun in Aquarius $18^{\circ}46'18''$, the Moon in Scorpius $9^{\circ}46'31''$.

13. Again of Antoninus, on the 9th of Pharmuthi, Ptolemy at Alexandria (as he has it, *Almagest* VII.2) observed the Moon distant from Regulus, that from this the place of Regulus might be deduced; but the motion was such that this observation seems useless to me, and proceeds by too uncertain a path; yet they use it.

Lansbergen, in the *Thesaurus*, Class 7, in order to conclude the position of Regulus from the centre of the Moon, in consequence falls short by $57^{\circ}10'$, as Ptolemy and Bullialdus [Boulliau], *Astronomia Philolaica* V, chapter [?], suppose the same distance, and, the parallaxes subtracted, gather the place of the Moon in Gemini $6^{\circ}31'56''$, and conclude that Regulus was in Leo $3^{\circ}42'$. That year was of Nabonassar 886, of Christ 139, the day 23 February.

14. In the year 192 of Diocletian, on the 21st of Athyr, Thius observed that the Moon had got in front of the upper Star of Venus, and was in Capricorn 13° from the Sun, distant from the Sun by 48° . Thus from a manuscript of the Library of the Most Christian King, Bullialdus, Book 3, chapter 12, brings it forth, who says this was in the year of Christ 475, November 18; and he supposes the observation to have been made at Athens at hour 5h 15m after the meridian, and he confirms the conjunction of the Moon with Venus from his own Tables.

15. From the same manuscript, Bullialdus in the same place reports, in the year 225 of Diocletian, Phamenoth 15, the following 16, *after the lamps are lit* [*post accensas lucernas*], that is, at first dusk after the withdrawal of twilight,

it was seen that the Moon followed the bright Hyad by one digit, up to falling short by a half: but it appeared that the Moon itself occulted it, since the Star indeed was placed at the part by which it was bisected, by the very edge of the illuminated Moon; and the Moon, near its true motions, was in Taurus $16^{\circ}30'$. So he observed. Bullialdus subjoins that this was in the year of Christ 509, March 11. And at Athens was observed the emergence of the Eye of Taurus a sesquihour after the setting of the Sun, at hour 7h 20m after the meridian, there; and as the place of the Moon — its true place from his own Tables he gathers in Taurus $20^{\circ}30'26''$; but it was seen in $19^{\circ}52'45''$, the true southern latitude —, whence he concludes that the prior observation was made the more quickly, since the time of the first phase does not square with a sesquihour after the setting of the Sun, but the Eye of Taurus was in $18^{\circ}45'32''$ of Taurus. He adds that it is impossible that the Moon truly occulted the Eye of Taurus. But he is mistaken; for since at the beginning of the night the Moon was now more eastern, were the Hyad the Palilicium [Palilicium], by the semidigit, when the Moon was in Taurus at degree

18°46', it could visibly — and it was able to occult the star with a greater parallax than Bullialdus employs, depressing the Moon toward the setting around the sixth hour after the meridian.

CAPUT II.

Lunar observations of Johannes Regiomontanus [Regiomontanus], Bernhard Walther [Bernhard Walther], Nicolaus Copernicus [Copernicus], and Abraham Zacuto [Abraham Zacuto], with respect to the places of the Moon outside of Eclipses, From the year of Christ 1462 to 1524.

1. In the year 1462, on January 11, Regiomontanus at Rome, at the beginning of the night, when the Moon was seen high at 61°15', and Sirius at 14°30', and Procyon 24°50', saw the Moon distant equally from both, the eye [placed] toward the Eye of Taurus, by as much as the Eye of Taurus is distant from the 13th of the Hyades.
2. In the same year, on January 12, with Sirius high at 26°40', and Procyon at 40°20', the same one, in the same place, saw the Moon joined to the star 19 of Taurus, that is, the extreme of the Southern horn, with respect to longitude, but it seemed more northern by 24 minutes, and that star seemed distant from the southern edge of the Moon by a fourth part of its visual diameter.
3. In the year 1462, on March 21, Regiomontanus at Rome saw the Moon in the Meridian high at 23°, and Jupiter likewise in the Meridian high at 24°30'; and then the Heart of Scorpius [Antares] high at 17°15', and the Moon, with Jupiter and with 7 of Sagittarius, was in one straight line.
4. In the year 1474, Abraham Zacuto, professor of Astronomy at Salamanca, observed Spica, and the application of the Moon to it, in the degree of Libra 17°10', as his pupil Augustinus Riccius [Agostino Ricci] reports in his book *On the Motion of the Eighth Sphere*, chapters 46 and 47.
5. In the year 1478, October 20, Bernhard Walther at Nuremberg, at hour 3½ before the rising of the Sun, saw the Moon distant toward the North from Regulus by about a semidegree; but at hour half before the rising of the Sun, the Moon, near the middle of the Heaven, seemed distant from Regulus by 1°52'.
Lansbergen, Class 7. With the refractions of the Lunar Observations computed, accelerating the rising of the Sun, he says that the prior observation was made at hour 3h 31m after midnight, and the Moon, from his Tables, was in Leo 23°8'10", but apparently in 23°58', with true northern latitude 1°35'. He places Regulus then

in degree $23^{\circ}8'41''$, and so [it was] then conjoined with the Moon — for Bernhard says that distance was [of] latitude.

6. In the year 1482, on January 12. *A second observation half an hour before the rising of the Sun*, says Walther, *the Moon was eclipsing Saturn*; for at that time it was not visible, and beforehand, and after, I noted the *positions written below*. *Since the Moon had been in the last*

quarter, or thereabouts, it certainly was failing at the western part, and when first it was looked at, namely about $2\frac{3}{4}$ hours before the rising of the Sun, Saturn had been more eastern, and as it appeared more southern than the Moon, distant by two Moons; afterward clouds intervened, so that I could not discern the beginning; but I judged it for certain that the Moon had taken Saturn by its southern horn. But after I saw it again, Saturn was distant in diameter by about two digits, or thereabouts, from the northern horn, and so it appeared in turn that it returned: it now passes the middle of this Heaven. At the very time, when I judged the middle of this Eclipse, I took the altitude of the Moon, existing nearly in the Meridian, and I found 32° . Which thing — namely that the Moon first took Saturn by its southern horn — does not seem possible, considering the path I set out above, namely that the Moon first took Saturn; but this indeed evidently appeared, that Saturn was distant in diameter from the Moon at the northern horn by two digits, or it ceased thereabouts. Kepler [Kepler], in the *Astronomia Optica*, page 409, weighed this observation, showing that it was done by the force of the parallax of the waxing of the latitude, and that Saturn, which had thus been more Meridional, afterward became so much nearer to the northern horn, that — wondrous to say, and impossible — it was seen by Walther by the bare motion of latitude.

7. In the year 1486, October 21, in the morning, with Walther observing, the Moon began to cover Regulus, high toward the rising at degree $45'$ [recte: gr. 45° ?]. For it was touching it at the edge. But the exit it was not possible to see, the air being disturbed. So my codex. But Lansbergen, Class 7 of the Lunar Observations, has *the day 20*, and says the hour was 17h 6m after the meridian of day 19, and the Moon was then in Leo $22^{\circ}29'$, but apparently in $23^{\circ}3'25''$, with true northern latitude $0^{\circ}46'10''$, but seen $17'5''$; and Regulus in Leo at degree $23^{\circ}13'44''$, with northern latitude $31'$; but since the Moon's semidiameter was $17'41''$, and added to the latitude it lifted the northern horn of the Moon to $34^{\circ}46''$ [?], it was able to cover Regulus. [Margin: *Lansbergen's error.*]

8. In the year 1487, February 28, Walther has it thus: *At hour 7h 52m after the meridian, namely while the Moon was in the middle of the Heaven, it had latitude*

47 degrees in altitude, and the Great Dog, namely Alhabor, at $23\frac{1}{2}$ in altitude after the meridian, was touching the Moon at its southern horn, the most Northern of the Pleiades. I wonder, therefore, whence Lansbergen, in the *Thesaurus*, and Class 7 of the Lunar Observations, in observation 3, says: *In the year of Christ 1487, when the meridian altitude of the Lesser Dog (not of the Moon) was 47° , Walther observed, &c. The Moon at its southern horn was touching the most Northern of the Pleiades.* Was the Great Dog [Alhabor] perhaps changed into the Lesser Dog? or was the Moon transformed into the Lesser Dog? Moreover, from his own calculation it was more northern. The Pleiades in Taurus $22^\circ 55'$, with northern latitude 4° ; the seen place appearing in Taurus $22^\circ 47'$, with latitude seen $4^\circ 45'$.

9. In the year 1497, Copernicus, as he himself relates Book IV, chapter 27, at Bologna, on the Ides of March, after the setting of the Sun observed the Moon about to occult the bright Hyad, or Palilicium; he saw the Star applied to the part of the Lunar body in shadow, and now disappearing between the horns of the Moon, at the hour nearer indeed to the southern horn, by about a third part of the Lunar diameter. He adds that Palilicium was in Gemini $2^\circ 52'$, with southern latitude $5^\circ 10'$; and so the centre of the Moon appeared to have preceded the Star by half a diameter, and so the seen place of the Moon was in Gemini $2^\circ 36'$, and in latitude $5^\circ 2'$ nearly, but the true place of the Moon in Gemini $3^\circ 24'$, with latitude $4^\circ 35'$; but that then the Moon was distant from the Pole of the Horizon by degree 84.

Hence Lansbergen, Class 7. He observes — he says the hour was 10h 45m from the meridian, but he assumes the altitude of the pole at Bologna [to be] $43^\circ 54'$, when it is $44^\circ 30' 20''$; whence his calculations are corrupted, from which he gathers the seen place of the Moon in Gemini $3^\circ 0' 45''$, with latitude seen southern $5^\circ 30'$; which latitude he assigns to Palilicium, with longitude in degree $3^\circ 15'$ of Gemini.

10. In the year 1522, on the fifth before the Calends of October, at hour 5h 40m after midday, Copernicus at Frauenburg, with the parallactic Rules, observed the distance of the Moon from the vertex [to be] degree $82^\circ 50'$; and, computing from his Tables the true distance of 82 degrees, he deduced the true parallax of altitude to be 50 minutes; thus he, Book IV, chapter 16.

11. And in the year 1524, on the seventh of the Ides of August, at hour 6 after the meridian, the same one in the same place observed the distance of the Moon from

from the vertex $81^{\circ}55'$; but from the calculation it comes out as $80^{\circ}55'$. From this he infers a parallax of 1° . So Copernicus, *De Revolutionibus* IV.16.

CAPVT III.

Tycho's Lunar Observations outside Eclipses, selected with regard to the places of the Moon.

1. In the year 1582, on 25 February at hour $4:2\frac{1}{2}$, Tycho [Tycho Brahe] observed with armillary instruments the western limb of the Moon in Pisces at $26^{\circ}3\frac{1}{2}'$; and from this he computes the place of the Moon's center to be in Pisces 26° . [Margin: Octans 1.] It is, moreover, recorded in the observations recently published at Vienna under the care of Lucius Barretus [Albert Curtz] — that is, *Albertus Curtius* of the Society of Jesus, who enclosed his own name in an anagram — where many other [observations] are likewise contained, but most of them are azimuthal, and not of much precision, as Tycho himself in the end acknowledged. Besides, the times were frequently noted by rotary clocks, which are subject to error; and so I have selected only a few.
2. In the same year, on 26 February at hour $1:37'$, [Tycho] observed the western limb of the Moon in Taurus $9^{\circ}55'$ [as it became] visibly [visible], when the altitude of the upper limb was $48^{\circ}56'$ toward the west; and at hour $2:13'$ he saw the same western limb in Taurus $10^{\circ}10'$, the upper limb being at $51^{\circ}26'$. From this he concludes that the Moon had traversed a space of $33'$ in the interval. He computes the [correction made by] $15'$.
3. Likewise in the year 1582, on 26 February at hour $7:20\frac{1}{2}$, from the Tychonic observations the upper horn of the Moon was seen to be distant from Aldebaran $23^{\circ}12\frac{1}{2}'$, and at that time this horn was seen to be at an altitude of $35^{\circ}15'$; and at hour $7:25\frac{1}{2}$ the same horn was seen to be distant from the Lucida of the Head of Aries [α Arietis] $12^{\circ}18'$, when it was seen at the same altitude of $32^{\circ}36'$.
4. In the year 1582, on 28 February at hour $4:36'$, the Moon was seen at the 90th degree from the Ascendant, and its [upper limb] [Margin: $\square$] was at an altitude of $58^{\circ}16\frac{1}{2}'$, in azimuth from the meridian toward the rising in the east by $14^{\circ}11'$.
5. Again in the year 1582, on 5 March at hour 11, the Moon being situated near the nonagesimal, its limb stood nearer [and] was distant from the heel of Gemini $46^{\circ}51\frac{1}{2}'$, when [the heel] was seen at an altitude of $43^{\circ}40'$; and at

hour 11:5' it ceased to be distant from Regulus 8°25', when [Regulus] was seen at an altitude of 43°20'.

In the year 1587, in January, Tycho exhibits three observations of the Moon in the *Letters to the Landgrave of Hesse*, page 59, together with the Alphonsine and Copernican calculation, as below:

Day of January	H. p.m.	M.	Moon	Longitude — Sign	G r M . .	Latitude — Gr.	M . / B	A
6	9	6:5 8	Observ ed	♐	1 0 ½	4	2 8	A
			Alphon sine		2 0	3	4 9	
			Copern ican		1 4 5	3	5 0	
7	14	13: 40	Observ ed	♑	1 3 0 9	5	5 5	A
			Alphon sine		9 5 9	4	2 4	
			Copern ican		1 6 0	4	2 3 ½	
8	15	15: 5	Observ ed	♑	2 3 5 8 ½	4	1 9	A
			Alphon sine		2 3 4 4	3	3 9	
			Copern ican		2 4 4 2	3	3 8	

But because the Moon had been observed near the nonagesimal from the Ascendant, and the observed longitude coincided with the true longitude, therefore only the discrepancy of the observed latitude from the true latitude — that is, the parallax of latitude — is noted, as below.

[Margin: Parallax.]

January Day	9 — Gr.	M . 14 — Gr.	M . 15 — Gr.	M .
Observed Latitude	4	2 5 8	5 4	1 9
True Latitude of the Moon	3	5 4 9	3 3 5	4 6
Parallax of latitude	0	2 0 9	3 0 0	3 3

9. In the same year 1587, on 18 August at hour 17:25' a.m., Tycho observed the true place of the Moon in Gemini 26°23'; so he himself, *Progymnasmata* vol. 1, ch. 1 — but *Longomontanus*, [*Astronomia Danica*] I.6, puts it at 21½.

10. In the same year, month, and day, at hour 7:25' a.m., he observed the Moon in quadrature [□], and its true southern latitude as 5°13'15". Tycho, in the same place.

11. In the year 1592, on 12 February at hour 8:12', Tycho observed the true northern latitude of the Moon as 16'5"; *Progymnasmata* vol. 1, ch. 1. In the year 1594, in the month of December, Tycho at Uraniborg observed the longitudes and true latitudes of the Moon written out below, which Kepler exhibits before the Ephemeris for the year 1617, page 13, adding that it is most difficult to represent all of them by a tabular calculation.

Decembris — D.	H . M.	Longitude	MS (Sig . . n)	Latitude (Austral/Boreal) — Gr.	A M/ . B
12	1 4:0 0	6	4 4 ♀ 7 5	3	3 A 8
13	1 5:6 1	19	2 4 ♀ 0 0	2	1 A 8
14	1 8:3 4 4	29	5 2 ♂ 0	1	6 B
15	1 9:5 5 6	13	1 5 II 3 0	2	1 B 9
16	2 3:5 0 0	13	4 3 ♀ 9 0	4	2 B 7
17	2 6:0 1	29	4 3 ♀ 4 0	3	5 B 9

Decembris — D.	H . M.	Longitude	» — Gr.	MS (Sig . . n)	Latitude (Austral/Boreal) — Gr.	A M/ . B
18	2 6:3 2 0	14		2 4 𐌆 8 5	3	2 B 8
19	2 7:3 3 6	29		2 5 𐌆 7 0	2	2 B 4
20	2 9:4 6 0	12		3 2 𐌆 0	2	1 A 5
21	2 10: 7 10	25		2 0 𐌆 6	2	1 A 5
22	2 7:4 8 5	7		5 2 𐌆 0 0	3	1 A 1

Boulliau [Ismaël Boulliau], in his *Astronomy* [*Astronomia Philolaica*] III.12, reduced [these] to the mean time of Uraniborg by a calculation adduced from the Tables, in order to exhibit that Variation which the Tychonics ascribe to the Moon in the octants from the syzygies and the quadratures — [maintaining that it is] not always of the same magnitude. He is worthy to be consulted.

23. In the year 1595, on 18 February at hour 5:43' a.m., the true northern latitude of the Moon was observed to be 5°20" by Tycho, as *Progymnasmata* vol. 1, ch. 1 has it.

24. In the year 1596, on 4 January at hour 11:43' p.m., the southern latitude of the Moon was observed to be 4°31', but the true [latitude] 4°59'3", Tycho observing; *Progymnasmata* vol. 1, ch. 1.

In the year 1600, on 10 April, old style, at hour 7:27½, Tycho at the fortress of Benátky near Prague observed the western limb of the Moon to be distant from Regulus 18°19'; and at hour 7:45½' after midday, distant from Procyon 21°18½'. From this he concludes that on 10 April at hour 7:32½ the Moon was in Leo 6°20'22", with southern latitude 1°33'40", as Snel [Willebrord Snel] reports in the *Bohemian Observations*.

CAPVT IV.

Several Lunar Observations of Kepler, Lansbergen, and Longomontanus outside Eclipses, from the year 1598 to 1608.

1. In the year 1598, on 29 March, old style, Kepler [Kepler] at Graz in the evening at hour 8 saw the Moon joined to the western [stars] in the quadrilateral of the Pleiades in such a way that it receded no more than a sixth part of a lunar diameter from the nearest [star]; but it was distant from the bright [lucida] of the Pleiades [by] the breadth of its [the Moon's] body — for the Moon was three days old, tending toward apogee. Kepler, *Astronomia Optica* [*Paralipomena ad Vitellionem*], page 347. Lansbergen [Philips van Lansbergen], in his *Thesaurus*, Class 7, observed: the Moon, from his own tables, is found in the Pleiades in Taurus $23^{\circ}35'$, with northern latitude $4^{\circ}12'$; and the bright [lucida] of the Pleiades in Taurus $24^{\circ}23'$, with latitude $4^{\circ}6'$; and the more northerly Pleiad in Taurus $24^{\circ}2'$, with latitude $4^{\circ}29'$. But the seen place of the Moon in Taurus was $23^{\circ}43'16''$, with northern latitude $4^{\circ}31'57''$. [continues p. 156]
2. In the same year, on 17 July, old style, Kepler in the morning between hours 2 and 3 saw the Moon, with its horns turned away from the Pleiades, so that, [a line] drawn perpendicular [and] from the lower horn, it would graze the Pleiades from above. The Moon had already passed beyond the Pleiades — indeed, beyond the brightest of them — and was distant by more than a Palilician [the distance of Aldebaran]; that is, from the nearest [star] by little less than a [span], with the horns turned toward the rising [in the east], [the Moon] thus passing across the Pleiades. So [Kepler] writes, *Astronomia Optica*, page 347.
3. In the year 1600, on 26 March, old style, Lansbergen at Goes observed the Moon equally at the meridian, distant from the Sun in consequence $89^{\circ}50'$; he judged it to be in Aries $1^{\circ}25'$, and the Sun in Cancer $1^{\circ}15'$, near the nonagesimal, where the seen longitude does not differ from the true [longitude]. But because the Moon was at the eccentric perigee 82° , near which the place is computed in his *Thesaurus*, Class 2, where the tables he uses present [the matter] thus: he himself in his *Thesaurus* finds the Moon's place in Cancer $1^{\circ}15'$, with northern latitude $2^{\circ}18'47''$. He makes no mention of parallax. [Margin: Parallax.]
4. In the same year and day — indeed, at the same hour 6 — at midday at the meridian, [Lansbergen] there [observed] the Moon's meridian altitude of

the upper limb [to be] $64^{\circ}7\frac{1}{2}'$; and because he puts the semidiameter of the Moon at $16\frac{2}{3}'$, therefore he supposes the seen [altitude] of the center to be $64^{\circ}7\frac{1}{2}'51''$ [recte: 64° ? — the printed value chains as $64.7\frac{1}{2}.51$ and the seconds reading is ambiguous], and the true [altitude] to have been $64^{\circ}17\frac{1}{2}'$; and therefore, the altitude diminished, the seen [altitude] of the center [to be] $26^{\circ}30''$, that is, in his *Thesaurus*. [Margin: Parallax.]

5. Likewise in the year 1600, on 26 March, old style, Lansbergen at Goes observed the Moon at the meridian, distant from the Sun in precedence [in antecedentia] $96^{\circ}36'$, because the Sun was seen in Aries $16^{\circ}19'$, and the Moon in Capricorn $10^{\circ}3'$, when it was in degree 89 from the eccentric apogee. From this, and from other observations, he contends that the maximum difference occurs when the Moon is at dichotomy distant from the eccentric apogee 98° ; and that it amounts to no more than $7^{\circ}28'$, as Tycho holds — but he himself [puts it at] $7^{\circ}40'$. So he observed in his *Thesaurus*, Class 2.
6. In the year 1600, on 17 August, new style, Kepler at the border of Styria and Hungary, beneath the pole at $47^{\circ}24'$, in the evening saw the Moon, an hour before its own setting, joined with the heart of Scorpio [Antares]: for it entered with the heart of Scorpio in the more northerly part, so that [it was] almost a third part of the section [that] projected above [the heart], and [the part] hidden below differed but little from a straight line. The Sun was in Leo 2° , yet [the Moon] was seen much broader than that little star [the heart of Scorpio], inasmuch as it intercepted the brighter part of that section, lucid above and [by reason of] the larger remaining part placed beneath. Kepler, *Astronomia Optica*, page 117. Lansbergen, in Class 5 of his Lunar Observations, supposes the Moon there to have been at hour 7:40' at the meridian: at occultation [hour] 8:50', and at egress [hour] 9:40'; and from this, from his tables, he gathers the place [at hour] 8:[?], to have been seen in Sagittarius $4^{\circ}29'$, with true southern latitude $3^{\circ}42'$; the place seen [at hour] 8:17½, with latitude truly southern $3^{\circ}[?]2'$; but the heart of Scorpio in Sagittarius $4^{\circ}30'23''$, with southern latitude $4^{\circ}26'$.
7. In the year 1601, on 29 November, old style, Lansbergen at Goes at hour 11:15' after midday observed the meridian altitude [of the Moon] $61^{\circ}23'$, [and] compared it with the true [value] $61^{\circ}55\frac{1}{2}'$; he sets out the parallax of altitude $0^{\circ}32''$, adding [that] the observation is certain, because [it was] made not many hours [removed] from the very aspect of the section's dichotomy, since the shadow of the Moon at perigee, vividly illuminated by

a higher dioptric instrument, could be discerned in the dioptric instrument set in a lower plane. Lansbergen, in Class 5 of his Lunar Observations. [Margin: Parallax.]

8. In the year 1602, on 26 September, old style, Lansbergen at Goes observed the Moon's meridian altitude $59^{\circ}39'$, and judged it to have been $60^{\circ}12\frac{1}{2}'$; and therefore the parallax of altitude $33'30''$; and because the shadow of the Moon was seen [there]... Lansbergen, Class 5 of his Lunar Observations. [Margin: Parallax.]
9. In the year 1602, on 21 December, new style, in the evening, [Lansbergen] says (Kepler, in his *Astronomia Optica*, page 237) that, not having regard to the quadrature hour, the Moon: "I see [it]," he says, "in dichotomy at an hour and a half after the sixth past midday; but because I had come to the determination of the dichotomy [late]" — for the Sun was in Capricorn $9^{\circ}29'30''$ — "from this I conclude the delineation of the waxing and waning of the Moon [is] such as Albategnius [al-Battānī] teaches in his chapter 51."
10. In the year 1603, on 14 March, old style, Kepler, contemplating the new phasis of the Moon, saw the entire circle of [the Moon] illuminated, [and] that it was deficient at no semicircle. This, however, he demonstrates in his *Astronomia Optica*, page 345: that the Moon's diameter, for the most part, is greater than the Sun's diameter as seen [visualis], and therefore that the whole Sun can be covered by the Moon. [Margin: Diameter.]
11. In the year 1608, on 12 February, old style, Lansbergen at Goes, a third of an hour after the seventh hour of the evening, saw the Moon enter with its dark part into the Palilician [Aldebaran]; the more northerly star of the Moon's center, by a quadrant [dodrans], [was] nearly a semidiameter [from] the Pleiades. So I write, [Lansbergen], Class 5 of the Lunar Observations, where, from his tables, he computes the true place of the Moon in Gemini $4^{\circ}15'$, with latitude seen $4^{\circ}15'52''$; and with northern latitude truly seen $5^{\circ}10'43''$; and the place of the Palilician [Aldebaran] in Gemini $4^{\circ}23'48''$, with southern latitude $5^{\circ}30''$.
12. Likewise in the year 1608, on 12 February, old style, Longomontanus at Hafnia [Copenhagen] in the morning at hour 8:43' observed the conjunction of the upper horn of the Moon with Aldebaran, when the Moon was nearly at quadrature and had withdrawn from the middle course; this same conjunction was seen at Wittenberg at hour 8:46', as Melchior Levitlinus writes; and Longomontanus reports [it] in his

Astronomia Danica I.6, where, from his tables, he computes the longitude of Aldebaran in Gemini $4^{\circ}16'20''$, with southern latitude $5^{\circ}31'$; and the true place of the Moon in the ecliptic [in] Gemini $4^{\circ}16'48''$, where he gathers the parallax of longitude greater than $30'$, since the apparent [place] had been $4^{\circ}16\frac{2}{3}'$ of Gemini, and the seen latitude to have been nearly $5^{\circ}47'$.

Lansbergen, Class 7, observed: he says the Lunar [observation] at Hafnia to have been at $8^{\circ}36'$, not $43'$, because Hafnia he supposes more easterly than Goes by $11^{\circ}15'$, that is, from the place of the Palilician [Aldebaran], or [from] Aldebaran [it] differs from Longomontanus by $7\frac{1}{3}$. Boulliau, in his *Astronomia Philolaica* III, retains [the value] $8^{\circ}43'$ in his narration, because nevertheless the Sun was in Pisces $3^{\circ}42'44''$, and the Moon was at $39^{\circ}45'$ apparent [recte: gr. $45'$? — the printed " 39.45 " runs the degree and minute together; reading ambiguous]; whence he gathers the true altitude $49^{\circ}35'$; therefore he gathers the hour $8:36'$, and, time added, the equation $11'7''$; the mean time at Hafnia [being] hour $8:47'$, at which time, from his tables, he gathers the true place of the Moon in Gemini, with true latitude $5^{\circ}12'43''$, but seen [latitude] $5^{\circ}44'4''$ southern; he adds [that] the Moon had not yet, by the quadrature, reached perigee, as had been supposed nearly $5^{\circ}47'$.

13. Afterward, subjoining the observation of the same conjunction, [Longomontanus] reports it as made by his father in his own *Inniodunum* [Lange's farmstead] at hour 7 in the evening, when the Moon began to occult Aldebaran — "of which conjunction," he says, "we were ourselves a witness when the other limb of the Moon appeared next to the star." He adds [that] the altitude of the pole at Inniodunum is $48^{\circ}1'$; and from his tables [he holds] the occultation to have begun there at hour $6:54'$, the end indeed to have been at hour $7:54'$, and the true place of the Moon [in] Gemini $4^{\circ}31'$; but [as for] whether [the matter] itself is seen, if one pleases, by a manifold practical calculation. [Margin: □]

CAPVT V.

Lunar Observations outside Eclipses by Boulliau, Gassendi, Hevelius, Hodierna, Hortensius, Michael Florent van Langren, and Vicenç Mut, from the year 1623 up to the year 1653, with regard to the places of the Moon.

1. In the year 1623, on 5 July, Boulliau at Paris, at hour $9:30'$ after midday, [observed] Spica occulted by the Moon at an altitude of $17^{\circ}7'$; the Moon being at an altitude of $17^{\circ}20'$. Boulliau, *Astronomia Philolaica* III, ch. 10. He

says that on that occasion Spica was in Libra $18^{\circ}34'$, with southern latitude $1^{\circ}59'$, and the true place of the Moon in Libra $18^{\circ}35'10''$; and the center of the Moon... [continues p. 157]

the latitude of the Moon as seen he held to be $1^{\circ}46'$, the parallax of latitude $59'50''$; and the true latitude $46'10''$. He had observed the center [of the Moon] from the bright northern [star] Spica, distant $1^{\circ}5'$.

2. In the year 1624, in September, Michael Florentius Langrenus [Michael Florent van Langren], cosmographer to the Catholic King, at Brussels, when the equator culminated at the meridian, [observed] the Eye of Taurus [Aldebaran] at $35^{\circ}1'10''$; he saw the Oculus Tauri [Aldebaran] left behind at the dark margin of the Moon. So [Langren] in letters written to me, as I noted above. [Margin: □]
3. In the year 1626, on 3 February, Michael Florentius Langrenus at Brussels, the equator culminating, [observed] the Moon at an altitude of $45^{\circ}12'$; he saw the eleventh [degree] of Taurus, which is above the nose, covered by the dark part of the Moon, and in that very instant a wind arose, [a thing] most difficult, [such] as scarcely anyone has ever excited [discerned], who put a stop to the hour, about... So [Langren] in letters written to me, by himself.
4. In the year 1627, on 22 February, Michael Florentius Langrenus saw the Eye of Taurus [Aldebaran] emerge from the part of the Moon a little higher than the middle of the Caspian spot [Mare Crisium], or [the Sea] of the Caspian Crisium; perpendicular minutes [being] $10\frac{1}{2}'$; Sirius transiting the meridian, from which he gathered [it] to have culminated at hour $9:7'21\frac{3}{4}'$. So [Langren] himself in letters written to me.
5. In the same year 1627, on 18 February, old style, Martinus Hortensius [Maarten van den Hove (Hortensius)] at Leiden at hour $5:36'$ after midday saw, by a telescope, the Heart of the Lion [Regulus] distant from the limb of the Moon by about two lunar digits, or at that time by minutes $5\frac{1}{2}'$; but the center of the Moon [was] more easterly than Regulus, according to longitude, by lunar digits $10\frac{2}{3}'$, and southerly by digits $6'$, [or rather] truly by minutes [recte: digits] $19'$. Lansbergen, in his *Thesaurus*, Class 7 of the Lunar Observations.
6. In the year 1627, on 17 February, Gassendi [Pierre Gassendi] at Digne at hour $10:30'$ after midday, [the] tail of the Lion [being] at its setting at an altitude of $25^{\circ}13'$, saw, by a Basilican [Regulus] telescope, that it touched

the eastern limb [and] the dark part [with] the lower horn, through about a quadrant of the Moon. Boulliau [*Astronomia Philolaica*] III, ch. 12, and Gassendi himself in his *Epicurus*, page 901. But Boulliau takes it thus: the quadrant of that [limb], as the Basilican [Regulus] stood distant from the center of the Moon at its setting, [up] to the highest minute 11'; and therefore he places the Moon's place in Leo 24°59', [and] the true [place] of the Moon in degree 24°55'; and Gassendi saw it to be in degree 24°27'·1", observing it at hour 7:32'. But he prefers this observation, made by telescope, to that made by the naked eye at occultation at hour 9:35', because by the splendor of the Moon the occultation of the Basilican [Regulus] appears sooner to oneself than [it] truly happens. But Gassendi judged he understood the place of the Moon as the one distant from Regulus at its setting, not from the distance of Regulus at occultation, but from the situation by which the Moon touched Regulus.

7. In the year 1633, on 14 February, Gassendi observing at Digne at hour 11:30', the Moon nearest [to] the fully fashioned dichotomy on its obscure part, and at the twentieth or twenty-fifth obscure minute of the limb, beneath the lowest horn the star preceding the most projecting [one] in the tail of Aries; Gassendi in his *Epicurus*, page 902.
8. In the year 1634, on 30 December, Boulliau at Iuliodunum [Jonzac?] near the Pictones [Poitou] in the evening at hour 5:42', [observed] the other [star], Aldebaran, [at] 32°42'; he saw the bright [star] of the Pleiades occupy the margin of the obscure Moon [at] the inferior limb [by] minutes 4'. Boulliau, *Astronomia Philolaica* III, ch. 12, who adds that that star was in Taurus 24°52', with latitude southern 4°8', and the place of the Moon as seen in Taurus 24°18 $\frac{2}{3}$ '; the true [place] in degree [Taurus] 24°17'·53", with latitude as seen northern 4°8'·21"; the true [latitude] in degree 4°45'·48".
9. In the year 1635, on 23 January, [Gassendi] observing, Michael Florentio Langreno [Michele Florenzio Langreno] at Brussels [observed] the Moon occulting Taygeta of the Pleiades, when the equator culminated at degree 132°55 $\frac{2}{3}$ '; and the Sterope of the Pleiades culminating at degree 138°11 $\frac{1}{2}$ '. So [Langren] in letters written to me. But [it was] Taygeta itself, [the] star 33, in southern Taurus, at Bayer [Bayer]. [Margin: □]
10. In the year 1635, on 26 August, Gassendi at Digne saw the Moon, near full moon, approach beneath the preceding star of the two in the tail of Capricorn at the very part of its limb internal, that is, [the part] near the [region] of the spot which we have in our *Almagest* [the *Almagestum*

Novum] noted. Hevelius [Johannes Hevelius] so concludes from the things said by Gassendi in his *Epicurus*, page 902.

11. In the year 1636, on 25 November, in the same [year], Michael Florentio Langreno [Michele Florenzio Langreno] at Brussels observing, when the equator culminated at degree $345^{\circ}8'$, [observed] the knee of the Twins [Gemini] emerge from the limb of the Moon in a line drawn through the mountain Guthschovii [and] Moret, distant from the Moret mountain by as much as Moret is distant from Eugenia.

In our *Selenographia* — that is, in our [own *Almagestum Novum*], the *New Almagest*, lib. 4 — is set forth Guthschovius [as] Ariadaeus, and Moretus, Proclus, and Eugenia Vitruvius.

12. In the year 1637, on 29 March, at Paris in the evening at hour 8:19', Boulliau observing — [the Moon] indeed near sextile of Gassendi — saw Aldebaran [at] degree $20^{\circ}55'$; that is, at hour 8:43'·36". The Moon constricted [strinxit] [it], that is, [the Moon] occulted the angle of the four [quadrilateral] of the Pleiades a quadrant of its southern [part]; for that day the bright [star] of the Pleiades, in the preceding [part], [was] entering at the middle of the bright [star] [from] the angle of the Corner of the Lunar [limbs] from the southern cusp, [it] being seen at hour 9:26'. The Moon occulted the star [at] the angle of the southern limb of the Moon, [at] about the seventh [part] from the southern cusp; and at hour 9:40'. The star at the angle was occulted [and] emerged a little beneath the middle of the Moon, near [the middle] toward the north, nor either so distant [from] the limb [as] more than a dotted [hundredth] of a minute. The Moon occulted at hour 9:54' the bright [star] of the Pleiades [at] three sevenths of the obscure limb; from the southern cusp it emerged 8'; the angle of the northern [limb] emerged [at] the bright [star], one minute beyond — and so distant as 8" — from the bright limb; [the star] which lay in the middle near the angle [at] the northern cusp, and [at] the Sea of the Spot of the Crisium [Mare Crisium], Boulliau in his *Epicurus*, page 902. He adds: Boulliau [*Astronomia Philolaica*] III, ch. 12, at Paris [observed] the highest margin impending over the northern angle of the Pleiades, higher [than] that 8', and in the same azimuth [it was] to have been at that time in Taurus, by the degree $24^{\circ}55'28''$; and at the occultation [at] quadrature in degree $24^{\circ}22'28''$; and the occidental [setting] at quadrature in Taurus $24^{\circ}22'28''$; truly indeed in degree $24^{\circ}56'22''$.

13. But Michael Florentius Langrenus, on the same year and day, on 29 March, at Brussels saw Maia occulted by the Moon, or the more northerly Sterope of the Pleiades, when the equator culminated at degree $140^{\circ}29\frac{2}{3}'$; and the most northerly Asterope of the Pleiades, [the] seventh culminating at degree $152^{\circ}9'18''$; and Electra, that is [at] the angle of the western [limb] culminating at degree $161^{\circ}56'18''$; he reckons the intervals of the temporal [moments] by the oscillations [of the pendulum] perpendicular, or he himself wrote it to me.
14. Likewise in the year 1638, on 14 January, Gassendi at Digne in the evening saw at hour 7:21', the bright [star] of the Pleiades transit near [the] preceding angle of the quadrilateral of the Pleiades, [at] the western angle, nor either so distant [as] more than the tenth part [of] the diameter of the Moon. At hour, indeed, 7:31', [it] touched the southern angle [with] the obscure limb, by about four [of] the parts of the eastern southern [cusp at] the same southern cusp boreal. At hour 8:21', the southern angle emerged, distant from the limb obscure [by] one [of] the twelfth [part] of the diameter of the Moon; and [at] three of the [parts] of the same limb, about a seventh from the northern cusp distant — in the meantime [it] touched the eastern Pleiad. At hour 9:19', the bright [star] of the Pleiades emerged, distant [from] a third of the limb obscure boreal [by] one [of] the diameter of the Moon; and the third [part] of the limb boreal [by] one [of] the diameter of the Moon; the most southern Pleiad emerged [at] degree $10^{\circ}20'$; the most eastern Pleiad emerged from the bright limb, distant; and either part [at] 48 [of] the diameter of the Moon: Gassendi in his *Epicurus*, page 902, and Boulliau [*Astronomia Philolaica*] III, ch. 12, concerning which [I have spoken] in the end of the following observation.
15. Likewise in the year 1638, on 11 December, Boulliau observing at hour 4:37' after the middle of the night, [saw] the Moon, in the part eastern, occult the dark limb [of] the western [star]; [it was] that [star which is] at the extreme pede [foot] of Castor, anteceding [preceding] the other, which lies at the foot of the preceding Twin [Gemini] of Gassendi in his *Epicurus*, page 902. Boulliau likewise [*Astronomia Philolaica*] III, ch. 12. He reports, as Gassendi observed, [that the star is] in Gemini $7^{\circ}3'$ at hour 8:5'; he reckons the place of the Moon as seen [to have been] beneath the fifth [cusp] from the boreal cusp. From this he gathers the center of the Moon to be a fifth minute distant from the star, in longitude existing in Taurus degree $24^{\circ}56'18''$; and so the place of the Moon as seen [to have been] in

Taurus $24^{\circ}51'18''$; and [with] true latitude in degree $4^{\circ}55'$; seen in degree $5^{\circ}44'48''$.

16. In the year 1639, on 13 February, in the same sextile, Gassendi observing the transit of the Moon over the preceding of the two [stars] in the foot of Gemini, at degree $7^{\circ}45'$, having indeed [the Moon at] $10^{\circ}19'$; he noted [that] the [two stars] which were in the same line met [in] longitude, distant [by] minutes 1", from the obscure horn; and so [the place of the Moon] in degree $5''$. Boulliau [*Astronomia Philolaica*] III, ch. 12, [says] this star was in Gemini $7^{\circ}5'$, observing the true place of the Moon in Gemini $28^{\circ}48'48''$; and the parallax in longitude to fall as $5'48''$, [with] latitude $5'22''$.
17. In the year 1639, on 7 April, Boulliau at Paris, [the] high [star] Procyon [being] at degree $33^{\circ}52'$, that is, at hour 9:8', saw the Moon [at] the limb obscure...

Caput V (continued) — Selected lunar observations outside eclipses

18. In the year 1641, on April 13, Boulliau [Ismaël Boulliau] at Paris observed at sunrise that, with the Moon's eastern horn toward the setting point, hour 24 [recte: of the preceding civil reckoning], the fifth-magnitude star which lies in the origin of the northern horn of Gemini was occulted by the lower horn — this being the Tychonic [reading]. The Moon occulted, with two fifth-magnitude stars somewhat obscured from the lower horn, and the Moon's latitude was northern, $46'$. The center of the Moon was 4° distant from the preceding [star] of Gemini, in $4^{\circ}13'$; whence by Boulliau, lib. 3, cap. 12, where the star is said to have been in Capricorn, gr. 29, $5'$; with the latitude seen, Bor. gr. 4, $41'$; and from this the Moon's place is seen in Capricorn $29^{\circ}40'54''$, with the latitude seen gr. 4, $8'$. Bor. & Parallax, longitude $9'13''$, latitude $32'$.

19. In the same year 1641, and in the month of April, Michael Florentius Langrenus [Michael Florent van Langren] at Brussels observed the eye of Taurus in a straight line with the maculae, which he himself culminated in his *Selenographia*, with the equator at $149^{\circ}26'$. As I have it in writing addressed to me.

20. In the year 1641, on June 24, Boulliau at Paris, also toward sunset, Arcturus gr. $41^{\circ}37'$. He saw the third-magnitude star which lies lower in the horns of Capricorn next to its margin; whence by Boulliau, lib. 3, cap. 12, the star is said to have been in Capricorn gr. 29, $5'$; with the latitude seen Bor. gr. 4, $41'$; and from

this the Moon's place is seen in Capricorn gr. $29^{\circ} 40' 54''$, with the latitude seen gr. 4, 8'. Bor. & Parallax, longitude $9' 13''$ [recte: $9' 13''$], latitude $32'$.

21. In the year 1643, on October 2, with Markab in the meridian of Brussels, Michael Florentius Langrenus observed the eye of Taurus in a straight line with the maculae which he himself in his *Selenographia* calls Promontorium Bæri, and Mons Bæri, so that the eye of Taurus would be a little more remote from Mons Bæri than Promontorium Clavij is distant in the same Bæri. Thus he wrote in his letters. With us, in our *Selenographia*, Mons Bæri is called Hercules, [the place] distant; the latitude is in the macula, the particular of 7, since the lunar diameter appears to be 200. And so the eye of Taurus is then more western, and at egress from the Moon.

22. In the year 1643, on November 10, at hour 7, at midnight, Johannes Hevelius [Johannes Hevelius] at Danzig saw with the telescope the last Phase of the aged Moon, the day before the conjunction in 2 gr. of Scorpio (*Selenographia*, cap. 44).

23. In the year 1643, on November 26, at hour 11 after noon, Johannes Hevelius at Danzig saw the Moon decrease in its horns by the opposite movement; nor more than 30 hours after the flux it had already sensibly decreased; the telescope showed [it]. (*Selenographia*, cap. 27.) Here he refuted Biancani [Giuseppe Biancani] and Argoli [Andrea Argoli], thinking this decrement by no means double, since indeed it can be discerned by opposition on different days. And he learnedly demonstrates that it does not always appear from the lower limb of the Moon when this decrement appears.

24. In the year 1644, on April 13, at hour 9 after noon, Hevelius at Danzig observed the Moon in the first quadrature, in the chart cap. 23, around the maximum Libration, and yet the lines of the sections separate the obscure parts from the luminous, notably differing at a determined center of the tenth lunar day, by that part of the lunar diameter. Which he himself attributes to libration, cap. 18 (*Selenographia*). But to this concurs the equation of parallaxes.

25. In the year 1644, on October 8, at hour 7 after noon, Hevelius at Danzig observed the Moon before the true quadrature, of which the lines of the sections separate notably; it would exceed the center of the lunar disk, so that it would already appear in much greater [degree], the seventh lunar day having been completed (*Selenographia*, cap. 18).

26. In the year 1644, on November 13, Hevelius at Danzig observed the eclipse of Palilicium [Aldebaran] by the Moon, beginning to be occulted at hour 3, minute 5; at the middle of the eastern limb; emerging at hour 4, 5'; above the middle of the

western limb, & hour 4, 10' ½. Palilicium distant from that limb, in the duodecimal parts of the lunar diameter (*Selenographia*, pag. 472).

27. In the year 1645, on April 5, on feast-day 5, hour 8, in the evening, Hevelius at Danzig saw the first Phase of the Moon, the other after [continues].

A new full moon, with the Moon in Taurus, the sign of long descensions, and in Perigee, and in maximum austral latitude, elapsing toward the conjunction with the Sun at hour 42 (Hevelius, pag. 278, *Selenographia*).

28. In the year 1645, on October 8, Hevelius at Danzig observed the eclipse of Palilicium by the gibbous Moon, beginning to be covered at the eastern limb, the dimidiation [half-disk] of the limb also remaining; at the other higher limb gr. 38, 48'; it is here at 1, 47'; nevertheless at night, an emersion at the middle of the western limb above the bright shoulder of Orion gr. 38, 45'; namely hour 2, 57'; & the line seen most assuredly from the lower center of the Moon, to which time the middle of the Tychonic [reading] would have been; it was hour 1, 14'; hour vero 3, 30'. The Moon arrives at the nonagesimal of the Ecliptic (Hevelius in *Selenographia*, pag. 473).

29. In the year 1645, on November 17, Hevelius at Danzig saw the aged Moon's last phase at hour 27, before the conjunction; for the Moon was turned in gradu 13 Scorpio; and in maximum northern latitude (Hevelius, *Selenographia*, cap. 43).

30. In the year 1645, on December 2, with the Moon in Perigee & in opposition to the Sun, the eastern limb being occulted; the Moon high & rising gr. 43, 30'; from the southern limb, so that the middle of the western limb, rising in the west, would emerge higher gr. 49, 28'; D. Vicenç Mut [Vicenç Mut] at Majorca observed; & wrote it out to me.

31. In the year 1647, on April 8, D. Vicenç Mut at Majorca, with the high Auriga toward sunset gr. 35, 14'; that is, hour 8, 19'; saw with the optical tube the appulse of the Moon at the Hyades star, which is higher in the southern horn of Taurus, that which the star seen at ingress [obscured] by nearly the third part as the Moon's dark Septentrional [edge] (*Just as in the letter to me*).

31 [bis]. In the same year 1647, on April 12, D. Vicenç Mut at Majorca saw Jupiter entering the northern part of the Moon, high toward sunset of Regulus gr. 57, 18'; that is, hour 9, 56'; then the egress of Jupiter & the Moon obscured, the Moon high to Regulus toward sunset gr. 49, 12'; namely hour 10, 48'; so that it would have lain hidden for 52 minutes. *So the same man in his letters to me.*

33. In the year 1647, on June 6, Hevelius observed the high Lyra gr. 53, 16'; that is, hour 10, 10' ½; at Danzig, by the corniculated [reading] in the straight line drawn through the apices of the Moon's horns, & distant from the lower cusp, the fifth part of the lunar diameter. So he wrote, & engraved it in a most beautiful schema (Hevelius, among other things most liberally transmitted to me).

34. In the year 1650, on August 4, with the Moon in the very nonagesimal, around the quadrature, & nearly with the full latitude, D. Vicenç Mut at Majorca with the naked eye saw the Moon still hollow [cava], but with the optical tube not hollow at all, the hour being 9, 30'; its lines of section remained in the straight-line section of the dichotomy; but the relics of the parts, except at the horns, were somewhere hollow, somewhere running forward toward the line of section of the dichotomy toward the west, & still at hour 10, 15'; with the naked eye the hollow [Moon] would be seen somewhere as in Kepler [Kepler], *Astronomia Optica* pag. 237. So through the quadrature hour the Moon was seen still hollow. So D. Vicenç Mut wrote in the same year to me, whose many Epistles full of Astronomical erudition I preserve.

35. In the year 1653, on the 19th day of May. D. Io. Baptista Hodierna [Giovanni Battista Odierna], the most expert Sicilian Astronomer, after — as in the *Almagestum Novum* — the dichotomies & the Dichotomy of the Moon had been indicated, [found] the Moon depending on the Dichotomy beneath the meridian at 15, 46'; in the meridian of Palma, which lies between Gela the more eastern, & Agrigentum the more western; for then the line of the section of dichotomy persisting toward the western Margin of Anaxagoras, & cut in two Archimedes, & Alpetragius; in the luminous part there were still the whole Plato, & Tycho, & the western margin of Cunium, & the whole Biancanus. See in lib. 4 of the *Almagestum* [Novum] the situation of the new maculae. And so, with Aquila culminating with gr. 39¼ at hour 8 of the night, 15, 46'; the Moon was seen perfectly dichotomous with the horns prominent. He admits, nevertheless, that it is difficult to discern with certainty in this Phase the deception of the half-hour. It is also in his most courteous & most learned Epistles to me, which I preserve.

36. In the year 1654, on May 1. With D. Vicenç Mut at Majorca observing, the Moon began to cover Regulus, high & toward sunset, & Rigel gr. 34, 16'; that is, hour 8, 6' ½. Regulus emerged from the Moon, high toward the western reddish shoulder of Orion, that is, hour [continues].

CAPVT VI.

Continuation of the heading running into the upper margin of the table page:

... 9' 7". The Angle of the Ecliptic & of the Moon's path was gr. 12; & thus the Moon was seen in Leo at gr. 24, 48', with northern latitude. Let it have been to Lansbergen [Philips van Lansbergen] in gr. 25, 24', with latitude 34' 15". To the Danish [tables] indeed, & to Argoli [Andrea Argoli] in gr. 24, 57'; & to Boulliau in gr. 25, 2'; with the latitude seen 35, 45'. Thus Mut [Vicenç Mut] in his most erudite letter addressed to me.

Table title (printed as a vertical block in the source): *A table is here presented of XXIV Lunar Observations with the calculation of Ismaël Boulliau, which he himself promised in Lib. 3, cap. 12 of the Astronomia Philolaica*, but afterward deferred to page 175 of his* Tables*. And it has been reduced by Io. Boulliau to the mean time, [and] reduced to the Meridian of Uraniborg [Uraniborg]. The remaining X [observations] are by D. P. Gassendi [Pierre Gassendi].**

The 24-observation table follows. **In the source it is printed rotated 90° counterclockwise** (see Parsing notes). The columns are: index; Year [*Anni*]; Month [*Menses*]; *Temp. Med.* (mean time: D[ay]·H[our]·I[']·II["]); *Locus Solis verus* (Sig·Gr·I·II); *Locus* › *secundo Aequatus*; *Locus* › *observatus & reductus*; *Differentia* (of the equated from the observed); *Anomalia simplex*; *Distantia Lunae à Sole*; *Motus latitudinis aequatus*; *Reflectio maxima in limite & futura* (Add./Subtr.); *Differentia variationis observatae à Tychonica*.

The bracket note in the *Menses* column spans the eleven 1594-December entries — rows 4–14 (*Decemb. I* through *XI*) — and reads: "**Haec XI. loca observata sunt Anno 1594. Decembri diebus stylo veteri.**" ("These eleven places were observed in the year 1594, in December, by the old style.")

Zodiac sign glyphs in the Sig. sub-columns are rendered by their standard abbreviations (♈ Ari, ♉ Tau, ♊ Gem, ♋ Cnc, ♌ Leo, ♍ Vir, ♎ Lib, ♏ Sco, ♐ Sgr, ♑ Cap, ♒ Aqr, ♒ Psc). The *m.* / *p.* prefixes on the *Differentia* and *Diff. à Tychonica* columns (= *minus* / *plus*) are transcribed as printed.

CAPVT VII.

Selected Lunar Observations out of many made at Bologna by the Fathers Io. Baptista Riccioli [Giovanni Battista Riccioli] & Franc. Maria Grimaldi [Francesco Maria Grimaldi] of the Society of Jesus, for the Moon's places outside Eclipses.

1. In the year 1642, on April 14, the night following, an eclipse was observed, of which see the eclipse observations; that part of the night, the meridian altitude of the Moon's center was seen gr. 35, 31'; and from the transit of Arcturus the [stars] were numbered by M.C. perpendicular 28° 16'.

2. In the year 1642, on June 18, the night following, minutes 34½; after the transit of Aquila across the middle of the Heaven, the meridian altitude of the Moon's center was seen gr. 24, 25'; the same center from Fomalhaut [Fomalhaut] gr. 33, 18' apparent, & after three minutes of time the altitude of Fomalhaut was seen gr. 20, 4'.

3. In the year 1642, on July 7, the night following, the meridian altitude of the upper limb of the Moon was seen gr. 10, 28'; from the transit of the middle Star in the front of Scorpio we numbered 44° 5'. On the eighth day truly the night following [it] was seen gr. 27, 18'; from the transit of the lower horn of Scorpio per M.C. we numbered 11° 40'.

4. In the year 1642, on July 15, the night following, from the transit of Fomalhaut per M.C., the eastern margin of the Moon waxed [flowed] gr. $42^{\circ} 26'$; & then the altitude of the lower limb of the Moon was seen gr. $47, 14'$; & from the physical rising of the Sun we numbered $42'$.
5. In the year 1642, on July 18, in the morning at sunrise, the meridian altitude of the Lunar center was seen gr. $51, 59'$; & after 2 times, the altitude of the center was seen gr. $7, 2' \frac{1}{2}$.
6. In the year 1642, on August 6, in the evening, from the transit of Ophiuchus we numbered $14^{\circ} 8'$; & after the transit, the meridian altitude of the Lunar center was seen gr. $25, 55'$.
7. In the year 1642, on August 16, in the morning, the altitude of the upper margin of the Moon was gr. $56, 24'$; & a little after, [that] of the lower margin gr. $55, 56'$; then after $2'$, the Lucida of Aries transits per M.C.
8. In the year 1642, on August 20, in the morning $24' \frac{1}{2}$, before sunrise, the Moon was seen with its northern & eastern horn distant from the eastern Capella gr. $20, 27'$; the altitude indeed of the western horn of Capella was gr. $30, 29'$.
9. On the same day, in the morning $21' 18''$, after the transit of the Lucida of Aries per M.C., the Moon's center was seen distant from the bright shoulder of Orion gr. $10, 12' \frac{1}{2}$; & after the time $2' 50''$, it was distant from Rigel [Rigel] gr. $47, 57'$; & for exploring the refractions the times are to be noted in the times written below, & the altitudes seen [as follows].

Tempora post transitum lucidae Υ per M.C.	Altitudo visa centri Lunae orientalis

10. In the year 1642, on August 23, in the morning 48'; before the true rising of the Sun, the Moon's center was seen distant from the bright shoulder of Orion gr. 41, 16'; & after 4 min. distant from Rigel gr. 56, 21' ½.

11. In the year 1642, on October 15, in the morning, from the transit of Sirius per M.C., namely from hour 7 after noon, 17, 12'; we numbered 18' 52"; in which end the Moon's center was seen distant from Sirius gr. 34, 10'; whence we numbered 7' 42"; & then the altitude of the Moon's center was seen distant from the bright shoulder of Orion gr. 23, 47'; whence to the meridian transit of the Lunar center we numbered 10' 16"; & then the meridian altitude of the Moon's center was seen gr. 62, 14' ½; & not long after the beginning of Cancer, opportune for exploring parallaxes. The hour was 17, 49' p. merid. of day 14.

12. In the year 1642, on October 19, in the morning, minutes 5' 10"; after the transit of Sirius per M.C., the Moon's center was seen distant from the heart of Hydra [Cor Hydrae] gr. 20, 38'; whence after min. 7' 12"; it was seen distant from the tail of the Lion gr. 20, 19'.

13. In the year 1642, on October 30, in the evening, at the same moment in which the western bright altitude of Aquila was seen gr. 51, 21'; the Moon's center transits per M.C., & its meridian altitude was seen gr. 30, 49'; the hour was 7, 56' 16"; after noon.

14. In the year 1642, on November 2, in the night, the meridian altitude of the Moon's center was seen gr. 43, 14'; from which transit we numbered 5' 37"; we captured Aldebaran [Palilicium] in altitude gr. 24, 9'.

15. In the year 1642, on November 10, in the morning under the civil hour 11½; when the Moon would be in the beginning of Cancer, & the southern limit was taken nearby, the altitude of the western [limb] was gr. 58, 37'; from this the transit of Procyon per M.C. was 4' 16"; & then the meridian altitude of Procyon was gr. 51, 36'.

16. In the year 1642, on December 5, the night following, the meridian altitude of the Moon's center near the full Moon was gr. 62, 41'; from this to the transit of Rigel per M.C. we numbered the meridian altitude [which] was gr. 36, 49' 50".

17. In the year 1642, on December 16, the night following, from the transit of Procyon per M.C. we numbered min. 27' 41"; the center of the Moon transits per M.C. & was seen distant from it by 2 altitudes, in the meridian by two observations gr. 61, 12'; whence we numbered min. 27' 52"; the Moon near the full

Moon would be seen high gr. 60, 36'; at sunset, & near the beginning of Cancer, & not long from the Apogee.

18. In the year 1643, on January 31, the night following, from the transit of the Lunar center per M.C., the altitude of its meridian was gr. 68, 8'; we numbered min. 6'; & then [the altitude] of the eastern Procyon, gradum 50, 17'; whence, would the Moon be in gradu nearly 9 of Cancer, & in the very Nonagesimal, it could from this elicit parallax.

19. In the year 1643, on February 3, in the evening, two minutes before the transit of the heart of Hydra per M.C. — that is, the very thing — at hour 12 after midday, the altitude of the meridian center of the Moon was seen gr. 57, 20'; when it would be in the Apogee, & at the hour around the full Moon, two minutes or so from the full Moon.

20. In the year 1643, on February 12, in the morning a little after Quadrature, the meridian altitude of the Moon's center was seen gr. 29, 14'; whence we numbered min. 5' ½; the rising altitude of the heart of Scorpio was seen gr. 19, 50'; the Moon would appear already hollow at about half [an hour].

21. In the year 1643, on March 5, the meridian distance of the Moon's center from the vertex was seen gr. 57, 36' ½; the hour after midday 12, 21' 34"; & it was established from Regulus.

22. In the year 1643, on March 13, the Moon was seen in the Meridian gr. 26, 40'; at the same moment the rising bright Aquila toward the height was gr. 42, 41'.

23. In the year 1643, on March 26, in the evening the altitude of the Moon's center was seen gr. 63, 19'; whence to the transit of Procyon per M.C. there flowed 80'; in the end of which the meridian altitude of Cancer was gr. 51, 37'. On the day following, the meridian altitude of the Moon was seen gr. 62, 40'; whence we numbered min. 11'; the altitude of Procyon toward the rising gr. 51, 24'; on the same night by my request P. Theodorus Moretus [Theodorus Moretus, S.J.] at Breslau, where the altitude of the Pole [is] gr. 49, 21'; observed the Meridian altitude of the Moon gr. 57, 17' 25"; finally on day 28, the meridian altitude of the Moon's center was seen by us gr. 58, 59' 15"; at the same moment the altitude of the rising austral Cancer center [was] high gr. 51, 45'.

24. In the year 1643, on April 3, the night following, the meridian altitude of the Moon's center was seen gr. 41, 30' ½; whence we numbered min. 9' 41"; the altitude of the rising Spica [Spica] gr. 35, 48'; whence we shall then reckon the

hour after midday [to be] 11, 52' 44"; & therefore the transit of the Moon was at hour 11, 42'.

(Caput VII, "Lunares Observationes selectae... pro Lunae locis extra Eclipses," continues. The numbered entries are Riccioli & Grimaldi's selected Bologna lunar observations.)

25. Year 1643, June 7. In the morning the Moon, near perigee [perigeum], was seen on the meridian at an altitude of $32^{\circ} 38'$. From there to the observed altitude of the Sun, gr. $8^{\circ} 6'$, 60' 10" of time elapsed; [Margin: Perig.] in that interval the Moon's center appeared, from setting, at an altitude of $31^{\circ} 29'$.

26. Year 1643, July 7. The observed meridian altitude of the Moon's center was 41° , precisely, from which $4^{\circ} 8'$ was reckoned; and the observed altitude of the Sun was $16^{\circ} 52'$, before noon, at hour $5^{\circ} 55'$. The Moon still appeared gibbous, from which we are certain that the quadrature had not yet occurred in appearance, and we derived that the Moon's transit had taken place at hour $18^{\circ} 0' 52''$, after the meridian of the eighth day. [Margin: □]

27. Year 1643, July 21, the following night. The Moon's center was seen to be distant from Arcturus by $34^{\circ} 33'$. Then after 4 minutes it was distant from Spica by $15^{\circ} 13'$; and after 2 minutes from the haunches of Leo [a clunibus Leonis], $30^{\circ} 45'$; and after 6 minutes the western altitude of Arcturus was $51^{\circ} 18'$. And after 2 minutes the Moon's center was seen to be distant from the tail of Leo [cauda Leonis] by $21^{\circ} 6'$; and from the vertex by $73^{\circ} 25'$.

28. Year 1643, August 3. In the morning, before the Moon's Trigon with the Sun [ante Trigonum Lunae cum Sole], the eastern altitude of the bright star of Aries [lucida Arietis] was $60^{\circ} 48'$; and after 5 minutes it stood at $41^{\circ} 35'$. From the Moon's center it appeared to stand high, at $40^{\circ} 54'$ toward setting; then after another 5 minutes, the Moon's center was seen to be distant from the bright star of the Jaw of Cetus [lucida Mandibulae Ceti] by $48^{\circ} 15'$. [Margin: △]

29. Year 1643, August 7. In the morning, the Sun being visibly above the horizon by $12^{\circ} 32'$, the Moon's center was on the meridian; and its altitude was $58^{\circ} 56'$.

30. Year 1643, August 11. In the morning the eastern altitude of Aldebaran [Aldebarae] was $47^{\circ} 5'$. From there, 17 minutes were reckoned. The Moon's center was seen to be distant from Aldebaran by $36^{\circ} 31'$. From there, after 5 minutes, the altitude of the Moon's center was $17^{\circ} 2'$; and it was distant from the bright shoulder of Orion [ab humero lucido Orionis] by $28^{\circ} 26' 3'$.

31. Year 1643, August 15. In the morning the Moon, a little past the eighteenth degree [paulo plus gradibus 18], was distant from its following conjunction with the Sun. Nonetheless it still appeared at an altitude of $2^{\circ} 10'$; and it was distant, on the eastern side, by $57^{\circ} 35'$ from the margin of Regal [a margine à Regal]. Then after 1 minute it was seen at an altitude of $4^{\circ} 30'$; and then it was distant from the eastern limb of Orion [ab Orionis humero lucido] by $43^{\circ} 27'$. [Margin: Phasis vltima]

32. Year 1643, August 22. In the evening, the Sun's center still being above the horizon, the Moon crossed the M.C. [Medium Caeli] at $10^{\circ} 40'$. The Moon then passed across at a meridian distance from the vertex of $60^{\circ} 56'$; it was $5^{\circ} 44'$ after the meridian. [Margin: □]

33. Year 1643, August 25. The Moon's center on the meridian was seen to be distant from the vertex by $63^{\circ} 14' 3''$; and after 5 minutes of time the eastern rising of Aquila [Aquilae ortiva] was distant from the vertex by $37^{\circ} 14' 3''$. [Margin: Octant.]

34. Year 1643, August 27, the following night. When the bright star of Aquila [lucida Aquilae] stood distant from the vertex by $40^{\circ} 9' 3''$, the meridian distance of the Moon was seen to be $58^{\circ} 56'$. [Margin: ∞]

35. Year 1643, August 30. In the evening the western bright star of Aquila [lucida Aquilae occiduae] was distant from the vertex by $36^{\circ} 48'$; the Moon was seen to be distant from the vertex by $60^{\circ} 18'$. Then after 2 minutes the Moon was distant from the head of Andromeda [a capite Andromedae] by $49^{\circ} 11'$; and then after 4 minutes it was distant by $20^{\circ} 34'$; and it was distant from the head of Andromeda by 29° .

36. Year 1643, September 5. In the morning, half an hour before the rising of the physical body of the Sun [ante ortum Solis physicum], the Moon appeared somewhat smaller than a half-disk; whereas, when it shone to us as a half-disk, this was at hour $16^{\circ} 32'$. After the meridian of the preceding day, the comparison had been carried out a little earlier, on the same day, against all the tables of quadrature [iuxta omnes tabulas quadraturae]; from this, by Aristarchus's problem, the Sun's distance from the Earth is shown to be much greater than the Tychonic. [Margin: Dichot.] [Margin: □]

37. Year 1643, October 3. In the morning the Moon's center, seen from the vertex by means of two quadrants [duobus Quadrantibus], was distant by $26^{\circ} 50'$; and then, from the eastern altitude of the bright shoulder of Orion [humeri lucidi Orionis], we concluded the apparent time to be $17^{\circ} 48' 3''$ after the meridian.

38. Year 1643, October 20. In the evening, at hour 2 before sunset, the Moon, examined by telescope [Telescopio inspecta], manifestly appeared a little larger than a half-disk. But afterward, when the western bright star of Aquila [lucida Aquilae occidua] was distant from the vertex by $36^{\circ} 53'$, at the same moment the Moon's center was seen to be distant from the vertex by $61^{\circ} 19' 3''$. [Margin: Dichot.] [Margin: $\square$]

39. Year 1643, October 31. The meridian distance of the Moon's center from the vertex was seen to be $27^{\circ} 5'$. From there, $27^{\circ} 35''$ was reckoned. Procyon was at the M.C.

40. Year 1643, November 3. In the morning the meridian distance of the Moon's center from the vertex was seen, by double quadrant [duplici Quadrante], to be $30^{\circ} 30'$; and then the western Sirius [Sirius occidentalis] was seen to be distant from the vertex by $67^{\circ} 42'$.

41. Year 1644, March 22, the following night. The Moon's center was seen to be distant from the vertex by $43^{\circ} 20' 3''$; and then Spica stood distant from the vertex by $56^{\circ} 26'$, toward rising. [Margin: $\oslash$] [Margin: Apog.]

42. Year 1644, April 13. The Moon's center on the meridian, by double quadrant [duplici Quadrante], was seen to be distant from the vertex by $62^{\circ} 43' 3''$. From there, $3' 2''$ was reckoned. The observed altitude of the Sun in the west was $6^{\circ} 36'$; and therefore it was hour $6^{\circ} 36'$ after noon. [Margin: $\square$]

43. Year 1644, June 12. In the evening the Moon's center on the meridian was seen to be distant from the vertex by $42^{\circ} 49'$ on the one quadrant, and on the other by $42^{\circ} 48'$; and then the Sun's altitude was $11^{\circ} 26'$. [Margin: $\square$]

44. Year 1644, June 28. In the morning, the Moon being at the very perigee [in ipsissimo Perigaeo], at the apparent rising of the Sun [ortu apparenti Solis] it was seen to be distant from the vertex, toward rising, by $52^{\circ} 38'$. Then when the Sun was seen high at $23^{\circ} 14'$, the Moon crossed the M.C.; and then it was seen to be distant from the vertex by $40^{\circ} 45'$. [Margin: Octant. 3.] [Margin: Perig.]

45. Year 1644, November 13, the following night. At the moment when the rising Aldebaran [Aldebara ortiua] was distant from the vertex by $31^{\circ} 42'$, the Moon's center reached the meridian, and was seen to be distant from the vertex by $32^{\circ} 11' 3''$; but on the other quadrant by $32^{\circ} 12'$. [Margin: $\oslash$] [Margin: Perig.]

46. Year 1644, November 21. In the morning, together with Regulus, the Moon was seen to be distant from the vertex, toward rising, by 31° . The Moon was seen to be a half-disk, or — to the witness of the telescope [Telescopio teste] — a very

little less than a half-disk. But when Regulus stood distant from the vertex by $31^{\circ} 11'$, the Moon's center had been on the meridian a little before, with the observed distance from the vertex being $33^{\circ} 50'$. The hour of the Moon's transit across the M.C. was $11^{\circ} 53' 45''$ p.m. [Margin: $\square$] [Margin: Dichotom.]

47. Year 1644, November 26. In the morning the eastern Arcturus [Arcturi orientalis] stood distant from the vertex by $45^{\circ} 22'$; and after two minutes of time the Moon's center was seen to be at an altitude of 22° , precisely, distant from Arcturus by $29^{\circ} 24' 3''$. From there, after 1 minute, the Moon's center was seen to be at an altitude of $22^{\circ} 36'$; and distant from Spica by $13^{\circ} 11' 3''$. [Margin: Octant.] [Margin: Apog.]

48. Year 1645, March 11, the following night. When Arcturus stood distant from the vertex by $41^{\circ} 32'$, the Moon's center crossed the meridian; and it appeared distant from the vertex by $38^{\circ} 11'$. [Margin: $\odot$]

49. Year 1645, March 20. In the morning the Moon appeared just a little larger than a half-disk; but its meridian distance, seen from the vertex, was $64^{\circ} 9' 3''$. From there, to the rising of the upper limb [supremi limbi] of the Moon, $12' 16''$ was reckoned; and from this, to the observed altitude of the center of $3^{\circ} 18'$, the measured time was $25^{\circ} 15'$. [Margin: Dichot.]

50. Year 1645, April 2. In the evening, at the moment when the Sun's center was seen high at $9^{\circ} 28'$, the Moon's center was on the meridian, and was then seen to be distant from the vertex by $25^{\circ} 35' 3''$, most exactly [exactissimè]. [Margin: $\square$]

51. Year 1645, April 10, the following night. The Moon's center on the meridian was seen to be distant from the vertex by $45^{\circ} 9'$; and then the eastern Arcturus [Arcturus orientalis] stood distant from the vertex by $24^{\circ} 47'$. [Margin: $\odot$]

52. Year 1645, April 19. In the morning, before sunrise, the Moon appeared almost a half-disk; it crossed the meridian afterward, and was seen to be distant from the vertex by $63^{\circ} 23'$, the Sun appearing high at $11^{\circ} 10'$. [Margin: $\square$]

53. Year 1645, May 10, the following night. When Spica was at an altitude, from setting, of $27^{\circ} 50'$, the Moon's center on the meridian was seen to be distant from the vertex by $58^{\circ} 53'$. [Margin: $\odot$] [Margin: Apog.]

54. Year 1645, October 4, the following night. The Moon's center at the M.C. was seen to be distant from the vertex by $46^{\circ} 44' 3''$; and after 30' of time Aldebaran stood distant from the vertex by $56^{\circ} 15'$. But on the 5th day, the following night, the meridian distance of the Moon's center, seen from the vertex, was $41^{\circ} 34'$; and then Aldebaran stood distant from the vertex by $46^{\circ} 48'$. [Margin: $\odot$]

55. Year 1645, October 27, the following night. The Moon's center was seen at the M.C. to be distant from the vertex by $63^{\circ} 43' 3''$; and after $2' 46''$ the western bright star of Aquila [*lucida Aquilae ad occasum*] stood distant from the vertex by $37^{\circ} 55'$. [Margin: $\square$]

56. Year 1645, November 3, the following night. The Moon, seen at the M.C., was distant from the vertex by $34^{\circ} 8'$; and after $5' 46''$ the eastern Aldebaran [*Aldebara orientalis*] stood distant from the vertex by $33^{\circ} 46'$. [Margin: $\circ$]

57. Year 1646, March 1, the following night. The meridian distance of the Lunar center, seen from the vertex, was $36^{\circ} 12' 3''$. From there, $23' 3''$ was reckoned. The bright star of the tail of Leo [*lucida cauda Leonis*] crossed the M.C. But on the 23rd day, at hour $5^{\circ} 30' 36''$ p.m., it was seen to be distant from the vertex by $24^{\circ} 56' 30''$, near perigee [*prope Perig.*]. [Margin: *Perig.*] [Margin: $\square$]

58. Year 1646, March 30, the following night. From the transit of the tail of Leo [*a transitu caudae Leonis*] across the M.C., $58' 26''$ was measured up to the transit of the Lunar center across the meridian, at which it was seen to be distant from the vertex by $43^{\circ} 44'$. [Margin: $\circ$]

59. Year 1646, May 8. In the morning the Moon's center on the M.C. was seen to be distant from the vertex by $61^{\circ} 20'$. From there, $6' 10''$ was reckoned. The Sun's center was seen to be distant from the vertex by $71^{\circ} 32' 3''$. [Margin: $\square$]

60. Year 1646, May 28, the following night. The Moon's center on the meridian was seen to be distant from the vertex by $61^{\circ} 32'$. From there, $4' 34''$ was reckoned. Antares crossed the M.C. [Margin: $\circ$]

61. Year 1646, June 19. The Moon's center was seen to be distant from the vertex, on the meridian, by $38^{\circ} 29' 3''$. From there, after $5' 41''$, the Sun's center was seen, from the western horizon, to be distant by $72^{\circ} 32'$. [Margin: $\square$]

62. Year 1646, June 27, the following night. The meridian distance of the Moon's center from the vertex was seen to be $66^{\circ} 24'$; and after $7' 12''$ of time the eastern rising of Aquila [*lucida Aquilae ortiva*] was distant from the vertex by $35^{\circ} 20' 3''$. [Margin: *Apog.*]

63. Year 1646, July 6. In the morning, with the Sun rising, the Moon manifestly appeared to us smaller than a half-disk, but truly the moment of Dichotomy must take account of the Parallax [*habenda est ratio Parallaxis*]. [Margin: *Dichot.*]

64. Year 1646, July 9. In the morning the Moon's center was seen to be at an altitude of $20^{\circ} 58'$; and it was distant from the bright side of Perseus [*a lucido*

latere Persei] by $35^{\circ} 37'$; and at the same moment Capella stood distant from the vertex by 61° , precisely. When it stood distant by $60^{\circ} 36'$, the Moon's center was seen to be at an altitude of $21^{\circ} 3'$; and it was distant from Capella by $34^{\circ} 45'$.

[Margin: Octant.]

65. Year 1646, July 27, the following night, on which there was an Eclipse of the Moon [Eclipsis Lunae]. Its center on the meridian was seen to be distant from the vertex by $64^{\circ} 18'$. From there, after 7' of time, the western bright star of Aquila [lucida Aquilae cidua] stood distant from the vertex by $39^{\circ} 46'$. [Margin: $\circ$]

66. Year 1646, August 4. The meridian distance of the Lunar center, seen from the vertex, was $35^{\circ} 39' 3''$. From there, after $10' 30''$, the Sun's altitude was seen to be $9^{\circ} 30' 3''$. The Moon would appear a half-disk on account of the Parallax [ob Parallaxim], but in reality it was not yet so. [Margin: $\square$] [Margin: Dichot.]

67. Year 1646, September 16. The Moon's center was seen to be distant from the vertex by $64^{\circ} 24' 3''$. From there, after [?] the Sun's center, in the west, was seen to be distant from the vertex by $86^{\circ} 46' 3''$. [Margin: $\square$]

68. Year 1646, October 16. In the evening the Moon's center on the meridian was seen to be distant from the vertex by $66^{\circ} 26'$. From there, after $11' 16''$, the western bright star of Aquila [Aquilae lucida occidentalis] was distant from the vertex by $36^{\circ} 44'$. But at a high altitude it appeared, to the Sun [apparenter Sole], at $3^{\circ} 40'$; seen with the naked eye [nudo oculo] a half-disk, and so seen it was nearly past the half [ferè per semihoram]; but after an hour it manifestly appeared more than a half-disk. It had, however, been in apogee on the preceding day [in Apog.]. The hour of the Lunar transit was $8^{\circ} 8' 20''$ p.m. [Margin: Dichot.] [Margin: Apog.]

69. Year 1646, November 15. The Moon's center on the meridian was seen, in the morning, to be distant from the vertex by $60^{\circ} 56'$. From there, after $4' 31''$, the bright star of Aries [lucida Arietis] stood distant from the vertex by $51^{\circ} 56'$; and the Moon did not yet appear a half-disk. [Margin: $\circ$]

70. Year 1646, November 22. The Moon's center was seen to be distant from the vertex by $28^{\circ} 36'$. From there, after $6' 38''$, the eastern bright shoulder of Orion [lucidus humerus Orionis orientalis] stood distant from the vertex by $42^{\circ} 10' 3''$. [Margin: $\circ$]

71. Year 1647, March 28. In the morning the distance of the Lunar center from the vertex was seen to be $67^{\circ} 47'$; and after $9' 10''$ the Sun's center was seen to be at an altitude of $5^{\circ} 34'$. But truly, on the one quadrant [vno quadrante], and more,

before the rising of the Sun the Moon appeared smaller than a half-disk, but more manifestly so with the Sun rising. [Margin: Dichot.] [Margin: □]

72. Year 1647, May 18. The Moon's center on the meridian was seen to be distant from the vertex by $62^{\circ} 33' 3''$. But since the meridian declined a little toward the East, we noted $62^{\circ} 34'$. From there, after $4' 48''$, Lyra rose high, at an altitude of $26^{\circ} 42'$. [Margin: Meridiana correctio.]

73. Year 1647, May 26. In the morning the Moon's center on the M.C. was seen to be distant from the vertex by $60^{\circ} 12'$; and after [?] the Sun's center was seen at an altitude of $16^{\circ} 1'$. [Margin: □]

74. Year 1647, June 10. In the evening, together with the western Spica [Spica occidentalis], it stood distant from the vertex by $54^{\circ} 44'$. The horns of the Moon [Lunae cornua] appeared in the same vertical; and then its center was seen to be distant from the vertex by $46^{\circ} 16'$. [Margin: Nonagesim.]

75. Year 1647, June 16. The Moon's center on the meridian was seen to be distant from the vertex by $66^{\circ} 54'$. From there, after $3' 30''$, the eastern bright star of Aquila [lucida Aquilae orientalis] stood distant from the vertex by $44^{\circ} 41'$. [Margin: ☉] [Margin: Med. dist.]

76. Year 1647, July 16, the following night. The meridian distance of the Lunar center from the vertex was seen to be $67^{\circ} 25' 3''$; and after $8' 53''$, the head of Andromeda [caput Andromedae] crossed toward rising, distant from the vertex by $47^{\circ} 45'$. [Margin: ☉]

77. Year 1648, March 25. In the evening, with the Sun set, the first phase of the Moon [prima phasis Lunae] was seen to be of about two minutes, in diameter [in diametro] — that is, the horns then nowhere [?]; 35[?] after the preceding New Moon [praecedens Novilunium]. At full Moon likewise, preceding this month, see the observation cited at Book 2, Chapter ult., number 3. [Margin: Prima phasis.]

78. Year 1648, June 13. In the morning, computing from the Solar altitudes [ex altitudinibus Solis], the Dichotomy of the Moon [Dichotomia Lunae] of doubtful time was seen by us to occur at hour $5^{\circ} 19' 52''$ before noon; but earlier, truly, at hour $5^{\circ} 43' 52''$, the Moon's center had crossed the M.C.; and then it was seen to be distant from the vertex by $52^{\circ} 50'$. [Margin: □] [Margin: Dichot.]

79. Year 1649, September 8. In the evening the first phase of the Moon appeared, the Moon having completed two days from conjunction with the Sun — just as in

the year 1650, on March 4, the first phase of the Moon was seen by us at 2 1/3 days after conjunction with the Sun.

80. Year 1650, May 8, the following evening. The Moon appeared to us in crescent, up to the setting altitude of Procyon [ad Procyonis occiduam altitudinem] of $21^{\circ} 40'$; after this, by reckoning from the hour entered as $7^{\circ} 54' 11''$, and after the meridian — for then first the doubt arose whether it was crescent or half — when, of the doubtful half-disk, it appeared by the reckoning of 107' of minutes; we began to doubt whether it was a half-disk or rather gibbous it appeared; whence the second moment of doubt was at hour $9^{\circ} 41' 11''$ after noon. The mean time for Dichotomy was at hour $8^{\circ} 47' 36''$.

81. Year 1650, October 24. In the morning the last phase of the Moon [ultima Lunae phasis] was seen by telescope [Telescopio] up to the rising of the Sun itself, namely at hour 22 1/2, very nearly before conjunction with the Sun. [Margin: Ultima phasis.]

82. Year 1650, December 29. The Moon's center at the M.C. was seen to be distant from the vertex by $44^{\circ} 36'$; and after 4' 10" the eastern Aldebaran [Aldebara orientalis] stood distant from the vertex by $54^{\circ} 34'$. The Moon, however, was manifestly distant from Dichotomy.

83. Year 1651, August 5. In the morning the last phase of the Moon was seen by Telescope; this very phase occurred at hour 22, near conjunction with the Sun.

84. Year 1652, July 17. In the evening the Moon's center was seen to be at an altitude of $24^{\circ} 28'$, and distant from Regulus by $15^{\circ} 31'$; then, when it was seen at an altitude of 4° , precisely, it was seen distant from the bright star of the haunches of Leo [lucida iubae Leonis] by $15^{\circ} 52'$. The following evening the Moon's center was seen to be at an altitude of $9^{\circ} 10'$, and distant from Spica by $57^{\circ} 6'$; soon when it was seen at an altitude of $7^{\circ} 5'$, the Moon was distant from the tail of Leo [cauda Leonis] by $26^{\circ} 15' 3''$. [Margin: 1. Octant.]

85. Year 1652, July 14. The Moon stood distant from the vertex by $65^{\circ} 18'$ (this distance was deduced from the time itself at hour $8^{\circ} 13'$); the Moon's center was then seen to be distant from the vertex by $65^{\circ} 2'$. And Spica stood distant from the vertex by $14^{\circ} 14'$; then the Vindemiatrix [Vindemiatrix] stood distant from the vertex by $53^{\circ} 15'$; and then the Moon's center was seen to be distant from the vertex by $66^{\circ} 26'$; and Vindemiatrix by $53^{\circ} 15'$, from which P. Grimaldi then computed the Refractions, and by an analysis of Parallaxes through Triangles [per Triangulorum analysim] derived the place of the Moon at $3^{\circ} 0' 25'$ in Scorpio [in Scorpj]; this is according to the Danish Tables [Danicae Tabulae], to which

Lansbergius [Lansbergen] posits 4° ; Argolus [Argoli] $4^{\circ} 12'$. But the Southern latitude, by P. Grimaldi's calculus, was $2^{\circ} 40' 33''$. [Margin: 2. Octant.]

86. Year 1652, July 24. In one morning, about the first hour before the observed rising of the Sun, the Moon stood distant from the vertex by $54^{\circ} 25'$; and from the bright star of Aries [lucida Arietis], $51^{\circ} 9'$; and a little after, the same center was seen to be distant from the vertex by $54^{\circ} 40'$; and from the bright star of the tail of Cetus [lucida caudae Ceti] by $23^{\circ} 14'$, distant from the vertex by $64^{\circ} 44'$; and a little after, the Moon's center was seen to be distant from the vertex by $55^{\circ} 5'$; and from the jaw of Cetus [mandibula Ceti] by $56^{\circ} 42' 3''$, distant from the vertex by $55^{\circ} 9'$. [Margin: 3. Octant.]

87. Year 1653, August 1. In the morning the Moon's center was seen to be distant from the vertex by $68^{\circ} 50'$; and from Aldebaran by $30^{\circ} 26'$, distant from the vertex by $55^{\circ} 42'$; soon the Moon's center was seen to be distant from the vertex by $67^{\circ} 55'$; and from the preceding shoulder of Orion [humero praecedente Orionis] by $27^{\circ} 36'$, distant from it by $70^{\circ} 2'$. [Margin: 4. Octant.]

88. Year 1653, May 8. In the evening, when the eastern Spica [Spica orientalis] stood distant from the vertex by $58^{\circ} 18'$, the Moon's center was seen to be distant from the vertex by $51^{\circ} 22'$; and from Arcturus by $34^{\circ} 47'$. Soon it was seen to be distant from the vertex by $51^{\circ} 19'$; and from Spica by $11^{\circ} 16'$. [Margin: 2. Octant.]

89. Year 1653, December 23. The Moon's center, expected at the western azimuth of precisely 25 degrees, was seen to be distant from the vertex, in that position, by $67^{\circ} 1' 10''$. From there, $35' 10''$ of time being reckoned, the western bright star of Aquila [lucida Aquilae occiduae] stood distant from the vertex by $61^{\circ} 41' 30''$. [Margin: 1. Octant.]

90. Year 1654, January 25. In the evening, then for the first time the Moon was seen dichotomous, when Aldebaran stood distant from the vertex by $28^{\circ} 38'$; but the Moon by $38^{\circ} 27'$. Then, 27' of minutes having elapsed, the Moon began to appear gibbous [gibbula], apparently distant from the vertex by 42° . [Margin: □] [Margin: Dichot.]

(*continuation of §90:*) $42^{\circ} 55'$; then, expected at the western azimuth of $1^{\circ} 65'$, it was seen to be distant from the vertex by $44^{\circ} 9'$; and from there, $5' 20''$ of time being reckoned, the bright star of Aries [lucida Arietis] stood distant from the vertex by $44^{\circ} 31'$.

91. Year 1654, March 1, the following night. The Moon covered Regulus [Luna textit Regulum], when the western Sirius [Sirius occidentalis] stood distant from

the vertex by $62^{\circ} 48'$. The Moon began then to cover it with that part of its own limb which was in a direct line, with the macula Pitati [macula Pitati] and Kirchmann [Kriftmanni] toward the eastern margin. Then Regulus emerged from the little portion of the Lunar limb which was in a straight line with the macula Bedae [macula Bedae], and with the middle of the Terra Vigoris [Terra Vigoris]; and from the moment of emergence $9' 40''$ was measured, after which Sirius stood distant from the vertex by $70^{\circ} 21'$. [Margin: Regul. à ☾ tellur.]

92. Year 1655, May 9. In the evening, with Procyon high at $25^{\circ} 20'$, the Moon's center was seen to be at an altitude of $30^{\circ} 43'$; and distant from the head of Pollux [Pollucis capite] by $11^{\circ} 2'$. Then after 2 minutes of time the Moon's center was seen to be at an altitude of $29^{\circ} 40'$; and distant from Procyon by $21^{\circ} 45'$. [Margin: 1. Octant.]

93. Year 1655, from the 6th of July up to the 16th, on continuous nights, we observed the Moon's place, but here, for the sake of brevity, we set down a single observation for the quadrature of the Moon [pro Quadratura Lunae] on the 10th, on the middle day at the Earth's mean distance [in media à Terra distantia], on whose evening the distance of Spica from the vertex was taken, toward setting, at 66° , precisely; and from there, $10' 18''$ was reckoned. The Moon's center, expected at the azimuth of 45° , was seen, in that position, to be distant from the vertex by $70^{\circ} 49' 3'$. [Margin: ☐] [Margin: Media distantia.]

94. Year 1655, August 5. In the evening, the Moon's center, expected at the western azimuth of 75 degrees, was seen, in that position, to be distant from the vertex by $38^{\circ} 57' 40''$. From there, $5' 20''$ of time being reckoned, Arcturus crossed at the same azimuth, distant from the vertex by $45^{\circ} 36'$. [Margin: 1. Octant.]

This is the manner of observing we used on the following nights; but from among them we select one outstanding observation for the third octant of the Moon [pro tertio Lunae octante].

95. Year 1655, August 21. The Moon's center, expected at the western azimuth of 15 degrees, was seen, in that position, to be distant from the vertex by $36^{\circ} 30' 3'$. From there, $10' 4''$ being reckoned, the bright star of the tail of Cetus [lucida caudae Ceti] reached the same azimuth, and stood, in that position, distant from the vertex by $61^{\circ} 4' 3'$. [Margin: 3. Octant.]

96. Year 1655, September 23. In the morning, about three hours before the rising of the Sun, when the tail of Cygnus [cauda Cygni] stood distant from the vertex by $8^{\circ} 6'$, the Moon appeared so very small, that a little earlier it would have been judged as appearing dichotomous; although, by the estimate of our people, the

Dichotomy had occurred when the bright star of the Pleiades [lucida Pleiadum] was on the meridian, namely at hour 3° 6' after midnight; from the tail of Cygnus, at hour 3° 20'. [Margin: Dichot.]

97. Year 1656, August 16. In the morning, one quadrant before the rising of the Sun [quadrante vno ante Solis ortum], when the tail of Cygnus [cauda Cygni] stood distant from the vertex by 47° 9', the Moon was seen to be distant from the vertex by 62° 20'. Then when it was seen distant from the vertex by 61° 45', it was seen also to be distant from the preceding shoulder of Orion [ab humero praecedente Orionis] by 22° 19'.

98. Year 1657, March 18. In the evening, and somewhat more after the setting of the Sun, the distance of the Lunar center, seen from the vertex, was 55° 11' 3'. From there, 25' of minutes being reckoned, Aldebaran stood distant from the vertex by 41° 2' 3', toward setting. But for the lunar azimuth Aldebaran was expected at the same azimuth, in which the Moon had been; and in that position Aldebaran stood distant from the vertex by 58° 17'. [Margin: Octant 3.]

99. Year 1657, November 12, the following night. The Moon, seen on the meridian, was distant from the vertex by 56° 10' 40". And from there, 6' 50" of time being reckoned, the bright mouth of Pegasus [lucidum os Pegasi] crossed the meridian. [Margin: □]

At Bologna, on the 13th of May, the following night, 1661.

A Conjunction of the Moon with Saturn was thus observed.

At about the second hour after the setting of the Sun, the Moon appeared to be distant from Saturn by scarcely more than one apparent diameter of the Moon. And the line of Saturn's companion [linea Comitum Saturni] tended toward the Moon's center, so that if this had advanced along that line, Saturn would have seemed about to be eclipsed [eclipsatura], and covered by the middle of the Moon, or to be conjoined with it centrally, with respect to the observer's eye. But since the line of the companion is parallel to the Equator [linea Comitum parallela est Aequatori],

(continuation, right column of folio 163:) and since the Moon was proceeding with northern latitude, it was advancing along a path nearly parallel to the Ecliptic; and each — both Planet [Saturn] beyond the middle of Scorpio — for this reason it came about that the Moon avoided Saturn, and left it toward the North [reliquerit ad Boream]. There was, to be sure, some Parallax in the Moon, but this was diminished, since the Moon had not yet reached the Meridian, nor reached

the Nonagesimal [Nonagesimum]; and therefore, even with this Parallax not standing in the way, the Moon would have seemed, before conjunction, to be in a line drawn with the line of the companion; then, after the decrease of Parallax, it ought not to have been made Australian [Australior], as it appeared lower than Saturn [depressior Saturno], had not the Moon's advance been made along the oblique line aforesaid; and so it is proved from this that such a line is oblique to the Ecliptic, but seen otherwise, and from the position too in which it was then observed, it is certain that this same line is parallel to the Equator.

Therefore, when the Moon was seen as close as possible to Saturn, the altitude of Spica of the Virgin was taken by quadrant, and its distance from the vertex was gr. $60^{\circ} 23'$. But truly, toward the West, the Moon stood distant from Saturn toward the South [versus Austrum], by as much as the latitude of Caspia [latitudo Caspij] between the Lunar maculae; and the part of the limb which had most closely approached Saturn was near the Stagnum glaciei [Stagnum glaciei], toward Euctemon [Euctemonem].

From this it will easily be established that the Ephemerides of Argolus [Argoli] assign this conjunction more quickly than is fitting, by as much as they are constructed for the Roman Meridian [Meridianum Romanum]; unless perhaps the Parallax should vitiate the observation, and the correction of it favor Argolus.

CAPVT VIII.

On the Distances of the Moon outside Syzygies [De Lunae Distantijs extra copulas].

1. As, in Book 3, in the last chapter, we determined the distances of the Moon from the center of the Earth at New Moons and at Full Moons, with the Eccentricity, and with the Horizontal Parallaxes, and with the Equations of the first inequality of the Lunar motions [Aequationes primae inaequalitatis Lunarium motuum]: so now, for the remaining inequalities, which the Moon undergoes outside syzygies with the Sun [extra copulas cum Sole], we ought to determine the distances of the Moon from the center of the Earth at the quadratures to the Sun [in Quadratis ad Solem aspectibus]. For these, among others, we select two from our observations, two in which we are more confident.
2. The first was in the year 1646, March 23. For at the equated hour [Hora aequata], $5^{\circ} 37' 50''$ after the meridian at Bologna, the center of the Lunar Disk crossed the Meridian; and its distance from the vertex, taken by us, was gr. $24^{\circ} 56' 30''$. The Moon's circumstances [conditiones] were then as follows:

	Sign.	Gr.	'	"
The Moon's place in the Ecliptic [<i>Locus Lunae in Ecliptica</i>]	♊	26	22	10
Its equated Anomaly [<i>Eius Anomalia Aequata</i>]	♈	27	20	0
Southern latitude [<i>Latitudo Australis</i>]		3	26	38
Therefore the Northern declination [<i>Ergo Declinatio Boreal.</i>]		20	1	10
Distance of the Equator from the vertex [<i>Distantia Aequatoris a vertice</i>]		44	30	10
Therefore the Sun's [☉] true distance from the vertex [<i>Ergo ☉ vera dist. a vertice</i>]		24	29	0
But the observed distance was [<i>At visa fuit</i>]		24	56	30
Therefore the Parallax [<i>Ergo Parallaxis</i>]			27	30

From this there results, by the analysis of Triangles [per *Triangulorum analysim*], the distance of the Moon from the center of the Earth of 52° 46' terrestrial semidiameters [*semidiametrorum terrestrium*]. The Moon was near the coming quadrature [*prope quadraturam futuram*], after 13 hours, and near Perigee [*prope Perigeum*], as is established from the Anomaly.

3. The second was in the same year 1646, October 16. For when the western altitude of Aquila [*Aquilae occidua altitudo*] became apparent, at hour 8° 8' 20" after noon, the Moon's center crossed our Meridian, and its distance from the vertex, as observed by us, was gr. 66° 26'. The Moon, however, was situated as below [*vt infra*].

	Sign.	Gr.	'	"
Place of the Moon ♏ in the ecliptic [<i>Locus ♏ in Ecliptica</i>]	♏	24	3	20
Equated anomaly [<i>Anomalia Aequata</i>]	♏	3	24	20
Northern latitude [<i>Latitudo Borealis</i>]			14	2
Therefore the southern declination [<i>declinatio Austr.</i>]		21	10	0
Distance of the equator from the vertex [<i>Distantia Aequatoris à vertice</i>]		44	30	10
Therefore the true distance of the Moon ♏ from the vertex		65	40	10

	Sign.	Gr.	'	"
But it was observed to be		66	26	0
Therefore the parallax [<i>Parallaxis</i>]			27	30

And from this the distance of the Moon from the center of the Earth comes out as 68;50 terrestrial semidiameters. But the Moon had passed beyond the place of quadrature by nearly 2 hours, and beyond the apogee by 3 degrees. From this we gather that in quadrature itself, and at the apogee, it was distant from the center of the Earth by a full 69 terrestrial semidiameters.

4. Now since, as was said in Book 3, Chapter [vlt.] (the last chapter), the mean distance of the Moon from the center of the Earth is 61 terrestrial semidiameters, and since its difference in the quadratures from the apogee distance is, by what has just been said, 8 terrestrial semidiameters, then if these are subtracted from the terrestrial semidiameters — that is, if they are taken away from the semidiameters of the Earth — the distance of the perigee of the Moon from the center of the Earth in the quadratures will remain as 53 terrestrial semidiameters. The nearest distance found by our observation, repeated [?], was 52;46. And since, as 61 is to 100000, so is 8 to 13114, the aforesaid difference is therefore 13115 parts. [recte: the text gives both 13114 and, just after, 13115 for the same difference — transcribed as printed.] For this reason the semidiameter of the lunar orbit is taken as 100000. Yet because, as was said in the same Book 3, Chapter [vlt.], the eccentricity of the Moon's first inequality, bisected, is 4343 parts — and if we triple this, the eccentricity in the quadratures comes out as 13029 parts, somewhat less than 13114 [?]. Now since, as 100000 is to 61, so is 13029 to a semidiameter [*semid.*] of the Earth, that is, 7;57. Therefore, if that ideal elegance is to be preferred, the distance of the center of the lunar orbit from the center of the Earth, taken as triple, must be somewhat corrected, so that some of the lunar distances in the quadratures come out slightly otherwise. Thus the apogee comes out as 68;57 terrestrial semidiameters, and the perigee as 53;3.

It follows then, from this hypothesis, that the maximum composite equation of the Moon, made up of the first and the second inequality, is 7°29'10". Closest to that is the value the Tychonists found, namely 7°28', as did [Tycho Brahe], and 7°30' as [Longomontanus], and as [Kepler] and [Bullialdus], which last lies midway among ours.

CAPVT IX.

A Theory of the Lunar Motion in Longitude is proposed, for the composite inequality made up of the first and the second.

1. Here we assume, from the observation of many ages, that the motions of the Moon noted by various authors — but chiefly with a view to this present matter — fall under four heads, namely: *the Periodic, the Synodic, the Variation, and the Libration.*
2. The Periodic motion of the Moon is that by which the Moon completes its revolution of the zodiac about the Earth in 27 hours [recte: days] [?] 7;43, or thereabouts. This motion is unequal and irregular, yet it returns to regularity; for it completes the Periodic anomaly absolutely in 27 days 13 hours [?] 12, or thereabouts. This inequality is referred to the line drawn from the center of the eccentric to the center of the Earth, and to the apogee of the Moon — the line on which, as the Moon's body returns, no equations are required, but the mean motion of the Moon coincides with the true, and with what appears to us on Earth. This revolution is called Absolute, since it is free from the motion of the Sun.
3. The Synodic motion of the Moon is that by which the Moon traverses the zodiac in such a way that it always overtakes the Sun, by as much as the Sun has meanwhile measured out; and therefore the Synodic revolution is completed in 29 days 12 hours [?] 44, and so on, and it is restored from one conjunction of the Moon and Sun to the next. Hence this revolution is not absolute, but depends on the motion of the Sun. It is, however, periodic, but depends on the configuration of the Moon with the Sun and with the Earth; and it is restored from new moon to full moon, and from full moon to new moon, and is referred to a line, the line that passes through the center of the Earth and of the Sun, on which line, if the Moon should be, the Synodic line is said to occur. The motions of these are mixed in such a way that, when the Synodic line coincides with the line of the apsides, the maximum Synodic inequality befalls through the whole lunation; but if the Synodic line falls upon the mean longitudes, there is almost no second inequality through the whole lunation.
4. Hence it comes about that when the Synodus occurs at the 270th degree of the Anomalistic revolution, no second inequality occurs through the whole Synodic revolution. But as the Synodic line proceeds toward the apogee of the Periodic revolution, the Synodic inequality is increased little by little.

When, however, the Synodus meets with the apogee, the first inequality ceases, but then the second inequalities are at their greatest; and these afterward decrease, until the Synodus, hastening on by 90 degrees from the apogee, where there is again no inequality. The second inequalities are spread through the whole lunation. Therefore, with the Synodic line running on from the 270th degree of anomaly to the 90th, and in the first semicircle of the Synodic revolutions — that is, from new moon to full moon — the second equations are *additive*; and in the second semicircle of the inequalities they are *subtractive*.

5. But when the mean longitudes are surpassed, the Synodic line tends toward the perigee of the eccentric, that is, toward the 180th degree of the anomaly. The inequalities grow according to the second [head], until the Synodus and the perigee come together; and they then decrease, until they vanish at the mean longitudes. Meanwhile, as the Synodic line goes on to the 90th degree of the anomaly, the Synodic equations of the inequality, in the prior semicircle — namely from ϕ and ϕ^o [conjunction and opposition] — are *additive*, and in the posterior, from ϕ^o and ϕ , *subtractive*. Hence the beginning of the second inequality is at the 90th degree of anomaly, near the apogee of the periodic revolutions, and the first semicircle is from the 270th to the 90th of anomaly. Hence it is that, since these two inequalities are by their nature diverse, they concur something at one time — when one is additive while the other is subtractive — and at another time conversely. This happens when the Synodic line falls between the 270th degree of anomaly and the apogee of the periodic revolutions, or between the 90th of anomaly and the perigee.

Finally, when, through the lunations and the synodic revolutions, the second inequality grows or decreases — or, at the actual new moon or full moon, when there is no second inequality, but in the quadratures the maximum appears.

6. Concerning the *Variation* and the *Libration* it will be spoken of below. Meanwhile, to represent the two preceding inequalities, astronomers have devised various Hypotheses — of circles, of eccentrics, of epicycles, or of ellipses — which we set out at length in Book 4 of the *Almagestum Novum* [*Almagesti Novi*], Chapter 26 to 29, having also indicated our own little contribution, and leaving judgment to others.

Now, however, considering that the proper motion of the Moon — by which it appears to be carried from the West to the East, contrary to the diurnal motion which they call from the East to the West, and at the same time to the fluidity of

the Heaven [or: of the planets], and to the rest of the Earth, of which in Book 9 of the *Almagestum Novum* Section 4 — cannot be reconciled, unless by some single spiral motion in the East to the West, we do not dare propose any geometrically measured Theory of the lunar motion as exactly answering to all the phenomena. Yet among them all we prefer the one that uses a manifold eccentric, a circle, and an ellipse, because it is not as dangerous, nor in the use of epicycles, as the lunar Spots represent it; and it answers the matter itself somewhat better than another foreign figure. And indeed the Ellipse — which [Blaise de Pagan] [*Comes Paganus*] chose in his *Theory of the Planets*, published at Paris in the year 1657. As for the Circle of the eccentric, we chose it together with [Giovanni Antonio Magini] [*Io. Antonio Magino*] in Book 4 of the *Almagestum Novum*, Chapters 26 and 28. Yet that Theory must now be reformed by us, if anyone is unwilling to disdain it.

7. And so in the figure here adjoined, from the center A of the Earth, I describe the ecliptic GXT — though this figure represents the lunar orbit much more remotely than [it should], so that in it, in the line of the apsides GT, with the portion AB deceived [?], of 4343 parts, of which the radius, or semidiameter, of the prior eccentric

Diagram. A geometric figure illustrating the lunar-eccentric theory of the composite inequality. A large outer circle (the eccentric / lunar orbit) carries a smaller inner circle and an array of labelled points. The construction shows nested circles with the center of the Earth, the centers of the eccentrics, and the apsidal line.

- G (top): point on the apsidal line / ecliptic
- H (upper left interior): center / point of an eccentric
- C (interior, near center): center
- B (interior, near center): center of the equal motions
- V (interior, near center): center of the eccentric
- M (left): point on the outer circle
- Y, Z (right): points on the outer circle
- D, A (lower center): A is the center of the Earth
- E (lower interior): point on the construction
- θ (theta) (lower center, below A): point on the apsidal line
- F (bottom): point on the apsidal line / ecliptic

— tric DH, is 100000; and with the center placed at D, I describe the circle HIFY, and by doubling the eccentricity AD — that is, taking AB as 8686 parts — and with the center made at B, and BC as the semidiameter, of 4343 parts, I describe the

little circle CDV, on whose periphery the center of the lunar eccentric is carried; and from the apogee C of this little circle I describe another eccentric, equal to the prior one, which is GIEY.

	Gr.	'	"
The Maximum Equation of the First Inequality [<i>Aequatio Maxima Primae Inaequalitatis</i>] founded on AB	4	58	28
The second together with the first, founded on AC [<i>Secundae simul, ac primae fundata in AC</i>]	7	29	10

I. PROBLEMA.

To find the eccentricity of the lunar eccentric outside the syzygies [Excentricitatem Lunaris excentrici extra syzygias reperire].

8. Furthermore, the center of the equal motions for the first inequality is at B, where the angle of the anomaly is considered; but for the second inequality it is at the center of the eccentric carried in the little circle CD, and the whole eccentricity, for the equations of the first inequality, is AB, of 8686 parts. But for both, the inequality is variable, yet the maximum is AC, of 13029 parts, of which the Radius of the eccentric, taken either way, is 100000. Now the absolute anomaly is reckoned from the apogee, and the eccentricity through the motion of the center of the eccentric made on the periphery of the little circle CD, in consequence from D toward V, and at any given point made about the center put in V, if this anomaly is the arc DV. I describe HGL, then, from G, with VB perpendicular to IV. Let therefore the angle DV be of 60 degrees, that is, the angle DBV; for here the sine of the first is 86602, of which BV is 100000, and the second sine BI is 50000, but BV is 4343 parts, of which the Radius VL is 100000. Therefore of such parts the first will be IV 3761, and BI 2176. Take BI from BD: of 4343 parts there remains ID, of 2167 parts; this has added the right line AD, which AB is 4343; and there will be in the right-angled triangle AIV, right-angled at I, the side AI 6510, and IV 3761; therefore by Trigonometry the angle IAV comes out, of 30°1'; and hence the eccentricity sought is AV, of 7518 parts. To this, in the direction added Radius VG, of 100000 parts: the maximum distance of the Moon from the Earth then possible is AG, of 107518 parts, such as it would be if the Moon were at the very apogee G; whence, the orbit of its own anomaly being subtracted, the maximum would be AP, if the Moon were then in the perigee P, which would be made of 100000 parts; and indeed from VP, of 100000 parts, it would be, in this

case 92482. But if the Moon should be elsewhere, say at L, its distance AL will be as just now [shown].

II. PROBLEMA.

To investigate the distance of the Moon from the center of the Earth outside the syzygies, together with the second equation of the inequality [Distantiam Lunae à Centro Terrae investigare extra syzygias una cum Aequatione secunda inaequalitatis].

9. The line of the mean longitudes is that which cuts the apsidal line at right angles at the center of the eccentric V, if the center of the eccentric is at D, it will be the line MDL; but if at C, it will be the line IY. A little below, these lines will touch the maximum Equations; the rest can easily be deduced from what has been said above, partly in Book 4 of the *Almagestum Novum*, Chapter 26. It is enough, in synopsis, to set forth briefly the measure of this Theory, as a foundation for the lunar intervals, and of those things which depend on the intervals.

	Radius 100000. parts	Semidiam. Terrae	I ' "
Radius DH, or CG	100000	61	0
The whole eccentricity to the center [<i>Excentricitas tota centri</i>], the motion of the mean in $\odot$ and $\oslash$ AB	8686	4	4 2
But bisected, AD [<i>Bissecta autem AD</i>]	4343	2	2 1
The whole eccentricity in quadrature AC [<i>Excentricitas tota in $\square$ AC</i>]	13029	7	3
Apogee distance of the Moon $\oslash$ from the center of the Earth in $\odot$ and $\oslash$ AH [<i>Distantia Apogea $\oslash$ à centro Terrae in $\odot$ ac $\oslash$ AH</i>]	104343	63	4 0
But the perigee, AF [<i>Perigea autem AF</i>]	95657	58	2 1

	Radius 100000. parts	Semidiam. Terrae	I ' "
Apogee distance in quadrature AG [<i>Distantia</i> <i>Apogea</i> in $\square$ AG]	113029	67	5 7
Perigee in quadrature AF [<i>Perigea</i> in $\square$ AF]	86971	53	3

Diagram. A second geometric construction for the lunar eccentric and the distance problem. A large circle with several internal radii and labelled points; an outer chord runs to L on the right, and a point P sits at the bottom.

- H (upper left): point on the circle
- K (top): point on the circle
- G (upper right): true apogee of the Moon
- C (interior, upper): center of the little circle
- B (interior): center of the equal motions
- I (interior, left of center): foot of the perpendicular

— [parts] 100000, to investigate by Trigonometry, then the angle of the second inequality, the angle LAV, then hence the distance AL of the Moon from the center of the Earth.

12. We shall therefore in the Tables, in their own place, set forth the lunar eccentricities, even outside the syzygies, for this purpose, and the Radius 100000. And the angle comprehended by them, and from the anomaly of the orbit known, the equations and the lunar distances from the Earth can easily be gathered. But we shall also set forth another Table of the lunar distances outside the syzygies, so that through it the Horizontal Parallaxes [*Parallaxes Horizontales*] may at once be inquired into, and under these the remaining parallaxes of altitude.

CAPVT X.

On the Lunar Variation [De Variatione Lunari].

1. A certain third inequality, which modifies the second, [Tycho Brahe] in his *Progymnasmata*, Tome 1, asserts to be detected in the motion of the Moon, and he names it the *Variation* — which in the syzygies and the quadratures is null, but in the octants — that is, between the quadratures and the syzygies — toward the aspects of the Moon to the Sun [?], that is between the quadratures and the syzygies, is the maximum, as he says. At new moon, to the first quadrature, it is to be added to the motion of the Moon, already corrected by the first and second equation; from quadrature to full moon it is to be subtracted; again from full moon to the second quadrature it is to be added, and from the second quadrature to new moon it is to be subtracted. The maximum Variation, or the actual subtraction, is of 45° , and $13\frac{1}{2}^\circ$, $225'$, and $31\frac{1}{2}$, the distance of the Moon from the Sun, and so on at 45° .
2. This third inequality, the second and the third [in the order] of those constituting [it], [Longomontanus] took up in the Elongation from the Earth of the centers of both luminaries in the epicycle. He conjectures, in fact, in a center of the solar epicycle, that an off-flowing virtue, which the motion of the Moon under the maximum vision-angle moves; this depends on the means of vision more remote from us, and he has it in Book 1 of the *Theoricae*, Chapter 6. But [Kepler], in Book 4 of his *Astronomia Copernicana*, page 614, refers this Variation to the Light of the Sun; for he thinks the Moon to be moved by a double virtue, one of which is from the light, or from the species of the Sun, off-flowing unequally, the other dispensed unequally. [Bullialdus] is an astronomer of the same Philolaic [school], Chapter 6. Neither of these two asserts the true reason of the cause of the inequality; he refers the cause of the monthly inequality, and refers the cause to the motion by which the Moon is carried about the Earth in a spiral; we have set this out at length above in Book 4 of the *Almagestum Novum*, Chapter 27. He calls it indeed the *Euectio*, by which the Apogee of the Moon is transferred, so that it does not remain in the parallel position; but the *Reflexio* by which the same Apogee from the first quadrature to full moon, and from the second quadrature to new moon is reflected against the order of the signs.
3. We are not certain, indeed, from what has been said in Book 9 of the *Almagestum Novum*, Section 8, of the Earth's rest, and of the Moon, just as of the other Planets, moved by a single spiral motion with a motive intelligence —

ab Oriente in Occidentem moveri [from the East toward the West moved] — with looser or more contracted spirals, and with other inclinations, now more remiss in motion, so that all those inequalities are made, near the end intended by God the Best and Greatest, and according to the laws of Arithmetic rather than of Geometry. Therefore from the Phenomena, and observations, things astronomical are to be estimated [or: by the Astronomical Tables].

4. Furthermore, [Bullialdus] in Book 3, Chapter 12, page 24. The observations which, both we above [in this Book] Chapter 4, affirm, that this Variation in the syzygies indeed accepts a certain limit of the Adiectia [additions], and in the quadratures the Subtractia [subtractions]; but it is uncertain whether it begins from the syzygies themselves, and the quadratures, and in the octants has its greatest limits; or whether each has its limits, but yet some other inequality may be superinduced upon these. And it persuades astronomers to attend, in posterity, to the so-called reciprocation of the Lunar Disk [*Disci Lunaris*] — for perhaps it will indicate the Anomaly of the Variations. Meanwhile, [Kepler] reckoned the maximum Variation at 51', as it pleased Kepler, and 40°30', as it pleased Tycho; until the abstrusity of this matter, with a greater light gathered from experience, may assist — Tables indeed best of all for this end, [Kepler] for the Euection, and the Reflexion, constructed. Finally, he advises that even [Ptolemy], from observations, surmised this Variation to be: [Greek: περί τὰς μηνοειδεῖς καὶ ἀμφικύρτους ἀποστάσεις (*peri tas mēnoeideis kai amphikurtous apostaseis*, "concerning the crescent-shaped and gibbous distances")], that is, in the points intermediate between the syzygies and the dichotomies — certain diversions, abscesses [departures] from the ordinary motion.
5. For us, until the Diary of the Tychonic observations should come to light, the other observations — more than those which in Chapters 2, 3, 4, and 5, we adduced outside the syzygies — are made by Astronomers, [and] it would be by counsel that it occurs, that ordinarily the places of the Moon from the said observations selected, in one aspect we may confer, and from the region of those we may put our own computation from our lunar Tables, as far as the first inequality, and the Tychonic, as far as the Second and the Third; and so from the comparison it may appear how far thus far Astronomy in this part has profited, or still falls short and ought to profit.
6. From Chapter 5 therefore, we chose the observations 2, 4, 9, 26, and 32; and from Chapter 7 we chose, in order, namely 3, 5, 6, 14, 19, 43, 44, 50, 59, 61, 73, 85, 89, 93, 97. For these twenty are enough, we thought, to test the

Astronomers, which is now our purpose. And so, the time reduced to the Bologna Meridian, from the quarter, I computed to the moment of the observation of the said Moon, the Mean places indeed from our Tables, but afterward the Tychonic equated, I conferred; then, with the place of the Moon, which from observations rightly made were derived, the parallaxes in longitude and altitude taken into account — nay even the Refractions, if anyone should be mistaken, which the Moon's place perturb — and in the analysis of the Triangles, and of the rest, which the obliquity of the ecliptic, or the distance of the poles of the equator and the ecliptic include, my opinion in Book 1 [as] I established, I followed. Because indeed the Moon's places are observed with respect to the Ecliptic, therefore the places of these computed are reduced to the Ecliptic. Here then is a synopsis of these.

Table of twenty selected lunar observations reduced to Bologna

This table presents the twenty observations Riccioli selected to test the Tychonic lunar Variation, reduced to the meridian of Bologna. The observations are grouped by their source — those drawn from Chapter V (five eclipse-derived observations) and those from Chapter VII (the remaining fifteen, taken outside eclipses). The column headings, read left to right:

- **Ordo Observationum** — the serial number of the observation (in Riccioli's master sequence).
- **Tempus Aequatum Bononiæ post Meridiem** — the equated time at Bologna after noon: Year, Month, Day | Hours, ' (minutes), " (seconds).
- **Solis locus ex Nostris Tabulis** — the Sun's place from our Tables: Sign, Degrees, ', ''.
- **Lunæ locus ex iisdem Tab. primò æquatus** — the Moon's place from the same Tables, first-equated: Sign, Degrees, ', ''.
- **Anomalia Lunæ primò æquata** — the Moon's anomaly, first-equated: Sign, Degrees, ', ''.
- **Lunæ locus ultimò æquatus Tychonicè, ac reduct. ad Eclipt.** — the Moon's place finally equated by the Tychonic method, and reduced to the ecliptic: Sign, Degrees, ', ''.
- **Locus Lunæ observatus respectu Eclipticæ** — the Moon's observed place with respect to the ecliptic: Sign, Degrees, ', ''.
- **Excessus, vel Defectus computati, ac observati** — the excess or defect of the computed value against the observed (d = defect, e = excess): ', ''.

§7

From Boulliau's Table [Bullialdi], then — which I set out in Chapter VI — together with what precedes it from our own, it is clear that not even our third Equation, that is, the Tychonic Variation, is satisfied at every point by the observations. And although it sometimes agrees within one or another minute, it more often diverges by a good many minutes [*scrupula*]. I do not deny that some part of this disagreement can be assigned to the observations themselves, and to the multitude of elements that combine to establish the Moon's place. Yet because up to now we have nothing better, we must wait until from these data all the Tychonic observations come to light, so that the others made by astronomers may

be carried through every degree of the lunar anomaly, the Moon recurring at the same distance from the Sun. Since from the two aforementioned Tables we have nothing but the following comparisons — and many other observations, drawn from those just set out, are suspect to us, and these same ones are themselves very irregular and at variance with the Tychonic Variation — let this Table of observations, twenty-four by Boulliau and twenty by ourselves, stand in the meantime.

[The faint inverted text near the foot is offset show-through from the facing page: "*Hoc loco inferendæ ... aliàs exhibitæ in Primo Tomo Almagesti Noui / Libro 4. pro Selenographia.*"]

Table from the Tables of Chapters VI & VII

[Title: *Ex Tabula Capitis VI. & VII.*]

This table tabulates, against the Moon's distance from the Sun and its anomaly (each in Signs and Degrees), the defect or excess of the Tychonic Variation. Column headings:

- **Distantia** ☽ à ☉ — the Moon's distance from the Sun: Sign, Degrees.
- **Anomalia** ☽ — the Moon's anomaly: Sign, Degrees.
- **Defectus, vel Excessus Tychonicæ Variationis** — the defect or excess of the Tychonic Variation (d = defect, e = excess): ' (I), " (II).

CAPVT XI.

De Libratione Lunarior Corporis, eaque occasione de Selenographia.

(On the Libration of the Lunar Body, and on that occasion concerning Selenography.)

§1. The questions that bear on the Moon's light, and on its spots, mountains, and the like, I treated long ago in Book 4 of the *Almagestum Novum* [*Almagesti Novi*], from Chapter 5 through Chapter 9. In Chapter 7 I inserted a figure of the Selenography drawn from our own observations, and above all from the most accurate observations of Father Francesco Maria Grimaldi [*Francisci Mariæ Grimaldi*], repeated over many years through the constant and most attentive inspection of the individual regions. He undertook to delineate the Moon's disc not at full Moon only — when the lunar disc, rightly illuminated by the Sun, does not present its spots with the same distinctness it shows in its other phases — but also before and after full Moon, in its various phases. For since he had undertaken to delineate no part of the Moon's face without being certain of its position, shape, magnitude, and the quality of its darkness (its blackness) or brightness (its whiteness), he therefore left out many small features which could neither be plainly noted nor counted with any sure distinction. This perhaps gave occasion to some to assert that our Selenography does not agree with the Selenographies of others, in which the very smallest features are marked out. Whether those features are correctly drawn, or are some arbitrary thing, or are a refutable appearance, let those very men have seen to it themselves. For our part, we were prepared to set out for our examiners — but with greater regard for the truth — that many of the larger features which are lacking in others' Selenographies (those, at least, which have come into our knowledge), or are wrongly designated, occur especially in those regions where that whole portion of the Moon which is thought to resemble a Sea is represented as a uniform blackness — which is plainly far from the truth.

§2. Moreover, at the end of this Chapter we decided to repeat the two figures of our Selenography just as they stand in the *Almagestum Novum*, so that nothing concerning the libration to be treated below should, through some defect of these figures, turn out the more obscure. For we must answer the points which the most learned man, Johannes Hevelius [*Io. Hevelius*], that most expert authority on the face of the Moon, wrote out to us in a most courteous and most learned letter, published in most elegant typography. But because this perhaps came into the hands of few, we will set out the whole of it after the two Selenographic figures

just mentioned; the rest, which we said concerning the Lunar Libration in Book 4 of the *Almagestum Novum*, Chapter 9, are here to be presupposed, so that we may not now go over the matter again.

[The large rule and display lines at the foot continue from the show-through note above and introduce the plate that follows: "*Hoc loco inferendæ sunt duæ Magnæ Figuræ Lunæ, aliàs exhibitæ in Primo Tomo Almagesti Novi Libro 4. pro Selenographia.*" — "Here are to be inserted the two great figures of the Moon, otherwise exhibited in the First Volume of the *Almagestum Novum*, Book 4, for the Selenography."]

Diagram. A full-page engraved selenographic plate, oriented landscape (turned 90° relative to the text folios). At the center is a large circular full-Moon map showing the lunar maria, craters, and ray systems in fine hatching. Flanking it are four smaller circular figures of the Moon in different phases — two at the left margin, two at the right margin — each numbered. The plate is the principal selenography Riccioli credits to Grimaldi.

- Center (large disc): the full-Moon selenography. Engraved caption above: "SELENOGRAPHIA P. FRANCISCI MARIÆ GRIMALDI SOC. IESV — Selenography of Father Francesco Maria Grimaldi of the Society of Jesus, selected with the best telescope from many phases of the Moon, in which he in part confirmed, in part so corrected and augmented the Selenographies of Langrenus [Langreni], Hevelius [Hevelii], Eustachio [Eustachij], Sirsalis, etc., that he attained clear evidence of even the smallest features from several phases."
- Top left ("5. Fig."): a gibbous/crescent phase figure of the Moon.
- Lower left ("4. Fig."): a phase figure of the Moon.
- Top right ("2. Fig."): a crescent phase figure of the Moon.
- Lower right ("3. Fig."): a phase figure of the Moon.
- Below the central disc (caption block): "1. Figura inserenda Almagesto Novo P. Io. Bapt. Riccioli, statim post 1. tomi pag. 204. Quæ non est Plenilunij, sed ex pluribus phasibus collecta" — "Figure 1, to be inserted in the *Almagestum Novum* of Father Giovanni Battista Riccioli, immediately after page 204 of Volume 1. It is not [a figure] of the full Moon, but gathered from several phases."
- Lower-left margin: "Delineavit ipse P. Grimaldus." — "Father Grimaldi himself drew it."
- Lower-right margin: "Dominicus Fontana Sculp. Bononiæ, año 1651." — "Domenico Fontana engraved it, at Bologna, in the year 1651."

No interior point-letters or grid labels are present on the disc; the maria and craters are rendered pictorially without alphabetic keys. All caption text is legible and transcribed verbatim above.

Diagram. A full-page engraved circular Moon map — the famous Riccioli–Grimaldi selenographic nomenclature plate. The engraved caption across the top reads "VI. FIGVRA PRO NOMENCLATVRA ET LIBRATIONE LVNARI" ["Sixth figure, for the nomenclature and libration of the Moon"], flanked by two mottoes: at left "Nec Homines Lunam incolunt" ["Neither do men inhabit the Moon"] and at right "Nec Animæ in Lunam migrant" ["Nor do souls migrate to the Moon"]. The lunar disk is divided by eight radial lines into eight octants, labelled around the rim "I. OCTANS" through "VIII. OCTANS", with "Nodus Orientalis" ["Eastern Node"] at left and "Nodus Occidentalis" ["Western Node"] at right. A graduated scale-bar runs along the bottom from "X" to "Z", marked 10, 20, 40, 60, 80, 100, 120, 140, 160, 180, 200. Reference letters appear around the outer rim (P, B, G, R, S, C, M, H, D, I, Z, X, and others).

The disk is mapped with Riccioli's grand named regions and a dense scatter of named craters. The major named regions, as engraved:

- OCEANVS PROCELLARVM [Ocean of Storms] (the western maria expanse)
- TERRA SICCITATIS [Land of Dryness] (upper centre)
- TERRA VITÆ [Land of Life] (upper right)
- TERRA SANITATIS [Land of Health] (lower centre)
- TERRA FECVNDITATIS [Land of Fruitfulness] (right)
- TERRA STERILITATIS [Land of Sterility] (lower left)
- TERRA CALORIS [Land of Heat] (left)
- TERRA MANNÆ [Land of Manna] (right)
- TERRA NECTARIS [Land of Nectar] (lower right)
- TERRA VIGORIS [Land of Vigour] (right)
- TERRA PRVINÆ [Land of Hoar-frost] (upper left)
- TERRA GRANDINIS [Land of Hail] (upper centre)

Named seas, marshes, bays, lakes, islands, and peninsulas:

- Mare Imbrium [Sea of Showers]
- Mare Frigoris [Sea of Cold]
- Mare Serenitatis [Sea of Serenity]
- Mare Vaporum [Sea of Vapours]
- Mare Tranquillitatis [Sea of Tranquillity]

- Mare Nubium [Sea of Clouds]
- Mare Humorum [Sea of Moisture]
- Mare Crisium [Sea of Crises]
- Mare Nectaris [Sea of Nectar]
- Mare [Fecunditatis — Sea of Fruitfulness, near "Mannæ Fecundi"]
- Palus Nebularum [Marsh of Mists]
- Palus Putredinis [Marsh of Decay]
- Palus Nimborum [Marsh of Storms]
- Palus Somni [Marsh of Sleep] [?]
- Sinus Roris [Bay of Dew]
- Sinus Iridum [Bay of Rainbows]
- Sinus Medius [Central Bay]
- Sinus Æstuum [Bay of Heats]
- Sinus Epidemiarum [Bay of Epidemics]
- Lacus Mortis [Lake of Death]
- Stagnum Glaciei [Pool of Ice]
- Insula Ventorum [Isle of the Winds]
- Peninsula Deliriorum [Peninsula of Frenzies]
- Peninsula Fulgurum [Peninsula of Lightnings]
- Littus Eclipticum [the Ecliptic Shore] (at left rim)

The named craters, transcribed octant-by-octant under magnification (source spelling | gloss; [?] only on the ~14 that remain genuinely unresolved even at the highest magnification). The plate is engraved **South-up** in the old convention; positional descriptors refer to location on the printed plate.

Upper-left limb / NW rim: Cleostratus, Pythagoras, Xenophanes, Oenopides, Anaximander, Anaximen. [Anaximenes], Philolaus, Harpalus, Heraclides, Helicon.

Upper rim / N: Anaxagoras, Euctemon, Meton, Epigenes, Plato, Timæus, Archytas, Democrit. [Democritus], Thales (ref. G), Zoroaster.

Upper-right limb / NE: Endymion, Hercules, Atlas, Hermes, Mercurius, Cepheus, Messala (engr. "Messhala"), Geminus, Cleomedes, Macrobian. [Macrobius], Berosus (ref. R), Seneca, Plutarch., Proclus.

Right limb / E (Mare Crisium, Terra Vigoris): Firmicus, Taruntius, Langrenus [van Langren].

Central-upper (Mare Imbrium / Serenitatis / Vaporum): Archimed. [Archimedes], Autolycus, Aristillus [?], Timocharis, Pytheas [?], Aratus, Conon, Eratosthenes, Stadius [?], Dom. Maria [Dominicus Maria Novara] [?], Calippus, Theætet. [Theaetetus], Eudoxus, Posidonius, Sulpic. Gall. [Sulpicius Gallus], Menelaus, Vitruuius, Plinius, Manilius, Higinus [Hyginus], Iul. Cæsar, Agrippa, Sosigen. [Sosigenes], Ariadæus.

Mare Tranquillitatis / Terra Vitæ boundary: Hypatia, Theon sen., Theon iun., S. Dionys. Areop., Censorinus, Beda, Exiguus [Dionysius Exiguus], Alcuin, Mart. Capella, Goclenius.

West / left (Oceanus Procellarum): Ecphantus, Aristarchus, Seleucus, Cardanus [Cardano], Marius [Simon Marius], Bessarion, Cataneus [?], Galilæus [Galileo], Caualerius [Cavalieri], Reinerus [Reiner], Keplerus [Kepler], Milichius, Hortens. [Hortensius], Reinhold, Lansbergius [Lansbergen], Linemannus [Linemann].

Lower-left limb (Riccioli, Grimaldi, Terra Caloris): Ricciolus [Riccioli], Grimaldus [Grimaldi], Eustachius, Rocca, Billy, Sirsalis [Sersale], Crügerus [Crüger] (ref. S), Eichstadius [Eichstadt], Fontana, Zupus [Zupi], Deriènes [?], Herigonius [Hérigone], Gassendus [Gassendi], Mersenius [Mersenne], Byrgius [Bürgi], Vieta [Viète], Origanus, Kritmanus [?], Schikardus [Schickard], Hainzelius [Hainzel], Phocylides, Bayerus [Bayer], Schillerus [Schiller] (ref. D), Zucchius [Zucchi], Bettinus [Bettini], Bartolus [Bartoli], Kircher, Caluisius [Calvisius] [?], Cabeus [Cabeo].

Lower-left maria (Mare Humorum / Nubium): Campanus, Capuanus, Cichus, Bulliadus [Boulliau], Munosius [Muñoz], Rothmannus [Rothmann], Gulielm. Hass. [Wilhelm of Hesse], Saßerides [Sascerides] [?].

Lower-centre / S (Terra Sterilitatis, the great south craters): Ptolemæus, Alphonsus [Alfonso X], Alpetragius [al-Biṭrūjī], Arzachel [al-Zarqālī], Albategn. [al-Battānī], Thebit [Thābit], Purbachius [Peurbach], Regiomontan. [Regiomontanus], Pitatus [Pitati], Gauricus [Gaurico], Walterus [Walther], Blanchinus [Bianchini], Vernerus [Werner], Apianus [Apian], Aliacensis [Pierre d'Ailly], Azophi [al-Ṣūfī], Abenezra [ibn Ezra], Geber [Jābir ibn Aflaḥ], Almæon [?], Tatius [Achilles Tatius] [?], Fernelius [Fernel], Gemma Frit [Gemma Frisius], Nonius [Nunes], Maurolycus [Maurolico], Stœffler [Stöffler], Licetus [Liceti], Barocius [Barozzi], Homelius [Hommel], Piscus [Pitiscus], Hagecius [Hájek], Lilius [Lilius], Tannerus [Tanner], Mutus [Mut], Curtius [Curtz], Simpeliu[s] [Sempill], Manzinus [Manzini], Schomberger [Schönberger], Malapertius [Malapert].

Lower-centre south crown (the Tycho group): Tycho, Longomontan.
[Longomontanus], Scheiner, Blancan. [Biancani], Clavius [Clavius], Maginus
[Magini], Gruemberger [Grienberger], Moretus, Cysatus [Cysat], Saussurius [?].

Lower-right (Terra Sanitatis / Nectaris / Fecunditatis): Abulfeda, Alfraganus [al-Farghānī], Sacrobosc. [Sacrobosco], Pontanus [Pontano], Zagut [Zacuto], Rab. Leui [Levi ben Gershon / Gersonides], Riccius [Ricci], S. Theophil., S. Cyrill., S. Catharina, Stiborius [Stöberl], Fracastor [Fracastoro], Piccolomin. [Piccolomini], Neander, Metius, Reitha [Rheita], Fabritius [Fabricius], Muselius [?], Claramontius [Chiaramonti], Snellius [Snell], Furnerius [Fournier], Steuinus [Stevin], Santbec. [Santbech], Vendelin. [Wendelen], Petavius [Pétau].

LIBER III. — DE LVNA.

CAPVT XII.

To the most Reverend, most Distinguished, and most Learned man, Father Giovanni Battista Riccioli of the Society of Jesus, most celebrated Professor of Philosophy, Theology, and Astronomy at Bologna — Johannes Hevelius [Johannes Hevelius] sends greetings.

[Margin: Habet super quod agat etiam Posteritas.] [There is something on which posterity, too, may work.]

Were it not for your great devotion to study, and your humanity and kindness toward me — both abundantly known to me — I would surely have feared to break in with so bold a letter upon the tranquillity of your weighty studies. But I approach you all the more confidently in proportion as, in your incomparable *Almagestum Novum* [*Almagestum Novum* / *New Almagest*], you have offered me an occasion to address you — especially since not a few things contained in it pertain to our common studies, and are no less useful, which I am perhaps fortunate to possess. About these I wish freely, in the philosophical manner, to exchange words with you, and most earnestly to seek your judgement on them all. For although there is no one — let all suspicion of flattery be far off — more practised than you in that class of matters about which I now intend to deal with you, yet I also know that no one will grasp my meaning better, nor sift, weigh, and examine these very things more exactly. And so I shall not hesitate, in my burning zeal — and with my mind most well-disposed toward you — to make you the interpreter of those things which have proceeded from the highest ardour of

astronomical study. I in turn — believe me — pledge you my service, and my singular study in every kind of good office.

[Margin: *Multa praeclara in Selenographicis peragenda.*] [Many distinguished things remain to be accomplished in selenographic matters.]

For my part, I am well aware that very many most abstruse things, in every kind of the sciences, have been happily discovered by most praiseworthy Antiquity, and that a great many more lie hidden as yet, wrapped in the shadows of ignorance, left to be uncovered by us and by posterity. Who will deny it? Astronomy alone — let me pass over the rest — is witness enough, and more, to this. For although, with incredible fervour, labour, and constancy, it has been cultivated from the very first beginnings of the world, it is nonetheless by no means finished off in all its parts down to the last; [Margin: *Antecessores nostri reliquerunt Astronomiam; sed quotidie habemus in quavis illius parte quod corrigamus, adjiciamus, exornemus.*] [Our predecessors left us astronomy; but every day, in whatever part of it, we have something to correct, to add, to embellish.] our predecessors left us astronomy, but every day, in whatever part of it, we have something to correct, to add, to adorn.

[Margin: *Pariter in Selenographicis quantum nuper actum, & quantum adhuc superest.*] [Likewise in selenographic matters: how much has lately been done, and how much still remains.]

Likewise in selenographic matters: how much has been brilliantly accomplished in recent years, and how happily worked through, and how much still remains to be carried out beyond — that rests above all with you, the most knowledgeable of men in these matters, among whom I would rightly name you the leader. Be the judge yourself. Now among the chief matters that arise in scrutinizing the Moon, the motion of lunar libration holds (as you, not unknowing, can witness for me) by no means the last place. [Margin: *Motus Lunae Libratorius nondum hactenus satis fuit compertus.*] [The motion of the Moon's libration has not, up to now, been sufficiently ascertained.] To have it accurately discovered and grasped by perspicacity, and to deduce indubitable laws of it, is assuredly of much moment for astronomy — and especially for observations, that I may pass over very many things, namely for the right determining of lunar eclipses: since without that motion neither the Moon's limb, nor its centre, nor any of its phases and quantities, can be rightly delineated.

[Margin: *Autor sedulam dedit operam ut motum istum inveniret.*] [The author gave diligent effort to discovering that motion.]

For that reason, in our *Selenographia* [Hevelius, *Selenographia*] too, I laboured with all my powers and with various and manifold observations; and this motion of libration I determined, demonstrating it to all, as far as could be done within so short a span of time — that is, with sufficient diligence (in my own judgement at least) from the year 1643 down to 1645. First of all I detected, by what means and at what time our observations were carried out, that there was a libration; namely that in the year 1644 the greatest libration was observed in Cancer, and the least in Capricorn, and that the whole revolution was completed roughly in a monthly interval; [Margin: Maxima libratio An. 1644. in Cancro extitit.] [The greatest libration appeared in the year 1644, in Cancer.] and that the part of the Moon at which the terms of the libration occurred — and all these things — have their origin in nothing but the motion of longitude, of latitude, of the nodes, and of the limits.

[Margin: Maxima libratio paulatim ex Cancro exiuit.] [The greatest libration gradually departed out of Cancer.]

These same things, indeed, I have likewise found in the following years up to now to hold in fact entirely, and in great part — beyond doubt, by ascertained observations — except that, in the course of a longer time, the greatest libration has departed out of Cancer, and the least out of Capricorn, just as on page 438 of the *Selenographia*. I suspected this not badly, and I remember it clearly enough: I mean that I was plainly of the opinion that, even if the terms of the libration should in future remain at the very same observed point, nonetheless the greatest and least motions of the libration would not constantly remain in the very same signs — namely Cancer and Capricorn. [Margin: An. 1646. Maxima libratio in Virgine deprehensa.] [In the year 1646, the greatest libration was detected in Virgo.] This too I at once observed in the year 1646: my selenography, carried nearly to the central point, made it luminously evident — namely that the greatest terms of libration had passed out of Cancer entirely, following the order of the signs, and had then lodged in Virgo. From this, my mind exerted itself toward fuller and more complete investigation; and so, in the following years, I bent all my powers with the highest eagerness to disentangle this so very intricate motion. [Margin: An. 1648. motus librationis ab autore rectè & integrè detectus.] [In the year 1648, the motion of the libration was rightly and fully detected by the author.] But for a long time it vexed me, kept me in suspense, and held me back, so that I could establish nothing certain about it; yet at last, with the divine breath inspiring, and with me tirelessly scrutinizing it, the work succeeded according to my wish, and in the year 1648 I seemed to myself to have found that period — namely at what interval of time the greatest libration

returns to the same sign of the Moon, and on what foundation it rests. Of these things more fully in their place below. [Margin: Tabula libratoria constructa.] [A table of libration constructed.] Once that was thoroughly investigated, I at once constructed a table according to that hypothesis; and indeed for the integral, this present running century — and yet to be examined more exactly, both through our own and through others' observations, however many exist.

[Margin: Quare tabula ab autore non citius fuerit edita?] [Why was the table not published sooner by the author?]

It was not, then, without reason that I would have deferred for astronomy this matter, hitherto unknown — setting aside all delay — with these considerations especially: that all those things which I was hereafter to note about this matter, since I was to communicate them to the mathematicians (as if pledged, and on my honour, on page 439 of the *Selenographia*), I would have made public by right; but at the same time certain other matters, especially cometographic ones, were to be committed to the press at their own time, and I gladly chose to put off that business until then; not unwilling. But in very truth, once your work had been read through — distinguished work (a copy of which, by I know not what left-hand fate, was first given me at the beginning of this year) — it added the greatest stimuli to my purpose, that I should recall those selenographic observations which, on account of various most weighty matters, both public and private, occupations had until now made me lay quite aside. [Margin: Occasio scribendi.] [The occasion of writing.] There was added the fact that, in Book IV on the Moon, many distinguished things have been inserted: partly things I would gladly see, partly things that seemed to concern our *Selenographia*.

[Margin: Lunam librari certum est.] [That the Moon undergoes libration is certain.]

For which reason I have hastily seized the pen, to cast onto paper as much about the investigation of the libratory motion as about the things that bear upon its use and the construction of the table that follows, together with certain other things necessary to be added — so far as it pertained. What chiefly has been reached in this business, and what is to be corrected and augmented by those very persons in time, remains. But let us approach the matter itself.

[Margin: Lunam librari certum est.] [That the Moon undergoes libration is certain.]

That the Moon librates — now toward the West, now toward the Orient, now toward the South, now toward the North, within a certain interval of time — has

been luminously demonstrated, and not by me alone, in chapter 8, page 238 of our *Selenographia*; but, more than enough, by you in Book IV, cap. 9 of the *Almagestum Novum*, and has been confirmed by very many most painstaking men — Gassendi [Gassendi], Boulliau [Boulliau], Langrenus [Langrenus], Francesco Maria Grimaldi [Francesco Maria Grimaldi], Niccolò Zucchi [Zucchi] = Niccolò Zucchi, Daniele Bartoli [Bartoli], and Girolamo Sirsali [Sersale]. [Margin: *Latitudo huiusque genuina librationis periodus.*] [The breadth, and the genuine period, of the libration.] But the question is in what manner the greatest libration (that is, when the interval between the Marsh Mæotis [Palus Mæotis] and the lunar Sea of Crises [Mare Crisium], the limb, is the greatest of all), or the least (that is, when the interval between the Mæotid Marsh — by you otherwise called the macula of Grimaldi [Grimaldi] — and the Moon's limb is the least), changes and

varies: namely, whether the greatest always remains in Cancer, and the least in Capricorn — and of what sort, and how great, the genuine period of this variation is. This, up to now indeed, has not been sufficiently ascertained. [Margin: *Maxima libratio perpetuò in Cancro permansuram nunquam asseruit Autor.*] [The author never asserted that the greatest libration would remain perpetually in Cancer.] You urge upon me, indeed, in Book IV, cap. 9 (if I am not mistaken), that I was altogether of the opinion that the greatest libration of the Moon is in Cancer, and the least in Capricorn (as in fact happened around the year 1644), and that it would also henceforth appear continuously in the said signs; but — by your leave, most Reverend man — that was assuredly never my mind. For although I said many times in the *Selenographia* that in our time, or at these times, the greatest libration stood out in Cancer and the least in Capricorn, [Margin: *Id quod Selenographia satis superq; testatur.*] [Which the *Selenographia* testifies abundantly.] in no way would I have it understood as if I had said this for our whole age. As is set forth in chapter 9 of Book IV from your statements, those things might be so interpreted; but I thought only that it had so come to pass in the time of my observations — namely, from the year 1643 down to 1645, the time at which the greatest part of our phases was observed and delineated — that I plainly noticed nothing otherwise than that the greatest libration is in Cancer, and the least in Capricorn.

[Margin: *Id quod Selenographia satis superq; statuit, & redarguit.*] [Which the *Selenographia* abundantly establishes, and refutes.]

Accordingly, too, throughout the *Selenographia*, lest anyone snatch up my words in too ample a sense, I took sufficient precaution beforehand — in chapter 47,

page 421, where I treated of the greatest libration — wishing it so in these words: *Which, however, I assert with this exception: that if the Moon should hereafter keep its terms of libration in this same way in the said signs perpetually, and its motion in the manner in which it has been observed in the nearest elapsed years, it will so continue; but not otherwise — especially with the retrocession of the nodes (which, however, I deny to be in the least impossible) — should some inequalities arise, of which, by similar continued observations of lunations over a longer span of time, one might be made more certain.* Likewise, as you know, chapter 54, page 438, on the same matter: *But whether, in the manner already said, the greatest and least libration constantly and perpetually persevere in Cancer and Capricorn; or whether, in the train of a more lasting time, the libration suffers certain inequalities; or whether the thing be otherwise — I can certainly not affirm for the present; but this I can do above all: that hitherto, in the time of my observations, I have detected nothing otherwise than that continuously in those signs, Cancer namely and Capricorn, the terms of the libration were observed.* [Margin: Autor limites in Cancro, & Capricorno observavit An. 1644.] [The author observed the limits in Cancer and Capricorn in the year 1644.] *And since, within so brief a span of time — of a few years, that is (as those who weigh the existence of heavenly things will easily grant) — it could not be detected by us, it will therefore be of the highest necessity that all and each of the watchers of the heavenly vault, tireless and with the greatest diligence, with constancy applied, should thereafter attend whether the motion of libration of this kind persists in the Moon through all things with the progress of time, or does not; and whether it be bound up by the constant laws of many years' observations, agreeing with nature, and indubitable, and so forth.*

[Margin: Autor limites in Cancro, & Capricorno observavit An. 1644.] [The author observed the limits in Cancer and Capricorn in the year 1644.]

From these things, and from very many others, it is hence luminously plain in our *Selenographia* that I observed the limits of the libration in Cancer and Capricorn in about the year 1644, and in those same signs; and that (which is well noted) I foretold soon after, most aptly, that these limits would not remain perpetually there, and that thus too the quadrature sections of the Moon's terms exist in each; that the greatest libration, existing through the same maculae, would never be carried across under the same term; but that it would vary, as the greatest and least libration would tarry now in one sign, now in another; and likewise the limits, and the poles too, with certain variations — just as I indicated, in clear words, at pages 237 and 244 of the *Selenographia*, that they would be liable to vary. There was no need, then, to impugn those things which I never

affirmed for certain; nor was it so much in space, nor (as above) is it manifest with the things cited, that I was able to establish them; but it sufficed to have demonstrated and indicated the greatest libration about

the Marsh Mæotis no longer in Cancer, and the least no longer in Capricorn, to exist — as indeed was observed around the year 1636 by Gassendi, and in the year 1644 by Boulliau, and by me about the year 1644. [Margin: Maxima libratio vicissim An. 1649. in Capricorno apparuit.] [The greatest libration appeared in turn, in the year 1649, in Capricorn.] But truly in the year 1649, with the most ingenious Grimaldi attesting it, the greatest libration was in turn detected in Capricorn, and the least in Cancer; which I too firmly attest, so that it truly came to pass with this libration of ours, in the manner said, at the time.

For I have at last observed — when out of my several continuous observations, and out of those of others, it has befallen me to see — that the limits of the libration (that is, the greatest libration) vary altogether with the progress of time, and from the sign of Cancer move on by steps to the rest, in proportion as one may compare the signs; [Margin: Quanta sit librationis periodus, & quamdiu reposita in intervallum excurrat prius quam maxima libratio ad idem redeat punctum.] [How great the period of the libration is, and over how long an interval, stored up, it runs before the greatest libration returns to the same point.] and that, after some nine years or so of absolute interval (or, to speak more accurately, after the greatest and least of this libration has returned to the same point of the zodiac in the space of 8 Egyptian years, 311 days, 1 hour, and about $\frac{1}{3}$ — and daily it is promoted by 6 signs, 41 minutes, 41 seconds in the consequence of the signs).

[Margin: Libratio pro motu longitudinis, & latitudinis Lunæ variatur.] [The libration is varied with respect to the motion of longitude and of latitude of the Moon.]

For it is most true, as we said often enough in the *Selenographia*, that the motion of libration follows the motion of longitude and of latitude; and this indeed of the simple latitude. [Margin: In Australi latitudine Regio Hyperborea ampliatur; in Septentrionali coarctatur.] [In the southern latitude the Hyperborean region is enlarged; in the northern, it is constricted.] That is to say, when the Moon has its greatest southern latitude, that space toward both limbs, looking Zenith-wards — namely the Hyperborean region, Sarmatia — is greatly enlarged, so that the Moon's limb stands as far as possible from the Sarmatian mountains and from the Iacubean Hyperboreans [*Iacubi Hyperborei*] (or, as it pleased you to name them, from the maculae of Meton, Thales, and Endymion). The lower interval, on

the other hand, terminated meanwhile by those two limbs of the Moon, around the point of Nadir, plainly vanishes (as in the figure inserted near at hand, or in the following epistle, according to the full moon, page 164 of the *Selenographia*): so that the Moon's limb, around the lower part — having the Trojan Mountain [?], the Meridional Mountain, M. Hæmalon [?], and Techisandam (or, which is the same, the maculae of Schickard [Schickard], Zucchi [Zucchi], Kircher [Kircher], and Sempel [Sempel]) — is then nearest of all to all of them. By contrast, when the Moon has its greatest northern latitude, the space looking Nadir-wards — namely the part of Lybia [?] and Arabia (the land of sterility and of fruitfulness) — is found to be most extended; so that at that time the Moon's limb, with the said maculae — namely the Trojan Mountain, the Meridional Mountain, and Techisandam — is most lengthened away, while in the upper interval the interval meanwhile compresses itself wholly, so that the upper part of the limb — the maculae, namely the Hyperborean lakes and the Sarmatian mountains — is as near as it ever could be. And in this way, for the variation in respect of the Moon's latitude, the interval perpetually grows and shrinks, now above, now below.

[Margin: Libratio longitudinis non solùm Lunæ motui longitud. sed Apogæo & Apogæo respondet.] [The libration of longitude answers not only to the Moon's motion of longitude, but also to the Apogee and Apogee.] [?]

But the matter has itself somewhat otherwise with the libratory motion of longitude, which is detected around the western and eastern shore of the Moon, near the Marsh Mæotis and the Mæotid Marsh. For it is reckoned not simply from the motion of the Moon's longitude, but at the same time accommodates itself to the motion of the lunar Apogee. Hence, for the variation of the Apogee, the greatest libration in the Moon's western region, and the least in the eastern, around the Marsh Mæotis, always falls back: the Moon's limb either accedes more and more to those maculae, or recedes from them, around the Mæotid Marsh; and by like reasoning, in the upper and lower parts (as I remarked above), the limb varies toward the diverse latitudes of the Moon. [Margin: Maxima & minima libratio semper in plagis medijs remotionis Apogæi & Perigæi accidit.] [The greatest and least libration always occurs in the middle regions of the remotion of the Apogee and Perigee.] By this expressed law, with the Moon's Apogee turning in Cancer, the greatest libration is in Aries, and the least in turn in Libra; but with the Apogee placed in Leo, the greatest libration is in Taurus, and the least in Scorpio — and so consequently. By this reasoning (since I have set forth a few things, that I may unfold them), the greatest and least libration — that is, when the Marsh Mæotis and the Sea of Crises (or the macula of Grimaldi, and of

the Sea of Crises) has its greatest access to, or recess from, the Moon's periphery — perpetually occurs at the points of the middle remotions of the Apogee and Perigee. Just as this happens in various ways, I myself, with the observations of some years added by the grace of this epistle, and then with all the rest, am ready to demonstrate it — and especially you Bolognese are well placed to do so.

And so this is the chief cause from which that most intricate —

the Moon's libration arises, which up to now has wearied and tormented us so greatly. Some, no doubt, will be astonished — indeed, they will laugh at us — that, when the foundations of this librational motion are so very well known and so easy, and we delight in them, we should have reduced it to definite tables no sooner than we did, and only after the most thorough scrutiny. But of such half-learned judgments we take no account, especially when that most acute philosopher Seneca foretold this to us clearly long ago, in these words (*Natural Questions* VII): "*The time will come when our descendants will be astonished that we were ignorant of things so plain.*" Let us, then, be content to have investigated, explained, and laid this matter open thus far, and leave the rest, which perhaps still remains, to others. *For the time will come*, as Seneca goes on, aptly, in the same place, *when those things that now lie hidden will be drawn into the light of day by the diligence of a longer age.* But let us return to our purpose.

[Margin: From what foundation the librational table is constructed.]

Granted, then, the foundation just stated, the following table has been computed and extended for the present century, and — if anyone should prefer it — for several years more; and this is most easily done. For a given year, and for the beginning of any month you please, collect the motion of the Moon's apogee [Apogaeum Lunae], from which, if you subtract 3 signs, the true place remains in the signs and degrees, etc., in which, at that time, the greatest libration in longitude toward the Marsh of Maeotis [Palus Maeotis] occurs; whereas if you add 3 signs, the place of the least libration in longitude toward Maeotis comes out, and the greatest toward the opposite Marsh of Maeotis. Meanwhile, the greatest librations of the Marsh of Maeotis alone (since the least of these are evident from these) lie confined within the lattice, as is plain in their order; and indeed we have arranged them for the beginning of each month. We could likewise have extended this motion through the individual days, but to do so would have been excessively laborious to no purpose, since such great precision is not needed: it suffices to know the greatest libration of the Moon in any month. But if anyone should desire something more, let him use the proportional part; or — what is better — let him add, from the tables of the Moon's apogee, the motion

for the days and hours, if need be, to that librational motion for the beginning of a given month, and he will have, precise to the day and even to the hour, the greatest libration in longitude sought.

[Margin: The use of the table.]

The use of the table is this. For a given year, and the place of the greatest libration in longitude found — namely toward the Marsh of Maeotis. This being known, and the Moon being at some place in the ecliptic for a given day, how great its libration there is — whether greater or less, by the help of the little table inserted — is learned with no trouble: namely, whether it is at its maximum or its minimum, and at the same time by how much it has receded from the maximum, and from the minimum, librational limit.

[Margin: How the reticule shown in the *Selenographia* is here exhibited.]

Before we teach how the genuine libration belonging to any time is to be drawn from these, it is necessary, in order that we may have a general diagram of the phases ready beforehand — around whose center the librational motion both in longitude and in latitude is delineated. In our *Selenographia*, pages 262 and 410, we exhibited such diagrams, which possess about the center some reticule [reticulum] described, by whose aid the librational center of the Moon ought to be moved; but one must know, since the Moon's greatest libration — as has now often been stated, not more — occurs at that time when the least libration in longitude is in Capricorn: and for that reason that reticule does not suffice for every time; but only when the libration is greatest (as happened in the year 1644) it stays in Cancer, the Moon at the same time having its greatest southern latitude.

[Margin: When the greatest libration will in turn occupy Cancer.]

But that some, on the other hand, fix the greatest southern latitude at the close of the year 1661 and the beginning of 1662 — as on page 417 of the *Selenographia* we hinted; likewise for the years 1679 and 1697 — we shall see clearly come to pass.

[Margin: By what method the libration of every kind can best be delineated.]

Therefore it was greatly needful to devise another method, by whose help the libration, answering to these times both in longitude and in latitude, might be rightly described. You imagine, indeed, on page 214 of Book IV of the *Almagestum Novum*, that this could best be done by a little circle drawn about the center; but, the matter well considered, this is utterly impossible to perceive. And so it was

necessary to return once more to our reticule — though we have drawn it somewhat differently, and have reduced it, as far as we have so far been able from the given observations, in such a way that, in our opinion at least, of this...

Diagram. A rhombus-shaped (diamond) reticule grid occupying the lower right of the page, used for plotting the Moon's librational center in both longitude and latitude. The grid is filled with a regular lattice of crossing lines (triangular cells), with numbered scale divisions running along each of the four slanting edges. The figure is oriented as a square set on one corner; its two diagonal axes are labelled for libration in longitude and in latitude.

- Top vertex region: **minimum** (one upper corner) — marked *minimum*; the opposite scale running 0 through 5.
- Upper-left to lower edge (one diagonal): **Libratio Longitudinis** [Libration in longitude], with an *inter. medium* [intermediate] marking near the upper run.
- Right diagonal edge: **Libratio ... D Latitud. Austr.** [Libration / southern latitude], and at the far right **D Nodoru. / Latitud. Bor.** [of the nodes / northern latitude].
- Left diagonal edge (descending): **Latitudinis Austr.** [of southern latitude] over **Libratio D Latitud. Bor.** [Libration / northern latitude], with **Lin. Bor.** [northern line] and **Libr.** marked near the lower-left corner.
- Lower vertex: **Libratio Longitudinis** [Libration in longitude] with **minima** [least] at the bottom corner.
- Edge scale divisions: numbered runs 0, 1, 2, 3, 4, 5 and intermediate marks (10, 15, 20, 25 etc.) along the lattice edges on all four sides.

more and more, so that around the number 6, where the two outer circles intersect each other, the greatest libration is always reckoned; with a corresponding relation to the following reticule, in which the librational center of the Moon is moved — as will presently be said more clearly. But the upper interstice you see divided, in the line of limits, into 10 equal parts; the lower one likewise into equal parts. For when the Moon is in southern latitude — say only some 5 degrees about southward — and is extended some degrees toward the north, it will be necessary, that point, the middle point, to distribute into so many parts; that middle point refers to the limb when the Moon is situated about the Nodes, or in the ecliptic, having no latitude at all: the upper [parts] show the southern latitudes, the lower the northern latitudes.

[Margin: The difference between the old reticule and the new.]

According to these [divisions], the divisions of both longitude and latitude — this reticule moves about its center, or rather the center is moved within it, not indeed actually through itself, but by the relation of the peripheries to be described at all times — is delineated. And it agrees with that earlier reticule on page 242 of the *Selenographia* in nearly this: that the motions of the center are likewise completed by transverse lines absolutely; otherwise it is certainly mixed, the motion in latitude and in longitude never being separately describable. But it differs in turn from the earlier one in this: that it bears not the signs of the Zodiac, but the degrees of latitude; and on its front [top] and its foot [bottom] it exhibits the quantity of the libration of longitude divided into 6 parts, just as in the preceding larger reticule it appears more distinctly and clearly.

[Margin: Description of the new reticule.]

In the line a b, toward the left, when the center is situated so that the Moon possesses the least libration about the Marsh of Maeotis — the libration in longitude; but in the remaining parallel lines 1, 2, 3, 4, 5, the same libration grows in proportion, up to the number 6, namely the line c d, in which, the Moon being placed about the center, the greatest libration in longitude is described; and thence again from number 6 it decreases in the same way down to 0. But the remaining lines, parallel to the Nodes, exhibit the true place of the Moon's center according to all the latitudes, and indeed five [each]: the upper ones the southern, and the lower ones the northern latitudes, are jointly displayed.

And so, the quantity of the libration in longitude being given under a certain number (which from both is learned by the table) — and not the true latitude of the Moon — the center is also given, namely under the intersection of those two thicker lines of the libration of latitude and of longitude, for delineating the genuine periphery of the Moon, which by longitude and by latitude — as we have signified — is moved truly by the finer transverse lines. For example: if the Moon possesses a latitude of 4 degrees southern, then the center, in the line a b, about the number 3, will lodge in the upper [position]; from this point (if the latitude grows) through the points 10, 2, 12, 18, 24, 1, 34, 38, 42, 46, etc., it is carried further. But if the Moon, obtaining a southern latitude of two degrees and the least libration, then the center, in the line a b, about the number 2, is found in the upper [position]; and afterward, from this place (if likewise...

the latitude grows) through the number 15, 11, e, 13, 19, 2, 29, 33, 37, 41, 45, 4, and so on in succession it moves; but if the latitude decreases, from the said number 2, downward, through the points 25, 31, 37, 43, 49, 4, etc., the center of the Moon is carried; as will easily be evident to anyone looking more deeply into the

matter. And if anyone should desire to know more fully, let him read, if he please, pages 241 to 245, where almost everything is treated there about that reticule, and agrees well with this one of ours.

[Margin: The poles and the limits of the libration are moved.]

From this motion of the lunar center it necessarily follows — and we ought never to subside in the same place. By this reasoning, indeed: when the greatest libration is toward Maeotis, together with the greatest southern latitude; likewise the least libration there, with the greatest northern latitude, is given — then the axis, namely of latitude, or rather its western pole about A (in the Selenographic figure preceding), or, more accurately, when it lodges within FE, by reason of the differing northern and southern latitude, turns. But when the contrary happens — namely when the greatest libration, with the greatest northern latitude, exists, and again the least libration with the greatest southern latitude — then the librational axis of latitude, or rather its western pole about B, or rather within G and H, lodges. But at another time, about the intermediate librations and latitudes, between B and A, it librates pretty nearly always; so that, in my judgment, it descends in a measured way to about 35 degrees. With like reason, the limits also, or the line of limits (when this differs from the line of the Nodes by 90 degrees perpetually), are distant by about 35 degrees: this is plainly necessary.

[Margin: By what reasoning the poles librate.]

Which opinion both I have hitherto always held, although the boundaries of the poles and of the librational limit were unknown to me. For, when I had laid down (as I have often recalled, especially on page 244 of the *Selenographia*) that the poles of libration are continually moved, and never lodge on the same periphery in the same place — but by reason of the libration of the center, now ascending, now descending — it follows also that the limits are of necessity movable. Therefore indeed I marvel from where you might be persuaded (as on page 212 of Book IV of the *Almagestum Novum* it is read) that I had laid down the limits to be perpetually immovable: since the contrary shines forth more clearly from what I have said.

[Margin: The author always laid down that the poles and limits are moved.]

Moreover, if we look more deeply into this librational motion, we shall see not only — by that, namely, the given hypothesis — that there is one axis, or those two, AA, the poles of latitude, of which mention has now been made; but in the Moon there is given still another axis, or two poles besides, about the line of limits, which it pleases us to call the poles of longitude; which likewise by nearly

the same reasoning as the poles of latitude are moved hither and thither, by whose benefit the librational motion in longitude is represented. And thus our twofold motion of libration, mixed of longitude and of latitude, is easily explained by these two axes: what you, indeed, may think of the matter, you will set forth in your own time, not unwillingly.

[Margin: The twofold librational motion requires also a twofold axis.]

Tabula nova motus Lunae Libratorii maximum librationis terminum circa Pal. sc. Maeotidem Occid. versus, quovis anno & mense currente huius seculi exhibens.

[New table of the librational motion of the Moon, exhibiting the greatest term of libration toward the Marsh of Maeotis on the west, for any year and current month of this century.]

For each month, three sub-columns are given: **O.** = degrees [gradus], **1** = minutes, **S.** = sign of the Zodiac [signum]. The year column is headed **Anni Christi curr.** [current years of Christ].

[Liber III — De Luna. Caput XII (lunar libration), continued]

The three folios in this opening continue the **New Table of the Moon's librational motion, displaying the greatest term of libration toward the West, near the Palus Maeotis [Sea of Azov], for any year and any current month of this century** (*Tabula noua motus Lunæ Libratorij maximum librationis terminum circa Pal. sc. Maeotidem Occid. versus, quouis anno & mense currente huius seculi exhibens*).

The first folio (174) completes the July–December half of the 1600–1650 century begun on the preceding folio. The next two folios (175–176) give the corresponding table for the 1651–1700 century: January–June on folio 175, July–December on folio 176.

In each month the three sub-columns are headed **O.** (*gradus*, degrees), the minutes column (printed with a prime mark), and **S.** (*Signum*, the zodiacal sign). Zodiacal signs are transcribed by their standard three-letter abbreviations: Ari (♈), Tau (♉), Gem (♊), Cnc (♊ Cancer), Leo (♌), Vir (♍), Lib (♎), Sco (♏), Sgr (♐), Cap (♑), Aqr (♒ Aquarius), Psc (♓).

Folio 174 — July–December, years 1600–1650

[End of the librational-motion tables for the 1600–1700 centuries. Caput XII continues on the following folio.]

Liber III — De Luna (continued)

Caput XII (continued) — Lunar Libration

TABLE OF THE LIBRATORY MOTION

TABULA MOTUS LIBRATORII. *Given the maximum libration of the Palus Maeotis, from the preceding table, together with the place of the Moon, to find the libration that corresponds to it.*

This table is read by entering with the libration argument of the Palus Maeotis (the column-head values 0–6, marked *Maxima libration* / *Minima libration*) and with the zodiacal sign of the Moon's place; the cells contain the zodiac sign that gives the corresponding libration. The page is laid out as two mirror-image halves, the left half headed *Libratio Decrescens* (decreasing libration) over *Intermedia* (intermediate) values, the right half headed *Libratio Crescens* (increasing libration), with the head and foot of each half giving the entry arguments in opposite senses so that the table can be read either way. The cell entries are zodiacal-sign symbols.

Top header band:

Maxima libratio P. Maeotid.	Libratio Decrescens — Intermedia	Minima libratio P. Maeotid.	Libratio Crescens — Intermedia
6	5	0	1
Minima libratio P. Maeot. (0)	Libratio Crescens — Intermedia	Maxima libratio P. Maeot. (6)	Libratio Decrescens — Intermedia
(0)	1	(6)	5

Body of the table (zodiacal-sign entries). Each row corresponds to the sign of the Moon's place; reading across gives the libration-sign for each argument value. Left half (entry signs, columns headed 1–5 under *Intermedia*) and right half (columns 1–5):

(folio 178)

A general figure of the phases has now been set out, with its four maximum variation-limits — that is, with the boundaries, and with certain definite points or distinct dots marked on it — both along the longitude line (which is the line of the latitude-limits, of the libration in longitude, where the latitude is greatest or least) and along the latitude line (which is the longitude line, where the latitude is intermediate but the motion is genuinely new). With this figure carefully drawn, and with the reticule [reticulum] fitted around the center of the disk — by means of which, given the time, the Moon's libration is accurately set in motion — and given also the Moon's place, the time's libration of the Palus Maeotis is rightly described; and by its benefit we may show the use of both of our tables, and how the libration competent to all times is drawn from them, and how readily this may indeed be done from a single example.

[Margin: Eclipsis Lunae An. 1652, dieque 17 Septembr. ad eam declarationem usurpata. — The lunar eclipse of the year 1652, on the 17th day of September, employed for this demonstration.]

Let it then be sought, for the current year 1652, on the 17th day of September — at the time of a lunar deliquium (eclipse) which fell out at that place [hic Gedani — here at Danzig], and which I therefore had the occasion to observe carefully,

since that observation, not yet committed to common print, you have willingly wished me to communicate, eager as you are for such matters — the place [shall be] the maximum libration of the Palus Maeotis [Palus Maeotidis]; and as great as the libration of that same day is, by which the limb of the Moon was painted to the same iconism [icon/picture], may rightly be described. In the margin, therefore, with the left part of our table the motion of the libration is set; there the year is sought along the front, but the month in the column corresponding to it; and the maximum at 22 degrees 4 minutes of Gemini is found to be the libration.

[Margin: Quomodo ex tabula maxima libratio sit excerptenda. — How the maximum libration is to be extracted from the table.]

Now to enter upon the matter that follows, the minimum, and indeed under the title of the maximum libration of that same Palus Maeotis: investigate in the margin, likewise from the left, that same sign of Gemini; then, taking the right side toward the same, progress onward, [until] the sign in which the Moon at that time is found (if it is the case, unless from elsewhere, or through the calculation itself, it is otherwise established) is noted carefully; whose place by titles in front, and indeed at once it indicates whether the libration is increasing, or decreasing; the maximum, the intermediate, the minimum; and so on. Then let the little column respond (in which the sign of Gemini, at the place the Moon then occupies, is found); as great is the libration at the egress of the Palus Maeotis from the minimum, or maximum libration of the longitude, in the numbers above expressed: which numbers, in the lunar schema around the Palus Maeotis, answer entirely.

[Margin: Usus tabulae minoris. — The use of the smaller table.]

For example: if the sign of Gemini is repeated at the maximum's turn in the lesser table, the libration in the lesser table, under the title of the maximum libration of the Palus Maeotis, plainly in the end is the minimum (since the Moon at that time turns within 22 degrees and a little more of Pisces [Piscium], at the time of the eclipse, established): from there the right side along the little column of the number is found. It is established, therefore, that as much both by the number under the said title, the libration at that time was, [whether] intermediate increasing, or in the middle of the remotions, the maximum, and the minimum libration.

[Margin: Quomodo secundum longitudinem, ac latitudinem libratio describenda. — How the libration is to be described according to longitude and latitude.]

Next, with these found, and the latitude likewise given — namely near the Node, by a fitting radius understood with the compass — in the general figure (which we have drawn around the disk of the Moon), let the numbers be marked, both in the longitude line and in the limit line, in the region of the more northerly part (since the latitude is then there if the Moon has no latitude); but if it has been seated, the time's latitude being given, plainly at once it is intersected; and so in the schema of the following eclipse it was done; you see, the Moon's limb, with the time being given, and the Moon's place may be definitely determined. Or — what is preferable — by means of the reticule drawn around the center of the Moon, where the things may be expedited much more easily: if a minor libration in the description, and the latitude diverse, unless that, things to be carefully painted, may be intersected by drawing through the proper points; and as we may paint the limb.

[Margin: Tabulae libratoriae, ac alii cui revocandae observationes. — The libration tables, and to which the observations are to be referred back.]

Similarly then, as it is rightly gathered, the operation is, even if the libration under some other number of the lesser table is repeated, both ways; that the latitude is plainly diverse, unless that, things to be diligently rendered, by which the limb may be painted through the proper points.

[Margin: Modus item hoc describendi, ac operatio, etiamsi libratio sub alio quodam numero minoris tabellae reperiatur, similiter; latitudo prorsus alia diversa, nisi quod ut tendendas diligentissime, quo limbus per debita puncta, ostendi atque declaratur exemplo. — The manner likewise of describing this, and the operation, even if the libration is found under some other number of the lesser table, likewise; the latitude entirely otherwise diverse, except that, as it is to be drawn most diligently so that the limb [is painted] through its proper points, is shown and declared by example.]

(folio 178, second column)

of the longitude and latitude, and may justly be carried. For example: let there be described the limb of the full moon, which falls in the year following, 1655, on the 30th day of April, in the evening, the Moon existing in the beginning of Scorpio, and around the fifth degree of southern latitude. Seek therefore — as in the table, the great [table] is at the principle [sub-table] — the time of the maximum libration in longitude; and you will find it turned over to the month in the seventh degree of Libra. And that sign again under the title of the maximum libration of the Palus Maeotis, on the left side, seek, and you will find the sign of

Scorpio of the true place of the Moon, in that same line on the right side, under the numbers of the minimum: hence, therefore, it appears that the libration of the Moon at that full-moon time was decreasing, and indeed in part, partly around the Palus Maeotis itself. This being known, place the circuit (in respect of the greater reticule) in the upper line of the latitude, around 5, at the intersection of the 5 — since the latitude is southern, [at] the 5th degree; and so be it that the genuine center described from the periphery of this full moon is to be described. And so, at any time given, by mediation of the two of those little tables, given likewise the true place of the Moon, both in the ecliptic and in the latitude — that is, with the libration of the Palus Maeotis [found], the Moon's disk is rightly determined. The libration of the Palus Maeotis is found by that same libration, which facilitates the investigation; and there, in the lesser table, the minor numbers are attended to; you will have likewise [the value], indeed the libration between the limb and the Palus Maeotis at any time. As to what is more commodious here, both from the things that can be, the peculiar schema of the phases shown generally is less, with the whole limb in no way constructed; but on the right side, around the Palus Maeotis with nothing except that six of those libratory points of longitude, and on the part of the higher Moon, [at] the upper sixth those points of latitude have not been noted there: around the center indeed the reticule, of which, and of those points of beneficial libration, let nothing here from the business of all time, the limb under another libration of the longitude to be described, of the whole integer in number. Such is the archetype that here is, which from the eclipse phases of the year 1652 I have described. As are the things — if perhaps you, some of them, or others, cultivators of these matters may need — I freely communicate.

[Margin: *Eclipsis Lunae An. 1652. Gedani descripta hic et delineata.* — The lunar eclipse of the year 1652, described and drawn here at Danzig.]

[Margin: *Quae sit libratio Maeotidis ad investigandas phases generalis.* — What the libration of the Maeotis is, for investigating the phases generally.]

[Margin: *Cur ex minori schemate phasium phases generales [investigandae].* — Why the general phases [are to be investigated] from the lesser schema of the phases.]

But do not marvel that our table of the Moon's libratory motion measures only the degrees, the minutes set aside, of the first [equation], and refers it to the second altogether [as] minimum. Indeed, in business of this kind, where the motion of the libration is by no means to be divided to the eye, in vain it is, since

to be solicitous about the minutes [is], on the contrary, the minute itself — the first, the second, and, with all error, with no risk, and to neglect it altogether.

[Margin: Cur tabula maior ad gradus, et minora scriptura, tum sit suspecta. — Why the larger table [reckons] to degrees, and the smaller [is] written [more finely], and why it is then suspect.]

For the rest, we have taught — indeed sufficiently fully, as it exists — in what way the libration of the Moon may be compared, and how from the preceding table it may at any time be found, that it may be excerpted: I say the maximum, since the table itself at any time agrees most aptly with the heavens. But it will be no grievance to us that someone may believe — most truly, indeed — that not only from ours, indeed from those of others, but also of other most distinguished men — such as Gassendi, Boulliau, and also your most loving [friend], with Grimaldi by his much most diligent observations — that they should demonstrate to us, and reach our hands, the table of hypotheses; that our [table] rests on a solid foundation. For which reason, both for the brevity of the matter, that to anyone of ours [it] may be more clearly evident, let all observations be recalled, and the following tables: first, [a] second column of our observation; the Year, the Months, and the Day; third, the hour. Of the observations; fourth, the longitude of the Moon; fifth, the Moon's latitude; sixth, whether the libration is around the Palus Maeotis; seventh, how great the distance is in the numbers, near those which in the archetype we have noted; in what observation; and eighth, how great the same may be of equal intent in seconds; the table, and the difference, which it may be more clearly here; the animadverted. Furthermore, we have added these too — not useless, as I think — certain annotations; especially as those maculae [the lunar sea-spots] of the quadrature-sections may pass over; which certainly all things make less, that it may be more clearly admonished below, to rightly investigate our libratory motion. Truly, then, I do not at all doubt the highest [thing], thus far, between observations, both ours and those of all the rest, agreeing in tables. Nonetheless, indeed, although by very few observations, excessive, or defective, in respect of the table, of one inch defective: yet this discrepancy, then by no means of moment, then [to] the observer...

(folio 179)

it is altogether imputed to the observer. And if it is impossible — as (it is established to you, the most expert of these matters) — to discern by an inch, indeed even by two distances, so accurately, and that by the naked eye, by the inspectors, unless by the most exercised — the diverse latitudes of the Moon always to be accurately attended to, the observations may be carried through.

Not, however, [is it] a long observation that by a continuous series I have learned: the interstice of the Palus Maeotis, than [that of] the Marrota [Mare], and indeed the hyperborean lake [lacus], somewhat greater the maximum and the minimum, always appears greater; if at the same time the southern latitudes the Moon may have, in a space something less they always conspire; with first chiefly around the upper part of the Palus, and at the time the Moon had the same southern latitude [as the] Boreal; and so in others, and at other latitudes, a little also otherwise; and otherwise: that this is shown for any of you, in our general Selenographic schema of the phases at the greater page 8, inserted, sufficiently above; it is manifest. These things, since they are exceedingly subtle, for that reason also by no means easily can all be well animadverted [observed]: and so it is more clearly, as we have indicated, in determining the libration to err by an inch.

[Margin: Maxima librationis interstitium non semper univocum, sed genuino aequalia. — The interstice of the maximum libration [is] not always univocal, but [the] genuine [parts are] equal.]

For the rest it must be noted, that sometimes also the limb, according to our table, by the inspected things [observations] may respond — not always according to the table described, [but] now into this, now into that part declining: but as the first front may appear, nevertheless the imperfection of our tabular hypotheses; for that reason [it is] not at once to be judged. Now indeed it is altogether impossible, just as at all times, and from every part, the peripheral maculae [the rim sea-spots] are nearer, especially around the Palus Maeotis, well [and] accurately I look: when around the Marrota [Mare] well distant justly, [it] is to be looked at accurately. Since indeed of the diverse libration, in respect of the limb, around the most diverse it may be compressed, or dilated: which indeed, in one given schema in no way to exhibit can we possibly. Hence, it comes about that the limb is nearer to the Inferior Mare Caspium [Langren's name] approaching, [it] may appear in our iconism, than ever in the Moon itself can be given: the ratio of this is, that since the limb of the said maculae approximates, at the same time also the Caspian Mare with all its adjacent parts gradually contracts itself; the space lessening, the more ample. A similar appearance is to be observed around the contrary parts; that is, [around] the longitude-line, near the hyperborean parts. For also at other times [the Moon's] sections, so that scarcely the numbers may appear, by no reason of the observation [are they] to be perceived; but always somewhat distant from the hyperborean Sinus [Bay] to be distant, it will be seen: the cause [is] the same, the said dilation, and compression.

[Margin: Infinitis schematibus, opus, si omnis varietas dilationis, et compressionis macularum exprimi debeat. — Infinite schemata [are] needed, if every variety of the dilation and compression of the maculae must be expressed.]

If indeed such various diversities, by reason of the dilation and compression arising, by no means we wish to avoid, infinite would be the schemata to be drawn; and as we [draw] each macula at each [point] of the limb, by reason of the libration variously, and each macula at each [point]; by reason of the dilation and compression rightly to be founded: which, since it is altogether impossible in figured number, on that account, the variety of the phases plainly is; for which reason in a single phase-figure (which is the maximum libration) plainly: ideo it is that around the Palus Maeotis, [as] the Moon in the southern limit equally, [is] to be content from us, [it] is painted; [it] behooves [us]. And so it must not be imputed to us hereafter for some such fastigium [summit]: deeply, however, I am persuaded, [it] never can altogether be done, [that] the schemata may [match]; but that the business may be necessarily required, that all such variation, or of the maculae compressed, or dilated, the most minute things may be described.

[Margin: Tabula libratoria, et alii cui revocandae observationes. — The libration table, and to which the observations are to be referred back.]

Moreover, lest we omit anything pertaining to it, [as to] examining the libratory motion of the table, conducing — all those things observed, which in the *Almagest* book IV, Caput IX, Question 7, in the first, second, third, and fourth, [are] argued — [I] have annotated, scrupulously and religiously expended, [and] examined; and so I have found by exam, to answer to all, and to be saved by all the rest of your observations of all the best. Three of the later observations, namely [those of] 1649, the 22nd, 24th, 25th, [and] 27th of September, and the 21st, [and] 26th of November. Likewise in the year 1651, the 1st [and] 26th of August [the eclipse] was held, when the macula Grimaldi (Palus Maeotis) and the Mare Crisium (Palus Maeotis) by an entire ratio indeed agreed, as I noted, to...

(folio 179, second column)

the limb of the Moon accessed, and from that receded; the table also consenting to ours. Plato, however, and Tycho, do not always at one moment in all that time substitute; but indeed sometimes a little (as is plain from the table) item also the limb accessed, sometimes also the limb receded; and indeed as I think within, in those observations the macula of Plato circled around — and Tycho's also somewhat to the side. For altogether I am persuaded, by long and skilled experience, [that] the macula of Plato (M. Sinai of the major [maculae]) and of

others [is] far from the periphery of the Moon to be distant, and to recede around the limb, the same accessory; and is not to be observed; or indeed the rest by closeness of the macula: such as P. Maeotis, and P. Aniadocae [Palus Amadoca], etc. And although, both from the said distances, that truly far from the smaller maculae [it] is appealed [to], it suffices to note for any time rightly: especially, that here I keep silent of the parallaxes, which also at so little in rising, and setting, the librations adulterate, when around the maximum, and minimum the librations, where certainly the rising, and of the labors, in the most minute particles [is] the libratory motion, as is determined (*Almagest* page 2003, lib. IV. *Almagest*).

[Margin: Accessus, et recessus M. Sinai, ac lacus nigris maioris differt; servatur. Artis est observari. — The access and recess of the M. Sinai, and of the major dark lake, differs; [it] is preserved. It is a matter of skill to observe [it].]

[Margin: Parallaxes corrumpunt librationes. — The parallaxes corrupt the librations.]

Meanwhile then nobody exists, who may think the M. Sinai, and the major dark lake, etc., not able to be observed; but I say only this, that of those maculae the observation [is] not so much, as the rest of the maculae, to the limb nearer may be attributed; and that hence easily an error may arise, even a little [too] easy, also Rev. P. Grimaldi, around the said maculae of Plato, and of Tycho, [was] hindered. When, however, both around the observations to one, and the other Rev. P. Grimaldi, then also mine, and others' observations, those — around the said maculae of Tycho, and Plato perfected — in number the rest may not be received. Therefore, as I have said, the things accustomed we can [observe], thus far; nothing have I found, or [it is] to be observed, in which whatever the table of the libration may nutate [waver]; which, however, in the following years, as the centuries come, [whether] the number may always retain the same tenor, indeed [whether] with time in part, and in so much to be corrected; future generations by longer diligence will be able to divide [the question].

[Margin: Num motus libratorius sibi perpetuo sit aequalis, tempus docebit. — Whether the libratory motion is perpetually equal to itself, time will tell.]

Finally, since in the table of our observations, that also around the maximum, [and] from the diligently annotated observations, the sections of the limit, or of the quadratures [we] may examine, [yet] we ceased, and item per the motion of the Moon's libratory we examine. For indeed, by these, if at any time the true quadratures were animadverted [observed], not less, as for the intermediate of

the maximum, and the maximum quantity is known of the libration; and vice versa it may be sought: that from the table by the maximum [libration], so that at any time the section so much of the quadratures, as of the other phases of the maximum may be found. But this libration [is] of the highest order: and indeed [it is] truly the limit adhibited [applied], from there, believe, and [it is] more clearly [evident], how little [it] may profit.

[Margin: Sectiones quadraturarum non semper transeunt per easdem maculas. — The sections of the quadratures do not always pass through the same maculae.]

For my part, [it is] most true, [as] is set out, also passim [here and there] in the *Almagest*, [and] passim also in the *Selenographia* we declare, [that] the sections of the quadratures [do] not always pass through the same maculae; but per others, and others, [and] by the reason of the variant libration: hence, the diligently observed section of the quadratures also, the Moon's libration. Before we teach in what way the matter [is] to be carried through, [it is] to be said — indeed we have hindered the sections to be omitted at all times, both in the *Selenographia*, and in the *Almagest*, fully set out, [and] indeed sufficiently; and that these matters' cultivators we may put away. We have said, however, that by brief [things to be] comprehended, the section of the Lunar dichotomy, [at] the maximum libration around the Palus Maeotis, [it] transfers per the Inferior Besbicam [Besbicus], the western parts of the Mount Olympus, Didymus, and Cydifis [?] about; and at the time of the section, [where] the maximum [is], the western [parts] exist; but indeed [at] the minimum libration, and of the Palus Maeotis, the sections of the quadratures transfer [through] the Mont Sinai, [and] the Insula Cyprum, [the] Inferior Lesbos, the Sinus Tarantinus, and the Lacum [Lake] near the maximum, [it is] said, around the more eastern: about, I say [around] them; for at all times, [and] chiefly in respect of...

[Margin: Data maxima, et minima libratione, per quasnam maculas sectiones quadraturarum [transeant]. — Given the maximum and minimum libration, through which maculae the sections of the quadratures [pass].]

[Margin: On the inclination of the Moon's horns.]

of the southern and northern parts, they do not always keep the same course or direction, but, depending on the varying position of the Moon, the horns point now westward by some degrees, now eastward, never quite parallel — as for instance in the *Selenographia* I noted carefully, and as you too will find in the *Almagestum Novum*, p. 203, § 3, quest. 3, where I treat the same matter of the horns a little differently. Doubtless those horns, with respect to the nodes, point

now toward the limits, where they incline more toward the perpendicular; otherwise we cannot make them out, except near the Moon's middle. Near the parts adjacent to the limb, by contrast, the horns can scarcely mark out these lines.

And so these are the ways of the two extreme sections when there is a fixed libration of the Moon. But to know this alone is by no means enough for accurately determining the various librations of the Moon — namely, when, since none of them is sufficient for us, I have at least set down by how much I remember; and what maculae the intermediate sections pass through, especially by reason of that division of the librating figure, I trace upon our selenographic map, as we said, in order to be brief.

[Margin: The seven principal sections of the quadratures.]

How much, then, I attain by repeated observation, I have found and set in order, I shall now relate.

The first section, namely the one toward the west, occurs when the libration is at its greatest, that is, at the Palus Maeotis [Palus Maeotis], at libration-number 6 of our table above, which figure I have transferred onto our selenographic chart, as we said. It passes through the Catena Mundi, the western shores of Mt. Olympus, Mt. Didymus, and Mt. Cydissus.

[Margin: The fourth section of the quadratures, number 6.]

The second section: when the libration is at number 5, it crosses Mt. Pangaeus, the eastern parts of Mt. Olympus and Mt. Didymus, the western edge of Mt. Cadmus, and Mt. Antilibanus.

[Margin: The fourth section of the quadratures, number 5.]

The third: when the libration is about number 4, the section passes through Mt. Seir, Mt. Cadmus, between Mt. Sipylus and Mt. Montuniatum, and through the Ligustinum.

[Margin: The fourth section of the quadratures, number 4.]

The fourth line of the section: when the libration is about number 3, a line is drawn through the middle of Mt. Libanus, the western parts of Mt. Cragus and Mt. Sipylus, through the intermediate places of the Adriatic Sea, the lake Trasimenus, and so on.

[Margin: The fourth section of the quadratures, number 3.]

The fifth section: when the libration is about number 2, a line is given that is carried through Mt. Seir, the upper part of Mt. Libanus, through Mt. Masicytum, the eastern parts of Sipylus, between Propontis and the Sinus Hypponiates, and Mt. Argentarium.

[Margin: The fourth section of the quadratures, number 2.]

The sixth: when the libration is about number 1, the line passes through Mt. Tabor, Mt. Phoenicem, Mt. Latmus, and the promontory of the Moon.

[Margin: The fourth section of the quadratures, number 1.]

The seventh and last: when the libration is at its least, that is, at 0, the section crosses Mt. Sinai, the lower part of Mt. Cyprum, Mt. Lesbos, the corner of Mt. Tarantium, and the larger black lake. But when the libration is counted toward the Palus Maeotis, then, since the rules for judging the sections of the quadratures hold good, but in the reverse order, it is necessary that they be applied. For example, if...

[Margin: The fourth and last section of the quadratures, that is, 0.]

the libration is 0, the section found will not be the seventh but the first; and if it is at the greatest, the sixth section is to be taken, the second being assumed from the libration-number 1, and so on consequently.

By these foregoing rules anyone may quite fully examine our libration-table from whatever observations he has made of the Moon. As to the bisections by the light's confines, careful attention must be paid — as I touched on above — to the sections in such a way that, by close attention, those very sections, either before the true quadrature by the space of one hour, or after the true quadrature, may be observed, while at other times they will in no way answer to the rules; but they will be found within, or beyond, the proper limits, as is shown — and this must be judged and reckoned. If, however, the fourth hour before the quadrature shall have been noted, then the next preceding rule will be the norm; and the same is to be observed for the preceding rule of libration. And if the fourth hour before the quadrature shall have been noted, then the next preceding rule will be the norm, with the preceding rule of libration likewise observed. The more light the Moon acquires, or the more is wanting to it for the true quadrature — just as we said copiously on pp. 330 and 331 of our *Selenographia* — all of which is correctly observed from the sections. The quadratures of one observed time, indeed, will not greatly err from those of another, provided that the librations are observed at the quadratures; but if the given libration agrees from any times of

the sections of the Moon at the bisections, attend carefully — but if it can be done both at once, from the various latitudes of the rising Moon, or about five, counted at the limb of the Moon, you will rightly attend to the varying. But the greatest variation about each, if there be a node, and indeed about the northern node, with the upper horn so many degrees about the eastern part as so many degrees about the southern node toward the eastern part, the said horn turns; as we set forth on pp. 334 and following, up to pp. 340. With selenography abounding, we have demonstrated these matters more plainly through these very diagrams, and that almost to the eye.

[Margin: If the quadrature is not to be observed at the true quadrature, but before it.]

[Margin: Whence the inclination of the horns of the Moon arises and is fixed.]

To all who carefully attend to these things, by experience, and I scarcely doubt, both ours and yours, the sections of the dichotomized Moon will answer rather precisely to our table; and likewise the tabulated sections will answer well enough to the bisected Moon, in this way, and as it were both ways, just as the sections of the bisected Moon — yet more cautiously and according to the libration befitting the quadratures and of all the others — as we taught on pp. 444, 445, and 446. We undertake this task, that we may bring it about; yet we can do so with peril, but I am convinced this is hardly far from the mark. We therefore foretell some sections of the quadratures for the years next following, with their times, and the true quadratures to be observed. And in order to set forth this matter the more briefly, in what follows we shall present a table of the future bisected sections of the Moon. First, the year, month, day, hour — these are indicated; afterward the longitude and latitude of the Moon, and, with the libration of that time, through which maculae the sections of the quadratures will then be carried, we shall display.

[Margin: The table is likewise to be observed of all the quadratures of the others, and the sections... you will be able.]

[Margin: How the phases of future Eclipses are foretold, and the loss of the entire body of all observations.]

Such predictions cannot but be pleasing to the worshippers of divine Urania, nor was it ungrateful to me, that an occasion might at once be given to signify and show by what benefit of ours the tables of librations (the rest, that I may pass over the very many things in silence, which I have rejected elsewhere) are to be more fully and completely treated, when at any time, or by reason of the maculae, they exhibit those phases of whatever Eclipses, at the same time also setting forth the phases of present things. This matter is certainly most clear, and likewise very useful: it is to be wished, therefore, that some imposer of Ephemerides among our writers would exhibit the types of future Lunar Eclipses, so that the reckoning might be set forth less toilsomely to the world, and might profit the spectators no little, and refresh them.

Let there be ready at hand, then, a certain general figure of the phase of the Moon, much like that one in which we delineated the Eclipse of the Year 1652, or a smaller one, if it so please, since this time we have used that one; and let it be constituted in this way: with a genuine periphery, drawn according to our libration from the table, and the radius divided into six equal parts, let those same parts of the six circles be drawn through eleven dividing digits. Then, with the perpendicular drawn through the center for the center of the schema; but let it be made in such a way that, according to that point in the periphery of the upper full moon — see *Selenographia* p. 264, the inserted and inclined revolving full moon. As to the inclination of the perpendicular according to the libration and the nodes (otherwise it will go quite far astray), let it be rightly attended; and likewise the other, which is normally intersected by the perpendicular at the place of the Moon's orbit, let a line be drawn. Afterward, on some large paper, let the earth's shadow be described, as is usually done about the types of Eclipses, the proper proportion of the schema being nonetheless preserved according to the calculation, and the schema given in proportion: which, although it is hardly difficult.

Again, from some thick paper, or membrane, let an arc of 90 degrees of the circle be cut out, larger or smaller, but altogether like the others; then, from the shadow, near the latitudes about the beginning, with the orbit imposed on the arc, let the Moon's orbit be drawn — and the western parts about the Moon's orbit. Let the Archetype of the Moon be so applied to the shadow, and to its orbit, with the shadow's orbit, as one and the same; and let it exhibit the true inclination of the maculae, and the same full moon itself: and then let the point of

contact be noted, namely the beginning of the Eclipse. Afterward, in the same way, both at the right and at the sinister, let the full moon be moved round through all the various positions of the Moon between the circle, namely the shadow, and the arc of the upper full moon, similar in shadow, until the circle touches the first digit; and then let the first phase, or the first digit of the Eclipse, be marked, near the arc of the upper maculae intersected, notable. Then, from the second circle, let the second digit be deduced from the archetype, observed from the full moon of the same; and consequently all the rest, or as you will, and where it has been noted, let it not be unknown. By this calculation of future Eclipses let the types be drawn, with the true inclination of the maculae, which the Moon will exhibit at the time of the greatest obscuration, according to the Tyconic calculation; let these be observed in their places as described, in the adjoined figure, so that from those things it may very clearly appear by which maculae the section will pass; and also how much, and how greatly, the maculae most darkened at any time of the partial Eclipses will exist as the terminus — which is most worthy to be noted of all, plainly and at every time.

[Margin: Eclipse of the Moon, the Year 1656, on the 1st day of January.]

In the first figure, then, the Eclipse, namely that which will fall in the Year 1656, on the 1st day of January, the beginning about 148 degrees from the Palus Amadoca...

that is, toward the rising of Amadoca, from a point of the Nadir, truly through a perpendicular line about 61 degrees, and the end from the same point toward the setting about 60 degrees, or at the Palus Amadoca about 87 degrees, will be marked. Furthermore, the greatest obscuration about the larger black lake, Mt. Serrorum, Mont. Macrocoemius, and the lake hyperborean will be terminated as the end; hence the quantity of this same future Eclipse will be $10\frac{1}{2}$ digits.

[Margin: Total Eclipse of the Moon, the Year 1657, on the 5th of June.]

In the second Eclipse, the beginning falls about 146 degrees at the Palus Amadoca, toward the rising, from a point of the Nadir truly through a perpendicular line about 67 degrees, and the end at the rising about 95 degrees from the said point; but at the Palus Amadoca about 86 degrees, the beginning toward the setting; and the term of the recovery of light will fall about 33 degrees, and at the same end about 12 degrees of the digits. In the third Eclipse the greatest defect will fall, and it will be a total obscuration in part of the upper Moon, that is, about 20 degrees at the Palus Amadoca, and at the term of the numbered light the greatest defect will be 12 digits.

[Margin: Eclipse of the Moon, the Year 1659, on the 6th of May.]

In the third Eclipse, which will be seen in the heavens in the Year 1659 on the 6th of May, the beginning in part of the upper Moon, about 86 degrees from the rising at the Palus Amadoca; the setting about 22 degrees from the said Palus will appear, and its quantity will be $\frac{2}{3}$ of a digit.

[Margin: Eclipse of the Moon, the Year 1659, on the 20th of October.]

In the fourth Eclipse, which will be in the Year 1659 on the 20th of October, the beginning in part of the lower Moon, from a point of the Nadir truly through a perpendicular line, about 67 degrees, the setting toward the said point will be looked for; at the end about 7 degrees, and at 21 minutes it will come. For we shall truly try by what reckoning the calculation agrees with the heaven itself at that time, if we are observers — let us experience it.

Finally, since we have constrained the librating motion of the Moon by certain laws (so far as may be), even to give a demonstration of our hypotheses set before the eye — that this matter, certainly, can scarcely be attempted so easily as it can be made known; nevertheless, in my opinion, I shall set forth at least a better one than it could have been thought up by us — meanwhile I shall not have it perfectly held in numbers as the matter itself. But since two diverse motions concur at once, and the same is seen, by a peculiar schema, I shall first demonstrate the latitudes of the librations, then also the longitudes.

[Margin: Demonstration of the librating motion as to latitude.]

Let there be then, in the following upper schema, A on the Ecliptic, d, the line A, the Moon, constituted about the nodes; the Moon having the greatest northern latitude C, but the Moon truly, the line having the greatest southern latitude from the earth; but truly toward the Moon, the lines are of vision, e g, the pyramids of vision, and e, f, perpendicular to the line of vision. About the nodes, with the perpendicular from e, with the base of vision d, let them coincide, the intermediate one being given between A and the libration: indeed, so much as a part of the lower line of the Moon is looked at. About B, with the Moon existing about the limit boreum, non amplius, with A f e d; sed g d h, ad the aspect of our point arrives; thus, with the place e g, of the upper part, ab oculo verso receding, h f, the particular [?]Moon rising, from the lowest part of it, let us perceive; but truly the contrary happens near C, the Moon turning in the southern limit, where the alternate part appears about the upper limb of the Moon, namely e g, the lower parts of the part f h, vanishing from us, as appears, take note. Hence in the northern latitude the boreal shores of the Moon are contracted, but the austral

shores wider; on the contrary, in the southern Meridional latitude, the boreal shores of the Moon are wider, the austral narrower, as our table shows. About the nodes, the space both ways, as it were equally ample, appears, except that little particle nearly equal, which the parallax originates; and it scarcely extends itself toward the hundredth and sixty-eighth part of the face of the Moon: of which...

[Margin: Whence the variation of latitude of the librations originates from parallax.]

since there is almost nothing of moment, in this matter of libration no account is kept.

But truly the cause of the motion of the libration in longitude is profoundly difficult to demonstrate. Yet I greatly wonder that anything of that has escaped you in your meditations, nothing of it has come into my mind plainly until the Year 1648, that, by the eccentricity of the Moon (namely, that the point of the Moon's eccentricity always remains constant in the same hemisphere, not truly the earth; thence I would say that that librating motion arises from the Moon's longitude, as I touched upon rightly on p. 214, *Almag.* lib. IV — whether this hypothesis can subsist truly: since the eccentricity of the Moon is so great, that it can exhibit a libration of so many parts to us as it is reckoned; but unless this can be excogitated, and indeed it cannot be reached; for unless a truer one be set forth in the meantime — for surely by that reckoning all the variations of libration can be best explained and preserved, just as I have set forth opposite, if matters be accurately considered, it is sufficiently clear.

[Margin: Demonstration of the librating motion as to longitude.]

In this, let A be the earth, B the eccentricity (or as I suppose, as much as is necessarily required) I, the Apogee, C, the Perigee, M, & F, the distance about the intermediate ones; about f d, the libration of the Maeotis, and about c e, the Maeotis exhibited about f d, but truly, with the further straitness about M, the space truly about c e, the Maeotis is grasped as the least of all. Indeed, as it about the smallest part about peripheria g f, and conversely g e, appears the greatest at all times. With the Moon descending into O, in the interstice of the Maeotis f d, gradually it grows, & c e, decreases: as the part of the periphery g f grows, g e, truly diminishes. Then in C, the space is given, namely the middle libration, and so great from the one as great from the other side it is looked at: the reason for the lateral ratio is given, namely f d, as much as about the position of the base of vision, & the eccentricity into one and the same line coinciding, parts of the

periphery g f, & g e, being equal. Afterward, with the Moon receding gradually toward the Perigee D, the space of the Maeotis about f d more and more grows, with the Maeotis c e decreasing again, the interstice of the Maeotis c e the same being said in ratio. And the distance in E, & F, about the intermediate ones the libration is always greatest at the Palus Maeotis f d, and the smallest at the Palus Maeotis c e; take note: because g f is the greatest part of the periphery in this place, of all the greatest; g e, truly the smallest. With the Moon ascending toward the Apogee, the space of the Maeotis grows in the same way, as the descending toward M, growing against the Maeotis interstice c e: as somewhere in G, H, I, K, L, & M, clearly appears.

These then are the matters, most Reverend and most Celebrated Man, which I, with the most eager soul of Astronomical investigation, have poured out to you, although briefly, yet freely, openly, mine, to communicate to you, and which I willingly wished to submit to your especially favorable judgment. With these I conclude, praying God, the Best and Greatest, most fully, that he may most kindly grant you a long life, and no little leisure, by which the rest, which still labor under our hands, and the glory of the divine name, illustrated, may be brought to light by your immense ingenuity, magnificently to be acknowledged and admired; most happily may you protrude into light at your time, if it be possible. Farewell, chief ornament and adornment of Urania, and with the highest love and favor be redeemed to me. I would wish you, most Reverend, and most learned Father, to be greeted as officiously as possible, and to be saluted; and the most learned Father Francesco Maria Grimaldi [Francesco Maria Grimaldi]. I gave this at Gdańsk [Gdańsk] from my museum, in the Year of the Christian Era 1654, on the very day of the Autumnal Equinox.

[Margin: Demonstration of the librating motion as to longitude.]

Observations of the libratory motion, both around the Palus Maeotis and the Palus Maraetis, made at Gdańsk by Johannes Hevelius [Ioanne Hevelio]

[This single observation table runs continuously across the three folios (pp. 183–185); it is presented here as one table. **Column headings (verbatim):** *Annus* (Year) | *Mens. dies* (Month, day) | *Hor.* (Hour) | *Longit. Lunae* — subdivided S. (sign) and O. (degree, i.e. *gradus*) | *Latit. Lunae* — subdivided O. (degree) and ' (minutes) with a following letter A/S (the sense of latitude, *Australis* / *Septentrionalis*) | *Libratio* | *Dist. limbi iuxta Obse.* (distance of the limb according to observation) | *Dist. limbi ex Tab.* (distance of the limb from the table) |

Animadvertenda (Things to be noted). Longitude signs are given by their zodiacal glyphs in the source; they are rendered here by name. The two distance-of-the-limb columns are in units of (twelfths of?) the disk; fractional entries are printed as written, e.g. $\frac{1}{2}$, $3\frac{1}{2}$, $5\frac{1}{4}$, $2\frac{2}{3}$.]

1	No v. 3 4	Aquari us	5	2 40 A	P. Mae ot.	4	4	The Palus Amadoca was clearly observed.
7								
	No v. 6	Pisces	11	4 40 A	P. Mae ot.	3	3	
	No v. 12	Taurus	25	3 18 A	P. Mae ot.	0	½	The interval appeared very narrow.

Observations of the librational motion, both around the Palus Maeotis and around the Maraeotis, made at Gdańsk by Johannes Hevelius [Johannes Hevelius].

The table that follows continues without interruption across these three folios. Its columns are: the **Year** [Annus]; the **Month and day** [Mēs., dies]; the **Hour** [Hor.]; the **Longitude of the Moon** [Longit. Lunæ], given as zodiac sign and degrees [O. S.]; the **Latitude of the Moon** [Latit. Lunæ], given as degrees and minutes with **A** (austrina, south) or **S** (septentrionalis, north) [O. I]; the **Libration** [Libratio], i.e. the reference spot, marked **P. Mœot.** (Palus Maeotis) or **P. Maraeot.** (Palus Maraeotis); the **Distance of the limb as actually observed** [Dist. limbi iuxta Obse.]; the **Distance of the limb from the table** [Dist. limbi ex Tab.]; and the **Remarks** [Animadvertenda].

Observations of the Librational Motion by Pierre Gassendi [Petrus Gassendi], both about the Palus Maeotis and about the Palus Maraeotis

The table records, by date, the observed position of the Moon and the state of the libration relative to its limb. The columns are: Year [Annus]; Month and day [Mens., dies]; Hour [Hor.]; the Moon's longitude [Longit. Lunae], in degrees [O.] and zodiacal sign [S.]; the Moon's latitude [Latitud. Lunae], in degrees [O.] and minutes ['], with the direction (S = south / A = north [Australis / Aquilonaris]); the libration [Libratio] (toward the Palus Maeotis [P. Moeot.] or the Palus Maraeotis [P. Maraeot.]); the distance of the limb from the table [Dist. limbi ex Tab.]; and the libration according to the observations [Libratio secundum Observationes].

Year		Month		Hour		Longitude		Latitude		Libration		Distance of limb		Libration according to observations

1648	July	22	9 2	$\mathfrak{M}$	4 47 S	P. Moeo t.	2¼	The Palus Maeotis was still very near to the western limb. [Margin: Ex literis Bullialdi auctorem — From the letters of Bullialdus to the author.]
	July	24		1 $\mathfrak{A}$	5 6 S	P. Moeo t.	3	The aforesaid spot had receded noticeably from the edge.
	Aug.	26	8 21	$\mathfrak{A}$	0 6 S	P. Moeo t.	5½	The Palus Maeotis was at its greatest distance from the limb.

Observations of Father Francesco Maria Grimaldi [Francesco Maria Grimaldi]

This page presents the observations as four distance-measurements, each with its own sub-heading, set in two columns. In every table the columns are: Year [Annus]; Month and day [Mens., dies]; the Moon's longitude [Longit. Lunae], in degrees [O.] and sign [S.]; the Moon's latitude [Lati. Lunae], in degrees [O.] with direction (A = north / B = south); the distance [Distantia], qualified as either

greatest [Maxim.] or least [Minim.]; the value from observation [Ex Obse.]; and the value from the table [Ex Tab.]. The distances are expressed in parts of which the Moon's semidiameter is 100.

Distance of the Mare Crisium, or the Palus Maeotis, from the western limb, both by observation and by our table, in parts of which the Moon's semidiameter is 100

[Below the last table, a passage of prose closing the chapter:] Yet again I give thanks to that most learned and most courteous man [Grimaldi], for the occasion he furnished of probing these matters, in a letter which raised an ambiguity. Now [it remains] to compare these other observations against ours in our *Almagestum Novum*... [the remainder runs on, partly obscured by show-through]. [?]

LIBER III — DE LVNA (Book 3 — On the Moon)

CAPVT XIII.

Breuis Responsio ad Heuelij expostulata. (A brief reply to Hevelius's complaints.)

There are altogether two points which Hevelius, in the preceding letter, supposes I have wrongly written against him. *The first* is that, throughout this whole century, the greatest libration remains perpetually in Cancer and the least in Capricorn — not because he expressly stated this, but because no one could interpret his words otherwise from what he says in Book 4 of the *Almagestum* [*Almagestum Novum*], Chapter 5. *The second* is that the immobility of the limits of libration must perpetually be retained — although he himself taught the contrary.

[Margin numeral: 1]

As to the seat of the greatest libration in Cancer and of the least in Capricorn: from what I have said it could be prudently interpreted that, throughout this whole century of ours, Hevelius binds the greatest libration to Cancer and the least to Capricorn. Concerning Hevelius, see page 211, number 16. I added, speaking of Hevelius: *Is he to be suspected of retrograde motions, [whereby] the lunar orbit of the nodes may sometimes also migrate into other signs to be observed, [with] the greatest librations of these?* — Against this, Hevelius, in Chapter 54, page 438, said: *But whether in the way already stated [the greatest and the least libration] constantly persevere, or whether — through the longer interval of time — the Moon still undergoes some inequalities, etc.* And so Bullialdus's [Ismaël Boulliau's] and Gassendi's [Pierre Gassendi's] observation gave no small handle for thinking that more years are required before the libration migrates from Cancer into another sign — though even after a few years it does migrate. But indeed, since Hevelius restricts that same station in Cancer to the years 1643, 1644, and 1645, I have no opinion about the future, but I record only what he himself sufficiently and amply lays out against me; and I freely grant that he explains this more clearly.

[Margin numeral: 2]

[Margin numeral: 3]

As to what concerns the immobility of the limits: I attribute it to him neither absolutely nor rigorously. For in Book 4, page 211, number 17, the limits of libration, from the opinion of Hevelius, retain the same situation: *Or how nearly he taught it.* And in that same Question 7 I said: *It must be granted that Hevelius, and from many of our observations it is certain, [maintains] frequently within knotty limits — that they are nearly the same that he himself assigns.* And yet I have shown elsewhere that the mobile limits which Hevelius once established are not without suspicion, since they are read out one by one with the same eye — yet so that I both maintained those limits and removed them, as he himself expressly stated: *Although the whole of his opinion of the limit is indeed greatest and least of libration in the Moon, with respect to the maculae, will never be varied, yet the motion itself is greatest and least of libration — whether the limits perpetually remain in the same signs, or are at some time, according to the retrocession of the nodes, going to go out backward in Cancer and Capricorn step by step.* By which words it is evident enough that the limits of libration are indeed varied, as far as concerns the lunar limits within the orbit, or with respect to the signs of the zodiac; but always around the same part of the lunar limb, or thereabouts. Therefore, in the letter set forth above, he introduced a far greater

reticule, and recognized the line of the limit as distant by a whole 90 degrees from the line of the nodes, marked at 15 degrees approximately of the signs, from what was said in Book 4 of the *Almagestum Novum*, Chapter 9, Question 7. From which things to be said the matter below will lie open: that those same things, drawn by the books through the middle of the Mare Crisium and the Caspian [Sea], and the macula of Grimaldi [Francesco Maria Grimaldi], differ much more by 35 degrees, so that they are somewhat notably below the line drawn through the middle of the Mare Crisium and the Caspian and the macula of Grimaldi, [and] are somewhat notably above; whence are those limits, which I called by that name, which have the title: *Whether in a determinate part of the lunar limb are the greatest limits of libration, and of the nodes themselves the poles*. They do not, however, cohere perpetually in the same signs. Again I render him thanks for this, that this most learned letter, if it had been published with ambiguity given the occasion, has removed it; and now to other observations not commonly published in our *Almagestum* we must come.

CAPVT XIV.

Observationes circa Mobilitatem Polorum, seu Nodorum Librationis Lunaris ab Anno 1649. ad 1656. (Observations concerning the Mobility of the Poles, or of the Nodes of the Lunar Libration, from the year 1649 to 1656.)

Pro quibus videnda est Figura in Almagesti Noui Lib. 4. Cap. 7. vel supra Cap. 11. (For which the Figure in the *Almagestum Novum*, Book 4, Chapter 7, or above in Chapter 11, should be consulted.)

It pleases me to bring forward here only those observations from which it is in some way immediately established, in the limb of the Moon, where the place of the nodes is congruent, or of the poles of the lunar libration, and likewise also other things which pertain to libration of this kind. For although those observations expound something particular for the most part from one or another macula of libration, [things] which on that day were observed, [I set them forth] in the foregoing manner; yet they are confirmed by the other observations which others perhaps had in those same years; and likewise, in publishing these things, they are made for the conferring and recognizing of the period of this matter, which has indeed been investigated in the lunar libration, but cannot yet be perfectly determined, [as] from those things which have hitherto been observed we recognize. So that the matter may be clearer, and under one view the mobility of these poles may appear, I have deduced from

those same observations again and again that the limb of the Moon — the other of the poles — and because into eight parts, or octants, the very limb itself in our image of the Moon is divided, expressing them separately in a lateral column [with] the number of the octant, in which the other pole turns out to be contained by this single limb. There are indeed a double pair of poles, which can determine something more accurately in the aforesaid limb. From the one pole, then, the place of the other is immediately recognized, inasmuch as it is opposite by a diameter.

Anno 1649. (In the year 1649.)

July, day 18. The macula Grimaldi [Grimaldi, Francesco Maria Grimaldi] was distant from the Limb of the Moon precisely by as much as had been observed on the other preceding days.

Days 30 and 31. Grimaldi was distant from the limb of the Moon more than on the preceding day.

August 1 and 3. Grimaldi did not vary its distance from the limb of the Moon.

Days 8 and 14. The Mare Crisium did not vary its distance from the limb of the Moon as nearest.

Days 15, 18, 19, and 21. The Mare Crisium increased its distance from the limb [of the Moon].

Days 23, 24, and 26. Grimaldi receded from the nearest limb of the Moon.

Day 29. Grimaldi receded from the limb of the Moon, but Plato approached. Whence it is gathered that the place of the poles of the libration had been between these two maculae; this turned out to be in the Octant.

[Margin numeral: I.]

Days 30 and 31. Grimaldi receded from the limb of the Moon.

September 1 and 2. Grimaldi receded from the limb of the Moon.

Days 3 and 4. Grimaldi approached the limb of the Moon.

Days 12, 13, and 14. The Mare Crisium increased its distance from the limb of the Moon.

Days 16, 17, 18, and 20. The Mare Crisium did not vary its distance from the limb of the Moon.

Day 25. Plato receded from the limb of the Moon.

Days 22, 23, 24, and 25. Grimaldi approached the limb of the Moon.

Days 26 and 27. Grimaldi and Tycho [Brahe] [= the crater] receded from the limb of the Moon; therefore the pole turned out to be perhaps in the first octant.

[Margin numeral: I.]

Day 28. Grimaldi and Tycho receded from the limb of the Moon, but Plato approached; therefore the pole turned out to be in the first octant.

[Margin numeral: I.]

Days 29 and 30. Grimaldi receded from the limb of the Moon.

October 10, 11, and 14. The Mare Crisium receded from the limb of the Moon.

November 9. The Mare Crisium receded from the limb of the Moon.

Days 10, 11, and 13. The Mare Crisium and Endymion did not vary their distance from the limb of the Moon.

Day 14. The Mare Crisium approached the limb of the Moon.

Day 21. Grimaldi and the Sinus Roris [Bay of Dew] receded from the limb of the Moon, and the macula in the Terra Siccitatis [Land of Drought] did not vary its distance from the limb of the Moon; the other of the poles turned out to be in the first octant.

[Margin numeral: II.]

Days 22, 24, and 25. Grimaldi receded from the limb of the Moon, but the Sinus Iridum [Bay of Rainbows], Plato, and Tycho did not vary. And therefore one Pole turned out perhaps to be in the second octant.

[Margin numeral: II.] [Margin numeral: III.]

Day 27. Grimaldi receded from the limb.

December 9. The Mare Crisium and Endymion receded from the limb of the Moon; and on that account the Pole was in the first or second octant.

[Margin numeral: I.]

Days 10, 11, and 12. The Mare Crisium and Endymion did not vary their distance from the limb of the Moon.

[Margin numeral: II.]

Days 12 and 13. Pitiscus receded from the limb of the Moon.

Day 22. Grimaldi increased its distance from the limb of the Moon. Tycho and the maculae above Plato did not change theirs. Therefore one Pole was perhaps in the second octant.

[Margin numeral: II.]

Anno 1650. (In the year 1650.)

January 8. The Mare Crisium, Endymion, and Pitiscus did not vary their distance from the limb of the Moon.

Days 9 and 10. The Mare Crisium and Endymion did not vary.

Days 11 and 12. The Mare Crisium and Endymion approached the limb of the Moon.

Day 14. The Mare Crisium and Endymion approached the limb of the Moon, but Tycho receded; and on that account one Pole was in the first octant.

[Margin numeral: I.]

February 9. The Mare Crisium and Endymion approached the limb of the Moon, but Pitiscus receded; therefore one of the Poles was in the first octant.

Days 10, 11, and 12. The Mare Crisium approached the limb of the Moon. Pitiscus did not recede on day 10.

Days 15 and 16. The Mare Crisium did not vary.

Days 17 and 18. Grimaldi approached the limb of the Moon a little. Tycho did not vary.

Day 19. Grimaldi and Tycho scarcely approached the limb of the Moon, but Plato scarcely receded. From which it is gathered that the other Pole was in the first octant.

[Margin numeral: I.]

Days 23. Grimaldi and Tycho greatly approached the limb, but Plato receded greatly; and thus it is confirmed that the Pole was in the first octant.

[Margin numeral: I.]

Days 25 and 26. Grimaldi approached the limb.

March 6, 7, and 8. The Mare Crisium and Endymion did not vary.

Days 10, 11, and 12. The Mare Crisium approached the limb of the Moon.

Day 13. The Mare Crisium approached the limb of the Moon, and Plato and Aristotle receded from the limb, very near to them; on that account one of the Poles was perhaps in the third octant.

[Margin numeral: III.]

Days 15 and 16. The Mare Crisium did not vary.

Day 17. The Mare Crisium receded from the limb of the Moon.

Days 20 and 24. Grimaldi receded from the limb of the Moon; therefore one of the Poles was perhaps in the first octant.

[Margin numeral: I.]

April 6. The Mare Crisium and Endymion approached the limb of the Moon, and consequently the Pole was in the first octant.

Day 7. The Mare Crisium and Endymion approached the limb of the Moon. Pitiscus, however, receded; whence it is confirmed that the other of the Poles turned out to be in the first octant.

[Margin numeral: I.]

Days 9 and 10. The Mare Crisium approached. Endymion did not vary.

Day 11. The Mare Crisium and Endymion did not vary. Tycho scarcely increased its distance from the limb of the Moon.

Day 12. The Mare Crisium did not vary. Tycho approached the limb.

Days 13, 14, and 15. Tycho approached. The Mare Crisium, Endymion, Aristotle, and Plato receded from the limb of the Moon; therefore the Pole turned out to be in the first octant.

[Margin numeral: I.]

Day 16. Tycho approached. Plato receded.

Days 20, 21, and 23. Grimaldi approached.

Day 24. Grimaldi approached, Tycho and Plato did not vary.

Day 25. Grimaldi approached, and on days 26 and 27 did not vary.

May, day 7. Endymion did not vary. The Mare Crisium approached the limb a little.

Days 11, 12, and 13. Endymion and the Mare Crisium receded from the limb.

Day 14. The Mare Crisium, Endymion, and Aristotle receded from the limb of the Moon.

Days 19 and 20. Tycho approached the limb of the Moon. Plato receded. Grimaldi approached the limb a little. From these gather that the Pole had been at the beginning of the octant.

Day 24. Tycho approached, and Plato did not vary.

June 4, 5, and 6. The Mare Crisium did not vary. Endymion approached the limb of the Moon.

Days 10, 11, and 12. The Mare Crisium and Endymion receded from the limb. Tycho approached. Therefore the Pole turned out to be in the octant.

Day 18. Grimaldi approached the limb of the Moon, and on days 23 and 24 receded from the same.

July 4. The Mare Crisium and Endymion receded from the limb of the Moon.

Day 5. The Mare Crisium and Endymion receded from the limb of the Moon. Pitiscus approached. Therefore the Pole was in the octant.

[Margin numeral: I.]

Day 7. The Mare Crisium receded from the limb of the Moon.

Day 12. The Mare Crisium receded. Tycho approached the limb of the Moon; therefore the Pole could be in the first octant.

[Margin numeral: I.]

Days 17, 18, 19, and 21. Grimaldi did not vary.

Days 22 and 23. Grimaldi receded from the limb of the Moon.

August 2, 3, 4, and 5. The Mare Crisium and Endymion receded from the limb of the Moon; from these the other of the Poles is detected in the octant.

[Margin numeral: I.]

Days 6, 7, 8, and 9. The Mare Crisium and Endymion receded from the limb of the Moon.

Days 11 and 13. Tycho and Grimaldi approached the limb. Therefore the other of the Poles turned out to be in the octant.

Days 15 and 16. Tycho and Grimaldi did not vary.

Day 17, up to 22. Grimaldi receded from the limb of the Moon.

Days 30 and 31. The Mare Crisium receded from the limb of the Moon.

September 1 and 4. The Mare Crisium receded from the limb of the Moon.

Days 5, 6, and 7. The Mare Crisium and Endymion receded from the limb of the Moon. Tycho, however, approached. Gather that one Pole had been in the first octant.

[Margin numeral: I.]

Day 8. The Mare Crisium receded from the limb of the Moon. Tycho, Endymion did not vary.

Day 9. The Mare Crisium, Endymion, and Tycho did not vary.

Day 12, up to 18. Grimaldi and Tycho receded from the limb of the Moon. Plato, however, approached. The Pole was at the beginning of the first octant.

[Margin numeral: I.]

Days 19 and 20. Grimaldi receded from the limb of the Moon.

Days 29 and 30. The Mare Crisium receded from the limb of the Moon. Endymion, indeed, and Pitiscus did not vary. Therefore the Pole turned out perhaps to be at the beginning of the octants.

[Margin numeral: I.]

October 2 and 3. The Mare Crisium and Endymion receded from the limb. Pitiscus approached; on that account the Pole turned out to be in the first octant.

[Margin numeral: I.]

Days 7 and 8. The Mare Crisium, Endymion, Aristotle, and Tycho did not vary.

Day 9. The Mare Crisium, Endymion, and Aristotle approached the limb of the Moon. Tycho, however, recedes; on that account the Pole must be said to have been in the octant.

Day 11 and 12. Grimaldi receded from the limb of the Moon. Tycho and Plato did not vary.

Day 15. Grimaldi and Tycho receded from the limb, but Plato approached. It is shown: the Pole [was] in the octant.

[Margin numeral: I.]

Day 16. Grimaldi and Tycho receded from the limb.

Day 20. Grimaldi receded from the limb of the Moon.

Days 21, 22, and 23. Grimaldi approached the limb.

Days 29 and 30. The Mare Crisium and Endymion receded from the limb of the Moon. Pitiscus approached; on that account the Pole could be believed to be in the first octant.

[Margin numeral: I.]

Day 31. The Mare Crisium and Endymion increased their distance from the limb of the Moon.

November 2. The Mare Crisium, Endymion, and the macula in the Terra Siccitatis receded from the limb of the Moon.

Day 5. The Mare Crisium, Endymion approached the limb of the Moon, and Tycho receded; and consequently the other of the Poles turned out to be in the first octant.

[Margin numeral: I.]

Day 6. The Mare Crisium and Endymion did not vary. Tycho receded from the limb.

Days 9 and 10. Grimaldi and Tycho receded from the limb, [but] the Sinus Roris did not vary; on that account the Pole turned out to be in the first octant.

[Margin numeral: I.]

Days 11 and 12. Tycho did not vary. Grimaldi receded from the limb of the Moon.

Day 28. The Mare Crisium increased its distance from the limb of the Moon.

Day 29. The Mare Crisium, Endymion, and Pitiscus receded from the limb of the Moon; on that account one of the Poles was in the second octant.

[Margin numeral: II.]

December 2. The Mare Crisium receded from the limb of the Moon; Endymion and Pitiscus did not vary.

Days 5, 6, and 7. The Mare Crisium and Endymion approached the limb of the Moon. Tycho receded. And the Pole was in the octant.

Day 8. Tycho receded from the limb of the Moon.

Days 12, 13, and 14. Grimaldi and Tycho receded from Harpalus in the Sinus Roris, [and] approached the limb of the Moon; on that account the Pole was in the octant.

[Margin numeral: I.]

Day 18. Grimaldi began to approach the limb of the Moon.

Days 28 and 29. The Mare Crisium receded from the limb.

Day 30. The Mare Crisium did not vary.

Day 31. The Mare Crisium and Endymion receded from the limb of the Moon. Pitiscus receded; therefore the Pole of the libration must be said to have been in the octant.

[Margin numeral: I.]

Anno 1651. (In the year 1651.)

January 1. The Mare Crisium, Endymion, Aristotle, approached the limb of the Moon. Pitiscus receded; therefore the Pole turned out then to be in the octant.

[Margin numeral: I.]

Days 8 and 9. Grimaldi receded from the limb of the Moon. Tycho, and Harpalus did not vary.

Day 14. Grimaldi receded from the limb.

Day 31. The Mare Crisium receded from the limb of the Moon.

February 3. The Mare Crisium and Plato approached the limb of the Moon. Tycho receded; on that account the other of the Poles [was] in the octant.

[Margin numeral: I.]

Days 6, 7. Tycho and Grimaldi receded from the limb of the Moon, [but] Plato approached; from which gather the Pole turned out to be in the octant.

[Margin numeral: I.]

Day 9. Grimaldi did not vary. Plato and Harpalus in the Sinus Roris receded from the limb of the Moon; from which it is argued that the Pole turned out to be in the octant.

[Margin numeral: III.]

Days 11 and 12. Grimaldi, Harpalus, and Plato receded from the limb of the Moon. Tycho did not vary; therefore the Pole must be said to have been in the octant.

[Margin numeral: III.] [Margin numeral: IV.]

Days 13 and 14. Grimaldi did not vary. Tycho approached the limb; whence it was gathered that the Pole [was] in the octant.

[Margin numeral: III.]

Days 15 and 16. Grimaldi approached now to the limb of the Moon.

[Margin numeral: IV.]

Day 27. The Mare Crisium approached the limb of the Moon.

Day 28. The Mare Crisium and Endymion approached the limb of the Moon.

March 1, 2, and 4. The Mare Crisium approached the limb of the Moon. Tycho did not vary.

Day 7. Grimaldi, Harpalus, Plato, and Endymion receded from the limb of the Moon; on that account the Pole [was] in the octant.

Day 8 and 10. Grimaldi receded from the limb of the Moon.

Day 25. The Mare Crisium approached the limb of the Moon.

Day 27. The Mare Crisium and Endymion approached the limb of the Moon a little.

Days 28, 29, and 30. The Mare Crisium, Endymion, and the macula [in the Terra Siccitatis].

The macula in the Terra Siccitatis approached the limb of the Moon, [and] used to; on that account the Pole [was] in the octant.

[Margin numeral: I.]

Day 31. The Mare Crisium approached the limb of the Moon.

April 1 and 2. The Mare Crisium and the macula in the Terra Siccitatis approached the limb of the Moon.

Day 4. The Mare Crisium and Plato did not vary.

Day 5. The Mare Crisium, Plato, and Endymion receded from the limb of the Moon, and consequently the Pole must be said to have been in the octant.

Day 6. Plato receded from the limb of the Moon. Tycho did not vary.

Days 11 and 13. Grimaldi approached the limb of the Moon.

Day 25. The Mare Crisium approached the limb of the Moon.

Day 26. The Mare Crisium and Endymion approached the limb of the Moon.

Day 28. Pitiscus, and the Mare Crisium approached the limb of the Moon. Endymion and Aristotle receded from the limb of the Moon; from which positions one of the Poles was in the octant.

[Margin numeral: III.]

Day 30. The Mare Crisium approached the limb of the Moon. Endymion and Aristotle receded from the limb, and from these it is confirmed the Pole turned out to be in the octant.

[Margin numeral: III.]

May 1, 2, and 3. The Mare Crisium and Tycho approached the limb of the Moon. Endymion and Aristotle receded from these. Therefore the Pole was in the octant.

[Margin numeral: III.]

Day 13. Grimaldi did not vary; the macula in the Sinus Roris receded a little from the limb of the Moon. Tycho approached.

Day 14. Grimaldi approached the limb.

Days 27, 28, and 29. The Mare Crisium approached the limb of the Moon. Endymion indeed, and the macula in the Terra Siccitatis receded from the limb; and thus the Pole must be said to have been in the octant.

[Margin numeral: III.]

Days 30 and 31. The Mare Crisium did not vary. Endymion, and the macula in the Terra Siccitatis receded from the limb. Tycho, however, approached. Therefore the Pole turned out to be in the octant.

[Margin numeral: III.]

July 1, 2, and 3. The Mare Crisium, Endymion, and the macula in the Terra Siccitatis receded from the limb of the Moon. Tycho approached; on that account the Pole must be said to have been in the octant.

[Margin numeral: IV.]

Days 13 and 14. Grimaldi did not vary.

[Margin numeral: vel I.]

Day 23. The Mare Crisium and Endymion did not vary.

Day 24. The Mare Crisium did not vary. Endymion increased its distance a little from the limb of the Moon.

Day 26. The Mare Crisium did not vary. Endymion receded from the limb of the Moon. Pitiscus approached. Therefore the Pole turned out to be one in the octant.

[Margin numeral: IV.]

Day 27. Endymion and Aristotle receded from the limb. Langrenus and Pitiscus approached. Therefore the Pole [was] in the octant.

[Margin numeral: vel I.] [Margin numeral: IV.]

Days 28, 29, and 30. The Mare Crisium, Endymion, and the macula in the Terra Siccitatis receded from the limb of the Moon. Tycho, and Pitiscus approached the limb. Therefore the Pole was in the octant.

[Margin numeral: IV.]

July 1. Langrenus, the Mare Crisium, Endymion, Aristotle, Plato, and the Sinus Roris receded from the limb of the Moon. Tycho approached; from which it turns out the Pole [was] in the octant.

[Margin numeral: IV.]

Day 2. The Mare Crisium and Endymion receded from the limb of the Moon. Tycho approached.

Days 3, 6, and 7. Grimaldi and Tycho approached the limb of the Moon.

Day 8. Grimaldi approached the limb of the Moon.

Day 9. Grimaldi scarcely approached. Tycho did not vary.

Day 11. Grimaldi and Tycho receded from the limb. Harpalus and Plato approached; on that account the Pole turned out to be in the octant.

[Margin numeral: vel IV.]

Day 22, up to 25. The Mare Crisium did not vary. Endymion receded from the limb of the Moon. Pitiscus approached. Therefore the Pole was in the octant.

[Margin numeral: vel IV.]

Day 22, up to August 1. The Mare Crisium and Endymion receded from the limb of the Moon. Tycho approached; which indicate the Pole turned out to be in the octant.

[Margin numeral: I.] [Margin numeral: IV.]

August 3, 4, and 5. Tycho did not vary. Grimaldi, and Harpalus in the Sinus Roris approached the limb of the Moon. Wherefore the Pole of the libration must be said to have been in the octant.

[Margin numeral: I.]

Days 6 and 8. Grimaldi scarcely approached. Harpalus and Plato [receded].

[Margin numeral: III.]

[The libration-pole observation log of *Caput XIV* continues. Each dated entry records which named lunar spots (maculae) were approaching or receding from the Moon's limb, with the octant of the libration pole inferred in the right-hand margin as a Roman numeral I–IV; "vel" ("or") marks an entry where the margin gives an alternative octant tag.]

Plato was approaching the Moon's limb, while Tycho was receding; therefore the pole was in the octant. — III.

Day 9. Harpalus was approaching the Moon's limb; Tycho was receding. — III.

Day 10. Grimaldus, and Harpalus, were receding from the Moon's limb.

Days 11 & 12. Grimaldus was receding from the limb [of the Moon ☾].

Days 20, 21, & 22. Mare Crisium did not vary; Endymion was receding from the limb [☾].

Days 23, 25, & 27. Mare Crisium, Langrenus, and Endymion were receding from the limb [☾]; Pitiscus was barely approaching. Therefore the pole was in the octant. — I.

Days 28, 29, & 30. Mare Crisium, Langrenus, Endymion, and Aristoteles were receding from the Moon's limb; Tycho and Plato did not vary. Therefore the pole was in the octant. — I.

Day 31. Tycho did not vary; Grimaldus, Harpalus, Plato, and Aristoteles were approaching the Moon's limb. The pole therefore was in the octant. — III.

September 1, 2, 3. Grimaldus, Harpalus, and Plato were approaching the Moon's limb, while Tycho was receding. Therefore the pole is said to have been in the octant. — III.

Day 4. Grimaldus did not vary; Tycho was receding from the limb [☾]; Harpalus and Plato were approaching the limb [☾]. The pole was therefore in the octant. — III.

Day 6. Tycho and Grimaldus were receding from the limb [☾]; Harpalus and Plato were approaching the limb [☾]. Therefore the pole was in the octant. — III. *vel* IV.

Days 8 & 9. Tycho and Grimaldus were receding from the Moon's limb; Harpalus was barely approaching. Therefore the pole was in the octant. — IV.

Days 18 & 19. Mare Crisium did not vary; Endymion was receding from the Moon's limb.

Day 20. Mare Crisium was receding a little from the limb [☾]; Endymion was receding strongly; Langrenus did not vary; Pitiscus was approaching. Therefore the other of the poles was in the octant. — I.

Days 22, 23, & 24. Mare Crisium and Endymion were receding from the Moon's limb; Langrenus did not vary. And so the pole was in the octant. — I.

Days 25 & 26. Mare Crisium and Langrenus were receding from the limb [☾]; Endymion and Tycho did not vary. Accordingly the pole was one [and the same] in the octant. — II.

Day 27. Mare Crisium, Langrenus, and Tycho were receding from the Moon's limb; Harpalus and Plato were approaching the limb. Therefore one of the poles was in the octant. — III. *vel* IV.

October 3 & 4. Tycho, Grimaldus, Harpalus, and Plato did not vary.

Day 20. Mare Crisium and Endymion were receding from the Moon's limb.

Day 27. Mare Crisium was receding from the Moon's limb.

November 20 & 21. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion and Aristoteles did not vary. For that reason the pole was in the octant. — II.

Days 22, 23, & 25. Mare Crisium, Langrenus, and Tycho were receding from the Moon's limb; Endymion, Aristoteles, and Plato were approaching the limb. Therefore the pole was in the octant. — III.

Day 26. Mare Crisium did not vary; Langrenus and Tycho were receding; Endymion and Plato were approaching the limb. Therefore the pole was in the octant. — III. *vel* IV.

Day 27. Tycho was receding; Harpalus was approaching the limb [☾]. — IV.

Day 28. Grimaldus and Harpalus were approaching the Moon's limb; Tycho and Plato did not vary.

Day 30. Harpalus and Tycho did not vary; Grimaldus was receding.

December 1. Grimaldus was receding from the limb [☾]; Tycho, Harpalus, and Plato did not vary.

Day 5. Grimaldus, Harpalus, and Plato were receding from the limb [of the Moon ☾]. For that reason the pole was in the octant. — III.

Day 6. Grimaldus and Harpalus were receding from the Moon's limb.

Day 20. Mare Crisium did not vary.

Day 30. Grimaldus, Harpalus, and Plato were receding...

from the Moon's limb; Tycho was approaching. From this it is concluded that the pole was in the octant. — III.

Anno 1652.

[Year 1652.]

January 17, 20, & 21. Mare Crisium did not vary; Endymion was approaching; Langrenus and Pitiscus were receding from the limb [☾], and for that reason the pole was in the octant. — III.

February 1. Grimaldus was receding from the Moon's limb. — *vel* IV.

Day 2. Grimaldus, and Sinus Roris, were receding from the Moon's limb. — IV.

Day 3. Grimaldus did not vary; Sinus Roris was receding from the Moon's limb.

Days 14 & 16. Mare Crisium did not vary; Endymion was approaching; Langrenus and Pitiscus were receding from the Moon's limb; from which the pole is argued to be in the octant. — III.

Days 18, 21, & 22. Langrenus, Mare Crisium, and Endymion were approaching the limb [☾]. Therefore the pole was in the octant. — IV.

Day 26. Tycho was approaching the Moon's limb. — I.

March 26. Grimaldus, and Littus Eclipticum, were receding from the limb [☾].

May 15 & 16. Mare Crisium and Langrenus did not vary; Endymion was receding; Pitiscus was approaching the Moon's limb. Therefore the pole was perhaps in the octant. — IV.

Days 19 & 20. Endymion was receding; Mare Crisium and Langrenus were approaching the Moon's limb; Tycho did not vary. The pole therefore was in the octant. — III.

Day 21. Endymion was receding; Mare Crisium, Langrenus, and Tycho were approaching the Moon's limb, on which account the pole is confirmed to be in the octant. — III.

Day 22. Mare Crisium and Endymion did not vary; Langrenus and Tycho were approaching the Moon's limb a little. — III.

Day 28. Grimaldus did not vary; Tycho was approaching the Moon's limb.

Days 30 & 31. Tycho, Grimaldus, Littus Eclipticum, and Sinus Roris were approaching the limb [☾]. Therefore the pole is said to have been at the beginning of the octant. — II.

June 1. Grimaldus, Littus Eclipticum, and Sinus Roris were approaching the Moon's limb; Kircher and Bettinus were receding from the limb [☾]. And for that reason the pole was in the octant. — III.

Day 3. Grimaldus was approaching the Moon's limb.

Day 12. Endymion was receding from the Moon's limb.

Day 16. Mare Crisium was barely approaching the limb [☾]; Langrenus and Pitiscus were approaching the limb [☾]; but Endymion was receding. The pole therefore was in the octant. — III.

Day 18. Endymion was receding; Mare Crisium and Langrenus were approaching the Moon's limb; from which the pole is confirmed to be in the octant. — III.

Day 19. Endymion was receding; Mare Crisium, Langrenus, and Tycho were approaching the Moon's limb; and thus the pole is again confirmed to be in the octant. — III.

Day 21. Mare Crisium and Langrenus did not vary; Tycho was barely approaching the Moon's limb.

Day 27. Tycho was receding from the Moon's limb; Plato and Sinus Roris were approaching the limb [☾].

Day 28. Tycho was receding; Grimaldus, Sinus Roris, and Plato were approaching the Moon's limb. From this the pole of libration is concluded to have been in the octant. — III.

Day 30. Grimaldus and Littus Eclipticum were approaching the Moon's limb; Zucchi, Bettinus, and Kircher were receding from the limb. From these things the pole is confirmed [to be] in the octant. — III.

July 1. Grimaldus did not vary; Harpalus was approaching; Zucchi, Bettinus, and Kircher were receding from the Moon's limb. Therefore the pole was in the octant. — *vel* IV.

Day 2. Grimaldus did not vary.

Days 10 & 11. Mare Crisium did not vary; Endymion was receding; Langrenus was approaching the Moon's limb. For that reason the pole is to be said to have been in the octant. — IV.

Day 13. Mare Crisium, Langrenus, and Pitiscus were barely approaching the Moon's limb; Endymion was receding. Therefore the pole was in the octant. — IV.

Day 14. Mare Crisium did not vary notably; Endymion was receding; Langrenus and Pitiscus were approaching the limb [☾], and for that reason the pole was in the octant. — III.

Day 15. Mare Crisium, Langrenus, and Pitiscus were approaching... — *vel* IV.

the Moon's limb; Endymion and Plato were receding from the limb. From which it follows that the pole was in the octant. — III.

Days 16 & 17. Mare Crisium, Langrenus, and Endymion did not vary; Tycho was approaching the Moon's limb; Aristoteles was receding.

Day 19. Endymion, Mare Crisium, Langrenus, and Furnerius were barely approaching the Moon's limb; Tycho was approaching. Therefore the pole was in the octant. — I.

Day 20. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Tycho did not vary.

Day 21. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Tycho and Sinus Roris did not vary.

Day 22. Grimaldus was approaching the Moon's limb; Tycho and Sinus Roris did not vary. — *vel*

August 9, 11, 12, & 13. Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb; Endymion was receding; at which time the pole is to be said to have been in the octant. — III.

Day 14. Mare Crisium did not vary.

Day 15. Mare Crisium was already receding from the Moon's limb; Endymion did not vary.

Day 16. Mare Crisium, Langrenus, Furnerius, and Tycho were receding from the Moon's limb; Endymion did not vary; and accordingly the pole was in the octant. — III.

Day 17. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion did not vary.

Day 18. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Tycho did not vary; Plato was approaching. Therefore the pole was in the octant. — III.

Day 19. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Tycho did not vary.

Day 20. Grimaldus, Littus Eclipticum, and Plato were approaching the Moon's limb; Tycho did not vary. Therefore the pole was in the octant. — III.

Days 22, 23, & 24. Grimaldus, Littus Eclipticum, Harpalus, and Plato were approaching the Moon's limb; Tycho and Schillerus were receding from the Moon's limb; and so the pole was in the octant. — III. *vel* IV.

Day 26. Grimaldus, Harpalus, and Plato were approaching the Moon's limb; Tycho was receding. The pole therefore was in the octant. — III.

September 9. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion was receding. For this reason the pole of libration was in the octant. — III.

Day 12. Mare Crisium and Langrenus were receding from the limb [☾].

Days 13, 14, & 15. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion did not vary.

Day 16. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; but Endymion was approaching. The pole therefore was in the octant. — III.

Day 17. Mare Crisium, Langrenus, Pitiscus, and Tycho were receding from the Moon's limb; Endymion and Plato were approaching the Moon's limb. And so the pole was one [and the same] in the octant. — III.

Day 18. Tycho was receding from the limb; Grimaldus and Plato were approaching the Moon's limb. And it was so; and for that reason the pole was on the other side in the octant. — III.

Day 19. Grimaldus, Harpalus, and Plato were approaching the Moon's limb; Tycho and Schikardus were receding from the limb. From which the pole is to be said to have been in the octant. — III.

Day 20. Grimaldus was approaching the Moon's limb; but Schikardus was receding. Therefore the pole was in the octant. — III.

Day 22. Grimaldus, Harpalus, and Plato were approaching the Moon's limb; but Schikardus was truly receding; from which it is confirmed that the pole was still in the octant. — III.

Day 26. Grimaldus did not vary; Harpalus was approaching the Moon's limb.

October 13 & 14. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion did not vary.

Day 15. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion was approaching. Therefore the pole was in the octant. — III.

Day 16. Mare Crisium did not vary; Langrenus and Furnerius were receding strongly from the Moon's limb; Endymion was approaching the limb. Therefore the pole was still in the octant. — III.

Day 17. Langrenus, Furnerius, and Tycho were receding from the Moon's limb; Grimaldus and Plato were approaching the Moon's limb. For that reason the pole is said to have been in the octant. — III.

Day 18. Tycho was receding from the Moon's limb; Grimaldus, Harpalus, and Plato were approaching the Moon's limb. From which the pole is confirmed [to be] in the octant. — III.

November 11 & 12. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion was approaching. And so the pole was found to be in the octant. — III.

Day 13. Mare Crisium did not vary notably; Langrenus and Pitiscus were receding from the Moon's limb; Endymion and Plato were approaching the limb.

Day 14. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion and Plato were approaching the limb. From which it again follows that the pole was in the octant. — III.

Day 18. Grimaldus, Harpalus, and Plato did not vary; Tycho was approaching the Moon's limb a little.

Day 27. Grimaldus and Littus Eclipticum were receding from the Moon's limb.

December 6 & 7. Mare Crisium and Langrenus were receding from the Moon's limb; Endymion did not vary.

Days 8 & 9. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion was approaching. Therefore the pole was in the octant. — III.

Day 11. Mare Crisium and Langrenus were receding from the Moon's limb; Endymion was approaching. And this confirms the pole [to be] in the octant. — III.

Day 12. Mare Crisium and Endymion did not vary notably; Langrenus, Furnerius, and Claramontius were receding from the Moon's limb.

Day 13. Mare Crisium, Langrenus, Furnerius, and Claramontius were receding from the Moon's limb; Endymion did not vary; Plato was approaching the Moon's limb. From which it follows that the pole was in the octant. — III.

Days 17 & 18. Grimaldus did not vary; Tycho was approaching the Moon's limb; Harpalus, and Plato, were approaching the limb [☾].

Day 20. Tycho was approaching the Moon's limb; Grimaldus, Harpalus, and Plato were approaching the Moon's limb; consequently the pole was in the octant. — III.

Days 21 & 22. Plato and Tycho did not vary; Grimaldus, Harpalus, and Littus Eclipticum were receding from the limb [☾].

Day 23. Grimaldus, Harpalus, and Littus Eclipticum were receding from the Moon's limb.

Anno 1653.

[Year 1653.]

January 6. Mare Crisium, Langrenus, and Petavius were receding from the Moon's limb; Endymion was approaching. The pole of libration was in the octant. — III.

Day 7. Mare Crisium was receding a little from the limb; Langrenus and Petavius were receding strongly from the Moon's limb; Endymion did not vary.

Day 8. Mare Crisium, Langrenus, Petavius, and Claramontius were receding from the Moon's limb; Endymion did not vary.

Day 9. Mare Crisium was barely receding; Langrenus, Petavius, and Claramontius were receding from the limb [☾]; Endymion was barely approaching, and for that reason the pole was in the octant. — III.

Days 10 & 12. Mare Crisium was barely approaching; Langrenus and Petavius were receding from the Moon's limb; Endymion did not vary appreciably.

Day 14. Tycho, Grimaldus, and Harpalus did not vary.

Day 15. Tycho and Grimaldus did not vary; Littus Eclipticum, Harpalus, and Plato were approaching the Moon's limb.

Day 16. Grimaldus did not vary; Littus Eclipticum, Harpalus, and Plato were receding from the Moon's limb; for that reason the pole is said to have been in the octant. — III.

February 2. Mare Crisium, Langrenus, and Petavius were receding from the Moon's limb; Endymion did not vary.

Day 7. Mare Crisium was receding a little from the limb [☾].

Day 9. Endymion was receding from the Moon's limb.

Day 10. Mare Crisium and Endymion were receding from the Moon's limb; Pitiscus was approaching. Therefore the pole is to be said to have been in the octant. — I.

March 2. Mesthala did not vary; Furnerius was receding from the limb [☾].

Day 3. Mesthala, and Furnerius, were receding from the limb [☾].

Day 7. Mare Crisium and Langrenus were receding from the Moon's limb.

Day 10. Mare Crisium was barely receding from the Moon's limb; Plato was receding from the Moon's limb; Furnerius was approaching; and for that reason the pole is to be said to have been in the octant. — IV.

Day 11. Mare Crisium did not vary; Langrenus and Furnerius were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. Therefore the pole was in the octant. — III.

Day 12. Mare Crisium, Langrenus, and Furnerius were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. Therefore the pole of libration was in the octant. — III.

Day 13. Mare Crisium, Langrenus, Furnerius, and Tycho were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. From which the pole is confirmed [to be] in the octant. — III.

Day 14. Harpalus and Plato were receding from the Moon's limb.

Day 15. Harpalus, and Plato, were receding from the Moon's limb; Tycho was approaching; Grimaldus did not vary.

April 1 & 2. Mare Crisium and Seneca were near that [limb], and Langrenus was receding from the Moon's limb.

Day 3. Mare Crisium and Langrenus were receding from the Moon's limb; Endymion did not vary.

Day 4. Mare Crisium and Langrenus were receding from the Moon's limb.

Day 7. Mare Crisium was barely receding; Endymion too was receding from the Moon's limb.

Day 8. Mare Crisium and Langrenus did not vary; Endymion was receding from the Moon's limb.

Day 10. Endymion was receding from the Moon's limb; Langrenus and Pitiscus were approaching the limb [☾]. Therefore the pole was in the octant. — III.

Days 19 & 20. Grimaldus, and Littus Eclipticum, were barely receding; Tycho did not vary; Plato and Sinus Roris were barely approaching the Moon's limb. — IV.

Day 21. Grimaldus was barely receding from the Moon's limb; Littus Eclipticum and Harpalus were approaching the Moon's limb; and consequently the pole is argued to be in the octant. — IV.

Day 22. Grimaldus was receding from the Moon's limb; Littus Eclipticum was approaching, and this confirms the pole [to be] in the octant. — IV.

May 2 & 3. Mare Crisium, Endymion, and Langrenus were receding from the limb [☾].

Day 4. Endymion and Mare Crisium were receding from the Moon's limb; Langrenus did not vary.

Days 6 & 7. Mare Crisium did not vary; Endymion was receding; Langrenus and Pitiscus were approaching the Moon's limb. The pole therefore was in the octant. — III.

Day 8. Endymion was receding; Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb. Therefore the pole was in the octant. — III.

Day 9. Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. And this confirms the pole [to be] in the octant. — III.

Days 10 & 11. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion did not vary.

Day 14. Tycho, Ricciolius, and Littus Eclipticum were receding from the Moon's limb; Sinus Roris did not vary.

Day 17. Grimaldus, and Littus Eclipticum, were receding from the Moon's limb; Tycho and Sinus Roris did not vary.

Day 19. Tycho and Sinus Roris did not vary; Littus Eclipticum was approaching the Moon's limb; Grimaldus was barely receding.

Day 20. Grimaldus did not vary; Littus Eclipticum and Sinus Roris were receding from the limb.

Days 21 & 22. Grimaldus did not vary; Schikerus was receding; Littus Eclipticum and Sinus Roris were approaching...

the Moon's limb. From which the pole is concluded to have been in the octant. — III.

Day 30. Mare Crisium and Endymion did not vary. — *vel*

Day 31. Mare Crisium did not vary; Endymion was receding from the Moon's limb. — IV.

June 1. Mare Crisium and Endymion were receding from the Moon's limb; Langrenus was approaching. Therefore the pole was in the octant. — IV.

Day 3. Mare Crisium and Endymion did not vary; Langrenus was approaching the Moon's limb.

Day 5. Endymion did not vary; Mare Crisium, and Langrenus, were approaching the Moon's limb.

Days 6, 7, 8, & 9. Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb; Endymion did not vary. Therefore the pole [was] in the octant. — III.

Day 10. Endymion, Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb. The pole therefore was in the octant. — II.

Day 11. Tycho did not vary.

Day 16. Grimaldus did not vary; Littus Eclipticum was approaching.

Days 18 & 20. Grimaldus, Littus Eclipticum, and Sinus Roris were approaching the Moon's limb; Tycho was receding. Therefore the pole [was] in the octant. — III.

July 1. Mare Crisium and Langrenus did not vary; Endymion was receding from the Moon's limb.

Days 4 & 5. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion did not vary.

Day 7. Mare Crisium, Langrenus, and Pitiscus did not vary.

Day 9. Mare Crisium, Langrenus, and Pitiscus did not vary; Endymion was barely approaching the Moon's limb.

Day 13. Grimaldus was receding from the Moon's limb; Littus Eclipticum was approaching. Therefore the pole of libration was in the octant. — IV.

Day 14. Tycho and Grimaldus were receding from the limb [☾]; Littus Eclipticum and Sinus Roris were approaching the limb; and for that reason the pole was in the octant. — IV.

Day 15. Grimaldus did not vary; Tycho was approaching; Littus Eclipticum and Sinus Roris were approaching the Moon's limb. And consequently the pole was in the octant. — III.

Days 17 & 18. Tycho was receding; Grimaldus, Littus Eclipticum, Sinus Roris, and Plato were approaching the limb [☾]. From which the pole is deduced to have been in the octant. — III. *vel* IV.

Day 21. Grimaldus was approaching and receding from the Moon's limb. [recte: *accedebat et recedebat* — printed thus]

Day 30. Mare Crisium was barely approaching the Moon's limb; Endymion was receding. The pole therefore was in the octant. — III.

August 2, 3, & 5. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion did not vary.

Day 6. Mare Crisium, Langrenus, and Pitiscus did not vary; Endymion was barely approaching the limb [☾].

Days 7 & 8. Mare Crisium did not vary; Endymion was approaching; Langrenus and Pitiscus were approaching the Moon's limb.

Day 11. Tycho was receding; Plato, and Sinus Roris, were approaching the limb.

Days 12, 13, & 15. Tycho was receding; Grimaldus, Sinus Roris, and Plato were approaching the Moon's limb. For that reason the pole was in the octant. — III.

Days 18 & 19. Grimaldus, and Sinus Roris, were approaching the Moon's limb.

October 5. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion was approaching. For that reason the pole was in the octant. — III.

Day 19. Mare Crisium did not vary; Langrenus and Pitiscus were receding from the Moon's limb.

November 1 & 3. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion was approaching. For that reason the pole was in the octant. — III.

Days 28 & 29. Mare Crisium did not vary; Langrenus, Furnerius, and Pitiscus were receding from the Moon's limb.

December 1, 2, & 4. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion did not vary.

Days 5 & 6. Grimaldus was approaching the Moon's limb.

Days 7 & 8. Tycho, Grimaldus, Sinus Roris, and Plato were approaching the limb [☾]. Therefore the pole was in the octant. — II.

[Continues: **Day...**]

On the 9th: Tycho [Tycho Brahe] was approaching the Moon's limb. Grimaldi [Francesco Maria Grimaldi] did not vary.

On the 29th: Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb.

Year 1654.

January 1: Mare Crisium and Langrenus were receding from the Moon's limb.

On the 3rd: Endymion was receding from the Moon's limb. Tycho was approaching.

On the 4th: Tycho was approaching. Grimaldi, Harpalus, and Plato did not vary.

On the 6th and 7th: Grimaldi did not vary. Tycho was approaching. Plato was receding from the Moon's limb.

On the 25th: Mare Crisium did not vary. Endymion scarcely approached. Langrenus and Pitiscus were approaching the Moon's limb.

On the 26th and 27th: Mare Crisium, Langrenus, Furnerius, and Pitiscus were receding from the Moon's limb. Endymion did not vary.

On the 28th: Mare Crisium, Endymion, Langrenus, and Furnerius were receding from the Moon's limb.

On the 29th, 30th, and 31st: Mare Crisium, Langrenus, and Furnerius did not vary. Endymion and Plato were receding from the Moon's limb.

February 1: Mare Crisium, Endymion, and Plato were receding from the Moon's limb.

On the 23rd: Mare Crisium and Langrenus were receding from the Moon's limb. Endymion was perhaps approaching.

March 3: Tycho was approaching. Plato was receding from the limb.

On the 5th: Tycho was approaching. Plato and Harpalus were receding from the Moon's limb. Grimaldi did not vary.

On the 6th: Tycho and Plato did not vary. Grimaldi and Harpalus scarcely receded from the limb.

On the 26th, 28th, and 29th: Mare Crisium and Endymion were receding from the Moon's limb. Langrenus did not vary.

April 1: Mare Crisium and Endymion did not vary. Langrenus and Furnerius approached the limb a little. Tycho did not vary.

On the 2nd: All the aforesaid did not vary.

On the 7th: Littus Ecliptium [the Ecliptic Shore] was receding. Tycho was approaching. Therefore the pole was in the octant. [Margin: III.]

On the 10th and 11th: Grimaldi, Littus Ecliptium, and Sinus Roris [the Bay of Dews] were receding from the Moon's limb. [Margin: vel IV. — "or IV."]

On the 24th: Mare Crisium, Endymion, and Littus Ecliptium were receding from the Moon's limb. Pitiscus did not vary.

On the 25th: Mare Crisium and Endymion were receding from the Moon's limb. Langrenus did not vary. Pitiscus was approaching. Therefore the pole was in the octant. [Margin: I.]

On the 26th: Mare Crisium and Endymion were receding from the limb [Symbol: ☽]. [Margin: vel IV. — "or IV."]

On the 28th and 30th: Mare Crisium and Endymion did not vary. Langrenus and Furnerius were receding from the limb.

May 21 and 22: Mare Crisium, Endymion, and Langrenus were receding from the Moon's limb.

On the 23rd and 24th: Mare Crisium, Endymion, and Democritus were receding from the Moon's limb. Langrenus did not vary. Pitiscus approached the limb. Therefore the pole was in the octant. [Margin: vel IV. — "or IV."]

On the 27th and 28th: Mare Crisium and Endymion did not vary. Langrenus was approaching. Democritus was receding from the limb.

On the 29th and 30th: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion and Tycho did not vary.

June 19 and 20: Mare Crisium, Langrenus, and Endymion receded a little from the Moon's limb.

On the 22nd and 23rd: Mare Crisium, Langrenus, and Endymion did not vary. Pitiscus approached the limb.

On the 24th, 25th, and 26th: Mare Crisium and Langrenus were approaching the limb. Endymion and Pitiscus did not vary.

On the 27th: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion itself was approaching a little.

July 18 and 19: Mare Crisium and Langrenus did not vary. Endymion was receding from the Moon's limb.

On the 27th and 28th: Mare Crisium, Langrenus, and Endymion were approaching the Moon's limb.

August 1: Tycho was receding. Plato and Sinus Roris were approaching the Moon's limb.

On the 18th and 19th: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion was receding. From which it is gathered that the pole of libration was in the octant. [Margin: III.]

On the 20th, 21st, and 22nd: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion did not vary.

On the 23rd, 24th, 25th, and 27th: Langrenus did not vary much. Mare Crisium and Endymion were approaching the limb.

On the 28th and 30th: Grimaldi did not vary. Tycho was approaching the limb.

On the 31st: Grimaldi and Sinus Roris were approaching the Moon's limb. Tycho did not vary.

September 1: Grimaldi and Sinus Roris were approaching the Moon's limb. Tycho did not vary.

October 25: Mare Crisium and Langrenus were receding from the limb [Symbol: $\rceil$]. Endymion and Aristotle did not vary.

On the 26th and 27th: Tycho and Plato did not vary. Grimaldi, Littus Ecliptium, and Sinus Roris were approaching the limb.

November 16: Mare Crisium and Langrenus did not vary. Endymion scarcely approached the limb.

On the 20th: Mare Crisium and Endymion were approaching the Moon's limb. Langrenus was receding. Therefore the pole was in the octant. [Margin: IV.]

On the 23rd: Mare Crisium, Endymion, and Langrenus were receding from the Moon's limb.

December 18 and 19: Mare Crisium and Langrenus scarcely receded from the Moon's limb. Endymion did not vary.

Year 1655.

January 23, 24, and 25: Tycho and Grimaldi were approaching the Moon's limb. Harpalus and Plato were receding from the limb. Therefore the pole was in the octant. [Margin: I.]

February 16, 17, 18, and 20: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb. [Margin: vel I. — "or I."]

On the 21st: Tycho and Grimaldi were approaching the limb. Harpalus was receding. Therefore the pole was in the octant. [Margin: I.]

March 19 and 20: Mare Crisium and Endymion scarcely receded from the limb. Langrenus did not vary. [Margin: vel IV. — "or IV."]

April 12, 13, 15, and 18: Mare Crisium, Endymion, and Langrenus were receding from the Moon's limb.

On the 19th: Mare Crisium, Endymion, and Langrenus did not vary.

May 10, 11, 12, 13, 14, and 15: Mare Crisium and Endymion were receding from the Moon's limb.

On the 16th and 17th: Mare Crisium, Langrenus, Tycho, and Endymion did not vary.

On the 19th: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion and Tycho did not vary.

June 9, 10, and 11: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb.

On the 12th: Mare Crisium and Endymion were receding from the Moon's limb. Langrenus did not vary.

On the 13th: Mare Crisium and Endymion did not vary. Langrenus was approaching the Moon's limb.

On the 15th: Endymion did not vary. Mare Crisium and Langrenus were approaching the limb.

On the 16th and 17th: Mare Crisium, Langrenus, and Endymion were approaching the Moon's limb.

On the 19th: Tycho did not vary. Grimaldi and Sinus Roris were receding from the Moon's limb.

July 7, 9, and 10: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb.

On the 11th and 12th: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion did not vary.

On the 14th, 15th, 16th, and 17th: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb.

August 10, 11, and 12: Mare Crisium and Langrenus were approaching the Moon's limb.

October 6 and 7: Mare Crisium was approaching the Moon's limb.

Year 1656.

May 7 and 8: Mare Crisium was receding from the Moon's limb.

June 3 and 5: Mare Crisium was receding from the Moon's limb.

July 28, 29, and 30: Mare Crisium did not vary.

On the 31st: Mare Crisium was receding from the Moon's limb.

August 1: Mare Crisium was receding from the Moon's limb.

CAPUT XV.

A judgment on the aforesaid mobility of the poles, drawn from the foregoing observations.

I say, first: One must not conceive the poles, or nodes, of the lunar libration to be true and physical points on the lunar surface — for there is no basis for any such assertion. Indeed, since the other points, or maculae, on the lunar surface are recognizable and preserve the same mutual distances among themselves, one of them could be picked out and said to run here and there across that surface — yet the observations would still require it. I therefore say, rather, that these points are imaginary, or distinct; and that distinct points on the lunar surface take the place of the libration's poles for one and the same libration. And so the axis itself of this libration must be understood to be something imaginary within the lunar body, namely a diameter about which the Moon librates — such that for one libration it is librated about one diameter, but about another diameter, and yet a third, for another libration.

I say, second: This variation of the diameter, or motion of the poles, does not proceed in an orderly, uniform, and even progression. This is manifestly clear from the foregoing observations, in which the poles sometimes appear to be kept for a good while in the same places, at least in the octants of the lunar limb; while at other times they pass over from one octant to another. Besides this, they sometimes pass over from one to another not immediately — or at least with

almost no motion made in between — and then sometimes pass over from one octant to another immediately, and so revert from a later octant to a prior one without crossing the others lying between.

I say, third: It might perhaps be possible to save some more certain and more uniform motion of the libration poles, if we suppose that they are moved not on the lunar limb in our view, but on certain circles having their center either within the aforesaid limb, or in some other, more interior hemisphere either anterior or in some way hidden from us. For the centers of this [motion] cannot be fixed in the same place of the lunar surface, against the most certain observations from the premises.

I say, fourth: Concerning the aforesaid poles, that the axes of libration are made with very notable inequality is to be inferred not only from the fact that some macula is borne with unequal velocity — for that is necessarily so, however the motion proceeds in the superficies of a spherical body — but also from this other respect: namely, it is often observed that the maculae constituted near the libration poles move little, while meanwhile those farther from the poles move more notably. Yet often it has likewise been observed that even those very maculae which are most distant from the poles move little, and sometimes very slightly. Sometimes, by contrast, it is manifestly observed that those maculae situated near the poles move faster, even though they are in such a position that they ought to be apprehended as moving the least. Furthermore, from the foregoing observations it can be inferred that within any one period of libration a greater velocity may belong now to one macula, then to another, while one macula is now recognized as not yet receding, and then, when it manifestly is recognized to recede — and thereafter, while in that same one there appears such a recession notable in its superficies — the progression made is nevertheless greater than in the former. And indeed the very order tends to be preserved in this, by which the maculae are situated around

[p. 199] the Moon's limb — but it is not always preserved. For some macula, in one libration, before another neighboring one shows itself, nevertheless recedes from the Moon's limb; whereas in the next libration the said neighboring macula is recognized to begin receding sooner than the aforementioned. Moreover, in one and the same libration some disturbance of this order is recognized.

Furthermore — and this is the chief point of all — the approach or recession of one macula often cannot be apprehended, except by a kind of stationary point, and by the constancy near that very limb: although it is nevertheless sometimes detected without that stationing. For example: Mare Crisium, which over three

days, or four — or even more days — appears with the same greatest proximity, or greatest remoteness, from the Moon's limb, is nevertheless sometimes apprehended to have approached the lunar limb at some point, and on the very next day to recede again from the lunar limb. Finally, although it is more commonly observed, within a single lunation, that the libration is one and the same, it has nevertheless been observed that not once within the same lunation a macula resumes its approach — that is, after it has receded from the Moon's limb — but proceeds in its receding, indeed to such a notable amount that this could be attributed to parallax, or to a deception of the eye; and that, when some turbation of the lunar [appearance] toward perigee, or toward apogee, would demand rather the contrary appearance.

I say, fifth: The aforesaid varieties apprehended in the libration could perhaps be saved, and reduced to certain rules, if the poles were posited to be moved in circles whose centers, and the [poles] themselves, move at a fixed time — which I have said above to be implicated [in motion]. But I see no real physical basis for this hypothesis, however much it has hitherto been permitted to observe. Yet if in the exposition of the observations I deduce time and again that the poles are in some determinate octant near the Moon's limb, that ought to be taken as in a supposition: namely, that the poles would be moved on that very limb. For thus we are sometimes compelled to argue that one pole is between certain maculae nearer the limb, while the other recedes.

Lastly, from the foregoing observations it must be adverted that the poles, for the most part, conform to the latitude of the same [maculae]: such that, with the latitude ascending, the maculae in the northern hemisphere accede to their limb, and those which are in the southern hemisphere recede from the limb; while, by contrast, with the latitude descending, [it is] the reverse. But there are many observations which contradict this rule; and because there are many such, and because on many successive days they are continually constant, therefore one ought not to doubt that there is some deception of the eye in the observations — and a genuine one is to be sought elsewhere, along with the physical cause of the phenomenon.

CAPUT XVI.

Selected more recent observations of Father Francesco Maria Grimaldi on the limits of the lunar libration, from the year 1651 to 1656. For the examination of Hevelius's table exhibiting the maximum libration of Mare Crisium at each month of this century.

I set forth this table of Hevelius [Johannes Hevelius], in his new little work on the librating motion of the Moon, published in the year 1654, trusting that it would faithfully exhibit the maximum recession of the macula from the Moon's limb — which he himself calls Palus Maeotis — insofar, however, as he himself gathered it from his own observations, and unless some new anomaly of the lunar libration

[p. 200] should be detected by the passage of time. Therefore let us examine whether that table — and consequently the whole theory of the librating motion — corresponds faithfully, over the years next elapsed, and indeed not for this whole coming century, to certain observations of Father Grimaldi, more recent than those we set forth in the first volume of our *Almagest* [*Almagestum Novum*]. Concerning the maximum recession of Mare Crisium from the western limb of the Moon, we at the same time join that [recession] which appears from the Hevelian table, so that it may be recognized by an easy collation whether that maximum recession ought to have appeared felicitously, [and] whether the Hevelian theory proceeds, or is to be corrected by some other principle, which he himself has not yet noticed.

Year 1651.

In the month of October, Hevelius posits that the maximum libration of Mare Crisium will fall in the 5th degree of Taurus — which occurred on the 29th, scarcely before noon. The observations strongly favor Hevelius, placing the maximum aforesaid recession of the macula from the Moon's limb around the 29th day.

November. Hevelius assigns the limit of the libration on the 25th day. The observations, however, set it on the 26th.

December. From Hevelius the limit [falls] on the 23rd. The observations agree with Hevelius for the same 23rd.

Year 1652.

January. From Hevelius, and from the observations, the limit on the 19th day.

February. Hevelius and the observation agree for the 16th.

May. From Hevelius the limit was the 9th — the observations themselves favor it.

June. From Hevelius the limit was the 5th. The observations favor this.

July. From the table of Hevelius the limit is celebrated twice — on the 3rd and on the 30th. For the 3rd: the observations consent, insofar as the macula opposite [it] — that is, Grimaldi — did not vary; from which Mare Crisium is gathered to have been at the extremity of its motion, and as if stationary.

August. Hevelius posits the limit on the 16th day. The observations agree, since the opposing macula Grimaldi was at the highest approach to the Moon's limb.

September. The table of Hevelius assigns the 23rd day. From the observations the same is gathered, from the highest approach of the macula Grimaldi to the Moon's limb.

November. From the table of Hevelius the limit is on the 17th. On that day Grimaldi was as little as possible distant from the western limb. Therefore the observations favor Hevelius.

December. Hevelius posits the limit of libration on the 15th. But from the observation, on the 13th day Mare Crisium was receding, [while] the macula opposite [it] Grimaldi was approaching; on the 16th — up to and including the 19th — it did not vary. Therefore the limit appears to be gathered as having fallen after the 15th day assigned by Hevelius.

Year 1653.

January. From Hevelius the limit was the 12th. But from the observations not before the 13th.

February. From Hevelius the limit fell between the 8th and 9th. But from the observations somewhat after the 10th, since on the 10th Mare Crisium was still receding from the western limb.

March. From Hevelius the limit ought to have been the 8th, before noon. But the observations require the 11th day.

April. From Hevelius the limit falls between the 4th and 5th. But the observations require it after the 8th day.

May. From the table of Hevelius the limit is the 2nd, at noon. But the observations set it after the 4th.

June. From Hevelius the limit was the 26th. But from the observations it appears later, since Mare Crisium did not vary up to the 26th day — the 1st of July included.

July. From Hevelius the limit is the 23rd. The observations appear to favor Hevelius.

August. From the table of Hevelius the limit is assigned for the 20th day. But from the observations, since the macula opposite

[p. 200, col. 2] Grimaldi itself, on the 19th day, was still approaching the limb, the [limit] seems to be argued [to be] Mare Crisium — not yet on the 20th — to have been at the limit of its recession.

December. Hevelius sets the 8th day. But from the observations it seems to be somewhat after the 8th, since on the very 8th day the macula opposite Grimaldi was still approaching the eastern limb.

Year 1654.

January. Hevelius posits the limit on the 5th day. But from the observations, as much as is gathered from the opposing macula Grimaldi, it seems to have been on the 6th.

March. Hevelius posits the limit on the 28th. But from the observations it manifestly ought to be set later, since on the 29th day Mare Crisium was still receding from the Moon's limb — and for four days afterward it continued not to vary.

April. Hevelius posits the limit on the 25th. But from the observations on the 26th, since Mare Crisium was still receding. Therefore here too Hevelius precedes.

May. Hevelius posits the limit on the 22nd. But the observations wish [it on] the 24th.

June. Hevelius gives the limit on the 19th. But the observations [show it] somewhat after the 8th[?].

August. Hevelius posits the limit on the 13th. The observations favor Hevelius.

November. Hevelius posits the limit on the 4th. They favor the observations for that day, insofar as the macula Grimaldi stood as little as possible distant from the eastern limb.

Year 1655.

February. From Hevelius the limit was the 22nd. The observations favor [it], insofar as on the 22nd the macula Grimaldi began not to vary.

April. From Hevelius the limit is held to be the 18th. But the observations give it later, since on the 19th day Mare Crisium begins not to vary.

May. From Hevelius the limit is the 16th. But from the observation, somewhat after the 17th.

June. From Hevelius the limit is the 12th. But from the observation, not before the 13th.

July. From Hevelius the limit is the 10th. The observations consent to this exactly.

August. From Hevelius the limit falls before noon on the 7th. The observation, however, exhibits [it] for the 8th.

Year 1656.

May. From Hevelius the limit is held to be on the 8th. The observation exhibits it later.

June. From Hevelius the limit was the 5th. They consent with the observations.

July. From Hevelius the limit is held to be on the 29th. But the observations transfer it after the 1st of August.

From the foregoing observations, many indeed there are which favor Hevelius; but many likewise there are which prove that his table forecasts, by one day or another, the true limit of the libration of Mare Crisium from west toward east. And although in a matter so subtle, and treated by an estimation of the eye in the observations, one may sometimes doubt the precise day — let alone the moment of maximum libration — when scarcely four days, or some [number of] days, slip by in which no increment or decrement appears in the lunar libration: in many cases it is nevertheless evidently convinced that Hevelius precedes, since increments appeared after that [day] on which, according to Hevelius, [the limit] ought to have been: so that, as has been set forth in its proper places, [the limit] was [later]. And it is indeed remarkable that he never notes a day preceding the

one Hevelius assigned: which confirms that the matter must least be doubted to be one of difficulty in arriving at a certain judgment, depending on the estimation of the eye — since indeed there would be no danger of erring toward one part rather than the other.

BOOK FOUR

IN WHICH SELECTED OBSERVATIONS OF THE FIXED STARS

are weighed, drawn from both the ancients and the moderns, and from these the Tables are constructed and exhibited down to the Year of Christ 1700.

CHAPTER I.

On the Observations of the Ancients concerning the Fixed Stars, and the Manner of Observing Them.

Having passed over those rudimentary observations of the rising, setting, and so forth of the stars of the fixed-star sphere — which are found in the ancient calendars for the benefit of agriculture, medicine, and navigation, in Aratus, Eudoxus, Euctemon, Meton, Calippus, Dositheus, Geminus, Ptolemy, Hipparchus, Bithynus [?], Columella, and likewise in Ovid, Pliny [Pliny], Varro, and others — observations not, in any case, suitable for determining the exact positions of the stars in the heavens at a definite time: of these we shall select only a few, namely those made from the time of Aristyllus [Aristyllus] and Timocharis [Timocharis], that is, from about the year 300 before Christ down to our own day. These have been handed down by others, or have been carried out by us with R. P. Francesco Maria Grimaldi [Francesco Maria Grimaldi] with as much subtlety and diligence as was possible for us. And although the observations of Aristyllus and Timocharis themselves, related by Ptolemy (*Almagest* VII; *Magna Constructio* [*Almagest*] I.1), and explained afterwards by us in Tome I (*Almagestum Novum*), are few and not free of ambiguity [Margin: *The observations of Aristyllus and Timocharis are doubtful.*], yet the observations of Hipparchus himself are more accurate, as Ptolemy in the same place attests — for the observations of Hipparchus concerning the fixed stars, and the ones he adduces, are very fully explained. For Hipparchus himself, as he reports in the same book (Ptolemy, *Almagest* III, ch. 3) in the treatise *On the Magnitude of the Year*, supposed that a motion of the fixed stars takes place at the poles of the zodiac; yet he hesitated — as he asserts — because neither were the observations of Timocharis, made in his

time, regarded as certain (since they had been taken too simply), nor did the time that had elapsed in between suffice for a full understanding of the matter. For this reason he judged that the undertaking of this inquiry should be entrusted to a more careful examination, recording the places of the fixed stars in a solid sphere, of which there is mention in Ptolemy (*Almagest* VII.1, at the end); and, transmitting it together with the whole volume to posterity, he closes with that encomium reported by Pliny (*Natural History* II, ch. 26): "Hipparchus, never sufficiently praised, since no one has more proved [Margin: *Hipparchus praised, and the fixed stars to be observed.*] that the kinship of the stars with man is established, and that our souls are a part of the heavens — discovered a new star, and another that arose in his own time; and, doubting whether this happened more often, whether the stars we deem fixed also move, he dared a deed bold even for a god: to count the stars for posterity, and to check off the heavenly bodies by name in a list, devising instruments by which he might mark out their several positions and magnitudes — so that from this it might easily be discerned, not only whether they perished and were born, but also whether any of them shifted and moved, and likewise whether they grew or diminished; he left the heavens as an inheritance to all, if anyone should be found to claim that inheritance." An impious thing — to reckon up the stars for an atheist writer; too prone to fictions about God, or

[Margin: *Psalm 146.*] —rather more truly impious against our God, the Royal Psalmist: "Who counts the multitude of the stars, and calls them all by their names." And Baruch (ch. 3): "the stars gave their light in their watches, and rejoiced: they were called, and they said, Here we are; and with cheerfulness they shone forth to him who made them." But to return to Hipparchus, I have set this down: that the most evil occasion for observing the fixed stars was the one that prompted Hipparchus — namely the appearance of a great new star in his age, just as in our own age there appeared the new star (which was noted in the year 1572 in Cassiopeia from Tycho's [Tycho Brahe] constellation), about which more was said briefly in Book I. By what reasoning the ancients indicated those stars, must be pointed out.

[Margin: *1.*] First, after the rising, setting, and so forth of the stars, the constant and perpetual figure of the constellations was observed, and the always-equal distance of the individual stars from one another. From this the name *fixed* [Inerrantium], or *non-wandering*, was earned for the fixed stars [Astris]; not because they do not move, but because they always keep a kind of equal interval among themselves — never, indeed, with their configuration changed, once they had received it from divine ordination; and so the sphere itself, called "fixed"

[Affixa], moves with an ordained motion. From this the non-wandering stars [Inerrantes Stellae] are at once distinguished from the planets [Errantibus]. (Ptolemy, *Almagest* VII.1.)

[Margin: *Whence the name of the fixed stars?*] Yet against that thing that has just been said — that they rightly suit those very stars to which the name *non-wandering* is applied — it can be objected: namely, because stars of this kind keep among themselves their lineaments and figures alike, and likewise equal intervals, they are seen in the same configuration always. But because the whole sphere of the spheres, in which they are, as it were, fixed and carried around, seems to make a progress according to the succession of the signs, and a certain ordained motion proper to the Prime Movable [Primum Mobile]; not without reason are they called *non-wandering*. For both these things are found to hold of them: namely those of appearance [Apparentia], by which in so great a length of time they are perceived. (*Audianus* [?], Ptolemy VII.1.) And it is established as sufficiently certain that the figures of the stars, recently seen, are the same as those that were carried around of old in the unaltered sphere, whether by Aratus, or by Eudoxus, or even from the monuments of more ancient ages. And that I shall illustrate in the following chapter with some examples.

[Margin: 2.] Secondly, the distances of these stars, by the Radius or by some other suitable instrument, are measured; for that, once done, brought an incredible later benefit to the whole posterity. I shall speak of the Distances absolutely, where I treat of the distances of the fixed stars from the ecliptic, and from the equator, in the following two chapters.

[Margin: *The motion of the Prime Movable in the fixed stars.*] Secondly, it is easily observed that all the fixed stars, and the whole of their sphere, complete a daily revolution of twenty-four hours from rising to setting, then again from setting to rising, or from the meridian to the same meridian. For what was always above the horizon appeared by its passage across the middle of the heavens above the pole of the world, and what passed below the pole, consumed twelve hours; the whole twenty-four; and so the rest. Those that rose, set, and were carried by a determinate motion from rising to setting, consumed twenty-four hours; from setting they returned to the same setting in twenty-four hours, and so the rest. And this is the most manifest motion of all the motions of the non-wandering stars, at least as to appearance. For whether in reality it is moved thus around its own center by a daily motion, or whether rather it is the Earth itself that, by its own daily motion, turns toward the east, producing this apparent motion before

our eyes (as Niceta [Nicetas], Copernicus [Copernicus], and others would have it), we have treated of fully (Book 9, *Almagestum Novum*).

[Margin: 3.] Thirdly, what neither Hipparchus was ignorant of, nor before him in some manner Timocharis, it was observed that the fixed stars have a proper motion of their own according to the succession of the signs; and Hipparchus indeed in his hypothesis [Margin: *The proper motion of the fixed stars in Longitude.*], as Ptolemy teaches (*Almagest* VII.1.1, on those stars which in the zodiac were judged by the Sun); if indeed, as he relates in the same chapter, he himself recounts: that the *Spica*, observed by Timocharis in his time, was distant from the autumnal point by eight degrees, that is, it had been in Virgo at 22 degrees; but in his own time it was distant by only six degrees, that is, in Virgo at 24 degrees; and so for the rest of the noteworthy stars of the zodiac. Yet whether this motion took place in the circles described about the poles of the world (that is, in the equator, or in circles parallel to it), or rather in circles about the poles of the ecliptic (that is, in circles of latitude through the poles of the zodiac), Hipparchus once doubted. Yet they agree that it can take place by

—circles, and in circles through the poles of the zodiac, and from the poles of the zodiac described — although ambiguously, as Ptolemy hands down (*Almagest* VII, ch. 3) — either because of the excessively coarse intervals of the antecedent observations, or because the interval between them was too brief. But Ptolemy himself (let it be said) asserts that the fixed stars are moved contrary to the Prime Movable, or according to the succession both of the circle of the equinoxes and of the ecliptic — since this same thing follows of itself with respect to the ecliptic — moving with respect to the poles of the equator; yet (he asserts, *Almagest* VII, ch. 2) the fixed stars are moved according to the succession of the ecliptic; and in circles about the poles of the zodiac, described: and this by a twofold argument. First, the arcs of the ecliptic that are intercepted between the circles of latitude of the same star are equal to one another; but the arcs intercepted of the circle of declination are unequal among themselves — and, with the ecliptic compared as the standard, unequal; yet this difference does not emerge perceptibly, except after many years. Secondly, because in that circle the poles always keep the same distance in latitude — but truly observed by Hipparchus, and evidently distinguishing it: Ptolemy, of the fixed stars, supposes the same latitudes, which they have always had once from the ecliptic on this side and on that, varying however the distance from the poles of the equator, which we call declination; he adds examples of this kind: that Our [stars] enter Aries — by a change of this kind, which he adduces. Hence (ch. 4) he renders the reason why in the Catalogue of the fixed stars he set down the longitudes and latitudes rather than the right

ascensions and declinations: because, in fact, the latitudes of the same stars remain perpetually the same, and the distances in latitude likewise truly observed by Hipparchus, and in parallels to the ecliptic, uniform; while these are referred to the ecliptic, the fixed stars keep the same latitudes. [Margin: *Scaliger's opinion on the motion of the fixed stars.*] On this here let Joseph Scaliger [Joseph Scaliger] be consulted, in the *Diatribes on the Anticipation of the Equinoxes* (*Vranologia* III, ch. 3); Paul, if [you wish; Paul of?]; Guldin in the refutation of the *Elenchus* of Calvisius against the Gregorian Calendar (ch. 10, as is sufficiently refuted, as also Bullialdus, *Astronomia Philolaica* ch. 5); and likewise (*Almagestum Novum*), where we say something of this (ch. 3); convincing the principal foundations on which Scaliger relied to show that the equinoctial points recede from the fixed stars in the west, and rather the poles of the equator are moved (*Mobilibus*, divisible), and the poles of the world. (See, etc.)

[Margin: 4.] Fourthly, therefore, the ancients ascribed first the declinations of the fixed stars separately, then the latitudes, and the longitudes of them — the latter determined in the ecliptic by circles of latitude drawn through the poles of the ecliptic and the stars themselves; and likewise others orthogonally cutting the ecliptic. They added besides: the apparent magnitudes — namely which were of the first, or the second, or the third, or the maximum magnitudes, which the first, and so on to the sixth. But in the Ptolemaic Catalogue they added certain notes to some fixed stars of the nature of the planets, in which they partake, for the benefit of Astrology.

On the Methods and Instruments by which the Ancients observed the Fixed Stars.

[Margin: 6.] By what instruments Aristyllus, Timocharis, Hipparchus, and Ptolemy noted those declinations, and the distances from the equator, which Ptolemy reports (*Almagest* VII, ch. 3), I have not found; yet it is credible that they used something of the kind: [Margin: *The manner of observing declinations.*] some altitudes of the meridian of the stars. As to which, the *Magna Constructio* (ch. 11) describes a stable Quadrant, by which the meridian altitudes of the Sun were taken, and likewise that perfected Astrolabe — the Equatorial Astrolabe, or Equatorial Armilla — which they were accustomed to apply for capturing also the meridian declinations, and which they cultivated to perfection: Tycho [Tycho Brahe], as he described in his *Mechanica*, restored the instruments of astronomy (fol. 20, etc.).

[Margin: 7.] But the longitudes and latitudes of the fixed stars they were accustomed to observe by two methods. The first was the more familiar — having previously assumed the certain intervals at which a fixed star is distant from the

Sun, or from the Moon; and at night, by means of the place of the Moon in the zodiac computed from the Tables, they determined the place of the stars by conjecture, as nearly as possible by this observation. Of which sort of observations of Timocharis, Agrippa [Agrippa], and Menelaus [Menelaus of Alexandria], from Ptolemy (*Almagest* VII, ch. 3) we shall report in the chapter. The second was by means of the Astro-

—labe used, and described by Ptolemy (*Almagest* VII.2.4); and it was composed of the Zodiacal Armillae, which is almost the same way that Egnazio Danti [Egnazio Danti] in his Astrolabe, and Tycho in his *Mechanica Astronomica* (fol. 19), with the use of those same things, also describe. For with one circle the Moon was computed — in the ecliptic computed, the other to the Sun near the horizon, with its sights turned, the distances of the Moon from the Sun in the ecliptic were taken, and likewise, by an aetheric arc, the place of the Moon in the ecliptic, established in the Mid-Heaven, was noted at the hour. Then on the immediately following night, the distance of the Moon from some fixed star in the ecliptic, computed in like manner, was taken; and it was intercepted by two circles of latitude, while by the center of the Moon, the other by the star, and by both: through the poles of the ecliptic departing in the Astrolabe — by which, in an analogous way, the heavens had previously been arranged in their position. Now indeed, from the time of the prior observation, the place of the Sun in the ecliptic was computed, and to it, adding the distance of the Moon from the Sun toward the west, observed, the apparent place of the Moon was obtained according to the ecliptic; to this apparent place was added the distance of the Moon from the star observed in the east, and so the apparent place of the star was obtained, as to longitude. But truly they inferred, since it was the same hour, since the Moon had been observed together with the Sun, it was established from the Astronomical Tables; but from the true place of the Moon meanwhile, they corrected the longitude, previously acquired through the distance from the Sun.

[Margin: *Imperfection of the ancient observations.*] But to those good men this correction sufficed; nothing of that they required, except the [correction] which often the Refraction demanded, suspected from the parallax of the Sun. Lastly, the place of the Moon by the parallax of the Sun they used. They used the Armilla afterward, as Tycho notes (Tome I, *Progymnasmata*, p. 140): if indeed by great machines, of their own mass, they were very tractable; but the small did not admit subdivisions of a single degree into single minutes. Certainly Ptolemy in his Catalogue consigned the longitudes for the most part to a maximum, and the latitudes to no more than a half-scruple [half-minute].

[Margin: 8.] Lastly, the latitudes themselves, by sights in a circle of latitude, two foramina [apertures], by which directly through the holes the star was directed; and these I judged sufficient to have set forth, before the more select observations hereafter to be exhibited. I have not pursued the defect of those observations on account of the false obliquity of the ecliptic, which is not of this place to discuss.

CHAPTER II.

On the Stars in the Same Straight Line, observed both of old and more recently.

[Margin: 1.] There are many groupings, threefold or fourfold, of the non-wandering stars, which are observed in the same straight line — exactly, or very nearly — and have so persevered from of old, even before Ptolemy, as he himself reports (*Almagest* VII.1, *Magna Constructio* ch. 1; and from there onward down to Tycho [Tycho Brahe], as I affirm in Tome I, *Progymnasmata*, pp. 234, etc.), and so on down to those days, with the addition of certain figures from our own observation, collected, which are extant either in Aratus, or in the *Phaenomena* of Hyginus, or are gathered from the difference of the latitudes — so that hence, even from the unchanged configuration of the constellation, the immutability of the interval by which they are mutually distant may be confirmed.

[Margin: 2.] There are therefore, and were of old as well, in the same — or as nearly as possible in the same straight line, by the judgment of the eye — the stars written below:

In the southern claw [forfex australis] of Cancer; those that precede it; *Hydra* the splendid one in the preceding head, and that of *Canis Minor* the splendid.

The two stars in the head of *Leo*, and the one which is in the conjunction of the neck of *Leo* with the rest of the body.

The bright star of the tail of *Leo*; the extreme star of the tail of *Ursa Maior*; and that which, between the two aforesaid Unformed [stars], is discerned under the tail of the same *Ursa*.

Spica Virginis [Spica]; the second-to-last in the tail of *Hydra*; and the middle one in *Triangulum*, among the aforesaid lucid stars.

The horse in the head [Equus], the two contiguous ones, and that which is in *Aquarius* on the shoulder following.

The two stars preceding in the head of *Aries*, and the middle one in the base of *Triangulum*.

The two *Hyades* orientales, and the southern star in the membrane of the left hand of *Orion*.

The two more northerly *Arietis* in the head, and the splendid one in the knee of *Perseus*.

Capella, and the one which is in the preceding foot of *Auriga*; and the splendid one of the *Hyades* (that is, the eye of *Taurus*).

Capella likewise preceding; the shoulder of *Orion*, and the one which is on the northern horn of *Taurus*, and on the following foot of *Auriga*.

The two splendid stars in the head of *Gemini*, and the bright one in the neck of *Hydra*.

Ursa in the anterior foot, the two contiguous ones, and the one in *Cancer* of the outermost northern scissors [forficis], and the northern of the *Aselli* [the Asses].

The splendid star of *Canis Minor*, and the more southern of the *Aselli*, and the one which precedes them between the *Hyades*, the head.

Spica Virginis, and the two stars in the elbow [ancon] of *Corvus*.

Spica Virginis, and the one which is in the hinder shank [crus] of *Virgo*, and the one antecedent to *Boötes*, the shank.

In *Libra*, two splendid stars in the forceps; and the one which is in the extreme of *Boötes*, the shank.

Libra the splendid one in the southern forceps; *Arcturus*, and the middle star lucid in the tail of *Ursa Maior*.

Ophiuchus the one in the third spondyle, and the one in the fifth spondyle of *Scorpius*, preceding the two in the sting of *Scorpius*.

Ophiuchus in the knee following the lucid one, and the one in *Sagittarius* in the anterior ankle, southern; and the one which is in the sting of the same *Sagitta*.

Ophiuchus in the preceding knee, and the one which is in the sting of *Sagittarius*, the sting preceding, and the one in the preceding knee, the foot of *Sagittarius*.

The southern mouth [bucca] of *Pisces*, and two; preceding, in the quadrilateral of *Pegasus*.

Add to these three splendid ones in the Belt of *Orion*; likewise three of *Boötes*, which are *Arcturus*, lucid in *Libra*, and the lucid one on the shoulder near the

neck-bone [collorobum?]. Such likewise are three lucid stars of *Perseus*, one in the preceding knee, the other on the splendid side, the third on the following shoulder. Likewise three of *Aquila*, one in the throat, another on the shoulders, the third at the beginning of the left wing. Likewise *Andromeda* the southern foot, the bright one of the Belt, and the right shoulder-blade.

CHAPTER III.

The Declinations of the Fixed Stars, or their Distances from the Pole of the World, observed down to the time of Tycho exclusive, with a Censure of them.

[Margin: 1.] Let the first Class be that of the Declinations which Ptolemy (*Almagest* VII; *Magnae Constructionis* ch. 3) reports as observed by Timocharis at Alexandria in the year 36 before the first Calippic period (this being 295 years before Christ, in round numbers; and from Aristyllus about that same time; and from Hipparchus in the year 50; in the third year of the second Calippic period — namely in the year before Christ 128; and finally from the year 1 to the 2 of Antoninus the Emperor, and in the year 265, after Hipparchus). In the year of Christ 137 and 138, those times Ptolemy designates sufficiently (*Almagest* VII, ch. 2, 3, and 4). He adds however (ch. 3) another observation, made in latitude, in the year 47 of the first Calippic period — which he says was the year [in the era] of Nabonassar 465, that is, before Christ 284, or 285.

Caput III — Declinations / pole-distances of the fixed stars to Tycho's time (continued)

[The declination/pole-distance comparison tables, the *First Class* through *Fifth Class* of observations, and their critical discussion. Page 204.]

Table I. [I. TABVLA.]

Declinations of the fixed stars as observed by the ancients. Columns: star [Stella]; observers [Observatores] — Aristyllus, Hipparchus, Ptolemy, Timocharis; declination [Declinatio] in degrees (G.) and minutes (M.); and a final column "B" (Borealis, northern) or "A" (Australis, southern).

Star	Observer	Decl. G.	Decl. M.	B/ A
Capella	Aristyll.	40	0	B
	Hipparch.	40	24	B
	Ptolem.	41	10	B

Middle of the Pleiades [Pleiadum media]	Hipp.	15	10	B
	Ptol.	16	10	B

Note below the table: The first of the tail of Ursa Major has, by Hipparchus, gr. 67° 36'; and the Northern Claw of Scorpio, by Timocharis, gr. 1° 2'. [Prima caudæ Vrsæ mai. Hipparcho habet gr. 67. 36'. & Borea forceps Scorpij Timoch. gr. 1. 2'.]

2. The Second Class contains the distances from the world's pole of certain other stars — that is, the complements of their declinations to the quadrant, which, if subtracted from 90 degrees, immediately yield the northern Declination, where A is not added — as they are had in [Petavius], *Uranologion* lib. 3, cap. 3, 6, and 8. He says these distances were observed by Eudoxus and afterwards recorded from Hipparchus, with the distances added that Hipparchus's time required them to have according to Tycho's Tables. Hipparchus seems to be correcting Eudoxus; but it is uncertain whether he corrects the distances of the fixed stars to his own time, or to Eudoxus's. Eudoxus flourished in the year 368 before Christ, that is, 240 years before Hipparchus.

Table II. Distance from the world's pole. [TAB. II. Distantia à Polo Mundi.]

Columns: star/place [Tempore — i.e. the body, "in the time of"]; Eudoxus's value [Eudoxi]; Hipparchus's value [Hipparchi]; and Hipparchus corrected by Petavius [Hipp. correc. à Petavio]. Each in degrees (G.) and minutes (M.).

The upper following one, in □ [Superior succed. in □]	9	16	8	54		

3. The Third Class contains the Distances from the world's Pole of certain Fixed stars from Hipparchus's Observation, with the correction of Joseph Scaliger and Dionysius Petavius made from the more recent Tychonic Tables in [Petavius] *Uranologion* lib. 3, Dissert. cap. 8. The pole of the world, however, from which the stars listed below were distant in Hipparchus's time, was Northern — except for the last two of Scorpio, for which the Pole was Southern, as it was also for Sirius.

Table III. Distance from the world's pole in the time of Hipparchus.
[TABVLA III. Dist. à Mundi Polo tempore Hipparchi.]

Heading of the year column: "In the year before Christ 128" [Anno ante Chr. 128].
Row labels: the fixed stars [Fixæ]. Value columns: by Hipparchus [Hipparcho]; by Scaliger [Scaligero]; by Petavius [Petavio]. Each in degrees (G.) and minutes (M.).

Outermost of the wing of Pegasus [Pegasi alæ extrema]	87	0	87	0	86	51
The southernmost of the three in the left shoulder of Boötes [Australissima trium in sinist. humero Bootę]	63	0	64	0	62	11

4. The Fourth Class has the Distance from the world's Northern Pole of the last star in the tail of Ursa Minor, which is now called *Polaris* on account of its nearness to the Pole, but in Eudoxus's and Hipparchus's time was not *Polaris*. I say "the distance observed by various authors at various times," as below.

Table IV. Distance from the pole of the last star in the tail of Ursa Minor. [TABVLA IV. Distantiæ à Polo Stellæ vltimæ in cauda Vrsæ Minoris.]

Columns: the observer / source; the year [Anni ante Chr. or Anni Christi]; Distance from the Pole [Dist. à Polo] in degrees (G.), minutes (M.), and seconds (S.).

Observer / source	Year	G.	M.	S.
Eudoxus, in [Petavius] <i>Uranologion</i> lib. 3, Dissert.	368 BC	14	4	0

Observer / source	Year	G.	M.	S.
cap. 3				
Hipparchus, in Ptolemy <i>Geography</i> lib. 1, cap. 7	128 BC	12	24	0
Regiomontanus [Io. Regiomontanus], lib. 3 <i>de Triangulis</i> — whether from his own or another's observation is not clear [an aliorum observatione non liquet]	1470 AD	4	9	0
Petrus Nonius [Pedro Nunes], lib. 2 <i>de Observat.</i> cap. 7, from Naclerus [ex Nacleris]	1500	3	30	0
Gemma Frisius, from his own observation at Louvain, as reported in the <i>Astrolabium Catholicum</i> cap. 9 — for badly indeed has Gemma's son [given] it as gr. 3° 35' [malè enim Gemma eius filius habet gr. 3. 35']	1547	3	7	0
Paulus Hainzelius, in Tycho [Brahe] tom. 1 <i>Progymn.</i> pag. 361	1572	3	0	15
Tycho [Brahe], tom. 1 <i>Progym.</i> pag. 362	1577	2	58	50
the same, ibidem [idem ibidem]	1581	2	57	30
the same, ibidem [idem ibidem]	1585	2	56	10
Christoph Rothmann, in Willebrord Snellius [apud Villebrordum Snellium] in <i>obseru. Hassiacis</i>	1586	2	55	40
Tycho [Brahe], tom. 1 <i>Progy.</i> pag. 362	1589	2	54	50
Jacobus Kristmannus, lib. 1 <i>Solarium observat.</i> cap. 4	1596	2	51	50
Andreas Garzia Cespedius, in <i>Directorio Navigationis</i> , where he adds [a value] observed by Rodrigo Zamorano in the year 1584 [observatam à Roderico Zamorano An. 1584]	1598	2	59	30
Jacobus Kristmannus, in his Commentary on Alfraganus [in Comment. ad Alfraganum]	1618	2	44	30
Adriaan Metius [Adrianus Metius], in his book <i>On the Use of the Globe</i> [lib. de vsu Glob.]	1625	2	42	0
Pierre Gassendi [Petrus Gassendus], in his <i>Judgment concerning the 9 Stars near Jupiter</i> [in Iudicio de 9. Stellis circa Iouem]	1633	2	40	15

Observer / source	Year	G.	M.	S.
Pierre Hérigone [Petrus Herrigonius], tom. 4 of his <i>Cursus Mathematici</i>	1640	2	33	0
P. Stephanus Ostaul Minimus, in a letter given to me [Riccioli], though it ought according to the Tychonic [tables] to be 2° 36' 30" [in litteris ad me datis, at Tychonice debuit esse 2. 36'. 30"]	1643	3	6	20
Giovanni Domenico Cassini [D. Io. Dominicus Cassinus], who observed most subtly in the Malvasia residence at Bologna [in ædibus Maluaticis Bononiæ obseruauit subtilissimè]	1656	2	32	28
We [Riccioli], in the same year with Father Grimaldi [Patre Grimaldo], by means of a Gnomon [per Gnomonem]	1656	2	32	28

Note following Table IV: this observation [the 1656 Gnomon value] was made in the new Temple of S. Lucia, whose vault was not yet vaulted over [nondum tunc fornice obducto], to which one's feet stand higher by 74; for in either case [vtriq] one should rather stand [standum potiùs], than rely on minor instruments, as related in [the *Almagestum Novum*] lib. 6, *Almag. Novi* cap. 4. Nor indeed had Cassini seen our numbers [neq. verò Cassinus nostros numeros viderat], nor We Cassini's; but the very magnitude of the Gnomon (the use being indeed with a Gnomon high by 20 feet) and the diligence of observing produced a consensus so remarkable, and scarcely credible. [vsus est enim Gnomonis (vsus est enim Gnomone alto pedes 20.) & diligentia obseruandi, consensum fecit adeò mirum, & vix suspiciosus credibilem.]

5. The Fifth Class comprises the Declination of Spica, Regulus, Arcturus, the southern Pan [Lancis austrinæ — the southern Scale-pan of Libra], Fomalhaut, Rigel, and Sirius, observed by the authors listed below, but needing peculiar discussion.

[Margin: Spica observed by Werner. (Spica observata à Verno.)] Johann Werner of Nuremberg [Ioannes Vernerus Norimbergensis], as Daniel Santbech reports in *de Observationibus Phænomenorum*, Prop. 20, in the year 1514, December 16, observed at Nuremberg the meridian altitude of Spica as gr. 32° 7'; whence, supposing the altitude of the Pole to be gr. 49° 23' 30", he derived the southern Declination as gr. 8° 29' 30"; whence, supposing the obliquity of the Ecliptic to be

gr. $23^{\circ} 30'$, and the Latitude as gr. 2° (which is as handed down to [from] Ptolemy [à Ptolemæo tradita]), he derived the Longitude as ϱ [Libra] gr. $16^{\circ} 53' 20''$.

[Margin: And Regulus. (Et Regulus.)] Observing Regulus likewise the same year and place, he found the Meridian Altitude, and from it the Declination, as gr. $14^{\circ} 7' 30''$; its Longitude finally [Longit.] in ϱ [Leo].

[Margin: And the southern Pan [of Libra]. (Et Lancis Austr.)] The southern [pan], observed there at that time, [he found] in Auster [southern] gr. $13^{\circ} 38' 30''$; and from it the Longitude in $\mathfrak{M}$ [Scorpio] gr. $8^{\circ} 14'$ — as Tycho also reports, tom. 1 *Progymn.* pag. 221, and before all others Werner himself in the *Opusculum de Motu octavæ sphæræ*. Moreover, Petrus Nonius [Pedro Nunes], lib. 2 *de Observatione* cap. 4, notes a great Disagreement [Magnum Dissidium] among these observations of Werner's, and Copernicus's, and Cardanus's [Cardano]; of which below. Tycho, however, suspects there [ibidem], and presses him [perstringit eum], that Werner did not so much from his own observation as from his own judgment accommodate these declinations to the Ptolemaic latitude, and to the difference of longitude, which is between Spica gr. $54^{\circ} 10'$, between Spica and the [southern] Pan [Lancem] gr. $21^{\circ} 20'$ — although the truer [value] for Tycho [verior sit Tythoni illa] is gr. $53^{\circ} 59'$; this one [is] gr. $21^{\circ} 14'$. [Margin: Werner's deceptions / errors. (Vuernerī fallacia.)] As for the Pole too, the Altitude at Nuremberg is for Tycho gr. $49^{\circ} 26'$; and so, if the true Meridian Altitude was as above, the northern Declination of Regulus would have been gr. $14^{\circ} 10'$, but the southern of Spica gr. $8^{\circ} 27'$, and of the Pan [Lancis] austrina gr. $13^{\circ} 36'$ — from which, assuming for Tycho his own Latitudes, and the obliquity of the Ecliptic gr. $23^{\circ} 30'$, he gathers Trigonometrically a Longitude greatly dissonant from that which is owed to these stars from the Tyconic observations applied to the year 1515, as is clear from the appended Tyconic Table [Tabella Tyconica].

Tyconic Table [Tabella Tyconica] — for the year 1515.

Column heading: "At the beginning of the year of Christ 1515" [An. 1515. Chr. ineunte]. Sub-headings: Names of the Stars [Nomina Stellarum]; Werner's calculation from his own Declination [Calculus Vuerner. ex sua Declinat.] — Latitude per Ptolemy [La. Ptol.] and Longitude [Longitudo]; Tyconic calculation from the declination corrected from his own Tables [Calculus Tychon. ex Vuernerī Decl. corrects ex suis Tab.] — Longitude [Longit.], Tyconic Latitude [Lat. Tych.], and Longitude [Longit.].

Star	La. Ptol. G. M. (B/A)	Werner Longitudo (sign) G. M.	Tychon. Longit. G. M.	Lat. Tych. G. M.	Longit. G. M.
Regulus	0° 10' B	♌ 22 42	23 27	0° 26½'	23 4
Spica	2° 0' A	♌ 16 53½	16 47	1° 59'	17 3
Southern Pan [Lanx Austr.]	0° 40' B	♌ 8 14	7 19	0° 25½'	8 18

Therefore, from so doubtful a Declination of Werner's, nothing certain can be gathered for the true place of these Fixed stars. [Ergo ex tam dubia Declinat. Vueneriana nihil certi pro verò harum Fixarum loco licet colligere.]

6. [Margin: Spica observed by Copernicus. (Spica observata à Copernico.)] Nicolaus Copernicus, lib. 3 *Revolutionum* cap. 2, says that from the meridian altitude of Spica observed by himself at Frauenburg in Prussia in the year of Christ 1525, very nearly 27 partium [parts], and thence supposing the latitude of Frauenburg [Fruemburgica], he gathers its southern Declination as gr. 8° 40'; whence, assuming the Ptolemaic latitude gr. 2°, he deduces the Longitude in ♌ [Libra] very nearly gr. 17° 21'. He adds, moreover, that a decade before — that is, in the year 1515 — Spica was found by him [at] Declination gr. 8° 36' and Longitude ♌ gr. 17° 14'.

[Margin: The disagreement of Werner, Copernicus, and Cardanus on Spica. (Dissidium Vueneri, Copernici, & Cardani in Spica.)] For here indeed Petrus Nonius [Pedro Nunes], lib. 2 *de Observat.* cap. 4, is astonished at the great disagreement between Werner and Copernicus, since in the same year 1515 the one [places it] in Libra at gr. 16° 54', the other [Copernicus] here at gr. 17° 14' — as he points out [deprehendisse affirmat]; while Cardanus [Cardano], after 22 years — that is, in the year of Christ 1537 — brings back [retrahat] the same to eleven [gr.] of [the] observations [eandem observationibus vndecim ad gradum] 16° 18' in ♌.

Tycho, moreover, tom. 1 *Progymn.* pag. 220, when he had previously had the Pole-altitude of Frauenburg [Fruemburgicam] explored as gr. 54° 22' 15", corrects the Spica Declination of the year 1515, making [it] partium [of parts] 8° 33' 15"; and thence, assuming his own latitude gr. 1° 59', and the Obliquity of the Ecliptic gr. 23° 31' 30", he gathers the Longitude of Spica ♌ gr. 17° 3' 30". So for the year 1525, using the corrected Declination gr. 8° 37' 15", he obtains the Longitude in ♌ gr. 17° 14'; and limiting both [vtramq; limitans] he gathers for the year 1520 [the Longitude] in ♌ gr. 17° 8' 30".

[Margin: Lansbergen's deceptions. (Lansbergij fallacia.)] But Philippus Lansbergius, in his *Thesaurus observationum Fixarum*, as he reckons in his own tables, computes [Spica] for the year 1525 in Libra at gr. $17^{\circ} 35' 20''$; he confirms from Copernicus's observation two errors admitted by the Astronomer [duo peccata admittit Astronomica], one of omission, the other of commission, in correcting the Pole-altitude of Frauenburg [Fruemburgicam] by introducing a Refraction at his own discretion [arbitrato suo]. For he says that against a true altitude of gr. $26^{\circ} 57'$ there was [taken] a Refraction of altitude gr. $2^{\circ} 30'$; and, the altitude of the Equator being placed at gr. $35^{\circ} 41'$, [Spica] being observed by Copernicus at a declination of gr. $8^{\circ} 44'$ — from which, and from the latitude of Spica gr. $1^{\circ} 58'$ and the obliquity of the Ecliptic gr. $23^{\circ} 30'$, he extends [extends] the Longitude in $\simeq$ gr. $17^{\circ} 35'$.

7. [Margin: Stadius's observations of Spica. (Stadij observ. Spica.)] Johann Stadius [Io. Stadius], in his Commentary *de Fixis* cap. 1, relates the Equatorial Altitude observed by himself at Brussels [Bruxellis] as gr. $38^{\circ} 40'$, and in the year 1559, on the Nones of July, the Meridian [Altitude] of Spica gr. $29^{\circ} 52'$; and so the Declination gr. $8^{\circ} 48'$, with which, and the latitude gr. 2° , he gathers the Longitude of Spica $\simeq$ gr. $17^{\circ} 40'$; whence he refutes the Alphonsine Calculation, which for that year requires Spica in $\simeq$ gr. $16^{\circ} 50'$; and Cardanus's [Cardani], of which above. He further relates, cap. 2, [Margin: And Arcturus, Sirius. (Et Arcturi, Sirij.)] [that] there [ibidem] in the year 1559, observed on the day before the Ides of April, the Meridian Altitude of Arcturus [was] gr. $73^{\circ} 20'$; and thence the Declination gr. 69° ; and in the year 1598, on the Nones of March, the Meridian Altitude of Sirius [was] gr. $22^{\circ} 45'$; and so its southern Declination gr. $15^{\circ} 55'$; [Margin: Fomalhaut. (Fomahat.)] and the Meridian Altitude of Fomalhaut gr. $5^{\circ} 6'$; and its Declination gr. $33^{\circ} 33'$. Finally [Margin: Rigel. (Rigel.)] the Meridian Altitude of the left foot of Orion, Rigel, [was] gr. $29^{\circ} 28'$; and the southern Declination gr. $9^{\circ} 12'$; and from these the longitude of Fomalhaut in $\approx$ [Aquarius] gr. 28° , and Rigel in $\amalg$ [Gemini] gr. $10^{\circ} 10'$. [Margin: Stadius's errors. (Stadij errores.)] But in our *Geographia Reformata*, from the observations of Langren [Langreni] and of Wendelin [Vuendelini], I have shown the Pole-altitude at Brussels [Bruxellis] to be gr. $50^{\circ} 48'$, and the Equator to be gr. $39^{\circ} 12'$; and so, supposing the meridian altitude of Stadius, his Declinations are to be corrected, as below — which nevertheless do not cohere with the required Tychonic Table. [quæ tamen non cohærent, cum requisitis à Tychonica Tab.]

Comparison table of Stadius's declinations.

Heading: Declination & Observation of Johann Stadius [Declin. & Observ. Io. Stadij]. Columns: Year [Anno]; star; False [value] of Stadius [Falsa Stadij] in G. and M.; Corrected by Stadius [Correcto Stadio] in G. and M. (with B/A); Tychonic [value] [Tychonica] in G., M., S.

A n n o	Star	Falsa Stadij G. M.	Correcto Stadio G. M. (B/A)	Tychonica G. M. S.
1 5 5 9	Arcturus [Arcturi]	22 0	22 32 B	21 32 30
1 5 5 9	Sirius [Sirij]	15 55	16 27 A	16 9 22
1 5 5 9	Fomalhaut [Fomahant]	33 33	34 6 A	30 56 36
1 5 5 9	Rigel	9 12	9 44 A	9 21 6
1 5 5 9	Spica [Spicæ]	8 48	9 20 A	8 47 40

It is therefore clear that, from declinations so false, the places of the said Stars derived by Stadius are likewise false — including even Regulus, which he affirms in Caput 2 of his *Commentary de Fixis* to have been found by himself in the year 1555 in ♌ [Leo] gr. 23° 30'. [Patet igitur ex tam falsis Declinationibus, quam falsa sint loca dictarum Stellarum à Stadio inuecta, atq; adeò etiam Reguli, quem Capite 2. Commentarij de Fixis affirmat à se Anno 1555. in ♌ gr. 23. 30'. repertum.]

CAPUT IV.

The Longitudes and Latitudes of the Fixed stars selected from observations down to the time of Claudius Ptolemy exclusively, with a critical assessment of them.

[Fixarum Longitudines, ac Latitudines selectæ ex observationibus vsq; ad Claudij Ptolemæi tempus exclusivè, cum censura de illis.]

Besides the twofold method of Observing the Longitudes of the Fixed stars — namely, by the Ecliptic distance between them, and from the Moon captured by the naked eye, or by Astrolabes, and likewise the Ecliptic distance of the Moon from the Sun, which we indicated in chapter 1 — Later Astronomers down to Tycho have used also a third mode: namely, assuming their latitude as found from Ptolemy, as being unchangeable, with which, and with the obliquity of the Ecliptic, they investigated the longitudes of those stars observed by Declination at that time, through the analysis of Triangles [per Triangulorum analysim]. We shall therefore set forth the longitudes acquired in one or other of these modes by the Ancients down to Ptolemy, then those of Ptolemy himself, selected, and of his successors down to the time of Wilhelm, Landgrave of Hesse [Vilhelmi Lantgrauj Hassiæ], and of Tycho Brahe — noting in each what we shall judge worth knowing.

By way of foundation, however, we must first set down [Præmittendum tamen fundamenti loco] from our *Chronologia Reformata* the best Chronographies: the year 1 of the vulgar Epoch of Christ falls on the 23rd of August, Julian Calendar [die 23. Augusti Iuliani Kalendarij], beginning at the Nabonassar year 749; whence, the years from Nabonassar being determined from Ptolemy, we shall easily gather the years before or after Christ — these things being established.

1. [Margin: Spica observed 1st by Timocharis. (Spica 1. observatio Timocharidis.)] Timocharis of Alexandria, as Ptolemy reports lib. 7 *Almagest* cap. 2, observed Spica to be distant in advance of [in præcedentia à] the point of the Autumnal Equinox gr. 8° very nearly, that is, in ♍ [Virgo] gr. 22° very nearly; but he does not express the Year as it is now [sed Annum non exprimit sicut neq; cap. 3]: when [Ptolemy] relates that Timocharis observed the northern declination of Spica gr. 24° — below the same chapter he notes the first year, which for Timocharis he says to have been Nabonassar 454, that is, before Christ 295 [idest ante Christum 295]; on which account this Year for either observation is not improbably accepted by Bullialdus [Boulliau], lib. 5 *Astronomiæ Philolaicæ* c. 3, where, about the Nabonassar year 455, from the foresaid Declination and latitude of Spica, he gathers its place in ♍ gr. 21° 59'.

2. [Margin: Spica observed 2nd by Timocharis. (Spica 2. observ. Timoch.)]
Timocharis likewise at Alexandria, as Ptolemy has lib. 7 *Almag.* cap. 3, in the year 36 of the first Calippic Period, lasting 76 years [Constantis annis 76], on day 15 of Elaphebolion, that is, in the Nabonassar year 454, before Christ 294, on day 6 of the Egyptian month Tybi [die Tybi Mensis 5. (recte: see below)] — at the beginning of the third hour, that is, four hours before midnight, both temporal and equinoctial [tertia hora incipiente, idest quarta ante mediam noctem hora, tam temporali, quam æquinoctiali] — saw the Moon reach Spica with its Eastern limb, and so cross it [transgredi], such that Spica had exactly separated [diseparauerit] a third part of the Lunar diameter toward the North; whence Ptolemy, from his own Lunar tables, gathers the Longitude of Spica in $\text{M}\text{gr. } 22^{\circ} 20'$, and the southern Latitude very nearly $\text{gr. } 2^{\circ}$. Copernicus uses this observation, lib. 3. [Vtuntur hac observatione Copernicus lib. 3.]

(*De Revolutionibus* I.2 and Tycho, *Progymnasmata* I) — and he rightly adds that, from this observation to the one Spica made in the year of Christ 1585, 1879 years had elapsed. But Timocharis does not correctly say that the observation was completed in that year, because Ptolemy deduces it from his own calculation, not from Timocharis's observation, which placed Spica in $22^{\circ}10'$ of Virgo [in $\text{M}\text{gr. } 22. 10'$]. Ptolemy indeed deduces it from his own calculation, as we shall say; and he placed it very nearly at 22° . Lansbergen, however, in his *Thesaurus* of observations records it as fixed (see *Thesaurus* p. 146), and gathers from his Lunar Tables the position at $22^{\circ}4'58''$ of Virgo [in $\text{M}\text{gr. } 22. 4. 58'$], and the true latitude at 2° south. Here Lansbergen errs enormously, yet sins only in this, that in setting out the history of the observation he plainly relates a contradiction with Ptolemy: he gives a third of the diameter of the Moon as left over [*Trientem diametri Lunaris relictum*] toward the north from Spica, and at the end of the calculation it comes out at $4^{\circ}45'$. This is a third of the semidiameter, not of the diameter.

[Margin: Lansbergii error.]

3. Timocharis likewise at Alexandria, as Ptolemy relates (*Almagest* VII, cap. 3), in the 47th year of the first Calippic period, on the morning of the 8th of Pyanepsion, which had passed into the 9th of Thoth, in the 10th hour and a half, saw Spica exactly touching the northern part of the Moon, while the horizon was then rising. This is computed to have been the year 466 of Nabonassar, that is, before Christ 283, and at one and a half temporal hours past midnight; he concludes the true place of Spica very nearly at $22^{\circ}30'$ of Virgo [in $\text{M}\text{gr. } 22. 30'$], with a southern latitude of about 2° . Among the readings of this observation, "promoted"

[*promotam*] stands for "12" between the earlier reading and this observation, and for the sake of one degree of difference, with the Greeks reading "Spica promoted." The codex has 5, that is, the sigma with an acute accent, which signifies not "ten" but "six," with the Latin interpreter rendering it.

Longomontanus, however, in the *Astronomia Danica* (lib. 2, Theor., cap. 1, in the Commentary *De Stellis Fixis*), from his Lunar hypotheses places Spica at 22°30' of Virgo [in ♍ gr. 22. 30'], at the equal hour 15h 54' past midnight at Alexandria, in the year 466 of Nabonassar — but 1884, not 1600, before Christ now current. But Lansbergen in his *Thesaurus* of observations (p. 146) places the hour as equal at Alexandria at 2°30' [gr. 2. 30'] past midnight, and Spica from his tables at 22°12'21" of Virgo [in ♍ gr. 22. 12. 21].

[Margin: Spicæ observatio. Timoch.]

4. Timocharis from Ptolemy (*Almagest* VII, cap. 3): at Alexandria, in the 47th year of the first Calippic period, at Nabonassar 465, or before Christ 284, on the 29th day of the month Athir, in the 3rd hour of the night, that is at 3h 20' of equal time past midnight, he carefully noted the Moon's middle southern part applied to the middle of the Pleiades, or to the third following in succession, whence Ptolemy concludes the Fixed Star here to be in 29°30' of Aries [in ♈ gr. 29. 30'], with a northern latitude of 3°40' very nearly. Longomontanus, however, places it (as above) in 29°32' of Aries [in ♈ gr. 29. 32'] past midnight.

[Margin: Pleias Lucida observat. à Timoch.]

5. Timocharis, finally, in Ptolemy (*Almagest* VII, cap. 3): at Alexandria, in the first year of the first Calippic period, and at Nabonassar 454, on the 25th day of Poseideon, or the 7th of Phaophi, in the 16th hour incipient, that is at 4h 10' past midnight (but at equal time 3h 10'), he observes the Moon by its northern extremity touching the boreal extremity of the three in the front of the Scorpion, where Ptolemy deduces it to have been in the Scorpion at 1° [in ♏ gr. 1.] with a southern latitude of 1°20'. But Longomontanus (as above) places it at 15°30' [gr. 15. 30'] past midnight; the place of the star with the Moon in the Scorpion at 1°58' [gr. 1. 58']. Lansbergen in his *Thesaurus* (p. 148) asserts that Ptolemy was here deceived by a faulty longitude of the star, for he gives Spica's place at 1°26'29" [gr. 1. 26. 29] with a southern latitude of 1°15'; and so he supposes the conjunction of the Moon and the Fixed Star to have been seen on the horizon, at 2°30' [gr. 2. 30'] of equal time past midnight, and the true place of the Moon in the Scorpion at 0°50'32" [gr. 0. 50. 32]; and the true latitude north 1°16'49" [gr. 1. 16. 49].

[Margin: Scorpij frons.]

6. Hipparchus, as Ptolemy relates (*Almagest* VII, cap. 2), from his own time, that is from a following observation, gathers that in the year 3 of the third Calippic period — this is 128 years before Christ — he saw Spica distant in the preceding autumnal section by 6° [gr. 6.], but at it being in degree 24 of Virgo [in $\mathfrak{M}$ gr. 24.]. Bullialdus (*Astronomia Philolaica*, cap. 3) gives the latitude of Spica, gathering its place in 23°59' of Virgo [in $\mathfrak{M}$ gr. 23. 59']. Longomontanus, however, with respect to the true Equinox, where above, locates it in 24°25' of Virgo [in $\mathfrak{M}$ gr. 24. 25'].

[Margin: Spicæ observ. ab Hipparch.]

7. Hipparchus likewise, with Ptolemy reporting (*Almagest* VII, cap. 2)... the Sun was to be [*Solem... fuiſſe*]

he observed in the year 50 of the third Calippic period that Stella, which is in the Heart of the Lion [in Corde Leonis] in Cancer [in Cancrī], at 29°50' [gr. 29. 50']. Tycho gives the place from here for tome 1, *Progymnasmata* (p. 253), and reckons — but not rightly — it as completed, flowing from the years 1713 and 8. With Copernicus (lib. 3, cap. 2), having flowed around to the year 196 from the death of Alexander the Great [à morte Alexandri M.]. Bullialdus, however, in the place mentioned, gives the year of Nabonassar 621, since indeed Ptolemy reckons the years 265 between his own observations and Tycho's, whom (a little before this) he had said to have observed in the year of Antoninus the Emperor, hence the year of Nabonassar at 886. But Lansbergen in his *Thesaurus* (p. 153) reckons from his tables the place of Regulus in Cancer at 29°49'4" [in Cancrī gr. 29. 49. 4'], from that year up to which he reckons 6 solid Nabonassar years, 618. The Egyptian year is 365, with the sum 366. The first year of the Calippic period was the year of Nabonassar 454, begun, and at the end of the Calippic period 50 years; the third year of the Calippic period likewise ran with Nabonassar 620, increasing now to 621.

[Margin: Regulus observat. ab Hipp.]

[Margin: Chronologiæ diffidium Bullialdi, & Lansbergij.]

8. Agrippa, as Ptolemy writes (*Almagest* VII, cap. 4), in Bithynia, in the year 12 of the reign of Domitian the Emperor [Domitiani Imperat. & 840 Nabonassari], on the 7th of Metroi, and the 2nd of Tybi at the beginning of night, in the third hour past midnight, that is at 2 temporal hours, observed the southern part of the Moon applied to the middle of the Pleiades. Ptolemy adds that it was the Alexandrian hour of that equinoctial at 2°41' [gr. 2. 41'] past midnight. Hence

from his Lunar tables he deduces the place of the Pleiades in Taurus at $3^{\circ}5'$ [in Tauri gr. 3. 5'], with a northern latitude of $3^{\circ}40'$. It was then the year of Christ 92.

[Margin: Pleias obf. ab Agrippa.]

9. Menelaus at Rome, in the first year of Trajan the Emperor [Anno primo Traiani Imperat.], as he holds (*Almagest* VII, cap. 3), and at 845 of Nabonassar, on the 15th of Mechir, the sequence at the 16th hour temporal at $4^{\circ}5'$ [gr. 4. 5'] past midnight, observed the southern part of the Moon to the southern Spica; and after the middle of the night, Spica was to have appeared distant from the center of the Moon in the preceding hour by one diameter of the Moon, equal and remote from the Lunar horns; whence Ptolemy concludes that, before that same time, at the Alexandrian hour of $6^{\circ}15'$ [gr. 6. 15'] past the middle of the night, Spica was to be in Virgo at $25^{\circ}45'$ [in ♍ gr. 25. 45']. Lansbergen in the *Thesaurus* (p. 147) gives the place to have been at Rome at the equal hour $4^{\circ}57'$ [gr. 4. 57'] at the middle of the night, and at the year of Christ completed 97. Therefore Spica appears in $26^{\circ}1'$ of Virgo [in ♍ gr. 26. 1']; but as Copernicus (lib. 3) revolved, it was in the year of Christ 99, but the latter [reckoning] by 2' [gr. 2'], according to Copernicus (lib. 3). It is revolved at the year of Christ 99, but at the latter being 2' from the years of Nabonassar.

[Margin: Spica observata à Menelao.]

10. Menelaus again in the same year 1 of Trajan, from Ptolemy above (*Almagest* VII, cap. 3, sentence 18), Mechir the sequence at the 19th hour, the 11th: at Rome he saw the southern horn of the Moon in a straight line with the middle, and with the southern horn touching the heart of the Scorpion [centrum austrum Scorpij], the center not standing off from the straight line, indeed differing in the middle of those same things, which both [points were] as northern in the front of the Scorpion. Ptolemy concludes it was at the Alexandrian hour of $7^{\circ}10'$ [gr. 7. 10'] past the middle of the night, and from his tables concludes the boreal front of the Scorpion in the Scorpion at $5^{\circ}10'$ [in Scorpij gr. 5. 10'] with a northern latitude of $1^{\circ}10'$ [gr. 1. 10']. Lansbergen in his *Thesaurus* (p. 149) gives the hour at the middle of the night to be $6^{\circ}12'$ [gr. 6. 12'], equal to Rome, and the star to have been in the Scorpion at $5^{\circ}24'36''$ [in Scorpij gr. 5. 24. 36'], with a northern latitude of $1^{\circ}15'$ [gr. 1. 15'].

[Margin: Scorpij frons à Menelao.]

11. Ptolemy himself (*Almagest* VII, cap. 3): the declination of Spica at 0° [gr. 0.] he observed to be distant in the southern part, and as he had said in the year 2 of Antoninus the Emperor, on the 9th of Pharmuthi, hour past midnight at $5^{\circ}30'$ [gr.

5. 30'], with the Astrolabe he observed; thus to be at the third degree, and at 0°20' [gr. 0. 20'] past midnight in the place of the Lion [in Leonis loco] following the Ecliptic in succession; whence he gathers the place of Regulus in the Lion at 2°30' of the Lion [in Leonis gr. 2. 30'] to have been. Copernicus (lib. 3, Revol. cap. 2) affirms the place [located] at the year 462 from the death of Alexander the Great. Longomontanus, in the said Commentary *De Stellis Fixis*, from this gathers Regulus to have been in the Lion at 3°55' [in Leonis gr. 3. 55'], with refractions computed thence, the western [observations] both diminishing the longitude of the Sun, and diminishing the longitude of the Moon. Now that was the year of Christ 138 and 261; afterwards Hipparchus's observation is recounted, that the lesser Longitude of Ptolemy is numbered in the observation at 1600, the year of Christ being numbered 1454, until at last 1461 is completed. Lansbergen in his *Thesaurus* (p. 153) places the year of Christ 138. Regulus, in the Lion at 3°30'4" [in Leonis gr. 3. 30. 4'], with nothing about the curve of Refraction of the Sun, which doubtless represents a lesser one [than] he represented to Ptolemy, the longitude of the Moon, with the Sun being said to be...

[Margin: Spica & Regulus observ. à Ptolem.]

[Margin: Lansbergij inconstans.]

to have been close to setting, and yet otherwise, as Lansbergen [says], as we have seen, he did not neglect Refraction. Let us now compare in one view the places of the Fixed Stars stated above.

12. Since we have now arrived at Ptolemy, it would seem fitting to subjoin here the Ptolemaic Catalogue of the Fixed Stars, which we have collated with the Greek Basel text, with the Translation of George of Trebizond [Georgij Trapezuntij], revised by Andreas his son and by Luca Gaurico [Luca Gaurico]; and likewise with the abacus of Alphonsine, Prutenic, Copernican, Clavian, and Piserian [tables]. But why burden Typographers and Readers with so great a mass of false Longitudes and Latitudes? For, excepting a few Fixed Stars whose places can be compared, the Ptolemaic [places] with those of recent learning of the astronomical art, the rest are useless, since they labor under manifest or suspect falsity — a fault, whether from the rudeness of the observations, or from Refractions omitted in the capturing of distances of the Sun from the Moon (through which the places of the Fixed Stars are sought, as Ptolemy himself testifies, *Almagest* VII, cap. 4), or from the fallacious place of the Sun itself and of the Moon, from an excessive Parallax, and from the false and fallacious obliquity of the Ecliptic. It will therefore be enough to select Stars of the first and second

magnitude, and a very few more notable third [magnitude]. The places of the rest, up to Ptolemy's time, are better gathered from our Universal Catalogue, from the annual motion of the Fixed Stars, or from the difference of Longitude among them — these which we here give.

[Margin: Ptolemaici Catalogi imperfectio.]

The selected Ptolemaic catalogue (Tabula II, AD 137–138) continues. Each constellation is given as a rubric, followed by its stars in Ptolemaic order (the *Ordo Ptolemæus* column). Longitude is given as zodiacal Sign / Degrees / Minutes; latitude as Degrees / Minutes with **B** = *Borealis* (north) and **A** = *Australis* (south). The **Magnitudo** column gives stellar magnitude; the **Natura** column gives the planetary nature (Ptolemy's astrological assignment), shown by planetary glyphs. Variant readings drawn from other sources — the *Græcus Codex* (Greek manuscript), the *Alphonsinis* (Alphonsine Tables), the *Prutenicis* (Prutenic Tables), *Copernico* (Copernicus), and *Clavio* (Clavius) — are entered as their own sub-rows beneath the star they qualify, with the longitude/latitude they record.

The Ptolemaic star catalogue (Tabula II) continues. Columns: **Ordo Ptolem.** (Ptolemy's ordinal number) | **Constellationes, & Stellæ** (constellations and stars) | **Longitudo** (longitude: Sig. = zodiac sign, G. = degrees, M. = minutes) | **Latitudo** (latitude: G. = degrees, M. = minutes; A = north [Australis here used as boreal/austral marker — printed "A"], B = south) | **Magnitudo** (magnitude) | **Natura** (nature: the planetary character). The italic sub-rows (*Prutenicis*, *Alphonsinis*, *Græcus Codex*, *Copernico*, *Clavio*, etc.) give variant longitude/latitude values from those authorities for the star on the line immediately above.

[End of the Ptolemaic catalogue, Tabula II.]

CAPUT V

The longitudes and latitudes of the fixed stars as observed and arranged, from Ptolemy's time exclusive, down to the observations of Hesse [Hassiacas] and Tycho, exclusive.

[Margin: Albategnius's observation of the fixed stars [Albategnius Fixarum observator].]

For 1740 whole years, between Ptolemy and al-Battānī [Albategnius], there was a remarkable silence concerning the fixed stars. At last al-Battānī, the foremost of the Arabs in Syria — and at that time easily the most learned in the science of the stars — observed in the year 1627 of Nabonassar [years of Nabonassar], that is, AD 879 now completed, beginning 880. He observed Regulus in 14° of Leo, as he himself reports in chapter 51 of his *Science of the Stars*, adding that Ptolemy had observed and recorded Regulus in 2° [?] of Leo and the sixth part of a degree [grad. 2. & sexta gradus parte] — that is, 10 minutes — in the year 836 of Nabonassar. Reckoning, then, that the fixed stars had advanced $11^{\circ}50'$ over all the Ptolemaic figures, he added $11^{\circ}50'$ to the longitude, while retaining the Ptolemaic latitude.

Add, then — and you, reader, to the longitude of the fixed stars handed down just now in the preceding chapter, in the last Table — and you will have the positions of the fixed stars at al-Battānī's epoch, according to his opinion. For the rest, Ptolemy's codex has Regulus in $2^{\circ}30'$ of Leo,

[Margin: To be corrected in al-Battānī [Corrigenda in Albategnio].]

and so does the manuscript codex of Clavius, and the Greek codex of Basel, and the version of Trapezuntius [George of Trebizond]; and therefore only $11^{\circ}30'$ would have to be added. Moreover, al-Battānī retrogressed from the year 845 of Nabonassar, in which Menelaus [Menelaus of Alexandria] had observed the fixed stars, and therefore, distributing those $11^{\circ}50'$ of his over 782 years, he said that the fixed stars complete one degree in 66 solar years. But if the interval were taken between his own epoch and the Ptolemaic time — namely 741 years — they would have advanced only 63 years to a single degree, or $62\frac{1}{3}$ [?]; indeed, if Ptolemy's place [$2^{\circ}30'$] were used, the years would be $64\frac{1}{6}$ [?]. — [The example: Regulus in Leo.]

[Margin: Ebenesophim restored the position of Regulus among the fixed stars, AD 936 [Ebenesophim Fixarum restitutor Reguli locus Ann. 936].]

2. After al-Battānī, by 57 years, Ebenesophim [Ibn Yūnus?][?] the philosopher — in the year of the Arabs, or of the Hijra, 325, that is AD 936 — verified the positions of the fixed stars to the day of that year, the 18th of November, on the 7th feria [Friday]; and he wrote a book on the places of the fixed stars, which Boulliau [Bullialdus] (*Astronomia Philolaica*, book 5) asserts he himself saw in manuscript by the favor of Pierre Gassendi [Petri Gassendi], and of Forcalquier, the magistrate [proprætor] of his town in Provence. And Gassendi himself, in his second *Epistle* — written on the Ides of July 1636 to Wendelen [Wendelinus] — mentions that codex of Arnaldus[?]; in which the place of the Heart of the Lion [Cor Leonis, Regulus] is noted in 15°12' of Leo.

[Margin: The Persian Table of the fixed stars, AD 1115 [Persica Tabula Fixarum Anni 1115].]

3. After 180 years, the Persian Mathematicians [Mathematici Persæ], from their own observations, established the positions of the fixed stars; and Boulliau, in the appendix to his *Astronomia Philolaica*, brings out their Tables — from the Royal Library of Paris, and from the manuscript of M. Georgios Chrysokokkes. The Table was constructed in the year of the Arabs 509, that is AD 1115, on May 27, the 5th feria [Thursday], with which that year of the Arabs began; and from it the positions of 25 fixed stars are taken, with the Latin Name added, according to Boulliau's opinion — which rests upon the ecliptic distance between these fixed stars and the Heart of the Lion [Regulus], which is found in Ptolemy.

Caput V (continued) — Observed Longitudes and Latitudes of the Fixed Stars from the Time of Ptolemy down to the Hessian and Tyconic Observations

Persian Table for the Year of Christ 1115

The names are given first in their Latinized Persian form, then in the form used by [Ismaël] Bullialdus [Boulliau]. Longitudes are given by sign [Sig.], degree [G.], and minute [M.]; latitudes by degree [G.] and minute [M.]; with the magnitude [Magnit.]. The letters **A** and **B** in the latitude column mark whether the latitude is north or south (Boreal / Austral).

The compilers of the Alphonsine Tables, in the year of Christ 1252, had followed the opinion concerning the trembling [trepidation] of the eighth sphere and the anomaly of the motion of the fixed stars. Afterward, however, in the year 1256, by command of King Alphonso [Alfonso X], having seen the codex of al-Battānī [Albategnius], they chose his view of the uniformity of this motion, and—reckoning by 66 years to a single degree, with the necessary computations—placed Spica in Libra at 13° 48', where Ptolemy had set it in Virgo at 26° 40', in the

year of Christ 138. Al-Battānī, however, [had placed it] in Libra at 8° 30', in the year of Christ 879. The difference between the Ptolemaic and Alphonsine position is 17° 8'. Between the position of al-Battānī and that of the Alphonsines it is 5° 18'.

If you add this 17° 8' to the position derived from the table of the preceding chapter, you will have the positions of the fixed stars corrected according to the mind of Alphonso for the year of Christ 1256. But if, taking the years 1118 that fell between al-Battānī and the Alphonsine correction, you divide by 66, there result 17 38/66 degrees, that is, 34 minutes; and so, following Ptolemy's position, they ought to have placed Spica in Libra at 14° 14'. Dividing instead the 377 years that fell between al-Battānī and the Alphonsine correction by 66, there remain 5 47/66 degrees, that is, very nearly 43 minutes; and adding these to the Battanian position, Spica was to be placed in Libra at 14° 13'.

[Margin: *Alphonsine Table of the fixed stars.*] [Margin: *The defect of the Alphonsine [tables].*]

[5.] Rabbi Levi [Levi ben Gerson / Gersonides], as he himself relates in Book 5 of his *Wars of the Lord* [*Defensionum Dei*], chapter 62, and Augustinus Riccius in his treatise *On the Motion of the Eighth Sphere*, in the year of Christ 1336, observed Spica and several other affixed stars to have advanced from al-Battānī's time by 6° 58', and so to differ from the Ptolemaic time by 18° 48'. For he followed al-Battānī's opinion most closely, of one year for [one] degree out of 66.

[Margin: *Positions of the fixed stars for the year 1336, after Rabbi Levi.*]

6. In the year of Christ 1364, the positions of certain fixed stars were verified by some astronomer or other, whose table Petrus Gassendus [Pierre Gassendi] produced from the Arnaldine Codex in his letter to Wendelin [Vendelinus], which stands at the end of Tome 4 of Gassendi's works; and it runs thus, with the longitude reduced to its signs:

At the foot of the table these words of a more recent author were to be read: *Note that the motion of the eighth sphere, from the time of Alphonso down to 1406, was 1° 44' 30".*

7. At the end of the *Works of Cardinal Nicholas of Cusa* [Nicolaus Cusanus] there stands a certain table of the fixed stars constructed from the observations of Cusa himself and of Cardinal [Nicholas] of Nicaea and of [Pierre d'Ailly, the] Alliensis, as is there asserted, and reduced to the year of Christ 1440. In it I do not doubt there is an error of one and a half degrees, and sometimes more, if it be compared with the Tychonic hypothesis of the fixed stars, as is plain from the stars of first magnitude written below, which I have selected from Cusa's table:

Table of Cardinal Cusa

Name	Anno 1440 — Long. Sig.	G M . . Lat. G.	M N . /S
Orionis humerus dext.	♊ Gemini	2 0 17 3	0 A
Capella	♊ Gemini	1 0 22 6	3 B 0
Sirius	♋ Cancer	8 4 39 0	5 A 0
Procyon	♋ Cancer	2 1 16 0 0	0 A

Spica	♎ Libra	1 4 2 7 0	0 A
Arcturus	♎ Libra	1 0 31 8	3 B 0
Cor Scorpij	♏ Sagittarius	3 4 4 0	0 A

8. In the year of the Lord 1474, Abraham Zacutus [Abraham Zacuto] observed Spica in Libra at 17° 10', as his disciple Augustinus Riccius reports in his treatise *On the Motion of the Eighth Sphere*; and comparing this position with the one determined by the Alphonsines for al-Battānī, he concluded—to the mind of al-Battānī—that the fixed stars complete one degree in 66 years. Yet if you compare this position, carried back to this same year by the Tychonic [reckoning], you will see it exceed [the truth] by half a degree and more, and accommodated rather to the Battanian opinion, which the Arabs strove to support, than derived from exact observation.

[Margin: *Spica observed by Zacuto.*]

9. Bernardus Vualtherus [Bernhard Walther], as we have in his own observations, observed the longitudes of the fixed stars written below by means of armillae rectified through the position of Venus—yet these are inconsistent with themselves in the case of Sirius, whether on account of refractions or some

defect of the armillae. He says, moreover, that the observation of Aldebaran was most diligent, and that of Orion most certain; but the position of Aldebaran falls short of the Tychonic by 5'—unless the minutes are written faultily in both, 18' for 48'. And that of Orion differs by 32'.

[Margin: *Walther's method.*]

Year	Star	Sig.	G	M
			.	.

	Orion. hum. dext.	♊ Gemini	2	1
			1	8

10. How much trust the positions of the fixed stars of Johannes Werner [Io. Vuernerus], Copernicus, Cardanus [Girolamo Cardano], and Johannes Stadius [Io. Stadij] deserve, or how much correction they require, we have shown well enough, on the occasion of the declinations, in chapter 3, from number 5 to the end.

11. Petrus Appianus [Peter Apian], in the *Astronomicum Caesareum*, places Regulus—taking the beginning [of the year] as the year of the Lord 1500—in Leo at 22° 8'; that is, 19° 38' beyond the Ptolemaic position. But afterwards, in the Catalogue of the year 1532, which Clavius records in his *Sphaera*, page 182 (in my copy), he places Regulus and the remaining fixed stars 19° 58' beyond the Ptolemaic position.

Therefore, by adding the aforesaid degrees and minutes to the Ptolemaic positions from Chapter 4 (the last table of those selected), you will have the positions of the fixed stars to the mind of Apian for the year 1532.

[Margin: *Apian's Catalogue.*]

12. Clavius himself, who had not seen Tycho's Catalogue, exhibits in his *Sphaera* a Catalogue of the fixed stars in which he supposes Spica and the rest of the fixed stars to be advanced from Ptolemy by $21^{\circ} 7'$ to the year of Christ 1575. If, then, these are added to the Ptolemaic positions of the fixed stars, you will have the Clavian Catalogue, that is, the positions of the fixed stars for the year 1575 according to the opinion of Clavius, by which he also constructed a Globe, as he there asserts. For example, Spica, which in Ptolemy stands in Virgo at $26^{\circ} 40'$, is in Clavius—in the use he makes of his Table—in Libra at $17^{\circ} 47'$. In the year 1575, therefore, it had advanced, as I said, $21^{\circ} 7'$. But because in this very Table he imitated Copernicus in placing the elongations of the fixed stars from the first star of Aries, and made it elongated [from there] by 170° , he therefore supposes the first star of Aries to be in longitude $27^{\circ} 47'$ from the vernal equinox.

Hence, if you wish to elicit the Ptolemaic positions of the fixed stars from Clavius's Catalogue (according to the manuscript codex by which Clavius attests he used it), add to the elongations of Clavius $27^{\circ} 47'$; and you will have the Clavian longitudes for the year 1575 from the vernal equinox. From these in turn subtract $21^{\circ} 7'$, and you will have the Ptolemaic positions for Ptolemy's time. But since Clavius for the most part followed Copernicus, it is no wonder if, together with him, he departed from the goal of the true positions of the fixed stars; as appears from Spica itself, which by Tycho ought, in the year 1575, to have been in Libra at $17^{\circ} 54' 45''$. Clavius therefore falls short by about $8'$. Which is no error, nor enormous; rather one ought to congratulate astronomy that it has so far advanced, and approached so near the Hessian [Lantgravian] observations—indeed, that the Tychonic observations differed from it by within ten minutes of error.

[Margin: *Clavius's Catalogue.*] [Margin: *Clavius corrected.*]

CAPUT VI

On the Positions of the Fixed Stars Observed by Wilhelm, Landgrave of Hesse, and his Astronomers

1. Tycho [Brahe] testifies, in the dedicatory epistle of his *Letters* addressed to Prince Maurice and Landgrave of Hesse, that Wilhelm [Gulielmus], father of

Maurice, held the foremost place among the astronomers of his age—indeed of all Germany—through exquisitely wrought instruments and instruments of every kind; and that, well furnished with craftsmen skilled in this science, he himself applied himself to nightly observations for the reform of astronomy, so far that he duly set in order four hundred stars to within five minutes of certainty. Then, in the Argument of the Epistles of Tome 1, [Tycho] asserts a difference of five minutes between the Tychonic and the Lantgravian longitudes of the fixed stars, referred by Christoph Rothmann to azimuth, and the altitudes carelessly taken by quadrants.

[Margin: *Praises of Wilhelm of Hesse.*]

I should like, however, to draw from Tycho (page 49 of the Epistles) the longitudes and latitudes of certain stars, which Tycho computed from the Canon of Sines, [working] from the data provided by the Lantgravian observations, and from the assumed Right Ascension of Aldebaran of $63^{\circ} 10'$ to the beginning of the year 1587; and with the obliquity of the ecliptic at $23^{\circ} 30'$, and the altitude of the Pole at Cassel $51^{\circ} 20'$ —which, however, Tycho confessed (page 39) to be $51^{\circ} 19'$.

CAPUT VII

On the Observations of Tycho Brahe, especially concerning the Fixed Stars, their Certainty, their Order, and the Method of reforming them

[The following table opens Caput VI's material but is printed at the head of page 218 under Caput VI; the running structure resumes with Caput VII's prose below.]

The prose of Caput VII (on Tycho's observations of the fixed stars) follows the ornamental band; the right column of page 218 continues the discussion begun under Caput VI:

[2.] ...and perhaps of two minutes. For in Book 1 of the Theorics, in the *Astronomia Danica*, chapter 4, [Longomontanus] says: *I afterwards, from the year 1590, for a five-year stretch, was not only present at this business of restoring the fixed stars to the heavens and carrying it out, but indeed presided over it; so that I may affirm in good faith—so far as can ever be expected from human industry—that to the restoring of these [stars] according to longitude and latitude, [a certainty] accommodated by us, and every doubt, by reciprocal [checks] on both sides, often repeated where there was need, was [removed], so that they did not stand at the same minutes as nearly as possible [from one another]. Although, on account of the longitude of the Sun being diminished by us by half a minute beyond a minute, just so much, star by star, of the longitudes of the stars did we subtract from Tycho's Canon.* Hence the longitude of the fixed stars in the Danish Tables is less by a whole minute than in the Tychonic and Rudolphine [tables]; and it is plain that Longomontanus labored at it, and that he observed the declinations, [and] the distances of the fixed stars—not all, but most nearly in the same [stars]—to be consistent. Let us now hear that other Tycho, so to speak, or his very eye-pupil, or his very hand, namely Kepler.

[Margin: *Longomontanus's testimony.*]

3. Johannes Kepler, in his work *On Mars* [the *Astronomia Nova*], chapter 10, speaking of the Tychonic observations made on the island of Hven, says: *In use it often happens, even in the observations on the island, that Right Ascensions deduced from two stars differ by three scruples [thirds]. When I consulted Christian [Longomontanus] about this, whether it should be ascribed to a defect of observations, or to a weakness of sight, he answered that it was not unusual.* He

speaks of Christian Longomontanus; and in the explanation of the foundation of his *Ephemerides*, page 15, he says: *The motion of the Sun differs from the fixed stars by six minutes—Tycho's [datum] wavering, and Brahe's [observation] undecided; here testimony fails me.* He goes on: there he indicates many suspicions of errors, which, joined together as it were from heaps of snow, a great [one], and the error of some minutes, could effect. Briefly, concerning Brahe's observations, he says (page 14): *Nothing in this matter rests on any authority but that of a most diligent Artificer, on whom I rely; with whose observations relying, may I become, through a comparison of many others, guilty of some minutes [of error].* He adds, however (page 15): *Yet it is easy [for me] to think the quadrant of one degree's observers visible.*

[Margin: *Kepler's testimony.*]

4. If we compare the Tychonic observations among themselves, and these with those which Paulus Hainzelius—most commended by Tycho himself—acquired by a quadrant of 14 cubits, we shall detect a disagreement of some minutes, not only once, in the Tables of Distances and Declinations to be exhibited a little below. As for the Distances also, deduced trigonometrically from longitude and latitude, if we compare them with the distance [given] by Tycho through sextants, that same disagreement is rarely repeated. Gassendus too noted this in his *Commentaries on Celestial Matters*, page 96. For the distance between the Scales of Libra is, by Tycho in the *Epistles*, $9^{\circ} 8' 20''$; and from the solution of the triangles through longitude and latitude the same Tychonic [distance] comes out, according to Gassendi, at $9^{\circ} 11'$.

5. As for Tycho's Method in reforming the positions of the affixed stars: First, he inquired through the circumpolar stars, especially the one that shines in the tail of Ursa Minor and from its nearness to the Pole of the World is called *Polaris*, the altitude of the Pole at Uraniborg; and he obtained it as once $55^{\circ} 54' 30''$, but afterwards more accurately as $54^{\circ} 40''$, and sometimes $55^{\circ} 54' 40''$ —as is plain from the very *Epistles*, page 40, and from Tome 1 of the *Progymnasmata*, page 28. Secondly, he caught the distances of most of the fixed stars among themselves not with the astronomical radius, which he found deceptive, but with great sextants, and sometimes with a hemicycle. Thirdly, he investigated the meridian altitudes of the fixed stars with various quadrants and with the trigonic sextant. Fourthly, he hunted out the Right Ascension of the bright star of Aries—not, as Werner and the ancients did, but from Venus seen in the morning and evening, [tracing] its rising exponent until [it came] to the right ascensions [of the stars]. Fifthly, from the Right Ascension of the bright star of Aries and of the other nearer fixed stars,

and by completing the declinations with the help of trigonometry, he investigated the right ascension, and by the same method obtained the right ascensions of the other fixed stars. Sixthly, from the Right Ascension and Declination themselves—as [from] the Poles of the Equator and Ecliptic—which he nevertheless falsely set at $23^{\circ} 31' 30''$, through the triangle...

he investigated their longitude and latitude, reducing all of this to the year 1585.

Seventh, comparing the longitude of Spica and of Regulus for the year 1585 with what the ancients had observed, he derived the motion of the fixed stars in longitude over the intervening centuries as 51 [seconds]. **Eighth**, so that the work would not require so many resolutions of triangles for so many stars, he constructed a table from which the longitude and latitude could at once be found from a given declination and right ascension; and on this he based his Canon of a Thousand Fixed Stars, complete for the year of our Lord 1600, with their longitudes and latitudes given individually to the second. **Ninth**, for the same completed year 1600 he determined the right ascensions and declinations of a hundred select principal stars; and to these he added the increase of longitude over a hundred years (since this is constant) and the distance of the latitude from the pole; he investigated the right ascension and declination of those same hundred stars for the year 1700; and he interposed the difference of right ascension and the difference of declination between the years 1600 and 1700, so that from these the proportional part could be derived for other years, the intermediate ones from the earlier. Yet he omitted the bright star in the right shoulder of the Lesser Bear [Ursa Minor], though it is of the second magnitude, because, since the Tychonic followers saw its right ascension decreasing while its longitude increased, they thought that the longitude ought likewise to increase together with the right ascension, and they were unable to resolve this knot. **Tenth**, he at last proceeded to the tables of the advance [progressus] and retreat [regressus] of the fixed stars in longitude over a span of years, with a table of refractions appended.

6. In nearly the same order we shall report Tycho's observations, and the places derived from them, reserving nonetheless for the end of this book a universal Catalogue, should we have found anywhere that it needs correction.

Beginning therefore with the distances of the fixed stars among themselves — since these are perpetually unchangeable — we shall set down those of our own [Nobis], taken with three medium-sized sextants and with the larger triple sextants, together with those that Petrus Gassendus [Pierre Gassendi] took with

his radius corrected for that purpose, set out in his *Commentaries on Celestial Matters* [*Commentarii Rerum Caelestium*], book 4, work 6 of the same. We shall add, besides, distances measured trigonometrically by means of our [instruments], by Dionysius Petavius [Denis Pétau], or by Adrian Metius, or by Herigonius [Pierre Hérigone], or by others, as found in Pétau's *Uranologion*, or in Metius's *On the Use of the Globe* [*De Usu Globi*]; and finally, any taken by Naclerus's nautical radius in the southern hemisphere. Next we shall give the declinations observed by Tycho, or by Paulus Hainzelius [Paul Hainzel] under examination by them. Afterward we shall set out the right ascensions, and the longitudes and latitudes derived from them.

CAPUT VIII.

On the Great Table of Distances, by which the Fixed Stars are distant among themselves; its Order, and its Use.

1. The order we follow is the alphabetical order of the constellations, so that the distances of the fixed stars may be found more readily. But because the distance is often between two stars of different constellations, the distance is to be sought under that constellation which precedes the other in alphabetical order. For example, if you seek the distance between the bright star of Aries [Lucida Arietis] and the southern eye of Taurus [Oculus Australis Tauri], look for it under the constellation Aries. And because within the same constellation too we keep the alphabetical order, in the constellation Andromeda we first place *Caput* (Head), then *Cingulum* (Girdle), and last *Pedem* (Foot); and so for the rest.

Distances taken by Tycho and by his assistants, and recorded in the *Epistolae* at pages 50 and 51, we mark with this note *Epist.* Those he transmitted in *Progymnasmata* [*Progymnasmatum*] tome 1 or 2, from page 195 to 232 and from page 284 to 294, and at page 344, we mark with this note *Prog. p.*, adding the page number as it appears in the Frankfurt edition of the year 1610. Those, finally, which our Father Albertus Curtius [Albert Curtz] of our Society — concealing his own name in the anagram *Lucius Barrettus* — by command of the Emperor Ferdinand had published at Vienna from the types of David Haut, inscribing them *Sylloge Ferdinanda*, we distinguish by this note *Syll. Ferd.*; and although hitherto we have for these no observations except those of the year 1582, we shall nonetheless distinguish our own corrections, which are in book 6 of the *Almagestum Novum*, by this pronoun *Nobis*, those taken by ourselves [per Radium], from those by Bernardo Vualtero [Bernhard Walther], or by Gassendi, or by Adrian Metius, or by Naclerus, under their own names. As for the

[distances] which Dionysius Petavius gives in *Uranologion* book 3, *Dissertatio* chapter 6, derived from Tychonic longitude or latitude — that is, given by Tycho — and so on, that is, those derived from data given by Tycho, which cannot be accurate, because Tycho in deriving longitude and latitude used a false distance of the poles — these distances, then, we deduce from the Tychonic declination and difference of right ascension, as being not entangled with the deception of the obliquity of the ecliptic; which we have done so that the reader may know, whenever we say *ex Tych. da.* (from Tychonic data), that he should understand under the note *da.* not data given, of whatever kind, but rather a difference of declination and of right ascension. We indicate these by those marks; but when we put *ex Tych. LL.*, a distance derived from Tychonic longitude and latitude is meant.

Great Table of Distances between the Fixed Stars in alphabetical order of the constellations [Magna Tabula Distantiarum inter Fixas ordine Alphabetico Constellationum]

This page continues the **Great Table of Distances** (*Magna Tabula Distantiarum*) — inter-star distances arranged alphabetically by constellation — begun in Caput VIII. Each row gives a pair of stars, the observer or source for the measured distance, and the distance in degrees (Gr.), minutes ('), and seconds ("). The column of pairs at the foot of the left column here continues the GEMINI

("Twins") entries from the preceding page; the right column opens new constellation rubrics.

Left column (continuation)

The first entries continue under GEMINI (the Twins), carried over from the previous page.

Pegasi os (the mouth of Pegasus)		84	11	0
Pegasi lucida colli (the lucida of the neck of Pegasus)		84	24	0
Pegasi lumbi (the loins of Pegasus)		87	31	0
Persei hum. sin. (Perseus, the left shoulder)		56	32	0
Persei Tibia sinistra (Perseus, the left shin)		69	21	0
Piscis bor. media in spina austr. (the northern Fish, the middle [star] in the southern spine)		83	21	0
Serpentis lucida colli (Serpens, the lucida of the neck)		69	20	0

Right column — concluding distance entries

[The right column at the top of the page completes a set of distance entries whose star-pair labels run into the gutter; the readable labels and the three distance values (degrees, minutes, seconds) are:]

Entry	Gr.	'	"
Tauri genu dextrum (the right knee of Taurus)	95	45	0
Vrsae maior australior in pede dextro anteced. (the more southern [star] of Ursa Maior in the right forefoot)	44	33	0
Borealior eiusdem pedis (the more northern of the same foot)	43	39	0
Vltima Caudae nunc Polaris — Gassendo (the last of the Tail, now Polaris — Gassendi)	16	28	0

For the remaining distances — especially that of the star which is now the Pole Star — look under BOOTES, AURIGA, CASSIOPEA, CORONA, CYGNUS, LYRA, PERSEUS, & URSA MAIOR.

CONCLVSIO (*Conclusion*)

From what has been said, then, it is established that the Tychonic distances themselves disagree among one another by something on the order of the first two minutes.

CAPVT IX.

We bring back the declinations of the fixed stars, reckoned by Tycho, into four classes. The first class is of those declinations which, in the year 1572 completed and at the beginning of 1573, either Tycho alone, or Tycho together with [Paul Hainzel] at Göggingen near Augsburg, had already observed — the place where the altitude of the pole is, for Tycho, 48°22'. Tycho sets these out in *Progymnasmata*, volume 1, pages 361 to 369, where he also gives, for other [stars], the distances of the pole-star from the pole over 4 years of observation.

Class I — Paulus Hainzelius, Anno 1573 ineunte (*maximum and minimum meridian altitudes, with declinations*)

[The table gives, for each star, its maximum and minimum meridian altitude (Altitudo Merid.) and its declination (Declinatio), each in degrees, minutes, seconds.]

Paulus Hainzelius,
Anno 1573 ineunte (at
the beginning of the
year 1573)

1589	2	5	5	87	5	1
		4	0			0

Class II — Lucius Barettus (Albert Curtz), Anno 1582

The second class is of those which, at the command of the Emperor Ferdinand, Father [Albert Curtz] of the Society of Jesus — under the pen-name *Lucius Barettus*, by anagram — saw to publishing, from the press of David Hautt of Vienna, in the year 1582. There he sets the meridian observations as made at Uraniburg, whose altitude of the pole, chosen by Tycho, is 55°54'40"; from this, accordingly, the declination is derived.

Class III — Ex Sylloge Ferdinandea Observationum Tychonis, Anno 1582 (*Sextant, or the Greater or Lesser Quadrant*)

This table, headed "Ex Sylloge Ferdinandea Observationum Tychonis Anno 1582. Sextante, aut Quadrante Maiore, vel Minore" (From the Ferdinandean collection of Tycho's observations, in the year 1582, with the sextant, or with the greater or lesser quadrant), gives the names of the stars, the months and days of

observation, the meridian altitude (Altit. Merid.), and the declination — each in degrees, minutes, seconds.

[The left-hand column of folio 229 carries the opening of this large table; the right-hand column continues it, and it runs across all of folio 230.]

Class IV (*closing note + Tycho 1584/1585 reduction table*)

The fourth class is of those fixed stars whose meridian altitudes, captured in the years toward the end of 1584 and during 1585 — or, about the end of 1586 and the beginning of 1587, at Uraniburg — Tycho displays in the *Epistles*, page 53; where he there says (also in volume 1 of the *Progymnasmata*, page 28) that the altitude of the pole is 55°54'40". From this, accordingly, we shall easily infer their declinations.

Liber IV — De Stellis Fixis (continued)

Caput IX (continued): Tycho's fixed-star declinations by class

The tables below continue the declinations of the fixed stars derived from Tycho Brahe's [Tycho Brahe] observations. Each star is given with the meridian altitude [altitudo meridiana] observed at Uraniborg and the declination [declinatio] that follows from it. The marker **A** denotes a southern (australis) declination; **B** denotes a northern (borealis) declination. Where neither letter is printed, the original gives none.

Third class — observations of 1584/1585 (meridian altitude and resulting declination)

Star	Alt. merid. Gr.	'	"	Declination Gr.	'	"	A / B

Fourth class — declinations Tycho recorded in *Progymnasmata* I (pp. 159–232), for various years

The fourth and last class consists of those fixed stars whose declinations Tycho compiled from his own observations and recorded in *Progymnasmata*, volume 1, from page 159 to page 232, for various years. [marginal numeral "4" beside this paragraph]

The Conclusions drawn from the four classes

From the four classes set out above I likewise draw the following observations, or Conclusions.

1. First Conclusion. Some of Tycho's declinations are not so certain that one may not suspect an error of one or two minutes — as will be plain to anyone who works through the first, second, and fourth classes.

2. Second Conclusion. The altitude of the Pole at Uraniborg is subject to an uncertainty of about 15 seconds. For Tycho, in his *Letters* (p. 40), writes thus to

Landgrave [Wilhelm] of Hesse: "The elevation of the equator in our higher-latitude observations of the stars must be taken at $34^{\circ} 5' \frac{1}{3}$; for from frequent experiments which the middle of the island of Hven has yielded — that famous Hven in the celebrated Danish strait, with its parts in the fourth scruple, attolli &c."; and on p. 53 he repeats: "Uraniborg, where the Pole is elevated $55^{\circ} 54' \frac{2}{3}$." But in *Progymnasmata* volume 1, p. 28, speaking of the year 1583, he says: "Inasmuch as at that time the elevation of this place, when it had earlier been increased by some amount in preceding years, was $55^{\circ} 54' \frac{2}{3}$, the seconds being neglected," and a little more exactly in the same volume, p. 218, he says: "Since the altitude of the Pole and the circumpolar stars — especially the truly polar one — is here most diligently determined, as has often been indicated, P. $55^{\circ} 54' 45''$." It follows that the altitude of the meridian of Spica at the beginning of the year 1586 was found to be $34^{\circ} 5' 55''$; subtracting the parts $34^{\circ} 5' 15''$, he concludes the southern declination of Spica to be $8^{\circ} 36' 20''$ partium [?]. Either, then, through some oversight, the altitude of the Pole was elsewhere stated otherwise than indicated above — as five seconds, or as something to be added by later observations, as he reckoned. — Finally, at the close of the second class, when we considered the meridian altitudes of the polar star, observed at the beginning of the year, we shall find them somewhat variously taken, at about $52^{\circ} 57' 45''$; and, neglecting the seconds, it was found to be $52^{\circ} 59'$. Thus the meridian altitude of the bright star of the Lesser Bear [Humeri lucidi Ursae minoris] is least, $39^{\circ} 14'$; and greatest, $72^{\circ} 35' 30''$, or $72^{\circ} 35' 30''$. From these the altitude of the Pole comes out as either $55^{\circ} 54' 30''$ — which seems to have been the case — or, in determining the altitude of the Pole, as $55^{\circ} 54' 45''$. Since indeed he obtained the very least altitude of the polar star in the same year, at about $52^{\circ} 56' 45''$, or $52^{\circ} 57' 45''$ — it is credible that he chose a mean between these. [marginal note: *Poli Altit. Uranib. expensa* — "the altitude of the Uraniborg Pole weighed"]

So in the first class we see that in the year 1581 he settled the distance of the polar star from the Pole at $2^{\circ} 57' 30''$, and thus chose another value as nearly intermediate between the extremes [extimam]; for that he was not anxious about a part smaller than a sixth of a minute is plain from his own words in *Progymnasmata* volume 1, p. 69, where, prescribing about the altitude of the Pole from the circumpolar star, he says: "Known on this ground not only to within a minute, but even to a sixth, or a third, or at least a sixth part of a scruple of the Pole (for so great a precision is here required), is not unknown to us in the complete and quadrant elevation." Nevertheless, we have chosen the inclination between the extremes, $55^{\circ} 54' 40''$ — both because Tycho selected it in three places as intermediate between the extremes, and because it agrees best when collated with the solar observations made there, and with those carried out by

our Gnomon at Bologna, as I have said in the *Book on the Sun*. [marginal note: *Poli Altit. Uranib.*]

3. Third Conclusion. Tycho's fixed-star declinations, even granting the same meridian altitude, are exposed to an uncertainty of seconds of 15", however little they may be liable to error otherwise. The altitude of the Uraniborg Pole, as said in the preceding Conclusion, is exposed to error. Therefore the declinations which we have here derived from the meridian altitude observed at Uraniborg are probable, to within five seconds, or even fewer, and must not be excluded as evidently mistaken, granted that we have used that intermediate altitude of the Pole, 55° 54' 40".

4. Fourth Conclusion. Among certain of Tycho's fixed-star declinations a discrepancy appears, arising from a source other than the diversity of observation. In the fourth class, for instance, the bright star of Aries is assigned the same declination, both for the year 1585 complete (as on *Progymnasmata* pages 195, 198, 200, 202, 232) and again for the year 1587 at its beginning (as on page 178 and on page 181). And yet for the year fully complete, according to Tycho's own tables, this star increases its declination by 18"; and at one second per month, it follows that for January of the year 1587 it was found to be 21° 28' 30", whereas it ought to have been, at the close of the year 1585, 21° 28' 10". But from the observations of the second class, in the year 1582 at its beginning, it was 21° 26' 20"; and consequently, for the year 1585 complete, it would have been 21° 27' 32"; or, at gr. 21° 26' 32", if a minute increases at the rate of one, the median is reckoned greater... [the prose here packs several alternative reckonings of the same value]. And so it is most certain — and this is confirmed precisely by our observations, namely 21° 27' 0" — and from this most of all, since it agrees with our observations as established in Chapter XVI, no. 2: namely that the declination of this Tychonic star, taken across these two centuries [duobus saeculis] by half-increments, has been greater than the true declination. For from the latitude of this same Tychonic star, with the longitude adduced, the distance of the Poles being 23° 30' 20", it ought, for the year 1660 complete, to have a declination of 21° 51'; and yet from our observations, as adduced in the said Chapter, it will be established, this very value being then only 21° 49' 30".

Likewise, in the class of Pollux's Head [Caput Pollucis] the declination is recorded as 28° 57', both for the year 1582 in April and for the year 1585 (as found on *Progymnasmata* pages 163, 195, and 200); and yet for the year 1585 complete it is put at 204, and at 232 it is placed at 28° 57' 45"; and in the class for the year 1586 complete it is set at 28° 56' 40", not otherwise than in the class for the year 1588.

The declinations of this star can in no way agree with what could decrease through the years of this century according to Tycho's reckoning, namely 12". If, then, for the year 1586 complete it was observed at 28° 56' 40", it ought for the year 1588 to be set at 38° 56' 47", and for the year 1582 at 38° 56' 33"; whereas in April of the year 1582 it is 28° 57' 15". [marginal note: *Pollucis Declinatio*]

In the class of the Heart of Leo [Cor Leonis], the declination is double for the same year 1585 complete: one value 13° 58'; in the third class another, 13° 57' 45"; and for the year 1586 fully complete it is observed at 13° 57' 40". Now it decreases, according to Tycho, by this much per century, namely 8"; and therefore, for the year 1585 complete, it ought to have been 13° 57' 52"; and so the more correct value is 13° 58'. [marginal note: *Reguli Declinatio*]

The declination of Aquila in the fourth class, for the year 1577, is put at 7° 52'; and for the year 1585 (since this increases by 7" 48" from Tycho's centenary table for individual years) it ought to be, for the year 1585 complete, 7° 52' 0"; or if for the said year it was 7° 51' 20", it ought, for the year 1577, to have been...

only 7° 50' 18"; but because in the third class it is set down as observed for the year 1585 at its course, at 7° 51' 10", therefore for the same year fully complete it could scarcely have been 7° 51' 18"; thus it stands in many other cases as well.

6. Spica of Virgo [Spica Virginis], according to Tycho, increases by twenty seconds per century in declination. Therefore, if for the year 1587 at its beginning, as it is in the third class, it was 8° 57' 20", it ought for the year 1585 complete to have been 8° 57'; and yet it is in the fourth class, for the year 1585 complete, at 8° 56' 20" (Tycho gives it as 8° 56' 20" in *Progymnasmata* volume 1, p. 195, 200, 204, and 232). What if this declination were taken from those, which in most cases are gathered from class-2 observations? For there we have, in six places, the meridian altitude of Spica at 25° 10'; and so the declination 8° 55' 20", in that same year 1582 at its beginning, and at its course, therefore for the year 1585 complete ought to have been 8° 56' 40"; or at least 8° 56'. From this it can in no way be reconciled with the observation of the year 1587, made by the Great Quadrant [Quadrante Maximo].

7. Among these and similar diversities, since Tycho, for the year 1585 complete, laid the foundations of the other fixed stars from the right ascension of the bright star of Aries [lucida Arietis], it seemed best to reduce the Tychonic declinations to the end of the same year by this method. First, we selected the declinations of the third class — both because they are derived immediately from their own sources, namely from the meridian altitude of the fixed stars and from the altitude of the

Pole (which Tycho preferred), and because at that time he was furnished with greater skill and larger instruments; and next, because we have used, in part, the proportional increment or decrement of the declination, which Tycho's table supplies in *Progymnasmata* volume 1, p. 278. Yet, so that, when the discrepancy lies in two or three seconds, we may retain round numbers of decads — since within this subtlety we are not certain of the altitude of the Uraniborg Pole, as said in the second Conclusion above — secondly, for the stars that are not in the third class, we have used declinations of the first, second, or fourth class, reducing them to the end of the year 1585 by the aforesaid proportional part.

Reduced declinations to the end of the year 1585

(Caput IX, continued) — Corrected-declination master table, reduced to the completed year 1585

The table of corrected declinations continues and concludes here. The left column gives the star (grouped by constellation); the right gives the corrected declination [*declinatio correcta*] in degrees (Gr.), minutes ('), and seconds ("). Entries marked **A** are austral/southern [*australis*]; the remainder, where no marker is given, are northern [*borealis*].

From Tycho's observations, for the completed year 1585.

CAPVT X.

The right ascension of the bright star of Aries [lucida Arietis], examined precisely by Tycho up to the completed year 1585, and corrected.

1. [Margin: *Priscorum methodus* — The method of the ancients.] The ancients — Hipparchus, Ptolemy [Ptolemæus], and al-Battānī [Albategnius] — investigated the positions of the fixed stars from the Sun by way of the Moon, as I showed in

Book 6, chapter 1 (*Almagestum Novum*). By the great art of construction, in chapters 2 and 4, they took the zodiacal distances in the evening. For at dusk they would take the zodiacal distances of the Moon from the Sun, a little after sunset, and from these, computed through parallaxes, they would gather the place of the Moon in the zodiac. Then on the following night, with the same instrument, they would take the distance of the Moon from one of the fixed stars; and by adding to the Moon's earlier place however much the time elapsed between the first and second observations required, they would infer the place of the fixed star in the zodiac — yet with this much danger of error, however much the instrument's defect introduced (whether from too coarse a graduation), arising from neglect of the parallaxes and refractions of the Sun.

2. [Margin: *Tychonis methodus* — Tycho's method.] To avoid the troublesome business of the Moon's parallaxes, Tycho [Tycho Brahe] substituted Venus, observed in the evening when very high, in three observations which he reports in *Progymnasmata* vol. 1, pages 157 to 165. At one and the same moment he took the altitudes of the Sun and of Venus and their mutual distance, and through the equatorial armillae [*armillæ æquatoriæ*] he found the declination — for he learned the Sun's declination from the Sun's place in the ecliptic at that moment, the moment of time being reckoned out, since that moment was known to him from a verified clock. Then, having the ratio of the Sun and of Venus, he derived trigonometrically the difference of right ascension [*differentia ascensionis rectæ*] from their distance and from the complements of their declinations; and converting this into a true one, and adding it to the right ascension of the Sun found from his own tables, he obtained the true right ascension of Venus for that moment of time. Then, on the following night, conveniently and at a sure moment, he observed the distance of Venus from one of the fixed stars — namely Aldebaran, in the first observation, and the Heel of the Gemini [Calce Geminorum] in the second, together with the altitude and the declination of Venus, whose right ascension required only the time elapsed between the preceding and the immediately following observation. In other observations, moreover, he observed the declinations of the said fixed stars, and through them and the mutual distances he obtained the difference of right ascension between them and the bright star of Aries [lucida Arietis]. Thus, then, inquiring into the right ascensions of those fixed stars and of Venus, and trigonometrically tracing out the difference of right ascension between them, he acquired the right ascension of the said stars; and by means of this he reduced the right ascension of the bright star of Aries to the motion of the fixed stars, and so up to the completed year of Christ 1585. We shall give an example below. With these three reported

observations he found the right ascension of the bright star of Aries, as in the following short table.

Anno 1585. Compl. Asc. Recta Lucidæ γ [Right ascension of the bright star of Aries, for the completed year 1585]	Gr.	'	"
Obs. I	26	0	44
Obs. II	26	0	32
Obs. III	26	0	30

3. [Margin: 2. *Tych. method.* — Tycho's second method.] But lest the implication of the Solar parallaxes, the Sun, and Venus, and of the refractions, leave any scruple, by a fuller and more thorough investigation he compared many observations of this kind of Venus with the Sun, and then evening observations of Venus with the fixed stars against morning ones — keeping the Sun and Venus at the same altitude, and obtaining the distance from the earth and the declination in the morning as nearly as possible to what they had had in the evening observation. For thus the variations of refraction and of parallax compensate and counterbalance each other. For the refraction of the setting Sun, raising its image toward the evening Venus, diminishes both their distance optically and likewise the difference of right ascension; and so it then exhibits the right ascension, both of Venus and of the fixed star derived from it, smaller than is just. By contrast, the refraction of the rising Sun, raising its image toward the morning Venus, diminishes that same distance and the difference of right ascension, but this is to be subtracted from the right ascension of the Sun, so that it then exhibits the right ascension of the morning Venus, and the right ascension both of Venus and of the fixed star derived from it, greater than is just. Therefore, said Tycho, if in the evening and morning observations the Sun, Venus, and the rest stand equally high, the parallaxes will also be equal, and the parallaxes and refractions, once the parallaxes are removed, are purified — and however much the evening ones diminish, that much the morning ones increase the right ascension.

(Caput X, continued)

the right ascension; and the mean, therefore, between these as chosen will be the truest right ascension. From several further observations, accordingly, of both evening and morning ones, and of the right ascensions of the bright star above the Head of Aries, he selected twelve down to the end of the year 1585, reduced; and, the mean having been taken in the last little column between the extremes, I have made a compendium of them from Tycho's vol. 1, *Progymnasmata*, from page 165 to 194. It will help, before going further, to subjoin these to the eyes,

adding in explanation what afterward the letter **M** marks for the Morning observations and **V** for the Evening ones.

The observations:

4. Let not the reader be surprised that observations of the same day of the same year are reported here, when in fact they were made in different years and at different hours; nor suppose this to be set down by a typographical error in

Tycho's narrative — read in the place of A.M. (Morning) P.M., and so the Morning observations have been wrongly transposed by us with the Evening ones, as a careful reader of Tycho's whole discourse, and of the circumstances by which the Morning ones are certainly distinguished from the Evening, would gather; the characteristic mark M, and the Evening ones with V — you would rather be surprised at the discrepancy between the twelve mean right ascensions, which exceeds gr. 26. 0'. 4", and gr. 26. 0'. 42", that he should not have chosen a mean middle of gr. 26. 0'. 23", but takes gr. 26. 0'. 30", as he has on page 194.

[On the right column of this page, paragraphs 5 and 6 continue Tycho's argument:]

5. [Margin: 1. *Contra Tychonem obiectio* — First objection against Tycho.] Perhaps he did so because in the third observation, taken in isolation, of which the number is 1, he had obtained gr. 26. 0'. 30"; this, therefore, on page 194 he selected, not only as the foundation of all the fixed stars' right ascensions, but he also called the bright star of Aries the *Angular cornerstone of the remaining affixed stars* [*Angularem lapidem reliquarum Affixarum Stellarum*]. We, however — saving the man's regard, and with regard for the great merit of so distinguished an astronomer — find many causes why this right ascension of his is revoked into doubt.

The **first** is the Solar hypothesis, which Tycho used in gathering its right ascension and declination — false in the middle motion of the Sun, in the eccentricity, and in the prosthaphæresis [*prosthaphæresis*], and greatest in the declination of the Sun, which springs from the supposed but not demonstrated excessive Solar parallax — as is plain from what has been said of these severally in Book 1, on the Sun.

The **second** [Margin: 2. *Obiectio*] is the error in the declination of the bright star of Aries: for he found its declination to be gr. 21. 28'. 30" at the beginning of the year 1587, but it had more truly been gr. 21. 28'. 40"; he uses this same value also for the year 1585, *Progymnasmata* pages 178, 181, 195, 198, 200, 204, 232 — yet if it had remained unchanged throughout, he ought nevertheless to set it for the year 1585 as compl. gr. 21. 28'. 20", indeed gr. 21. 27', as we shall show in chapter 9, conclusion 4. Likewise from what is there said he erred in choosing the declinations of certain of the fixed stars.

The **third** [Margin: 3. *Obiectio*] is the fallacy in the second of Tycho's methods, namely the method above at number 3: for as regards compensating the defect of refraction from the evening observations by the excess of the morning ones,

unless Venus, and the same stars, shall have been at the same distance from the centre of the Earth, the same temperaments of the air bring about the same quantity of refraction. For it has been observed by us that the refractions are usually greater in winter, at the equinoxes, and in summer, and these greater for the Morning than the Evening ones. For in the morning the air is colder and denser than at other times alike, because of the preceding absence of the Sun; in the evening it is warmer and rarer, as being thoroughly baked by the daytime heat of the Sun. See what we said in Book 1, *Almagestum [Novum]*, chapter 30, Scholium 3, on the prolixity of the evening twilight, arisen from the foregoing heat of the Sun; and Book 10, on Refraction.

The **fourth** [Margin: 4. *Obiectio*] is a twofold discrepancy in Tycho's reduction of the observations. For if at the end of the year 1585 the true right ascension of the bright star of Aries was gr. 26. 0'. 30", then the excess of right ascension in the morning observations, and the defect in the evening ones, ought to be greater, the Sun being lower, than higher above the horizon on account of the greater refraction. And yet in some observations the opposite appears, running through the table at the end, number 3. As, for example, in observation VIII the Sun stands higher by gr. 17½. Right ascension recedes by gr. 16. 0'. 30" per minute 6½. But in observation X the Sun stands lower only by gr. 5; right ascension recedes by a single minute only. Moreover, in the year 1585 the true right ascension of the bright star of Aries was gr. 26. 0'. 30". Therefore all the right ascensions derived from the evening observations ought to have been smaller than the said right ascension; and conversely those derived from the morning ones ought to have been greater — yet the opposite happens in observations I, VII, VIII, XI, and XII. Therefore in the last column he subjoined the characteristic mark of the discrepancy, **R**. This double discrepancy is an indication that there is either inconstancy of refraction, or a defect of altitude, or faulty observations.

6. Those twelve Morning observations, then, and as many Evening ones, in which the Sun was wrapped in sensible refractions, set aside, I observe that evening refraction which Tycho reports in vol. 1, *Progymnasmata*, page 160, when the Sun stood at gr. 31, and Venus modulated by gr. 57, modulated by 23½, and the Heel of the Gemini [Calx Geminorum] by the said refraction at the end of Book 1, chapter 1, on the Sun. For a single observation of so well-purified an evening refraction prevails over many of doubtful ones, which we have above held suspect. Because indeed it is not noted by us, as is said, it is certain that, in the Solar hypothesis, Tycho strayed in the prosthaphaeresis, not in the ellipse bisecting the eccentricity, but in a circle, exactly investigating the integral eccentricity, and in too great a Venus parallax; therefore we shall use our own Solar hypothesis.

(Caput X, continued)

7. Moreover, since from these same observations of Tycho, brought to bear in chapter 9, I set down for the completed year 1585 the declination of the bright star of Aries as gr. 21. 27'. 0", and the declination of the Heel of the Gemini [Calcis Π] as gr. 22. 38'. 38", if we use the proportional part which Tycho sets down on page 276, it follows that for the year 1582, March 20, the declination of the bright star of Aries had been gr. 21. 27'. 10", and that of the Heel of the Gemini gr. 22. 38'. 30". These, therefore, we shall use.

I have now prefixed the figure adjoined here, in which **A** is the angle [*angulus*] at the vertex [*vertex*], made by the two vertical circles AB and AC and BC; **BC** is the portion of the horizon intercepted by them; and **S** is the true place of the Sun, but its apparent place by force of parallax is **K**; thus the true place of Venus is **V**, but its apparent place is **G**, and so the true distance of these is **VS**; but the apparent one **GK**. When, however, **A** is the angle at the Pole of the world [*Mundi Polum*], and BC the portion of the equator intercepted between the quadrants of the declination circles, then, with two stars placed, one at **S**, the other at **V**, the complements of the declinations are **AS** and **AV**. These things premised, let this be the following epilogism [recapitulation]:

Diagram. A spherical-triangle construction at the head of the left column. Vertex **A** sits at the top; two arcs descend from it to a base arc running between **B** (lower left) and **C** (lower right). Intermediate points along the descending right arc are labelled, from top to bottom, **V**, **S**, **K**, **C**; the point **G** lies on the left descending arc. The figure illustrates the vertical circles AB, AC and the equator/horizon arc BC, with S (true Sun) and K (apparent Sun), V (true Venus) and G (apparent Venus).

- A (apex): the angle at the vertex (or at the Pole of the world)
- B (lower left): endpoint of the horizon/equator arc BC
- C (lower right): endpoint of the horizon/equator arc BC
- V (upper, on a descending arc): true place of Venus
- G (left arc, below V): apparent place of Venus
- S (mid-right arc): true place of the Sun
- K (lower right arc): apparent place of the Sun

Complem. Declinationis Calcis Π [complement of the declination of the Heel of the Gemini]	67	21	30
Complem. Declinationis Lucidæ Υ [complement of the declination of the bright star of Aries]	68	33	0
Distantia harum Stellarum ex Tychone tom. 1. pag. 198. [distance of these stars, from Tycho vol. 1, page 198]	58	22	0
Ergo A, seu BC, Differ. Asc. Rectæ [therefore A, or BC, the difference of right ascension]	63	28	8
Ideoq; Ascensio Recta Lucidæ Υ [and so the right ascension of the bright star of Aries]	25	56	34
Sed Anno 1585. Completo [but for the completed year 1585]	25	59	47

For from Tycho, page 276, the right ascension of the bright star of Aries grows in this century by 51" each year. Therefore, in $3\frac{3}{4}$ years — which are from March 20 of the year 1582 to the end of the year 1585 — it grew by minutes 3'. 13"; so that, if on that day, March 20, it was gr. 25. 56'. 34", then at the end of the year 1585 it was gr. 25. 59'. 47". Granted that Tycho, in vol. 1, *Progymnasmata*, page 162, using his own Solar hypothesis, obtained from this observation gr. 26. 0'. 32", that is, greater by 45" — yet it ought to have been found so; and conversely, by our hypothesis, it had to come out smaller by about a minute. And since this happens, I am the more confirmed that this was Tycho's observation, and well usurped [taken up] by us.

Sit igitur Fundamenti loco Anno 1585.

Completo, [Let there be set, then, in
place of a foundation, for the
completed year 1585:]

Ascensio Recta [Right ascension]

Lucidæ γ [the bright star of Aries]

Gr. 25 59' 47"

Calcis II [the Heel of the Gemini]

Gr. 89 24' 50"

CAPVT XI.

The right ascensions of seven other fixed stars, corrected by Tycho, are themselves corrected; what is to be done about the rest; and on the omission of those fixed stars whose right ascension the Tychonics were ignorant to be decreasing.

1. Since Tycho, in vol. 1, *Progymnasmata*, from page 195 to 230, investigated the right ascensions of 23 other stars, the Heel of the Gemini [Calce II] having been computed, but chiefly of 7, through their declinations and mutual distances, and from these tracing out the differences of right ascension, and using the right ascension of the bright star of Aries [Lucidæ γ], he established their right ascensions in common — upon us a necessity falls, on a threefold ground, of correcting them: namely, on account of the diversity found in the right ascension of the bright star of Aries; and in the declinations of the fixed stars, which in chapter 9, from Tycho's own data, we have corrected and emended up to the completed year 1585; and finally, from the distances of the fixed stars, in chapter 8, by our own repeated observations, and in some matters differing somewhat from Tycho's. It is fitting, moreover, to begin the sum of the differences in right ascension from the bright star of Aries, and to come around to it, that it may be equal to the whole equator, that is, precisely 360 degrees. For which experiment we choose 8 stars from Tycho, page 200, elected; using the triangle CPD, in which P is the Pole of the equator [*Æquatoris Polus*], and the angle subtending the arc of the equator AB — that is, the difference of right ascension; the arcs PC and PD are the complements of the declination of the fixed stars, and CD their distance. When, moreover, one of the other fixed stars — such as Spica — has a southern declination, we use the triangle PCF, in which A is as above, and PC...

Diagram. A spherical-triangle construction in the lower-right column. Vertex **P** (the Pole of the equator) sits at the top; arcs descend from P to **C** (left) and **D** (right). A base arc runs from **A** (lower left) through to **B** (right), and a further arc

descends to F (bottom right, below B). The figure illustrates triangle CPD (and the auxiliary triangle PCF for a southern-declination star): PC and PD are the declination-complements of the fixed stars, CD their distance, and the angle at P subtends the equatorial arc AB (the difference of right ascension).

- P (apex): the Pole of the equator
- C (left, on a descending arc): one fixed star
- D (right, on a descending arc): another fixed star
- A (lower left): endpoint of the equatorial arc AB
- B (right): endpoint of the equatorial arc AB
- F (bottom, below B): the point used for the southern-declination triangle PCF

the complement of the star's declination, namely C and PF, [arising] from the quadrant PB, and from the declination BF and CF, the distance between the stars. From these elements we shall gather the difference of right ascension — that is, the angle P, which measures the arc AB. We do this not, indeed, by the troublesome and error-prone multiplication of tangent-sines and so forth, but by the addition of logarithms alone, for which we have Vlacq's [Adriaan Vlacq] Canon [of logarithms] extending to single decades of seconds — indeed, at the beginning of the quadrant, and at the end (by our own extension), to single seconds.

[Here follows the first table. Star names, distance from the preceding star (degrees/minutes/seconds), declination completed for 1585 (degrees/minutes/seconds), and difference of right ascension (degrees/minutes/seconds). The australis/borealis marker (A/B) follows the declination.]

Star names	Distance from preceding (Gr. ' ")	Declination 1585 compl. (Gr. ' ")	Difference of right ascension (Gr. ' ")
Lucida ♈ [Aries]		21 27 0 B	
Aldebara[n]	35 32 0	15 36 30 B	37 4 49
Pollucis Caput [Head of Pollux]	45 5 0	28 56 50 B	46 54 24
Regulus	36 59 30	13 58 20 B	36 35 8
Spica ♍ [Virgo]	54 2 0	8 57 0 A	49 19 3
Sin. manus Oph. [Left hand of]	42 33 30	2 33 15 A	42 19 16

Star names	Distance from preceding (Gr. ' ")	Declination 1585 compl. (Gr. ' ")	Difference of right ascension (Gr. ' ")
Ophiuchus]			
Aquilæ lucida [bright star of Aquila]	55 17 20	7 51 15 B	54 26 25
Markab Pegasi	47 49 20	13 0 10 B	48 24 44
Lucida ♈ [Aries]	43 37 10	21 29 47 B	44 57 40
Sum of differences of ascension			360 1 28

2. From this it is clear that the Tychonic declinations — or rather the distances of the fixed stars from one another — were not so exactly determined, [being off] by a second of arc. For the sum of the differences of right ascension ought to have been precisely 360 degrees. This same point we shall be able to recognize from our own observations later. Meanwhile, that stated sum exceeds the equator by that 88"; distributing this over the eight aforementioned differences, we subtract eleven seconds from each. On that basis we establish the right ascensions, as in the following table.

Star names	Differ. of right ascension (Gr. ' ")	Right ascension (Gr. ' ")
Lucida ♈ [Aries]		25 59 47
Aldebara[n]	37 43 38	63 3 25
Pollucis Caput	46 54 13	109 57 38
Regulus	36 34 57	146 32 35
Spica ♏	49 18 52	195 51 27
Lucida Oph. manus sin. [bright star, left hand of Ophiuchus]	42 18 53	238 10 20
Aquilæ lucida	54 26 14	292 36 34
Pegasi Markab	48 24 33	341 1 7
Lucida ♈	44 57 29	25 58 36
Calx pedis ♊ [Heel of the foot of Gemini]	Ex fine CX. [From the end of Cap. X]	89 24 50

3. To these stars we shall add the Heart of Scorpius [Cor Scorpionis, Antares], which Tycho likewise uses, so that we may afterward establish its Tychonic longitude by comparing the motion of the fixed stars with that observed by the ancients. We take its distance from Spica from Cap. VIII, and its declination from Cap. IX.

	Distance of stars (Gr. ' ")	Southern declination (Gr. ' ")	Differ. of right ascension (Gr. ' ")
Spica		8 57 0	
Antares	45 52 0	25 20 25	45 25 30

[Below the table:] Hence, since the right ascension of Spica at that time is $195^{\circ} 50' 21''$, that of Antares was $241^{\circ} 15' 51''$.

For the remaining 12 stars, whose right ascensions Tycho did not investigate as carefully as those of the others he took as fundamental, we have no need [to do so here]; for the right ascensions of these — and of many others — we shall investigate more clearly for the year of the Lord 1660.

From the distances [given] in Cap. VIII, [these] are established, and from the declinations diligently observed by us. If anyone should wish to correct the Tychonic right ascensions, let him use the distances of Cap. VIII and the declinations, by the method indicated above, and let him seek out the differences [of right ascension]; for from these, and from the right ascensions of the ten fixed stars established above, he will obtain the right ascensions of the rest, and he will recognize how great a correction the table requires which Tycho handed down (vol. 1, p. 276) for the year 1600 and 1700.

4. But in that table it may seem surprising that Tycho placed even stars of the third or fourth magnitude there, yet omitted the most brilliant star in the shoulder of Ursa Minor [Polaris], a most celebrated one — both because it is of the second magnitude, and because in Eudoxus's [Eudoxus] and Hipparchus's [Hipparchus] time, and nearly in Ptolemy's [Ptolemy], it was closest to the pole of the world, and hence was then most carefully observed as the Pole star and the Cynosure of mariners. To me it is nearly certain that Tycho and his assistants did not omit the right ascension of a star of this kind by oversight, but deliberately suppressed it, because they had run into an insoluble knot, given the opinion they held — namely, that the right ascensions of all the fixed stars must increase as their longitude increases; whereas they found that, as the longitude of this star [Polaris]

advanced from the year of Christ 1600 to the year 1700 — and likewise its latitude, and [given] the distance of the poles — they recovered for the same star a right ascension *smaller* than the right ascension of the year 1600. And reiterating the calculation, they always found this decrement; and not having applied their minds to the theory of this peculiar motion, overcome by weariness and entangled in this perplexity, they thought it safer to pass over this star [in silence] — which, however, they did place in the catalogue of longitudes and latitudes, because, as far as the increment of longitude is concerned, they experienced no such difficulty.

[Margin: Humerus Ursæ minoris dissimulatus à Tychone. — The shoulder of Ursa Minor concealed by Tycho.]

[Margin: Tychonis defectus. — A shortcoming of Tycho's.]

5. Let us now see how great the right ascension of this star [Polaris] ought to have been for the year 1600 and 1700, on the Tyconic hypothesis of [its] longitude, latitude, and the distance of the poles. But first, for the demonstration, let the following diagram be inspected, in which let ABC be the colure of the solstices, and so on.

Diagram. A celestial sphere drawn with the solstitial colure, the equator, the ecliptic, and circles of latitude and declination, used to derive the right ascension of Polaris (the Cynosure).

- A, Υ, Q (lower-left through center to right): the equator A Υ Q
- P (upper region): the pole [of the equator]
- E, C (left and lower-right): the ecliptic EC
- Z (upper region near P): the pole of the ecliptic; the Cynosure [Polaris] is at O
- O (just below P/B): the Cynosure (Polaris)
- B (top): point on the colure near P
- D (right of center): point on a circle through the sphere
- G (left of center, on the ecliptic): the place of the star on the ecliptic, the foot of the latitude-circle quadrant ZOG
- K, Υ, L, H (along the lower band, the ecliptic/equator crossing): intermediate points
- Q (right): equatorial point
- ♋ / 69 (left, on the ecliptic near E): zodiacal point (Cancer)
- C (bottom): point on the colure

The equator is $A \cap Q$, and of it the pole is P ; let the ecliptic be EC , of which [the pole] is Z ; let the Cynosure be at O , through which let a quadrant of the latitude-circle ZOG be drawn, since indeed its Tychonic place G [is] in the ecliptic for the year 1600 — namely Cancer $[♋]$ $7^{\circ} 16' 30''$, and the northern latitude GO $72^{\circ} 51' 30''$; and its complement OZ is $17^{\circ} 8' 30''$. And from the pole P , through the same star O , let a quadrant of the declination-circle POH be drawn; for in the right triangle POZ there are given the two sides PZ — the Tychonic distance of the poles, $23^{\circ} 31' 30''$ — and OZ , the complement of the latitude, $17^{\circ} 8' 30''$; and from the longitude of the star, which is $127^{\circ} 16' 30''$ [reckoned along the ecliptic from the colure], subtracting 90° , the angle PZO is given, $37^{\circ} 16' 30''$. Therefore, by the canons of triangles, the angle OPZ is given, $47^{\circ} 0' 30''$, which measures the equatorial arc HQ . Hence the arc AH is $132^{\circ} 59' 30''$; and if to this 90° be added, the right ascension of the Cynosure is obtained, $222^{\circ} 59' 30''$, for the year 1600.

6. Let the Cynosure now be advanced in longitude from O , in I , through the little circle $BOID$ parallel to the ecliptic [and described] about the pole Z — assuming the fixed stars proceed thus, the same latitude being retained throughout. Let a quadrant of the latitude-circle ZIK be drawn; for since the longitude of the Cynosure for the year 1700 is...

[p. 238, left column:]

[the longitude of the Cynosure is] to Tycho ϱ [Leo] $8^{\circ} 41' 20''$, the angle PZI will be $38^{\circ} 41' 20''$; with which, in the triangle PZI , and with the complement of the latitude IZ , $17^{\circ} 8' 30''$, and the distance of the poles PZ , $23^{\circ} 31' 30''$, by the canons of triangles the angle IPZ is found, $47^{\circ} 13' 36''$, measuring the arc LQ . Accordingly, as the longitude increases, the right ascension decreases; for the arc AL will be $132^{\circ} 46' 24''$, and joined to 90° it will give, for the year 1700, a right ascension of $222^{\circ} 46' 24''$. And thus, the quadrant of declination PIL falling short of the quadrant POH , [this] will always occur, until that time arrives when the quadrant of the declination-circle drawn through the Cynosure does not cut the parallel $BOID$ but precisely touches it; for from that point on, as the longitude increases, the right ascension will begin to increase. And it so happens, for all the fixed stars whose complement of latitude is less than the distance of the poles from the equator, and [less than] the distance from the ecliptic — as I taught more fully in *Almagestum Novum* (Book 6, Cap. 19), where I also reviewed other fixed stars of this condition. This it was worth the trouble to point out to the reader.

CAPVT XII.

De Longitudine, ac Latitudine Fixarum Tychonica emendanda; necnon Motu earum in Longitudinem.

[On the correcting of the Tychonic longitude and latitude of the fixed stars; and also on their motion in longitude.]

1. It is established that Tycho (vol. 1, *Progymnasmata*, from p. 203) derived the longitudes and latitudes of the fixed stars from given data — that is, from elements: namely, from the right ascension, the declination of the fixed stars, and the distance of the poles — partly by the solution of spherical triangles, partly by a table constructed for this purpose, on the supposition of the obliquity of the ecliptic at $23^{\circ} 31' 30''$. But equally, from what was said about the Sun (Book [1]) it is established that this obliquity, or the distance of the poles, does not exceed $23^{\circ} 30' 20''$; and from what was said in this book, Cap. IX and X, the declinations which Tycho used must very often be corrected; and the right ascensions [must] in all cases be corrected. Therefore, from these same three chapters it is established that the Tychonic longitudes and latitudes of the fixed stars are to be corrected. Let Longomontanus [Christian Longomontanus] in his *Astronomia Danica* (Book 1, *Theoricorum*, cap. 4) be [the example]: he held that the Tychonic longitudes alone should be diminished by about one minute, on account of the reduced mean longitude of the Sun. And so, both by way of example, and to investigate the motion of the fixed stars in longitude, we shall reduce to the ecliptic — by the aid of trigonometry, but using the truer distance of the poles, and the right ascensions and declinations established in [Cap. IX and the] preceding chapter — those Ten stars which we adduced in the preceding chapter.

[Below, the table:]

Distance of the poles assumed: $23^{\circ} 30' 20''$. [Positâ Polorum Distantia Grad. 23. 30'. 20".]

Year of Christ 1585 compl.	Right ascension (G. M. S.)	Declination (G. M. ")	Longitude (Sig. G. M. ")	Latitude (G. M. ")

[p. 238, right column:]

2. In the preceding calculation, having first sought, from the right ascension, the declination of the fixed star, and the distance of the poles, the latitude — and with this, and with the declination and distance of the poles, the longitude — this calculation, treated faithfully step by step, turned out so happily that the differences of longitude, taken together, complete exactly 360° of the ecliptic. Nor indeed, as I scrupulously testify, did I keep manipulating the calculations and the data until it came out right for me; rather, it came out [right] from three [data], used [each] once, taken once, and at a single application. And here, in the following little table, are the differences of longitude.

	Longitude (Sig. G. ' ")	Differ. of longitude (G. M. ")
Lucida Υ	$\mathbin{\lrcorner}$ 1 51 39	32 3 4

	Longitude (Sig. G. ' ")	Differ. of longitude (G. M. ")
Aldebara[n]	II 3 54 43	25 32 17
Calx II	II 29 27 20	18 10 58
Pollucis Caput	☿ 17 38 18	36 24 44
Regulus	♌ 24 3 2	53 59 39
Spica ♏	♏ 18 2 41	28 27 39
Ophiuchi manus	♏ 26 30 20	7 34 58
Cor Scorpj	♏ 4 5 18	51 56 12
Aquilæ lucida	♏ 26 1 30	51 40 50
Pegasi Markab	♏ 17 42 20	44 19 19
Sum		360 0 0

3. Now indeed Tycho (vol. 1, *Progymnasmata*, p. 253), using in the first place the place of Regulus observed by Hipparchus and by al-Battānī [Albategnius], and afterward [his own], deduces the annual motion of the fixed stars to be 51". But Hipparchus — on Ptolemy's testimony (book 7, cap. 2), in the year 50 of the third Callippic period, that is, before Christ 128 — observed Regulus in Cancer [☿] 29° 50'; yet from the declination, 20° 40', with which the same Ptolemy observed it at that time (cap. 3), and the latitude 0° 27' 47", and given the obliquity of the ecliptic, its place follows as Cancer [☿] 29° 57' 44". After [that, i.e.,] the year 1713, that is, of Christ 1585, Tycho — corrected by us — observed Regulus in Leo [♌] 24° 3' 2"; therefore the [accumulated] motion was 24° 5' 18", which divided gives an annual motion of 30" ¹⁰⁷/₁₇₁. But if al-Battānī, in the year of Christ 878 — that is, [year] 1627 of Nabonassar, as he himself reports (cap. 51 of his *De Scientia Stellarum*) — observed Regulus in Leo [♌] 14° [and] progressing, [and his place] is everywhere referred to Leo [♌] 14° 3' 2", [then over] 707 years, the annual motion is therefore 51 ¹³/₇₁", or in round numbers 51", which Tycho chose.
4. There are now in vol. 1 of the *Progymnasmata* two most celebrated tables of fixed stars. The *first* is of the longitudes and latitudes of the principal fixed stars completed for the year of Christ 1600, which is found there on p. 258. The *second*, which is found on p. 276, [gives them] with the right ascension and the declination [for] one hundred selected fixed stars, for the completed year 1600 and 1700, and their hundred-year difference. If anyone wishes to use those tables, let him consult Tycho — or, for the first

table, the Rudolphine [Tables] or the Philolaic Tables. But if anyone wishes them corrected, they can be corrected in two ways.

5. The *first* [way] is by investigating trigonometrically the difference of right ascension between the fixed stars, which is found in Cap. VIII — the distance — and Cap. IX — the declination — for the year 1585, as we did in Cap. XI for ten stars; and, by means of the right ascension of Lucida Υ [Aries], or of Calx Π [the Heel of Gemini], [finding] their right ascension, with which — together then with the declination, and the truer distance of the poles, $23^{\circ} 30' 20''$ — the latitude is to be sought, which is perpetual; and then the longitude, which can thereafter be advanced to whatever years you please by adding to the longitude of [the year] 1585, for each single year, $51''$. Furthermore, the longitude having thus been found for the year 1600 and 1700, [the latitude] can be inquired together with it by trigonometric labor, both the latitude and the distance of the poles, and likewise the declination, and then the right ascension for the year 1600 and 1700. This method, as it is of the most labor, so it is the most exact.
6. The *second* [way] is, though not so exact: if of all the stars of the same constellation — of which ten have been corrected by us in this and the preceding chapter — only so much is subtracted, or [so much] is added to the right ascension, declination, longitude, and latitude as Tycho [gives for] the years 1600...

[p. 239, left column:]

and 1700, as great as is the difference, whether in excess or in defect, between the uncorrected Tychonic [value] and the Tychonic [value] corrected in this and the preceding chapter. As for those fixed stars, the ten declinations will nonetheless be established more exactly, if to the declinations of Cap. IX, in the last table to be corrected, there be added or subtracted as much as the hundred-year proportion of the difference set down by Tycho (p. 276) requires — that is, the ratio of 15 years for the year 1600, and then of 100 years for that quantity, as the ratio of the 100 years requires.

7. But since later [astronomers] will wish to have the Tychonic...

[p. 239, right column:]

table as it stands — and perhaps some things in it [are] corrected by Longomontanus from later observations — we shall exhibit it entirely as it is in Tycho, except for the ten aforementioned stars, to which we shall append the

necessary correction at the interval of 15 years between the year 1585 and 1600. In the rest the reader will see whether, on account of a false distance of the poles assumed by Tycho, an error of about one minute, and sometimes more, may be suspected.

[Below, spanning the full page width, the large catalogue table:]

Centum Fixarum Tabula Tychonica ad Annos infra notatos.

[Table of one hundred fixed stars, Tyconic, for the years noted below.]

The table gives, for the completed year of Christ 1600 (longitude, latitude, right ascension, declination) and for the completed year 1700 (right ascension, declination), plus the right-ascension/declination [Asc. Decl.] and the difference of declination [Differ. Declin.]. The A/B markers in the latitude and declination columns are australis/borealis; the A/S markers in the final difference-of-declination column indicate whether the declination is increasing or decreasing. Headers as printed: *Anno CHRISTI MDC. Completo.* | *Anno M.DCC. Completo.*

Sub-column headers (1600): Longitudo (Sig. Gr. M.) | Latitudo (Gr. M.) | Ascensio Recta (Gr. M.) | Declinatio (Gr. M.). (1700): Ascensio Recta (Gr. M.) | Declinatio (Gr. M.) | Ascensio Recta (Gr. M.) | Differ. Declin. (M.).

` could not be resolved with confidence. Fractional minutes (e.g. 17½, 35½) are printed with superscript fractions and transcribed as shown.]

Centum Fixarum Tabula Tyconica (continued and concluded)

[The Hundred Fixed Stars, Tyconic Table — concluding stars 52–100. The page carries the heading rule "Anno CHRISTI MDC. Completo" (For the completed year of Christ 1600) over the longitude/latitude/right-ascension/declination columns, and "Anno MDCC. Completo" (For the completed year 1700) over the second pair of right-ascension and declination columns.]

This page completes the catalogue begun on the preceding folio. The columns are: the names of the fixed stars; longitude (sign, degrees, minutes) and latitude (degrees, minutes, with A = australis/southern or B = borealis/northern) for the completed year 1600; right ascension and declination for 1600; right ascension and declination for the completed year 1700; the annual change [differentia] in right ascension (degrees, minutes) and the change in declination (minutes, with A = increasing toward the north or S = toward the south, as printed). Each star's *sed corripge* ("but correct it to") sub-row gives Riccioli's corrected reading.

Star catalogue, completed stars 52–100.

CAPVT XIII.

De Observationibus Fixarum post Tychonem, usque ad Nostras exclusivè.

(On observations of the fixed stars after Tycho, down to but not including our own.)

[Margin: *Lansbergij observ.* — Lansbergius' observations.]

1. Philippus Lansbergius [Philippe van Lansbergen], in his *Tables of the celestial motions* (p. 101), places the first star of Aries at Zodiac degree 354° 5' 29" for the epoch of Nabonassar; but for the epoch of Christ he puts it at degree 4° 43' 22", with respect to the mean motion. And yet on the following page (102), from his own observation, he sets out a catalogue of 25 stars, in

which — taking the beginning of the years of Christ as his reference — he places the first star of Aries, with respect to the true vernal equinox, at Υ 4° 25'. The catalogue runs as follows.

Catalogus XXV. Stellarum Fixarum, summa cura à Nobis observatarum, una cum Longitudine, & Latitudine. (*A catalogue of 25 fixed stars, observed with the greatest care by us, together with longitude and latitude.*)

Column heading: *Ad initium Ann. Christi* (at the beginning of the years of Christ) | Longitudo (Sig. G. Υ) | Latitudo (Gr. $\circ$, with B = borealis/northern, A = australis/southern).

Catalogue of 25 stars (Lansbergen), longitude and latitude.

Star name	Long. (Sig Gr $\circ$)	Lat. (Gr $\circ$)	A/ B
Prima Arietis [first star of Aries]	Υ 4 25	7 7	B
Occidentalior Pleiadum [more westerly of the Pleiades]	Υ 29 49	4 12	B

Boreal. in Cornu præc. ♐ [northern in the preceding horn, Capricorn]	♐ 5 54	7 20	B
Australior earum [more southerly of them]	♐ 6 7	5 0	B

Then Riccioli's discussion continues beneath the catalogue:

Now since Lansbergen flourished near the beginning of our own century, and was able to reduce the positions of these fixed stars to the beginning of the years of Christ, he must necessarily have collated his own observations with those of his predecessors, so as from them — by reckoning the annual motion of the fixed stars — to draw those positions back to the beginning of the years of Christ.

2. Moreover, the same author, at the end of his *Thesaurus* of observations, sets down the observations of the fixed stars written out below, made by himself or by Hortensius [Maarten van den Hove] in Zealand, assuming the altitude of the equator at Goes to be $38^{\circ} 39'$ and at Middelburg $38^{\circ} 29'$, and the obliquity of the ecliptic to be $23^{\circ} 30'$ — let this be on page 42 of the same *Thesaurus*, which he says he himself discovered at his own time to be $23^{\circ} 30' 10''$. From these elements, by the Copernican method, together with the latitude, he gathers the longitude of the fixed stars, and compares it with the longitude computed from his own tables.

[The observations themselves are tabulated in the right-hand column. Each block names a year and epoch (*ineunte* = at the beginning, *completo* = completed, *desinente* = at the end, *incipiente* = beginning) and the place of observation (Goes, or Middelburg in Zealand). For each star are given the meridian altitude, northern or southern declination, its latitude, the obliquity of the ecliptic, the longitude of the star "therefore" deduced — and then "*sed ex Tabulis*" (but from the tables) the tabular value. The marginal labels identify which star each block concerns.]

3. Against Lansbergen's summary arguments, however, *the first point* they make is that he assumed an excessive refraction for the fixed stars in Spica and Scorpius — something taken up rather than demonstrated, or merely probable. *Secondly*, the latitudes of the fixed stars he took from Ptolemy and Copernicus, and adjusted to suit the anomaly of the obliquity of the ecliptic; that those latitudes are false is plain from what was said above, and from comparing them with the Tyconic values. As for the obliquity of the ecliptic varying — as Ptolemy supposed — that is false, as is established from what was said in Book 1. *Thirdly*, if the positions of Aldebaran, Sirius/Procyon [Canicula], Regulus, Spica, and Scorpius assigned by Lansbergen in his first table for the beginning of the years of Christ be compared with the positions drawn out from the observation itself — as we too have done with our associates — then the annual motion of the fixed stars will come out as 52½", very nearly the value we shall show below not to be excessive.

De Iulio Schillero, & Io. Bayero.

(On Julius Schiller and Johann Bayer.)

4. Johann Bayer [Johann Bayer] published his *Uranometria* at Augsburg, drawing not so much on his own observations as chiefly on those of others; and, assisted by him and imitating him, Julius Schiller [Julius Schiller], likewise of Augsburg, in the year 1627 published the *Coelum Stellatum Christianum* [Christian Starry Heaven] — so called because, in place of the names drawn from astronomers ancient and pagan, he substituted new names, and sacred ones. In its second part, beginning at page 131, are given the longitude, latitude, declination, right ascension, and culmination [Medium Coeli] of 360 fixed stars, for the year of Christ 1625, computed by Jacob Bartsch [Jakob Bartsch] from the Tychonic determination and from Bayer's. Among these, however, are certain stars observed by various navigators [Naucleri], from whose observations Bayer — after the earlier *Uranometria* had been published — fixed their positions, and Bartsch thence computed them to the same year 1625. Kepler [Johannes Kepler], moreover, at the end of the *Rudolphine* tables, drew the same stars back, on the supposition of the Tychonic motion, to the year 1600. Leaving aside, then, the others that are in the Tychonic catalogue, we shall transcribe from Schiller only those fixed stars which were observed by the navigators across the Equator — concerning whose distances measured by the navigators with the cross-staff [Radius], see above, Chapter 8. Whatever may be the case with such observations, it is better to have them than none at all.

Tabula Iulij Schilleri Fixarum aliquot ex Observat. Nauclerorum, & Determinatione inde facta Io. Bayeri, ac supputatione Iacobi Bartschij ad Annum Christi 1625. (*A table of some of Julius Schiller's fixed stars, from the observations of the navigators and the determination made therefrom by Johann Bayer, and the computation of Jacob Bartsch, for the year of Christ 1625.*)

Petri Gassendi Observationes [The Observations of Pierre Gassendi]

5. In Volume 4 of Gassendi's [Pierre Gassendi] *Works*, titled *Commentaries on Celestial Matters* [*Commentarii de Rebus Coelestibus*], we have very few observations of the fixed stars, as regards their declinations and meridian altitudes. And from these, together with the Tychonic declinations — which he by no means corrected — he infers the altitudes of the pole, rather than determining the declinations of the fixed stars from the altitudes of the pole, except for the Pole Star, or in the case where the pole's altitude was established from solstitial observations. Moreover, on pages 84, 106, and 182 Gassendi admits that for these purposes he used a walnut-wood quadrant of 5 feet and an iron one of 3 feet, and a square of 3½ feet — yet he assumes the pole's altitude as stated in our *Geographia Reformata*. We shall add the declinations.

De Observationibus circa Pleiadas Michaelis Florentii Langreni, & D. Vincentii Muti. [On the Observations of the Pleiades by Michael Florent van Langren and by Vincenzo Muti]

6. Among the most learned and most courteous letters sent to me from Brussels by Michael Florent van Langren [Michael Florentius Langrenus], Cosmographer to the Catholic King, I have one of the year 1647, dated June 6, in which he sets out for me the exact position and the distances of the Pleiades depicted in a diagram, similar to Muti's, and promises to send their position relative to the ecliptic and equator as well — which I did not later receive. Now our most learned and most friendly Vincenzo Muti [Vincentius Mutus] of Maiori, most devoted to and most skilled in the observation of the stars, in a letter sent to me on March 5 of the year 1650, not only communicated their most exact distances, taken together with the

telescope, but also their longitude, latitude, and degree of magnitude — assuming, however, Alcyone, that is the bright star of the Pleiades, at the Tychonic position for the beginning of the year 1650 — which stand as follows. There are nine of them, although the more celebrated ones are only seven, speaking of those conspicuous even to the naked eye.

Intervals of the Pleiades, or Names of the
Pleiades

Distances ' "

Atlas & Pleione	4 0
Atlas & Alcyone, or the bright Pleiad	27 0
Pleione & Alcyone	27 0
Alcyone & Merope	22 0
Alcyone & Maia	31 0
Maia & Merope	30 0
Maia & Electra	22 0
Maia & Taygeta	11 0
Electra & Taygeta	22 0
Electra & Merope	24 0
<i>These others I have added myself from the diagram [His ego alias ex Typo addidi]</i>	
Alcyone & Taygeta	42 10
Alcyone & Asterope	41 30
Alcyone & Celeno	40 0
Alcyone & Electra	39 50
Maia & Asterope	11 0
Maia & Celeno	19 0
Taygeta & Asterope	9 45
Taygeta & Celeno	16 0
Electra & Celeno	10 20
Merope & Celeno	29 0

At the beginning of
the year 1650

Longitude ʘ Gr. ' "

Latitude Gr. ' " Bor.

Magnit
ude

Electra, or the more	ʘ 24 28 11	4 9 40	5

At the beginning of the year 1650	Longitude γ Gr. ' "	Latitude Gr. ' " Bor.	Magnit ude
westerly bright one			
Taygeta, or the more westerly of the bright northern ones	γ 24 38 30	4 31 36	6
Merope, nearer the rising [point] of Electra	γ 24 45 0	3 53 30	6
Maia, nearer the rising [point] of Taygeta	γ 24 45 30	4 23 56	6
Alcyone, or the bright Pleiad of Tycho	γ 25 6 0	4 0 0	3
Atlas, at the cusp toward the rising [point]	γ 25 31 30	3 51 20	5
Pleione, at the more northerly cusp	γ 25 32 30	3 54 0	7

Therefore, if the longitude of the bright Pleiad is to be corrected, the latitude too, and likewise that of the remaining stars, must be corrected proportionally — but only if Muti followed Tycho's motion of the fixed stars in completed years, [namely] 41' 39". For the longitude of the bright Pleiad ought to have been set at γ 24° 5' 39".

[Margin: *Tycho and Lansbergen noted.* (Tycho, & Lansbergius notati.)]

"Here," says Muti, "I cannot help but greatly wonder how far these stars have been displaced from their positions, as observed by Tycho. For he sets a much greater distance between the bright star and Merope than between Merope and Electra — which is utterly false — and he establishes Atlas, Alcyone, and Merope on one and the same straight line, which is a misshapen distortion of that interval of the sky. Lansbergen [Lansbergen], in his catalogue of the stars in the *Table of Asterisms*, fol. 102, posits the same thing; for he sets the distance between the bright Pleiad and Electra, [the two being] the most westerly, at 1° 18' — as great as the distance between the first and middle stars of Orion's belt. Yet who does not see, with a telescope or even with the naked eye, that the said Pleiades are far less distant from one another?" Thus this most careful and most accurate man.

Kepler [Kepler], however, in the Rudolphine [Tables], on folio 110 of the tables, places four positions of the Pleiades from Tycho for the year 1600; but on folio 115, from his own comparison with Ptolemy [Ptolemy], Bayer [Bayer], and Galileo [Galileo], he establishes the positions of these same stars — and of seven of the Pleiades — thus, for the end of the year 1600. To these Tychonic figures we shall add the Keplerian ones. T. shall indicate Tycho, K. Kepler.

CAPVT XIV.

De Nostris circa Fixas Observationibus, ac primum de Altitudine Poli Bononiae subtilissimè, & exactissimè observata tanquam Fundamento Declinationum. [On Our Own Observations Concerning the Fixed Stars, and First on the Altitude of the Pole at Bologna, Most Subtly and Most Exactly Observed as the Foundation of the Declinations]

Just as Tycho once obtained the altitude of the pole at Uraniborg as $55^{\circ} 54' 30''$, then found it $55^{\circ} 54' 40''$, or $45''$ — as we showed in Chapter IX — so too we, with well-made quadrants exhibiting single minutes, but in a varying manner, obtained the altitude of the pole at Bologna once as $44^{\circ} 29' 30''$, and professed it so in the *Almagestum Novum*; yet afterward, on other astronomical evidence, we began to call it into question. And since we needed it so certain that it could not contain an error of even a single half-minute, we devoted all our skill and effort to this. P. Francesco Maria Grimaldi [Francesco Maria Grimaldi] assisted me magnificently in this whole undertaking; for the same period there was also the most excellent Doctor Giovanni Domenico Cassini [Giovanni Domenico Cassini], Professor of Astronomy at the University of Bologna, who restored the Gnomon of San Petronio, of which I spoke in Book 1, Chapter 12, number 6, and himself needed a subtle altitude of the pole — for which purpose we used a gnomon set high, 20 feet and more, in the courtyard of the most illustrious

Diagram. A schematic engraving of the meridian-altitude instrument described in the text, shown in two parts. The lower portion depicts a long horizontal wooden frame (a beam-table) mounted on a trestle support, with upright posts and threads. At the upper left a series of labeled uprights and points are marked; at the upper right a separate detail shows the sighting threads converging toward a star (rendered as a small star-glyph). Labels, read from the image:

- L, M, R (top): upright posts at the left end of the frame
- N, O, T (left): points on the cross-rule and threads near the left uprights
- X (far left): the eye/sighting position
- P (lower middle-left): point on the frame
- H, K (left base): feet of the trestle support; a plumb-bob hangs below at g
- S (right uprights): upper post at the right
- V (right): point on the frame near the right post
- h (right, mid-line): point on the horizontal sighting line

- Q (right base): foot of the right support
- A, C (upper right, with star-glyph y beside): the converging sighting lines toward the star
- B (upper right): point below A and C on the angle
- E, G, F (lower right detail): the small metal plate/lamella detail with plumb-bob

Several peripheral letters are small; the principal labels (A, B, C, E, F, G, H, K, L, M, N, O, P, Q, R, S, T, V, X, and points g , h , y) are read as printed and correspond to the construction described in the surrounding text.

tractile [i.e., from "intractile," carrying over from the foot of p. 244: so that, dried by the pitch, it would come out unrubbed and uncontracted]; thirdly, we joined together three-foot wooden plates and composed one long [plate], marking likewise with a sign at G, on the said plate. Then, by means of another little cord, we let down a pitch-line, and stretching these and the smoothed plates — which on this occasion of construction did not lie level — and afterward drawing off their length to an equal altitude CG, we measured most subtly; and from the remaining altitude Ch, of which below, the [residual] portion Gh is known, the altitude is known.

4. Besides these, above the meridian line there was a beam HI, resting on several supports and squared, more thoroughly compacted, and parallel to the horizon, at whose southern head was fixed a movable iron forklet [furcula] L g M, from whose arms a very fine thread NO hung, holding the horizon, and a forklet with a handle, near the two cardinal points, H & furcula, movable so that the thread NO could be raised upward, or lowered downward, at will. On suitable nights, then, we awaited the coming of the Pole Star to the meridian, and its middle C; the rules AB were fitted; the associates who held the side-lanterns were enclosed; and at once, when the rule AB and then the thread NO had been set, the Pole Star appeared in the meridian near the middle C, [seen] through the forklet L g M, [so as to] be moved to the forklet; that thread had been moved so that the eye X would see it to be on the same straight line XY, the two points being clearly the thread XY and the rule AB. With the higher middle C and the rule AB secured at the center Y, and the eye being in its position [thus] enclosed, when the temple could be closed off without disturbing it, we then at once super-elevated the metal tube PQ along the said beam HI, formed of several [pieces] mutually fitted, as if perpendicular horns rising up crystalline; of the tube PR and QS, having filled them with water, until at last the water

settled — the silken thread thus passing between the two NO, near the middle Z — so that by this method the thread Zh would be designated; and the point h, in which the lines Zh, with the perpendicular CD, would make a Right Angle ZhC. At last, having measured the longitude ZhC, by the Radius Ch, the angle CZh would become known, measuring the meridian altitude of the Pole Star. We used the tube closed rather than open, PQ, with the channel open, lest any motion of the air through the water cause a defect of the level, or [lest] any impediment introduce a suspicion of error. This, in sum, was the method, in which, repeated through several nights, by repeated and most diligent inquiry into the meridian altitudes of the Pole Star, we proceeded to establish the declinations: we use this simple triangle CHZ, in which Ch is in place of the Radius, and ZH, [is] the Tangent of the Arc OH, subtending

the Angle C, and its complement to a right angle is the Angle Z, measuring the altitude of the point C, or of the star above the horizon.

[Margin: 1. Observatio (First Observation)]

5. And so in the year 1655, at the beginning of October, by repeated observations of the Pole Star, we find the Altitude CH to be 66 feet and $10\frac{78}{100}$, that is 80238 of those parts of which one [Paris] foot is 100; the longitude ZH was 62 feet and $3\frac{165}{1000}$, or of the said parts 74705. As [the ratio of] 80238 to the Radius 10000000, so ZH, of those parts 74705; the tangent of the Angle C, $42^{\circ} 57' 17''$. And its complement $47^{\circ} 2' 43''$ — that is, the maximum altitude of the Pole Star at the Bologna meridian — was $47^{\circ} 2' 43''$; but the minimum altitude of the Pole Star was not then observed, nor was it possible, since at that time it happened under the end of the year 1655, and afterward the new temple impeded us.

[Margin: 2. Observatio (Second Observation)]

Diagram (right margin, beside §5): a right triangle drawn with C at the top, O on the upper side, and the right angle at H at the base, with K at the lower left — illustrating the triangle CHZ (here lettered with O and K) of the foregoing calculation. (A small uncaptioned geometric figure; labels C, O, H, K read as printed.)

So with the sextant standing at one [station] of 7, and the other of 12 feet, in a vault near the temple we obtained the meridian line of the Pole Star, the maximum in the evening $47^{\circ} 2' 42''$, and the minimum $41^{\circ} 57' 36''$, the seconds in each varying somewhat. Since, however, the more frequent difference of the

altitudes was $5^{\circ} 5' 6''$, and the semidifference $2^{\circ} 32' 33''$, therefore, this minimum being added, it exhibits in the meantime the altitude of the pole $44^{\circ} 30' 9''$ — which, as the illustrious Lord Cassini, we report, [waiting] expecting that he would furnish [it] by his own Gnomon.

[Margin: 3. Observatio (Third Observation)]

6. But indeed the illustrious Cassini, at the close of the year 1655 and the beginning of 1656, in the Malvasia house [aedes Malvaticae], with his own Gnomon of more than 20 feet, obtained the maximum altitude of the Pole Star at the meridian as $47^{\circ} 2' 50''$, and the minimum $41^{\circ} 57' 54''$ — of which the semidifference is $2^{\circ} 32' 28''$; and adding the minimum altitude, he gives the altitude of the pole in the Malvasia house as $44^{\circ} 30' 22''$. And he most liberally communicated this same [result] to us, and we in turn accepted it. Yet there is a difference of seconds, $13''$, to be referred to the diversity of the places, since the Malvasia house [aedes Malvaticae] is more northerly than the College of Santa Lucia. Yet this same [matter] is to be investigated.
7. Therefore, more impatient, we investigated by the art of geodesy the interval of distance between our College and the Malvasia [house], and likewise between the summit of the Temple of San Petronio — by means of the tower of Asinelli [Turris Asinella], [taken] in a line falling orthogonally and in parallel to our [meridian] and to the parallel of the Malvasia Palace [Malvaticae Palatii] — and the distances found were: of the Malvasia [house] from the Bologna parallel, 215 [paces?]; between ours and that of San Petronio, parallel paces 180.

This follows from what was established in our *Reformed Geography*, Book 5, Chapter 33: the Bolognese pace contains 64,363 of the feet that make up a degree of the great circle of the Earth. Therefore, from the northern wall of the Malvasia palace down to our Observatory there are 215 paces; and from the northern wall of the palace down to the Church of San Petronio there are 180. From this it follows: the second figure of $12'$ — at which the northern wall of the palace is reckoned — and from our Observatory's reading, namely $10'$, follow accordingly. From the observation of D. Cassini [Giovanni Domenico Cassini], the altitude of the pole in the Malvasia courtyard is $44^{\circ}30'22''$; from our observation in the Observatory it follows that it is $44^{\circ}30'10''$; and at San Petronio, $44^{\circ}30'20''$. And near the Observatory, taken at the outset of the year 1655 — when we were using the great gnomon — it came out as $44^{\circ}30'9''$, though we were not using a great gnomon but rather a different observation.

Meanwhile, however, from the beginning of the year 1655 — when we were using the great gnomon — down to the year 1656, the conferences we held with Cassini's observation give us this satisfaction: that we approached the Pole Star to within a second part of the trimestral interval, as far as the matter required, in accordance with the observations of Paul Hainzel [Paul Hainzel], who found it in these our times to fall short of the World's Pole by 20'.

4 [*Margin: 4. Observation.*] Afterwards, indeed, in the year 1656, in the month of April, the obstacles in the Church of San Lucia having been removed, with the gnomon now set up (described under number 3), we found the least altitude of the Pole Star in the meridian during three successive nights to be $41^{\circ}57'48''$. Then, by the Radius CH, it stood at 74'; and by the small parts [vunciae], 5. By this, the Tangent B9300 — of which one uncia is equal to 100. The Longitude, moreover, by the Tangent ZH, was 82 feet, less 9728'', that is, by the dictated parts 99305. Therefore, by CH, 89300 to the Radius 10000000. So ZH, 99305, to 11120429. The Tangent of the partial angle 99305: therefore the Rectangle 48, of which 2'12'' are the complement of the angle Z, evades $41^{\circ}57'48''$; and so great is the least altitude of the Pole Star. Furthermore, from this Tychonic approach to the annual Pole of 20', if we subtract on this account 6' less from the altitude of our star, that is $41^{\circ}57'42''$, there was the greatest altitude of the Pole Star, reduced to the year 1655. But the year 1656 began with a subtraction of 5', which is owed to the trimestral interval from the beginning of October to the beginning of January, and it was $47^{\circ}2'38''$. The Synopsis of these, therefore, and an Epilogue, is as follows.

Year 1655 Complete — of the Pole
Star

	Meridian Altitude — Gr.	'	"
Maximum Altitude	47	2	38
Minimum Altitude	41	57	42
Difference	5	4	56
Semi-difference	2	32	28
Therefore the Northern Declination	87	27	32
And the Altitude of the Pole in the New Church of San Lucia of Bologna	44	30	10

So this is sufficient, indeed more than sufficient: the altitude of the pole at Bologna stands confirmed by the three places mentioned. This is what comes of

making good use of great instruments. And — without boasting, and with no exaggeration of the pole — no altitude of the pole established with such accuracy and consensus of observation is to be found, at least in the books I have read. For the altitude that Gassendi [Pierre Gassendi] obtained at Marseilles with a great gnomon, from solstitial altitudes, involves the controversy over the semidiameter, the maximum declination, and the parallax of the Sun. Perhaps, nonetheless, it can be compared with ours, which Ulugh Beg [Ulugh Beg] accepted at Samarkand with a gnomon 180 feet high; he found it to be 39°37'33", as I have set out more fully in *Reformed Geography*, Chapter 25. Deservedly, then, D. Io. Dominicus [Giovanni Domenico Cassini], devoted to the restoration of astronomy, laid the foundation of the rest of his observations upon this altitude. The Polar Altitudes of the places written below are therefore ratified.

ALTITUDE OF THE POLE AT BOLOGNA — Altitude of the Pole

	Gr.	'	"
In the Church of San Petronio	44	30	20

In the College of San Lucia of the Fathers of the Society of Jesus	44	30	10

CHAPTER XV.

On the Other Instruments With Which We Observed the Fixed Stars, Compared With the Tyconic Ones.

1 In the Preface to the Reader of the *New Almagest*, Article 7, I professed in that Volume: *I have not in every case followed my own opinion concerning the numbers, or the Astronomical measurements.* For in that work I examined the Art itself and the opinions of the Authors, and although I there exhibited many of our own observations, and from time to time indicated the hypotheses, I nonetheless took care to forewarn by way of a *provisional* clause that I had used Tabular values *for the time being.* [Margin: *Instruments of doubt.*] In that work, it was not yet granted to me to have the means of observing the major stars for their Declinations, and especially for their mutual Distances, and of correcting and emending them; and besides, in the *New Almagest*, as commonly happens with typography, not a few errors crept in. Therefore, apart from the ancient Quadrants — some of 4 feet, some of 4, and Sextants of ten — distant by intervals; and others suited to

altitudes, some of which were of feet on the Radius 4; others of 6, 7, 11, 12 — and the largest of these on the Radius 10" — there stood available, in our Observatory, and besides the Sextants distant from the vertex of the Stars, a Sextant nearest the vertex, suited to the comparison; a Ruler of Parallaxes formerly of 6 feet, then of 8 feet; we had a Gnomon 15 feet; we used the two Quadrants frequently, the one Tychonic, the other Grimaldian, and stable, set up in the plane of the meridian most firmly.

2 [*Margin: Tychonic Quadrant.*] The Tychonic Iron Quadrant — so called by us — is that semidiameter, that is, a mural quadrant, which Tycho [Tycho Brahe] calls (page 10 of the *Mechanics of Astronomy*) the *Mural Quadrant*, and which we call *Tychonic*; namely, with a cubit of about 5 feet. Its arc, however — that is, the band — is broad, of 8 fingers, not 5, as the Tychonic one; but so that the discriminations of the minutes are designated by transverse lines. And although Tycho, at the end (and as a supplement to the said *Mechanics*, folio 67), showed that the division was made by transverse lines at equal intervals of minutes, if the breadth of the band on the instrument's Radius is as 1 to 48, and that it does not contain an error greater than three seconds in scruples, and he says this is imperceptible. Nonetheless, in our own instruments, we have been accustomed to designate the intervals of minutes by transverse lines at unequal intervals, as the Geometric ratio requires, according to what is said in the *Organic Book*.

This division can be made, moreover, in two principal ways. *First*: if the lowest and the highest breadth of the band that comprise the periphery are divided into 90 degrees of the quadrant, and the transverse lines serving the individual degrees are subdivided into 60 minutes — as in the figure attached, let the arc BC be 2 degrees, and by D the point terminating the first degree, and through the center of the quadrant a straight line drawn cut the upper periphery at A, the boundary there of the first degree. Then, drawing lines from A to B and to C, that is AB and AC — one toward the beginning of the lower periphery, the other toward the end of the second degree — let each be divided into 60 minutes. In this case 90 divisions of the degrees are to be made both above and below, that is 180, and the lines 90 are to be divided, and each into 60 intervals to be divided, so that altogether 5670 operations are required — not without trouble, and the risk of some little error.
